CUMULATIVE AUTHOR INDEX

NOTES CONCERNING ARTICLE ABSTRACTS

1. The number following the abstract copyright notice is a Publisher Item Identifier (PII) code that provides a unique and concise identification of each individual published document. This PII number should be included in all document delivery requests for copies of the article.
2. PACS numbers are for subject classification and indexing. See June and December issues for detailed listing of acoustical classes and subclasses.
3. The initials in brackets following the PACS numbers are the initials of the JASA Associate Editor who accepted the paper for publication.

CONTENTS

SOUNDINGS

Section Editor: Richard Stern

This front section of the *Journal* includes acoustical news, views, reviews, and general tutorial or selected research articles chosen for wide acoustical interest and written for broad acoustical readership.

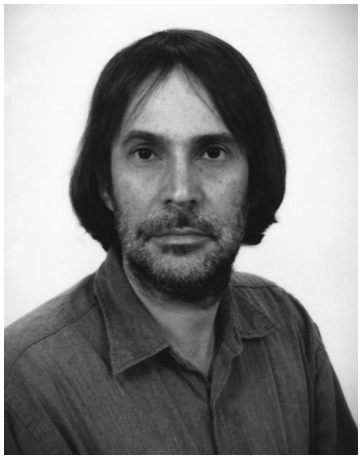
ACOUSTICAL NEWS—USA

Elaine Moran
Acoustical Society of America, 500 Sunnyside Boulevard, Woodbury, New York 11797

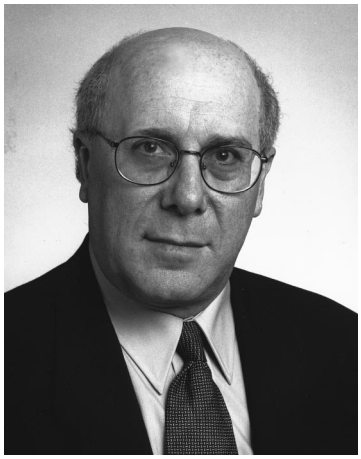
Editor's Note: *Readers of this Journal are asked to submit news items on awards, appointments, and other activities about themselves or their colleagues. Deadline dates for news items and notices are 2 months prior to publication.*

New Fellows of the Acoustical Society of America

Christopher W. Clark—For contributions to whale acoustics.

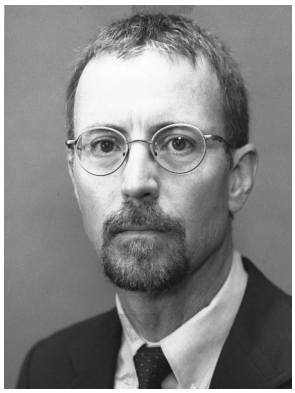


Rudolph Martinez—For contributions linking fluid mechanics and acoustics.

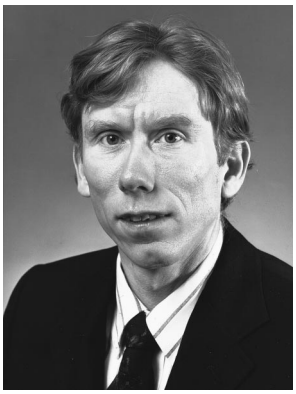


Philip Rubin—For contributions to modeling speech production.

Sid P. Bacon becomes new Associate Editor of the *Journal*



Sid P. Bacon



Joseph W. Hall

In January 1999 Professor Sid P. Bacon of the Department of Speech and Hearing Science at the Arizona State University, Tempe, Arizona, became a new Associate Editor of the *Journal* for papers in Psychological Acoustics (PACS 43.66). He succeeded Professor Joseph W. Hall of the Division of Otology at the University of North Carolina, who requested replacement after a three-year term of faithful and effective service. The Editor-in-Chief expresses his deep appreciation to Professor Hall and to his institution for support.

Sid P. Bacon received a B.G.S. degree in Speech Pathology and audiology from University of Kansas in 1977. He also received there the M.A. degree in Audiology in 1979. After his Ph.D. in Experimental Psychology in 1985 from University of Minnesota he spent postdoctoral periods in Psychophysics at University of Cambridge in UK and at Boys Town National Institute. From 1986 to 1988 Sid Bacon was at Vanderbilt University as assistant professor of Hearing and Speech Sciences and director of research at the Bill Wilkerson Hearing and Speech Center. In 1988 he moved to the Department of Speech and Hearing Science at Arizona State University where he is a Professor and the Director of the Interdisciplinary Ph.D. program.

Sid Bacon's psychoacoustical research interests have been in temporal effects, in forward masking, and modulation detection. He has published widely, including over 30 articles in our *Journal.* Sid has served on the ASA Education Committee and on the Technical Committee for Psychological and Physiological Acoustics. He has also served as an Associate Editor for the *Journal of Speech, Language, and Hearing Research.*

The Editor-in-Chief and his colleagues welcome Professor Bacon to membership on the Editorial Board.

DANIEL W. MARTIN
Editor-in-Chief

Semi J. Begun elected to National Inventors Hall of Fame

Semi J. Begun (1905–1995), past Fellow of the Acoustical Society of America, was inducted into the National Inventors Hall of Fame on 19 September 1998, in recognition of his inventions in magnetic recording. Much of his early magnetic recording was in labs at the Society for the Blind in New York City. In 1938, Begun joined the Brush Development Company located in Cleveland, Ohio. One of his applications there was the ''Black Box'' aircraft recorder used in investigating aircraft incidents. Thirty of his patents were reviewed in the Acoustical Patent Review section of our *Journal.*

Each year since 1973, the National Inventors Hall of Fame has honored the top inventors that have made a significant contribution to society. The nominations are open to any individual with at least one invention covered by a U.S. patent. ASA is represented on the NIHF selection committee along with about 40 national scientific and technical organizations. The 135 past inductees include Thomas Edison, Alexander Graham Bell, and Marvin Camras.

The NIHF highlights, through interesting displays, video, and patent application models, the lives and inventions of its inductees. The Hall of Fame was founded by the National Council of Intellectual Property Law Associations and the United States Patent and Trademark Office. In 1987 Akron, Ohio was selected as the permanent home for the National Inventors Hall of Fame and opened in 1995 as part of Inventure Place, an interactive museum that allows development of creativity and the exploration of invention. To learn more about the National Inventors Hall of Fame, or to nominate an inventor, visit the web site at ⟨http://www.invent.org⟩.

Position Open

Stanford University: Faculty Opening. Stanford University's Departments of Linguistics and Computer Science seek applicants for a tenure-track faculty position in areas combining linguistics and computation. Candidates will be expected to show breadth and depth in both areas and to demonstrate the ability to make an intellectual contribution to both linguistics and computer science. Example topics of interest include, but are not limited to, natural language dialogue processing and understanding, development and evaluation of linguistic methods using large speech and text databases, speech recognition, computational modeling of cognitive processing of language, lexical knowledge bases, symbolic and statistical methods of language processing, and linguistic knowledge representation. Interest in an application area, such as information retrieval, data mining, or web services is desirable. Higher priority will be given to the innovation and promise of the candidate's work than to any of these specific topics and applications.

Applicants should have a Ph.D. in a relevant field. Evidence of the ability to pursue a research program and a strong commitment to graduate and undergraduate teaching are required. The successful candidate will be expected to teach courses, both in the candidate's specialty area and in related subjects, at the graduate and undergraduate levels, and to build and lead a team of graduate students in Ph.D. research.

The appointment will be made at the level of an Assistant Professor. The position is available beginning Autumn 1999 and is offered jointly in the Linguistics and Computer Science Departments. Further information about these departments can be found at http://www-linguistics.stanford.edu and http://www-cs.stanford.edu, respectively.

Applications should include a curriculum vita, statements of research and teaching interests, and the names of five references. The application should be sent to: Professor John Mitchell, Search Committee Chair c/o Laura Kenny-Carlson Computer Science Department, Stanford University, Gates 2B, Stanford, CA 94305-9025.

The interview process will begin on 15 January 1999, but applications will be accepted until 15 February 1999. Stanford University is an equal opportunity employer and welcomes applications from women and minority candidates.

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future. The month/year notation refers to the issue in which a complete meeting announcement appeared.

1999

25–27 Feb.	24th Annual Conference, National Hearing Conservation Association, Atlanta, GA [National Hearing Conservation Association, 9101 E. Kenyon Ave., Suite 3000, Denver, CO 80237, Tel.: 303-224-9022; Fax: 303-770-1812; E-mail: nhca@gwami.com].
15–19 March	Joint meeting: 137th meeting of the Acoustical Society of America/2nd Convention of the European Acoustics Association: Forum Acusticum, integrating the 25th Anniversary DAGA conference, Berlin, Germany [Acoustical Society of America, 500 Sunnyside Blvd., Woodbury, NY 11797, Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: asa.aip.org].
10–12 May	AIAA/CEAS Aeroacoustics Conference, Bellevue, WA [Belur Shivashankara, The Boeing Company, P.O. Box 3707, MS 67-ML, Seattle, WA 98124-2207; Tel.: 425-234-9551; Fax: 425-237-5247; E-mail: belun.n.shivashankara@boeing.com].
6–7 June	1999 SEM Spring Conference, Cincinnati, OH [Katherine M. Ramsay, Conference Manager, Society for Experimental Mechanics, Inc., 7 School St., Bethel, CT 06801; Tel.: 203-790-6373; Fax: 203-790-4472; E-mail: meetings@sem1.com].
27–30 June	ASME Mechanics and Materials Conference, Blacksburg, VA [Mrs. Norma Guynn, Dept. of Engineering Science and Mechanics, Virginia Tech, Blacksburg, VA 24061-0219; Fax: 540-231-4574; E-mail: nguynn@vt.edu; WWW: www.esm.vt.edu/mmconf/].
6–11 July	1999 Clarinetfest, Ostend, Belgium [International Clarinet Association, Keith Koons, Music Dept., Univ. of Central Florida, P.O. Box 161354, Orlando, FL 32816-1354].
7–10 Oct.	Symposium on Occupational Hearing Loss, Philadelphia, PA [American Institute for Voice and Ear Research, Attn: Barbara-Ruth Roberts, 1721 Pine St., Philadelphia, PA 19103, Tel.: 215-545-2068; Fax: 215-735-2725].
1–5 Nov.	138th meeting of the Acoustical Society of America, Columbus, OH [Acoustical Society of America, 500 Sunnyside Blvd., Woodbury, NY 11797, Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW:asa.aip.org].
2–4 Dec.	ACTIVE 99, Fort Lauderdale, FL [Institute of Noise Control Engineering, P.O. Box 3206, Arlington Branch, Poughkeepsie, NY 12603, Tel.: 914-462-4006; Fax: 914-463-020; E-mail: INCEUSA@aol.com; WWW:users.aol.com/inceusa/ince.html].
6–8 Dec.	INTER-NOISE 99, Fort Lauderdale, FL [Institute of Noise Control Engineering, P.O. Box 3206, Arlington Branch, Poughkeepsie, NY 12603, Tel.: 914-462-4006; Fax: 914-463-020; E-mail: INCEUSA@aol.com; WWW:users.aol.com/inceusa/ince.html].

ACOUSTICAL NEWS—INTERNATIONAL

Walter G. Mayer

Websites—An update

Several national acoustical societies have established or changed addresses of homepages which contain information about various aspects of the organization, meeting announcements, and other items of interest. Below are the most recent new or updated listings:

Canadian Acoustical Association	www.uwo.ca/hhcru/caa/
Institute of Acoustics (UK)	ioa.essex.ac.uk/ioa/
French Acoustical Society	www.loa.espci.fr/sfa/
German Acoustical Society	www.dega.itap.de
Brazilian Acoustical Society	www.sobrac.ufsc.br
European Acoustics Association	wrangler.essex.ac.uk/eaa/
International Commission on Acoustics	gold.sao.nrc.ca/ims/ica/

Papers published in JASJ(E)

A listing of Invited Papers and Regular Papers appearing in the latest issue of the English language version of the *Journal of the Acoustical Society of Japan*, JASJ(E), was published for the first time in the January 1995 issue of the Journal. This listing is continued below.

The November issue of JASJ(E), Vol. 19, No. 6 (1998) contains the following papers:

M. G. S. Ali and A. R. Mohamed ''Numerical calculation of the frequency response of the radiation coupling in lossy medium''
T. Taniguchi, S. Kajita, K. Takeda, and F. Itakura ''Blind signal separation for recognizing overlapped speech''
N. Nakasako, Y. Mitani, and M. Ohta ''A practical and probabilistic evaluation method of sound insulation systems based on the extended regression analysis for roughly observed data''
H. Kamata, T. Endo, and Y. Ishida ''Practical private speech communication system with chaos using digital signal processor''

International Meetings Calendar

Below are announcements of meetings to be held abroad. Entries preceded by an * are new or updated listings with contact addresses given in parentheses. Month/year listings following other entries refer to issues of the *Journal* which contain full calendar listings or meeting announcements.

March 1999

10–12 *__Acoustical Society of Japan Spring Meeting__, Tokyo, Japan. (ASJ, Ikeda Building, 2-7-7, Yoyogi, Shibuya-ku, Tokyo 151-0053, Japan; Fax: +81 3 3379 1456; e-mail: kym05145@niftyserve.or.jp)

15–19 **Joint Meeting of EAA Forum Acusticum, and 137th meeting of the Acoustical Society of America**, Berlin. *6/97*

April 1999

27–29 **International Conference on Vibration, Noise, and Structural Dynamics**, Venice. *8/98*

May 1999

10–14 **4th International Conference on Theoretical and Computational Acoustics**, Trieste. *6/98*

24–26 **2nd International Conference on Emerging Technologies in NDT**, Athens. *8/98*

24–27 *__2nd EAA International Symposium on Hydroacoustics__, Gdańsk-Jurata, Poland. (EAA Symposium, Department of Acoustics, Technical University of Gdańsk, ul. G. Narutowicza 11/12, 80-952 Gdańsk, Poland; Fax: +48 58 347 1535; Web: www.hydro.eti.pg.gda.pl)

30–3 **16th International Evoked Response Audiometry Study Group Symposium**, Tromsø. *12/98*

June 1999

28–30 **1st International Congress of the East European Acoustical Association**, St. Petersburg. *10/97*

28–1 **Joint Conference of Ultrasonics International '99 and World Congress on Ultrasonics '99 (UI99/WCU99)**, Lyngby. *6/98*

July 1999

4–9 **10th British Academic Conference in Otolaryngology**, London. *10/97*

5–8 **6th International Congress on Sound and Vibrations**, Copenhagen. *2/98*

August 1999

2–6 *__International Symposium on High-Power Ultrasonics__, Vitebsk, Belarus. (Institute of Technical Acoustics, National Academy of Sciences of Belarus, Ludnikov av. 13, Vitebsk 210717, Belarus; Fax: +375 212 24 39 53; e-mail: 1pm@ita.belpak.vitebsk.by)

September 1999

1–4 **15th International Symposium on Nonlinear Acoustics (ISNA-15)**, Göttingen. *10/97*

15–17 **British Society of Audiology Annual Conference**, Buxton. *8/98*

October 1999

20–22 **Iberian Meeting of the Spanish Acoustical Society and the Portuguese Acoustical Society**, Avila. *12/98*

March 2000

20–24 **Meeting of the German Acoustical Society (DAGA)**, Oldenburg. *10/98*

July 2000

4–7 **7th International Congress on Sound and Vibration**, Garmisch-Partenkirchen. *12/98*

October 2000

3–5 **WESTPRAC VII**, Kumamoto. *6/98* *(new Web: cogni.eecs.kumamoto-u.ac.jp/others/westprac7)

16–18 **2nd Iberoamerican Congress on Acoustics, 31st National Meeting of the Spanish Acoustical Society, and EAA Symposium**, Madrid. *12/98*

16–20 **6th International Conference on Spoken Language Processing**, Beijing. *10/98*

September 2001

2–7 **17th International Congress on Acoustics (ICA)**, Rome. *10/98*

BOOK REVIEWS

James F. Bartram
94 Kane Avenue, Middletown, Rhode Island 02842

These reviews of books and other forms of information express the opinions of the individual reviewers and are not necessarily endorsed by the Editorial Board of this Journal.

Editorial Policy: *If there is a negative review, the author of the book will be given a chance to respond to the review in this section of the Journal and the reviewer will be allowed to respond to the author's comments. Nonlinear Acoustics

Mark F. Hamilton and David T. Blackstock, Editors

Academic Press, San Diego, 1998.
xviii+455 pp. Price: $95.00.

Contemporary nonlinear acoustics is essentially an interdisciplinary area. Historically, it is closely associated with classical fluid and solid mechanics, and in recent decades it also has become a branch of nonlinear wave theory. After World War II, the subject of nonlinear acoustics developed much faster but in a rather nonuniform manner. After a boom during the 1960s and 1970s due to a new type of antenna, namely parametric arrays, it kept a relatively low profile. A new wave of interest, associated with applications in biology and material diagnostics arose during the 1990s. An indicator of this interest is the appearance of new books on nonlinear acoustics.

Nonlinear Acoustics is a very good collection of 15 chapters written by many leading scientists in this area and carefully edited by Mark Hamilton and David Blackstock. It covers a wide spectrum of problems, from classical to brand-new. I read many of its sections with intense interest. This interest was stimulated by the opening historical Chapter 1 entitled ''History of nonlinear acoustics: 1750s–1930s,'' written by D. Blackstock. This is a brilliantly written history of relevant hydrodynamics and of a transition to the modern nonlinear acoustics of fluids. (I'd like to see an equally interesting outline of the history of nonlinear acoustics of solids.) The following chapter, ''The parameter B/A,'' written by R. Beyer, one of the founders of contemporary nonlinear acoustics, gives a good tutorial explanation and outline of methods for measuring a fundamental parameter of quadratic nonlinearity in fluids.

The next few chapters deal with approximate equations used in nonlinear acoustics, and their typical solutions. Chapter 3, ''Model equations,'' written by M. Hamilton and C. Morfey, summarizes different simplifications of basic nonlinear equations by using smallness of local effects of nonlinearity, dissipation, and diffraction. In particular, the most usable Burgers equation and Khokhlov–Zabolotskaya–Kuznetsov (KZK) equation are derived to describe progressive waves and wave beams. These equations are utilized in Chapter 4, ''Progressive waves in lossless and lossy fluids,'' by D. Blackstock, M. Hamilton, and A. Pierce. They consider, for the most part, classical aspects of nonlinear acoustics: simple wave propagation and shock waves in plane, cylindrical, and spherical geometry. This topic is continued in Chapter 5, ''Dispersion,'' in which M. Hamilton, Yu. Il'inskii, and E. Zabolotskaya consider waves in relaxing media, where dispersion is weak and is of a dissipative nature, and in waveguides and bubbles, where it can play a dominant role in wave interactions. Two subsequent chapters, 6, ''Radiation pressure and acoustic levitation'' by T. Wang and C. Lee, and 7, ''Acoustic streaming,'' deal not with the sound propagation, but rather with the action of sound on small bodies and inducement of the hydrodynamic motion of the medium itself.

As the editors state, these first seven chapters of the book are largely self-contained and can be used as a course text, while the remaining eight chapters cover more special topics. I found that the separation of these two parts of the book is not very distinct. Chapter 8, ''Sound beams,'' written by M. Hamilton, is based on the parabolic KZK equations and treats both perturbations of the linear diffraction theory results and the theory of strongly distorted wave beams. Chapter 9, ''Finite-amplitude waves in solids,'' by A. Norris, is a good summary of mostly classical results. Still, I find it unfortunate that this chapter is the only ''non-fluid'' piece in the book. The next two chapters, 10, ''Perturbation methods,'' by J. Ginsberg, and 11, ''Computational methods,'' by J. Ginsberg and M. Hamilton, discuss some analytical and computational aspects of nonlinear acoustics; the latter seems particularly useful; it contains an accessible explanation of numerical problems.

The rather lengthy chapters 12 and 13 deal with very general problems. The former, ''Propagation in inhomogeneous media (Ray theory),'' by C. Morfey and F. Cotaras, gives a clear and comprehensive narrative of nonlinear geometrical acoustics. To have a complete picture of this large area, it would be desirable to include more information on self-refraction problems and to discuss the relationship between ray theory and the theory of diffracting sound beams. The latter, ''Statistical phenomena,'' by S. Gurbatov and O. Rudenko, describes some results of the theory of nonlinear propagation of random acoustic waves and their interaction with regular signals.

The last two chapters are about two relatively new topics in nonlinear acoustics. In Chapter 14, ''Parametric layers, four-wave mixing, and wavefront reversal,'' H. Simpson and P. Marston discuss some ''four-wave'' processes associated mainly with cubic nonlinearity of the medium. Similar processes have long been commonplace in optics. I would have liked to see a brief discussion of this in the chapter. Also, since the early 1980s, these problems have been penetrating into nonlinear acoustics. They include, in particular, the different phase-conjugating processes, such as wavefront reversal, and some experiments in this area are also mentioned. The last chapter, 12, ''Biomedical applications,'' written by E. Carstensen and D. Bacon, gives an outline of one of the most important applications of intensive ultrasound. These applications, such as lithotripsy and ultrasonic surgery, have been known for a relatively long time, but actually, the theoretical approach based in principle on the nonlinear acoustics equations, has a rather short history in biological problems.

In general, this is a very good and useful book. The chapter-to-chapter inhomogeneity inevitable in books composed of a collection of essays, has been successfully minimized by the editors, and most of the materials are presented clearly and systematically. The book could be recommended both for scientists and for students. The only critical note I could have is that the book concentrates almost completely on acoustics of fluids (with the exception of chapter 9, which is rather short), somewhat ignoring recent progress in nonlinear acoustics of solids, including such ''nonclassical'' media as rocks and construction materials.

Coincidentally, only slightly later, a monograph entitled ''Nonlinear wave processes in acoustics'' by N. Naugolnykh and L. Ostrovsky was published by Cambridge University Press. Luckily, as a coauthor, I do not feel any conflict of interest regarding the reviewed book, or vice versa. Notwithstanding the natural overlap of a part of the topics, the books are rather complementary: while the first book gives detailed derivations of the main equations and their solutions and explains almost all the main effects of classical nonlinear acoustics of fluids and such important applications as biomedical acoustics, the second one gives a more compact, monographic outline of the problems of nonlinear acoustics. It includes more about solid state acoustics, the acoustics of dispersive media, and the problems relevant to nonlinear material characterization. As I mentioned earlier, the appearance of new books can be considered as an indicator of growing interest in nonlinear acoustics, which is stimulated by new and developing applications.

LEV A. OSTROVSKY
University of Colorado/NOAA Environmental Technology Laboratory, Boulder, Colorado 80303

Signals, Sound, and Sensation

William M. Hartmann

AIP Press, Woodbury, NY, 1997.
xvii+647 pp. Price: $80.00.

When I first saw this book, I was struck by the apparent similarity to another one that I reviewed in the December 1993 issue of *JASA: Signals and Systems for Speech and Hearing*, by Stuart Rosen and Peter Howell. Certainly the title is quite similar, and so is the intended readership. To quote Hartmann, ''*Signals, Sound, and Sensation* is a book for people who are actively interested in the perception of sound.'' Rosen and Howell target ''people working in the speech and hearing sciences.'' Both books seek to teach ''the mathematics of the signal'' to this audience in a friendly fashion.

Further reading soon reveals that the books have important differences: Hartmann's has twice as many pages as Rosen and Howell's (and costs twice as much). Whereas Rosen and Howell ''tell the entire story in words and pictures, with only minimal mathematics,'' Hartmann ''assumes that the reader is comfortable with the concepts and the practice of differential and integral calculus.''

What sort of book is this? Let me quote from the jacket: ''This is a unique book on the mathematics of signals written for hearing science researchers. Designed to follow an introductory text on psychoacoustics, *Signals, Sound, and Sensation* takes the reader through the mathematics of signal processing from its beginnings in the Fourier transform to advanced topics in modulation, dispersion relations, minimum phase systems, sampled data, and nonlinear distortion.''

To quote further, this time from the Preface, ''...*SS&S* resembles an engineering text, though it is friendlier than most of that genre.'' Well, with my background in electrical engineering, I regard such texts as old friends! On the other hand, I am delighted that Hartmann is so friendly in his exposition of concepts with which my knowledge is not so intimate: loudness, pitch, timbre, auditory filters, etc. In other words, I find that I can use the book to learn about psychoacoustics, already knowing about signals. This seems to be an inversion of what Hartmann intended, but it works for me.

Another feature I like about this book is the inclusion of biographical sketches of prominent workers in the field over the years: Hertz, Lord Reyleigh, Fletcher, Fourier, Barkhausen, Helmholtz, Von Békésy, Stevens, Hilbert, Fechner. I am concerned, however, about the biographical sketch of Hilbert. The author states that ''he invented the word 'spectrum.' '' I would venture to say that this gives short shrift to Isaac Newton, who used the word ''spectrum'' in *Phil. Trans. VI, 1671*.

This bit of ''nitpicking'' aside, I like Hartmann's book, and I recommend it, not only for those wishing to teach signal theory to students of psychoacoustics, but also for those wishing to teach basic psychoacoustic concepts to students already familiar with signal theory.

REVIEWS OF ACOUSTICAL PATENTS

Daniel W. Martin
7349 Clough Pike, Cincinnati, Ohio 45244

The purpose of these acoustical patent reviews is to provide enough information for a Journal reader to decide whether to seek more information from the patent itself. Any opinions expressed here are those of reviewers as individuals and are not legal opinions. Printed copies of United States Patents may be ordered at $3.00 each from the Commissioner of Patents and Trademarks, Washington, DC 20231.

Reviewers for this issue:

GEORGE L. AUGSPURGER, *Perception Incorporated, Box 39536, Los Angeles, California 90039*
DAVID A. PREVES, *Micro-Tech, 3500 Holly Lane N., Plymouth, Minnesota 55447*
D. LLOYD RICE, *11222 Flatiron Drive, Lafayette, Colorado 80026*
CARL J. ROSENBERG, *Acentech Incorporated, 33 Moulton Street, Cambridge, Massachusetts 02138*

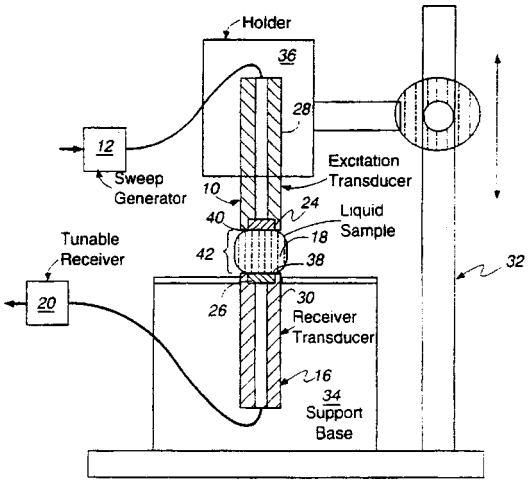
43.35.Yb ULTRASONIC CHARACTERIZATION OF SINGLE DROPS OF LIQUIDS

Dipen N. Sinha, assignor to the University of California
14 April 1998 (Class 73/579), filed 30 May 1996

This is a diagnostic system for characterizing the ultrasonic properties of a single drop of liquid. An excitation transducer **24** mounted on holder **10** rests lightly on droplet **18**, transmitting a pulse from surface **40** to the opposite surface **38** in contact with receiver transducer **26**. Examples of samples for which the apparatus and method can be used are tear drops, blood, and other body fluid samples and snake and bee venom, especially for forensic investigations.—DWM



5,764,784

43.38.Ja ELECTROACOUSTIC TRANSDUCER

Hiroshi Sato and Akira Yoshino, assignors to Sanyo Electric Company
9 June 1998 (Class 381/199); filed in Japan 12 September 1994

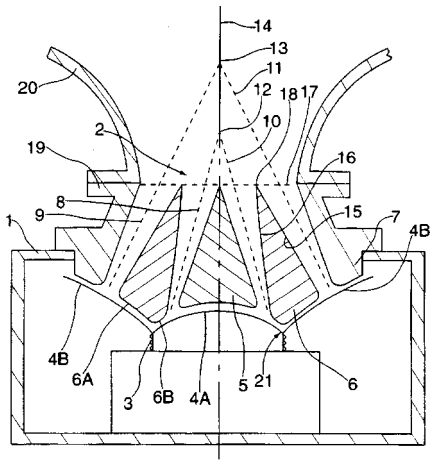
If a cylindrical voice coil is located close to a disk-shaped magnet, it will drive a cone or diaphragm without the need for a pot structure or pole pieces. The basic idea of a gapless dynamic loudspeaker has already been implemented in a number of patented designs. The variant described here is simple, inexpensive, and allows very thin assemblies. Whether it is really ''highly efficient'' is a question of semantics.—GLA

5,778,084

43.38.Ja LOUDSPEAKER WITH PHASE CORRECTION

Martin Kling and Jurgen Freitag, Hannover, Germany
7 July 1998 (Class 381/156); filed in Germany 27 January 1996

The patent explains that the function of a phasing plug is to transmit sound from all parts of the diaphragm to the horn throat with near-equal path lengths. The assertion is correct. The patent also implies that the insight is new. In fact, basic design criteria and practical implementations of multi-element phasing plugs were described by various researchers more than 60 years ago.—GLA



5,771,296

43.38.Lc AUDIO CIRCUIT

Toyoaki Unemura, assignor to Matsushita Electric Industrial Company
23 June 1998 (Class 381/28); filed in Japan 17 November 1994

Many pipe organs include ''synthetic'' ranks which fool the listener into hearing fundamental tones that do not exist. In the 1940s some radio receivers achieved a similar effect by adding controlled low-frequency distortion. The patented circuit is designed to process the output of a full-wave rectifier, and thereby deliver subjectively strong bass from a conventional TV set.—GLA

5,774,560

43.38.Lc DIGITAL ACOUSTIC REVERBERATION FILTER NETWORK

Alvin Wen-Yu Su and Li-Wei Wang, assignors to Industrial Technology Research Institute
30 June 1998 (Class 381/63); filed 30 May 1996

The filter network is a ''good sounding'' digital reverberator intended for use in recording studios. Digital wave-ladder filters and distribution matrices are used to model the response of an imaginary room. Reverberation effects are obtained by using a finite impulse response filter to mimic early reflections, then feeding the signal to the filter network for late reflections. The patent is interesting and easy to follow.—GLA

5,809,158

43.38.Si TRANSDUCER

Aart van Halteren and Onno Geschiere, assignors to Microtronic Nederland, B.V.
15 September 1998 (Class 381/200); filed 24 July 1996

An output transducer is described that is intended for use as a hearing aid receiver. The device includes a means for limiting the maximum output SPL produced via a connecting piece attached to the armature or by projections on the armature or coil.—DAP

5,742,687

43.38.Vk SIGNAL PROCESSING CIRCUIT INCLUDING A SIGNAL COMBINING CIRCUIT STEREOPHONIC AUDIO REPRODUCTION SYSTEM INCLUDING THE SIGNAL PROCESSING CIRCUIT AND AN AUDIO-VISUAL REPRODUCTION SYSTEM INCLUDING THE STEREOPHONIC AUDIO REPRODUCTION SYSTEM

Ronaldus M. Aarts, assignor to U.S. Philips Corporation
21 April 1998 (Class 381/1); filed in Belgium 17 January 1994

By processing and cross feeding left and right stereo signals, the perceived sound stage can be made wider than the distance between the two loudspeakers, and there are numerous patents to prove it. This patent describes ''...means by which the stereo image is enhanced without appreciable signal colouring occurring when mono signals are reproduced.''—GLA

5,751,817

43.38.Vk SIMPLIFIED ANALOG VIRTUAL EXTERNALIZATION FOR STEREOPHONIC AUDIO

Douglas S. Brungart, Salem, NH
12 May 1998 (Class 381/25); filed 30 December 1997

Active analog filter circuitry is used to simulate pinnae functions and to provide delay. When the circuit was designed, this approach could be described as ''simplified, low-cost'' in contrast to digital implementation. Only 2 years later the opposite is probably true.—GLA

5,768,393

43.38.Vk THREE-DIMENSIONAL SOUND SYSTEM

Masahiro Mukojima and Shigemitsu Yamaoka, assignors to Yamaha Corporation
16 June 1998 (Class 381/17); filed in Japan 18 November 1994

The patent document is short, clear, and interesting. It describes an improved method for coordinating sound image localization with three-dimensional computer graphics. High-quality sound generation can be achieved with relatively little processing load on the host computer.—GLA

5,768,394

43.38.Vk SURROUND AUDIO SIGNAL REPRODUCING APPARATUS HAVING A SUB-WOOFER MIXING FUNCTION

Jae-hoon Heo, assignor to Samsung Electronics Company
16 June 1998 (Class 381/18); filed in Rep. of Korea 18 August 1995

The public relations bandwagon for 5:1 consumer stereo is picking up speed, apparently fueled by the conviction that a variety of program material in one format or another will be available soon. The patent describes a method of eliminating one of the six power amplifiers by mixing the subwoofer channel into the left and right surround channels. High-level dividing networks extract the three signals and drive appropriate loudspeakers.—GLA

5,771,041

43.38.Vk SYSTEM FOR PRODUCING DIRECTIONAL SOUND IN COMPUTER BASED VIRTUAL ENVIRONMENT

Ian S. Small, assignor to Apple Computer, Incorporated
23 June 1998 (Class 345/326); filed 3 December 1996

Many graphics-intensive computer programs allow the user to move anywhere within a virtual environment. Ideally, the accompanying sound field should change accordingly. The system allows the user to create a sound map that establishes relative levels of individual sound sources at various locations. At run time, when a particular view is selected, a hearing area corresponding to that view is calculated, and various stored sound sources are mixed to provide the desired sound output.—GLA

5,771,295

43.38.Vk 5-2-5 MATRIX SYSTEM

James K. Walker, Jr., assignor to Rocktron Corporation
23 June 1998 (Class 381/18); filed 18 December 1996

The system attempts to provide discrete five-channel audio signals anywhere, any time, from any two-channel program source. ''The matrix system is compatible with all existing stereo materials and material encoded for use with other existing surround systems. Material specifically encoded for this system can be played back through any other existing decoding systems without producing undesirable results.''—GLA

5,778,087

43.38.Vk METHODS FOR STEREO LOUDSPEAKER PLACEMENT

John Harold Dunlavy, Colorado Springs, CO
7 July 1998 (Class 381/303); filed 24 March 1995

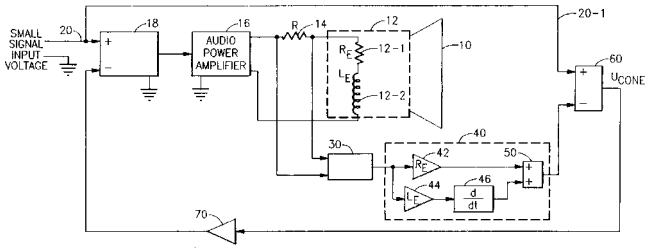
The patent argues that accurate two-channel stereophonic reproduction requires identical acoustic path lengths from the two loudspeakers to the listening location. Since slight variations between loudspeakers are likely, a tape measure does not necessarily serve as an accurate indicator. A better method is to feed the signal from a random noise generator (optionally band-limited) to both channels, and then move a sound level meter back and forth across the center line to find the location where the level peaks. Conversely, the two channels can be connected in reverse polarity and the sound level meter used to pinpoint the resulting null location. Both of these tricks have long been used by installers of professional playback systems.—GLA

5,771,300

43.50.Ki LOUDSPEAKER PHASE DISTORTION CONTROL USING VELOCITY FEEDBACK

Mark A. Daniels, assignor to Carrier Corporation
23 June 1998 (Class 381/71.5); filed 25 September 1996

Active noise reduction in chimneys and ducts utilizes at least one loudspeaker to cancel unwanted sound, and a microphone (located downstream from the loudspeaker) to sense the result and provide a feedback signal. The basis for the patent lies in two axioms. The first is that optimum performance and minimum physical separation require an undistorted electroacoustic transfer function. Ideally, the microphone, amplifier, and loudspeaker would all have flat response and negligible phase shift through the frequency range of interest. However, faced with the limitations of an im-



perfect loudspeaker, one can incorporate appropriate equalization in the amplifier circuitry. The second axiom states that a loudspeaker driving a long duct should act as a constant velocity piston all the way down to the lowest frequency of interest. This apparently has led to a number of questionable assumptions about loudspeakers in general, and then to design of a current feedback equalization scheme which involves deriving a voltage signal that mimics theoretical cone velocity. All of this is strongly reminiscent of several ''servo control'' high-fidelity loudspeaker patents. It can be made to work, but there are easier ways to achieve the desired results.—GLA

5,750,944

43.55.Ev FOIL SOUND ABSORBERS

Helmut Fuchs, assignor to Fraunhofer-Gesellschaft zur Foerderung der angewandten Forschung e.V.
12 May 1998 (Class 181/290); filed in Germany 15 March 1994

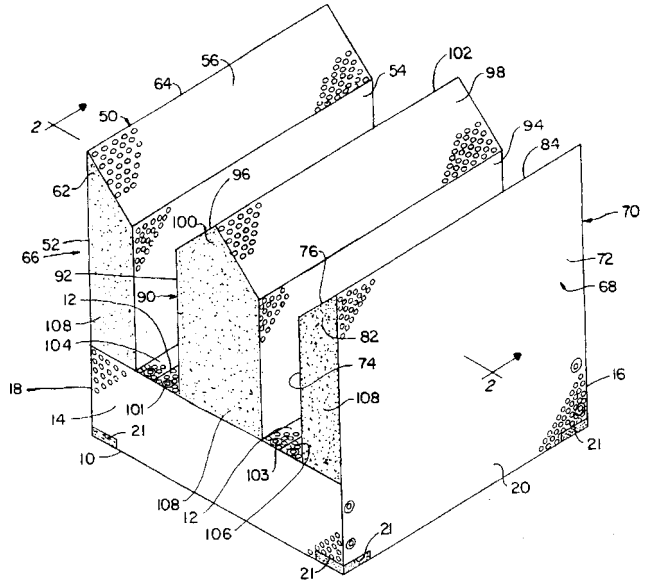
This foil absorber has at least two, preferably three, smooth air-impermeable foils spaced at varying distances from each other and from a reverberant (hard) back-up wall. The surface weight of the foils is approximately 0.05 to 1.0 kg/m^2, and the distance between the foils can be from 5 to 100 mm. The absorber is said to be simple to fabricate and easy to clean.—CJR

5,780,785

43.55.Ev ACOUSTIC ABSORPTION DEVICE AND AN ASSEMBLY OF SUCH DEVICES

Alan Eckel, Westford, MA
14 July 1998 (Class 181/295); filed 12 March 1997

This patent discloses a variation on acoustical treatments for use in an anechoic chamber. The device has spires with flat sides protruding from a



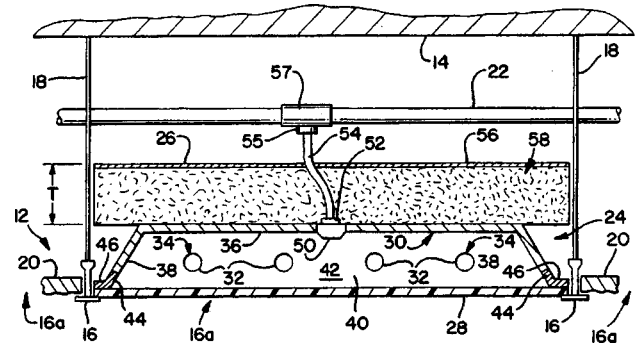
rectangular base instead of traditional wedges, and the device could be made of perforated metal to protect the glass fiber absorption material. The device can be arranged in an array with alignment at alternating right angles.—CJR

5,782,551

43.55.Ev ACOUSTICAL LIGHTING FIXTURE

Raymond W. Capaul, Aurora, IL
21 July 1998 (Class 362/148); filed 19 January 1996

The lighting fixture incorporates an absorptive material, such as glass fiber, directly into the fixture behind the light source. The bottom of the



fixture can be a louver which allows sound to not be reflected. The result is said to be a light fixture that is as effective as an acoustical tile at both absorbing sound and at blocking sound.—CJR

5,796,055

43.55.Ev SOUND ABSORBING ARTICLE AND METHOD OF MAKING SAME

Vernon C. Benson, Jr. and Glenn E. Freeman, assignors to PPG Industries, Incorporated
18 August 1998 (Class 181/208); filed 13 January 1997

The patent describes improvements on construction of sound damping glazing, with variations on the thickness and the number of interlayers between sheets of glass. The product is envisioned for use in the automotive industry, but would perhaps have applications in regular building construction as well.—CJR

5,787,187

43.58.Bh SYSTEMS AND METHODS FOR BIOMETRIC IDENTIFICATION USING THE ACOUSTIC PROPERTIES OF THE EAR CANAL

Ann Marie Bouchard and Gordon Osborne, assignors to Sandia Corporation
28 July 1998 (Class 382/115); filed 1 April 1996

This system is said to verify a person's identity based on differences in acoustic properties of ear canals. Acoustic signals are transmitted into the ear canal, and the resulting acoustic response signals are detected and compared against stored reference features for the individual. Several feature extraction, analysis, and pattern recognition techniques are employed.—DAP

5,792,072

43.58.Bh SYSTEM AND METHOD FOR MEASURING ACOUSTIC REFLECTANCE

Douglas H. Keefe, assignor to University of Washington
1 August 1998 (Class 600/559); filed 8 April 1996

A small probe assembly containing a sound source and microphone is inserted into the ear canal. The system measures at different stimulus levels the reflectance, admittance, and impedance as a function of static pressure applied to the ear. These are used to calculate the sound power absorbed by the ear and to develop level-dependent transfer functions.—DAP

5,809,149

43.66.Pn APPARATUS FOR CREATING 3D AUDIO IMAGING OVER HEADPHONES USING BINAURAL SYNTHESIS

Terry Cashion and Simon Williams, assignors to Qsound Labs, Incorporated
15 September 1998 (Class 381/17); filed 25 September 1996

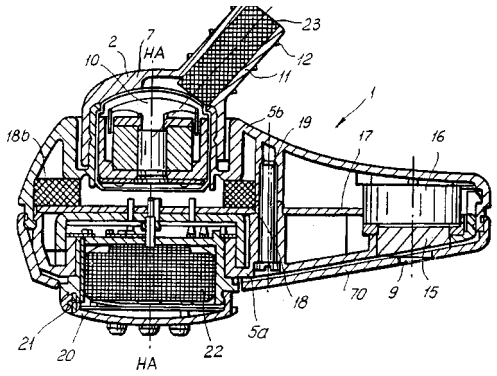
A sound image processing system is described that can produce large, smooth movements in the apparent sound source location for a listener wearing headphones.—DAP

5,784,471

43.66.Ts HEARING AID WITH AN ELECTRODYNAMIC ACOUSTIC TRANSDUCER

Wolf-Dietrich Bebenroth, assignor to Sennheiser electronic GmbH
21 July 1998 (Class 381/69); filed 11 July 1996

A mass-produced, modular two-piece hearing aid having a movable, foam-filled eartube to adapt to individual ear canals is described. The construction of an electrodynamic output transducer that provides wider bandwidth amplification than those in conventional hearing aids is disclosed. The replaceable foam transmits sound without attenuation while preventing dirt and cerumen from entering the hearing aid.—DAP



5,785,661

43.66.Ts HIGHLY CONFIGURABLE HEARING AID

Adnan Shennib, assignor to Decibel Instruments, Incorporated
28 July 1998 (Class 600/559); filed 17 August 1994

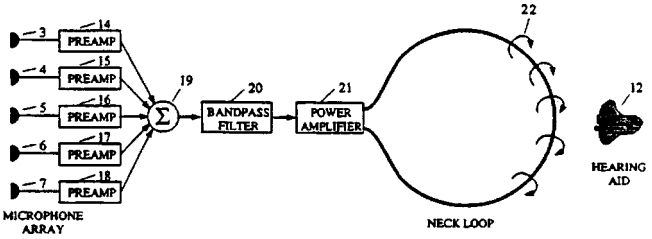
A binaural system using intracanal transducers is described that includes an SPL audiometer, a simulated hearing aid, and a real-ear measurement system. Acoustic test signals representative of real world listening environments are produced by the system. Individualized acoustic transfer functions in three-dimensional space are used to create virtual acoustic conditions and to set up the hearing aid specifications.—DAP

5,793,875

43.66.Ts DIRECTIONAL HEARING SYSTEM

Michael Lehr and Bernard Widrow, assignors to Cardinal Sound Labs, Incorporated
11 August 1998 (Class 381/684); filed 22 April 1996

A necklace housing an array of two or more microphones is disclosed. The system is made directional by processing the microphone output signals, and the amplified output signal drives a conducting loop encircling the



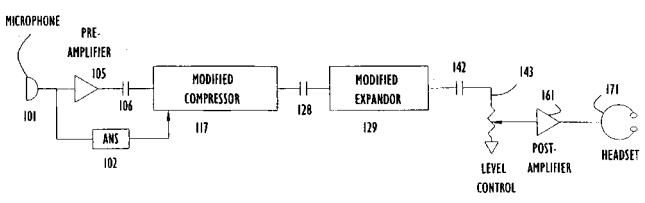
wearer's neck to produce a representative magnetic field. An induction pickup coil is housed on or in the wearer's ear and drives an electroacoustic transducer that produces an acoustic signal emphasizing sounds arriving from the frontal direction.—DAP

5,794,187

43.66.Ts METHOD AND APPARATUS FOR IMPROVING EFFECTIVE SIGNAL TO NOISE RATIOS IN HEARING AIDS AND OTHER COMMUNICATION SYSTEMS USED IN NOISY ENVIRONMENTS WITHOUT LOSS OF SPECTRAL INFORMATION

David Franklin and Michael Steele, assignors to Audiological Engineering Corporation
11 August 1988 (Class 704/225); filed 16 July 1996

A system is described that improves signal-to-noise ratio by a small automatic and rapid downward expansion (attenuation) of the signal by up



to a factor of three times when it determines that noise is present without speech. The noise-sensing algorithm assumes that signal amplitudes below a predetermined level constitute noise alone.—DAP

5,796,848

43.66.Ts DIGITAL HEARING AID

Raimund Martin, assignor to Siemens Audiologische Technik GmbH
18 August 1998 (Class 381/68); filed 6 December 1996

The digital hearing aid described is said to be relatively insensitive to electromagnetic interference. The hearing aid microphone and analog-to-digital converter are integrated together inside the microphone housing, thus eliminating long, low-level analog signal lines. Electromagnetic shielding is derived from the microphone housing.—DAP

5,765,135

43.70.Dn SPEECH THERAPY SYSTEM

Arye Friedman *et al.*, assignors to Speech Therapy Systems Limited
9 June 1998 (Class 704/276); filed in Israel 9 March 1994

This therapeutic speech training device is intended for use with stutterers and patients with respiratory-related speech problems. It records the respiratory state along with the speech, sound and displays both, allowing a patient to learn the breathing patterns related to normal and his or her own speech.—DLR

5,768,473

43.72.Ar ADAPTIVE SPEECH FILTER

Graham P. Eatwell and Kenneth P. Davis, assignors to Noise Cancellation Technologies, Incorporated
16 June 1998 (Class 395/2.35); filed 30 January 1995

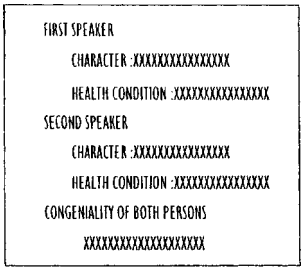
Wiener and Kalman filtering, as applied to speech processing, are similar to LPC except that computations are typically done on a sample-by-sample basis. This adaptive filter uses Kalman techniques to estimate the spectra of mixed speech and noise signals. The method is said to allow improved detection of voice presence.—DLR

5,774,850

43.72.Ar SOUND CHARACTERISTIC ANALYZER WITH A VOICE CHARACTERISTIC CLASSIFYING TABLE, FOR ANALYZING THE VOICES OF UNSPECIFIED PERSONS

Ichiro Hattori and Akira Suzuki, assignors to Fujitsu Limited & Animo Limited
30 June 1998 (Class 704/250); filed in Japan 26 April 1995

A typical karaoke system, during use, provides a voice channel relatively free of music, of an unknown speaker speaking (or singing) known words. This voice analyzer uses that information to extract vowel duration,



ANALYSIS RESULT OUTPUT SCREEN (B)

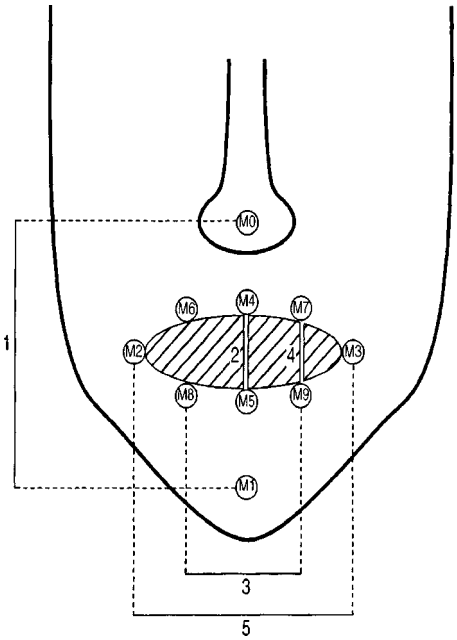
vowel spectra, and pitch range features and compares these to the features of stored reference words in an attempt to determine the health and stress level of the user.—DLR

5,771,306

43.72.Bs METHOD AND APPARATUS FOR EXTRACTING SPEECH RELATED FACIAL FEATURES FOR USE IN SPEECH RECOGNITION SYSTEMS

David G. Stork *et al.*, assignors to Ricoh Corporation
23 June 1998 (Class 382/100); filed 26 May 1992

This speech recognizer uses both acoustic and visual inputs to form analysis feature vectors. The sound is transformed to mel cepstral features while LED indicators attached to the face are tracked to provide point-to-



point distances from a video facial image. Visual and acoustic features are processed by separate time-delay neural networks that feed a classifier able to recognize one of ten utterances.—DLR

5,768,474

43.72.Dv METHOD AND SYSTEM FOR NOISE-ROBUST SPEECH PROCESSING WITH COCHLEA FILTERS IN AN AUDITORY MODEL

Chalapathy V. Neti, assignor to International Business Machines Corporation
16 June 1998 (Class 395/2.44); filed 29 December 1995

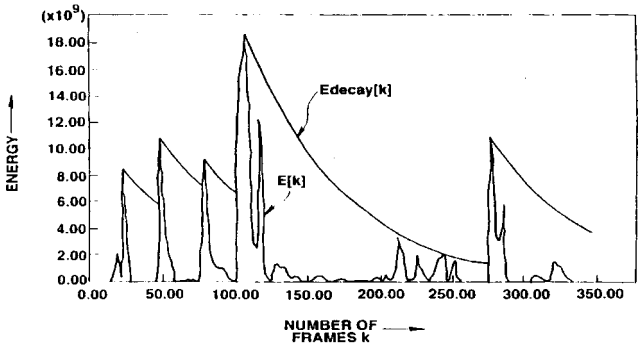
The patent begins by stating that auditory-based models are superior to standard spectral analysis techniques in extraction of the speech signal from noise. In the model presented here, the mechanisms of the ear are simulated by taking derivatives in both time and frequency of the output of a set of cochlealike bandpass filters. After negative clipping, frequency-scaled features are extracted from the time domain signals.—DLR

5,771,486

43.72.Dv METHOD FOR REDUCING NOISE IN SPEECH SIGNAL AND METHOD FOR DETECTING NOISE DOMAIN

Joseph Chan and Masayuki Nishiguchi, assignors to Sony Corporation
23 June 1998 (Class 704/200); filed in Japan 13 May 1994

This noise reduction system is based on computation of the frame-by-frame rms as a measure of the signal energy. The frame energy is compared



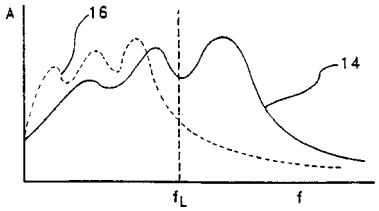
to a threshold to detect speech. Speech and nonspeech energies are adapted over time and subtracted to determine a signal-to-noise ratio. Speech is filtered by a maximum likelihood filter to reduce noise effects.—DLR

5,771,299

43.72.Ew SPECTRAL TRANSPOSITION OF A DIGITAL AUDIO SIGNAL

John Laurence Melanson, assignor to AudioLogic, Incorporated
23 June 1998 (Class 381/68.2); filed 20 June 1996

The patent describes a speech processing filter in which the spectral characteristics are removed and then reinserted by complementary zero and pole configurations. However, in the synthesis step, unit delays are replaced



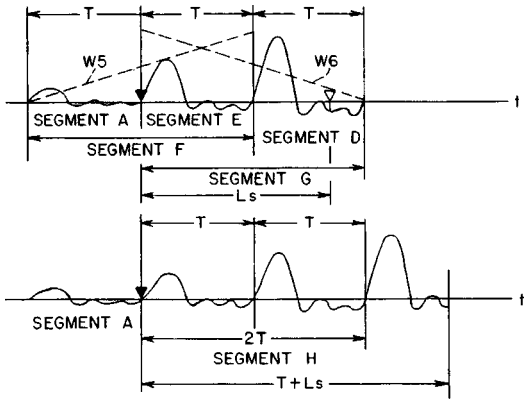
by non-unity-delay all-pass filters, resulting in controllable spectral compression, expansion, or inversion. In the figure, compression has lowered frequency f to frequency fL. The degree of shift may be frequency dependent.—DLR

5,781,885

43.72.Ew COMPRESSION/EXPANSION METHOD OF TIME-SCALE OF SOUND SIGNAL

Takeo Inoue and Shozo Sugishita, assignors to Sanyo Electric Company
14 July 1998 (Class 704/267); filed in Japan 9 September 1993

Many schemes have been proposed for varying a speech playback rate by adding or deleting pitch periods. In this variation, adjacent periods in the input waveform are averaged. For time scale compression, the average forms a single output period replacing the two originals, while, for expansion, the average period is inserted between the original two periods.—DLR

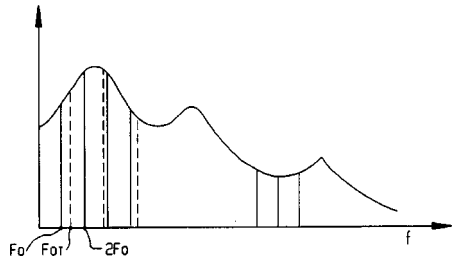


5,774,837

43.72.Gy SPEECH CODING SYSTEM AND METHOD USING VOICING PROBABILITY DETERMINATION

Suat Yeldener and Joseph Gerard Aguilar, assignors to Voxware, Incorporated
30 June 1998 (Class 704/208); filed 13 September 1995

This harmonic amplitude vocoder divides the speech spectrum into voiced and unvoiced portions. Based on an initial pitch estimate, a frequency point is determined below which the frame is considered voiced.



The voiced portion is analyzed for harmonic amplitude and phase information, while the unvoiced portion of the spectrum is analyzed by linear prediction.—DLR

5,778,335

43.72.Gy METHOD AND APPARATUS FOR EFFICIENT MULTIBAND CELP WIDEBAND SPEECH AND MUSIC CODING AND DECODING

Anil Wamanrao Ubale and Allen Gersho, assignors to The Regents of the University of California
7 July 1998 (Class 704/219); filed 26 February 1996

This wideband audio signal coder uses a single, 38th-order LPC analysis for the spectrum representation, but uses multiple codebooks dividing the excitation into multiple frequency bands. The input signal energy, short-term gain, and spectral flatness are analyzed to classify the input as speech or music and the excitation reconstruction is adjusted accordingly.—DLR

5,778,336

43.72.Gy SPEECH CODING AND JOINT DATA/CHANNEL BIAS ESTIMATION USING FINITE STATE VECTOR QUANTIZER DERIVED FROM SEQUENTIAL CONSTRAINTS

Wu Chou and Nambirajan Seshadri, assignors to Lucent Technologies, Incorporated
7 July 1998 (Class 704/222); filed 1 October 1996

This vocoder uses a trellis-encoded vector quantizer and decoder similar to that used in modem technology to estimate speech and transmission channel conditions. Similar decoders previously proposed were memoryless in that no use was made of the sequential spectral constraints in the speech signal. This system does use such constraints, helping to reduce channel bias and noise.—DLR

5,781,888

43.72.Gy PERCEPTUAL NOISE SHAPING IN THE TIME DOMAIN VIA LPC PREDICTION IN THE FREQUENCY DOMAIN

Juergen Heinrich Herre, assignor to Lucent Technologies, Incorporated
14 July 1998 (Class 704/219); filed 16 January 1996

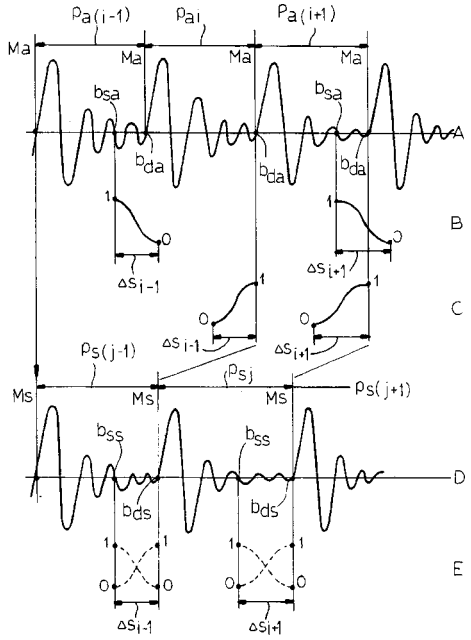
The patent describes a ''pre-echo'' problem often heard in previous perceptual coders when sending rapid-transient nonspeech sounds. The problem is caused by the temporal blurring of transient conditions throughout the frame. This solution avoids the ''pre-echo'' problem by using differential coding (DPCM) to encode the filter band outputs after the perceptual masking levels have been computed.—DLR

5,774,855

43.72.Ja METHOD OF SPEECH SYNTHESIS BY MEANS OF CONCENTRATION AND PARTIAL OVERLAPPING OF WAVEFORMS

Enzo Foti *et al.*, assignors to CSELT-Centro Studi e Laboratori Tellecomunicazioni S.p.A.
30 June 1998 (Class 704/267); filed in Italy 29 September 1994

This time-domain speech synthesizer creates the output speech waveform by adding overlapped segments of stored model waveforms. A fading



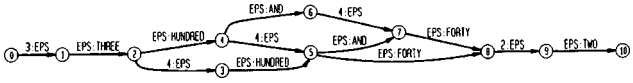
function controls the relative amplitudes of the overlapped segments during the addition process.—DLR

5,781,884

43.72.Ja GRAPHEME-TO-PHONEME CONVERSION OF DIGIT STRINGS USING WEIGHTED FINITE STATE TRANSDUCERS TO APPLY GRAMMAR TO POWERS OF A NUMBER BASIS

Fernando Carlos Neves Pereira *et al.*, assignors to Lucent Technologies, Incorporated
14 July 1998 (Class 704/260); filed 24 March 1995

This text-to-speech system for digit strings codes each digit according to its power-of-10 numerical value and uses a finite state grammar of number syntax patterns to generate an appropriate prosodic sequence for pronouncing the number. The pronunciation system is easily adaptable to languages other than English.—DLR



5,774,848

43.72.Ne REFERENCE PATTERN TRAINING SYSTEM AND SPEECH RECOGNITION SYSTEM USING THE SAME

Hiroaki Hattori, assignor to NEC Corporation
30 June 1998 (Class 704/244); filed in Japan 9 March 1995

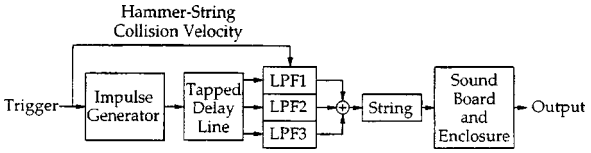
This speech recognition training system uses separate dictionaries of training words and recognition words. During training, phonetic context representations are built up from the training words and stored in such a way that reference patterns can be built for each phonetic context during recognition.—DLR

5,777,255

43.75.Mn EFFICIENT SYNTHESIS OF MUSICAL TONES HAVING NONLINEAR EXCITATIONS

Julius O. Smith III and Scott A. Van Duyne, assignors to Stanford University
7 July 1998 (Class 84/661); originally filed 10 May 1995

This patent discloses ''an efficient digital waveguide synthesizer for simulating the tones produced by a non-linearly excited vibrational element coupled to a resonator, such as in a piano.... The synthesizer creates an excitation pulse from a table containing the impulse response of a piano soundboard and enclosure.... The excitation pulse is fed into a filter that



simulates the collision of the piano hammer and string. Because the hammer-string interaction is nonlinear, the characteristics of this filter vary with the amplitude of the tone produced. The filtered excitation pulse is then fed into a filtered delay line loop which models the vibration of a piano string.''—DWM

5,747,715

43.75.Rs ELECTRONIC MUSICAL APPARATUS USING VOCALIZED SOUNDS TO SING A SONG AUTOMATICALLY

Shinichi Ohta and Masashi Hirano, assignors to Yamaha Corporation
5 May 1998 (Class 84/609); filed in Japan 4 August 1995

According to the patent this computerized electronic musical apparatus synthesizes successive syllables of vocal singing sounds at frequencies and times determined by operating a computer keyboard, which generates consonant sounds at times and vowel formant patterns at times and for durations corresponding to a melody designated by stored text and performance data. The production of a naturally sung song is said to be possible.—DWM

5,760,325

43.75.Tv CHORD DETECTION METHOD AND APPARATUS FOR DETECTING A CHORD PROGRESSION OF AN INPUT MELODY

Eiichiro Aoki, assignor to Yamaha Corporation
2 June 1998 (Class 84/613); filed in Japan 15 June 1995

This musical chord detection system automatically chooses appropriate chords in accordance with the progression of a melody, by comparing the frequencies of sequential tones with the frequencies in an existing chord and effecting appropriate transitions as the melody progresses.—DWM

5,763,802

43.75.Tv APPARATUS FOR CHORD ANALYSIS BASED ON HARMONIC TONE INFORMATION DERIVED FROM SOUND PATTERN AND TONE PITCH RELATIONSHIPS

Eiichiro Aoki and Kazunori Maruyama, assignors to Yamaha Corporation
9 June 1998 (Class 84/613); filed in Japan 27 September 1995

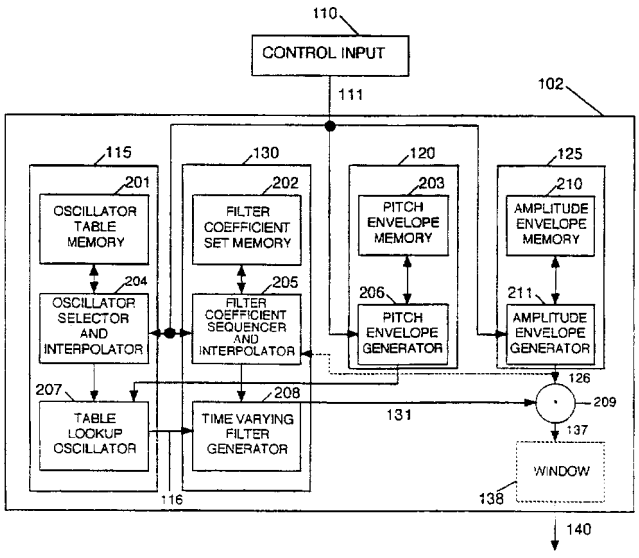
This is another chord analysis patent issued to the same inventor (and a coinventor) as 5,760,325 (reviewed above) in which the analysis uses tone frequency difference patterns compared to program memory tables.—DWM

5,744,742

43.75.Wx PARAMETRIC SIGNAL MODELING MUSICAL SYNTHESIZER

Eric Lindemann and Jeffrey Barish, assignors to EuPhonics, Incorporated
28 April 1998 (Class 84/623); originally filed 7 November 1995

Analog musical synthesizers and electronic musical instruments have long used formant filters to control the timbre of complex musical tone wave input signals of varying frequency. The relative efficiency of this method, in comparison to the digital storage of individual musical waveforms, is



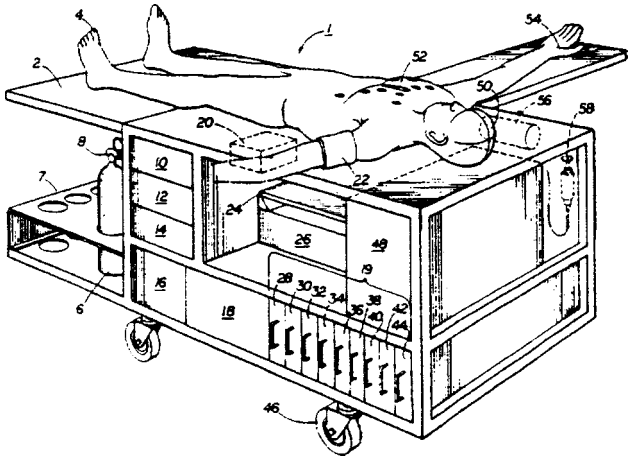
achieved in this digital musical synthesizer by providing multidimensional filters for which the filter coefficients can be programmed for smooth interpolation over fundamental frequency, intensity, and time. The noise components and tonal attacks are modeled separately.—DWM

5,779,484

43.80.Qf APPARATUS AND METHOD OF SIMULATING BREATHING SOUNDS

Samsun Lampotang *et al.*, assignors to University of Florida
14 July 1998 (Class 434/266); filed 17 December 1996

For training medical students about medical procedures (e.g., anaesthesia) a manikin **4** is provided having a pneumatically operated lung bel-



lows and a loudspeaker near the mouth for reproducing prerecorded audible breathing sounds corresponding to appropriate physiological sounds for various circumstances.—DWM

5,782,240

43.80.Qf METHOD OF CLASSIFYING RESPIRATORY SOUNDS

Gil Raviv and Charles A. Weingarten, assignors to SNAP Laboratories
21 July 1998 (Class 128/671); filed 22 December 1994

The respiratory sounds of this patent pertain to sleep apnea and snoring. Recording microphones mounted in a tubular structure worn by the sleeper provide signals to a data encoder for analysis along with other physiological signals for subsequent classification of the sound analyses in connection with respiratory events. Although apparatus is described in the patent, this is a method patent having to do with comparison of a second set of data to thresholds based on a standard or reference set of data.—DWM

5,788,636

43.80.Vj METHOD AND SYSTEM FOR FORMING AN ULTRASOUND IMAGE OF A TISSUE WHILE SIMULTANEOUSLY ABLATING THE TISSUE

Michael G. Curley, assignor to Acuson Corporation
4 August 1998 (Class 600/439); filed 25 February 1997

Imaging is accomplished by interlacing the times of the pulse-echo part of the ultrasonic imaging process and the times during which the current performing ablation is applied.—RCW

5,797,397

43.80.Vj ULTRASOUND IMAGING SYSTEM AND METHOD USING INTENSITY HIGHLIGHTING TO FACILITATE TISSUE DIFFERENTIATION

Mark Rosenberg, assignor to Hewlett-Packard Company
25 August 1998 (Class 128/660.04); filed 25 November 1996

An ultrasonic intensity range of interest is selected and ultrasonic image areas that contain these intensities are highlighted, typically with a distinctive color.—RCW

5,797,845

43.80.Vj ULTRASOUND APPARATUS FOR THREE DIMENSIONAL IMAGE RECONSTRUCTION

Leonid S. Barabash, Phoenix, AZ *et al.*
25 August 1998 (Class 600/443); filed 4 November 1996

This apparatus employs a phased transducer to produce flat transmit beams and flat receive beams that cross in space and are scanned to form a pencil beam from the product of the beams. A fast acquisition method that uses dynamic focusing of a scanned flat beam and synthetic receive apertures from stored amplitude information is included.—RCW

5,797,849

43.80.Vj METHOD FOR CARRYING OUT A MEDICAL PROCEDURE USING A THREE-DIMENSIONAL TRACKING AND IMAGING SYSTEM

Ivan Vesely and Wayne Smith, assignors to Sonometrics Corporation
25 August 1998 (Class 600/461); filed 7 March 1997

This method tracks the position of a surgical instrument within the body. The location of the instrument relative to its immediate surroundings is displayed. Procedures during which this method may be used include biopsy, amniocentesis, and transmyocardial myocardial revascularization.—RCW

5,806,521

43.80.Vj COMPOSITE ULTRASOUND IMAGING APPARATUS AND METHOD

Alan K. Morimoto *et al.*, assignors to Sandia Corporation
15 September 1998 (Class 128/661.01); filed 26 March 1996

Composite two- and three-dimensional images are produced from individual ultrasonic frames. The reconstruction uses transducer orientation and a known center. Motion compensation, rank value filtering, noise suppression, and tissue classification are included to optimize the composite image.—RCW

5,807,258

43.80.Vj ULTRASONIC SENSORS FOR MONITORING THE CONDITION OF A VASCULAR GRAFT

George E. Cimochowski, Dallas, PA and George W. Keilman, Woodinville, WA
15 September 1998 (Class 600/454); filed 14 October 1997

Flow through a graft or vessel is monitored by a conformal array transducer or a tilted element using either transit time or Doppler measurements. Implantable electronic circuits are connected to excite and to receive ultrasonic signals. A radio frequency coil is connected to the electronic circuits and also implanted. An external coil connected to a power supply and console is used to convey power and receive data from the implanted apparatus.—RCW

Capped ceramic underwater sound projector: The "cymbal" transducer[a),b)]

(Received 11 February 1998; accepted for publication 26 September 1998)

A new type of transducer has been developed for use as a shallow-water sound projector at frequencies below 50 kHz. Dubbed the ''cymbal,'' it is similar to the more commonly known ''moonie'' and class V ring/shell flextensional designs. Prototype cymbal arrays 2 mm thick with a radiating area of 11.4 cm^2 have been developed and calibrated. Two mounting schemes have been examined: unpotted (oil-filled) and potted in a 5-mm thick layer of stiff polyurethane. In both cases, a transmitting response comparable to the more widely used Tonpilz transducer (with an equivalent radiating area) is attainable. When tested under hydrostatic pressures, a standard cymbal configuration has been shown to withstand exposures of 2.5 MPa (which corresponds to 250 m of water depth) before failure. © *1999 Acoustical Society of America.* [S0001-4966(99)02801-5]

INTRODUCTION

Sound transmission is the single most effective means of directing energy transfer over large distances underwater.[1] The acoustic frequency range for various types of underwater transducer applications spans seven decades, from 10 Hz to 100 MHz.[2] There is currently a great interest in the development of shallow-water (<250 m) acoustic projectors that operate in the frequency range from 1 kHz to 100 kHz.[3] Potential applications include seabed penetration for buried mines as well as underwater surveillance, navigation, target detection and classification. Ideally, these transducers should be thin, lightweight, exhibit medium to high acoustic-output power, be able to conform to a curved surface, and be of simple design such that they are easy and inexpensive to mass produce.

Currently, the predominant underwater projector systems that operate in the 1 kHz to 100-kHz frequency band are Tonpilz transducers and 1-3 type piezoelectric composites. The Tonpilz transducer consists of a stack of piezoelectric ceramic (typically lead zirconate titanate-PZT) rings connected mechanically in series and electrically in parallel. The ring stack is sandwiched between two metal masses: a heavy tailmass and a light, flared headmass which serves to transmit the generated acoustic energy into the surrounding medium. Tonpilz transducers are characterized by their very large acoustic-output power, are typically tens of centimeters in thickness, weigh up to several kilograms, and are designed to operate at frequencies up to 100 kHz.

The 1-3 type piezoelectric composites consist of a number of piezoelectric ceramic rods separated by a 3-D interconnected polymer matrix. These composites have been manufactured in a number of ways.[4] The current state-of-the-art fabrication technique is injection molding.[5] The performance of 1-3 piezoelectric composites is strongly affected by the elastic properties of both the ceramic and polymer phases as well as the aspect ratio, the volume fraction, and the arrangement of the piezoelectric ceramic rods.[6] These types of composites can be conformed to a curved surface and acoustically matched with water. The 1-3 piezoelectric composites designed for use below 100 kHz are at least 10 mm thick.

Polyvinylidene fluoride (PVDF) and its chemically related copolymers are piezoelectric polymers that are readily available from a number of commercial manufacturers in material thicknesses ranging from 5 to at least 600 μm.[7] The high compliance and low density of these piezoelectric polymers allow them to be easily shaped to conform to curved surfaces and to acoustically match to water. The large piezoelectric voltage coefficient, g_h, of PVDF renders it an excellent acoustic receiver material. However, its low piezoelectric strain coefficient, d_h, makes it a rather poor sound projector. A low permittivity also requires the use of expensive built-in electronics packaging because of the large electrical impedance mismatch between the piezoelectric polymer and the circuitry.[8]

A third type of underwater projector that is seeing a resurgence in interest is the flextensional transducer. Flextensionals have been in existence since the 1920s and have seen use as underwater projectors since the late 1950s.[9] Flextensionals consist of a piezoelectric ceramic drive element or assembly encapsulated by a metal shell. The metal shell acts as a mechanical transformer to convert the large generative force of the piezoelectric ceramic into increased displacement. The shape of the shell has become quite diverse over the years, and so a classification system has been established to group the common designs together.[10] Flextensional trans-

ducers typically range in size from several centimeters to several meters in length and can weigh up to several hundreds of kilograms.

A miniaturized version of the class V flextensional transducer was developed in the late 1980s at the Materials Research Laboratory at The Pennsylvania State University for use as a hydrophone.[11,12] This transducer is named the moonie due to the crescent moon-shaped cavity on the inner surface of the caps. A second generation moonie-type transducer, which consists of a thinner cap with a slightly different shape, has recently been developed for use as a micropositioning actuator.[13,14] This transducer has been dubbed the cymbal due to the similarity in the shape of its caps to that of the musical instrument of the same name. The cymbal cap shape is also more conducive to mass production than the moonie. A comparison of the moonie and cymbal designs is shown in Fig. 1.

The moonie and cymbal transducers consist of a piezoelectric ceramic (usually PZT) disk poled in the thickness direction which is sandwiched between and mechanically coupled to two metal caps, each of which contains a shallow, air-filled cavity on its inner surface. When used as a sound projector, the caps convert and amplify the small radial displacement and vibration velocity of the piezoelectric ceramic disk into a much larger axial displacement and vibration velocity normal to the surface of the caps. This enhanced displacement and vibration velocity from the caps contribute to a much larger acoustic-pressure output than would occur in the uncapped ceramic. The principle of using the cymbal as a hydrophone has been explained previously.[15] The dimensions of the standard-size moonie and cymbal transducers are presented in Table I.

The cymbal cap design was an outgrowth of results obtained via finite element analysis (using SAP90, MARK, and ANSYS®) on transducers with the moonie-style cap. Large stress concentrations were calculated in the moonie cap in the region above the bonding area.[14,16] In order to reduce this stress concentration, ring-shaped grooves of varying size were introduced into the moonie-type caps. This design

TABLE I. Dimensions of the standard moonie and cymbal transducers.

Moonie parameter	Dimension (mm)
1—PZT diameter	12.7
2—PZT thickness	1.0
3—cap diameter	12.7
4—cap thickness	1.0
5—cavity depth	0.25
6—cavity diameter	9.0
Cymbal parameter	**Dimension (mm)**
1—PZT diameter	12.7
2—PZT thickness	1.0
3—cap diameter	12.7
4—cap thickness	0.25
5—cavity depth	0.32
6—base cavity diameter	9.0
7—dimple diameter	3.0

modification was found to not only reduce the stress concentration in the metal, but also enhanced the axial displacement at the center of the caps.[17,18] Onitsuka's results showed that the optimum groove size extended from the edge of the inner air cavity to the outer edge of the cap.[18] Dogan extended this concept and devised the cymbal cap design along with a fabrication technique applicable to mass produce the caps.[19] The effects of materials properties and cap geometry on the actuator performance of the cymbals have been modeled both analytically[20] and using finite element analysis.[21] Finite element modeling to ascertain underwater acoustic performance is ongoing.

I. PARAMETERS TO MEASURE

Among the relevant parameters required to fully characterize an underwater projector, the most important are resonance frequency, mechanical $Q(Q_m)$, electroacoustic efficiency, electromechanical coupling coefficient (k_{eff}), transmitting voltage response (TVR), source level (SL), and acoustic directivity (beam) patterns. Transmitting voltage response is equal to the ratio of the sound pressure produced by the projector, referenced (*re*:) to a distance of one meter from its acoustic center, to unit voltage applied across the electrical terminals of the transducer.[22] It is reported in terms of dB *re*: 1 μPa/V @1 m, or as 1 μPa·m/V. Source level is the intensity of the radiated sound field relative to the intensity of a plane wave of rms pressure 1 μPa referred to a point one meter from the acoustic center of the projector.[23] Source level is related to the transmitting voltage response through the applied input rms voltage as:

$$\text{SL} = \text{TVR} + 20 \cdot \log V_{\text{in,rms}}. \tag{1}$$

In general, a source level of greater than 200 dB *re*: 1 μPa @1 m is desirable. The beam pattern describes the response of the transducer relative to its main acoustic axis.

II. EXPERIMENTAL PROCEDURE

Single-element cymbal transducers were fabricated by first punching 12.7-mm-diam blanks from a sheet of metal foil. These blanks were then molded into caps of the desired

TABLE II. Relevant materials properties of the caps[a] and PZT.[b]

Cap material	Young's modulus	Density	Poisson's ratio
brass	100.6 GPa	8550 kg/m^3	0.35
titanium	120.2 GPa	4500 kg/m^3	0.361
molybdenum	324.8 GPa	10 200 kg/m^3	0.28

PZT type	d_{31}	d_{33}	Dielectric constant $(\varepsilon_{33}^T/\varepsilon_0)$
552 (5H)	−274 pC/N	593 pC/N	3400
5A	−171 pC/N	374 pC/N	1700
4	−123 pC/N	289 pC/N	1300
8	−93 pC/N	218 pC/N	1000

shape using a die press. Since there is no machining involved, this process is relatively inexpensive and hospitable to mass production. The flanges of the caps were bonded to a poled PZT-552 disk (Piezo Kinetics, Inc., Bellefonte, PA) using a very thin ($\approx$20 μm) layer of insulating epoxy (Eccobond® 45LV/Catalyst 15LV; Emerson and Cuming, Inc., Woburn, MA). The entire assembly was allowed to cure at room temperature for at least 24 h while under moderate pressure. The relevant properties of the cap materials and piezoelectric ceramics used are given in Table II.

The quality of the bonding layer after curing was characterized by measuring the in-air admittance spectra of the transducer using an HP 4194A impedance/gain phase analyzer. Spurious vibration modes are indicative of a poorly bonded transducer.[24] Admittance characteristics, both in air and in water, were also used to determine resonance frequency, k_{eff}, Q_m, and electroacoustic efficiency. Charge amplification on the PZT electrodes (due to the presence of the caps) was measured using a modified Berlincourt d_{33} meter. The water depths to which the cymbal transducers can be taken before failure was ascertained by measuring their effective hydrostatic piezoelectric charge coefficient (d_h^{eff}) as a function of hydrostatic pressure. A thorough explanation of this procedure has been previously provided.[15]

Single-element transducers utilizing the PZT-552 composition as the active component were incorporated into 9-element square arrays. Two mounting schemes were investigated: unpotted (i.e., oil-filled boot) and potted in approximately 5 mm of water-impedance-matching polyurethane

TABLE III. Typical air- and water-loaded characteristics of the standard-size brass-capped cymbal transducer.

	Air-loading	Water-loading
Resonance frequency	25.2 kHz	16.1 kHz
k_{eff}	0.214	0.219
Q_m	200	20
electroacoustic efficiency		90%
d_{33}^{eff} (PZT-552)	12 000 pC/N	
d_{33}^{eff} (PZT-5A)	8 000 pC/N	
d_{33}^{eff} (PZT-4)	6 000 pC/N	
d_{33}^{eff} (PZT-8)	5 000 pC/N	

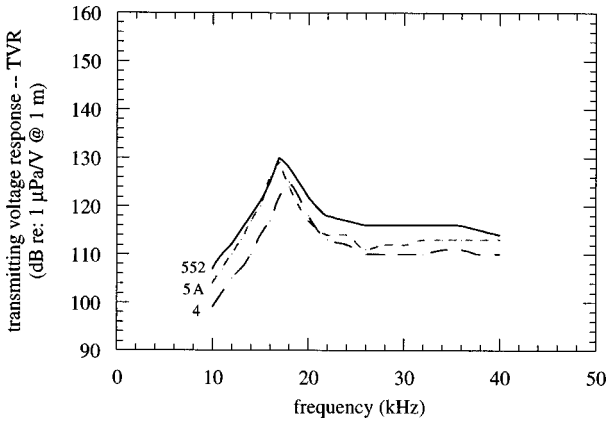

FIG. 4. Transmitting voltage response in the neighborhood of the fundamental resonance frequency of single-element, standard-size brass-capped cymbals utilizing PZT-552, 5A, or 4.

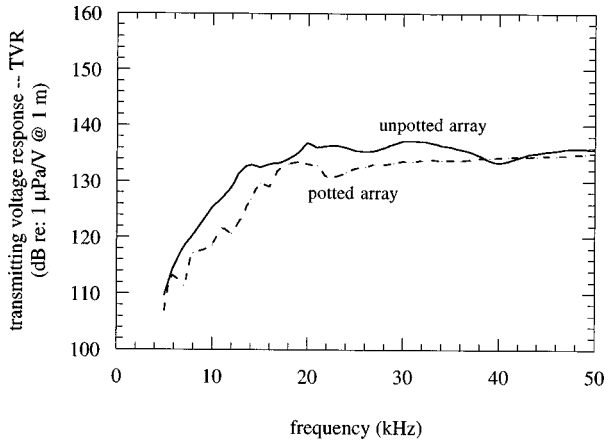

FIG. 6. Comparison of the transmitting voltage response of the potted and unpotted (oil-filled) 9-element cymbal arrays.

with hardness Shore-A90. In both cases, the center-to-center spacing between the elements was about 13.4 mm. For the potted array, electrical leads were attached to the caps on the positive side on each of the nine cymbals in the array using silver epoxy, and the assembly was wired together in parallel. The other surface of the array was attached to a kapton backing with conductive transfer tape, which served as the ground electrode.

The single elements in the unpotted array were sandwiched between two copper-clad printed circuit boards, each 1.5 mm thick. Holes 11.2 mm in diameter were drilled equidistant from one another through the boards which then housed the elements, thus allowing the dome of the cymbal caps to flex freely. Plastic spacers 1.5 mm thick were used to maintain a uniform distance between the upper and lower panels, which were screwed together tightly, as well as to keep the cymbal elements in place. Pictures of the two mounting configurations are shown in Fig. 2.

Underwater calibration tests were performed in the anechoic water tank at the Applied Research Laboratory at Penn State. The tank measured 7.9 m in length, 5.3 m in width, and 5.5 m in depth. A pure-tone sinusoidal pulse signal of 2 ms duration was applied to the test transducer, and its acoustic output was subsequently measured by a standard $F33$ recalibrated as a hydrophone. The test transducer and the standard were positioned so that they were at a depth of 2.74 m and separated by a distance of 3.16 m.

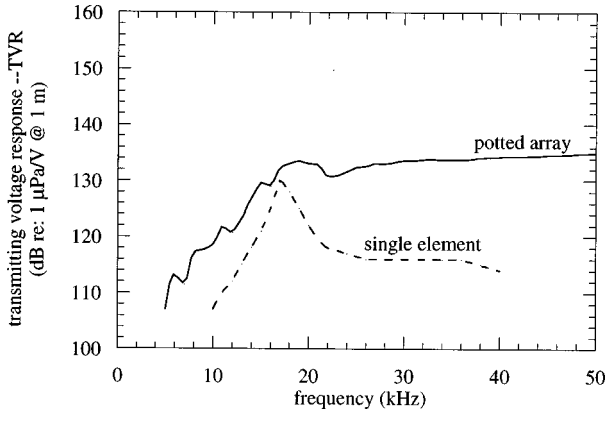

FIG. 5. Comparison of the transmitting voltage response of a single-element brass-capped cymbal with that of the potted 9-element array.

III. RESULTS AND DISCUSSION

Figure 3 shows the measured admittance spectra of a well-bonded, standard-size brass-capped cymbal transducer in the neighborhood of its fundamental resonance frequency both in air and in water. The downward shift in the resonance frequency is due to the acoustic mass-loading effect of the water. The resonance frequency of the cymbal transducer is controlled by the elastic properties of the cap material, the cap shape, and the overall diameter of the device.[21] Table III provides typical measured data for the parameters described in Sec. I. These are all values for standard-size, single-element brass-capped cymbals. The reported d_{33} coefficient is actually an effective d_{33} coefficient (since it is reported for a device) and will hereafter be designated as d_{33}^{eff}. The PZT type in parentheses is the type used as the active element in the transducer.

The transmitting voltage response in the neighborhood of the first resonance frequency for same-size, single-element brass-capped cymbal transducers utilizing different PZT types is shown in Fig. 4. The peak value of the transmitting response correlates with the d_{33}^{eff} coefficient of the device, as seen from Table III. The higher d_{33} (and thus d_{31}) coefficient of the piezoelectric ceramic results in a larger axial displacement in the caps; hence, a larger volume velocity which

TABLE IV. The calculated increase in TVR (in the neighborhood of the fundamental resonance of the single element) for unpotted oil-filled brass-capped cymbal arrays of different radiating area. The measured TVR at this frequency is shown for comparison. Active element is PZT-552.

Radiating area	Number of cymbals in the array	Expected increase in TVR at 18 kHz[a]	Measured TVR at 18 kHz
1.27 cm^2	1	0 dB	130 dB
11.4 cm^2	9	4 dB	134 dB
127 cm^2	100	23 dB	153 dB[b]
507 cm^2	400	35 dB	···

[a]As compared to the single element, includes mutual acoustic interactions between elements.

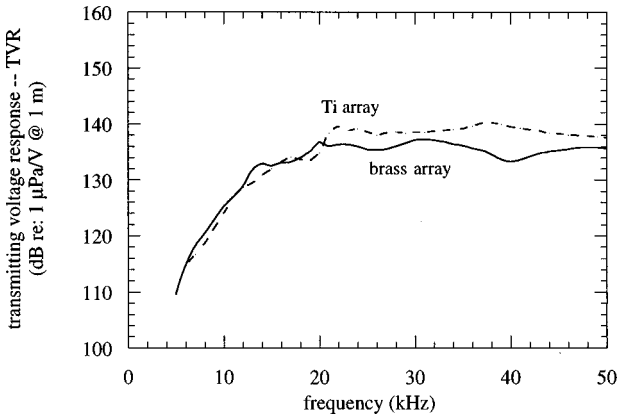

FIG. 7. Comparison of the transmitting voltage response of unpotted 9-element cymbal arrays with either brass caps or titanium caps.

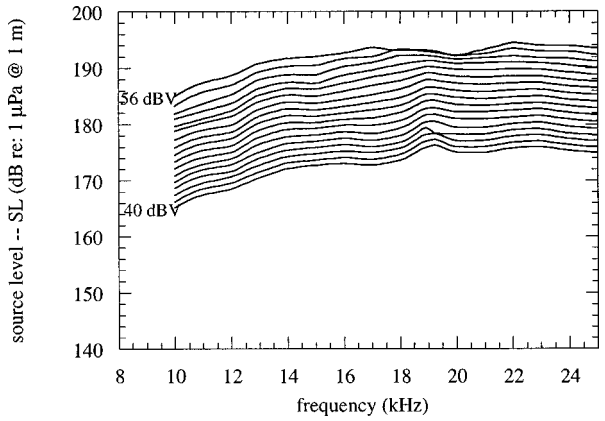

FIG. 8. Source level curves for the 9-element unpotted brass-capped array for drive levels starting at 40 dB *re*: 1 V and ending at 56 dB *re*: 1 V in increments of 1 dB *re*: 1 V.

leads to a higher acoustic-output pressure and subsequently, a higher TVR at resonance. Single-element cymbals are characterized by a relatively high $Q_m(\approx 20)$, low k_{eff} (≈ 0.22) and consequently, a narrow bandwidth.

If the acoustic impedance loading of a single cymbal were purely real (i.e., no mass loading), then incorporating the single-cymbal elements into a 9-element square array should theoretically enhance the transmitting voltage response by a factor of about 19 dB($=20\cdot\log 9$). A single cymbal, however, is mass loaded. Increasing the radiating area of the projector should serve to increase its radiation resistance and hence boost its acoustic-output power. Figure 5 compares the TVR of the single-element cymbal transducer to that of the 9-element potted array. When the single elements were potted in an array, the fundamental resonance was strongly damped, and there was only about a 4-dB enhancement in the TVR. The damping of the resonance was attributed to two detrimental effects: the shear components of the polyurethane potting layer acting to damp the resonance, and array element interactions. Interestingly, though, a more broadband transmitting response was observed. The larger radiating area also means that the array begins to approach ''ρc'' loading conditions as compared to the ''mass'' radiation loaded single element. The array resonance, therefore, does not shift down in frequency from the in-air measurement as much as does the single element. No significant difference in projector performance was observed when comparing results with the polyurethane layer (front) or the kapton layer (back) facing the standard receiver. The phasing of the displacements of the single-element cymbals relative to one another in the array was measured using a fiber-optic interferometer. When the array was driven at 100 V (peak) at 10 kHz, all the transducers were found to vibrate in phase within one deg.

In order to further examine the effect the potting layer had on the performance of the cymbal array, a second array was built and tested. This array was unpotted (i.e., oil filled). The TVR curves for the potted and unpotted arrays are compared in Fig. 6. Even in the case of the oil-filled array, the resonance frequency is again strongly damped. The mutual acoustic impedance between the individual radiators in the array was then estimated using a technique described by Pritchard.[25] In his analysis of same-size circular disks vibrating (all with the same velocity) in an infinite rigid plane, the mutual radiation impedance (Z_{12}) can be expressed as:

$$Z_{12}=(R_{12}+jX_{12})\cong\left\{\rho c\,\pi a^2\cdot\frac{(ka)^2}{2}\right\}\cdot\left[\frac{\sin(kd_i)}{kd_i}+j\,\frac{\cos(kd_i)}{kd_i}\right],\qquad(2)$$

when $(ka)^2\ll 1$ and $(a/d)\ll 1$ and where R_{12} is the mutual radiation resistance, X_{12} is the mutual radiation reactance, ρc is the characteristic impedance of the medium, a is the radius of the disk, d_i is the respective center-to-center spacing between the disks, and k is the wave number. Since the ka for the nine element array (≈ 2 at 18 kHz) is sufficiently large such that $R\gg X$, the mutual radiation impedance can be taken as simply the real part of Z_{12} at this frequency. The term in braces { } in Eq. (2) is equal to the self-radiation resistance (R_s) of a single radiator in the array. Ultimately, the mutual radiation resistance (R_m) seen by the array is equal to nine times the self-radiation resistance (due to the ninefold increase in area) multiplied by a factor representing the inter-element interactions, R_i [i.e., the bracketed term [ ] in Eq. (2)]. Taking the radiating frequency as 18 kHz and the closest center-to-center spacing between two adjacent elements in the array as 13.4 mm, the real part of the bracketed term, R_i, is equal to 5.714. The expected increase in TVR in an array as compared to a single element at a given frequency is therefore actually equal to $(20\cdot\log N-20\cdot\log R_i)$, where N is the increase in radiating area (or number of elements in the array). In the case of the nine-element arrays used in this analysis, the calculated increase in TVR (taking into account the mutual radiation impedance) at 18 kHz as compared to the single element should be 4 dB, which is what was experimentally observed in the case of the unpotted array (see Table IV). The slightly lower TVR seen in the case of the potted array can then be attributed to additional damping effects due to the stiff polymer. At frequencies beyond the resonance, mutual radiation impedance becomes less significant, and the approximate 19-dB increase in TVR as expected in the case of the unloaded array is observed.

Figure 7 compares the TVR curves for unpotted

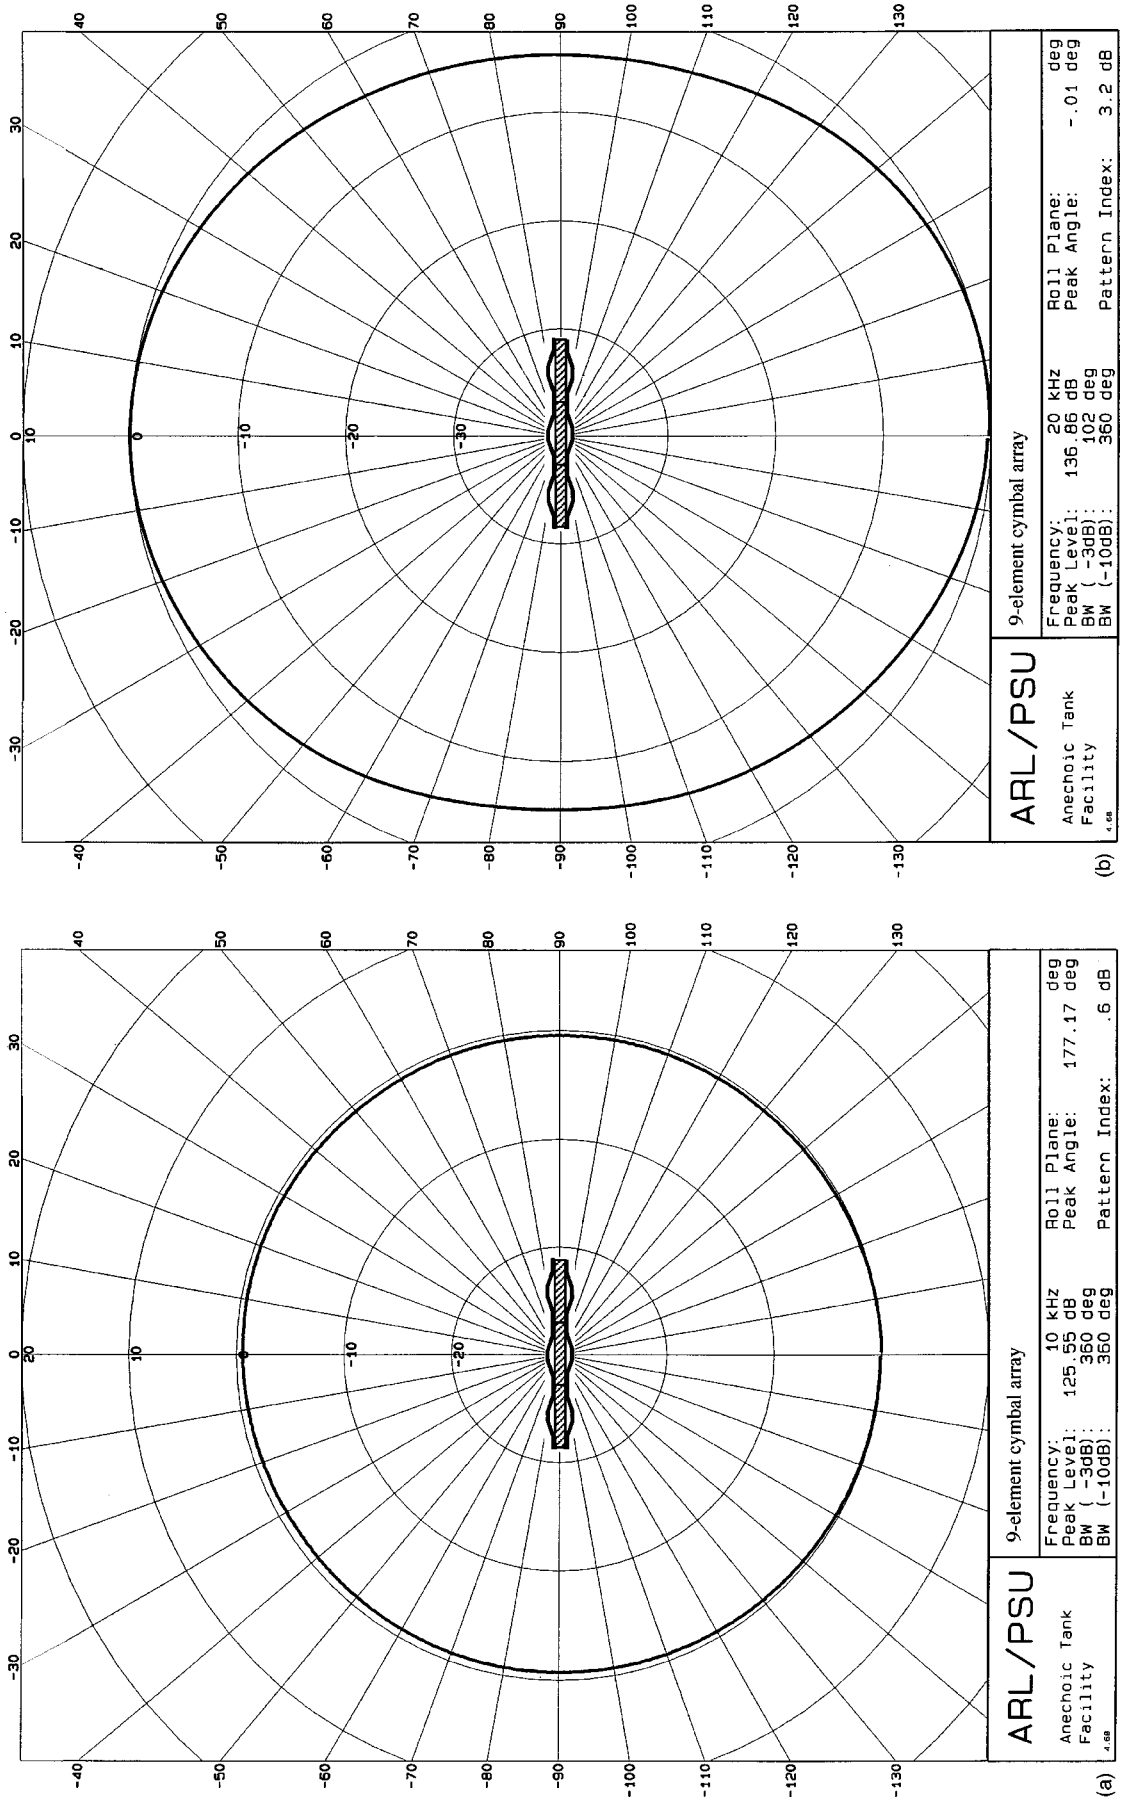

FIG. 9. Transmit-beam patterns for the cymbal arrays at (a) 10 kHz, (b) 20 kHz, (c) 30 kHz, (d) 50 kHz, and (e) 130 kHz.

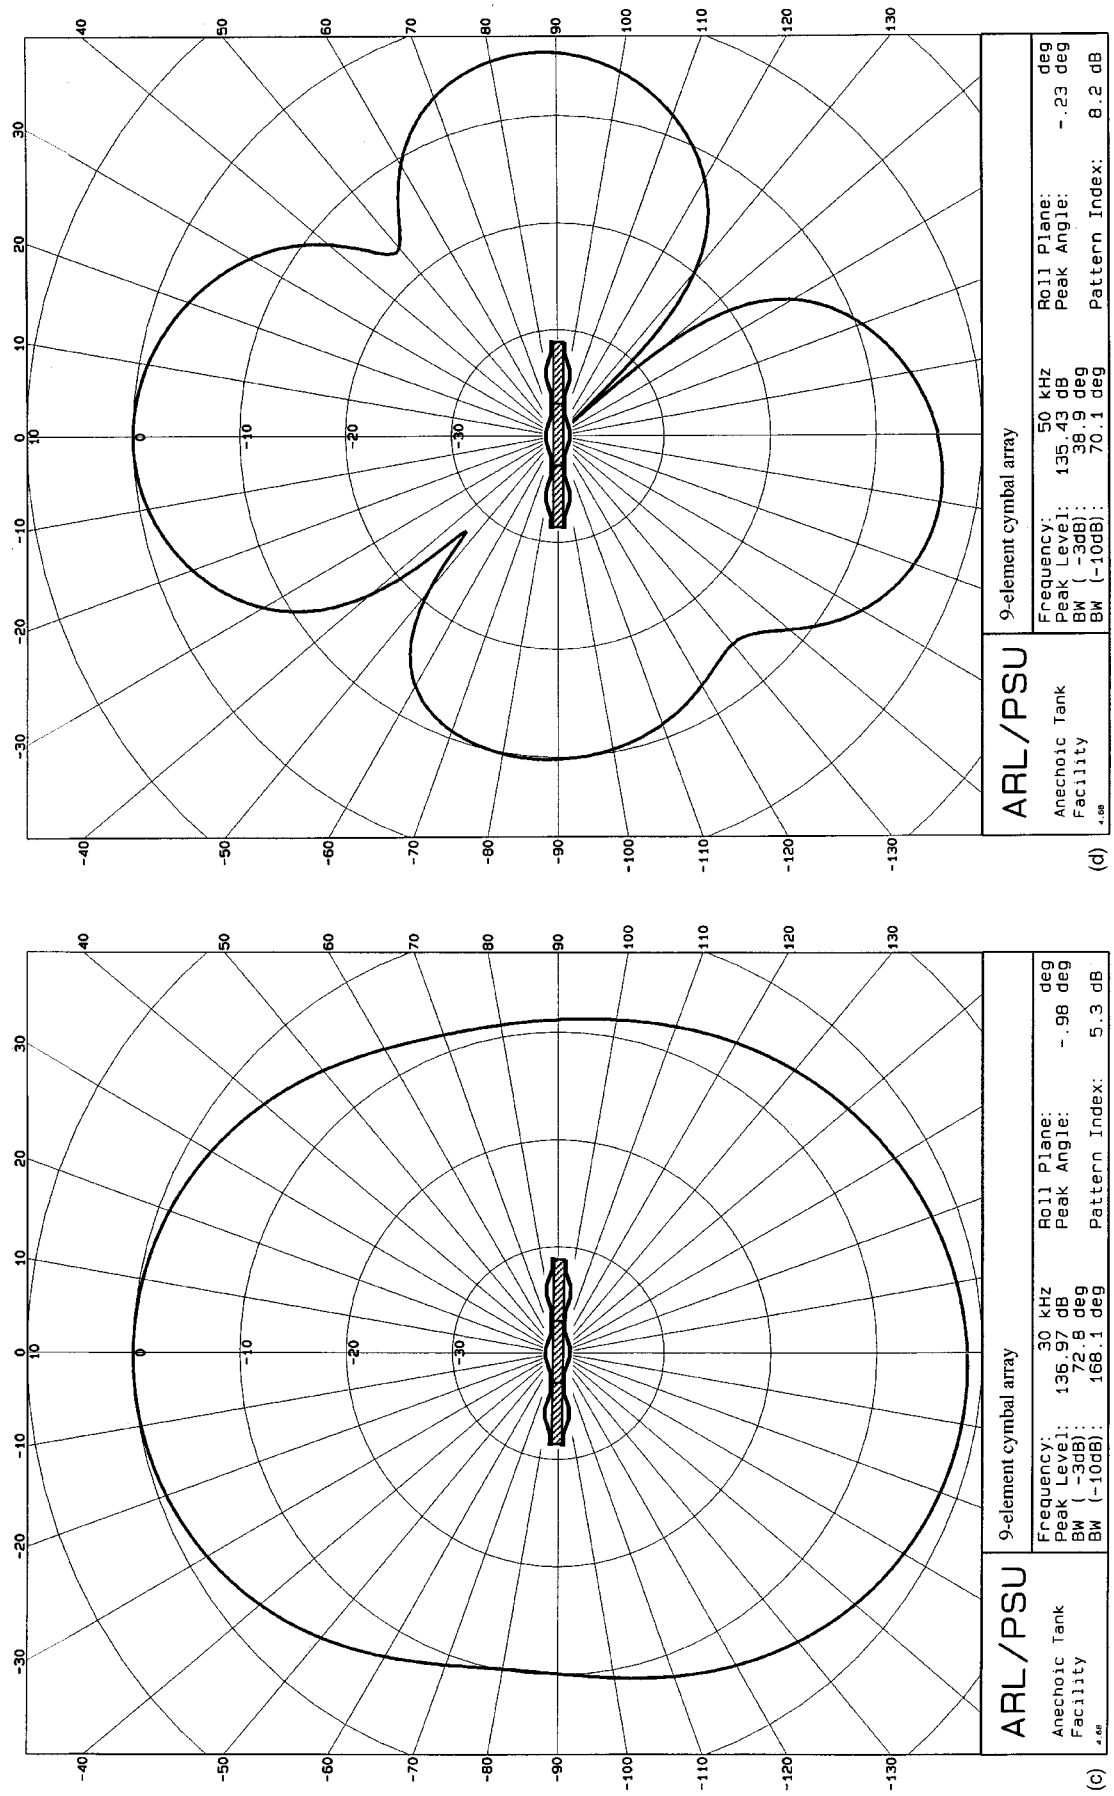

FIG. 9. (*Continued.*)

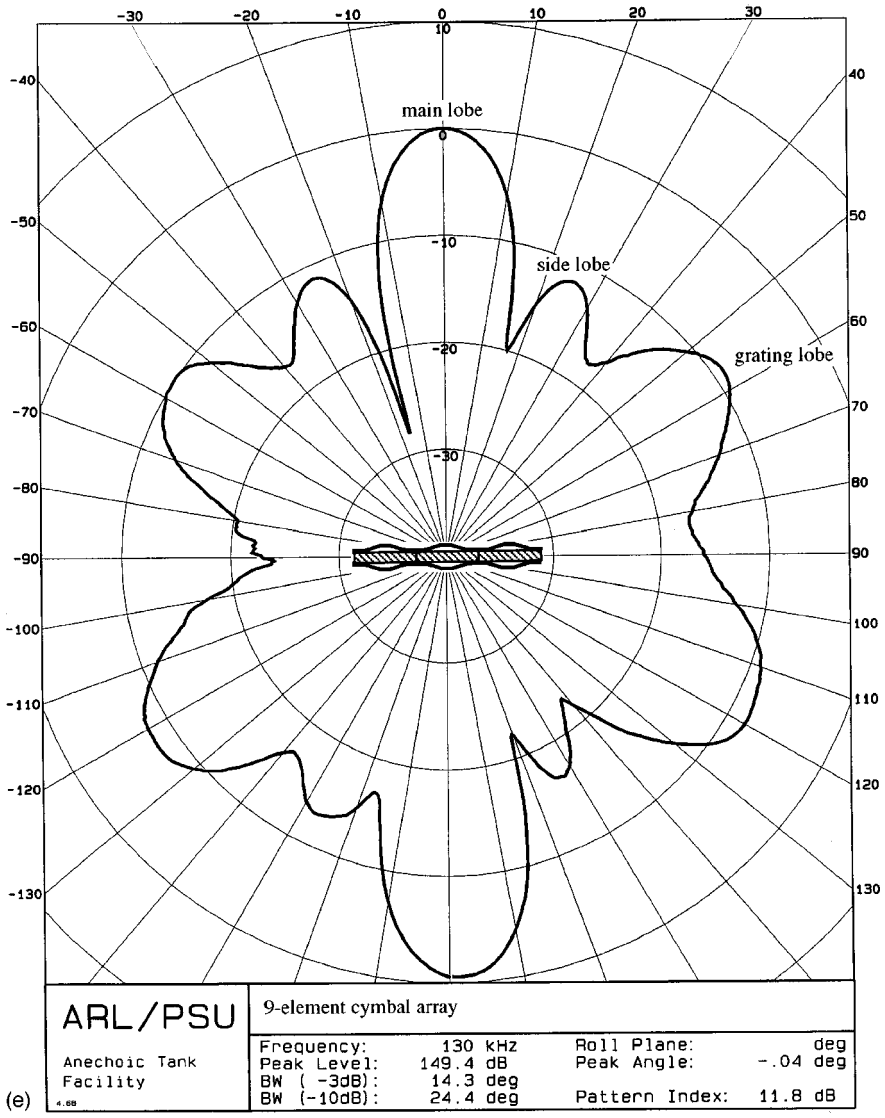

FIG. 9. (*Continued.*)

9-element cymbal arrays consisting of either brass or titanium caps. Below 20 kHz, the curves are practically identical. At higher frequencies, however, the titanium-capped cymbal array exhibits about a 3-dB higher TVR than the brass-capped cymbal array. The specific acoustic impedance ($z=\rho c$) of brass, titanium, and water are 40.4, 27.3, and 1.5 MPa·s/m, respectively.[26] Since the ratio of the characteristic impedance of brass to water is approximately $\sqrt{2}$ times the ratio of the characteristic impedance of titanium to water, and $20\cdot\log\sqrt{2}$ is 3 dB, the increase in TVR may be due to the better acoustic match of titanium to the water environment.

Figure 8 shows the measured source-level curves for the unpotted brass-capped array. The curves correspond to drive levels ranging from 40 dB *re*: 1 V to 56 dB *re*: 1 V in increments of 1 dB *re*: 1 V. At a drive level of 57 dB *re*: 1 V, the array failed and hence no measurement was recorded. The cause of failure was cracking in the caps due to work hardening.[27] The primary resonance is evident at 18.5 kHz, when the drive level is 40 dB *re*: 1 V and is present up to a drive level of 54 dB *re*: 1 V, above which it is suppressed and nonlinear behavior becomes apparent. When driven slightly below its failure level (e.g., 52 dB *re*: 1 V), a source level of 180 dB *re*: 1 μPa·m or greater is generated between 10 and at least 25 kHz. However, this is for a radiating area of only 11.4 cm^2. A simple way to enhance the source level is by increasing the number of elements in the array and hence increase the radiating area.

The beam patterns at various frequencies for the cymbal array are shown in Fig. 9. At low frequency (half-wavelength aperture or less), the array exhibits near-omnidirectionality. Interference between the signals generated by the individual elements in the array leads to more complex beam patterns seen at higher frequencies. Nonsymmetry in the patterns is a result of individual elements in the array not being matched in phase. It is important to be able to determine the theoretical patterns to know what to expect from the measured array. In order to calculate the patterns in this 3×3 array, simple line theory was used. The patterns in the horizontal plane can be calculated by using a line array consisting of N ($=3$ in this case) equally spaced, equally phased, equal strength sources. The relative strength, P, at any incident

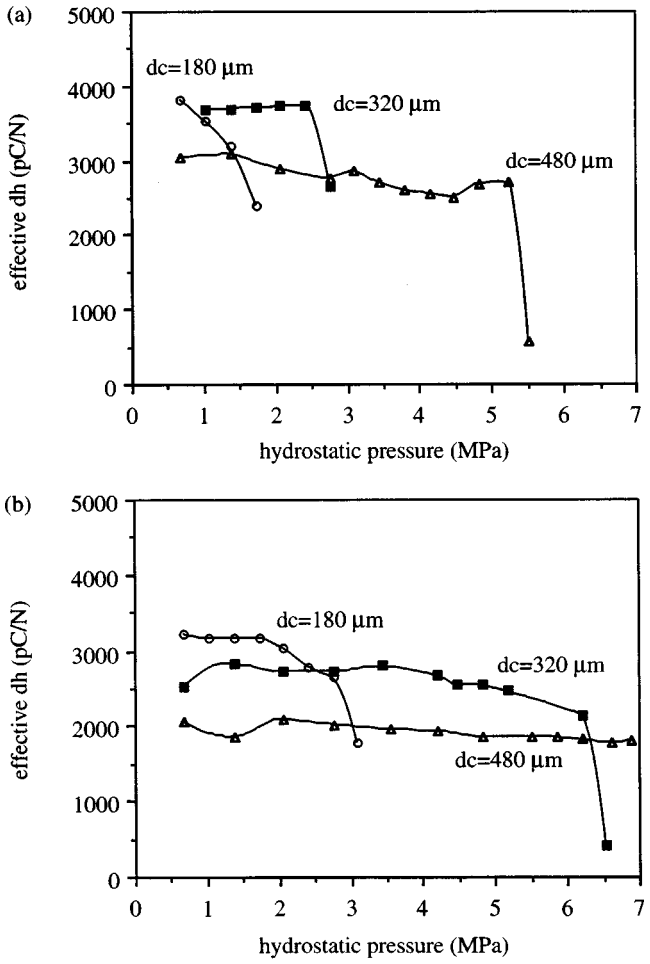

FIG. 10. Pressure dependence of the effective d_h coefficient for standard-size single-element cymbal transducers with (a) brass caps and (b) molybdenum caps of varying cavity depth.

angle, $\varnothing$, normal to the face of the projector can be calculated from the expression:[28]

$$P = \frac{\sin\left(\frac{Nkd \cdot \sin \varnothing}{2}\right)}{N \cdot \sin\left(\frac{kd \cdot \sin \varnothing}{2}\right)}, \tag{3}$$

where d is the center-to-center spacing between the elements and k is the wave number. The nulls are found by calculating the angles which make $P=0$. From Eq. (3), the appearance of the first null is predicted to occur at 37 kHz when $\varnothing$ is 90 deg. Nulls in the pattern occur at angles where the radiated waves from each cymbal are separated by a distance of one half-wavelength. Grating lobes, which are secondary major lobes, will appear at higher frequencies. The number of side lobes present between the main and grating lobes is equal to the number of cymbal elements along a side in the array less two. As seen at 130 kHz [Fig. 9(e)], there is one side lobe between the main lobe and the grating lobe. In Fig. 9(d), 50 kHz, the side lobes becomes significant. The only null in the first quadrant at 50 kHz was calculated to be about 48 deg, which compares well to the null seen in the pattern in Fig. 9(d). The first quadrant nulls at 130 kHz were calculated to be at about 17, 35, and 59 deg. The first two correlate well with those seen in the pattern [Fig. 9(e)]. However, the null at 59 deg is masked by the grating lobe.

Figure 10 shows the measured pressure dependence of the d_h^{eff} coefficients of single-element brass-capped and molybdenum-capped cymbal transducers with different cavity depths (dc). The standard brass-capped cymbal can withstand hydrostatic pressures of up to 2.5 MPa (250 m water depth) before failing. Failure was found to be due to the caps being deformed beyond their elastic limits, hence eliminating the effective stress-transfer mechanism between the piezoelectric ceramic and the caps.[27] As can be seen, the pressure tolerance of the transducer is dependent upon the stiffness of the cap material as well as the cap shape. With the stiff molybdenum caps, cymbals with deep cavities can withstand at least 7 MPa of pressure. Unfortunately, the stiff molybdenum caps cannot flex as readily as the softer brass caps, hence their displacement (and ultimately the TVR) is expected to be lower than that of the brass-capped cymbals.

IV. CONCLUSIONS

The cymbal transducer array appears to be a viable candidate for medium- to high-power shallow-water acoustic projector applications at frequencies below 50 kHz. Preliminary results indicate that it compares quite favorably with both the Tonpilz and 1-3 composites, at least in terms of output power. Its thin profile when incorporated into arrays makes it ideal for conforming to a curved surface. In addition, its simple design and uncomplicated construction method should render it easy and hence inexpensive to mass produce.

(Received 30 October 1997; revised 20 August 1998; accepted 9 September 1998)

An important aspect of oil production from a geological formation is the process of flow into a well penetrating the formation. Recent laboratory experiments indicate that well-inflow can be significantly reduced by a skin effect caused by the presence of a thin layer of low permeability around the wellbore. This impairment layer is drilling induced and differs from the mudcake that is usually encountered when logging a well. Whereas a mudcake may have built up on the borehole wall during drilling, the drawdown pressure often removes it when oil is produced from the well. In contrast with such a temporary mudcake, the impairment layer is believed to form a permanent flow impedance throughout the lifetime of a well unless extensive cleaning measures are taken. A simple poro-elastic model is constructed to investigate the propagation of Stoneley waves in a borehole with a thin impairment layer. If the impairment layer affects Stoneley wave propagation, it may be possible to acoustically detect this layer with sonic logging tools. Using realistic values for the impairment flow impedance, model calculations for a typical sandstone reservoir of 20% porosity indicate that the impairment layer changes the dispersion characteristics of borehole Stoneley waves. The magnitude of these changes increases with increasing mobility of the reservoir pore fluid. [S0001-4966(99)00101-0]

INTRODUCTION

The advent of full-waveform sonic logging tools such as the dipole sonic imager or DSI (trademark of Schlumberger) (Harrison *et al.*, 1990) has made it possible to record a variety of waveforms excited by various types of borehole acoustic sources. In addition to the compressional and shear head wave, which travel along the borehole wall at the formation compressional and shear wave velocity, a number of borehole modes can be excited. The most well known modes are the borehole Stoneley wave, or tube wave, which is efficiently excited by a low-frequency monopole source, and the borehole flexural wave excited by a dipole source. In general, the phase velocity of such modes propagating along the borehole wall varies with frequency. A theoretical overview of acoustic wave propagation in fluid-filled boreholes is given in Tsang and Rader (1979), Cheng and Toksöz (1981), Kurkjian and Chang (1986), and Winbow (1988).

In the oil industry, the primary measurements from full-waveform borehole sonic tools are the elastic wave velocities of the formation in which the logging tool is employed. The formation compressional and shear wave velocities are obtained from the waveform data in a direct way through first motion detection or semblance processing (Kimball and Marzetta, 1984). Other important measurements, such as permeability (Rosenbaum, 1974; Williams *et al.*, 1984; Chang *et al.*, 1987; Schmitt *et al.*, 1988; Winkler *et al.*, 1989; Tang *et al.*, 1991), formation mechanical properties (Sinha *et al.*, 1996) and anisotropy (Mueller, 1991; Hatchell and Cowles, 1992; Esmersoy *et al.*, 1994; Sinha *et al.*, 1994; Tichelaar and Hatchell, 1997) are obtained in a more indirect way and require extensive processing of the recorded waveforms. Furthermore, a borehole sonic tool has recently been used to image reservoir structure from a horizontal well (Esmersoy *et al.*, 1998).

An important aspect of oil production from a geological formation is the process of flow into a well penetrating the formation. Obviously this process is in part controlled by the permeability of the formation (the reservoir). In addition to reservoir permeability, however, well-inflow is also controlled by the permeability of a zone around the borehole that is altered by the drilling process. Such alteration is due to the interaction between the borehole fluid, which is a carefully designed drilling mud, and the porous reservoir. During drilling operations it is common practice to have the pressure of the drilling mud exceed the reservoir pore fluid pressure with a few hundred psi. Because of this overbalance in pressure, the drilling mud invades into the reservoir. One product of mud invasion that is well known in the logging industry is the build-up of a mudcake on the borehole wall which complicates acoustic log interpretation (e.g., Tang, 1994; Liu and Johnson, 1997). From the perspective of optimization of oil production rates, the mudcake is often not of major concern since it is designed to be removed by the drawdown pressure after a well has been producing for a certain amount of time.

A more serious problem encountered in production technology is caused by the invasion of mud solids into the res-

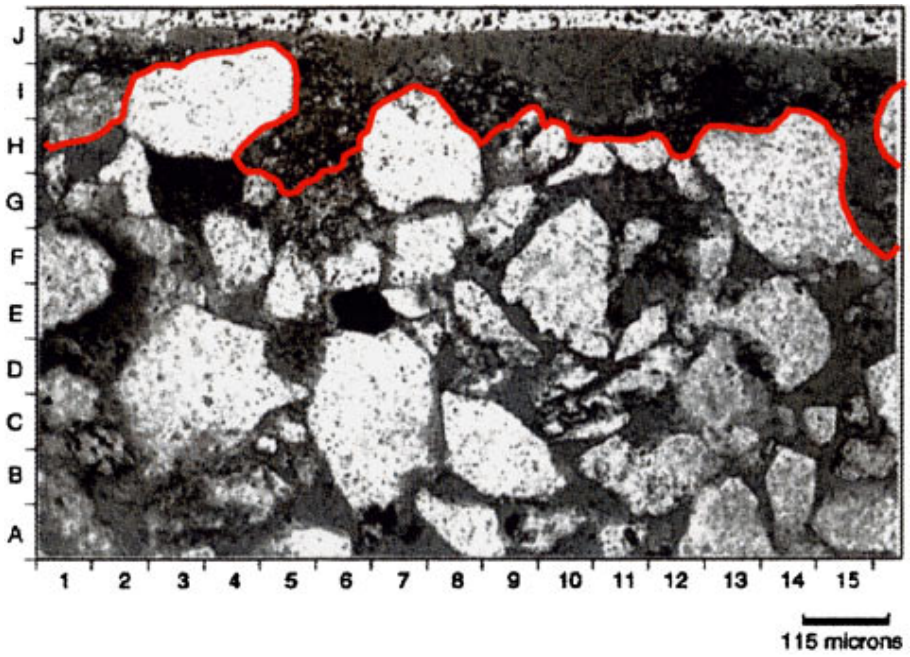

FIG. 1. Thin section in plane polarized light of a typical sample after drawdown with crude oil, showing that the impairment layer on the surface of the wellbore face (zone above red line) is not thicker than about 1 pore depth (e.g., H-I 5-6). The reservoir rock is a fine to medium grained sandstone. From Francis *et al.* (1995).

ervoir. Laboratory experiments by Francis *et al.* (1995) indicate that mud particles can invade the porous formation, creating a thin permeability barrier by plugging the pore throats exposed to the wellbore face. This thin impairment layer, with a thickness less than 0.5 mm, acts as a flow impedance and its presence reduces the flow of hydrocarbons into the well. The impairment layer is considered to be the dominant form of permanent permeability damage (Francis, 1997). The layer is not removed by drawdown of crude oil during production and can only be removed through extensive and time consuming cleaning measures. The laboratory core-flood experiments carried out under reservoir conditions by Francis *et al.* (1995) show that the impairment layer permeability is a factor of 100 to 20 000 less than the formation permeability. The thin impairment layer reduces the average core permeability with a factor of 2 to 150. Figure 1 shows a typical photomicrograph of a sandstone sample from the core-flood experiments after simulating mud invasion and subsequent back production of crude oil through the sample. The shallow invasion of mud solids is shown in this figure. Detailed examination of the cores shows no evidence of mud solids invasion deeper into the cores, fines migration, scale precipitates or emulsions.

There is currently no technology available to detect the impairment layer as a function of position along the wellbore. As a first step toward such a technology, this paper investigates the behavior of borehole Stoneley waves in a model consisting of a borehole penetrating a porous formation, where a thin layer of low permeability separates the well from the reservoir. Since the Stoneley wave is a surface wave that propagates along the borehole, its propagation characteristics are sensitive to properties of the region near the borehole wall. Winkler *et al.* (1989) have investigated the behavior of borehole Stoneley waves in permeable formations from an experimental and theoretical point of view and have demonstrated the significance of poro-elastic wave propagation theory in the borehole geometry. In the following section we describe the impairment model as well as the theory behind the model. The two subsequent sections show numerical results and address the validity of the model.

I. THE IMPAIRMENT MODEL

Figure 2 shows the impairment model in which we investigate the properties of borehole Stoneley wave propagation. The model consists of a fluid-filled borehole (blue) in a porous formation with porosity φ, the reservoir (yellow). The borehole is separated from the formation by a thin layer of low permeability, the impairment layer (red). The borehole fluid is treated as an acoustic medium and the reservoir as a poro-elastic medium (Biot, 1956a,b; Rosenbaum, 1974). In the following, the index 0 is used to indicate the acoustic medium, and the index 1 to indicate the poro-elastic medium. As waves travel along the borehole wall, the perturbed pressure of the borehole fluid, P_0, and that of the pore fluid, P_1, are related to each other via Darcy flow through the impairment layer. For the poro-elastic medium, two displacement fields must be distinguished, U_{r1} for the pore fluid and u_{r1}

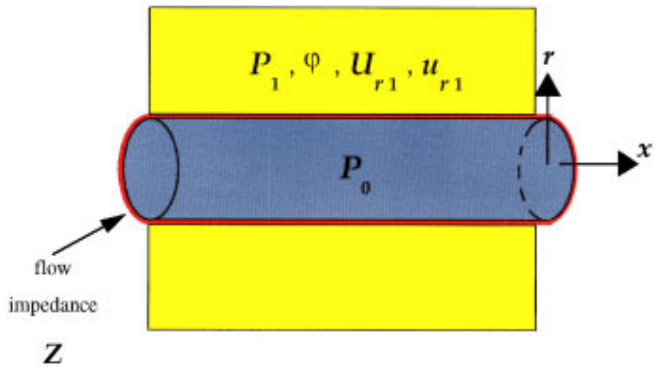

FIG. 2. Impairment model. The impaired layer (red) is described with a single parameter, Z, which is the flow impedance. See also main text. The coordinates r and x are the radial and axial coordinate, respectively.

for the solid frame, where the index r indicates the radial component. The flux, $\varphi(\dot{U}_{r1}-\dot{u}_{r1})$, through the impairment layer is related to the differential pressure, P_0-P_1, in the following way

$$\varphi(\dot{U}_{r1}-\dot{u}_{r1})=\frac{P_0-P_1}{Z}. \tag{1}$$

According to Darcy's law, the flow impedance, Z, can be written as

$$Z=\frac{d}{\kappa_{\rm imp}/\eta}, \tag{2}$$

which is the ratio of impairment layer thickness, d, and impairment mobility, $\kappa_{\rm imp}/\eta$, where $\kappa_{\rm imp}$ is the impairment layer permeability and η the pore fluid viscosity. Note that the impedance is a function of the pore fluid viscosity. Equations (1) and (2) combine into a continuity condition [Eq. (7)] at the boundary between the borehole fluid and the formation. Rosenbaum (1974) also uses this boundary condition. In the literature of well engineering and reservoir simulation (e.g., Woods, 1990) it is common to describe an impaired zone by its skin factor, s. The impairment impedance Z is simply related to s by

$$Z=\frac{R}{\kappa_0/\eta}\,s, \tag{3}$$

where R is the borehole radius and κ_0 the formation permeability. In principle s (and therefore Z) could be negative when, for example, there are deeply penetrating perforations in a cased hole. In this article we consider positive values for Z only.

There is a total of four boundary conditions:

$$U_{r0}=(1-\varphi)\,u_{r1}+\varphi\,U_{r1}, \tag{4}$$

$$-P_0=\tau_{rr1}-\varphi\,P_1, \tag{5}$$

$$0=\tau_{rz1}, \tag{6}$$

$$P_0-P_1=-i\,\omega\,Z\,\varphi\,(U_{r1}-u_{r1}). \tag{7}$$

Equation (4) reflects the continuity of average radial displacement, required by the balance of fluid volume and Eq. (5) the continuity of average normal stress. Since fluids have no shear strength, Eq. (6) prescribes a vanishing shear stress at the borehole wall.

A total of 13 model parameters (Table I) is needed to define the impairment model. Johnson *et al.* (1994a,b) describe how all of the parameters entering into Biot theory can be independently measured. Because the mobility of the reservoir pore fluid is controlled by viscous forces at low frequencies and by inertial forces at high frequencies, a dynamic permeability, $\tilde{\kappa}(\omega)$, is used, where ω is angular frequency. More precisely, a complex tortuosity, $\tilde{\alpha}(\omega)$, is calculated to determine the Biot general elastic coefficients and the three velocities for the Biot waves: the fast compressional wave, the slow compressional wave and the shear wave. See Johnson *et al.* (1987) for more details. The complex tortuosity is related to dynamic mobility, $\tilde{\kappa}(\omega)/\eta$, as follows:

TABLE I. Parameters of the impairment model and their values for the numerical simulations. The formation parameter values are typical for a fluid-filled sandstone reservoir.

Fluid-filled borehole	Fluid specific attenuation	$Q_{\rm MUD}^{-1}$	0.0037
	Fluid density	ρ_0	1.00 g/cm^3
	Fluid slowness	SF	666 μs/m
	Hole radius	R	14.5 cm
Impairment layer	Impairment mobility @ $d=0.5$ mm	$\kappa_{\rm imp}/\eta$	0.1–100 mD/cp
Porous formation	Formation mobility	κ_0/η	25–2500 mD/cp
	Bulk density	ρ_b	2.37 g/cm^3
	Compressional wave slowness	SP	279 μs/m
	Grain bulk modulus	K_s	35.0 GPa
	Pore fluid density	ρ_f	1.00 g/cm^3
	Pore fluid bulk modulus	K_f	2.24 GPa
	Porosity	φ	0.20
	Shear wave showness	SS	472 μs/m

$$\frac{\tilde{\kappa}(\omega)}{\eta}=\frac{i\varphi}{\tilde{\alpha}(\omega)\omega\,\rho_f}. \tag{8}$$

The complex tortuosity can be calculated from the formation mobility, κ_0/η:

$$\tilde{\alpha}(\omega)=\alpha_\infty+\frac{i\varphi}{\omega\,\rho_f}\left[\frac{\kappa_0}{\eta}\right]^{-1}\left[1-\frac{i\omega}{\omega_c}\right]^{1/2} \tag{9}$$

with the critical angular frequency, ω_c, defined as

$$\omega_c=\frac{2\,\varphi}{\rho_f\,\alpha_\infty}\left[\frac{\kappa_0}{\eta}\right]^{-1}. \tag{10}$$

The critical frequency is that frequency for which viscous and inertial forces are of the same order of magnitude (Johnson *et al.*, 1987). The tortuosity at infinite frequency, α_∞, is related to the electrical conductivity of the fluid-filled pores (Brown, 1980) through $\alpha_\infty=F\varphi$, where F is a geometrical factor referred to as the formation resistivity factor. Details are given in Johnson and Sen (1981). Using Archie's law, $F=\varphi^{-m}$, where the cementation exponent, m, is typically 2 for sandstones, yields

$$\alpha_\infty=\frac{1}{\varphi}. \tag{11}$$

After the Biot general elastic coefficients and the velocities for the three Biot waves are calculated (e.g., Liu and Johnson, 1997), the boundary conditions are evaluated at the borehole wall and the wave equation is solved to determine Stoneley wave slowness and attenuation, which are quantities that can be measured with full-waveform sonic logging tools. The details of the method are further discussed in the Appendix.

TABLE II. Biot velocities v_{c1}, v_{c2}, and v_{sh} and critical frequency f_c for frequencies of 1.0 and 5.0 kHz.

κ_0/η [mD/cp]	2500		250		25	
f [kHz]	1.0	5.0	1.0	5.0	1.0	5.0
v_{c1} [m/s]	3587 $-2i$	3591 $-3i$	3586 $-0i$	3586 $-1i$	3586 $-0i$	3586 $-0i$
v_{c2} [m/s]	293 $-183i$	491 $-107i$	84 $-80i$	200 $-157i$	26 $-26i$	58 $-57i$
v_{sh} [m/s]	2119 $-6i$	2129 $-6i$	2117 $-1i$	2118 $-3i$	2117 $-0i$	2117 $-0i$
f_c [kHz]	5	5	51	51	510	510

II. NUMERICAL SIMULATIONS

To investigate the behavior of Stoneley wave propagation, we calculate Stoneley wave slowness and attenuation for various values of impairment impedance and formation mobility. We choose to specify the impairment layer in terms of the impairment mobility, κ_{imp}/η [mD/cp] for a reference thickness $d=0.5$ mm, which is the same reference thickness used in the experimental work of Francis *et al.* (1995) to measure impairment in the laboratory. Note that Eq. (2) shows how to compute the impairment impedance from κ_{imp}/η and d.

Whereas the model consists of 13 parameters (Table I) we focus on the role of impairment mobility and reservoir mobility and use realistic fixed values for the other 11 parameters. We have computed Stoneley wave dispersion curves for reservoir mobilities of 2500, 250, and 25 mD/cp in the frequency range of 500 to 5000 Hz. This frequency range is typical for sonic logging tools when acquiring Stoneley waveforms. Table II gives values for the velocities v_{c1}, v_{c2}, and v_{sh}, which are the formation's fast and slow compressional wave velocities and shear wave velocity, respectively, as derived from the formation parameters in Table I. Furthermore, Table II gives values for the critical frequency, $f_c=\omega_c/2\pi$ [see Eq. (10)]. For frequencies less than f_c viscous forces dominate Stoneley wave fluid flow in the formation, while for frequencies higher than f_c inertial forces dominate the flow. Rather than going into details, we summarize the following general characteristics of the fluid pressure $|P_0|$, $|P_1|$, and the differential radial displacement, $U_{r1}-u_{r1}$ observed for the impairment model. For an open hole with no impairment, i.e., $\kappa_{\text{imp}}/\eta\to\infty$, fluid pressure is continuous across the borehole wall and maximum differential radial displacement, i.e., maximum fluid flow, occurs at the borehole wall. For a closed or fully impaired hole, i.e., $\kappa_{\text{imp}}/\eta=0$ mD/cp, fluid pressure drops discontinuously across the borehole wall and there is no fluid flow at the borehole wall. For impaired wells, i.e., for values of impairment mobility $\kappa_{\text{imp}}/\eta\in\langle 0,\infty\rangle$, fluid pressure and flow at the borehole wall are bound by the open hole and closed hole cases. Furthermore, for a given value of reservoir mobility and impairment mobility, an increase in frequency causes fluid pressure and fluid flow to decay more rapidly radially into the formation. Another observation is that, for a given frequency and impairment mobility, the decay is more rapid for lower values of reservoir mobility. This is due to the fact that the wavelength of the slow P-wave decreases with decreasing reservoir mobility.

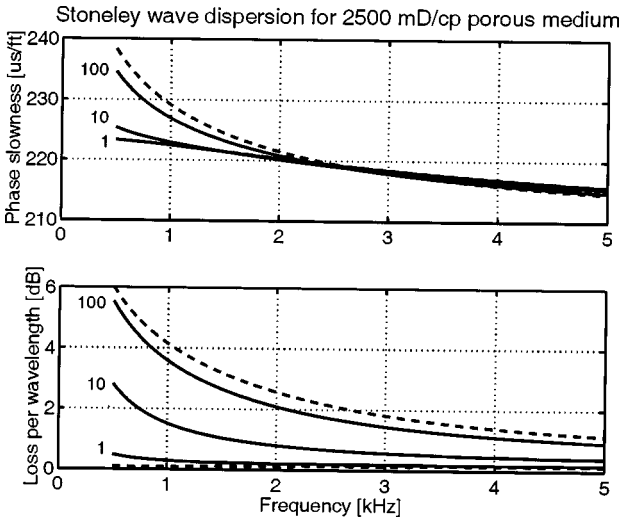

FIG. 3. Dispersion curves for a sandstone reservoir rock with a formation mobility $\kappa_0/\eta=2500$ mD/cp for various values of impairment mobility κ_{imp}/η. Each curve is labeled with the corresponding value of impairment mobility κ_{imp}/η in mD/cp. Dispersion curves for the open hole with no impairment and closed, fully impaired hole are shown as dashed lines. If dashed line is not visible it overlays with a solid curve. Amplitude loss per wavelength equals $27.287\,53^*Q^{-1}$ [Eq. (A35)].

To discuss the observed Stoneley wave dispersion characteristics we present the complex wave number, k_x^{St} [Eq. (A35)], in terms of phase slowness, S [μs/ft], and amplitude loss per wavelength [dB] which is proportional to Q^{-1}. Figures 3 and 4 show the results for a reservoir mobility of 2500 and 250 mD/cp, respectively. The figures show that Stoneley wave dispersion in an impaired well becomes nearly identical to that in a closed, fully impaired well if impairment mobilities are less than about 1 mD/cp. Furthermore, Stone-

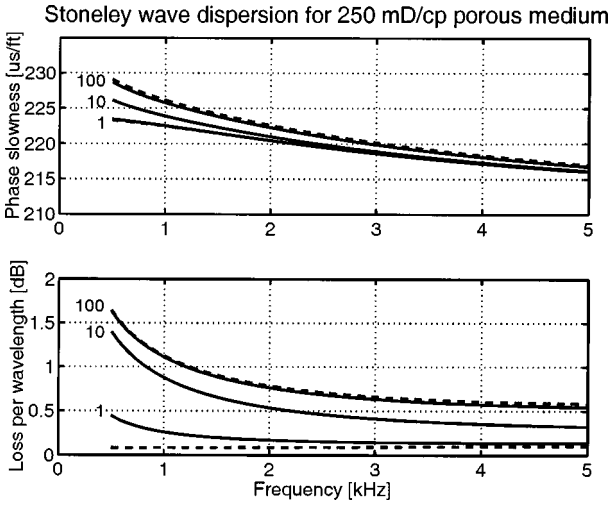

FIG. 4. As Fig. 3 but for a sandstone with a formation mobility of 250 mD/cp.

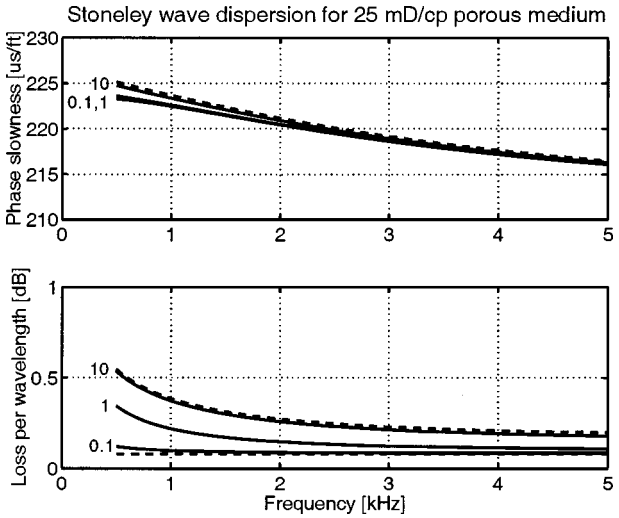

FIG. 5. As Fig. 3 but for a sandstone with a formation mobility of 25 mD/cp.

ley wave dispersion becomes nearly identical to that in a fully open hole with no impairment when impairment mobilities are larger than about 100 mD/cp. In between these two extremes, i.e., for impairment mobilities between about 1 to 100 mD/cp, the presence of the thin impairment layer gradually changes the curves from closed hole dispersion to open hole dispersion (see Figs. 3 and 4). The maximum variability in Stoneley wave slowness and attenuation at 500 Hz is about 15 μs/ft and 6 dB per wavelength for a reservoir mobility of 2500 mD/cp and 6 μs/ft and 1.5 dB per wavelength for a reservoir mobility of 250 mD/cp. This is the variability between the open hole without an impairment layer and the closed, fully impaired borehole.

Figure 5 shows the dispersion curves for a reservoir mobility of 25 mD/cp. For such a small value of reservoir mobility (i.e., ''tight reservoirs'') the range of impairment mobility for which the dispersion curves are different from closed and open hole dispersion is about 0.1 to 10 mD. However, the differences between the dispersion curves in Fig. 5 are quite small in terms of slowness (<2 μs/ft) as well as loss per wavelength (<0.5 dB). Table III gives values for the skin factor s in Eq. (3) for the various impairment scenarios in Figs. 3, 4 and 5.

TABLE III. Skin factor s for the scenarios of Figs. 3–5, where $\kappa_{\rm imp}/\eta$ [mD/cp] is the impairment layer mobility and κ_0/η [mD/cp] the formation mobility. The values of the dimensionless skin factor s range between 0.01 and 9.

$\kappa_{\rm imp}/\eta$ [mD/cp]	κ_0/η [mD/cp]		
	2500	250	25
100	0.1	0.01	⋯
10	1	0.1	0.01
1	9	1	0.1
0.1	⋯	⋯	1

III. DISCUSSION

The impairment model discussed in the previous sections is a relatively simple model, as the impaired zone is characterized by one single parameter, the impairment impedance. Schmitt (1988) has presented a more complicated and more computing intensive model that may be interpreted as an impairment model. The model of Schmitt consists of a circular borehole in a porous formation, where a thin porous layer is placed between the borehole and formation. The thin layer is a Biot medium characterized by 11 parameters, which are listed in Table IV. The boundary conditions are no-slip conditions similar to Eqs. (4) through (7). To compare the two models we first use Eq. (2) to calculate impairment impedance for Schmitt's model, then convert the impedance into impairment mobility to find that $\kappa_{\rm imp}/\eta = 15$ mD/cp. Formation mobility and borehole radius in Schmitt's model are 1500 mD/cp and 12 cm. Figure 6 shows the comparison of Stoneley wave velocity and attenuation. The similarity in Stoneley wave dispersion for the two models reflects the fact that the thickness of Schmitt's porous layer is less than the wavelength of the slow P-wave, which is 4.72 cm at 1 kHz and 2.11 cm at 5 kHz. As a consequence, the gradient of fluid pressure in Schmitt's thin porous layer (the impairment layer) is constant.

TABLE IV. Parameters for the porous thin layer in the model of Schmitt (1988). See Eq. (2) and Table I for parameter definition.

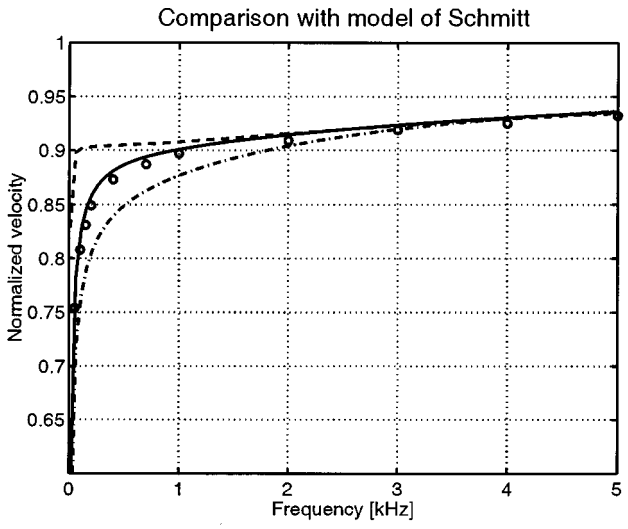
$\kappa_{\rm imp}$	300 mD	K_s	37.9 GPa
η	1 cp	ρ_f	1.00 g/cm
d	1 cm	K_f	2.25GPa
ρ_b	2.337 g/cm^3	φ	0.19
SF	666.7 μs/m	SS	480.8 μs/m
SP	267.7 μs/m		

Tang (1994) and Liu and Johnson (1997) have modeled Stoneley waves in a system where the well is separated from the porous formation by an elastic membrane. This membrane is meant to mimic the mudcake that builds up inward at the borehole wall. The boundary conditions used for the membrane model allow for slip between the membrane and formation. To shed light on the connection between the membrane model and the impairment model, let us assume that the thickness of the membrane reduces to zero. In this case, the boundary conditions in Eqs. (4), (5), and (6) are identical for both models. The boundary condition that specifies pressure communication between borehole and formation for the membrane model, however, is

$$P_0 - P_1 = W_{MC}\,\varphi\,(U_{r1} - u_{r1}), \tag{12}$$

which is physically different from the impairment model [see Eq. (7)]: the membrane stiffness, $W_{MC}+0i$, is constant and real-valued for the membrane model, whereas the impairment model has a constant flow impedance, Z, such that the impairment layer stiffness $W_i(\omega) = -i\omega Z$ is purely imaginary and depends on frequency. For the membrane model the differential pressure $P_0 - P_1$ is proportional to the differential fluid displacement while for the impairment model it is proportional to differential fluid velocity (flow velocity).

Liu and Johnson (1997) present a low-frequency approximation for the membrane model [Eq. (58) in Liu and Johnson] which gives the complex Stoneley wave number, $k_x^{St}(\omega)$, as a function of frequency [e.g., Eq. (A35) in the Appendix]. Because of the mathematical correspondence be-



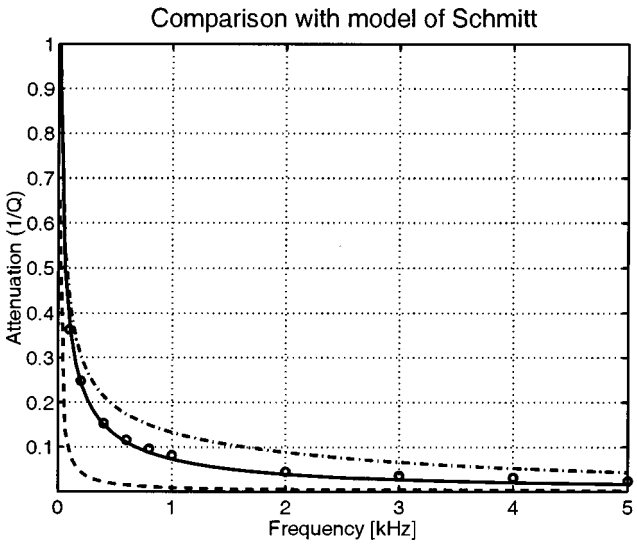


FIG. 6. Comparison between our impairment model and the radially layered model of Schmitt (1988). (Top) Solid curve is the phase velocity, $S^{-1}(\omega)$ [Eq. (A35)], normalized with the pore fluid velocity, calculated for the impairment model with $\kappa_{\text{imp}}/\eta = 15$ mD/cp. Open dots are data points picked by hand from Fig. 2 of Schmitt's paper. Dash-dotted curve is calculated for an open hole with no impairment. Dashed curve is calculated for the impairment model with $\kappa_{\text{imp}}/\eta = 1$ mD/cp. (Bottom) Same comparison, but now for attenuation Q^{-1}.

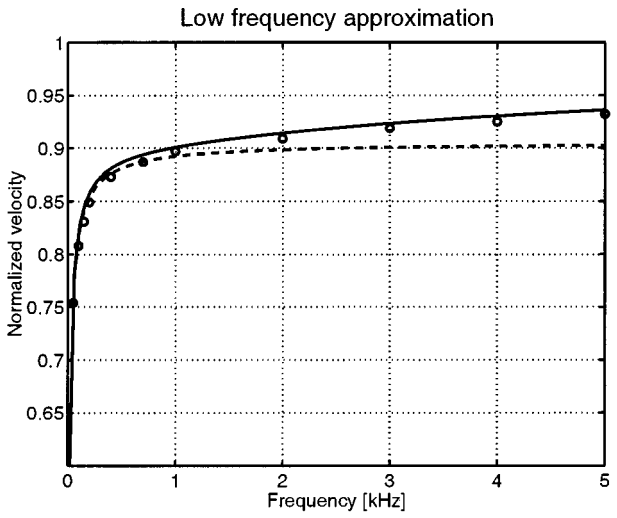

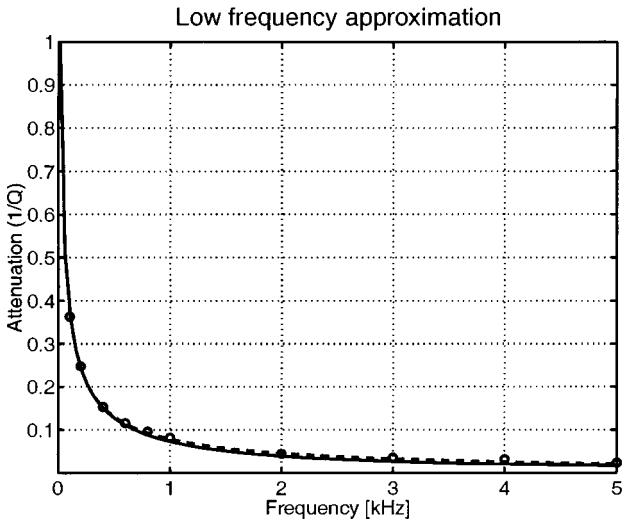

FIG. 7. Comparison between the exact representation of the impairment model (solid) and the low-frequency approximation (dashed) in Eq. (13). The top figure shows normalized velocity, $S^{-1}(\omega)$, and bottom figure attenuation, Q^{-1}. The data points picked by hand from Fig. 2 of Schmitt (1988) have also been added.

tween the membrane model and the impairment model, their Eq. (58) is valid for the impairment model and can be rewritten as follows, substituting an impairment layer thickness of zero:

$$[k_x^{St}(\omega)]^2 = \omega^2 \left[SF^2 + \frac{\rho_0}{\rho_b} SS^2 + \frac{2}{[W_i(\omega) + W_p(\omega)] SS^2 R} \frac{\rho_b}{} \right]. \tag{13}$$

The low-frequency approximation illustrates that the Stoneley wave number consists of three contributions. The right hand side of Eq. (13) shows a borehole fluid contribution of SF^2, where SF is borehole fluid slowness, a frequency independent formation contribution $SS^2(\rho_0/\rho_b)$, where SS is formation shear wave slowness, and a frequency dependent contribution related to permeability effects,

$$\frac{1}{SS^2} \frac{2\rho_b}{[W_i(\omega) + W_p(\omega)] R}, \tag{14}$$

where $W_p(\omega)$ is a stiffness due to the permeability of the formation in the open hole without impairment (Liu and Johnson, 1997). The impairment layer acts as an additional flow impedance, $Z = -W_i(\omega)/i\omega$, in series with that due to open hole fluid flow. The accuracy of the low-frequency approximation is illustrated in Fig. 7. The parameter values are the same as in Fig. 6. For frequencies below 1 kHz the approximation is within 2% of the exact theory for velocity and it is much better for attenuation.

IV. CONCLUSIONS

We have presented a model for borehole Stoneley wave propagation in a porous rock in the presence of skin effects. The parametrization of the model is based on laboratory core flood experiments that suggest the presence of a thin layer of

low permeability at the borehole wall. This permeability barrier, also referred to as impairment layer, may reduce the inflow of crude oil from the porous reservoir throughout the lifetime of a well; it is not a mudcake. The impairment layer is parameterized by a single parameter, the impairment impedance, or alternatively the impairment mobility at a specified thickness of the impairment layer. This parameter is related to the skin factor commonly used in well technology and reservoir simulation.

For Stoneley wave logging frequencies between 500 to 5000 Hz, the main effect of the impairment layer is to change the dispersion of Stoneley waves. Using parameters that are typical for a sandstone formation and using a porosity of 0.20 we find that for sandstones with a low reservoir mobility of 25 mD/cp the impairment layer changes Stoneley wave slowness and attenuation by at most 2 μs/ft and 0.5 dB per wavelength. For sandstones with an intermediate reservoir mobility of 250 mD/cp, the maximum change in slowness and attenuation at 500 Hz caused by the presence of the impairment layer is 6 μs/ft and 1.5 dB per wavelength. For sandstones with relatively high reservoir mobility of 2500 mD/cp this maximum change increases to 15 μs/ft and 6 dB per wavelength. Whereas we have not addressed the inverse problem of estimating the impairment impedance from measurements of Stoneley wave dispersion, it appears that such inverse problem will yield the best-resolved results for oil reservoirs of high permeability and low viscosity.

APPENDIX: DISPERSION RELATION

To derive the dispersion relation for borehole Stoneley waves in the presence of a permeability barrier, displacement potentials are defined in a fashion similar to, e.g., Winkler *et al.* (1989). We use a circular cylinder coordinate system where r and x are the radial and axial co-ordinates, respectively, and the x-axis is chosen parallel to the borehole axis (see Fig. 2 in main text). Since the Stoneley waves travel parallel to the borehole axis they vary as $\exp i(k_x x-\omega t)$, where k_x is the axial wave number, ω is frequency and t is time.

In the axial wave number–frequency domain, the displacement potential for acoustic waves in the borehole fluid (medium 0) is defined as

$$\Phi_0(k_x,\omega,r)=H_0^{(1)}(k_{r0}\,r)+A_0(k_x,\omega)\,J_0(k_{r0}\,r). \quad \text{(A1)}$$

In the permeable medium (medium 1) penetrated by the borehole, poro-elasticity prescribes the existence of three wave types; three potentials must be defined:

$$\Phi_{1c1}(k_x,\omega,r)=B_{1c1}(k_x,\omega)\,H_0^{(1)}(k_{r1c1}\,r), \quad \text{(A2)}$$

$$\Phi_{1c2}(k_x,\omega,r)=B_{1c2}(k_x,\omega)\,H_0^{(1)}(k_{r1c2}\,r), \quad \text{(A3)}$$

$$\Psi_{1sh}(k_x,\omega,r)=D_{1sh}(k_x,\omega)\,H_1^{(1)}(k_{r1sh}\,r), \quad \text{(A4)}$$

where Φ_{1c1} and Φ_{1c2} represent the fast and slow compressional wave, respectively, and Ψ_{1sh} represents the shear wave. $H_0^{(1)}$ and $H_1^{(1)}$ are Hankel functions of the first kind and J_0 is a Bessel function. The radial wave numbers k_{r0}, k_{r1c1}, k_{r1c2} and k_{r1sh} are equal to $(\omega^2/v^2-k_x^2)^{1/2}$, where v is the velocity of acoustic waves in the borehole fluid, the fast compressional wave, the slow compressional wave and the shear wave, respectively. Chang *et al.* (1988) give expressions for these velocities. We will now determine phase slowness and specific attenuation by solving the boundary conditions [Eqs. (4) through (7) in main text].

In the borehole the radial displacement, U_{r0}, and fluid pressure, P_0, are

$$U_{r0}=\frac{\partial\Phi_0}{\partial r}, \quad \text{(A5)}$$

$$P_0=\rho_0\omega^2\Phi_0, \quad \text{(A6)}$$

where ρ_0 is the borehole fluid density. In the poro-elastic medium the radial and axial displacements in the solid are

$$u_{r1}=\frac{\partial\Phi_{1c1}}{\partial r}+\frac{\partial\Phi_{1c2}}{\partial r}-ik_x\Psi_{1sh}, \quad \text{(A7)}$$

$$u_{x1}=ik_x(\Phi_{1c1}+\Phi_{1c2})+\frac{\partial\Psi_{1sh}}{\partial r}+\frac{\Psi_{1sh}}{r}, \quad \text{(A8)}$$

the radial and axial displacements in the pore fluid are

$$U_{r1}=G_+\frac{\partial\Phi_{1c1}}{\partial r}+G_-\frac{\partial\Phi_{1c2}}{\partial r}-ik_xG_{sh}\Psi_{1sh}, \quad \text{(A9)}$$

$$U_{x1}=ik_x(G_+\Phi_{1c1}+G_-\Phi_{1c2})+G_{sh}\left[\frac{\partial\Psi_{1sh}}{\partial r}+\frac{\Psi_{1sh}}{r}\right], \quad \text{(A10)}$$

where G_+, G_-, and G_{sh} are the potential factors described in Liu and Johnson (1997). Pore fluid pressure, P_1, and the normal stress, τ_{rr1}, and tangential stress, τ_{rz1}, on the solid are

$$P_1=-\frac{1}{\varphi}(Rd_{1f}+Qd_{1s}), \quad \text{(A11)}$$

$$\tau_{rr1}=(P-2N)d_{1s}+Qd_{1f}+2N\frac{\partial u_{r1}}{\partial r}, \quad \text{(A12)}$$

$$\tau_{rz1}=N\left(ik_xu_{r1}+\frac{\partial u_{z1}}{\partial r}\right), \quad \text{(A13)}$$

where P, Q, R and N are the Biot constants referred to as general elastic coefficients (Biot and Willis, 1957) and

$$d_{1s}=-\omega^2\left(\frac{\Phi_{1c1}}{v_{c1}^2}+\frac{\Phi_{1c2}}{v_{c2}^2}\right), \quad \text{(A14)}$$

$$d_{1f}=-\omega^2\left(G_+\frac{\Phi_{1c1}}{v_{c1}^2}+G_-\frac{\Phi_{1c2}}{v_{c2}^2}\right). \quad \text{(A15)}$$

Note that N is the shear modulus of the porous medium. Biot and Willis (1957) use a slightly different notation where

$P-2N=A$. The velocities v_{c1} and v_{c2} are the fast and slow compressional wave velocities, respectively.

We now substitute Eqs. (A5)–(A13) and (A1)–(A4) into the four boundary conditions specified in the main text and evaluate the resulting expressions at the borehole wall, $r=R$, which gives a system of four equations with four unknowns. In matrix form we can write

$$\begin{pmatrix} m_{11} & m_{12} & m_{13} & m_{14} \\ m_{21} & m_{22} & m_{23} & m_{24} \\ 0 & m_{32} & m_{33} & m_{34} \\ \varphi m_{21} & m_{42} & m_{43} & m_{44} \end{pmatrix} \cdot \begin{pmatrix} A_0 \\ B_{1c1} \\ B_{1c2} \\ D_{1sh} \end{pmatrix} = \begin{pmatrix} s_1 \\ s_2 \\ 0 \\ \varphi s_2 \end{pmatrix} \tag{A16}$$

or, in short notation,

$$\mathbf{M}(k_x,\omega)\cdot \begin{pmatrix} A_0 \\ B_{1c1} \\ B_{1c2} \\ D_{1sh} \end{pmatrix} = \mathbf{s}(k_x,\omega). \tag{A17}$$

The matrix elements are

$$m_{11}=-k_{r0}J_1(k_{r0}R), \tag{A18}$$

$$m_{12}=k_{r1c1}H_1^{(1)}(k_{r1c1}R)*(1-\varphi+G_+\varphi), \tag{A19}$$

$$m_{13}=k_{r1c2}H_1^{(1)}(k_{r1c2}R)*(1-\varphi+G_-\varphi), \tag{A20}$$

$$m_{14}=ik_xH_1^{(1)}(k_{r1sh}R)*(1-\varphi+G_{sh}\varphi), \tag{A21}$$

$$m_{21}=-\rho_0\omega^2J_0(k_{r0}R), \tag{A22}$$

$$m_{22}=C_+\frac{\omega^2}{v_{c1}^2}H_0^{(1)}(k_{r1c1}R)+2N\,k_{r1c1}^2 \times\left[H_0^{(1)}(k_{r1c1}R)-\frac{H_1^{(1)}(k_{r1c1}R)}{k_{r1c1}R}\right], \tag{A23}$$

$$m_{23}=C_-\frac{\omega^2}{v_{c2}^2}H_0^{(1)}(k_{r1c2}R)+2N\,k_{r1c2}^2 \times\left[H_0^{(1)}(k_{r1c2}R)-\frac{H_1^{(1)}(k_{r1c2}R)}{k_{r1c2}R}\right], \tag{A24}$$

$$m_{24}=2ik_xk_{r1sh}N\left[H_0^{(1)}(k_{r1sh}R)-\frac{H_1^{(1)}(k_{r1sh}R)}{k_{r1sh}R}\right], \tag{A25}$$

$$m_{32}=-2ik_xk_{r1c1}N\,H_1^{(1)}(k_{r1c1}R), \tag{A26}$$

$$m_{33}=-2ik_xk_{r1c2}N\,H_1^{(1)}(k_{r1c2}R), \tag{A27}$$

$$m_{34}=\left(2k_x^2-\frac{\omega^2}{v_{sh}^2}\right)N\,H_1^{(1)}(k_{r1sh}R), \tag{A28}$$

$$m_{42}=-i\omega Z\,k_{r1c1}\varphi^2(1-G_+)H_1^{(1)}(k_{r1c1}R)+\frac{\omega^2}{v_{c1}^2} \times(Q+G_+R)H_0^{(1)}(k_{r1c1}R), \tag{A29}$$

$$m_{43}=-i\omega Z\,k_{r1c2}\varphi^2(1-G_-)H_1^{(1)}(k_{r1c2}R)+\frac{\omega^2}{v_{c2}^2} \times(Q+G_-R)H_0^{(1)}(k_{r1c2}R), \tag{A30}$$

$$m_{44}=\omega Z\,k_x\varphi^2(1-G_{sh})H_1^{(1)}(k_{r1sh}R), \tag{A31}$$

where J_1 is a Bessel function, v_{sh} the velocity of the Biot shear wave and C_+ and C_- are defined as

$$\begin{aligned} C_+&=P-2N+G_+Q+Q+G_+R, \\ C_-&=P-2N+G_-Q+Q+G_-R. \end{aligned} \tag{32}$$

The source terms in **s** are

$$\begin{aligned} s_1&=k_{r0}H_1^{(1)}(k_{r0}R), \\ s_2&=\rho_0\omega^2H_0^{(1)}(k_{r0}R). \end{aligned} \tag{A33}$$

Borehole modes, including the Stoneley wave, are found by solving the dispersion relation

$$\text{Det}\ \mathbf{M}(k_x,\omega)=0. \tag{A34}$$

For each individual mode, Eq. (A34) is numerically solved with a root-finding algorithm. The borehole Stoneley wave is that mode traveling at the highest phase slowness for any single frequency. The Stoneley wave number, $k_x^{St}(\omega)$, is related to phase slowness, $S(\omega)$, and specific attenuation, Q^{-1}, as follows:

$$k_x^{St}(\omega)=\omega\,S(\omega)\left[1+\frac{i}{2Q}\right]. \tag{A35}$$

This equation is the dispersion relation used to compute Stoneley wave propagation in the presence of skin effects.

One-channel time-reversal in chaotic cavities: Theoretical limits

Carsten Draeger[a] and Mathias Fink

Laboratoire Ondes et Acoustique, URA CNRS 1503, Université Paris VII Denis Diderot – Ecole Supérieure de Physique et de Chimie Industrielles de la Ville de Paris, 10 Rue Vauquelin, 75005 Paris, France

(Received 15 December 1997; accepted for publication 5 October 1998)

One-channel time-reversal experiments in closed chaotic cavities produce excellent, but not perfect, time-reversed focusing. This paper investigates such experiments by a simple eigenmode analysis of the system. It shows that the process is, even for long reversed signals, subject to an information loss during recording and re-emission which prevents perfect time-reversal. This fact can be expressed by a simple equation, called the cavity equation, which states that the signal of a one-channel time-reversal is equal to the signal of a perfect time-reversal after convolution with the backscattering impulse response of the reversal point (i.e., from this point to this point). The latter convolution describes the introduction of the loss of information. Furthermore, arguments are presented suggesting that one third of the total energy of the time-reversed wave field is actually contained in the refocusing wavefront. The predictions are verified by numerical finite-difference time-domain simulations. [S0001-4966(99)04201-0]

INTRODUCTION

Unlike experiments using acoustic time-reversal mirrors, one-channel time-reversal can be easily obtained as it requires only one transmit and one receive channel, and a closed propagation medium with negligible absorption. Like every time-reversal experiment, it is a two-step process: In the first step, a short signal is injected at one point, *A*, and produces a reverberating wave field inside the cavity. At a second point, the reversal point *B*, amplitude and phase of the field is recorded over a long time. Then, in the second step, the cavity is cleared, the signal is time-reversed and reinjected at *B*. In this way, we obtain a sharp, focused peak at the initial source point *A*. Experiments[1] have shown that the focusing quality increases with the size of the time-reversal window, i.e., the duration of the reversed signal. This increase has been quantified by a simple statistical model, inspired by ray trajectories inside the cavity. However, for long windows, a saturation regime is entered where the focusing quality can no more be improved. Then, the amplitude of the refocused signal observed in *A* increases linearly with the reversed time but the shape of the peak and of the (temporal) sidelobes is not affected. The phenomenon of these residual sidelobes is not explained in a satisfactory way by the statistical model. Also, the choice of a cavity in the shape of a chaotic billiard has so far only been explained by the need of ergodic ray dynamics. However, a ray description of the wave field can hardly be justified, even if its conclusions fit to experimental data.

In this paper, we describe the time-reversal process using an approximate eigenmode decomposition of the wave field. Besides reconfirming the refocusing ability, this description is able to explain the saturation regime and provides additional explanations for the advantages due to the chaotic shape of the cavity. It is shown that an information loss occurs at the reversal point *B* and that this inhibits a perfect time-reversal, i.e., the creation of a wave field that behaves exactly as if time was counting backwards. The main idea is the following: By injection of a short pulse during the first step in *A*, the system acquires a certain eigenmode distribution. A long signal is recorded at *B* that can be interpreted as a superposition of all eigenfrequencies of the system. If the signal is sufficiently long and degeneracy is negligible (condition presumably enhanced by the level repulsion of a chaotic wave billiard), these eigenfrequencies are well resolved. During the injection of the reversed signal, every frequency excites then exclusively the corresponding eigenmode. To produce a perfectly reversed wave field, every reinjected eigenmode should have the same weight as during the first step of the experiment. However, *B* measures and injects each eigenmode with a factor proportional to the value of its eigenfunction at this point. In particular, the eigenmodes having a node in *B* cannot be measured at all. This confusion of the eigenmode weights is the origin of the information loss mentioned above, in the sense that the information about the wave field's eigenmode distribution can only be measured or reproduced in a distorted way by *B*.

We have to emphasize that a perfect time-reversal cannot be expected *a priori* in this case. Unlike ''usual'' time-reversal experiments, one-channel time-reversal as presented here is not a scattering experiment. In this case, time-reversal symmetry does not guarantee the possibility of a perfect reversal in the same way as it does in the case of the model of the ''closed time-reversal cavity,''[2] which reverses all outgoing wavefronts, since outgoing wavefronts cannot be defined here.

Section I presents some consequences of this information loss on the temporal shape of the refocused signal at a given point, expressed in a simple equation called here the cavity equation. Section II evaluates the importance of the noise introduced into the system by the information loss in terms of energy. The analysis suggests that, in general, the

[a]Current affiliation: Department of Electrical Engineering, University of Rochester, Rochester, NY 14627, Electronic mail: draeger@ee.rochester.edu

reversed wave field contains (energetically) two-thirds of noise and one-third of desired wave.

I. THE CAVITY EQUATION

Let $h_{XY}(t)$ be the impulse response from point X to point Y, i.e., the signal measured in Y after a Dirac excitation in X. After injection of the signal $f(t)$ in A, we observe hence in B the convolution $f(t)*h_{AB}(t)$. In a one-channel time-reversal process, this signal is time-reversed and reinjected in B, thus giving in A the signal $f(-t)*h_{AB}(-t)*h_{BA}(t)$. [This signal immediately implies refocusing: Reciprocity demands that $h_{AB}=h_{BA}$, and thus, $h_{AB}(-t)*h_{BA}(t)=\int d\tau\, h_{AB}(t+\tau)h_{AB}(\tau)$ is the autocorrelation function of h_{AB}, which has its maximum at $t=0$.] We are now going to compare this signal to the perfectly reversed situation. If we observe the wave field at the source point A during the first step of the experiment, we obtain the signal $f(t)*h_{AA}(t)$, i.e., a signal with a strong first peak due to the initial emission, followed by a long series of reflections from the boundary. We call h_{AA} the backscattering impulse response of A. A perfect time-reversal should reproduce in A exactly the reversed signal, i.e., $f(-t)*h_{AA}(-t)$. We show in the following that the information loss can be taken into account by a simple convolution of this signal by the backscattering impulse response $h_{BB}(t)$ of B. This fact is expressed in the cavity equation:

$$h_{AB}(-t)*h_{BA}(t)=h_{AA}(-t)*h_{BB}(t). \tag{1}$$

This equation is, of course, only valid in the context of an excitation function $f(t)$.

A. Derivation of the cavity equation

For simplicity, we suppose a scalar wave field φ inside the cavity, and a homogeneous wave speed c so that the wave equation is given by

$$\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\nabla^2\right)\varphi(\mathbf{x},t)=F(\mathbf{x},t),$$

where F is the excitation function. Let $\psi_n(\mathbf{x})$ be the eigenmodes of the cavity with $\nabla^2\psi_n=-k_n^2\psi_n$ and eigenfrequency $\omega_n=c\cdot k_n$. The ψ_n form an orthonormal basis of the system and the wave field can be expressed as a superposition of the eigenmodes:

$$\varphi(\mathbf{x},t)=\sum_n \varphi_n(t)\psi_n(\mathbf{x}).$$

As we are interested in impulse responses, we suppose $F(\mathbf{x},t)=F\delta(\mathbf{x}-A)\delta(t)$. The φ_n are then given by

$$\varphi_n(t)=\begin{cases}\dfrac{Fc^2}{\omega_n}\psi_n(A)\sin(\omega_n t), & t>0\\ 0, & t\leqslant 0,\end{cases}$$

and the impulse response h_{AB} becomes (with $Fc^2=1$):

$$h_{AB}(t)=\sum_n \psi_n(A)\psi_n(B)\frac{\sin(\omega_n t)}{\omega_n}\quad (t>0).$$

(Besides, reciprocity $h_{AB}=h_{BA}$ can be directly seen here.)

From this signal recorded in B, a part $\Delta T=[t_1;t_2]$ is reversed. For the second step of the experiment, we introduce the new time variable t_R, so that refocusing occurs at $t_R=0$. Hence, we reinject at B the signal

$$h_{AB}^{\Delta T}(-t_R)=\begin{cases}h(-t_R), & t_R\in[-t_2,-t_1]\\ 0, & \text{elsewhere}\end{cases}.$$

So, one obtains the refocused signal in A:

$$\begin{aligned}S_{\Delta T}(t_R)&=h_{AB}^{\Delta T}(-t_R)*h_{AB}(t_R)\\ &=\int_{t_1}^{t_2}d\tau\, h_{AB}(t_R+\tau)h_{AB}(\tau)\\ &=\sum_n 1/\omega_n\psi_n(A)\psi_n(B)\sum_m 1/\omega_m\psi_m(A)\psi_m(B)\cdot I_{mn}\end{aligned} \tag{2}$$

where

$$I_{mn}=\int_{t_1}^{t_2}d\tau\,\sin(\omega_n(t_R+\tau))\sin(\omega_m\tau).$$

The integral I_{mn} can be written as

$$\begin{aligned}I_{mn}&=\int_{t_1}^{t_2}d\tau[\sin(\omega_n t_R)\cos(\omega_n\tau)\\ &\quad+\cos(\omega_n t_R)\sin(\omega_n\tau)]\sin(\omega_m\tau)\\ &=\frac{1}{2}\sin(\omega_n t_R)\int_{t_1}^{t_2}d\tau[\sin((\omega_m-\omega_n)\tau)\\ &\quad+\sin((\omega_m+\omega_n)\tau)]\\ &\quad+\frac{1}{2}\cos(\omega_n t_R)\int_{t_1}^{t_2}d\tau[\cos((\omega_m-\omega_n)\tau)\\ &\quad-\cos((\omega_m+\omega_n)\tau)].\end{aligned}$$

The second term of each integral gives a contribution of order $1/(\omega_m+\omega_n)\ll\Delta T$, which can be neglected. Thus, we obtain

$$I_{mn}\cong\begin{cases}\dfrac{1}{2}\dfrac{\sin(\omega_n t_R)}{\omega_m-\omega_n}[-\cos((\omega_m-\omega_n)t_2)+\cos((\omega_m-\omega_n)t_1)]\\ \quad+\dfrac{1}{2}\dfrac{\cos(\omega_n t_R)}{\omega_m-\omega_n}[\sin((\omega_m-\omega_n)t_2)-\sin((\omega_m-\omega_n)t_1)], & \text{if } \omega_m\neq\omega_n\\ \frac{1}{2}\Delta T\cos(\omega_n t_R), & \text{if } \omega_m=\omega_n.\end{cases} \tag{3}$$

We are mostly interested in the second term of I_{mn}. Supposing that the eigenmodes are not degenerate, then $\omega_n=\omega_m \Leftrightarrow n=m$, and this term represents the diagonal elements in the sum over n and m. The first term of (3) is only important if the difference $\omega_m-\omega_n$ is small, i.e., for neighboring eigenfrequencies. In the case of a chaotic cavity, next neighbors tend to repulse each other; if the characteristic distance $\Delta\omega$ is sufficiently large so that $\Delta T \gg 1/\Delta\omega$, the nondiagonal terms of I_{mn} are negligible compared to the diagonal contributions, and one obtains

$$I_{mn}=\tfrac{1}{2}\delta_{mn}\Delta T\,\cos(\omega_n t_R)+O(1/\Delta\omega). \tag{4}$$

In the limit $\Delta T\to\infty$, the signal obtained in A by a reversal in B is finally given by

$$S_{\Delta T}(t_R)=\frac{1}{2}\,\Delta T\sum_n\ \frac{1}{\omega_n^2}\,\psi_n^2(A)\,\psi_n^2(B)\cos(\omega_n t_R).$$

This expression explains some properties that have been observed experimentally. The time dependence, given by $\cos(\omega_n t_R)$, implies the experiment's focusing property: If the frequency distribution can be considered as random, the only constructive interference of the sum we can expect is around $t_R=0$. This also agrees with the symmetry observed with respect to this point in time. Furthermore, the equation shows the obvious proportionality of the amplitude with ΔT.

The convolution of h_{AA} and h_{BB} is evaluated in the same way. As the two signals are of infinite length, the convolution integral diverges. So we define a convolution $\underset{(\Delta T)}{*}$, restricted to the interval ΔT, and we compare the result to $S_{\Delta T}$ in the limit $\Delta T\to\infty$:

$$\begin{aligned}C_{\Delta T}(t)&=h_{AA}(-t)\underset{(\Delta T)}{*}h_{BB}(t)\\&=\int_{t_1}^{t_2}d\tau\,h_{BB}(t+\tau)h_{AA}(\tau)\\&=\sum_n\,1/\omega_n\psi_n^2(B)\sum_m\,1/\omega_m\psi_m^2(A)I_{mn}.\end{aligned} \tag{5}$$

Here, I_{mn} is the same integral as in (3) and (4); its term δ_{mn} reduces the double sum to its diagonal elements. So we obtain immediately

$$S_{\Delta T}(t)=C_{\Delta T}(t)\quad(\Delta T\to\infty),$$

and

$$h_{AB}^{\Delta T}(-t)*h_{BA}(t)=h_{AA}(-t)\underset{(\Delta T)}{*}h_{BB}(t)\quad(\Delta T\to\infty).$$

This is our cavity equation (1). For simplicity, we omit the range ΔT. Of course, the equation is only valid in the context of an excitation function $f(t)$ which convolves the impulse responses.

B. Discussion

The convolution of the perfect signal $h_{AA}(-t)$ by h_{BB} introduces a reduction of the reversal quality. In fact, h_{BB} is a signal with a high peak at $t=0$ due to the initial emission and a long series of reflections afterwards. The more h_{BB} is similar to a single Dirac peak, the lesser the effect of the convolution and the better the reversal quality. So the relative amplitude of the series of multiple reflections in h_{BB} should be reduced in order to improve the refocused signal. This could be done, for example, by choosing a larger cavity: The amplitude level of the multiple reflections is related to the mean energy density, which is lower for larger systems (if the injected energy is the same). However, as the density of eigenfrequencies increases also, the characteristic level spacing $\Delta\omega$ is smaller and one has to reverse a longer signal.

The cavity equation is valid for long reversed intervals. When reversing small time-reversal windows, noise is introduced into the refocused signal by the nondiagonal terms of I_{mn} in (2) and (5). We do not give a quantitative description of this noise herein, as it is already described in Ref. 1. The equation may also be valid in some regular cavities with negligible level degeneracy. However, as there is no level repulsion, the convergence of the equation with increasing ΔT will be slower, i.e., one has to reverse longer signals to obtain good focusing.

C. Generalization

If we observe the signal of the reversed wave field at a point C other than the source point A, the cavity equation can simply be generalized:

$$S_\infty^C=h_{AB}(-t)*h_{BC}(t)=h_{AC}(-t)*h_{BB}(t).$$

Again, the result of the one-channel time-reversal is equal to a convolution of the perfectly reversed signal $h_{AC}(-t)$ and the backscattering impulse response h_{BB} of B.

As our system is linear, the introduction of several reversal points $B,C,D,\ldots$ can be taken into account by summing up the refocused signals for each transducer:

$$S_\infty^A=h_{AA}(-t)*[h_{BB}(t)+h_{CC}(t)+h_{DD}(t)+\cdots].$$

In this case, h_{BB} is replaced by the sum $H(t)=[h_{BB}(t)+h_{CC}(t)+h_{DD}(t)+\cdots]$ in the cavity equation. One can then draw the same conclusion for H as for h_{BB}: The smaller the series of multiple reflections, the better the focusing. The initial peaks of h_{BB}, h_{CC}, etc. superpose in a constructive way, thus the amplitude of the peak of H increases linearly with the number N of reversal points. If these points are far from each other, one may suppose an uncorrelated superposition of the multiple reflections. In this case, their rms level increases proportionally with $\sqrt{N}$. Hence, the peak-to-sidelobes ratio grows with the number of points, i.e., the information loss is reduced by using several reversal points. However, of course, the ratio cannot be better than that of a perfect time-reversal that also produces temporal sidelobes (multiple reflections in the h_{AA} signal).

D. Verification by numerical simulations

We have carried out a finite difference simulation in the time domain to verify the validity of the cavity equation (1). We simulate a chaotic scalar cavity in the shape of a disk with one segment cut off (Fig. 1).[3] It is described by a grid of 384×384 points with a step of $\Delta x=0.053$ mm, giving a diameter of 20.5 mm. The boundary of the cavity is defined by Dirichlet conditions, i.e., the field is set to zero. We use a

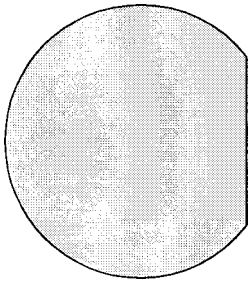

FIG. 1. Chaotic billiard in shape of a disk with one segment cut off.

temporal step of $\Delta t = 0.0094\ \mu$s and a uniform sound-speed parameter of 4000 m/s=4 mm/μs. As we are interested in long propagation times, the dispersion introduced by the numerical scheme cannot be simply neglected. However, dispersion has been shown to be harmless in time-reversal experiments as it is compensated by the process. [Besides, it is easy to see that the derivation of the cavity equation (1) is not altered by a frequency-dependent sound speed.] Thus, we do not need to take this fact into account.

The points A and B are located inside the cavity, and, in this case, far from the boundary and from each other. The impulse responses are measured by emitting a numerical Dirac at one of these points, and measuring at both of them. The impulse responses are then convolved over an interval ΔT. A final convolution is applied with an excitation function with a 1-MHz central frequency and a bandwidth of 100%. Figure 2(a) and (b) show the left- and the right-hand side of the cavity equation for an interval length of $\Delta T = 420\ \mu$s, respectively. The agreement of both signals confirms the equation.

Also of interest is the validity of the equation in the transition from small to great values of ΔT. The characteristic period of time to separate the eigenfrequencies is given by $\Delta T \gg T_H = 1/\Delta\omega$. The number of eigenmodes below a given frequency ω is approximately equal to $N(\omega) = (S/4\pi c^2)\omega^2$ (Refs. 4–6), where S is the surface of the cavity. Hence, we find $T_H = 1/\Delta\omega = \partial N/\partial\omega = S/2\pi c^2\omega$, which is, in our case (surface 300 mm^2, frequency 1 MHz), equal to 19 μs. The time interval $\Delta T = 420\ \mu$s is much greater than this value. Taking a shorter interval, $\Delta T = 210\ \mu$s, we find that $h_{AB}(-t)*h_{BA}(t)$ is clearly different from $h_{AA}(-t)*h_{BB}(t)$ (Fig. 3). If we compare Figs. 2(a) and 3(a), which represent the result of a one-channel time-reversal with windows of size 420 and 210 μs, respectively,

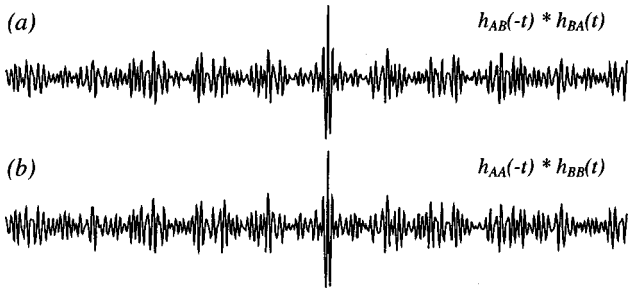

FIG. 2. Verification of the cavity equation by numerical simulations. The excitation signal is here of central frequency 1 MHz (bandwidth 100%); the convolution has been carried out over an interval of $\Delta T = 420\ \mu$s.

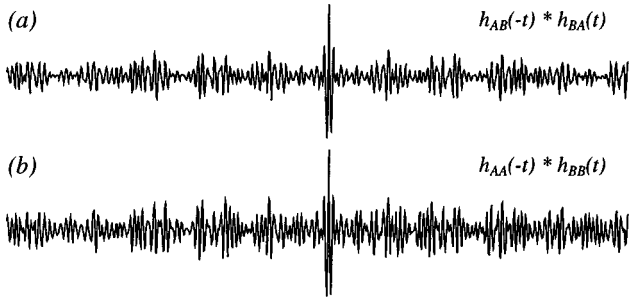

FIG. 3. Same as Fig. 2, but using an interval of $\Delta T = 210\ \mu$s. The cavity equation loses its validity.

we find only a small difference between them. The signal seems already to be in the saturation regime. Thus, $h_{AB}(-t)*h_{BA}(t)$ tends towards the limiting signal more quickly with ΔT than $h_{AA}(-t)*h_{BB}(t)$. This can be seen in the derivation of the cavity equation: The noise introduced into the system for short time-reversal windows is represented by the nondiagonal terms of I_{mn}, and the expected value of $\psi_n(A)\psi_n(B)\psi_m(A)\psi_m(B)$ in (2) is less than the expected value of $\psi_n^2(A)\psi_m^2(B)$ in (5) for $n \neq m$.

II. THE ENERGY OF THE REFOCUSED PEAK

The cavity equation (1) provides information about the temporal shape of the refocused signal at a given point, but does not compare the noise to the refocusing wave in terms of energy. To obtain this comparison, the energy of a perfectly reversed wave and the energy of the refocused peak obtained by a time-reversal in B must be considered. In the first case, the total energy of the system is in the refocused peak; in the second case, only a part of the energy is actually focused, while the rest is distributed as noise in the cavity that cannot be reduced by reversing longer intervals.

A. Theory

Leaving a proportionality factor aside, the field reversed by B is given by

$$\varphi_{TR(B)}(\mathbf{x},t_R) = \sum_n \frac{1}{\omega_n^2}\,\psi_n(A)\psi_n(\mathbf{x})\psi_n^2(B)\cos(\omega_n t_R).$$

The expression for the field initially emitted at A is

$$\varphi_A(\mathbf{x},t) = \sum_n \frac{1}{\omega_n}\,\psi_n(A)\psi_n(\mathbf{x})\sin(\omega_n t) \quad \text{for } t>0,$$

so the reversal of this formula gives the perfectly reversed field. Its time dependence is a sine, while for the one-channel it is a cosine. In view of this, it is more useful to compare the one-channel time-reversal to the temporal primitive of the perfect wave, i.e., to

$$\varphi_{\text{perfect}TR}(\mathbf{x},t_R) = \sum_n \frac{1}{\omega_n^2}\,\psi_n(A)\psi_n(\mathbf{x})\cos(\omega_n t_R).$$

Thus, the only difference between $\varphi_{TR(B)}$ and $\varphi_{\text{perfect}TR}$ is the factor $\psi_n^2(B)$ inside the sum. The energy of the wave field is the sum of kinetic and potential energy. This energy is given (again leaving a proportionality factor aside) by

$$E[\varphi]=\int dV\left(\left(\frac{\partial\varphi}{\partial t}\right)^2+c^2(\boldsymbol{\nabla}\varphi)^2\right).$$

The second term of this integral can be transformed by Green's formula:

$$\int dV(\boldsymbol{\nabla}\varphi)^2=\int_{\text{contour}} dn\ \varphi\ \frac{\partial\varphi}{\partial n}-\int dV\ \varphi\nabla^2\varphi.$$

The integral on the contour of the cavity vanishes with Dirichlet or Neumann boundary conditions. In the case of perfect time-reversal, the energy can then be calculated as

$$\begin{aligned}E[\varphi_{\text{perfect}TR}]&=\int dV\left(\left(\frac{\partial\varphi_{\text{perfect}TR}}{\partial t_R}\right)^2\right.\\&\quad\left.-c^2\varphi_{\text{perfect}TR}\nabla^2\varphi_{\text{perfect}TR}\right)\\&=\int dV\left(\sum_n\ \frac{-1}{\omega_n}\ \psi_n(A)\psi_n(\mathbf{x})\sin(\omega_n t_R)\right)^2\\&\quad-c^2\int dV\left(\sum_n\ \frac{1}{\omega_n^2}\ \psi_n(A)\psi_n(\mathbf{x})\cos(\omega_n t_R)\right)\\&\quad\times\left(\sum_n\ \frac{-k_n^2}{\omega_n^2}\ \psi_n(A)\psi_n(\mathbf{x})\cos(\omega_n t_R)\right).\end{aligned}$$

The double sum is reduced to a single sum due to the orthonormality relation $\int dV\ \psi_n\psi_m=\delta_{mn}$. With $\omega_n=c\cdot k_n$ and $\sin^2(\omega_n t_R)+\cos^2(\omega_n t_R)=1$, one obtains, finally,

$$E[\varphi_{\text{perfect}TR}]=\sum_n\ \frac{1}{\omega_n^2}\ \psi_n^2(A).$$

In the same way, the energy of the at B reversed wave field is found to be

$$E[\varphi_{TR(B)}]=\sum_n\ \frac{1}{\omega_n^2}\ \psi_n^2(A)\psi_n^4(B).$$

For this field, we estimate the energy of the peak by comparing the squared amplitude of the peak at A at $t_R=0$ to the perfect field:

$$E_{\text{peak}}[\varphi_{TR(B)}]=\left(\frac{\varphi_{TR(B)}(A,t_R=0)}{\varphi_{\text{perfect}TR}(A,t_R=0)}\right)^2 E[\varphi_{\text{perfect}TR}].$$

Then, we find the peak energy to total energy ratio as

$$\begin{aligned}&\frac{E_{\text{peak}}[\varphi_{TR(B)}]}{E[\varphi_{TR(B)}]}\\&=\left(\frac{\Sigma_n(1/\omega_n^2)\psi_n^2(A)\psi_n^2(B)}{\Sigma_n(1/\omega_n^2)\psi_n^2(A)}\right)^2\ \frac{\Sigma_n(1/\omega_n^2)\psi_n^2(A)}{\Sigma_n(1/\omega_n^2)\psi_n^2(A)\psi_n^4(B)}\\&=\frac{(\Sigma_n(1/\omega_n^2)\psi_n^2(A)\psi_n^2(B))^2}{\Sigma_n(1/\omega_n^2)\psi_n^2(A)\psi_n^4(B)\Sigma_n(1/\omega_n^2)\psi_n^2(A)}.\end{aligned}\tag{6}$$

As we do not know the eigenmode distribution, we cannot evaluate this expression directly. However, in chaotic cavities, one may use a statistical approach. It is widely conjectured[5,7] that an eigenmode of a chaotic system with ballistic trajectories inside can be considered as a superposition of a large number of plane waves with random amplitude and phase. This implies that the amplitude of an eigenmode at an interior point has a Gaussian distribution and is correlated over a short distance of the order of one wavelength. Thus, we approximate the energy ratio by replacing the sums in (6) by their expectation values $\langle ...\rangle$:

$$\frac{E_{\text{peak}}[\varphi_{TR(B)}]}{E[\varphi_{TR(B)}]}\cong\frac{(\Sigma_n(1/\omega_n^2)\langle\psi_n^2(A)\psi_n^2(B)\rangle)^2}{\Sigma_n(1/\omega_n^2)\langle\psi_n^2(A)\psi_n^4(B)\rangle\Sigma_n(1/\omega_n^2)\langle\psi_n^2(A)\rangle}.$$

For a Gaussian distribution of width σ, $\langle\psi^2\rangle=\sigma^2$. The higher moments can be calculated using the formula $\langle\psi^{2k}\rangle=1\cdot3\cdots(2k-1)\sigma^{2k}$.

If A and B are interior points sufficiently far apart for not to be correlated, then

$$\langle\psi_n^2(A)\psi_n^4(B)\rangle=\langle\psi_n^2(A)\rangle\langle\psi_n^4(B)\rangle=3\sigma^6$$

and

$$\langle\psi_n^2(A)\psi_n^2(B)\rangle=\sigma^4,$$

thus

$$\frac{E_{\text{peak}}[\varphi_{TR(B)}]}{E[\varphi_{TR(B)}]}\cong\frac{1}{3}.$$

Hence, we obtain from our approximate analysis that one-third of the energy is contained in the part of the wave forming the refocused peak and the other two-thirds appear as background noise in the cavity.

One particular case is given by the situation $A=B$; the location of the initial emission coincides with the reversal point. Then

$$\langle\psi_n^4(A)\rangle=3\sigma^4\ \text{ and }\ \langle\psi_n^6(A)\rangle=15\sigma^6,$$

thus,

$$\frac{E_{\text{peak}}[\varphi_{TR(B=A)}]}{E[\varphi_{TR(B=A)}]}\cong\frac{3}{5}.$$

For $A=B$, we expect to have 60% of the energy in the peak, hence a better result. Intuitively, this improvement can be understood for example by the fact that A, unlike B, cannot be on a node of one of the excited eigenmodes.

B. Verification by numerical simulations

To verify these results by simulations, we cannot simply determine the part of the energy in the peak. However, one may interpret these energy ratios not only as being the part of the peak during focusing, but it may be seen in general as the part of the energy forming the refocusing wave field. Thus, we should observe similar energy inhomogeneities in the case of a perfect and a one-channel time-reversal.

A new simulation was carried out on a grid of 512×512 points, using a step of $\Delta x=0.04$ mm, giving a cavity diameter of 20.5 mm. The excitation signal had a central frequency of 5 MHz and a bandwidth of 100%, and the temporal step was $\Delta t=0.0071\ \mu$s for a uniform sound-speed parameter of 4 mm/μs.

We have separated our numerical cavity into an upper and a lower half (Fig. 4), along its symmetry axis. The

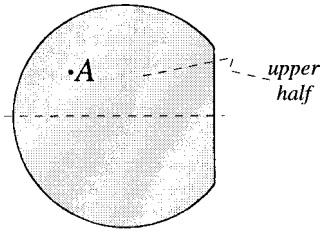

FIG. 4. In our example, the source point A is located in the upper half of the cavity.

source (and focal) point A is located in the upper half. We are now going to calculate the energy fraction $R_{\mathrm{up}}(t) = E_{\mathrm{up}}(t)/E_{\mathrm{tot}}(t)$ contained in this part of the cavity. First, we record R_{up} during the initial emission. The temporal evolution is given in Fig. 5. At the beginning, $R_{\mathrm{up}}=1$ because the energy is still near the source. Then, the wavefronts are reflected and propagate into the lower half, where they are reflected again. The energy goes back and forth several times until it acquires an almost uniform distribution ($R_{\mathrm{up}}=0.5$) inside the system, which continues. A perfect time-reversal should reproduce the scene backwards: Beginning with a (long-lasting) uniform distribution, R_{up} should start oscillating stronger and stronger until culminating at the value 1 at $t_R=0$. Then, the wave diverges again and restarts the same ''damped'' oscillations as before.

In a time-reversal at $B(\neq A)$, we obtain only one-third of the energy in the refocusing wave. Supposing the other two-thirds are uniformly distributed throughout the cavity, we obtain for the energy fraction in the upper half

$$R_{\mathrm{up}}^{TR(B)}(t_R) = \tfrac{1}{3} + \tfrac{1}{3} R_{\mathrm{up}}^{\mathrm{perfect}TR}(t_R).$$

Figure 6 shows a good agreement of this prediction and the value of $R_{\mathrm{up}}^{TR(B)}(t_R)$ actually observed in the simulation. In the case of $B=A$, the relation becomes

$$R_{\mathrm{up}}^{TR(A)}(t_R) = \tfrac{1}{5} + \tfrac{3}{5} R_{\mathrm{up}}^{\mathrm{perfect}TR}(t_R),$$

and the comparison of this prediction and the simulation is presented in Fig. 7. A good match is evident, even though

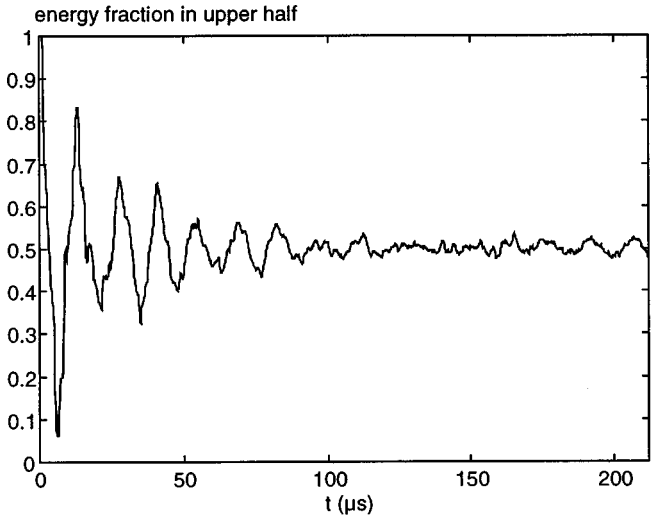

FIG. 5. The fraction of the total energy that is located in the upper half of the cavity during the initial emission.

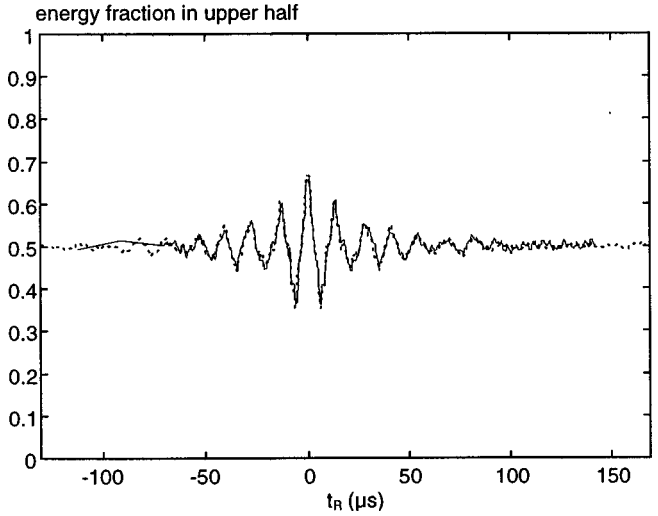

FIG. 6. Fraction of the total energy located in the upper half during refocusing for $A\neq B$: Comparison between theoretical prediction (dashed line) and simulation.

the maximum value of the simulation is lower than the expected one (53% of the energy in the peak versus a prediction of 60%).

III. CONCLUSION

In this paper, we have given a theoretical description of the one-channel time-reversal process in closed chaotic cavities using an approximate eigenmode analysis of the wave field. It mainly describes the process in the saturation regime, i.e., for long time-reversal windows. As the eigenfrequencies of chaotic cavities repulse each other, the signal recorded by the reversal point B after an initial excitation in A is a superposition of well-resolved frequencies, each one corresponding to exactly one eigenmode. Hence, during the reversal step, every frequency of the reversed signal excites mainly its own eigenmode and transmits the right phase to obtain focusing, but, in general, not the right amplitude. The phenomenon of residual (temporal) sidelobes, observed in experiments, is thus explained by this loss of (amplitude) in-

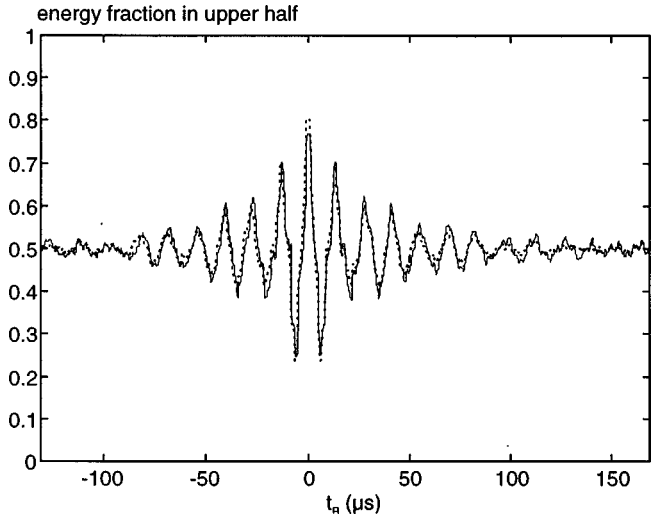

FIG. 7. Same as Fig. 6, for $B=A$.

formation occurring at the reversal point. In fact, B is unable to reproduce the exact weight of each eigenmode because it ''hears'' each eigenfrequency more or less, depending on the amplitude of the eigenmode at this point. One might say that the subjective point of view at B inhibits the creation of a perfectly reversed wave field.

The temporal shape of the refocused signal at a given point of the cavity can be easily compared to the perfectly reversed signal, as the shape results from a temporal convolution of the latter with the backscattering impulse response of B. This relation is expressed in the cavity equation: $h_{AB}(-t)*h_{BA}(t)=h_{AA}(-t)*h_{BB}(t)$. It shows again that the information loss occurs entirely at B. The information loss yields a residual noise in the reversed wave field, in which energy has been shown to be, in general, two-thirds of the total energy in the cavity, while the refocused part of the wave has been shown to carry one-third.

Hence, one may also interpret this result in the sense that this value represents the amount of energy of a wave field in a chaotic cavity that can be controlled using a single, randomly chosen emitting point. A chaotic shape of a given medium might then be useful for the wave field control. Knowing certain characteristics of the reversal point (for example, the amplitude of each eigenmode), one might even compensate for the subjectivity of B and obtain an almost perfect control of the wave field (except the eigenmodes having a node at B). We are now trying to obtain a perfectly reversed wave field by taking this compensation into account in the reversed signal.

(Received 15 December 1997; accepted for publication 5 October 1998)

Experiments are presented that show the feasibility of reconstructing a point source using acoustic time-reversal with a single transmitter/receiver. The propagation medium is a closed 2-D silicon cavity with chaotic ray dynamics and negligible absorption. Injection of a short pulse at one point yields a long signal at a second one; by reversing a part of this signal, we obtain a focus at the initial injection point. The characterization of the focus was observed by scanning with an optical interferometer and by measuring the signal at the focal spot. With circular converging wavefronts, the reconstructed focus was excellent (corresponding to an aperture of 360°), but not perfect. The increase in quality of the focus with growing length of the reversed signal is described by a statistical ray model. Despite the irreversibility in classical chaos (due to strong sensitivity to initial conditions), the underlying chaotic ray dynamics is useful in this case. © *1999 Acoustical Society of America.* [S0001-4966(99)04301-5]

INTRODUCTION

Acoustic time-reversal mirrors are devices able to generate the time-reversed counterpart of a given wave, usually emitted by a point-like source.[1–5] This is done by measuring the incident acoustic field over a large surface, using an array of piezoelectric transducers. The signal of each channel is recorded, time-reversed, and finally re-emitted by the same element. This process creates a wave with the same shape as the incident one, but propagating in the opposite direction, thus focusing on the location of the initial source. One of the main problems of acoustic time-reversal experiments is the need of independent transmit/receive channels for every transducer element. A reduction of the number of elements generally implies a smaller aperture, and thus larger focal spots. In several experiments, it has been observed that multiple reflections and scattering tend to enhance focusing quality in resolution and amplitude. Roux *et al.*[6] carried out time-reversal experiments in waveguides: The reflections on the boundary artificially enlarge the aperture of the time-reversal mirror and thus reduce the focal spot size. Derode *et al.*[7] performed time-reversal experiments through multiply scattering media. Besides the surprising temporal recompression of the reversed signals, the focal spot size corresponds more closely to an aperture associated with the size of the multiple scattering medium rather than to the physical aperture of the mirror itself. In both cases, the information contained in the wider angles, which is lost for small apertures, is redirected or scattered onto the active surface of the mirror, which thus may be reduced. The price to pay for this gain of information is a longer recording time for the signal.

In this study, we examine the reduction of the receivers down to one. In this case, the propagation medium has to be a closed cavity to avoid information loss at infinity, with very weak absorption to allow recording over a long period of time. We have chosen a 2-D silicon wafer as the propagation medium; waves are injected and measured by transversal transducers, fixed to aluminum cones. It will be shown that our measurements are consistent with the hypothesis that the shape of the cavity is of crucial importance. In fact, we use a cavity with chaotic ray dynamics: The information contained in each ray emitted by the source can only be recorded if the ray, after several reflections, passes sufficiently near the time-reversal transducer. This behavior is ensured by ergodicity, which can be easily obtained by choosing a cavity in the shape of a *chaotic billiard*. Such a cavity also ensures mixing of the ray angles.

However, we have to point out one fundamental difference of this setup as compared with the experiments cited above. This is no longer a scattering experiment where we measure the outgoing waves after scattering from the medium. In the closed cavity, we measure instead the wave field at some given point inside the medium. Thus, unlike in scattering experiments, the wavefronts here continue to propagate in the medium after being measured and may even be measured again after several reflections at the boundary. This possibility of a multiple measurement is a disadvantage; it will be shown that it ultimately leads to a reduction of the quality of the time-reversed wave field.

In Sec. I, we present the general characteristics of our experimental setup. Section II shows how one-channel time-reversal experiments are carried out, and presents the spatial and temporal focusing properties. It turns out that the focusing quality increases with the length of the reversed signal. Section III describes this growth by a statistical approach of the ray dynamics of the cavity. Section IV gives two examples of cavities, where the assumption of ergodicity is not fulfilled, and the time-reversal process fails to work properly.

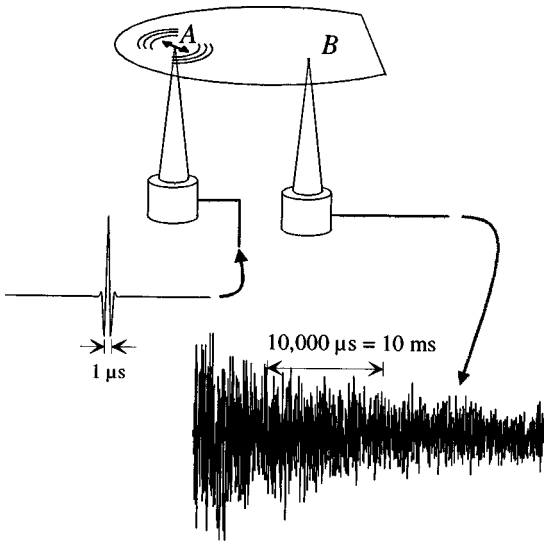

FIG. 1. Elastic waves are injected by means of transversal transducers fixed to Al-cones. A short signal, injected at one of the transducers, *A*, creates a long-lasting, reverberating wave field: The signal obtained at a second point, *B*, is slowly decaying.

I. EXPERIMENTAL SETUP AND SYSTEM PROPERTIES

The propagation media we use are circular wafers of 100- or 125-mm diameter, with a segment of variable size cut off (between 4% and 75% of the diameter). A billiard of the same shape has been shown to have chaotic trajectories.[8] The wafers are 525 μm thick and cut parallel to the plane (100) of the crystal lattice. If we neglect anisotropy, only three modes of propagation exist in the frequency range we used (around 1 MHz): *SH* waves with a nondispersive velocity around 5000 m/s, the Lamb mode S_0 with approximately 8300 m/s, and the highly dispersive A_0 mode with respective phase and group velocity of 2600 ± 100 m/s and 4400 ± 200 m/s. During the typical scale of time (1 ms) of an experiment, the waves are reflected between 40 and 80 times at the boundary. The *SH* and S_0 waves are coupled by reflections at the border of the cavity; the A_0 mode propagates independently. Besides, the A_0 propagation is isotropic in the plane. While, by definition, the *SH* mode has no normal surface displacement, this displacement of the S_0 mode is only very weak, as this mode is quasilongitudinal in the frequency range we use. The A_0 mode, being quasitransversal, is the only mode having sufficient normal surface displacements to be detected by an optical interferometer. This mode also has stronger coupling to the surrounding air, which results in a higher decay rate.

Sound injection and measurement is done by transversal transducers fixed to Al cones whose tips touch the wafer (Fig. 1). This technology has initially been developed by J.-P. Nikolovsky in our school for sound injection in glass plates.[9] It permits a point-like coupling to the system with negligible perturbation of the wave field. The tip of the cone acts as a dipole source and/or measuring point. The A_0 and S_0 waves are mainly emitted in directions around the polarization axis *x*, and the *SH* waves travel in the perpendicular directions (Fig. 2). It turns out that the use of a dipole source is not the best choice as it permits *a priori* only dipole focusing in time-reversal experiments. However, using a trick, we show in Sec. II how it is possible to obtain monopole focusing. Also, in Sec. IV, we point out how the use of a dipole source reveals interesting aspects of the chaotic behavior of the medium.

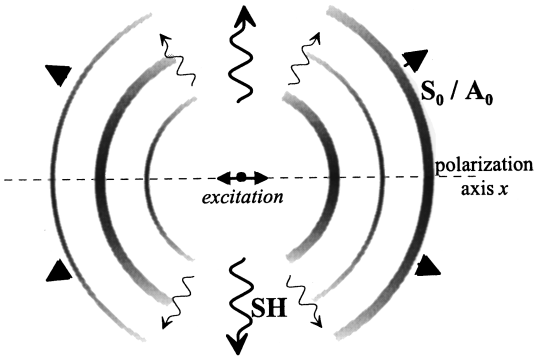

FIG. 2. The modes S_0 and A_0 are mostly emitted in directions around the polarization axis *x* of the dipole source point, the *SH* waves mainly in the perpendicular directions.

Injection of a short pulse in one of the transducers, *A*, creates inside the cavity a reverberating acoustic field with weak attenuation. In fact, the signal observed (after preamplification) by a second transducer, *B*, is slowly decaying (Fig. 1) with a decay period thousands of times longer than the injected signal (1 μs). Figure 3 shows the intensity decay on a logarithmic scale. One observes indeed two different regimes: During the first few milliseconds, the mode A_0 dominates, but decreases relatively quickly with a period of approximately 3 ms, thus revealing the slow decay of the coupled S_0/SH waves (10 to 20 ms, depending on the wafer's size). The length of the signals to be time-reversed (the time-reversal windows) is, with a maximum of 2 ms, always small compared to the latter decay period, and the intensity level inside the window will be considered as constant in the regime S_0/SH. For experiments involving the A_0 mode, we give only qualitative results.

The electronics of the time-reversal mirror provide for the initial emission a short sinusoidal burst of 1 MHz central frequency and a Gaussian envelope of width 0.4 μs, with an

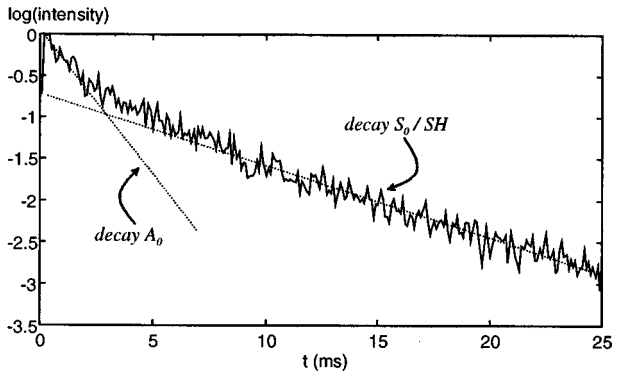

FIG. 3. Decay of the average intensity received at point *B* after injection of a short signal in *A*. For relatively short propagation times, the Lamb mode A_0 dominates. But as this mode is better coupled to the surrounding air, it decreases more quickly than the S_0 and *SH* modes that are permanently converted into each other at the boundary.

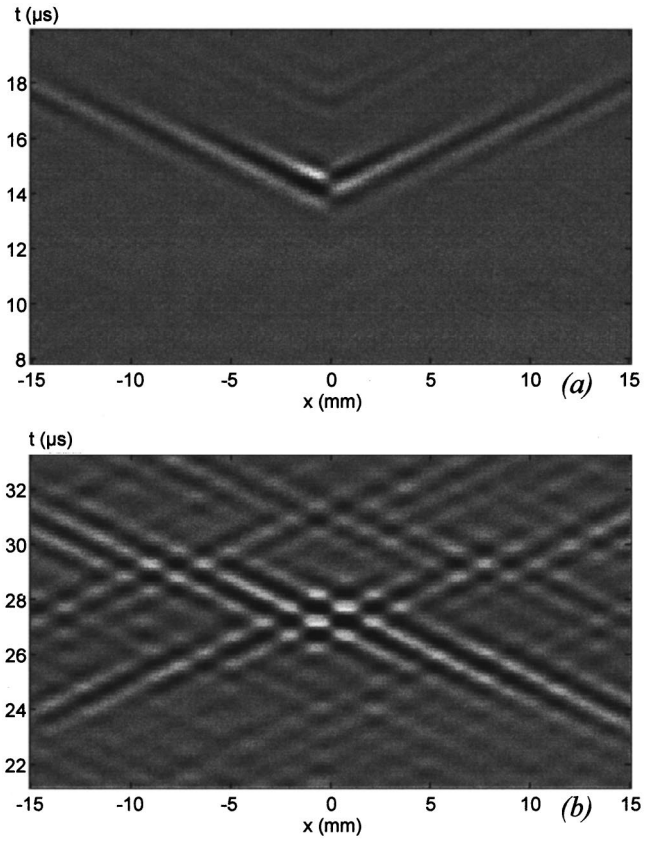

FIG. 4. *B*-scans of the normal surface displacement as measured with an optical interferometer along the polarization axis *x* of the dipole source *A* (at $x=0$), (a) during the initial emission, (b) during refocusing. The *B*-scans have been obtained using a spatial step of 0.1 mm and a sampling frequency of 15 MHz.

amplitude between 10 and 80 V into a 50-Ω impedance. The received signals are digitized using 8 bits with a sampling frequency of either 7.5, 10, or 15 MHz.

II. THE TIME-REVERSAL EXPERIMENT

In the first step of the experiment, the transducer at *A* emits a short pulse at $t=0$. At point *B*, the signal is recorded and, after time-reversal and amplification, a part $\Delta T=[t_1,t_2]$ (the time-reversal window) is reinjected at this same point during the second step. Using a new (simply shifted) variable of the time scale t_R, we start re-emission at $t_R=-t_2$. This leads to a focusing in *A* at $t_R=0$.

A. Spatial recompression

We used a heterodyne Mach–Zehnder type of interferometer that was developed in our laboratory by D. Royer[10] to scan the acoustic field of the A_0 wave around the point *A*. The wafer is, in this case, mounted on a set of two motors able to translate the system in two dimensions, parallel to its surface. The emission is then repeated for every point where the time variation of the field is to be recorded. Figure 4(b) shows a *B*-scan of the normal surface displacement on the polarization axis *x* of *A* after a time-reversal of 1.5 ms in *B*. It has to be compared to the direct emission of the short pulse in *A*, shown in Fig. 4(a). In both figures, one observes

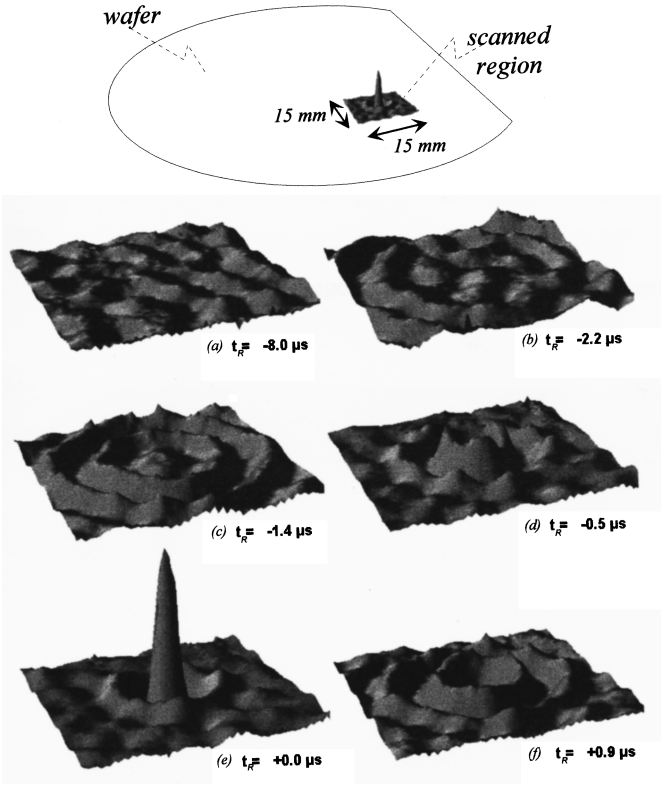

FIG. 5. Linear representation of the monopole refocusing A_0 wave, measured by the interferometer. Note the circular shape of the wavefronts and the background noise level, best seen in (a): One-channel time-reversal produces excellent, but not perfect, results.

the dipole character. However, if the *B*-scan of (b) was the real time-reversal of (a), there should be no outgoing wave after focusing. This is a common property of all time-reversal experiments: The energy in the system is not sucked out at the moment of focusing (which would be the time-reversal of the initial energy injection), so that the wave diverges again afterwards. Also, one can see some noise level elsewhere than the converging and diverging wavefronts. In summary, Fig. 4(a) and (b) show that it is possible to obtain a good, but not perfect, time-reversal with a one-channel time-reversal in *B*. But for a quantitative evaluation, a monopole focusing is preferable.

We have used a trick to obtain a monopole focal spot using transversal transducers. In the first step, the short pulse is now injected by the transducer at *B* instead of *A*. Instead of the second transducer, we use the interferometer to record the signal at point *A*. Being sensitive to normal surface displacements, the interferometer acts as a monopole receiver. The reciprocity principle tells us that the signal obtained is exactly the same as the one that would be recorded with a monopole emitter in *A* and a dipole receiver in *B*. Thus, this signal can be used to simulate a time-reversal experiment with a monopole source at *A* and a dipole reversal point at *B*. In the second step, we reinject a part of the signal at *B*. This leads to a monopole focusing at *A*. A linear representation of the A_0 wave field around the focal spot is given in Fig. 5. It has been measured on a square of 15×15 mm with a step of 0.25 mm for a time-reversal window of size 2 ms. One observes circular incoming wavefronts which focus at $t_R=0$ in

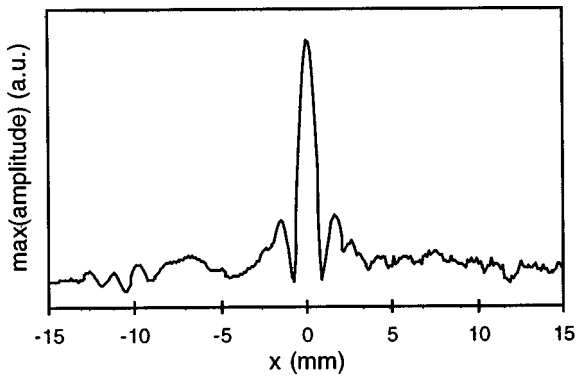

FIG. 6. Cut through the focal spot.

A. This means that in a closed reflecting medium, using a single emission point (the reversal point *B*), it is possible to obtain a focusing quality which corresponds to an angular aperture of 360°. But there is a certain noise level inside the system. This shows that the spatial recompression of the time-reversal process is less than perfect far from the focus. However, the cut through the focal spot, shown in Fig. 6, has a width of 1.1 mm for a central wavelength of 2.6 mm. This indicates that the A_0 wave is almost perfectly focused near the peak.

B. Temporal recompression

Again using transducers for both *A* and *B*, we now observe the refocused signal at *A* after time-reversal at *B*. One obtains a sharp peak at $t_R=0$, standing out from more or less temporal sidelobes (Fig. 7). If we change the position of the time-reversal window, the peak does not change in shape or amplitude, unlike the sidelobes (Figs. 8). As the medium is linear, the signal obtained by a reversal of a long window (which can be cut into several small windows) is the same as the superposition of the contributions of all the small windows. This implies that the amplitude of the peak increases linearly with ΔT (which stands, depending on the context, for the interval $[t_1,t_2]$ of the time-reversal window or, as here, for its length). It means also that higher amplitudes at the focus can be obtained not only by emission of a stronger, but also with a longer, signal. Excluding the possibility of a destructive superposition of the (temporal) sidelobes, their rms value increases linearly with $\sqrt{\Delta T}$ if the contributions of different windows are perfectly uncorrelated, or faster if they are not.

In Fig. 9, we present refocused signals for different window sizes, and, in Fig. 10, the peak/sidelobe intensity ratio. From a certain value of ΔT on (about 1 ms), the shape of the sidelobes does not seem to change any more. The intensity ratio, which increases linearly for small ΔT, saturates for

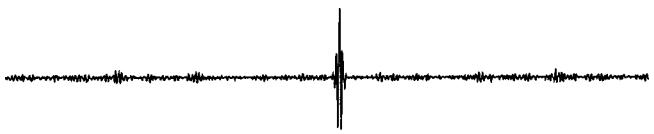

FIG. 7. Refocused signal obtained at *A* after a time-reversal of 1600 μs at *B*. The presented signal is about 210 μs long.

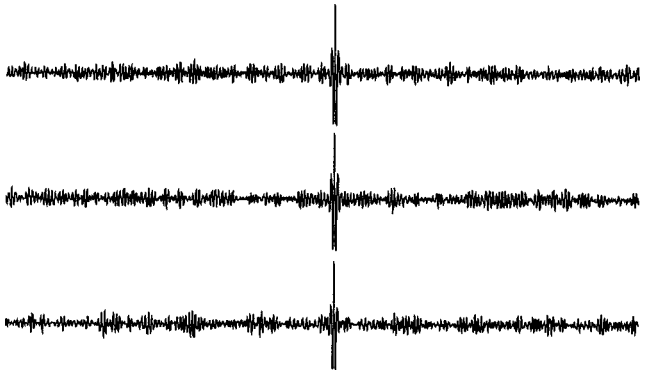

FIG. 8. Refocused signals for different time-reversal windows of same size (120 μs). The sidelobes change, but the peak is not altered.

high values. The refocused signal $s_{\Delta T}(t_R)$ approaches then an asymptotic shape, $S_\infty(t_R)$, and increases linearly with ΔT: $s_{\Delta T}(t_R)=\Delta T\cdot S_\infty(t_R)$, for $\Delta T\to\infty$. In particular, for large time-reversal windows, the refocused signal does not depend on their position, but only on their length. We consider the refocused signal $s_{\Delta T}(t_R)$ as a superposition of two contributions: A first part, $\Delta T\cdot S_\infty(t_R)$, which does not change in shape and which contains the peak as well as certain unavoidable sidelobes, called *residual sidelobes*. The

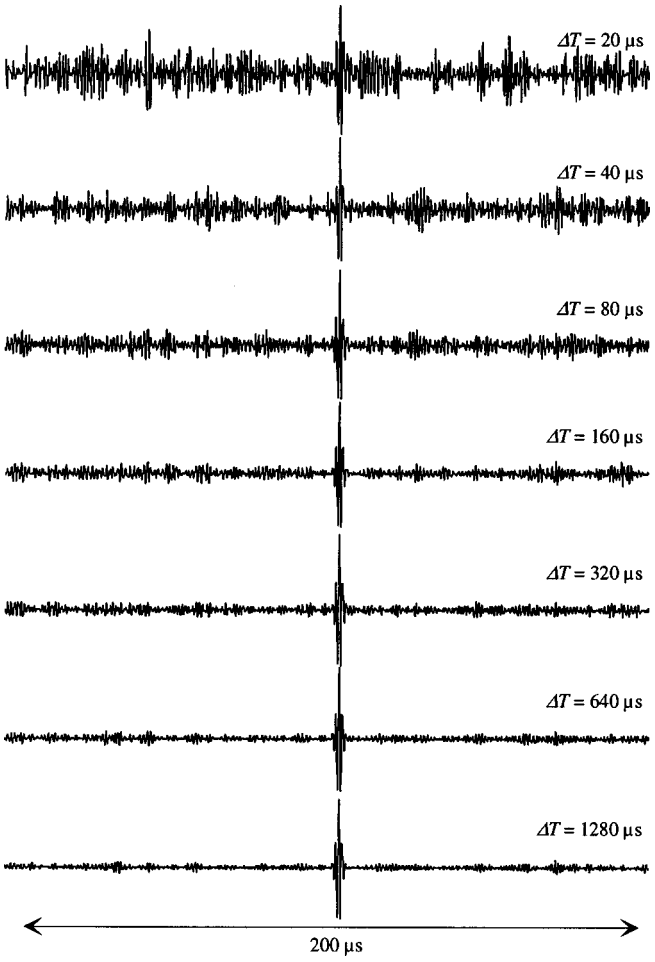

FIG. 9. Refocused signals for different time-reversal window sizes. The quality of the focus increases with the size. (Each amplitude has been normalized by a division by ΔT.)

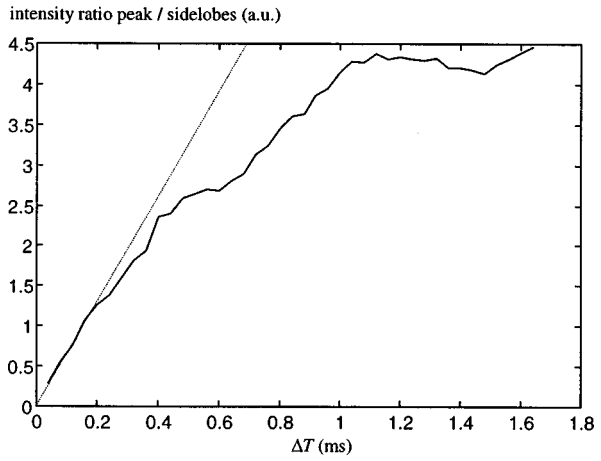

FIG. 10. For small time-reversal window sizes, the peak/sidelobe intensity ratio increases linearly, but enters a saturation regime for longer reversed signals.

second part changes with position and size of the window and can hence be reduced by reversing a longer signal. We designate it *noise*: $s_{\Delta T}(t_R)=\Delta T\cdot S_\infty(t_R)+\text{noise}$. This noise is not a measurement noise that can be reduced by averaging over several acquisitions. On the contrary, this noise is reproducible from one acquisition to the other; its origin is only in the limited size of the time-reversal window.

III. THE RAY MODEL

A. Introduction

In this section, we propose a simple statistical approach to explain the noise appearance. It is inspired by ray trajectories inside the cavity. The description of the wave field by a ray approximation is mostly intuitive and even difficult to justify as the radius of curvature of the cavity is relatively small and the paths are long. However, as we shall see, it fits exactly the experimental observations of the signal-to-noise ratio. The main idea is the following: In the first step of the experiment, imagine that A emits acoustic rays in all directions. (For simplicity, let A and B be monopole sources/receivers and the short pulse be a δ-function.) As the cavity is ergodic, every ray passes after more or less reflections sufficiently near B to be measured. The signal obtained is then a series of pulses, each one corresponding to a particular path between A and B. In the second step, a part of this signal is time-reversed and reinjected at B. Unlike a time-reversal mirror that creates the reversed wavefront in front of its active surface, B does not send back each peak only in the direction where the corresponding ray came from, but in all directions. Rays taking the ''good'' direction trace exactly their path back and arrive at $t_R=0$ at A. At this point, they superpose in a constructive way, giving the refocusing peak. All the rays taking ''bad'' directions may also superpose, thus giving rise to noise. But their superposition may be considered as random, thus increasing more slowly with the length of the time-reversal window than the refocusing peak: The signal-to-noise ratio is higher for longer reversed signals.

B. Calculation of the signal-to-noise ratio

Let $h(t)=h_{AB}(t)=h_{BA}(t)$ be the impulse response from A to B. Imagine that $h(t)$ is a superposition of Dirac pulses with arrival time t_i and amplitude A_i:

$$h(t)=\sum_i A_i\delta(t-t_i).$$

[This assumption is not strictly true as, in 2D, the impulse response is *not* giving δ-peaks, but peaks of type $\mathrm{H}(t-r/c)\cdot(t^2-r^2/c^2)^{-1/2}$, where H is the Heaviside step function, r the distance and c the wave speed. However, for long distances and short pulses, the only effect of the different impulse response is a change in shape of the received signal, which can be formally included in the excitation function $f(t)$ emitted by A that convolves finally the impulse response.]

We define $\rho(t)=\langle\Sigma_i\delta(t-t_i)\rangle$ as the average density of ray arrival times. The brackets $\langle.\rangle$ are defined as an ensemble average over all possible pairs of points (A,B). Of course, the impulse response is different for every pair of points, but because of the ergodic character of the cavity, we expect the same statistical properties. Let $\overline{A}(t)=\langle A(t)\rangle$ denote the average amplitude as a function of time, and $\overline{A^2}(t)=\langle A^2(t)\rangle$ denote the average of its square. As excitation signal $f(t)$, we take a short pulse centered around $t=0$ and with $\int dt\ f(t)=0$, i.e., of average zero. The signal measured at B is then

$$S_{AB}(t)=h(t)*f(t)=\sum_i A_i f(t-t_i)$$

and its expectation value is

$$\langle S_{AB}(t)\rangle=\int dt_i\ \rho(t_i)\overline{A}(t_i)f(t-t_i).$$

We assume that $\rho\overline{A}$ varies slowly enough during the duration of f so that the integral vanishes: $\langle S_{AB}(t)\rangle=0$.

We reinject a part of the signal $\Delta T=[t_1,t_2]$ in B. The part of the reversed impulse response is

$$h^{\Delta T}(-t_R)=\begin{cases}h(-t_R), & t_R\in[-t_2,-t_1]\\ 0, & \text{elsewhere}\end{cases}.$$

Due to reciprocity, the impulse response from B to A is the same as the one from A to B, and we obtain for the signal at A after reversal in B (for $\Delta T\gg$ width of f)

$$S_R(t_R)=f(t_R)*(h^{\Delta T}(-t_R)*h(t))$$

$$=f(t_R)*\int_{\Delta T}d\tau\ h(\tau)h(t_R+\tau).$$

As h is a Dirac function for every arrival time, $h(\tau)h(t_R+\tau)$ is nonzero if and only if τ and $t_R+\tau$ correspond to two arrival times. Let $t_i=\tau$ and $t_j=t_R+\tau=t_R+t_i$, then the signal can be written

$$S_R(t_R)=\sum_{t_i\in\Delta T}\ \sum_{t_j}A_iA_jf(t_R-(t_j-t_i)).$$

Hence, the refocused signal is a superposition of many elementary signals $f(t)$. We are going to split this sum into

three parts. The first one, responsible for the refocusing peak at $t_R=0$, is given by $t_i=t_j$, i.e., the diagonal elements of the double sum:

$$S_{\text{peak}}(t_R)=f(t_R)\sum_{t_i\in\Delta T}A_i^2.$$

The second part can be evaluated by assuming a random superposition of the elementary signals, given by all pairs (t_i,t_j) whose difference behaves as a random variable. We call them *uncorrelated pairs* (t_i,t_j) and the corresponding part of the signal *incoherent noise*.

$$S_{\text{noise}}(t_R)=\sum_{\substack{t_i\in\Delta T\\ t_i\neq t_j\text{uncorr.}}}A_iA_jf(t_R-(t_j-t_i)).$$

This sum contains almost all pairs of arrival times. But there are also pairs $t_i\neq t_j$ that are correlated. This fact can be ascribed to rays that, with origin at *A*, pass over this same point before arriving at *B* and to rays passing over *B* several times during propagation. These pairs give rise to the residual sidelobes, the third part of the sum:

$$S_{\substack{\text{residual}\\ \text{sidelobes}}}(t_R)=\sum_{\substack{t_i\in\Delta T\\ t_i\neq t_j\text{corr.}}}A_iA_jf(t_R-(t_j-t_i)).$$

The latter sum cannot be evaluated *as is*; the residual sidelobes are not described in a satisfactory way by our ray model. However, a model using a decomposition of the wave field in eigenmodes of the cavity gives a complete description of this phenomenon. It is published in a second paper.[11]

Now we want to evaluate the signal-to-noise ratio, i.e., the peak-to-noise ratio.

The expectation value of the peak is

$$\langle S_{\text{peak}}(t_R)\rangle=f(t_R)\int_{\Delta T}dt_i\ \rho(t_i)\overline{A^2}(t_i).$$

The expression $\rho\overline{A^2}=I_0$ represents the average intensity measured in *B* during the first step. Assuming an ergodic lossless cavity, its value must be constant in time, thus

$$\langle S_{\text{peak}}(t_R)\rangle=f(t_R)I_0\Delta T.$$

The amplitude of the peak is proportional to the excitation function and the window size ΔT. It does not depend on the density of arrival times or the corresponding amplitudes. The incoherent noise is, of course, of average zero. Its variance is given by

$$\begin{aligned}\langle S_{\text{noise}}^2(t_R)\rangle&=\left\langle\sum_{\substack{t_i\in\Delta T\\ t_i\neq t_j\text{uncorr.}}}A_iA_jf(t_R-(t_j-t_i))\sum_{\substack{t_i'\in\Delta T\\ t_i'\neq t_j'\text{uncorr.}}}A_{i'}A_{j'}f(t_R-(t_j'-t_i'))\right\rangle\\&=\left\langle\sum_{\substack{t_i\in\Delta T\\ t_i\neq t_j\text{uncorr.}}}A_i^2A_j^2f^2(t_R-(t_j-t_i))\right\rangle+\left\langle\sum_{\substack{t_i\in\Delta T\\ t_i\neq t_j\text{uncorr.}}}A_iA_jf(t_R-(t_j-t_i))\sum_{\substack{t_i'\in\Delta T\\ t_i'\neq t_i,t_j'\neq t_j\\ t_i'\neq t_j'\text{uncorr.}}}A_{i'}A_{j'}f(t_R-(t_j'-t_i'))\right\rangle.\end{aligned}$$

In these sums, several terms are excluded corresponding to correlated or same-arrival times. As these terms are small in number compared to the other ones, we commit only a small error by reintroducing them, but supposing them uncorrelated. The average of the double-sum terms can then be changed to a product of two averages, in which each factor is equal to the noise average $\langle S_{\text{noise}}(t_R)\rangle$ that is zero. The only contribution is given by the diagonal terms. Thus,

$$\langle S_{\text{noise}}^2(t_R)\rangle=\int_{\Delta T}dt_i\int dt_j\ \rho(t_i)\overline{A^2}(t_i)\rho(t_j)\overline{A^2}(t_j)\times f^2(t_R-(t_j-t_i)).$$

We replace $\rho\overline{A^2}$ by I_0. The integral over t_j simplifies to $E_f=\int dt\ f^2(t)$, the ''energy'' of the excitation function. One obtains finally

$$\langle S_{\text{noise}}^2\rangle=E_fI_0^2\Delta T,$$

independent from t_R.

The peak-to-noise ratio is found to be

$$R_{\text{p/n}}=\max\langle S_{\text{peak}}(t_R)\rangle/\sqrt{\langle S_{\text{noise}}^2\rangle}=(\max(f(t))/\sqrt{E_f})\sqrt{\Delta T},$$

which is proportional to the square root of ΔT. Thus, a short signal of high amplitude is better suited for high signal-to-noise ratios than a longer signal with a lower peak value, but containing the same energy.

C. Comparison with experiments

The signal-to-noise ratio calculated above is not convenient for the description of experimental data. First, we prefer a value which does not depend on the shape of the signal. We consider, therefore, the energy of the peak instead of its maximum:

$$E_{\text{peak}}^{\text{exp}}=\int dt_R\ S_{\text{peak}}^2(t_R);$$

$$E_{\text{peak}}^{\text{theory}}=\int dt_R\langle S_{\text{peak}}^2(t_R)\rangle=E_fI_0^2\Delta T^2.$$

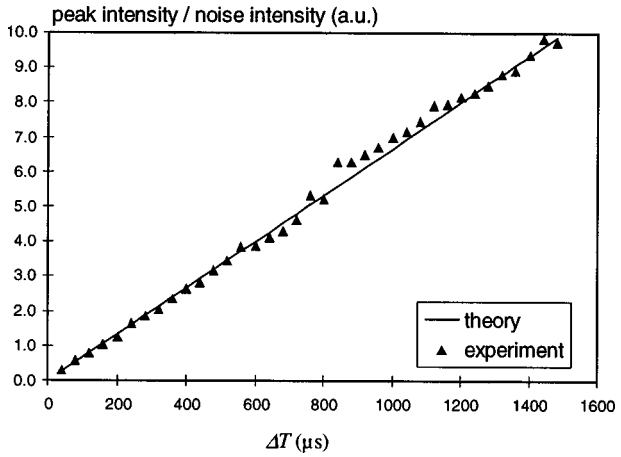

FIG. 11. Evolution of the peak/noise intensity ratio (after subtraction of the residual sidelobes) for increasing time-reversal windows.

Second, as we cannot directly measure the variance of the noise, we estimate its value by taking the average over a window Δt_R in the refocused signal. (Given the ergodic character of the system, this should be a good estimator.) The energy of the noise inside this interval is given by

$$E_{\text{noise}}^{\text{exp}} = \int_{\Delta t_R} dt_R \; S_{\text{noise}}^2(t_R);$$

$$E_{\text{noise}}^{\text{theory}} = \int_{\Delta t_R} dt_R \langle S_{\text{noise}}^2 \rangle = E_f I_0^2 \Delta T \Delta t_R .$$

The theoretical ratio is linear in ΔT:

$$E_{\text{peak}}^{\text{theory}} / E_{\text{noise}}^{\text{theory}} = \Delta T / \Delta t_R .$$

Third, we do not have direct access to the incoherent noise as it is superposed to the residual sidelobes. However, the difference of two refocused signals, $S_{\Delta T_1} - S_{\Delta T_2}$, for two nonoverlapping time-reversal windows ΔT_1 and ΔT_2 of the same size, erases the peak and the residual sidelobes. The noise behaves like a refocused signal obtained by a window of size $\Delta T = \Delta T_1 + \Delta T_2$. These facts have been taken into account to obtain the experimental data in Fig. 11. The agreement is excellent. Note that the straight line is the theoretical ratio, drawn without fit to the experimental data. This justifies thus, *a posteriori*, the model.

IV. TIME-REVERSAL IN REGULAR CAVITIES

In order to show the importance of the ergodic and mixing character of the cavity, we present here two examples of cavities, where this assumption is not, or not completely, fulfilled.

A. Rectangular cavities

Rectangles are a favorite example of regular billiards. The angle of the trajectory is a constant of motion and so the path of a ray can be predicted in the long term. By symmetry considerations, it is easy to see that a one-channel time-reversal in a rectangular cavity produces several focal spots other than the source point *A*, with different amplitudes. (In fact, there are up to nine.) In the experimental setup shown in Fig. 12, some of these image points superpose at A'. Figure 13 presents a *C*-scan, taken at the focusing instant, showing the monopole at *A* and its image at A', symmetrical to the reversal point *B*. The fact that *B* is a dipole source gives another interesting aspect to this experiment: *B* is only able to emit or receive in directions around its polarization axis. As the angle of each ray is conserved, the monopole focal spots at *A* and A' no longer have circular symmetry, but are biased by the directivity pattern of the reversal point.

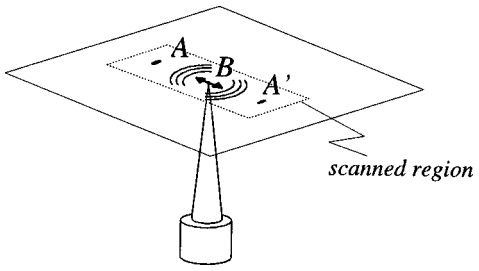

FIG. 12. One-channel time-reversal in rectangular cavities produces several focal spots. In this particular configuration (*A* located on the polarization axis of *B*, which is parallel to one side of the rectangle), some of them are superposed in A'.

B. Temporal dependence of mixing

Chaotic cavities whose shape is only slightly different from the regular case do not reveal their ergodic properties over short time-scales. For the *C*-scans presented in Fig. 14, we have used an almost circular wafer, with a segment of only 4% of the diameter cut off. In circular billiards, the constant of motion is the angular momentum. If *A* and *B* are at the same distance from the center, this would lead, just as in the case of rectangular billiards, to monopole focal spots with the directivity pattern of the dipole reversal point. In the case of our almost regular cavity, the time-reversal of the first 2 ms ($\Delta T = [0;2\text{ ms}]$) shows exactly this behavior [Fig. 14(a)]. If one reverses instead the following two milliseconds ($\Delta T = [2\text{ ms};4\text{ ms}]$), the focal spot is of circular symmetry [Fig. 14(b)]. Obviously, the angular momentum of a ray is conserved over medium periods of time. To be mixed, the ray has to be reflected at least once at the small part of the boundary where the segment is cut off. And only a mixing of the angular momenta allows rays to approach the focal spot from other sides than the directivity pattern of the reversal point.

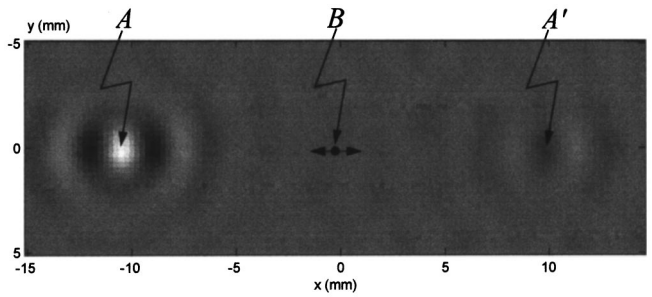

FIG. 13. *C*-scan of two (monopole) focal spots in a rectangular cavity as measured by an optical interferometer. The converging wavefronts are no more circular, but biased by the directivity pattern at the reversal point *B*.

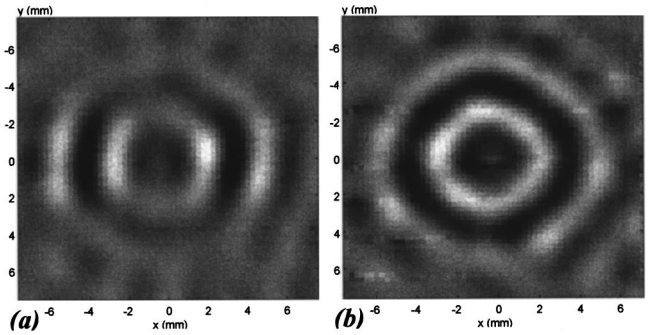

FIG. 14. *C*-scans of the refocused waves in a weakly chaotic billiard. (a) Time-reversal of a window directly after emission ($\Delta T=[0,2000\ \mu s]$) still shows the directivity pattern of the reversal point. (b) Ray angles mix after longer trajectories ($\Delta T=[2000\ \mu s,4000\ \mu s]$) and arrive from all directions at the focal spot.

V. CONCLUSION

Acoustic time-reversal experiments usually need large arrays of transducers. In this paper, we present experiments proving the possibility of reducing the number of elements down to one by using multiple reflections inside the propagation medium. The experiments are carried out with a 2-D silicon wafer, wherein the injection of a short ultrasonic pulse at one point reverberates over a very long time. The signal is recorded at a second point, time-reversed and reemitted. We obtain an excellent focusing at the initial source location.

The focusing peak has been observed using two methods: First, we scanned the field of one propagation mode (A_0) around the focal spot using an optical interferometer. One is able to obtain circular converging wavefronts that collapse at the initial source point and diverge afterwards. However, a certain noise level cannot be avoided. Second, we observe the refocused signal using the transducer located at the initial source. We obtain a short peak standing out from more-or-less temporal sidelobes. The refocused signal depends crucially on the size of the time-reversal window, i.e., the length of the reversed signal. The amplitude of the peak increases linearly with the reversed time; the peak to sidelobes level improves. For long time-reversal windows, a saturation regime is entered where the sidelobes can no more be reduced. The increase of the focusing quality with the reversed time can be successfully described by a simple statistical model, inspired by ray trajectories inside the cavity. However, the residual sidelobes are not taken into account by this model. A more rigorous analysis, based on an eigenmode decomposition of the wave field, explains this phenomenon and is presented in a second paper dealing with the theoretical limits of the time-reversal process.[11]

The use of a chaotic cavity is of crucial interest. First, its ergodic ray dynamics ensures that every ray emitted by the source point can be recorded by the reversal point. Second, we give examples of regular cavities wherein the one-channel time-reversal does not work properly. Third, a theoretical analysis, given in another paper, also takes advantage by assuming some properties of chaotic wave billiards such as, for example, spectral rigidity. While classical chaos inhibits time-reversal experiments due to strong sensitivity to initial conditions, the wave chaos of this case is actually useful.

One-channel time-reversal experiments can be easily reproduced. Unlike usual time-reversal experiments which need, in general, up to 100 transducers and the corresponding independent transmit/receive electronics, one-channel experiments have an extremely simple and low-cost experimental setup. Only two transducers are needed, and one transmit and one receive channel. We used a 2-D cavity in our experiments, but a 3-D cavity should work as well.

Our lab is currently working towards a better characterization of the time-reversal experiments in the transition from regular to chaotic cavities. We also want to try waveguides with a cross section in the shape of a chaotic billiard to obtain time-reversed focusing using a time-reversal mirror with fewer transducer elements.

On energy definition in electromagnetism: An analogy with viscoelasticity

J. M. Carcione[a)]
Osservatorio Geofisico Sperimentale, P.O. Box 2011 Opicina, 34016 Trieste, Italy

(Received 15 March 1998; accepted for publication 7 October 1998)

Electromagnetic media as, for instance, imperfect dielectrics, semiconductors, and materials with magnetic losses, have time- (and frequency-) dependent permittivity, magnetic permeability, and electric conductivity, and, therefore, energy dissipation and pulse distortion occurs. The electromagnetic Umov–Poynting's theorem is reinterpreted in light of the theory of viscoelasticity in order to define the stored and dissipated energy densities in the time domain. A simple dielectric relaxation model equivalent to a viscoelastic mechanical model illustrates the analogy that identifies electric field with stress, electric induction with strain, dielectric permittivity with reciprocal bulk modulus, and resistance with viscosity. © *1999 Acoustical Society of America.*

INTRODUCTION

Energy-balance equations are important for characterizing the energy stored and the transport properties in a field. However, the definition of stored (free) energy and energy dissipation rate is controversial, both in electromagnetism[1] and viscoelasticity.[2] The problem is particularly intriguing in the time domain, since different definitions may give the same time-average value for harmonic fields. This ambiguity is not present when the constitutive relation can be described in terms of springs and dashpots (e.g., Refs. 3 and 4). That is, when the system can be defined in terms of internal variables and the relaxation function has an exponential form.[5] Christensen[6] and Golden and Graham[7] give a general expression of the viscoelastic energy densities which is consistent with the mechanical model description.

Formal analogies, in the mathematical sense, exist between electromagnetism and other fields like mechanics[8] and viscoelasticity. In this case, Carcione and Cavallini,[9] for instance, show an analogy for vector wavefields and material properties that allows the acoustic and electromagnetic problems to be solved with the same analytical methodology. In this work, the stored electric and magnetic energies are defined in terms of the viscoelastic expression by using the analogy. The theory is applied to a simple dielectric relaxation process that is mathematically equivalent to the Zener model or standard linear solid viscoelastic rheology.[10]

It is important to point out that the theory cannot be applied to the whole range of electromagnetic (e.m.) problems, since a mathematical analogy may not necessarily imply a physical analogy. In viscoelasticity, the real part of the complex moduli (describing pure deformation modes) is positive, and the presence of intrinsic dissipation implies velocity dispersion and vice versa (Kramers–Krönig relations[11,12]). These properties preclude the use of the theory for an ionized gas whose complex permittivity may, in some cases, be negative (e.g., Ref. 13), or for a lossless dispersive dielectric that does not satisfy the Kramers–Krönig relations.

The definition of energy is important in a large number of applications where it is necessary to know how the energy transferred by the e.m. field is related to the strength of the field. This context involves the whole electrical, radio, and optical engineering, where the medium can be assumed dielectrically and magnetically linear. In particular, the Debye model has been applied to bioelectromagnetics[14,15] in the analysis of the response of biological tissues, and to geophysics, in the simulation of ground-penetrating radar wave propagation through wet soils.[16,17,18]

I. MAXWELL'S EQUATIONS AND CONSTITUTIVE RELATIONS

Maxwell's equations for isotropic dispersive media, in the absence of external electric and magnetic currents, are

$$\nabla\times\mathscr{E}=-\frac{\partial\mathscr{B}}{\partial t}, \tag{1}$$

$$\nabla\times\mathscr{H}=\frac{\partial\mathscr{D}}{\partial t}+\mathscr{J}, \tag{2}$$

where $\mathscr{E}$ is the electric field, $\mathscr{H}$ is the magnetic field, $\mathscr{D}$ is the electric induction, $\mathscr{B}$ is the magnetic induction, and $\mathscr{J}$ is the conduction current. The symbol $\times$ denotes the vector product.

For time-harmonic fields with time dependence $\exp(i\omega t)$, where ω is the angular frequency, Eqs. (1) and (2) read

$$\nabla\times\mathbf{E}=-i\omega\mathbf{B}, \tag{3}$$

$$\nabla\times\mathbf{H}=i\omega\mathbf{D}+\mathbf{J}, \tag{4}$$

respectively, where **E**, **D**, **H**, and **B** are the corresponding time-harmonic fields.

We consider constitutive relations $\mathscr{D}(\mathscr{E})$ and $\mathscr{B}(\mathscr{H})$ of the form

$$\mathscr{D}=\epsilon*\frac{\partial\mathscr{E}}{\partial t} \tag{5}$$

a)Electronic mail: carcione@gems755.ogs.trieste.it

and

$$\mathscr{B}=\mu * \frac{\partial \mathscr{H}}{\partial t} \tag{6}$$

(i.e., nonmoving media), where ϵ and μ are the dielectric permittivity and magnetic permeability functions, and * denotes time convolution. Similarly, generalized Ohm's law can be written as

$$\mathscr{J}=\sigma * \frac{\partial \mathscr{E}}{\partial t}, \tag{7}$$

where σ is the conductivity function.

For harmonic fields, the constitutive relations read

$$\mathbf{D}=\mathscr{F}\left(\frac{\partial \epsilon}{\partial t}\right)\mathbf{E}, \quad \mathbf{B}=\mathscr{F}\left(\frac{\partial \mu}{\partial t}\right)\mathbf{H}, \tag{8}$$

and

$$\mathbf{J}=\mathscr{F}\left(\frac{\partial \sigma}{\partial t}\right)\mathbf{E}, \tag{9}$$

where $\mathscr{F}(\cdot)$ is the Fourier transform operator. For convenience, the medium properties are denoted by the same symbols, in both the time and the frequency domains, i.e.,

$$\mathscr{F}\left(\frac{\partial \epsilon}{\partial t}\right) \rightarrow \epsilon, \ldots, \text{etc}\ldots$$

II. UMOV–POYNTING'S THEOREM FOR HARMONIC FIELDS

The scalar product of the complex conjugate of Eq. (4) with $\mathbf{E}$, use of $\nabla\cdot(\mathbf{E}\times\mathbf{H}^*)=(\nabla\times\mathbf{E})\cdot\mathbf{H}^*-\mathbf{E}\cdot(\nabla\times\mathbf{H}^*)$, and substitution of Eq. (3) gives Umov–Poynting's theorem for harmonic fields,

$$-\nabla\cdot\mathbf{P}=\tfrac{1}{2}\,\mathbf{J}^*\cdot\mathbf{E}-2i\omega(u_e-u_m), \tag{10}$$

where

$$\mathbf{P}=\tfrac{1}{2}\mathbf{E}\times\mathbf{H}^* \tag{11}$$

is the complex Umov–Poynting vector, and

$$u_e=\tfrac{1}{4}\mathbf{E}\cdot\mathbf{D}^*, \quad u_m=\tfrac{1}{4}\mathbf{B}\cdot\mathbf{H}^*, \tag{12}$$

are the harmonic (complex) (di)electric and magnetic energy densities. The symbol * denotes complex conjugate.

Substitution of the constitutive relations (8) and (9) into Eq. (10) yields

$$2i\nabla\cdot\mathbf{P}=-\omega(\epsilon_T^*|\mathbf{E}|^2-\mu|\mathbf{H}|^2), \tag{13}$$

where

$$\epsilon_T=\epsilon-\frac{i}{\omega}\,\sigma. \tag{14}$$

Taking real and imaginary parts of (13) gives

$$\begin{aligned} 2\,\mathrm{Im}(\nabla\cdot\mathbf{P}) &= \omega[\mathrm{Re}(\epsilon_T)|\mathbf{E}|^2-\mathrm{Re}(\mu)|\mathbf{H}|^2] \\ &= \text{power energy density}, \end{aligned} \tag{15}$$

$$\begin{aligned} 2\,\mathrm{Re}(\nabla\cdot\mathbf{P}) &= \omega[\mathrm{Im}(\epsilon_T)|\mathbf{E}|^2+\mathrm{Im}(\mu)|\mathbf{H}|^2] \\ &= \text{rate of dissipated energy}, \end{aligned} \tag{16}$$

respectively. The time-average energy densities are such that

$$\begin{aligned} &\tfrac{1}{4}\,\mathrm{Re}(\epsilon)|\mathbf{E}|^2=\mathrm{Re}(u_e) \quad \text{stored (di)electric} \\ &-\tfrac{1}{2}\,\omega^{-1}\,\mathrm{Im}(\sigma)|\mathbf{E}|^2=\mathrm{Im}(u_\sigma) \quad \text{stored electric} \\ &\tfrac{1}{4}\,\mathrm{Re}(\mu)|\mathbf{H}|^2=\mathrm{Re}(u_m) \quad \text{stored magnetic} \\ &\tfrac{1}{4}\,\mathrm{Im}(\epsilon)|\mathbf{E}|^2=\mathrm{Im}(u_e) \quad \text{dissipated (di)electric} \\ &\tfrac{1}{2}\,\omega^{-1}\,\mathrm{Re}(\sigma)|\mathbf{E}|^2=\mathrm{Re}(u_\sigma) \quad \text{dissipated electric} \\ &\tfrac{1}{4}\,\mathrm{Im}(\mu)|\mathbf{H}|^2=\mathrm{Im}(u_m) \quad \text{dissipated magnetic}, \end{aligned} \tag{17}$$

where

$$u_\sigma=\tfrac{1}{2}\omega^{-1}\mathbf{J}^*\cdot\mathbf{E}=\tfrac{1}{2}\omega^{-1}\sigma^*|\mathbf{E}|^2 \tag{18}$$

is the (complex) electric energy density.

III. ENERGY DEFINITION IN ELECTROMAGNETISM

Time-average energies for harmonic fields are precisely defined. Let us consider, for instance, the formulation of the energy balance equation given in Oughstun and Sherman.[1] Upon taking the scalar product of Eq. (1) with $\mathscr{H}$ and Eq. (2) with $\mathscr{E}$ and taking the difference, Oughstun and Sherman (Ref. 1, Eq. 2.2.5) obtain

$$-\nabla\cdot\mathscr{P}=\mathscr{J}\cdot\mathscr{E}+\frac{\partial U}{\partial t}, \tag{19}$$

where $\mathscr{P}=\mathscr{E}\times\mathscr{H}$ is the Umov–Poynting vector and U is the total energy per unit volume given by

$$U=U_e+U_m, \tag{20}$$

with

$$\frac{\partial U_e}{\partial t}=\mathscr{E}\cdot\frac{\partial \mathscr{D}}{\partial t}, \tag{21}$$

the time rate of (di) electric energy density, and

$$\frac{\partial U_m}{\partial t}=\mathscr{H}\cdot\frac{\partial \mathscr{B}}{\partial t}, \tag{22}$$

the time rate of magnetic energy density.

The time average of the scalar product of two harmonic vector fields, with the same oscillation frequency, is given by

$$\langle \mathscr{A}\cdot\mathscr{B}\rangle=\tfrac{1}{2}\,\mathrm{Re}(\mathbf{A}\cdot\mathbf{B}^*). \tag{23}$$

Note that taking the time average of Eqs. (19) yields

$$-\langle\nabla\cdot\mathscr{P}\rangle=\tfrac{1}{2}\,\mathrm{Re}(\mathbf{J}^*\cdot\mathbf{E})+2\omega[\mathrm{Im}(u_e)-\mathrm{Im}(u_m)], \tag{24}$$

which can be obtained from Eq. (10) by taking its real part. Equation (24) gives the balance of the rate of dissipated energy density and is equivalent to Eq. (16).

We now review some of the statements discussed by Oughstun and Sherman.[1]

(1) Poynting's theorem *provides a mathematically consistent formulation of energy flow* (p. 24). This does not preclude the existence of an alternative formulation. For instance, Jeffreys[19] gives an alternative energy balance,

implying a new interpretation of the Poynting vector (see also the interesting discussion in Robinson[20] and Jeffreys[21]).

(2) *... it cannot be definitely concluded that the time rate of energy flow at a point is uniquely given by the value of the Poynting vector at that point, for one may add to the Poynting vector any solenoidal vector field without affecting the statement of conservation of energy...* (p. 26). In fact, as the authors state, there is no strictly valid justification for the accepted interpretation of the Poynting vector.

(3) *... one cannot, in general, express the electric energy density and the dissipation separately in terms of the dielectric permittivity and electrical conductivity of a dispersive medium* (p. 31). In the general case [i.e., the time-domain equation (19)], it is not possible to separate the stored energies from the dissipated energies. Relating u_e and U_e gives [see Eq. (2.2.38)],

$$\mathrm{Im}(u_e)=\frac{1}{2\omega}\left\langle\frac{\partial U_e}{\partial t}\right\rangle, \tag{25}$$

and no relationship of this type for the real part of u_e. The same reasoning applies to the magnetic energy. We present in the next section an alternative definition where energy can be, in principle, separated between stored and dissipated.

(4) For time-harmonic fields, the separation is shown in Eq. (17). However, there is no relation between the time-average energies defined in Eq. (17) and the time averages of U_e, U_m (p. 36). In the next section, a link between harmonic energy densities and transient energy densities is obtained.

Note that Oughstun and Sherman [Ref. 1, Eq. (2.1.19)] use an $\exp(-i\omega t)$ time dependence.

IV. UMOV–POYNTING'S THEOREM FOR TRANSIENT FIELDS

Poynting's theorem (19), omitting Oughstun and Sherman's interpretation of the energies, is

$$-\boldsymbol{\nabla}\cdot\mathscr{P}=\mathscr{J}\cdot\mathscr{E}+\mathscr{E}\cdot\frac{\partial\mathscr{D}}{\partial t}+\mathscr{H}\cdot\frac{\partial\mathscr{B}}{\partial t}. \tag{26}$$

Let us consider a stored (di)electric (free) energy density of the form

$$W_e(t)=\frac{1}{2}\int_{-\infty}^{t}\int_{-\infty}^{t}K(t-\tau_1,t-\tau_2)\times\mathscr{D}'(\tau_1)\cdot\mathscr{D}'(\tau_2)d\tau_1\,d\tau_2, \tag{27}$$

where the prime denotes the first-order derivative with respect to the argument. Hunter (Ref. 3, p. 545) and Golden and Graham (Ref. 7, p. 12) define a similar form for the linear viscoelastic case. The underlying assumptions are that the dielectric properties of the medium do not vary with time (nonaging material), and, as in the lossless case, the energy density is quadratic in the electric field. Moreover, the expression includes a dependence on the history of the electric field. However, it is important to note that the above assumption as to the structure of the formula for the free energy density is by no means the only possible one (see Rabotnov,[22] p. 72). Moreover, as we shall see below, the general expression of the free energy is not uniquely determined by the relaxation function.

Differentiating W_e yields

$$\frac{\partial W_e}{\partial t}=\frac{\partial\mathscr{D}}{\partial t}\cdot\int_{-\infty}^{t}K(t-\tau_2,0)\mathscr{D}'(\tau_2)d\tau_2+\frac{1}{2}\int_{-\infty}^{t}\int_{-\infty}^{t}\frac{\partial}{\partial t}K(t-\tau_1,t-\tau_2)\mathscr{D}'(\tau_1)\cdot\mathscr{D}'(g t_2)d\tau_1\,d\tau_2. \tag{28}$$

The constitutive relation (5) can be rewritten as

$$\mathscr{E}=\beta*\frac{\partial\mathscr{D}}{\partial t}, \tag{29}$$

where $\beta(t)$ is the dielectric impermeability function, satisfying

$$\frac{\partial\epsilon}{\partial t}*\frac{\partial\beta}{\partial t}=\delta(t),\quad \epsilon_\infty\beta_\infty=\epsilon_0\beta_0=1,\quad \epsilon(\omega)\beta(\omega)=1, \tag{30}$$

with the subindices ∞ and 0 corresponding to the limits $t\to 0$ and $t\to\infty$, respectively. If

$$\beta(t)=K(t,0)H(t), \tag{31}$$

where $H(t)$ is the Heaviside function, then,

$$\int_{-\infty}^{t}K(t-\tau_2,0)\mathscr{D}'(\tau_2)d\tau_2=\mathscr{E}(t), \tag{32}$$

and (28) becomes

$$\mathscr{E}\cdot\frac{\partial\mathscr{D}}{\partial t}=\frac{\partial W_e}{\partial t}+D_e, \tag{33}$$

where

$$D_e(t)=-\frac{1}{2}\int_{-\infty}^{t}\int_{-\infty}^{t}\frac{\partial}{\partial t}K(t-\tau_1,t-\tau_2)\times\mathscr{D}'(\tau_1)\cdot\mathscr{D}'(\tau_2)d\tau_1\,d\tau_2 \tag{34}$$

is the rate of dissipation of (di) electric energy density. Note that the relation (31) does not determine the stored energy, i.e., this can not be obtained from the constitutive relation. However, if we assume that

$$K(t,\tau_1)=G(t+\tau_1), \tag{35}$$

such that

$$\beta(t)=G(t)H(t), \tag{36}$$

this choice will suffice to determine K, and

$$W_e(t)=\frac{1}{2}\int_{-\infty}^{t}\int_{-\infty}^{t}G(2t-\tau_1-\tau_2)\mathscr{D}'(\tau_1)\cdot\mathscr{D}'(\tau_2)d\tau_1\,d\tau_2, \tag{37}$$

$$D_e(t) = -\int_{-\infty}^{t}\int_{-\infty}^{t} G'(2t-\tau_1-\tau_2)\mathscr{D}'(\tau_1) \cdot \mathscr{D}'(\tau_2)\,d\tau_1\,d\tau_2. \tag{38}$$

Equation (35) is consistent with the corresponding theory implied by mechanical models.[6] Breuer and Onat[23] discuss some realistic requirements from which $K(t,\tau_1)$ must have the reduced from $G(t+\tau_1)$.

Let us calculate the time average of the stored energy density for monochromatic fields. Although $\mathscr{D}(-\infty)$ does not vanish, the transient contained in (37) vanishes for sufficiently large times, and this equation can be used to compute the average of time-harmonic fields. The change of variables $\tau_1 \to t-\tau_1$ and $\tau_2 \to t-\tau_2$ yields

$$W_e(t) = \frac{1}{2}\int_0^{\infty}\int_0^{\infty} G(\tau_1+\tau_2)\mathscr{D}'(t-\tau_1) \cdot \mathscr{D}'(t-\tau_2)\,d\tau_1\,d\tau_2. \tag{39}$$

Using (23), the time average of Eq. (39) is

$$\langle W_e\rangle = \tfrac{1}{4}\,\omega^2|\mathbf{D}|^2 \times \int_0^{\infty}\int_0^{\infty} G(\tau_1+\tau_2)\cos[\omega(\tau_1-\tau_2)]\,d\tau_1\,d\tau_2. \tag{40}$$

A new change of variables $u=\tau_1+\tau_2$ and $v=\tau_1-\tau_2$ gives

$$\langle W_e\rangle = \frac{1}{8}\,\omega^2|\mathbf{D}|^2\int_0^{\infty}\int_{-u}^{u} G(u)\cos(\omega v)\,du\,dv = \frac{1}{4}\,\omega|\mathbf{D}|^2\int_0^{\infty} G(u)\sin(\omega u)\,du. \tag{41}$$

From Eq. (36), and using integration by parts, we have that

$$\mathrm{Re}\left[\mathscr{F}\left(\frac{\partial\beta}{\partial t}\right)\right] = \mathrm{Re}[\beta(\omega)] = G(\infty)+\omega\int_0^{\infty}[G(t)-G(\infty)]\sin(\omega t)\,dt. \tag{42}$$

Using the property

$$\omega\int_0^{\infty}\sin(\omega t)\,dt = 1, \tag{43}$$

we obtain

$$\mathrm{Re}[\beta(\omega)] = \omega\int_0^{\infty} G(t)\sin(\omega t)\,dt. \tag{44}$$

Substituting Eq. (44) into Eq. (41), and since $\mathbf{E}=\beta(\omega)\mathbf{D}$, we finally get

$$\langle W_e\rangle = \tfrac{1}{4}|\mathbf{D}|^2\ \mathrm{Re}[\beta(\omega)] = \mathrm{Re}(u_e). \tag{45}$$

A similar calculation shows that $\langle D_e\rangle = 2\omega\ \mathrm{Im}(u_e)$.

Similarly, the magnetic term on the right-hand side r.h.s. of Eq. (26) can be recasted as

$$\mathscr{H}\cdot\frac{\partial\mathscr{B}}{\partial t} = \frac{\partial W_m}{\partial t} + D_m, \tag{46}$$

where

$$W_m(t) = \frac{1}{2}\int_{-\infty}^{t}\int_{-\infty}^{t} F(2t-\tau_1-\tau_2).\mathscr{B}'(\tau_1) \cdot\mathscr{B}'(\tau_2)\,d\tau_1\,d\tau_2, \tag{47}$$

$$D_m(t) = -\int_{-\infty}^{t}\int_{-\infty}^{t} F'(2t-\tau_1-\tau_2).\mathscr{B}'(\tau_1) \cdot\mathscr{B}'(\tau_2)\,d\tau_1\,d\tau_2, \tag{48}$$

are the stored magnetic energy density and rate of dissipation of magnetic energy density, respectively, such that

$$\mathscr{H} = \gamma * \frac{\partial.\mathscr{B}}{\partial t}, \quad \gamma(t) = F(t)H(t), \tag{49}$$

with γ the magnetic impermeability function.

The rate of dissipated electric energy density can be defined as

$$D_\sigma(t) = -\int_{-\infty}^{t}\int_{-\infty}^{t}\Sigma(2t-\tau_1-\tau_2)\mathscr{E}'(\tau_1) \cdot\mathscr{E}'(\tau_2)\,d\tau_1\,d\tau_2, \tag{50}$$

where

$$\mathscr{J} = \sigma * \frac{\partial\mathscr{E}}{\partial t}, \quad \sigma(t) = \Sigma(t)H(t). \tag{51}$$

Formally, the stored energy density due to the electric currents out of phase with the electric field, satisfies

$$\frac{\partial W_\sigma}{\partial t} = \mathscr{J}\cdot\mathscr{E} - D_\sigma. \tag{52}$$

In terms of the energy densities, Eq. (26) becomes

$$-\boldsymbol{\nabla}\cdot\mathscr{P} = \frac{\partial}{\partial t}(W_\sigma+W_e+W_m)+D_\sigma+D_e+D_m, \tag{53}$$

and the correspondences with the averaged time-harmonic values are

$$\begin{aligned}&\langle W_e\rangle = \mathrm{Re}(u_e), \quad \langle W_m\rangle = \mathrm{Re}(u_m),\\ &\langle D_e\rangle = 2\omega\ \mathrm{Im}(u_e),\\ &\langle D_\sigma\rangle = 2\omega\ \mathrm{Re}(u_\sigma),\\ &\langle D_m\rangle = -2\omega\ \mathrm{Im}(u_m).\end{aligned} \tag{54}$$

Note that $\langle\mathscr{J}\cdot\mathscr{E}\rangle$ is equal to the rate of dissipated energy density $\langle D_\sigma\rangle$, and that

$$\left\langle\frac{\partial W_e}{\partial t}\right\rangle = 0, \tag{55}$$

in contrast with Oughstun and Sherman's result (25). The same property holds for the stored electric and magnetic energy densities.

There are other alternative time-domain expressions for the energy densities whose time-average values coincide

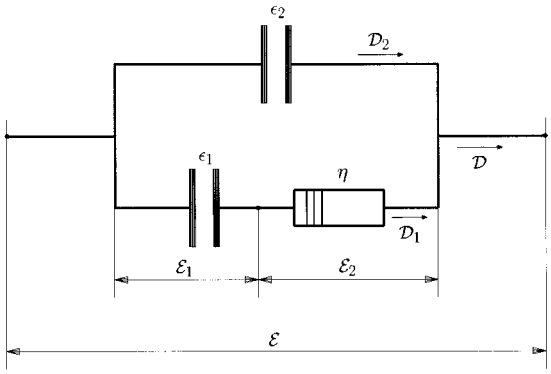

FIG. 1. This electric circuit is equivalent to a purely dielectric relaxation process, where ϵ_1 and ϵ_2 are the capacitances, η is a resistance, $\mathscr{E}$ is the electric field, and $\mathscr{D}$ is the electric induction.

with those given in Eqs. (54), but fail to match the energy in the time domain. For instance, the following definition,

$$W_e' = \tfrac{1}{2}\mathscr{E}\cdot\mathscr{D}, \tag{56}$$

as the stored (di) electric energy density, and

$$D_e' = \frac{1}{2}\left(\mathscr{E}\cdot\frac{\partial\mathscr{D}}{\partial t} - \mathscr{D}\cdot\frac{\partial\mathscr{E}}{\partial t}\right), \tag{57}$$

as the rate of dissipation, satisfy Eq. (53) and $\langle W_e'\rangle = \langle W_e\rangle$ and $\langle D_e'\rangle = \langle D_e\rangle$. However, W_e' is not equal to the energy stored in the capacitors for the Debye model given in the next section [see Eqs. (69) and (71)].

V. EXAMPLE

It is well known that the Debye model used to describe the behavior of dielectric materials[24] is mathematically equivalent to the Zener or standard linear solid model used in viscoelasticity. The following example uses this model to illustrate the concepts presented in the previous section.

A. Debye-type dielectric model

Let us consider a capacitor C_2 in parallel with a series connection between a capacitor C_1 and a resistance R. This circuit obeys the following differential equation:

$$U + \tau_U\frac{\partial U}{\partial t} = \frac{1}{C}\left(I + \tau_I\frac{\partial I}{\partial t}\right), \tag{58}$$

where $U = \partial V/\partial t$, I is the current, V is the voltage, and

$$C = C_1 + C_2, \quad \tau_U = R\left(\frac{1}{C_1} + \frac{1}{C_2}\right)^{-1}, \quad \tau_I = C_1 R. \tag{59}$$

From the point of view of a pure dielectric process, we identify U with $\mathscr{E}$ and I with $\mathscr{D}$ (see Fig. 1). Hence, the dielectric relaxation model is

$$\mathscr{E} + \tau_{\mathscr{E}}\frac{\partial\mathscr{E}}{\partial t} = \frac{1}{\epsilon_0}\left(\mathscr{D} + \tau_{\mathscr{D}}\frac{\partial\mathscr{D}}{\partial t}\right), \tag{60}$$

where

$$\epsilon_0 = \epsilon_1 + \epsilon_2, \quad \tau_{\mathscr{E}} = \frac{1}{\eta}\left(\frac{1}{\epsilon_1} + \frac{1}{\epsilon_2}\right)^{-1}, \quad \tau_{\mathscr{D}} = \epsilon_1/\eta, \tag{61}$$

with η a parameter that introduces the dissipation. Note that ϵ_0 is the static (low-frequency) permittivity and $\epsilon_\infty = \epsilon_0\tau_{\mathscr{E}}/\tau_{\mathscr{D}} = \epsilon_2 < \epsilon_0$ is the optical (high-frequency) permittivity.

We have that

$$\epsilon(t) = \epsilon_0\left[1 - \left(1 - \frac{\tau_{\mathscr{E}}}{\tau_{\mathscr{D}}}\right)\exp(-t/\tau_{\mathscr{D}})\right]H(t), \tag{62}$$

$$\beta(t) = G(t)H(t) = \frac{1}{\epsilon_0}\left[1 - \left(1 - \frac{\tau_{\mathscr{D}}}{\tau_{\mathscr{E}}}\right)\exp(-t/\tau_{\mathscr{E}})\right]H(t) \tag{63}$$

and

$$\epsilon(\omega) = \beta^{-1}(\omega) = \epsilon_0\left(\frac{1 + i\omega\tau_{\mathscr{E}}}{1 + i\omega\tau_{\mathscr{D}}}\right). \tag{64}$$

Equation (64) can be rewritten as

$$\epsilon(\omega) = \epsilon_\infty + \frac{\epsilon_0 - \epsilon_\infty}{1 + i\omega\tau_{\mathscr{D}}}. \tag{65}$$

For instance, the permittivity (65) describes the response of polar molecules, such as water, to the e.m. field.[16,25]

Substituting Eq. (63) into Eq. (29) and defining the internal variable

$$\xi(t) = \phi\,\exp(-t/\tau_{\mathscr{E}})H(t) * \mathscr{D}, \quad \phi = \frac{1}{\epsilon_0\tau_{\mathscr{E}}}\left(1 - \frac{\tau_{\mathscr{D}}}{\tau_{\mathscr{E}}}\right), \tag{66}$$

yields

$$\mathscr{E} = \frac{1}{\epsilon_\infty}\mathscr{D} + \xi, \tag{67}$$

where ξ satisfies

$$\frac{\partial\xi}{\partial t} = \phi D - \frac{\xi}{\tau_{\mathscr{E}}}. \tag{68}$$

The (di)electric energy density is that stored in the capacitors,

$$W_e = \frac{1}{2\epsilon_1}\mathscr{D}_1\cdot\mathscr{D}_1 + \frac{1}{2\epsilon_2}\mathscr{D}_2\cdot\mathscr{D}_2, \tag{69}$$

where $\mathscr{D}_1$ and $\mathscr{D}_2$ are the respective electric inductions. Since $\mathscr{D}_2 = \epsilon_2\mathscr{E}$, $\mathscr{D} = \mathscr{D}_1 + \mathscr{D}_2$, and $\epsilon_\infty = \epsilon_2$, we obtain

$$\mathscr{D}_1 = -\epsilon_\infty\xi, \tag{70}$$

where Eq. (67) has been used. Note that the internal variable is closely related to the electric field acting on the capacitor in series with the dissipation element. Substitution of the electric fields into Eq. (69), and after some calculations, yields

$$W_e = \frac{\epsilon_\infty}{2}\left[\left(\frac{\epsilon_\infty}{\epsilon_0 - \epsilon_\infty}\right)\xi\cdot\xi + \mathscr{E}\cdot\mathscr{E}\right]. \tag{71}$$

Let us verify that Eq. (37) is in agreement with Eq. (71). From Eqs. (63) and (66) we have

$$G(t) = \epsilon_0^{-1} - \phi\tau_{\mathscr{E}}\exp(-t/\tau_{\mathscr{E}}). \tag{72}$$

Replacing Eq. (72) into Eq. (37), and after some algebra, yields

$$W_e=\frac{1}{2\epsilon_0}\,\mathscr{D}\cdot\mathscr{D}-\frac{1}{2}\,\phi\tau_{\mathscr{E}}\left[\exp\left(-\frac{t}{\tau_{\mathscr{E}}}\right)H(t)*\frac{\partial}{\partial t}\,\mathscr{D}(t)\right]^2, \tag{73}$$

where the exponent 2 means the scalar product. Using Eqs. (66) and (68) gives

$$W_e=\frac{1}{2\epsilon_0}\,\mathscr{D}\cdot\mathscr{D}-\frac{1}{2\phi\tau_{\mathscr{E}}}\,(\phi\tau_{\mathscr{E}}\mathscr{D}-\xi)\cdot(\phi\tau_{\mathscr{E}}\mathscr{D}-\xi). \tag{74}$$

Using $\epsilon_\infty\tau_{\mathscr{D}}=\epsilon_0\tau_{\mathscr{E}}$, and a few calculations, shows that the expression in (74) is equal to the stored energy density (71). This equivalence can also be obtained by avoiding the use of internal variables. However, the introduction of these variables is a requirement to obtaining a complete differential formulation of the e.m. equations. This formulation is the basis of most simulation algorithms.[17,18]

The rate of dissipated energy density is

$$D_e=\frac{1}{\eta}\,\frac{\partial\mathscr{D}_1}{\partial t}\cdot\frac{\partial\mathscr{D}_1}{\partial t}, \tag{75}$$

which from Eqs. (70) and (68) becomes

$$D_e=\frac{1}{\eta}\left(\frac{\epsilon_\infty}{\tau_{\mathscr{E}}}\right)^2(\phi\tau_{\mathscr{E}}\mathscr{D}-\xi)\cdot(\phi\tau_{\mathscr{E}}\mathscr{D}-\xi). \tag{76}$$

Taking into account the previous calculations, it is easy to show that substitution of Eq. (72) into Eq. (38) gives Eq. (76).

B. Zener viscoelastic model

Fabrizio and Morro (Ref. 5, p. 42) define a viscoelastic solid with internal variables, for which the free (stored) energy density can be uniquely determined. For simplicity, we only consider dilatational deformations, since this choice does not affect the analysis of the problem. If T is the hydrostatic stress, E is the dilatation (trace of the strain tensor) and ξ is the internal variable, the constitutive relation and growth equation are

$$T=\beta_0E+\xi \tag{77}$$

and

$$\frac{\partial\xi}{\partial t}=-\alpha\xi-\beta E, \tag{78}$$

respectively, where α, β_0, and β are real and positive constants. Integration of (78) yields

$$\xi(t)=-\beta\,\exp(-\alpha t)H(t)*E(t). \tag{79}$$

It can be easily shown that Eqs. (77) and (78) correspond to a Zener mechanical model consisting of a spring of constant $k_1=\beta_0(-1+\alpha\beta_0/\beta)$ in parallel with a dashpot of viscosity $\nu=\beta_0^2/\beta$, together in series connection with a spring of constant $k_2=\beta_0$ (Fig. 2).

The relaxed and unrelaxed moduli are

$$G_\infty=\beta_0-\beta/\alpha,\quad G_0=\beta_0, \tag{80}$$

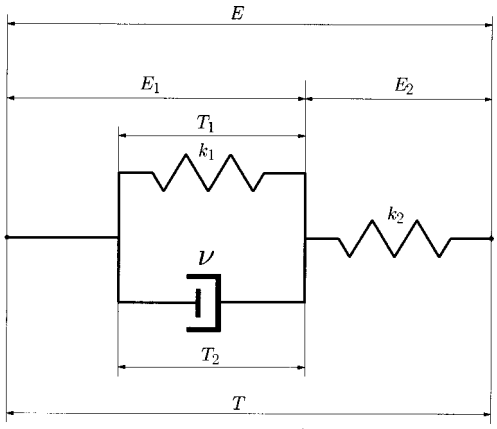

FIG. 2. The Zener viscoelastic model is mathematically equivalent to the electric circuit represented in Fig. 1. k_1 and k_2 are the springs constants, ν is the viscosity of the dashpot, E is the strain, and T is the stress.

respectively, and the relaxation times are

$$\tau_E=\beta_0(\alpha\beta_0-\beta)^{-1},\quad \tau_T=1/\alpha\quad(\tau_E>\tau_T). \tag{81}$$

The relaxation function is

$$G(t)=\alpha^{-1}[\alpha\beta_0-\beta+\beta\,\exp(-\alpha t)]. \tag{82}$$

Assuming that the potential energy is stored in the springs, we have that

$$W_e=\tfrac{1}{2}(k_1E_1^2+k_2E_2^2), \tag{83}$$

where E_1 and E_2 are the dilatations of the springs. Since $T=k_2E_2$ and $E=E_1+E_2$, and using (77), we obtain

$$E_1=-\xi/\beta_0,\quad E_2=E+\xi/\beta_0. \tag{84}$$

Note that the internal variable is closely related to the dilatation on the spring that is in parallel with the dashpot. Substitution of the dilatations into Eq. (83) yields

$$W_e=\frac{1}{2}\left[\left(\frac{\alpha}{\beta}-\frac{1}{\beta_0}\right)\xi^2+\frac{1}{\beta_0}\,(\beta_0E+\xi)^2\right]. \tag{85}$$

For isothermal processes, the free energy coincides with the stored energy. In general, the free energy is not unique (Ref. 5, p. 57). However, for exponential relaxation functions having one internal variable, like the Zener model, the free energy is unique.[26]

Day's free energy for Zener systems (Ref. 5, p. 61) is

$$\psi_D=\frac{1}{2}\,G_\infty E^2+\frac{1}{2}\left\{(G_0-G_\infty)^{-1/2}\times\int_0^\infty G'(s)[E(t)-E(t-s)]ds\right\}^2, \tag{86}$$

where G' is the first-order derivative of the relaxation function. Since

$$\int_0^\infty G'(s)ds=-\beta/\alpha,\quad \int_0^\infty G'(s)E(t-s)ds=\xi,$$

and using Eq. (80), Eq. (86) becomes

$$\psi_D=\frac{1}{2}\left(\beta_0-\frac{\beta}{\alpha}\right)E^2+\frac{\beta}{2\alpha}\left(E+\frac{\alpha}{\beta}\,\xi\right)^2=W_e. \tag{87}$$

This equation differs from the particular form obtained by Fabrizio and Morro (Ref. 5, p. 61) when only dilatational deformations are considered. The cause is a notation error in the book's equation.[27]

The rate of energy density dissipated in the dashpot is

$$D_e=\nu\left(\frac{\partial E_1}{\partial t}\right)^2, \tag{88}$$

which from Eqs. (84) and (78) becomes

$$D_e=\frac{1}{\beta}\,(\alpha\xi+\beta E)^2. \tag{89}$$

C. Mathematical analogy

The mathematics of the viscoelastic problem is the same as for the dielectric relaxation model previously introduced, since the mathematical equivalence identifies $\mathscr{E}$ with stress T and $\mathscr{D}$ with strain E. Then, from the analogy between stress and electric field, strain and electric induction, internal variables, and bulk modulus and dielectric impermeability, Day's free energy (86) in the electromagnetic case reads

$$\psi_D=\frac{1}{2\epsilon_\infty}\,\mathscr{D}\cdot\mathscr{D}+\frac{1}{2}\left\{\left(\frac{1}{\epsilon_0}-\frac{1}{\epsilon_\infty}\right)^{-1/2}\times\int_0^\infty G'(s)[\mathscr{D}(t)-\mathscr{D}(t-s)]ds\right\}^2, \tag{90}$$

where the exponent 2 means the scalar product.

Comparing Eqs. (72) and (82) we obtain the equivalences

$$\frac{\beta}{\alpha}=\frac{1}{\epsilon_\infty}-\frac{1}{\epsilon_0},\quad \beta_0=\frac{1}{\epsilon_\infty},\quad \alpha=\frac{1}{\tau_{\mathscr{E}}}. \tag{91}$$

Substituting these equivalences into Eq. (85), the electromagnetic stored energy density (71) is obtained.

On the other hand, applying the analogy and substituting the equivalences (91) into Eq. (89), yields the electromagnetic rate of dissipated energy density (76).

The complete correspondence between the dielectric and the viscoelastic models is

fields			properties		
$\mathscr{E}$	$\leftrightarrow$	T	ϵ_∞	$\leftrightarrow$	β_0^{-1}
$\mathscr{D}$	$\leftrightarrow$	E	$\tau_{\mathscr{D}}$	$\leftrightarrow$	τ_E
$\mathscr{E}_1$	$\leftrightarrow$	T_1	$\tau_{\mathscr{E}}$	$\leftrightarrow$	τ_T ,
$\mathscr{E}_2$	$\leftrightarrow$	T_2	η	$\leftrightarrow$	ν^{-1}
$\mathscr{D}_1$	$\leftrightarrow$	E_1	ϵ_1	$\leftrightarrow$	k_1^{-1}
$\mathscr{D}_2$	$\leftrightarrow$	E_2	ϵ_2	$\leftrightarrow$	k_2^{-1}
ξ	$\leftrightarrow$	ξ			

(92)

where the symbols can be identified in Figs. 1 and 2.

VI. REMARKS

It is important to keep in mind that Eq. (37) holds when $\mathscr{D}(t\to\infty)=0$, an assumption that is violated by time-harmonic fields. However, after the transient regime (large times after application of the field), the time average of W_e gives $\langle u_e\rangle$, and, for Debye-type dielectric processes (exponential relaxation functions), W_e is the energy stored in the capacitors.

Day's free energy [Eq. (90)] is unique for exponential dielectric functions with one internal variable. Actually, Day's free energy is a particular form of Eq. (37). Both energies coincide for Debye-type dielectric processes.

Transducer field modeling in anisotropic media by superposition of Gaussian base functions

Martin Spies
Fraunhofer-Institut Zerstörungsfreie Prüfverfahren (IZFP), Universität, Geb. 37, 66123 Saarbrücken, Germany

(Received 12 January 1998; accepted for publication 13 October 1998)

Anisotropic structural materials like fiber composites, but also columnar-grained stainless steels, raise considerable problems for ultrasonic inspection due to the well-known wave propagation phenomena of skewing, splitting and distortion. In this respect, simulation and optimization in ultrasonic nondestructive testing have gained a considerable importance. Among a variety of methods for transducer field calculation, beam superposition has proven to be highly efficient. In this article, a Gaussian beam approach for anisotropic media is presented. The Gaussian base functions are obtained from relationships previously derived for Gaussian wave packets. Each function is furnished with coefficients fixing the beam waists and their position. To test the approach, the case of a piston radiator is addressed for general transversely isotropic media. Using Gaussian beam superposition instead of—as a reference—applying a point source superposition technique leads to an enormous reduction in computer run time. © *1999 Acoustical Society of America.* [S0001-4966(99)05101-2]

INTRODUCTION

Difficulties in the inspection of anisotropic materials arise from those inherent effects like beam splitting, beam distortion and deviation between wave propagation and energy flow. Therefore, high interest has been dedicated to anisotropic wave propagation in the last few years. Respective studies consider plane wave theory as well as propagation of pulses in these media. Extending the scope to inhomogeneous materials, the theory gets unavoidably more complex. However, most of these models suffer from limited capability as they are approximative in character—assuming plane waves or certain beam functions—and/or require high computation time. More decisively, these approaches do not account for transducer-radiated wave fields, thus they are also unable to consider ultrasonic pulse radio frequency (RF) signals. To overcome these drawbacks, Rose *et al.*[1] have presented a numerical integration model using scalar Green's functions as point sources, derived for transversely isotropic media exhibiting mild anisotropy. In recent studies,[2–5] the modeling of ultrasonic transducer-radiation in transversely isotropic and orthotropic media with arbitrary orientation has been addressed by using a point source superposition technique. This generalized point source synthesis method (GPSS) is based on Rayleigh's surface integral and includes the influence of the material's stress-free surface onto the directivity patterns of normal and transverse point sources. Apart from using superposition of point sources, modeling of transducer-generated wave fields is also possible applying beam-superposition techniques. Newberry and Thompson[6] have introduced a model for anisotropic media employing Gauss-Hermite beams, while pure Gaussian beam techniques are known for isotropic media.[7,8]

In this article, a Gaussian beam approach for anisotropic media is presented which corresponds to the isotropic Gaussian beam superposition method by Wen and Breazeale (W&B[9]). The Gaussian base functions are obtained from the relationships previously derived for Gaussian wave packets which have been applied to general transversely isotropic media previously.[10] The procedure used in obtaining the transducer field solutions is analogous to that used to get a series solution to a boundary value problem. Starting with the respective wave equation, a solution that is used as a base function is established, then the relevant boundary conditions are expressed in terms of a set of base functions. Eventually, as described in Ref. 9, the coefficients of the base functions have to be determined so that the superposition of the single field solutions satisfies the boundary conditions.

In Sec. I, the derivation of the Gaussian base functions for anisotropic media is described. Also, a short comparison with isotropic Gaussian beam theory is given. Numerical results are shown and discussed in Sec. II, where—although the results presented here are valid for arbitrary anisotropy—the evaluations are performed for the case of transversely isotropic (TI) media. For comparison, the GPSS method is employed. In the calculations, beam parameters given by W&B[9] for a piston radiator are used.

I. THEORY

The equation of motion for the displacement vector $\underline{\mathbf{u}}$ in a homogeneous anisotropic solid reads

$$(\underline{\nabla}\cdot\underline{\underline{\underline{\mathbf{C}}}}\cdot\underline{\nabla})\cdot\underline{\mathbf{u}}(\underline{\mathbf{R}},t)-\varrho\,\frac{\partial^2}{\partial t^2}\underline{\mathbf{u}}(\underline{\mathbf{R}},t)=-\underline{\mathbf{f}}(\underline{\mathbf{R}},t), \tag{1}$$

and is explicitly dependent on space $\underline{\mathbf{R}}$ and time t. Here $\underline{\nabla}$ is the gradient vector, ϱ is the material density, and $\underline{\mathbf{f}}$ accounts for the volume force density. The elastic stiffness tensor $\underline{\underline{\underline{\mathbf{C}}}}$ depends on the elastic constants, which—for transversely isotropic media—are C_{11}, C_{33}, C_{44}, C_{66}, and C_{13}.

The consideration of plane wave solutions of Eq. (1) for these media shows that there exists one pure shear wave mode. This wave is usually called the *SH* wave, while the coupled waves are called the quasilongitudinal (qP) and quasitransverse (qSV) wave since their polarization is in general not purely longitudinal and transverse, respectively. The relationships characterizing these waves have been given in Ref. 10 for transversely isotropic media with arbitrary spatial orientation (TIA-media) and are summarized in Appendix A.

A. Gaussian wave packets

A solution to the homogeneous ($\underline{\mathbf{f}}=\underline{\mathbf{0}}$) equation of motion (1), which is in the form of a localized pulse, has been obtained by Norris.[11] This solution is governed by a Gaussian envelope and therefore called Gaussian wave packet (GWP). Starting with displacement vector $\underline{\mathbf{u}}$ in the general form

$$\underline{\mathbf{u}}(\underline{\mathbf{R}},t)=\underline{\mathbf{U}}(\underline{\mathbf{R}},t)e^{j\omega\phi(\underline{\mathbf{R}},t)}, \tag{2}$$

$$\underline{\mathbf{U}}(\underline{\mathbf{R}},t)=\sum_{n=0}^{\infty}(j\omega)^{-n}\underline{\mathbf{U}}^{(n)}(\underline{\mathbf{R}},t), \tag{3}$$

and introducing a high frequency and a second-order Taylor-series approximation with respect to space and time for phase $\phi(\underline{\mathbf{R}},t)$, the GWP solution follows in the notation adopted in this article as

$$\begin{aligned}\underline{\mathbf{u}}_\alpha(\underline{\mathbf{R}},t)=U\,\hat{\underline{\mathbf{u}}}_\alpha\,&\exp[j\underline{\mathbf{K}}_\alpha\cdot(\underline{\mathbf{R}}-\overline{\underline{\mathbf{R}}(t)})]\\&\cdot\left[\frac{\det\underline{\underline{\mathbf{M}}}_\alpha(t)}{\det\underline{\underline{\mathbf{M}}}(0)}\right]^{1/2}\exp\left[j\omega\,\frac{1}{2}(\underline{\mathbf{R}}-\overline{\underline{\mathbf{R}}(t)})\right.\\&\left.\cdot\underline{\underline{\mathbf{M}}}_\alpha(t)\cdot(\underline{\mathbf{R}}-\overline{\underline{\mathbf{R}}(t)})\right],\end{aligned} \tag{4}$$

where α designates the wave type. Thus, the GWP is initially in the form of a plane wave which is modulated by a Gaussian envelope in all directions about the pulse center $\overline{\underline{\mathbf{R}}(0)}$ and which travels along a particular ray. Let t be the ray parameter along that ray, then at time $t\geqslant 0$, the pulse center has propagated to

$$\overline{\underline{\mathbf{R}}(t)}=\overline{\underline{\mathbf{R}}(0)}+t\underline{\mathbf{c}}_\alpha, \tag{5}$$

where $\underline{\mathbf{c}}_\alpha$ is the group velocity; furthermore, $\hat{\underline{\mathbf{u}}}_\alpha$ and $\underline{\mathbf{K}}_\alpha$ are the (plane wave) polarization and wave vectors. The Gaussian shape is determined by the complex envelope matrix $\underline{\underline{\mathbf{M}}}$, its time dependence is given by

$$\underline{\underline{\mathbf{M}}}_\alpha(t)=\underline{\underline{\mathbf{M}}}(0)\cdot(\underline{\underline{\mathbf{I}}}+t\underline{\underline{\mathbf{N}}}_\alpha\cdot\underline{\underline{\mathbf{M}}}(0))^{-1}. \tag{6}$$

The evolution of the initial matrix $\underline{\underline{\mathbf{M}}}(0)$ with time t is governed by the real-valued matrix $\underline{\underline{\mathbf{N}}}_\alpha$, which is defined as

$$\underline{\underline{\mathbf{N}}}_\alpha=\partial\underline{\mathbf{c}}_\alpha/\partial\underline{\mathbf{K}}, \tag{7}$$

and which is related to the curvature of the slowness surface. Since it governs the spreading of the packets as these move through the medium, $\underline{\underline{\mathbf{N}}}$ is called the spreading matrix.

An axisymmetric pulse as generated, for example, by a piston transducer insonifying in the x-z plane, is described by

$$\underline{\underline{\mathbf{M}}}(0)=M_1^0\underline{\underline{\mathbf{I}}}+(M_3^0-M_1^0)\hat{\underline{\mathbf{K}}}\,\hat{\underline{\mathbf{K}}}, \tag{8}$$

where $\hat{\underline{\mathbf{K}}}$ designates the direction of insonification and where the quantities M_1^0 and M_3^0 are related to the initial width and length of the GWP. The corresponding envelope matrices $\underline{\underline{\mathbf{M}}}_\alpha(t)$ can be obtained according to their evolution equation (6). The explicit expressions for $\underline{\mathbf{c}}_\alpha$, $\hat{\underline{\mathbf{u}}}_\alpha$, $\underline{\mathbf{K}}_\alpha$, $\underline{\underline{\mathbf{N}}}_\alpha$, and $\underline{\underline{\mathbf{M}}}_\alpha$ have for TIA media been given in Ref. 10 and are summarized in Appendix B.

B. Gaussian base functions

The initial ansatz used for the derivation of the GWP solutions is similar to that of time-harmonic Gaussian beams (GB). The GB solutions are of infinite extent in the direction of propagation, whereas the GWP theory includes an extra degree of freedom in that the pulse is of finite length. In the limit as this length becomes infinite, it reduces to time-harmonic GB theory.

Mathematically, the special case of a GWP of infinite length is obtained by setting the parameter which refers to the pulse length in ray direction equal to zero, i.e.,[12]

$$M_3^0=0. \tag{9}$$

Setting $\overline{\underline{\mathbf{R}}(t)}=\underline{\mathbf{0}}+t\underline{\mathbf{c}}_\alpha$ and obeying that $\underline{\mathbf{K}}_\alpha\cdot\underline{\mathbf{c}}_\alpha=\omega$ allows us to write Eq. (4) as

$$\begin{aligned}\underline{\mathbf{u}}_\alpha(\underline{\mathbf{R}},t)=&\frac{U\,\hat{\underline{\mathbf{u}}}_\alpha\exp(-j\omega t)}{[(1+t\,M_1^0S_1^\alpha)(1+t\,M_1^0S_2^\alpha)]^{1/2}}\\&\cdot\exp[j\,\underline{\mathbf{K}}_\alpha\cdot\underline{\mathbf{R}}+j\omega\,\tfrac{1}{2}(\underline{\mathbf{R}}-t\underline{\mathbf{c}}_\alpha)\\&\cdot\underline{\underline{\mathbf{M}}}_\alpha(t)\cdot(\underline{\mathbf{R}}-t\underline{\mathbf{c}}_\alpha)],\end{aligned} \tag{10}$$

where $\det\underline{\underline{\mathbf{M}}}_\alpha(t)=\det\underline{\underline{\mathbf{M}}}(0)/(1+t\,M_1^0S_1^\alpha)(1+t\,M_1^0S_2^\alpha)$ has been used, S_1^α and S_2^α being the eigenvalues of $\underline{\underline{\mathbf{N}}}_\alpha$.[10,11] To obtain the GB functions in a form similar to the solutions given by W&B[9] for the isotropic case, ray parameter t [Eq. (5)] is replaced according to

$$t=(\underline{\mathbf{R}}\cdot\hat{\underline{\mathbf{K}}})/(\underline{\mathbf{c}}_\alpha\cdot\hat{\underline{\mathbf{K}}}). \tag{11}$$

Thus, suppressing the time-harmonic factor $e^{-j\omega t}$ and replacing M_1^0 by M, the Gaussian base functions follow from Eq. (10). The field solution is then written as a superposition of a series of base functions with different parameters U_n and M_n according to

$$\underline{\mathbf{u}}_\alpha(\underline{\mathbf{R}}) = \sum_{n=1}^{N} U_n \underline{\hat{\mathbf{u}}}_\alpha \exp[j \underline{\mathbf{K}}_\alpha \cdot \underline{\mathbf{R}}] \times \frac{(\underline{\mathbf{c}}_\alpha \cdot \underline{\hat{\mathbf{K}}})}{\sqrt{(\underline{\mathbf{c}}_\alpha + M_n S_1^\alpha \underline{\mathbf{R}}) \cdot \underline{\hat{\mathbf{K}}}} \sqrt{(\underline{\mathbf{c}}_\alpha + M_n S_2^\alpha \underline{\mathbf{R}}) \cdot \underline{\hat{\mathbf{K}}}}} \cdot \exp\left[\frac{j\omega}{2(\underline{\mathbf{c}}_\alpha \cdot \underline{\hat{\mathbf{K}}})} \underline{C}_\alpha \cdot \underline{\underline{\mathbf{M}}}_{\alpha,n}^{\mathrm{GB}} \cdot \underline{C}_\alpha \right], \tag{12}$$

where

$$\underline{C}_\alpha = (\underline{\mathbf{c}}_\alpha \cdot \underline{\hat{\mathbf{K}}}) \underline{\mathbf{R}} - (\underline{\mathbf{R}} \cdot \underline{\hat{\mathbf{K}}}) \underline{\mathbf{c}}_\alpha . \tag{13}$$

In analogy to GWP theory, $\underline{\underline{\mathbf{M}}}_{\alpha,n}^{\mathrm{GB}}$ will be called the beam shape matrix. For TIA media, it results as

$$\underline{\underline{\mathbf{M}}}_{\alpha,n}^{\mathrm{GB}} = M_{1\alpha}^{\mathrm{GB}} \underline{\underline{\mathbf{I}}} + M_{2\alpha}^{\mathrm{GB}} \underline{\hat{\mathbf{K}}}\,\underline{\hat{\mathbf{K}}} + M_{3\alpha}^{\mathrm{GB}} [\underline{\mathbf{a}}\,\underline{\mathbf{a}} - (\underline{\mathbf{a}} \cdot \underline{\hat{\mathbf{K}}})(\underline{\hat{\mathbf{K}}}\,\underline{\mathbf{a}} + \underline{\mathbf{a}}\,\underline{\hat{\mathbf{K}}})], \tag{14}$$

$$M_{1\alpha}^{\mathrm{GB}} = \frac{M_n}{(\underline{\mathbf{c}}_\alpha + M_n S_1^\alpha \underline{\mathbf{R}}) \cdot \underline{\hat{\mathbf{K}}}}, \tag{15}$$

$$M_{2\alpha}^{\mathrm{GB}} = M_{3\alpha}^{\mathrm{GB}} - \frac{M_n}{(\underline{\mathbf{c}}_\alpha + M_n S_2^\alpha \underline{\mathbf{R}}) \cdot \underline{\hat{\mathbf{K}}}}, \tag{16}$$

$$M_{3\alpha}^{GB} = \frac{M_n^2 (\mathcal{G}_\alpha - S_2^\alpha)(\underline{\mathbf{R}} \cdot \underline{\hat{\mathbf{K}}})}{\underline{\hat{\mathbf{K}}} \cdot (\underline{\mathbf{c}}_\alpha + M_n S_1^\alpha \underline{\mathbf{R}})(\underline{\mathbf{c}}_\alpha + M_n S_2^\alpha \underline{\mathbf{R}}) \cdot \underline{\hat{\mathbf{K}}}}, \tag{17}$$

where $\mathcal{G}_\alpha$, S_1^α, and S_2^α are given in Appendix B. The free parameters in Eq. (12) are the (complex) amplitudes U_n and the quantities M_n, which are the complex beam waist parameters of the GB functions, and N is the number of GB functions needed. The next step is to make Eq. (12) satisfy the boundary conditions by properly determining the coefficients of base functions, i.e., the beam waist parameters M_n and the amplitudes U_n, as is commonly done in finding a series solution to a boundary value problem. This has been described by W&B, so the reader is referred to their paper. In the next subsection, it is shown how the expressions presented above are related to isotropic Gaussian beam theory.

C. Comparison with isotropic GB theory

Introducing isotropic conditions leads to

$$\underline{\mathbf{c}}_\alpha = v_\alpha \underline{\hat{\mathbf{K}}}, \quad (\underline{\mathbf{c}}_\alpha \cdot \underline{\hat{\mathbf{K}}}) = v_\alpha , \quad S_1^\alpha = S_2^\alpha = v_\alpha^2, \tag{18}$$

where v_α designates the modulus of phase velocity. Setting $\underline{\hat{\mathbf{K}}} = \underline{\mathbf{e}}_z$, Eq. (14) transforms into

$$\underline{\underline{\mathbf{M}}}_{\alpha,n}^{\mathrm{GB,iso}} = \frac{M_n}{v_\alpha (1 + M_n v_\alpha z)} (\underline{\underline{\mathbf{I}}} - \underline{\mathbf{e}}_z \underline{\mathbf{e}}_z), \tag{19}$$

where $\underline{\mathbf{R}} = (x,y,z)$ has been used. Then, with $r^2 = x^2 + y^2$, Eq. (12) is put into the form

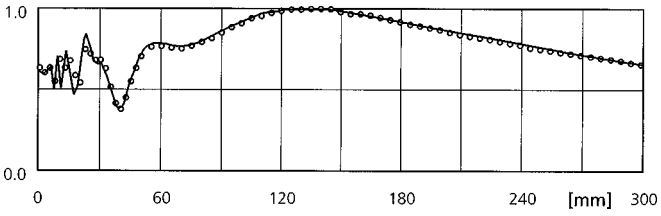

FIG. 1. On-axis field profile behaviour of longitudinal normal transducer in 0°-weld specimen (GPSS: solid curve, GB: dotted curve).

$$\underline{\mathbf{u}}_\alpha^{\mathrm{iso}}(\underline{\mathbf{R}}) = \sum_{n=1}^{N} \underline{\hat{\mathbf{u}}}_\alpha \frac{U_n}{1 + M_n v_\alpha z} \exp\left[j\omega \left(\frac{z}{v_\alpha} + \frac{M_n r^2}{2(1 + M_n v_\alpha z)} \right) \right]. \tag{20}$$

Comparison with the formulation by W&B [Eq. (C2) of Appendix C] relates their beam parameters A_n and B_n directly to U_n and M_n according to

$$U_n = A_n \tag{21}$$

$$M_n = 2j/(\omega B_n). \tag{22}$$

In the following section, numerical examples are presented, where beam parameters given in Ref. 9 have been used.

II. EXAMPLES AND DISCUSSION

The superposition of Gaussian base functions acccording to Eq. (12) is illustrated by simulating normal transducers insonifying into austenitic weld metal specimens exhibiting transversely isotropic symmetry. A ten-term GB solution is applied; the corresponding coefficients used are those determined by W&B for a piston radiator for values of wave number $\times$ radiator radius $ka = 107.8$. For comparison, computationally efficient versions of the GPSS method[3,4] are applied. The piston transducer is modeled by superposition of Huygens' point sources under neglect of the effect of the stress-free material's surface on the point source directivities. In order to account for a realistic transducer, these directivities are usually included in the GPSS calculation,[2] while for the GB method the coefficients for the individual beams would have to be determined correspondingly.

Figures 1 and 2 show the field profiles obtained for a longitudinal (qP) normal probe of 10-MHz frequency and 20-mm diameter, insonifying into an austenitic weld material with grains parallel to the surface. Both the on-axis behavior and the distribution at increasing distances z from the transducer agree well with the GPSS results. It can be seen that discrepancies exist only in the extreme near-field and in the outer side lobe structure.

Insonification into a nonsymmetry direction leads to beam skewing, as shown in Figs. 3 and 4 for a 2.25-MHz, 20-mm-diam probe generating *SH* waves. In this example, the grain orientation is at 30° to the surface. Again, good agreement between the GB and the GPSS results is found.

The most striking feature of the anisotropic GB method is the enormous savings in computer run time. The GPSS calculation performed for the longitudinal normal probe requires the superposition of about 7850 point sources,

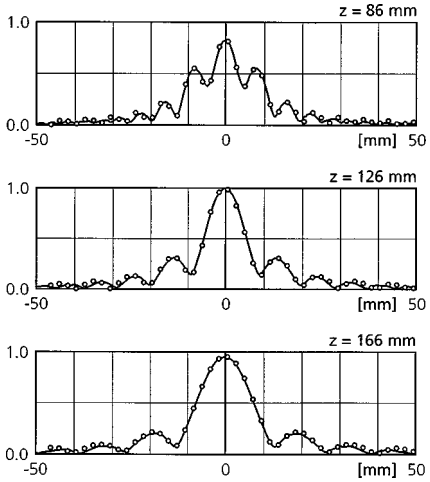

FIG. 2. Field profile distribution of longitudinal normal probe at increasing distances z from the transducer in weld specimen with grains at 0° to the surface (GPSS: solid curve, GB: dotted curve).

whereas the GB results have been obtained with only 10 beams superposed. Accordingly, run time is reduced to less than a thousandth of GPSS run time. This reduction is particularly significant at high frequencies, where GPSS requires higher discretization to fulfill the sampling theorem. Crucial to the GB method are the individual beam parameters U_n and M_n, which have to be evaluated according to the displacement distribution close to the radiator surface. Several approaches for their determination are available.[8,9] Although these parameters depend on the material's (anisotropic) propagation properties, application of the W&B values in the above examples leads to no significant differences in the displacement distribution calculated for the radiator surface as compared to the isotropic case. Principally, the beam parameters characterizing the transducer to be modeled would have to be determined separately for each anisotropic material considered. However, since specimen preparation—required to perform the calibration measurements—is usually tedious in the case of anisotropic complex-structured materials, the necessary supply data for the optimization procedure could be obtained from synthetic GPSS data.

Finally, it has to be mentioned that the presented relationships are valid for convex and concave parts of the slowness surface.[11] For inflection points—which in the above example occur for qSV-waves—cubic phase terms and higher-order transport terms would have to be considered.[13] For this case, an exact transducer field formulation presented previously could be used as a reference.[14]

The author would like to express his thanks to Professor W. Arnold and Professor M. Kröning, IZFP, Saarbrücken, Germany, for their interest in and support of the subject.

APPENDIX A: PLANE WAVE RELATIONSHIPS

The plane harmonic wave solutions of (1), i.e., the solutions to the homogeneous ($\underline{\mathbf{f}}=\underline{\mathbf{0}}$) equation of motion, are in the form

$$\underline{\mathbf{u}}_\alpha = U\,\underline{\hat{\mathbf{u}}}_\alpha \exp[jK_\alpha \underline{\hat{\mathbf{K}}}\cdot\underline{\mathbf{R}}], \tag{A1}$$

where $\underline{\hat{\mathbf{K}}}$ is the propagation direction. The wave numbers K_α are given by the dispersion relations as[10]

$$K_{SH}^2 = \varrho\,\omega^2/[C_{44}+(C_{66}-C_{44})(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2], \tag{A2}$$

$$K_{qSV,qP}^2 = \varrho\,\omega^2(B\pm(B^2-4A)^{1/2})/(2A), \tag{A3}$$

where

$$\begin{aligned} A = {} & C_{33}C_{66}+(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2 \\ & \times[C_{33}(C_{11}-2C_{66})-C_{13}(C_{13}+2C_{66})] \\ & +(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^4[(C_{11}-C_{66})(C_{66}-C_{33})+(C_{13}+C_{66})^2], \end{aligned} \tag{A4}$$

$$B = C_{33}+C_{66}+(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2(C_{11}-C_{33}). \tag{A5}$$

The discrimination into the pure transverse wave (SH: shear horizontal) and the two quasiwaves (qSV: quasishear vertical, qP: quasipressure) becomes apparent when the respective polarizations $\underline{\hat{\mathbf{u}}}_\alpha$ are considered, which are given by

$$\underline{\hat{\mathbf{u}}}_{SH} = \mathcal{N}_{SH}(\underline{\mathbf{a}}\times\underline{\hat{\mathbf{K}}}), \tag{A6}$$

$$\underline{\hat{\mathbf{u}}}_{qSV,qP} = \mathcal{N}_{qSV,qP}(F_1^{qSV,qP}\,\underline{\hat{\mathbf{K}}}+F_2^{qSV,qP}\,\underline{\mathbf{a}}). \tag{A7}$$

The abbreviated quantities can be found in Ref. 10. The group velocities are given by

$$\underline{\mathbf{c}}_\alpha = v_\alpha\underline{\hat{\mathbf{K}}}+\mathcal{F}_\alpha v_\alpha(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})(\underline{\underline{\mathbf{I}}}-\underline{\hat{\mathbf{K}}}\,\underline{\hat{\mathbf{K}}})\cdot\underline{\mathbf{a}}, \tag{A8}$$

where

$$\mathcal{F}_{SH}=\frac{C_{66}-C_{44}}{C_{44}+(C_{66}-C_{44})(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2}, \tag{A9}$$

$$\mathcal{F}_{qSV,qP}=\frac{1}{2A}\left(y_A+2(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2 z_A\pm\frac{F_1-(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2 F_2}{\sqrt{B^2-4A}}\right), \tag{A10}$$

$$y_A=C_{33}(C_{11}-2C_{66})-C_{13}(C_{13}+2C_{66}), \tag{A11}$$

$$z_A=(C_{11}-C_{66})(C_{66}-C_{33})+(C_{13}+C_{66})^2, \tag{A12}$$

$$F_1=[C_{66}^2-C_{11}C_{33}][C_{66}-C_{33}] -(C_{13}+C_{66})^2(C_{33}+C_{66}), \tag{A13}$$

$$F_2=F_1+[C_{66}^2-C_{11}C_{33}][C_{66}-C_{11}] -(C_{13}+C_{66})^2(C_{11}+C_{66}). \tag{A14}$$

APPENDIX B: GWP RELATIONSHIPS

Using Eqs. (7) and (A8) yields the spreading matrix for wave type α according to[10]

$$\underline{\underline{\mathbf{N}}}_\alpha=S_1^\alpha\underline{\underline{\mathbf{I}}}-\mathcal{G}_\alpha\underline{\hat{\mathbf{K}}}\,\underline{\hat{\mathbf{K}}}+(S_2^\alpha-\mathcal{G}_\alpha)[\underline{\mathbf{a}}\,\underline{\mathbf{a}}-(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})(\underline{\hat{\mathbf{K}}}\,\underline{\mathbf{a}}+\underline{\mathbf{a}}\,\underline{\hat{\mathbf{K}}})]. \tag{B1}$$

In this representation, use is made of its eigenvalues S_1^α and S_2^α, which are obtained as

$$S_1^{SH}=\frac{C_{44}}{\varrho}, \tag{B2}$$

$$S_2^{SH}=\frac{C_{44}}{\varrho}\,\frac{C_{66}}{C_{44}+(C_{66}-C_{44})(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2}, \tag{B3}$$

$$S_1^{qSV,qP}=v_{qSV,qP}^2(1-\mathcal{F}_{qSV,qP}(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2), \tag{B4}$$

$$S_2^{qSV,qP}=v_{qSV,qP}^2[1+\mathcal{F}_{qSV,qP}(1-2(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2) +(\mathcal{F}_{qSV,qP}^2+\mathcal{E}_{qSV,qP})(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2(1-(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2)], \tag{B5}$$

where $\mathcal{F}_{qSV,qP}$ is given above and $\mathcal{E}_{qSV,qP}$ is

$$\mathcal{E}_{qSV,qP}=\frac{2}{A}\left\{z_A-(y_A+2(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2 z_A)\mathcal{F}_{qSV,qP}\mp\frac{B(C_{13}+C_{66})^2[(C_{66}-C_{11})(C_{66}-C_{33})-(C_{13}+C_{66})^2]}{(B^2-4A)^{3/2}}\right\}. \tag{B6}$$

In Eq. (B1), the quantities $\mathcal{G}_\alpha$ are defined as

$$\mathcal{G}_{SH}=\frac{C_{44}}{C_{66}}S_2^{SH}, \tag{B7}$$

$$\mathcal{G}_{qSV,qP}=v_{qSV,qP}^2[1-2\mathcal{F}_{qSV,qP}(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^2 -(\mathcal{F}_{qSV,qP}^2+\mathcal{E}_{qSV,qP})(\underline{\mathbf{a}}\cdot\underline{\hat{\mathbf{K}}})^4]. \tag{B8}$$

APPENDIX C: ISOTROPIC GB FUNCTIONS ACCORDING TO W&B

For an axially symmetric sound (or light) beam, with its axis in the z-direction, the (scalar) velocity potential is in cylindrical coordinates written in the form[9]

$$\phi=u(r,z)\exp(jkz), \tag{C1}$$

where k designates the wave number. The GB solution given by W&B is in the form

$$u(r,z)=\frac{A}{B+(2j/k)z}\exp\left[-\frac{r^2}{B+(2j/k)z}\right], \tag{C2}$$

where A and B are arbitrary constants. The only restriction to its validity is $(ka)^2\gg 1$, where a is half the beam diameter at the waist. Thus, the field solution follows as a series of base functions as

$$\phi(r,z)=\frac{j}{k}\sum_{n=1}^{N}\frac{A_n}{B_n+(2j/k)z}\exp\left[jkz-\frac{r^2}{B_n+(2j/k)z}\right]. \tag{C3}$$

(Received 22 July 1998; revised 30 October 1998; accepted 2 November 1998)

A theory for nonlinear surface acoustic waves in isotropic solids [E. A. Zabolotskaya, J. Acoust. Soc. Am. **91**, 2569–2575 (1992)] is generalized to include the anisotropy of crystals. There is no restriction to material symmetry, orientation of the free surface with respect to crystal axes, or propagation direction in the plane of the free surface. Numerical simulations of waveform distortion, shock formation, and harmonic propagation curves are presented for two different cuts of potassium chloride. © *1999 Acoustical Society of America.* [S0001-4966(99)02802-7]

INTRODUCTION

Advances in theories for nonlinear elastic surface waves have been motivated to a large extent by the development of surface acoustic wave (SAW) devices that perform nonlinear signal processing operations.[1] Much of the theoretical work is restricted to isotropic solids, a review of which is provided in an earlier article.[2] SAW devices employ piezoelectric crystals, and material anisotropy substantially complicates the analysis of nonlinear effects on surface waves. The present article extends a theory developed previously for isotropic solids[3] to describe the evolution of nonlinear surface waves in crystals without any restriction to material symmetry, orientation of the free surface with respect to crystal axes, or propagation direction in the plane of the free surface. Inclusion of piezoelectric effects[4] will be described in a separate article.

Rigorous analyses of nonlinear surface waves in isotropic solids date back to the work of Kalyanasundaram and coworkers.[5–8] Their multiple scale approach was extended by Planat[9] and Lardner[10] to include effects of anisotropy. Planat presented numerical calculations of harmonic propagation curves for various cuts of quartz. Results for the first five harmonics were shown, although only eight harmonics were retained in the computations. Previous work[11] indicates that truncation of the spectrum at such low order has produced anomalous oscillations in harmonic propagation curves reported in investigations of surface waves in isotropic solids. Only very weak nonlinearity, and therefore no shock formation, can be modeled with so few harmonics. Moreover, it is unclear from Planat's article how his nonlinearity matrix depends on frequency.

The theory developed by Lardner[10] for nonlinear surface waves in materials with arbitrary anisotropy was used by Lardner and Tupholme[12] to perform calculations for cubic crystals. Only one geometry was considered, in which the free surface is a plane of symmetry, and the propagation direction is along one of the crystal axes. For this case surface waves exhibit simple exponential attenuation with depth as in isotropic solids (i.e., the wave numbers normal to the surface are imaginary), rather than the oscillatory depth dependence that is more typical in crystals (in which case the vertical wave numbers have nonzero real parts). Lardner calculated propagation curves for the first three harmonics for a surface wave in magnesium oxide.

By introducing a coordinate system that travels with the wave, Parker[13] avoided the multiple scale approach employed by Planat[9] and Lardner.[10] Although Parker's theory was developed for general anisotropic media, numerical simulations were presented only for isotropic solids. We demonstrate here that the present theory reduces to the result obtained earlier by one of the authors[3] for isotropic solids, which in turn has been shown[2] to be equivalent to Parker's theory in the same limit, even though the two theories were derived by entirely different methods. Parker's theory was extended by Kalyanasundaram *et al.*[14] to include effects of diffraction in directional surface wave beams, but no simulations were reported. Diffraction effects have also been included in the isotropic limit of the present theory,[2] for which both analytical and numerical solutions were given.[15]

The theoretical investigation presented here employs the Hamiltonian formalism used previously to describe nonlinear surface waves in isotropic solids.[3] The nonlinearity matrix obtained for isotropic solids has proven to be especially convenient for both interpretation of spectral interactions and development of evolution equations in the time domain.[16–18] The formalism entails calculation of the Hamiltonian to cubic order in the particle displacement for surface waves in anisotropic solids, selection of generalized coordinates, and derivation of coupled spectral equations for the particle velocity in a coordinate system that travels with the surface wave. Numerical simulations of waveform distortion, shock formation, and harmonic propagation curves are presented for two different cuts of a potassium chloride crystal.

The final form of the spectral evolution equation was reported in an earlier publication[19] without derivation or definition of terms in the nonlinearity matrix, and the theory was verified recently via comparison with measurements of shock formation in laser-generated surface waves in crystalline silicon.[20]

I. LINEAR THEORY

We begin with a review of linear theory for surface wave propagation in a crystal because it forms the basis for the nonlinear theory developed in Sec. II. The evolution equations obtained for nonlinear surface waves are assumed

to resemble the linear solution insofar as the depth dependence of each frequency component is taken to be the same as in linear theory.[2] Furthermore, results from linear theory are required to construct the nonlinearity matrix. We shall follow mainly the notation employed in the thorough review of surface waves by Farnell.[21]

A. Basic relations

In the absence of piezoelectric effects, the equation of motion for the particle displacement vector u_i as a function of the stress tensor σ_{ij} in a homogeneous elastic solid with density ρ is

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ij}}{\partial x_j}. \tag{1}$$

The general linear relation between the stress and strain for an arbitrary anisotropic solid is

$$\sigma_{ij} = c_{ijkl} e_{kl}, \tag{2}$$

where

$$e_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \tag{3}$$

is the linearized strain tensor. The elastic stiffness tensor c_{ijkl} is symmetric with respect to permutation of indices in each pair ij and kl, as well as with respect to permutation of the pairs themselves, i.e., $i \leftrightarrow j$, $k \leftrightarrow l$, $ij \leftrightarrow kl$. This symmetry permits Eq. (2) to be written

$$\sigma_{ij} = c_{ijkl} \frac{\partial u_k}{\partial x_l}, \tag{4}$$

the substitution of which into Eq. (1) yields the linear wave equation

$$\rho \frac{\partial^2 u_i}{\partial t^2} = c_{ijkl} \frac{\partial^2 u_k}{\partial x_j \partial x_l}. \tag{5}$$

Because of the symmetries involved, it is common to report values of the stiffness constants using the following abbreviated index notation:[22]

$$c_{ijkl} \rightarrow c_{IJ}. \tag{6}$$

The standard mapping is $(11) \rightarrow 1$; $(22) \rightarrow 2$; $(33) \rightarrow 3$; $(23,32) \rightarrow 4$; $(13,31) \rightarrow 5$; $(12,21) \rightarrow 6$. One may therefore regard the stress and strain tensors as six-component vectors and the elastic stiffness tensor as a six-by-six matrix. In Sec. III, numerical calculations of nonlinear surface waves are presented for a cubic crystal. In a coordinate system associated with the crystal axes, the stiffness matrix c_{IJ} for a cubic crystal has 12 nonzero elements, but only 3 are independent:

$$\begin{aligned} &c_{11} = c_{22} = c_{33}, \\ &c_{12} = c_{21} = c_{13} = c_{31} = c_{23} = c_{32}, \\ &c_{44} = c_{55} = c_{66}. \end{aligned} \tag{7}$$

The matrix c_{IJ} for an isotropic solid possesses the same nonzero elements, but only two are independent:

$$c_{11} = \lambda + 2\mu, \quad c_{12} = \lambda, \quad c_{44} = \mu, \tag{8}$$

where λ and μ are the Lamé constants.

If we seek a plane wave solution of the form

$$u_i = \alpha_i e^{i(\mathbf{k}\cdot\mathbf{x} - \omega t)} \tag{9}$$

where $\mathbf{k} = (k_1, k_2, k_3)$ and $\mathbf{x} = (x_1, x_2, x_3)$, substitution into Eq. (5) yields a homogeneous set of linear algebraic equations for α_i (the Christoffel equation):[23]

$$\rho \omega^2 \alpha_i = c_{ijkl} k_j k_l \alpha_k. \tag{10}$$

Equation (10) determines solutions of the wave equation in the form of homogeneous plane waves. When all k_i are real, the solutions correspond to bulk waves. Introducing the wave number k, phase velocity c, and unit vector $\mathbf{n} = (n_1, n_2, n_3)$ along $\mathbf{k}$, i.e.,

$$k = |\mathbf{k}|, \quad c = \omega/k, \quad n_i = k_i/k, \tag{11}$$

we may rewrite Eq. (10) in the form

$$\rho c^2 \alpha_i = c_{ijkl} n_j n_l \alpha_k. \tag{12}$$

The phase speed c of bulk waves is determined by requiring the existence of a nontrivial solution of Eq. (12):

$$\det(\Gamma_{ik} - \rho c^2 \delta_{ik}) = 0, \tag{13}$$

where δ_{ik} is the Kronecker delta and

$$\Gamma_{ik} = c_{ijkl} n_j n_l \tag{14}$$

is the Christoffel matrix.

Equation (13) is cubic in c^2. The three roots are the squares of the velocities of the three types of bulk waves that can propagate along a given direction $\mathbf{n}$. The velocity c depends on the propagation direction $\mathbf{n}$, but it does not depend on frequency. For an isotropic solid, the wave that propagates with the highest velocity is a compressional wave, and the other two are shear waves with different polarizations but with the same propagation speed.

B. Surface waves

Equation (5) also admits solutions that correspond to inhomogeneous plane waves. In this case $\mathbf{k}$ is complex. The inhomogeneous waves are constituent parts of the surface wave—a linear combination of inhomogeneous waves is constructed in such a way as to satisfy the boundary condition on the free surface of the crystal.

We now make a distinction between crystal axes, in reference to which the stiffness constants c_{ijkl} are normally provided, and a coordinate system that is aligned with the free surface of a crystal and provides a more convenient reference frame for describing surface wave propagation. We thus specify a coordinate system in which the (x_1, x_2) plane coincides with the stress-free surface of the crystal, and x_3 is the outward normal to that plane such that the crystal occupies the half-space $x_3 \leqslant 0$. In terms of this coordinate system the inhomogeneous plane waves are expressed as

$$u_i = \alpha_i e^{ik(\mathbf{l}\cdot\mathbf{x} - ct)}. \tag{15}$$

The components of $\mathbf{l} = (l_1, l_2, l_3)$ in the (x_1, x_2) plane, l_1 and l_2, are real, whereas l_3 may be complex, and $\mathbf{l}$ is normalized such that the magnitude of its projection in the (x_1, x_2) plane is unity, i.e., $l_1^2 + l_2^2 = 1$. At angular frequency ω the phase

speed along the free surface is thus $c=\omega/k$, and k is identified as the wave number corresponding to propagation along that surface.

For a plane wave that propagates along the x_1 axis we have $l_1=1$ and $l_2=0$, and we denote the complex quantity l_3 by ζ:

$$\mathbf{l}=(1,0,\zeta). \tag{16}$$

Equation (15) becomes

$$u_i=\alpha_i e^{i\zeta k x_3} e^{i(kx_1-\omega t)}, \tag{17}$$

and instead of Eq. (12) we have

$$\rho c^2 \alpha_i = c_{ijkl} l_j l_l \alpha_k . \tag{18}$$

Here, the stiffness constants c_{ijkl} are defined in terms of the coordinate system associated with the free surface and propagation direction. Values of the stiffness constants are normally provided in the coordinate system associated with the crystal axes, and therefore a transformation of the stiffness matrix is usually required, as discussed in detail by Auld.[22] Equation (18) has a nontrivial solution for

$$\det[\Gamma_{ik}(\zeta)-\rho c^2 \delta_{ik}]=0, \tag{19}$$

where

$$\Gamma_{ik}=c_{ijkl} l_j l_l . \tag{20}$$

Substitution of Eq. (16) into (20) yields

$$\begin{aligned}
\Gamma_{11}&=c_{11}+2c_{15}\zeta+c_{55}\zeta^2,\\
\Gamma_{22}&=c_{66}+2c_{46}\zeta+c_{44}\zeta^2,\\
\Gamma_{33}&=c_{55}+2c_{35}\zeta+c_{33}\zeta^2,\\
\Gamma_{12}&=c_{16}+(c_{14}+c_{56})\zeta+c_{45}\zeta^2,\\
\Gamma_{13}&=c_{15}+(c_{13}+c_{55})\zeta+c_{35}\zeta^2,\\
\Gamma_{23}&=c_{56}+(c_{36}+c_{45})\zeta+c_{34}\zeta^2,
\end{aligned} \tag{21}$$

where $\Gamma_{ik}=\Gamma_{ki}$.

With c regarded as a parameter, Eq. (19) is a sixth-order algebraic equation in terms of ζ. Since all coefficients in this equation are real, the roots ζ must be either real or complex conjugate pairs. Real roots correspond to the bulk waves described in Sec. I A. All roots are imaginary for surface (Rayleigh) waves in isotropic solids.

In the anisotropic half-space under consideration, all displacement components of any surface wave must vanish as $x_3\to-\infty$. To satisfy this condition, only roots for which $\mathrm{Im}\,\zeta<0$ are allowed [see Eq. (17)], and there are three such roots for any given value of c. The vector components α_i correspond to each of these roots according to Eq. (18), and a linear combination is constructed with the three corresponding terms given by Eq. (15). Each of these three terms has the same phase velocity c but a different value of ζ for each of the three roots. The assumed solution thus becomes

$$u_i=\sum_{s=1}^{3} C_s \alpha_i^{(s)} e^{ik(\mathbf{l}_s\cdot\mathbf{x}-ct)}=\sum_{s=1}^{3} C_s \alpha_i^{(s)} e^{i\zeta_s k x_3} e^{i(kx_1-\omega t)}, \tag{22}$$

where $\mathbf{l}_s=(1,0,\zeta_s)$. The coefficients C_s are chosen to satisfy the stress-free boundary condition

$$\sigma_{i3}=0 \quad \text{at } x_3=0. \tag{23}$$

From Eq. (4) we have $c_{i3kl}(\partial u_k/\partial x_l)=0$ at $x_3=0$, and Eq. (22) yields

$$c_{i3kl}\sum_{s=1}^{3} C_s \alpha_k^{(s)} l_l^{(s)}=0, \tag{24}$$

where $l_i^{(s)}$ are the components of $\mathbf{l}_s$.

It remains to solve Eqs. (18) and (24) for the wave speed c, eigenvalues ζ_s, eigenvectors $\alpha_i^{(s)}$, and coefficients C_s. For Rayleigh waves in isotropic solids, simple analytic expressions may be derived for ζ_s, $\alpha_i^{(s)}$, and C_s in terms of c, the value of which is determined by the root of a cubic polynomial. For surface waves in anisotropic solids, each of these quantities must be obtained numerically. The algorithm employed in the present investigation is described in Appendix A. See Ref. 21 for further discussion.

II. NONLINEAR THEORY

The theory for nonlinear surface waves in crystals is developed using the method introduced previously to model nonlinear Rayleigh waves in isotropic solids.[3] The method involves calculating the Hamiltonian at cubic order in the wave variables, choosing appropriate generalized coordinates, and deriving evolution equations in terms of slowly varying harmonic amplitudes. The model has no restriction with regard to crystal symmetry, orientation of the free surface with respect to the crystal axes, or propagation direction in the plane of the free surface.

A. Hamiltonian formalism

The Hamiltonian is written in the form

$$H=T+V+W, \tag{25}$$

where T is the kinetic energy, V is the potential energy at quadratic order in the particle displacement, and W is the potential energy at cubic order associated with nonlinear wave interaction. The energies are expressed initially in terms of the harmonic amplitudes $a_n(t)$ appearing in the following generalized form of Eq. (22):

$$u_i(x,z,t)=\sum_n a_n(t) u_{ni}(z) e^{ink x}, \tag{26}$$

where

$$u_{ni}(z)=\sum_{s=1}^{3} C_s \alpha_i^{(s)} e^{ink\zeta_s z} \tag{27}$$

and $u_{ni}=u^*_{(-n)i}$. Here, $x\equiv x_1$ is the coordinate along the direction of propagation, and $z\equiv x_3$ is normal to and directed outward from the free surface of the crystal. The vector $\mathbf{l}$ is thus defined by Eq. (16).

The functions a_n are chosen to be the generalized coordinates, in which case the corresponding momenta are defined by

$$p_n=\frac{\partial T}{\partial \dot{a}_n}, \tag{28}$$

and Hamilton's canonical equations become

$$\dot{a}_n = \frac{\partial H}{\partial p_n}, \quad \dot{p}_n = -\frac{\partial H}{\partial a_n}, \tag{29}$$

where the dots signify time derivatives. This general framework is identical to that used for nonlinear Rayleigh waves in isotropic solids.[3]

B. Energy relations

Before proceeding to the calculation of T, V, and W in Eq. (25), we present defining relations for the elastic (strain) energy in a crystal. The general expression we use for the elastic energy (per unit volume) is

$$\mathcal{E} = \tfrac{1}{2} c_{ijkl} e_{ij} e_{kl} + \tfrac{1}{6} d_{ijklmn} e_{ij} e_{kl} e_{mn} + \cdots . \tag{30}$$

Here the exact expression for the (Lagrangian) strain tensor is employed:

$$e_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} + \frac{\partial u_k}{\partial x_i}\frac{\partial u_k}{\partial x_j} \right), \tag{31}$$

where $e_{ij} = e_{ji}$. The nonlinear stiffness tensor d_{ijklmn} is symmetric with respect to permutation of the indices within each of the pairs *ij*, *kl*, and *mn*, and it is also symmetric with respect to permutation of the pairs themselves. As in linear theory, the symmetries permit the abbreviated index notation associated with Eq. (6) to be used:

$$d_{ijklmn} \rightarrow d_{IJK}. \tag{32}$$

In a coordinate system aligned with the crystal axes there are 20 nonzero elements of d_{IJK} for a cubic crystal, but only the following 6 are independent:[12]

$$\begin{aligned} &d_{111} = d_{222} = d_{333}, \\ &d_{112} = d_{113} = d_{122} = d_{133} = d_{223} = d_{233}, \\ &d_{123}, \quad d_{144} = d_{255} = d_{366}, \\ &d_{155} = d_{166} = d_{244} = d_{266} = d_{344} = d_{355}, \quad d_{456}. \end{aligned} \tag{33}$$

For isotropic solids only three of these elements are independent, and d_{IJK} may be expressed, for example, in terms of Landau's third-order elastic constants A, B, and C:[24]

$$\begin{aligned} &d_{111} = 2(A + 3B + C), \quad d_{112} = 2(B + C), \\ &d_{123} = 2C, \quad d_{144} = B, \\ &d_{155} = \tfrac{1}{2}A + B, \quad d_{456} = \tfrac{1}{4}A. \end{aligned} \tag{34}$$

Substitution of Eq. (31) into (30) yields, to cubic order in the displacement,

$$\mathcal{E} = \mathcal{E}_2 + \mathcal{E}_3, \tag{35}$$

where

$$\mathcal{E}_2 = \frac{1}{2} c_{ijkl} \frac{\partial u_i}{\partial x_j} \frac{\partial u_k}{\partial x_l}, \tag{36}$$

$$\mathcal{E}_3 = \frac{1}{2} c_{ijkl} \frac{\partial u_i}{\partial x_j} \frac{\partial u_p}{\partial x_k} \frac{\partial u_p}{\partial x_l} + \frac{1}{6} d_{ijklmn} \frac{\partial u_i}{\partial x_j} \frac{\partial u_k}{\partial x_l} \frac{\partial u_m}{\partial x_n}. \tag{37}$$

The expression for $\mathcal{E}_3$ may be simplified by rewriting the first term as

$$\frac{1}{2} c_{ijkl} \frac{\partial u_i}{\partial x_j} \frac{\partial u_p}{\partial x_k} \frac{\partial u_p}{\partial x_l} = \frac{1}{2} c_{ijln} \delta_{km} \frac{\partial u_i}{\partial x_j} \frac{\partial u_k}{\partial x_l} \frac{\partial u_m}{\partial x_n}. \tag{38}$$

The tensor $c_{ijln}\delta_{km}$ is not symmetric with respect to permutation of the pairs *ij*, *kl*, and *mn*, but only its symmetric part is required in Eq. (38) and the following substitution may be made:

$$c_{ijln}\delta_{km} \rightarrow \tfrac{1}{3}(c_{ijln}\delta_{km} + c_{jnkl}\delta_{im} + c_{jlmn}\delta_{ik}). \tag{39}$$

Equation (37) may thus be rewritten

$$\mathcal{E}_3 = \frac{1}{6} d'_{ijklmn} \frac{\partial u_i}{\partial x_j} \frac{\partial u_k}{\partial x_l} \frac{\partial u_m}{\partial x_n}, \tag{40}$$

where

$$d'_{ijklmn} = d_{ijklmn} + c_{ijln}\delta_{km} + c_{jnkl}\delta_{im} + c_{jlmn}\delta_{ik}. \tag{41}$$

Although d'_{ijklmn} is symmetric with respect to permutation of the pairs *ij*, *kl*, and *mn*, unlike d_{ijklmn} it is not symmetric with respect to permutation of indices within these pairs.[24] An abbreviated notation given by $d'_{ijklmn} \rightarrow d'_{IJK}$ must therefore have nine values for each of the new indices: (11)→1; (22)→2; (33)→3; (23)→4; (13)→5; (12)→6; (32)→7; (31)→8; (21)→9. Using this notation, Lardner and Tupholme[12] list the 45 nonzero elements of d'_{IJK} for cubic crystals, and they identify the 10 of these elements that are independent.

1. Kinetic energy

The kinetic energy (per unit area) is given by

$$T = \frac{\rho}{2\lambda} \int_x^{x+\lambda} \int_{-\infty}^{0} \dot{u}_i^2 \, dx \, dz, \tag{42}$$

where $\lambda = 2\pi/k$ here is the wavelength at the fundamental frequency in the Fourier expansion of u_i, and the summation convention applies to $\dot{u}_i^2 \equiv \dot{u}_i \dot{u}_i$. Substitution of Eq. (26) yields

$$T = \frac{\rho}{2} \sum_n \dot{a}_n \dot{a}_{-n} \int_{-\infty}^{0} |u_{ni}|^2 \, dz. \tag{43}$$

We introduce the notation

$$\beta_i^{(s)} = C_s \alpha_i^{(s)} \tag{44}$$

in Eq. (27) and let $z' = |n| k z$ to obtain

$$\int_{-\infty}^{0} |u_{ni}|^2 \, dz = \frac{1}{|n|k} \int_{-\infty}^{0} \left| \sum_{s=1}^{3} \beta_i^{(s)} e^{i\zeta_s z'} \right|^2 dz'. \tag{45}$$

The vectors $\beta_i^{(s)}$ may be normalized such that

$$\int_{-\infty}^{0} \left| \sum_{s=1}^{3} \beta_i^{(s)} e^{i\zeta_s z'} \right|^2 dz' = 1, \tag{46}$$

in which case Eq. (43) reduces to

$$T = \frac{\rho}{2k} \sum_n \frac{\dot{a}_n \dot{a}_{-n}}{|n|}. \tag{47}$$

2. Potential energy

The quadratic part of the potential energy (per unit area) is given by

$$V=\frac{1}{\lambda}\int_{x}^{x+\lambda}\int_{-\infty}^{0}\mathcal{E}_2\,dx\,dz. \tag{48}$$

The explicit relation for $\mathcal{E}_2$ given by Eq. (36) is not needed to evaluate the integral. Instead, Eq. (48) may be rewritten[3]

$$V=-\frac{1}{2\lambda}\int_{x}^{x+\lambda}\int_{-\infty}^{0}u_i\frac{\partial\sigma_{ij}}{\partial x_j}dx\,dz. \tag{49}$$

Elimination of the stress tensor using the momentum equation $\partial\sigma_{ij}/\partial x_j=\rho\ddot{u}_i$ and substitution of Eq. (26) yields

$$V=\frac{1}{2}\rho c^2 k\sum_{n}|n|a_n a_{-n}. \tag{50}$$

3. Interaction energy

The wave interaction energy (per unit area) is given by

$$W=\frac{1}{\lambda}\int_{x}^{x+\lambda}\int_{-\infty}^{0}\mathcal{E}_3\,dx\,dz, \tag{51}$$

or, following substitution of Eq. (40),

$$W=\frac{d'_{ijklmn}}{6\lambda}\int_{x}^{x+\lambda}\int_{-\infty}^{0}\frac{\partial u_i}{\partial x_j}\frac{\partial u_k}{\partial x_l}\frac{\partial u_m}{\partial x_n}dx\,dz. \tag{52}$$

It is evident that substitution of Eq. (26) into (52) yields an expression of the form

$$W=\sum_{n_1+n_2+n_3=0}w_{n_1n_2n_3}a_{n_1}a_{n_2}a_{n_3}, \tag{53}$$

where n_1, n_2, and n_3 are harmonic numbers associated with sum and difference frequency generation (not to be confused with the unit vector components n_i used only in Sec. I A), and $w_{n_1n_2n_3}$ is the matrix that characterizes the strength of the corresponding wave interactions.

To develop an expression for the matrix $w_{n_1n_2n_3}$ we begin by considering the contribution to W from the summation over positive n_1 and n_2, and denote this by

$$\overline{W}=\sum_{\substack{n_1>0,\,n_2>0,\\ n_3=-(n_1+n_2)}}\overline{w}_{n_1n_2n_3}a_{n_1}a_{n_2}a_{n_3}. \tag{54}$$

The symmetry of d'_{ijklmn} with respect to permutation of the index pairs *ij*, *kl*, and *mn* leads to symmetry of $w_{n_1n_2n_3}$ with respect to permutation of n_1, n_2, and n_3, and permits W to be expressed as

$$W=3(\overline{W}+\overline{W}^*). \tag{55}$$

Therefore only $\overline{W}$, or $\overline{w}_{n_1n_2n_3}$, needs to be calculated:

$$\overline{w}_{n_1n_2n_3}=w_{n_1n_2n_3}\quad\text{for } n_1,n_2>0. \tag{56}$$

After substituting Eq. (26) into (52) and integrating we obtain

$$\overline{w}_{n_1n_2n_3}=-\frac{k^2}{3}\sum_{s_1,s_2,s_3=1}^{3}\frac{n_1n_2n_3F_{s_1s_2s_3}}{n_1\zeta_{s_1}+n_2\zeta_{s_2}+n_3\zeta^*_{s_3}}, \tag{57}$$

where

$$F_{s_1s_2s_3}=\tfrac{1}{2}d'_{ijklmn}\beta_i^{(s_1)}\beta_k^{(s_2)}[\beta_m^{(s_3)}]^*l_j^{(s_1)}l_l^{(s_2)}[l_n^{(s_3)}]^*. \tag{58}$$

As shown in Appendix B, the matrix $F_{s_1s_2s_3}$ is a generalization of the parameters α, β, γ, etc., that were used in earlier articles on nonlinear Rayleigh waves in isotropic solids.[3,25]

The same expression $F_{s_1s_2s_3}$ appears in Eq. (70) below for the nonlinearity matrix in the evolution equation for the velocity components. Evaluation of $F_{s_1s_2s_3}$ requires (1) transformation of the stiffness tensors c_{ijkl} and d_{ijklmn} into the coordinate system associated with the free surface of the crystal and the direction of propagation in that plane, and (2) solution of the linear eigenvalue problem to determine the quantities $\beta_i^{(s)}$ (the normalized values of $\alpha_i^{(s)}$) and $l_i^{(s)}$. See Sec. I B and Appendix A.

C. Dynamical equations

We now express the energy relations in terms of a new set of canonical variables that permits simplified dynamical equations to be derived for the nonlinear evolution of progressive plane waves. Specifically, the new set of harmonic amplitudes $b_n(t)$ is defined according to[2,3]

$$a_n=b_ne^{-i|n|\omega t}+b^*_{-n}e^{i|n|\omega t}, \tag{59}$$

$$\dot{a}_n=-i|n|\omega(b_ne^{-i|n|\omega t}-b^*_{-n}e^{i|n|\omega t}), \tag{60}$$

with the momentum related to Eq. (60) via Eqs. (28) and (47):

$$p_n=\frac{\rho}{k}\frac{\dot{a}_{-n}}{|n|}. \tag{61}$$

Substituting Eq. (60) in (47), Eq. (59) in (50), and combining the results in Eq. (25) yields

$$H=2\rho c^2k\sum_{n}|n|b_nb^*_n+W. \tag{62}$$

At this point we may follow precisely the algebra used for nonlinear Rayleigh waves and proceed immediately to the result[3]

$$\dot{b}_n=-\frac{i}{2\rho c}\frac{\partial W}{\partial b^*_n}. \tag{63}$$

It remains to express Eq. (63) explicitly in terms of b_n.

The formal procedure is to substitute Eq. (59) in (54), which produces a summation of terms containing exponentials of the form $\exp[i(l+m+n)\omega t]$. As examined in detail for nonlinear Rayleigh waves,[2] averaging the result in time over a fundamental period $2\pi/\omega$ yields at dominant order only those terms for which $l+m+n=0$. These terms are associated with spectral interactions in progressive plane waves. The terms for which $l+m+n\neq0$ account for the negligible effect due to interaction between spectral components that propagate in opposite directions. For the purpose of expressing W in terms of b_n it is therefore expedient to consider *a*

priori only progressive wave propagation, say in the $+x$ direction. In this case Eq. (59) is replaced by

$$a_n = b_n e^{-in\omega t}, \quad n>0,$$
$$= b^*_{-n} e^{i|n|\omega t}, \quad n<0, \tag{64}$$

the substitution of which in Eq. (54) yields

$$\overline{W} = \sum_{n_1,n_2>0} \overline{w}_{n_1 n_2 n_3} b_{n_1} b_{n_2} b^*_{n_1+n_2}. \tag{65}$$

Equation (65) is the same result that is obtained by using Eq. (59) and averaging. Substitution of Eq. (65) into (55) and then evaluation of the derivative in Eq. (63) gives, for $n_1, n_2>0$,

$$\dot{b}_n = -\frac{3i}{2\rho c}\left(\sum_{n_1+n_2=n} \overline{w}_{n_1,n_2,-n} b_{n_1} b_{n_2} + \sum_{n_1} \overline{w}^*_{n_1,n,-(n+n_1)} b^*_{n_1} b_{n+n_1} + \sum_{n_2} \overline{w}^*_{n,n_2,-(n+n_2)} b^*_{n_2} b_{n+n_2} \right). \tag{66}$$

The second and third summations are equivalent and may be combined, and the result may be written, for $n>0$,

$$\dot{b}_n = -\frac{3i}{2\rho c}\left(\sum_{m=1}^{n-1} \overline{w}_{m,n-m,-n} b_m b_{n-m} + 2\sum_{m=n+1}^{\infty} \overline{w}^*_{m-n,n,-m} b_m b^*_{m-n} \right). \tag{67}$$

Equation (67), with $\overline{w}_{n_1 n_2 n_3}$ defined in Eq. (57), describes the nonlinear evolution in time of a plane progressive surface wave in a crystal. The first summation accounts for sum frequency generation, the second for difference frequency generation.

D. Evolution equations

The desired form of the evolution equation is in terms of particle velocity rather than displacement, and as a function of propagation distance rather than time. Thus define the velocity amplitudes $v_n(t)$ by

$$v_n = -in\omega b_n, \tag{68}$$

in terms of which Eq. (67) becomes, for $n>0$,

$$\dot{v}_n = \frac{n^2\omega}{2\rho c^3}\left(\sum_{m=1}^{n-1} S_{m,n-m} v_m v_{n-m} - 2\sum_{m=n+1}^{\infty} S^*_{n,m-n} v_m v^*_{m-n} \right), \tag{69}$$

where the nonlinearity matrix is given by

$$S_{n_1 n_2} = \sum_{s_1,s_2,s_3=1}^{3} \frac{F_{s_1 s_2 s_3}}{n_1\zeta_{s_1} + n_2\zeta_{s_2} - (n_1+n_2)\zeta^*_{s_3}}, \tag{70}$$

and $F_{s_1 s_2 s_3}$ is defined in Eq. (58). In general, there may be up to $3^3=27$ terms in the summation for $S_{n_1 n_2}$.

For isotropic solids there are only seven terms in the summation, all of them real, and $S_{n_1 n_2}$ reduces to the nonlinearity matrix $R_{n_1 n_2}$ used in previous work[2,11,15–18,26] for Rayleigh waves according to

$$R_{n_1 n_2} = -(\Lambda^3/\mu) S_{n_1 n_2}, \tag{71}$$

where

$$2\Lambda^2 = \xi_t + \frac{1}{\xi_t} + \eta^2\left(\xi_l + \frac{1}{\xi_l} \right) + 4\eta, \tag{72}$$

$\xi_t = (1-c^2/c_t^2)^{1/2}$, $\xi_l = (1-c^2/c_l^2)^{1/2}$, $\eta = -2\xi_t/(1+\xi_t^2)$, c_t is the propagation speed of bulk shear waves in the solid, and c_l is the speed of bulk compressional waves (see also Appendix B). The shear modulus μ renders $R_{n_1 n_2}$ dimensionless ($F_{s_1 s_2 s_3}$, and therefore $S_{n_1 n_2}$, have the same dimensions as the stiffness constants), and the expression for Λ follows from the normalization in Eq. (46).

Equation (69) is suitable for initial value problems, in which a spatial waveform is known at an instant in time and a description of the field is desired at later times. However, one is usually concerned with boundary value problems, in which a known waveform is radiated from a source at a given location, and the evolution of the wave as a function of propagation distance is of interest. A rigorous derivation of the transformation of Eq. (69) from an evolution equation in time to one in space has been provided for the case of isotropic solids.[2] Although the same formal procedure may be followed here for crystals, the result is the same. The space derivative $c(dv_n/dx)$ appears in place of the time derivative $\dot{v}_n$, and Eq. (69) becomes, for $n>0$,

$$\frac{dv_n}{dx} = \frac{n^2\omega}{2\rho c^4}\left(\sum_{m=1}^{n-1} S_{m,n-m} v_m v_{n-m} - 2\sum_{m=n+1}^{\infty} S^*_{n,m-n} v_m v^*_{m-n} \right), \tag{73}$$

where here $v_n = v_n(x)$, and the particle velocity vector is reconstructed as in Eq. (26):

$$v_i(x,z,t) = \sum_{n=1}^{\infty} v_n(x) u_{ni}(z) e^{in(kx-\omega t)} + \text{c.c.}, \tag{74}$$

where

$$u_{ni}(z) = \sum_{s=1}^{3} \beta_i^{(s)} e^{ink\zeta_s z}. \tag{75}$$

The spectral components for $n<0$ are given by $v_n = v^*_{-n}$.

Equation (73) is an appropriate form of the evolution equation for numerical integration. We now present an alternative form that reveals the symmetry properties of the nonlinearity matrix. Equation (73) may be rewritten as follows, with the summation on the right side performed over all indices, negative as well as positive:

$$\frac{dv_n}{dx} = \frac{n^2\omega}{2\rho c^4} \sum_{l+m=n} \frac{lm}{|lm|} S_{lm(-n)} v_l v_m. \tag{76}$$

The nonlinearity matrix in Eq. (70), expressed here as a function of three indices, is symmetric over permutation of these indices:

$$S_{n_1n_2n_3}=S_{n_2n_1n_3}=S_{n_3n_2n_1}=S_{n_1n_3n_2}. \tag{77}$$

When one of the indices is negative and two are positive, Eq. (70) becomes, with $n_1+n_2+n_3=0$,

$$S_{n_1n_2n_3}=\sum_{s_1,s_2,s_3=1}^{3}\frac{F_{s_1s_2s_3}}{n_j\kappa_{s_j}+i|n_j|\xi_{s_j}}, \tag{78}$$

where $\zeta_s=\kappa_s-i\xi_s$ has been separated into its real and imaginary parts, and the standard summation convention is employed:

$$n_j\kappa_{s_j}+i|n_j|\xi_{s_j}\equiv\sum_{j=1}^{3}(n_j\kappa_{s_j}+i|n_j|\xi_{s_j}). \tag{79}$$

When two of the indices are negative and one is positive, the value of the matrix is obtained from Eq. (78) by using the relation

$$S_{n_1n_2n_3}=S^*_{(-n_1)(-n_2)(-n_3)}. \tag{80}$$

It was shown previously[26] that the permutation symmetries in Eq. (77) guarantee conservation of energy for nonlinear surface waves in isotropic solids. The same analysis applies to nonlinear surface waves in crystals, and the same spectral form of the conservation law is obtained:

$$\sum_{n=1}^{\infty}\frac{|v_n|^2}{n}=\text{const.} \tag{81}$$

III. NUMERICAL RESULTS

It is convenient for numerical solution of Eq. (73) to employ the following dimensionless form:

$$\frac{dV_n}{dX}+A_nV_n=\frac{n^2}{8|S_{11}|}\left(\sum_{m=1}^{n-1}S_{m,n-m}V_mV_{n-m}-2\sum_{m=n+1}^{N}S^*_{n,m-n}V_mV^*_{m-n}\right), \tag{82}$$

where

$$V_n=v_n/v_0,\quad X=x/x_0, \tag{83}$$

v_0 is a characteristic velocity amplitude, and

$$x_0=\frac{\rho c^4}{4|S_{11}|\omega v_0} \tag{84}$$

is a length scale that characterizes the shock formation distance for a surface wave radiated at angular frequency ω and with amplitude v_0. The nonlinearity matrix element S_{11} appearing in Eqs. (82) and (84) corresponds to second harmonic generation, and for isotropic solids its magnitude is closely related to the overall nonlinearity of the material.[18] After $S_{n_1n_2}$ is calculated according to Eq. (70) [see the paragraph following Eq. (58)], Eq. (82) is solved using a standard Runge–Kutta algorithm. The *ad hoc* absorption term A_nV_n is required for numerical stability when shocks are formed, and the upper limit N in the second summation restricts the set of harmonics to $1\leqslant n\leqslant N$. The energy relation associated with Eq. (82) is[26]

$$\frac{d}{dX}\sum_{n=1}^{N}\frac{|V_n|^2}{n}=-2\sum_{n=1}^{N}A_n\frac{|V_n|^2}{n}, \tag{85}$$

which for $A_n=0$ becomes

$$\sum_{n=1}^{N}\frac{|V_n|^2}{n}=\text{const.} \tag{86}$$

Equation (81) is recovered for $A_n=0$ and $N=\infty$.

Calculations are presented for propagation in steel (a representative isotropic solid) and in potassium chloride (KCl, a cubic crystal). Steel is considered here in order to verify that calculations obtained from the present algorithm for arbitrary crystals reproduce results obtained in earlier investigations of surface waves in isotropic solids.[3,11] In addition, results for an isotropic solid provide a useful basis of comparison for the new results obtained here for crystals. The boundary condition for each case corresponds to a monofrequency source at $X=0$:

$$V_1=1,\quad V_{n>1}=0. \tag{87}$$

We let $A_n=n^2A_1$ to model thermoviscous losses exhibiting quadratic frequency dependence, with $A_1=0.025$. The absorption is sufficiently weak that the propagation appears lossless up to the point of shock formation, and the shocks exhibit well defined jumps. All calculations were performed with $N=200$ harmonics.

The linear and nonlinear stiffness constants used to calculate the elements of the nonlinearity matrix for steel are the same as in earlier work.[3,11] In Fig. 1(a) and (b) are shown the calculated horizontal ($V_x=v_x/v_0$) and vertical ($V_z=v_z/v_0$) components of the particle velocity waveform at two distances from the source ($X=0$ corresponds to the source waveform). It is seen that x_0 (the distance at which $X=1$) is an appropriate measure of the shock formation distance in this case. Shown in Fig. 1(c) are the magnitudes $|V_n|$ of the harmonics as functions of X. The calculated waveform distortion and harmonic propagation curves are in complete agreement with earlier work, where extensive discussion of these results is provided.[3,11]

The values of c_{IJ} and d_{IJK} for KCl were obtained from the table provided by Lardner and Tupholme,[12] in which the values of d_{IJK} are repeated from the list compiled by Hearmon.[27] Two different cuts of KCl are chosen to illustrate propagation of surface waves in a crystal. In the first case the free surface is the (111) plane, and in the second it is the (001) plane. Figure 2 shows normalized propagation speeds $C=c/(c_{44}/\rho)^{1/2}$ for surface waves in these two planes, where ϕ is the angle with respect to the projection of any crystal axis in the plane of the cut, and c_{44} is the stiffness constant in the crystal coordinate system. For an isotropic solid c_{44} equals the shear modulus μ, in which case $C=1$ would correspond to a value of c equal to the propagation speed of a bulk shear wave. There is a 60-degree periodicity for the propagation speed in the (111) plane of KCl, and a 90-degree periodicity in the (001) plane.

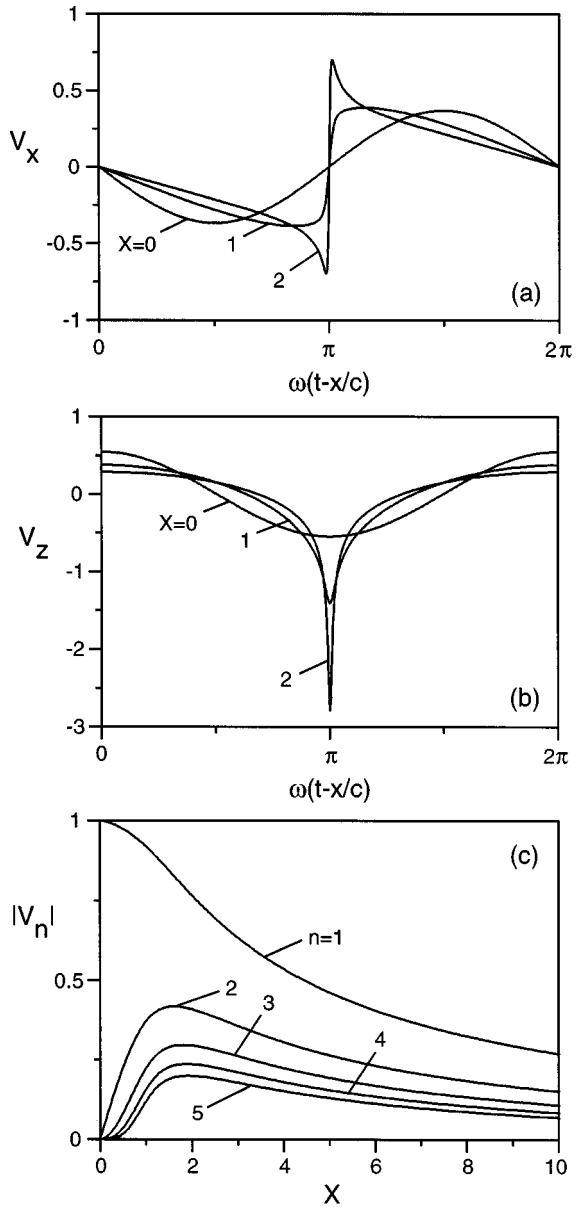

FIG. 1. Nonlinear surface waves in steel: (a) horizontal and (b) vertical velocity waveforms and (c) harmonic propagation curves.

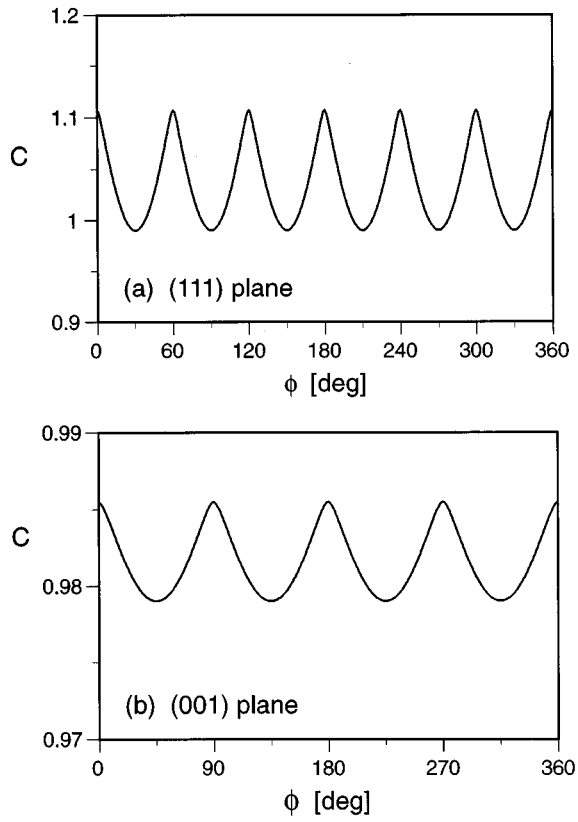

FIG. 2. Dependence of the normalized surface wave speed $C=c/(c_{44}/\rho)^{1/2}$ in KCl for propagation in the (a) (111) and (b) (001) planes. The angle ϕ is with respect to the projection of any crystal axis in the specified plane, e.g., the $[11\bar{2}]$ direction in (a) and the [100] direction in (b).

We first consider nonlinear propagation of a surface wave in the (111) plane of KCl. The direction of propagation is taken to be along the projection of one of the crystal axes, e.g., $\phi=0$ in Fig. 2(a), or say the $[11\bar{2}]$ direction. Because of the symmetry of this geometry there are only two velocity components in the surface wave, the (horizontal) component along the direction of propagation, V_x, and the (vertical) component along the normal to the surface, V_z. In this case $V_y=0$, where $y\equiv x_2$. The quantity x_0 is again a reasonable estimate of the shock formation distance. Note that waveform distortion occurs in a direction opposite that in steel, namely, positive portions of the horizontal velocity waveform recede in time (i.e., arrive later than the zero crossings), and negative portions advance. Accordingly, in the portion of the waveform where the horizontal component forms a shock, the vertical component forms a positive spike, whereas the spike is negative in steel. In contrast with isotropic solids, waveform distortion in KCl is not symmetric (the asymmetry is more noticeable in the vertical component). The reason for the asymmetry is that the elements of $S_{n_1n_2}$ are complex for KCl, whereas they are real for steel. Nevertheless, the harmonic propagation curves in Fig. 3(c) are very similar to those for the isotropic case, Fig. 1(c).

We now consider surface wave propagation in the (001) plane, with the direction of propagation taken to be one of the crystal axes, e.g., $\phi=0$ in Fig. 2(b), or say the [100] direction. Because of the symmetry for this cut and propagation direction, one might expect results that are similar to those for an isotropic solid. Moreover, the elements of matrix $S_{n_1n_2}$ are real in this case, as they are for all isotropic solids. Typical waveforms are shown in Fig. 4(a) and (b). Again there are only two velocity components, V_x and V_z, with $V_y=0$. Here, the nonlinearity has the same sign as nonlinearity in steel, with positive portions of the horizontal velocity waveform advancing in time and negative portions receding. Otherwise, the waveform evolution is substantially different from that in steel, and x_0 is no longer an indication of the shock formation distance. Since $S_{11}^{\text{steel}}/S_{11}^{\text{KCl}}=50$ for this case, the rate of second harmonic generation in steel is much greater than in KCl (for the cut and propagation direction under consideration). However, the differences in the waveform distortion depicted in Figs. 1 and 4 are due mainly to the relative rate of third harmonic generation. Specifically, we have $S_{12}^{\text{steel}}/S_{11}^{\text{steel}}=0.71$ as compared with $S_{12}^{\text{KCl}}/S_{11}^{\text{KCl}}=0.037$, showing that in KCl the efficiency of third har-

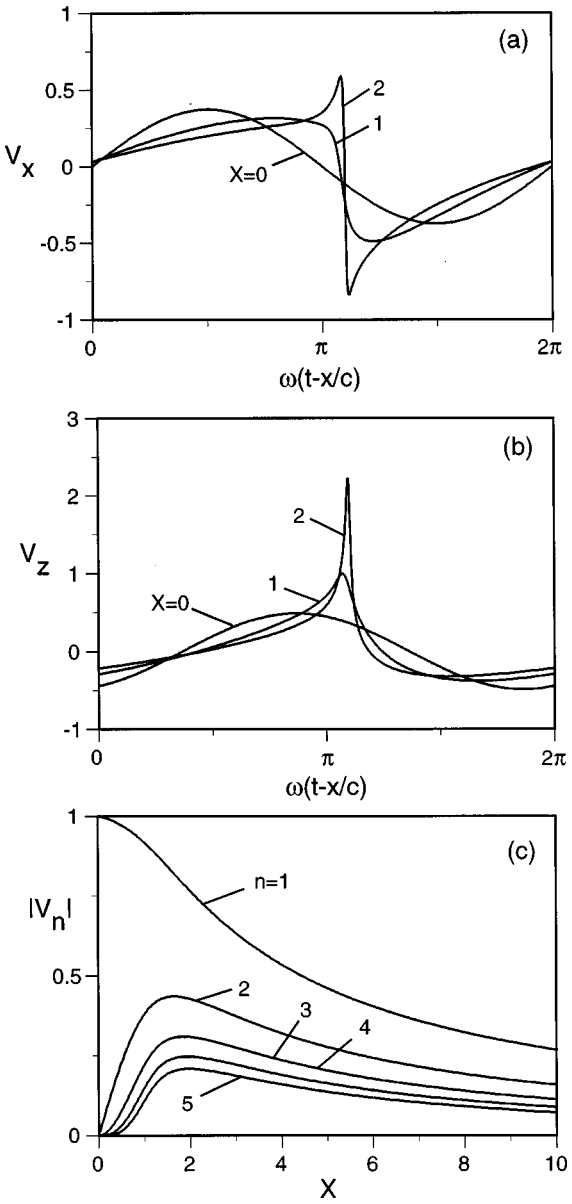

FIG. 3. Nonlinear surface waves in the (111) plane of KCl, for propagation along the projection of one of the cubic axes: (a) horizontal and (b) vertical velocity waveforms and (c) harmonic propagation curves.

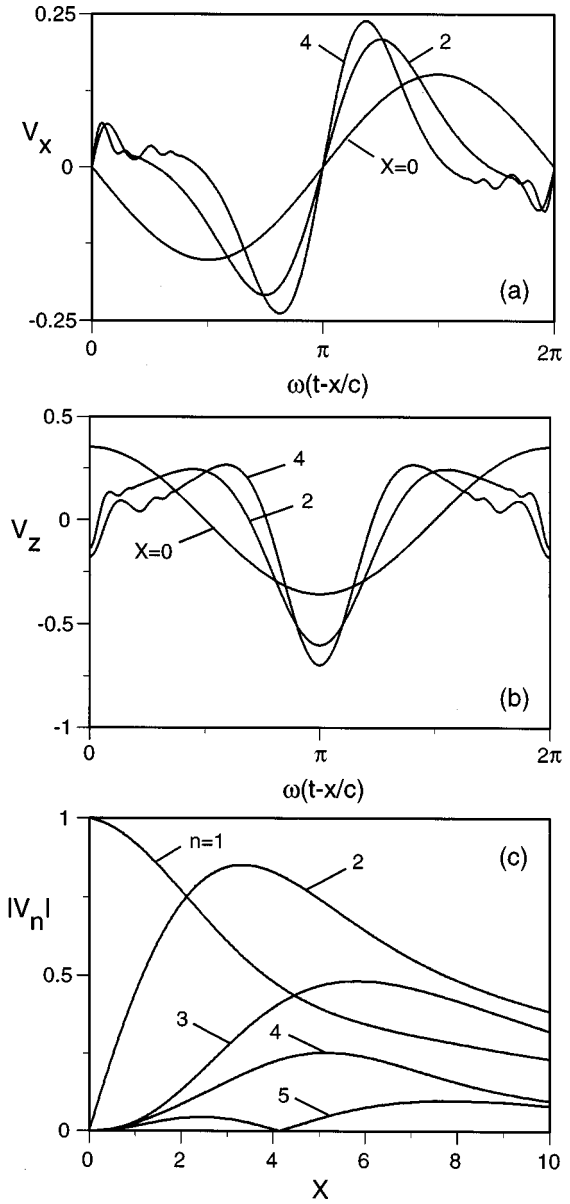

FIG. 4. Nonlinear surface waves in the (001) plane of KCl, for propagation along one of the cubic axes: (a) horizontal and (b) vertical velocity waveforms and (c) harmonic propagation curves.

monic generation is very poor, and therefore shock formation does not occur.

Because the energy in the wave is confined initially to the fundamental and second harmonic components, the second harmonic is seen in Fig. 4(c) to attain an amplitude equal to that of the fundamental at $X \simeq 2$, where the amplitudes of all higher harmonics are still relatively small. This fact permits investigation of second harmonic generation analytically near the source by ignoring third and higher harmonic generation completely. As shown in Appendix C, the analytic solution in this case, for no absorption, is

$$|V_1| = \operatorname{sech}(X/2\sqrt{2}), \tag{88}$$

$$|V_2| = \sqrt{2}\tanh(X/2\sqrt{2}). \tag{89}$$

These equations are compared in Fig. 5 (dashed lines) with the numerical results in Fig. 4(c) for $n=1$ and $n=2$ (solid lines). Agreement for the fundamental component is reasonable up to $X \simeq 5$, and for the second harmonic up to $X \simeq 2$. Equations (88) and (89) are in perfect agreement with numerical solutions of Eq. (82) for $N=2$ and $A_n=0$. Equations (88) and (89) coincide with the solution for two-wave interaction in nonlinear optics,[28] but the physical mechanisms that restrict the number of interacting waves are different in the two cases. In nonlinear optics it is dispersion, and in our case it is the inefficiency of third harmonic generation. The harmonic propagation curves in Fig. 4(c) are most unusual for nonlinear acoustic waves in nondispersive media.

IV. SUMMARY

Spectral evolution equations for nonlinear surface waves in crystals were derived within the theoretical framework developed previously for Rayleigh waves in isotropic solids.[3] There are no restrictions with regard to symmetry of the crystal, orientation of the free surface with respect to the

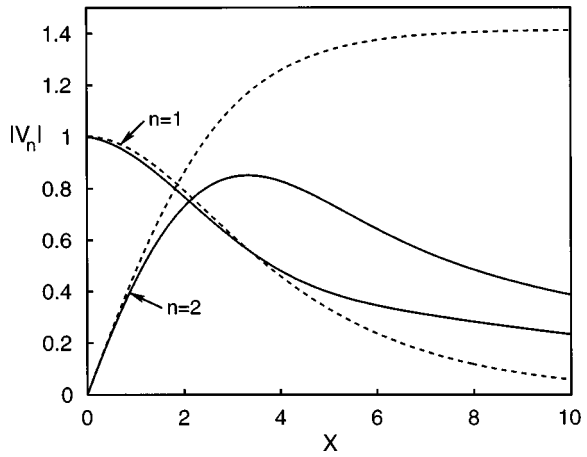

FIG. 5. Comparison of Eqs. (88) and (89) (dashed lines) with the curves for $n=1$ and $n=2$ in Fig. 4(c) (solid lines).

crystal axes, or the direction of propagation in the plane of the free surface. Numerical simulations of waveform distortion, shock formation, and harmonic propagation curves were presented for surface waves in two different cuts of a potassium chloride crystal. In one case the nonlinear distortion leading to shock formation resembles the evolution process in isotropic solids. In the other, the low efficiency of third harmonic generation prevents shock formation and leads to unusually strong second harmonic generation for a nondispersive medium.

APPENDIX A: NUMERICAL SOLUTION OF THE EIGENVALUE PROBLEM

Here we describe the numerical procedure used to solve Eqs. (18) and (24). Begin by introducing the dimensionless notation

$$q=\rho c^2/c_{44}, \quad G_{ik}=\Gamma_{ik}/c_{44}, \tag{A1}$$

such that Eqs. (18) and (19) may be written

$$(G_{ik}-q\,\delta_{ik})\alpha_k=0, \tag{A2}$$

$$\det(G_{ik}-q\,\delta_{ik})=0, \tag{A3}$$

where $G_{ik}=G_{ik}(\zeta)$. The stiffness constant c_{44} was chosen as a normalization factor because for an isotropic solid $c_{44}=\mu$ and thus $q=c^2/c_t^2$, where $c_t=(\mu/\rho)^{1/2}$ is the propagation speed of bulk shear waves. The value of q is thus expected to be of order unity. If we regard q as a known parameter, Eq. (A3) may be solved for ζ, the substitution of which in Eq. (A2) determines α_k. We refer to ζ and α_k as the eigenvalues and eigenvectors, respectively, of the linear system. The solutions for ζ and α_k are used to refine the estimate of q as described below, and the procedure is repeated iteratively until a desired accuracy is achieved.

We thus begin with an assumed value of q and express Eq. (A2) in matrix form:

$$(\mathbf{G}-q\mathbf{I})\boldsymbol{\alpha}=\mathbf{0}, \tag{A4}$$

where $\mathbf{I}$ is the identity matrix and, using Eqs. (21), we may write

$$\mathbf{G}=\mathbf{G}_0+\mathbf{G}_1\zeta+\mathbf{G}_2\zeta^2. \tag{A5}$$

With

$$\mathbf{A}=\mathbf{G}_2, \quad \mathbf{B}=\mathbf{G}_1, \quad \mathbf{C}=\mathbf{G}_0-q\mathbf{I}, \tag{A6}$$

Eq. (A4) takes the form

$$(\mathbf{A}\zeta^2+\mathbf{B}\zeta+\mathbf{C})\boldsymbol{\alpha}=\mathbf{0}, \tag{A7}$$

where

$$\mathbf{A}=\begin{pmatrix} c_{55} & c_{45} & c_{35} \\ c_{45} & c_{44} & c_{34} \\ c_{35} & c_{34} & c_{33} \end{pmatrix}, \tag{A8}$$

$$\mathbf{B}=\begin{pmatrix} 2c_{15} & c_{14}+c_{56} & c_{13}+c_{55} \\ c_{14}+c_{56} & 2c_{46} & c_{36}+c_{45} \\ c_{13}+c_{55} & c_{36}+c_{45} & 2c_{35} \end{pmatrix}, \tag{A9}$$

$$\mathbf{C}=\begin{pmatrix} c_{11}-q & c_{16} & c_{15} \\ c_{16} & c_{66}-q & c_{56} \\ c_{15} & c_{56} & c_{55}-q \end{pmatrix}. \tag{A10}$$

To solve Eq. (A7) for ζ we multiply by $\mathbf{A}^{-1}$ and define

$$\mathbf{B}'=\mathbf{A}^{-1}\mathbf{B}, \quad \mathbf{C}'=\mathbf{A}^{-1}\mathbf{C} \tag{A11}$$

to obtain

$$(\mathbf{I}\zeta^2+\mathbf{B}'\zeta+\mathbf{C}')\boldsymbol{\alpha}=\mathbf{0}. \tag{A12}$$

It is convenient for numerical purposes to rewrite Eq. (A12) as

$$\begin{pmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{C}' & -\mathbf{B}' \end{pmatrix}\begin{pmatrix} \boldsymbol{\alpha} \\ \boldsymbol{\beta} \end{pmatrix}=\zeta\begin{pmatrix} \boldsymbol{\alpha} \\ \boldsymbol{\beta} \end{pmatrix}. \tag{A13}$$

The equivalence of Eqs. (A12) and (A13) is confirmed by eliminating $\boldsymbol{\beta}$ in the latter. Equation (A13) may now be solved using standard methods for finding eigenvalues of the matrix

$$\mathbf{Z}=\begin{pmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{C}' & -\mathbf{B}' \end{pmatrix}. \tag{A14}$$

There are six eigenvalues of $\mathbf{Z}$. The desired eigenvalues are the three for which $\mathrm{Im}\,\zeta_s<0$. With the three values of ζ_s in hand, the corresponding eigenvector components $\alpha_k^{(s)}$ are determined (to within a constant C_s) by Eq. (A2).

The three constants C_s are determined by Eq. (24),

$$c_{i3kl}\sum_{s=1}^{3} C_s\alpha_k^{(s)}l_l^{(s)}=0, \tag{A15}$$

which may be rewritten, with the summation convention applied to the index s, as

$$D_{is}C_s=0, \tag{A16}$$

where [recall Eq. (16)]

$$D_{is}(q)=c_{i3k1}\alpha_k^{(s)}(q)+c_{i3k3}\alpha_k^{(s)}(q)\zeta_s(q). \tag{A17}$$

Nontrivial solutions for the constants C_s require that the determinant of the matrix D_{is} vanish. The eigenvalues and eigenvectors calculated above are substituted in Eq. (A17), and the result is used evaluate the function

$$f(q)=|\det D_{is}(q)|^2. \tag{A18}$$

A new value of q is chosen, the corresponding eigenvalues ζ_s and eigenvectors $\alpha_k^{(s)}$ are calculated, and the procedure is repeated until $f(q)$ is sufficiently close to zero. The final values of the matrix elements D_{is} are then inserted in Eq. (A16) to solve for the constants C_s.

APPENDIX B: ISOTROPIC SOLIDS

It is important to verify that the present theory for nonlinear surface waves in arbitrary anisotropic solids indeed reduces to the earlier theory[2,3] for nonlinear Rayleigh waves in isotropic solids. We shall perform this comparison in terms of the interaction energy W, because, as seen from Eq. (63) and the evolution equations that follow, this energy function determines completely the nonlinear properties of surface waves within the framework of the theory.

Begin by substituting Eq. (57) in (54) to obtain (recall that overbars signify $n_1, n_2>0$)

$$\overline{W}=\frac{k^2}{3}\sum_{n_1+n_2+n_3=0} a_{n_1}a_{n_2}a_{n_3} \times\sum_{s_1,s_2,s_3=1}^{3}\frac{n_1n_2|n_3|F_{s_1s_2s_3}}{n_1\zeta_{s_1}+n_2\zeta_{s_2}+n_3\zeta_{s_3}^*}. \tag{B1}$$

For an isotropic solid ζ_s is imaginary,

$$\zeta_s=-i\xi_s, \tag{B2}$$

and s assumes only two values because there are only two bulk wave modes, shear (transverse) and compressional (longitudinal), in an isotropic solid:

$$s=t,l. \tag{B3}$$

Specifically, we have[2,3]

$$\xi_t=\sqrt{1-c^2/c_t^2},\quad \xi_l=\sqrt{1-c^2/c_l^2}, \tag{B4}$$

where c_t is the propagation speed of a bulk shear wave in an isotropic solid, and c_l is the speed of a bulk compressional wave. Given that ζ is imaginary, and taking into account the form of the eigenvectors used in previous work,[2,3] it can be shown that $F_{s_1s_2s_3}$ in Eq. (58) must also be imaginary, i.e.,

$$\mathrm{Re}\,F_{s_1s_2s_3}=0. \tag{B5}$$

We therefore let

$$\hat{F}_{s_1s_2s_3}=(\Lambda^3/\mu)\,\mathrm{Im}\,F_{s_1s_2s_3}, \tag{B6}$$

where the dimensionless factor Λ defined in Eq. (72) accounts for the normalization in Eq. (46), and the shear modulus μ, which renders $R_{n_1n_2}$ dimensionless, was used as a normalization factor in the theory for isotropic solids.[3] Equation (B1) thus becomes

$$\overline{W}=-\frac{\mu k^2}{3\Lambda^3}\sum_{n_1+n_2=|n_3|} a_{n_1}a_{n_2}a_{|n_3|}^* \times\sum_{s_1,s_2,s_3=t,l}\frac{n_1n_2|n_3|\hat{F}_{s_1s_2s_3}}{n_1\xi_{s_1}+n_2\xi_{s_2}+|n_3|\xi_{s_3}}. \tag{B7}$$

The expression derived previously for the Rayleigh wave interaction energy in an isotropic solid is [Eq. (2) of Ref. 25]

$$W_{\mathrm{R}}=-\mu k^2\sum_{n_1+n_2+n_3=0} a_{n_1}a_{n_2}a_{n_3}|n_1n_2n_3| \times\left(\frac{\alpha}{|n_1|\xi_t+|n_2|\xi_t+|n_3|\xi_l}+\frac{\beta}{|n_1|\xi_t+|n_2|\xi_l+|n_3|\xi_l} +\frac{\gamma}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_l}-\frac{\delta n_1n_2/|n_1n_2|}{|n_1|\xi_t+|n_2|\xi_t+|n_3|\xi_l} -\frac{\varepsilon n_1n_2/|n_1n_2|}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_l}-\frac{\nu n_1n_2/|n_1n_2|}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_l}\right). \tag{B8}$$

We now compare Eqs. (B7) and (B8). Whereas Eq. (B7) is symmetric with respect to permutation of the indices n_1, n_2, and n_3, Eq. (B8) is not. To write the latter in symmetric form it is necessary to average Eq. (B8) with respect to permutation of (n_1,n_2,n_3), after which the summation may be written as follows for $n_1,n_2>0$:

$$\overline{W}_{\mathrm{R}}=-\frac{\mu k^2}{3}\sum_{n_1+n_2=|n_3|} a_{n_1}a_{n_2}a_{|n_3|}^*|n_1n_2n_3|\Bigg[\alpha\left(\frac{1}{|n_1|\xi_t+|n_2|\xi_t+|n_3|\xi_l}+\frac{1}{|n_1|\xi_t+|n_2|\xi_l+|n_3|\xi_t}+\frac{1}{|n_1|\xi_l+|n_2|\xi_t+|n_3|\xi_t}\right) -\delta\left(\frac{1}{|n_1|\xi_t+|n_2|\xi_t+|n_3|\xi_l}-\frac{1}{|n_1|\xi_t+|n_2|\xi_l+|n_3|\xi_t}-\frac{1}{|n_1|\xi_l+|n_2|\xi_t+|n_3|\xi_t}\right) +\beta\left(\frac{1}{|n_1|\xi_t+|n_2|\xi_l+|n_3|\xi_l}+\frac{1}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_t}+\frac{1}{|n_1|\xi_l+|n_2|\xi_t+|n_3|\xi_l}\right)+\frac{\varepsilon}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_t} +\frac{3\gamma}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_l}+\frac{\nu}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_l}\Bigg]. \tag{B9}$$

Equations (B7) and (B9) are consistent and can be compared term-by-term to show that

$$\hat{F}_{111}=0, \quad \hat{F}_{112}=\alpha-\delta,$$
$$\hat{F}_{211}=\hat{F}_{121}=\alpha+\delta, \quad \hat{F}_{122}=\hat{F}_{212}=\beta, \tag{B10}$$
$$\hat{F}_{221}=\beta+\varepsilon, \quad \hat{F}_{222}=3\gamma+\nu.$$

In Ref. 3, the new parameters α', β', and γ' were introduced to express Eq. (B8) more concisely as

$$W_{\mathrm{R}}=-\mu k^2 \sum_{n_1+n_2+n_3=0} a_{n_1}a_{n_2}a_{n_3}|n_1n_2n_3| \times\left(\frac{\alpha'}{|n_1|\xi_t+|n_2|\xi_t+|n_3|\xi_l}+\frac{\beta'}{|n_1|\xi_t+|n_2|\xi_l+|n_3|\xi_l} +\frac{\gamma'}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_l}\right), \tag{B11}$$

the symmetric form of which is, for $n_1, n_2>0$,

$$\overline{W}_{\mathrm{R}}=-\frac{\mu k^2}{3} \sum_{n_1+n_2=|n_3|} a_{n_1}a_{n_2}a^*_{|n_3|}|n_1n_2n_3| \times\left[\alpha'\left(\frac{1}{|n_1|\xi_t+|n_2|\xi_t+|n_3|\xi_l}+\frac{1}{|n_1|\xi_t+|n_2|\xi_l+|n_3|\xi_t} +\frac{1}{|n_1|\xi_l+|n_2|\xi_t+|n_3|\xi_t}\right)+\beta'\left(\frac{1}{|n_1|\xi_t+|n_2|\xi_l+|n_3|\xi_l} +\frac{1}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_t}+\frac{1}{|n_1|\xi_l+|n_2|\xi_t+|n_3|\xi_l}\right) +\frac{3\gamma'}{|n_1|\xi_l+|n_2|\xi_l+|n_3|\xi_l}\right]. \tag{B12}$$

Comparison of Eqs. (B7) and (B12) yields

$$\hat{F}_{111}=0,$$
$$\hat{F}_{211}=\hat{F}_{121}=\alpha', \tag{B13}$$
$$\hat{F}_{122}=\hat{F}_{212}=\beta',$$

as well as

$$\frac{\hat{F}_{112}+\hat{F}_{221}}{\xi_t+\xi_l}+\frac{\hat{F}_{222}}{2\xi_l}=\frac{\alpha'+\beta'}{\xi_t+\xi_l}+\frac{3\gamma'}{2\xi_l}. \tag{B14}$$

Using Eqs. (B13) to eliminate α' and β' in Eq. (B14) and solving for γ' yields

$$\gamma'=\frac{2\xi_l(\hat{F}_{112}+\hat{F}_{221}-\hat{F}_{211}-\hat{F}_{122})}{3(\xi_t+\xi_l)}+\frac{\hat{F}_{222}}{3}. \tag{B15}$$

Equations (B10) are substituted in Eq. (B15) to eliminate $\hat{F}_{s_1s_2s_3}$ from the expression for γ', and they are substituted in Eqs. (B13) to express α' and β' in terms of unprimed quantities. The results are

$$\alpha'=\alpha+\delta, \quad \beta'=\beta,$$
$$\gamma'=\gamma+\frac{1}{3}\left(\nu+\frac{2\xi_l(\varepsilon-2\delta)}{\xi_t+\xi_l}\right), \tag{B16}$$

which reproduce exactly the relations obtained previously for isotropic solids.[3]

APPENDIX C: ANALYTIC SOLUTION FOR TWO-WAVE INTERACTION

Here we derive an analytic solution of Eq. (82) for the case in which nonlinear interaction is restricted to the fundamental and second harmonic in the absence of absorption. Equation (82) reduces for $N=2$ and $A_n=0$ to the two coupled equations

$$\frac{dV_1}{dX}=-\frac{S^*_{11}}{4|S_{11}|}V_1^*V_2, \tag{C1}$$

$$\frac{dV_2}{dX}=\frac{S_{11}}{2|S_{11}|}V_1^2. \tag{C2}$$

Letting

$$V_n=\hat{V}_n e^{i\theta} \tag{C3}$$

yields

$$\frac{d\hat{V}_1}{dX}=-\frac{(S_{11}e^{i\theta})^*}{4|S_{11}|}\hat{V}_1^*\hat{V}_2, \tag{C4}$$

$$\frac{d\hat{V}_2}{dX}=\frac{S_{11}e^{i\theta}}{2|S_{11}|}\hat{V}_1^2. \tag{C5}$$

Now choose θ such that $S_{11}e^{i\theta}=|S_{11}|$ to obtain

$$\frac{d\hat{V}_1}{dX}=-\frac{1}{4}\hat{V}_1^*\hat{V}_2, \tag{C6}$$

$$\frac{d\hat{V}_2}{dX}=\frac{1}{2}\hat{V}_1^2. \tag{C7}$$

Monofrequency source radiation is assumed, for which the boundary condition at $X=0$ is expressed

$$\hat{V}_1=V_0, \quad \hat{V}_2=0. \tag{C8}$$

With V_0 taken to be real (and positive), and since Eqs. (C6) and (C7) have only real coefficients, we may seek real solutions for $\hat{V}_1$ and $\hat{V}_2$, in which case $\hat{V}_1^*=\hat{V}_1$. Now multiply Eq. (C6) by $\hat{V}_1$, Eq. (C7) by $\frac{1}{2}\hat{V}_2$, and add the results to obtain

$$\frac{d\hat{V}_1^2}{dX}+\frac{1}{2}\frac{d\hat{V}_2^2}{dX}=0. \tag{C9}$$

Integration of Eq. (C9) yields

$$\hat{V}_1^2+\tfrac{1}{2}\hat{V}_2^2=V_0^2, \tag{C10}$$

where the integration constant was determined by the boundary condition, Eqs. (C8). Equation (C10) agrees with Eq. (86). Using Eq. (C10) to eliminate $\hat{V}_1^2$ from Eq. (C7) gives, following separation of variables,

$$dX=\frac{4d\hat{V}_2}{2V_0^2-\hat{V}_2^2}. \tag{C11}$$

Integration yields

$$X = \frac{\sqrt{2}}{V_0} \ln\left(\frac{\sqrt{2}V_0 + \hat{V}_2}{\sqrt{2}V_0 - \hat{V}_2} \right), \tag{C12}$$

where the integration constant was again determined by Eqs. (C8).

Solving Eq. (C12) for $\hat{V}_2$ yields

$$\hat{V}_2 = \sqrt{2}V_0 \tanh(V_0 X/2\sqrt{2}) \tag{C13}$$

for the second harmonic, the substitution of which in Eq. (C10) gives

$$\hat{V}_1 = V_0 \operatorname{sech}(V_0 X/2\sqrt{2}) \tag{C14}$$

for the fundamental. From Eq. (C3) we have $|V_n| = |\hat{V}_n|$, and therefore setting $V_0 = 1$ in correspondence with Eq. (87) yields Eqs. (88) and (89).

A coherent line source in a turbulent atmosphere

Erik M. Salomons[a)]
TNO Institute of Applied Physics, P.O. Box 155, 2600 AD Delft, The Netherlands

(Received 3 February 1998; revised 1 October 1998; accepted 30 October 1998)

The sound field of a coherent line source in a nonrefracting, turbulent atmosphere is studied. An expression for the sound pressure level in the frequency domain is developed, based on a discretization of the line source into a set of point sources. Atmospheric turbulence is taken into account by the mutual coherence function. Numerical computations for various turbulent atmospheres show that the geometrical attenuation is 3 dB per distance doubling (3 dB/dd) at a small distance (cylindrical spreading), 6 dB/dd at a large distance (spherical spreading), and 7.5 dB/dd in a transition region. The anomalous value of 7.5 dB/dd is confirmed by an analytic approximation. Next, a computational method in the time domain is developed, for arbitrary wave forms emitted by the source. Atmospheric turbulence is taken into account in this method by including random fluctuations of the acoustic travel times, based on the spectral density of the travel time correlation function. For a harmonic coherent line source, the method yields results that agree with results computed in the frequency domain. © *1999 Acoustical Society of America.*

INTRODUCTION

A finite line source generates a field with cylindrical spreading at small distance and spherical spreading at large distance. As a consequence, the sound pressure level decreases with 3 dB per distance doubling at small distance, and 6 dB per distance doubling at a large distance. The transition from cylindrical to spherical spreading occurs at a distance that depends on the length of the line source.[1] Moreover, the transition distance is smaller for an incoherent line source (i.e., a set of incoherent point sources along a line) than for a coherent line source (e.g., a pulsating cylinder). Atmospheric turbulence causes a reduction of the coherence of the field of a coherent line source. Therefore, atmospheric turbulence is expected to reduce the transition distance from cylindrical to spherical spreading. This effect is investigated in this paper.

The propagation of sound waves from a line source to a receiver at a large distance is affected by various effects: geometrical attenuation (cylindrical or spherical spreading), atmospheric attenuation, atmospheric refraction, and ground reflections. In principle, these effects are not independent of each other. In many practical situations, however, the effects may be considered as independent, approximately. In this paper, only the effect of geometrical attenuation is studied, and the influence of atmospheric turbulence on it. It should be noted that the influence of turbulence on the geometrical attenuation is probably not independent of atmospheric refraction in situations where the receiver is in a refractive shadow.

The most obvious example of a physical realization of a coherent line source is a vibrating cylinder (tube). Another example is a one-dimensional array of coherent sound sources (e.g., loudspeakers). Finally, we mention two examples of nonlinear coherent line sources, a supersonic projectile,[2,3] and a spark source;[4] it should be noted that the analysis presented here cannot be applied directly to these sources, since nonlinear effects are ignored.

I. HARMONIC COHERENT LINE SOURCE

A. Discretization

We consider the system shown in Fig. 1, with a set of coherent, harmonic monopole sources along a finite line segment of length $2\Delta y$. This system represents a discretized approximation of a continuous line source. We will study the variation of the field in the direction perpendicular to the line source, in a nonrefracting, turbulent atmosphere. A rectangular xy coordinate system is used. The monopole sources are located on the y axis at positions (x_j, y_j), with $x_j = 0$ and $y_j = (j-1)\,\delta y - \Delta y$, where $j = 1,2,...,N$. The receiver is located on the x axis, at position (x,y), with $y = 0$. The complex sound pressure field at the receiver is

$$p = \sum_{j=1}^{N} p_j, \tag{1a}$$

with

$$p_j = p_0 \frac{\exp(i[kr_j + S_j - \omega t])}{r_j / r_0}, \tag{1b}$$

the contribution of source j, where p_0 is a constant pressure, ω the angular frequency, $k = \omega/c_0$ the wave number (with c_0 the average sound speed in the atmosphere), $r_0 = 1$ m, $r_j = \sqrt{x^2 + y_j^2}$, and S_j a fluctuating phase, with zero time average: $\langle S_j \rangle = 0$. The phase fluctuations S_j originate from sound speed fluctuations and wind speed fluctuations, i.e., atmospheric turbulence. It should be noted that amplitude fluctuations are neglected here, as these are assumed to saturate and are always considerably smaller than phase fluctuations.[5]

a)Electronic mail: salomons@tpd.tno.ni

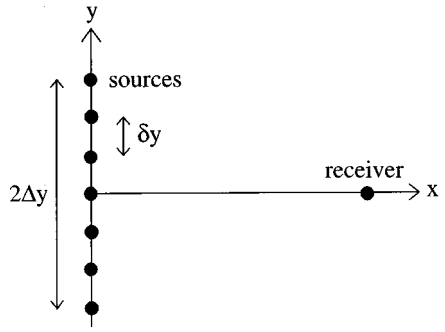

FIG. 1. A system with monopole sources on the y axis and a receiver on the x axis.

In the limit of vanishing distance δy between neighboring sources, the field (1) is identical with the field of a harmonically pulsating cylinder (for large kx). To demonstrate this, we set $S_j=0$ and $\Delta y\to\infty$. Omitting the factor $\exp(-i\omega t)$ in Eq. (1), we find for the pressure amplitude

$$p=\frac{p_0}{\delta_y}\int_{-\infty}^{\infty}\frac{\exp(ik\sqrt{x^2+y^2})}{\sqrt{x^2+y^2}/r_0}\,dy. \tag{2}$$

Evaluating the integral (for large k) by the method of stationary phase,[6] we find

$$p=\frac{p_0 r_0}{\delta y}\sqrt{\frac{2\pi}{kx}}\exp\left(ikx+i\frac{1}{4}\pi\right). \tag{3}$$

The amplitude of the field of a pulsating cylinder of radius b and infinite length is[7] $p=p_c H_0^{(1)}(kx)$, with $p_c=-w_c i\times\rho c_0/H_0^{(1)\prime}(kb)$, where w_c is the vibration velocity of the cylinder, ρ the density of the atmosphere, and $H_0^{(1)\prime}$ is the derivative of the Hankel function $H_0^{(1)}$. For large kx, we find[8]

$$p=p_c\sqrt{\frac{2}{\pi kx}}\exp\left(ikx-i\frac{1}{4}\pi\right). \tag{4}$$

This agrees with Eq. (3) if we set $p_0=-ip_c\delta y/(\pi r_0)$.

B. Mean squared sound pressure

It is assumed that the phase fluctuations S_j are slow compared with the harmonic variations of the field (frozen medium approximation[9]). Then the time-averaged squared sound pressure is obtained from Eq. (1) as (omitting the constant $r_0=1$ m):

$$\begin{aligned}\langle p^2\rangle&=\left\langle\frac{1}{2}\left(\sum_{j=1}^{N}p_j\right)\left(\sum_{m=1}^{N}p_m\right)^*\right\rangle\\&=\frac{1}{2}p_0^2\sum_{j=1}^{N}\sum_{m=1}^{N}\frac{\langle\cos(kr_j-kr_m+S_j-S_m)\rangle}{r_j r_m}\\&=\frac{1}{2}p_0^2\sum_{j=1}^{N}\sum_{m=1}^{N}\frac{\cos(kr_j-kr_m)}{r_j r_m}\Gamma_{jm},\end{aligned} \tag{5}$$

with Γ_{jm} the mutual coherence function (MCF), defined as[10,11]

$$\Gamma_{jm}=\langle\exp(i(S_j-S_m))\rangle=\langle\cos(S_j-S_m)\rangle. \tag{6}$$

To derive an integral expression for a continuous line source, we consider the limit of vanishing distance δy between neighboring sources. Then we can replace the double sum in Eq. (5) by a double integral (denoting y_j and y_m as y and y', respectively):

$$\langle p^2\rangle=\frac{p_0^2}{2(\delta y)^2}\int_{-\Delta y}^{\Delta y}\int_{-\Delta y}^{\Delta y}\frac{\cos(kr-kr')}{rr'}\Gamma(y-y')dy\,dy'. \tag{7}$$

This integral expression for the mean squared sound pressure is a new result, and will be used in the following sections.

C. The mutual coherence function (MCF)

For the MCF we use the expression[5,12]

$$\Gamma(\rho)=\exp\left(-\frac{1}{2}\sqrt{\pi}\mu_0^2k^2xL\left\{1-\frac{\Phi(\rho/L)}{(\rho/L)}\right\}\right), \tag{8}$$

which is valid for a Gaussian correlation function of the fluctuating acoustical index of refraction μ (defined as $\mu=c_0/c-1$, with c the fluctuating sound speed and c_0 the average sound speed):

$$\langle\mu(y)\mu(y')\rangle=\mu_0^2\exp(-\rho^2/L^2). \tag{9}$$

Here $\rho=y-y'$ (or $\rho=y_j-y_m$ in discrete form), μ_0 is the rms value of μ, L is the correlation length, and $\Phi(z)=\int_0^z\exp(-u^2)du=\frac{1}{2}\sqrt{\pi}\,\mathrm{erf}(z)$, where $\mathrm{erf}(z)$ is the error function.

D. The incoherent limit

In the limit $\mu_0^2\to\infty$, all sources are incoherent. In this case, $\Gamma_{jm}=0$ for $j\neq m$ and $\Gamma_{jj}=1$, and we obtain from Eq. (5),

$$\langle p^2\rangle=\frac{1}{2}p_0^2\sum_{j=1}^{N}\frac{1}{r_j^2}. \tag{10}$$

The corresponding integral expression for a continuous line source is

$$\langle p^2\rangle=\frac{p_0^2}{2\delta y}\int_{-\Delta y}^{\Delta y}\frac{1}{x^2+y^2}\,dy. \tag{11}$$

This gives

$$\langle p^2\rangle=\frac{p_0^2}{\delta y}\frac{1}{x}\arctan\frac{\Delta y}{x}. \tag{12}$$

A comparison of Eqs. (7) and (11) yields the following formal expression for the incoherent limit ($\mu_0^2\to\infty$) of the MCF:

$$\Gamma(y-y')=\delta y\,\delta(y-y'), \tag{13}$$

where $\delta(y-y')$ is the Dirac delta function.

E. Numerical examples

Figure 2 shows numerical examples of the sound pressure level as a function of distance x, for the two frequencies $f=400$ and 1000 Hz, and the three source lengths $2\Delta y=10$, 100, and 1000 m. A number of sources

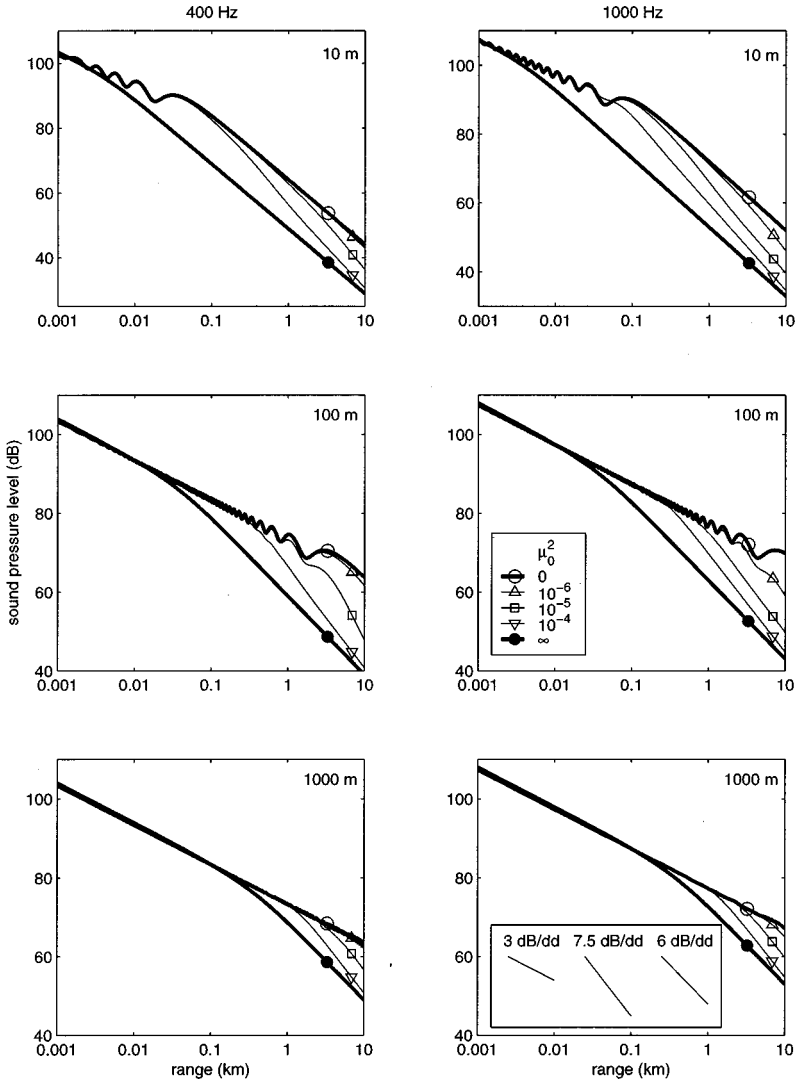

FIG. 2. The sound pressure level as a function of distance, for five values of μ_0^2 (see the legend), source lengths $2\Delta y = 10$, 100, and 1000 m (from top to bottom), and frequencies 400 Hz (left column) and 1000 Hz (right column). Slopes of 3, 7.5, and 6 dB per distance doubling (dd) are indicated.

$N = 2\Delta y f/125$ was used (Δy in m, f in Hz), so that $\delta y \approx \frac{1}{3}\lambda$. We used $p_0 = \sqrt{2}$ Pa, so that the sound pressure level $L_p = 10\log(\langle p^2\rangle/p_{\text{ref}}^2)$ of a single monopole source is 94 dB at a distance of 1 m ($p_{\text{ref}} = 20\,\mu$Pa).

The oscillating thick curves for $\mu_0^2 = 0$ are computed with Eq. (5) with $\Gamma_{jm} = 1$ (the oscillations will be explained in Sec. I F 2). The thick curves for $\mu_0^2 = \infty$ are computed with Eq. (12), but the use of Eq. (10) gives essentially the same result. The number of sources N indicated above was chosen so that the levels for $\mu_0^2 = 0$ and $\mu_0^2 = \infty$ are approximately equal for small values of the range x. For larger N, the curves are shifted but retain their shapes. The thin curves for $\mu_0^2 = 10^{-6}$, 10^{-5}, 10^{-4} are computed with Eq. (5), using Eq. (8) for the MCF. Following Daigle *et al.*,[5] we use $L = 1.1$ m. These authors also report that μ_0^2 varied roughly between 10^{-6} and 10^{-5} for their measurements. The value $\mu_0^2 = 10^{-4}$ represents extremely strong turbulence.

Figure 2 shows that the transition from cylindrical spreading ($dL_p/d\log x = -10$ dB, 3 dB per distance doubling) to spherical spreading ($dL_p/d\log x = -20$ dB, 6 dB per distance doubling) occurs at a smaller distance for an incoherent line source than for a coherent line source. The curves for the incoherent limit $\mu_0^2 = \infty$ show the transition at $x \approx \Delta y$, independent of the frequency. This will be explained in Sec. I F 1. The curves for the coherent limit $\mu_0^2 = 0$ show the transition at $x = \Delta y^2/\lambda$, where λ is the wavelength. This will be explained in Sec. I F 2. The curves for $\mu_0^2 = 10^{-6}$, 10^{-5}, 10^{-4} show a gradual transition from the coherent limit to the incoherent limit. The slope in the transition region is $dL_p/d\log x = -25$ dB (7.5 dB per distance doubling). This will be explained in Sec. I F 3.

F. Transition from cylindrical to spherical spreading

1. The incoherent limit $\mu_0^2 = \infty$

For $x/\Delta y \to \infty$, Eq. (12) for the incoherent limit reduces to

$$\langle p^2\rangle = N\frac{p_0^2}{2x^2}, \tag{14}$$

with $N = 1 + 2\Delta y/\delta y \approx 2\Delta y/\delta y$ the number of sources. This corresponds to spherical spreading. For $x/\Delta y \to 0$, $\arctan \Delta y/x \to \pi/2$, so that Eq. (12) reduces to

$$\langle p^2\rangle = \frac{\pi p_0^2}{2x\,\delta y}, \tag{15}$$

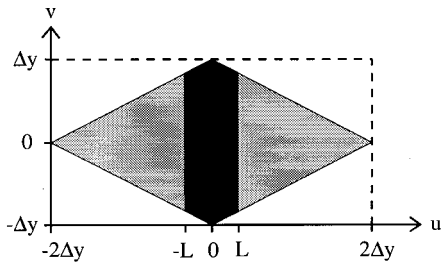

FIG. 3. The grey area is the integration area in the uv plane. The narrow black band around $u=0$ is the region where the MCF is significantly different from zero.

representing cylindrical spreading. Inspection of the arctan function yields that the transition occurs at $x \approx 2\Delta y/\pi \approx \Delta y$, in agreement with the work of Rathe.[1]

2. The coherent limit $\mu_0^2=0$

The oscillations in the curves for $\mu_0^2=0$ in Fig. 2 can be explained in terms of Fresnel zones.[2] The difference in the source–receiver distance between the point source at $y=0$ and the point source at $y=\Delta y$ is

$$\Delta r=\sqrt{x^2+\Delta y^2}-x\approx\frac{\Delta y^2}{2x}, \tag{16}$$

for $x \gg \Delta y$. Equating this difference to $(n-\frac{1}{2})\lambda$ with $n=1,2,3,...$, gives

$$x_n=\frac{\Delta y^2}{(2n-1)\lambda}. \tag{17}$$

The maxima in the oscillating curves occur at $x=x_n$. At $x=x_1$, the first Fresnel zone just fits on the line source. With increasing distance $x>x_1$, the phase differences between the point sources on the line source become small, and the line source behaves as a compact source with spherical spreading.

3. The case $0<\mu_0^2<\infty$

For $x \gg \Delta y$, Eq. (7) can be simplified. We set $r \approx r' \approx x$ in the denominator, and $kr-kr' \approx (k/2x)(y^2-y'^2)$ in the numerator:

$$\langle p^2\rangle=\frac{p_0^2}{2x^2(\delta y)^2}\int_{-\Delta y}^{\Delta y}\int_{-\Delta y}^{\Delta y}\cos\left(\frac{k}{2x}(y-y')(y+y')\right)\times\Gamma_x(y-y')dy\,dy', \tag{18}$$

where the x dependence of the MCF has been indicated by a subscript. We perform a coordinate transformation $(y,y') \rightarrow (u,v)$:

$$u=y-y', \quad v=\tfrac{1}{2}(y+y'), \tag{19}$$

with a Jacobian equal to unity. The integration area in the uv plane is shown in Fig. 3. The MCF is given by Eq. (8), which we write as

$$\Gamma_x(u)=\exp\left(-ax\left(1-\frac{\Phi(u/L)}{u/L}\right)\right), \tag{20}$$

with

$$a=\tfrac{1}{2}\sqrt{\pi}\mu_0^2k^2L. \tag{21}$$

Now we assume $ax>1$, so that $\Gamma(u)\approx 0$ if $|u|$ is larger than a value of the order of the correlation length L (see Fig. 3). Therefore, the integration area can be replaced by an infinite rectangle with vertical sides at $u=\pm\infty$, and horizontal sides at $v=\pm\Delta y$ (cf. Ishimaru[13]). We obtain

$$\langle p^2\rangle=\frac{p_0^2}{2x^2(\delta y)^2}\int_{-\infty}^{\infty}\int_{-\Delta y}^{\Delta y}\cos\left(\frac{k}{x}uv\right)\Gamma_x(u)dv\,du \tag{22}$$

or

$$\langle p^2\rangle=\frac{2p_0^2\Delta y}{x^2(\delta y)^2}\int_0^{\infty}H_x(u)\Gamma_x(u)du, \tag{23}$$

with

$$H_x(u)=\sin\left(\frac{k\Delta y}{x}u\right)\Big/\left(\frac{k\Delta y}{x}u\right). \tag{24}$$

To evaluate the MCF given by Eq. (20), we use the series expansion[8]

$$\Phi(z)=z-\tfrac{1}{3}z^3+O(z^5). \tag{25}$$

Neglecting terms of order z^5 and higher, we get

$$\Gamma_x(u)=\exp(-\tfrac{1}{3}axu^2/L^2). \tag{26}$$

We will consider two limiting cases, x small and x large.

a. x small. For small x, $\Gamma_x(u)\approx 1$, and

$$\langle p^2\rangle=\frac{2p_0^2}{kx(\delta y)^2}\int_0^{\infty}\frac{\sin u'}{u'}du'=\frac{p_0^2\pi}{kx(\delta y)^2}, \tag{27}$$

representing cylindrical spreading. This solution is valid only in a limited region (dependent on frequency), since in the foregoing we assumed that x is large $(x \gg \Delta y)$.

b. x large. For large x, $H_x(u)\approx 1$, and we use Eq. (26) to obtain

$$\langle p^2\rangle=\frac{2p_0^2\Delta y}{x^2(\delta y)^2}\int_0^{\infty}\exp\left(-\frac{1}{3}ax\frac{u^2}{L^2}\right)du, \tag{28}$$

or

$$\langle p^2\rangle=\frac{\pi^{1/4}\sqrt{6L}p_0^2\Delta y}{(\delta y)^2\mu_0kx^{5/2}}. \tag{29}$$

If ax is very large, we should use Eq. (13) instead of Eq. (26), and obtain

$$\langle p^2\rangle=\frac{p_0^2\Delta y}{x^2\delta y}, \tag{30}$$

which coincides with Eq. (14), the incoherent limit.

Equation (29) yields sound pressure levels that are in good agreement with the exact levels, represented in Fig. 2 by the thin curves (although Fresnel oscillations cause some deviations, for 400 Hz and $2\Delta y=100$ m). The slope $dL_p/d\log x=-25$ dB is confirmed by Eq. (29).

II. COMPUTATIONAL METHOD IN THE TIME DOMAIN

In this section we briefly describe a computational method in the time domain, for a coherent line source in a turbulent atmosphere. For some applications, this method may be more practical than the computational method in the frequency domain, described in Sec. I.

The line source is discretized in the same way as in Sec. I, with point sources at $y=y_j$. The field at the receiver is written as

$$p(t)=\sum_{j=1}^{N} \frac{w_j(t-r_j/c_0+\delta t_j)}{r_j}, \tag{31}$$

where the function $w_j(t)$ determines the emitted wave form of point source j, $t-r_j/c_0$ is the retarded time, and δt_j is a fluctuation of the acoustic travel time from source j to the receiver (this fluctuation is caused by atmospheric turbulence). The harmonic line source studied in Sec. I corresponds to the case that all $w_j(t)$ are equal to the same harmonic function.

For the construction of random realizations of the travel time fluctuations δt_j we start from the correlation function of the travel time:[5,12]

$$B_t(\rho)=\frac{1}{2}\sqrt{\pi}\mu_0^2 xL\frac{\Phi(\rho/L)}{(\rho/L)}. \tag{32}$$

We perform a spectral decomposition:[14,15]

$$B_t(\rho)=\int_{-\infty}^{\infty}\cos(\kappa\rho)V(\kappa)d\kappa\approx\Delta\kappa\sum_n \cos(\kappa_n\rho)V(\kappa_n), \tag{33}$$

with $V(\kappa)$ the spectral density, which we compute by the inverse Fourier transform:[14,15]

$$V(\kappa)=\frac{1}{\pi}\int_0^{\infty}\cos(\kappa\rho)B_t(\rho)d\rho$$

$$\approx\frac{\Delta\rho}{\pi}\sum_m \cos(\kappa\rho_m)B_t(\rho_m). \tag{34}$$

Random realizations of the travel times t_j are computed with the expression

$$t_j\equiv t(y_j)=\sqrt{2\Delta\kappa}\sum_n \cos(\kappa_n y_j+\phi_n)\sqrt{V(\kappa_n)}, \tag{35}$$

with random phase angles ϕ_n. It is easily verified that this expression yields the correlation function $B_t(\rho)=\langle t(y+\rho)t(y)\rangle$ given by Eq. (33). The fluctuations are given by $\delta t_j=t_j-\langle t_j\rangle$.

Our numerical implementation is as follows (cf. Chevret *et al.*[16]). First a set $\rho_m=m\Delta\rho$ $(m=0,1,...,N_\rho)$ is chosen, with $\Delta\rho=0.02$ m and $N_\rho\Delta\rho=300$ m. The corresponding set $\kappa_n=n\Delta\kappa$ $(n=0,1,...,N_\kappa)$ is generated, with $\Delta\kappa=2\pi/(N_\rho\Delta\rho)$ and $N_\rho\Delta\kappa=6\ \mathrm{m}^{-1}$ (the cutoff at $\kappa=6\ \mathrm{m}^{-1}$ can be considered as a low-pass filter). The spectral density $V(\kappa_n)$ is computed with Eq. (34). Next, random realizations of the set t_j are computed with Eq. (35), and the fluctuations $\delta t_j=t_j-\langle t_j\rangle$ are obtained.

The above method was tested for the harmonic line sources studied in Sec. I, by reproducing the results computed with Eq. (5), shown in Fig. 2. It was found that averaging the squared sound pressure over 100 random realizations yields sufficiently accurate results.

III. CONCLUSIONS

The field of a coherent line source in a turbulent atmosphere has been studied. An expression has been developed for the sound pressure level in the frequency domain, based on a discretization of the line source into a set of point sources. Atmospheric turbulence is taken into account by the mutual coherence function. Numerical computations have shown that the geometrical attenuation is 3 dB per distance doubling (3 dB/dd) at a small distance (cylindrical spreading), 6 dB/dd at a large distance (spherical spreading), and 7.5 dB/dd in a transition region. The anomalous value of 7.5 dB/dd has been confirmed by an analytic approximation.

Further, a computational method in the time domain has been developed. Atmospheric turbulence is taken into account in this method by including random fluctuations of the acoustic travel times, based on the spectral density of the travel time correlation function. For a harmonic coherent line source, the method yields results that agree with results computed in the frequency domain.

In this study we have focused on the variation of the geometrical attenuation with propagation distance in a turbulent atmosphere. Other propagation effects have been ignored, such as atmospheric refraction, atmospheric absorption, ground reflections, and nonlinear effects. In many practical situations, one may assume that the geometrical attenuation is approximately independent of these effects.

(Received 14 February 1998; revised 18 October 1998; accepted 30 October 1998)

Previous calculations of the coherence and extinction of sound waves propagating through turbulence have almost always used isotropic models for the turbulence. However, low-frequency sound waves are strongly affected by energy-subrange turbulence structure, which is anisotropic by nature. In this paper, coherence and extinction are calculated using several anisotropic models for turbulent velocity fluctuations in the neutral atmospheric shear layer. New anisotropic versions of the Gaussian and von Kármán models are developed. The Kristensen *et al.* spectral model [Boundary-Layer Meteorol. **47**, 149–193 (1989)] and Mann's rapid-distortion, constant shear model [J. Fluid Mech. **273**, 141–168 (1994)] are also considered. The turbulence models all predict that the crosswind extinction distance is longer than the along-wind value, although they disagree as to the extent of the lengthening: depending on the model, the ratio of crosswind to along-wind extinction varies from 2.1 to 13. These results point to the need for good experiments. Similarly, coherence of the propagating wavefronts is predicted to persist over longer distances in the crosswind direction. INTRODUCTION

Much previous research in the area of wave propagation through turbulence has focused on scattering from the small-scale motions of the inertial subrange.[1] But several studies,[2–9] some now decades old, provide convincing evidence that the larger-scale energy-subrange motions are also important for acoustic propagation through the atmosphere. An obvious situation in which energy-subrange scattering should be important occurs when the wavelength of the sound falls within the energy subrange (i.e., the wavelength is comparable to or larger than the turbulence outer scale). This situation occurs often in practical applications. Consider, for example, near-ground propagation through the atmospheric surface layer when shear (as opposed to buoyancy) production of turbulence dominates. The outer scale for propagation in a surface shear layer is roughly equal to the height of the propagation path. Hence if the wavelength is comparable to or larger than the height, energy-subrange scattering is significant.

But there are also less obvious circumstances, dependent upon the propagation geometry and the wave statistic being considered, in which the energy subrange becomes important. For example, phase fluctuations in line-of-sound propagation are driven by the most energetic turbulent motions along the propagation path. Since the largest scale motions are generally the most energetic, the energy subrange generally contributes most strongly to the phase fluctuations. Therefore energy subrange scattering can be important even for wavelengths very small compared to the outer scale. This fact is evident from several acoustical studies (Refs. 7–9), and has even been discussed in the context of optical propagation by Lawrence and Strohbehn[10] among others.

Unfortunately, calculation of the effects of energy-subrange turbulence on wave scattering is an inherently difficult subject. Unlike the inertial subrange, there are no universal statistical treatments available for the energy subrange. Turbulent motions in the energy subrange depend on the energetics of a particular flow, and are statistically anisotropic (dependent on orientation) and inhomogeneous (dependent on position) as a result. An example of anisotropy is that the variance for turbulent velocity fluctuations in the direction of the mean wind is several times larger than the variance for vertical velocity fluctuations. An example of inhomogeneity is the dependence of the variances on the height above the ground. Similar manifestations of anisotropy and inhomogeneity are evident in the turbulence length scales.

The subject of this paper is the effect of turbulence anisotropy on acoustic propagation. Statistical inhomogeneity is also introduced by assuming that the length scales of the turbulence are proportional to height. The specific case considered is that of a shear-driven, neutral atmospheric surface layer. *Neutral*, in the terminology of geophysical fluid dynamics, means an absence of buoyancy effects. Hence radiative heating and cooling of the ground (and the resulting vertical density contrasts in the overlying air) are neglected. This leaves wind shear as the dominant mechanism for generating the turbulence. Atmospheric conditions are usually nearly neutral when skies are cloudy and the wind is strong. By neglecting buoyantly generated turbulence, I do not intend to imply that this sort of turbulence is unimportant for acoustic wave propagation. The restriction to shear instabilities here is only for simplicity, and hopefully later studies can incorporate buoyancy instabilities.

The derivation of the turbulence models considered in

this paper is more rigorous than for the model developed in an earlier study by Wilson and Thomson.[8] Specifically, the models used here are consistent with the incompressibility property of the turbulent velocity field. All model parameters are chosen on the basis of atmospheric measurements, as opposed to the approximate scaling arguments that were used to infer some parameters in the Wilson and Thomson model. Furthermore, most of the models in this paper have a realistic inertial subrange. One drawback of the models considered here is that they are much more complex than Wilson and Thomson's.

Much of the turbulence modeling effort in this paper derives from the previous work of Kristensen *et al.*[11] They developed an anisotropic spectral model for turbulence and applied it to turbulence originating from various instability mechanisms, including the surface-layer shear. In this paper, I apply the Kristensen *et al.* model to acoustic propagation. Two simplified versions of the Kristensen *et al.* model are also developed: an anisotropic von Kármán model, and an anisotropic Gaussian model. These three models based on the work of Kristensen *et al.* are the subject of Sec. II.

A fourth model considered in this paper, due to Mann,[12] uses an entirely different approach than the one taken by Kristensen *et al.* It is based on rapid distortion theory, which hypothesizes that the shear distortions to an eddy can be calculated from linearized Navier–Stokes equations. The Mann model is summarized in Sec. III.

Before discussing the turbulence models, however, I will consider in Sec. I the equations needed for the acoustical calculations. The equations are based on those developed by Dashen[13] for propagation through random, anisotropic, and inhomogeneous media. Dashen's equations were derived using a path integral approach that assumes the validity of the parabolic approximation to the wave equation, as well as the Markov approximation. They are equivalent to equations given by Rytov *et al.*[14] and Ostashev[15] when specialized to the case of propagation through statistically isotropic and homogeneous turbulence.

I. EXTINCTION AND COHERENCE FOR PROPAGATION THROUGH ANISOTROPIC, RANDOM MEDIA

In this paper, only the first and second moments of the forward-scattered sound field will be considered. Propagation is assumed to be ''line-of-sound;'' that is, ground reflections and refraction are neglected. Validity of the Markov approximation is assumed, which most importantly requires that the outer scale of the turbulence and the coherence radius of the sound field are much larger than the wavelength.[14,15]

Let us designate the acoustic pressure field generated by a point source at the origin as $p(x',\mathbf{r}'_\perp)$. Here the x' axis is the nominal direction of propagation, $\mathbf{r}'$ is the receiver location, and $\mathbf{r}'_\perp=\mathbf{r}'-x'\,\mathbf{e}'_1$ is the separation transverse to the propagation path, with $\mathbf{e}'_1$ being the unit vector along the x' axis. (Primes are used in this paper for the coordinate system aligned with the direction of propagation; unprimed coordinates will be used later for the system having the x axis aligned with the mean wind.) Assuming the validity of the parabolic approximation to the wave equation, as well as the Markov approximation, the mean coherent pressure field decreases exponentially and is given by[13,15]

$$\langle p(x',\mathbf{r}'_\perp)\rangle = p_0(x',\mathbf{r}'_\perp)\exp\left(-\frac{\Phi^2}{2}\right), \tag{1}$$

where $p_0(x',\mathbf{r}'_\perp)=\exp(ik_0r')/(4\pi r')$ is the pressure in the absence of turbulence, k_0 is the acoustic wave number, and Φ is the rms phase fluctuation determined using first-order geometric optics. It can be shown that[13]

$$\Phi^2 \simeq k_0^2 x' \int_{-\infty}^{\infty} R(s\mathbf{e}'_1)\,ds, \tag{2}$$

where $R(\mathbf{r})$ is the three-dimensional (3-D) correlation function of $\mu=1-n$, n being the index of refraction. If we define the integral length scale in the direction of propagation as

$$\mathcal{L}=\frac{1}{\sigma^2}\int_0^{\infty} R(s\mathbf{e}'_1)\,ds, \tag{3}$$

where σ^2 is the variance of μ, the rms phase fluctuation becomes

$$\Phi^2 \simeq 2\sigma^2 k_0^2 x' \mathcal{L}. \tag{4}$$

The distance at which the mean pressure decays to $1/e$ times its value in the absence of turbulence is therefore

$$\xi=(\sigma^2 k_0^2 \mathcal{L})^{-1}. \tag{5}$$

In this paper ξ is called the *extinction distance*. An alternative expression for the extinction distance, which will be useful later on, involves the *two-dimensional (2-D) correlation function*

$$b(\mathbf{r}'_\perp)=\frac{1}{2\pi}\int_{-\infty}^{\infty} R(\mathbf{r}'_\perp+x'\mathbf{e}'_1)dx'. \tag{6}$$

Since $b(\mathbf{0})=(\sigma^2/\pi)\mathcal{L}$, the extinction distance is equal to $\xi=[\pi k_0^2 b(\mathbf{0})]^{-1}$.

The mutual coherence function (MCF), which represents the cross correlation between harmonic signals received by a pair of sensors whose separation is transverse to the direction of propagation, is given by[13,15]

$$\Gamma(x',\boldsymbol{\rho}'_\perp)=\frac{\langle p(x',\mathbf{r}'_\perp)p^*(x',\mathbf{r}'_\perp+\boldsymbol{\rho}'_\perp)\rangle}{p_0(x',\mathbf{r}'_\perp)p_0^*(x',\mathbf{r}'_\perp+\boldsymbol{\rho}'_\perp)}=\exp\left[-\frac{1}{2}D_\phi(\boldsymbol{\rho}'_\perp)\right], \tag{7}$$

where $D_\phi(\boldsymbol{\rho}'_\perp)$ is the phase structure function of first-order geometric optics, and $\boldsymbol{\rho}_\perp$ is the separation between the sensors. It is assumed that the separation is perpendicular to the direction of propagation. The phase structure function is equal to

$$D_\phi(\mathbf{r}'_\perp)=4\pi k_0^2 x'[b(\mathbf{0})-b(\mathbf{r}'_\perp)]. \tag{8}$$

It is convenient to define a *2-D structure function* as

$$d(\mathbf{r}'_\perp)=2[b(\mathbf{0})-b(\mathbf{r}'_\perp)], \tag{9}$$

so that

$$D_\phi(\mathbf{r}'_\perp)=2\pi k_0^2 x' d(\mathbf{r}'_\perp). \tag{10}$$

Note that the 2-D structure function can be written as

$$d(\mathbf{r}'_\perp) = \frac{1}{2\pi} \int_{-\infty}^{\infty} D(\mathbf{r}'_\perp + s\mathbf{e}'_1)\, ds, \tag{11}$$

where $D(\mathbf{r})$ is the usual 3-D structure function encountered in the turbulence literature, given by

$$D(\mathbf{r}) = \langle [n(\mathbf{r}) - n(\mathbf{0})]^2 \rangle = 2[R(\mathbf{0}) - R(\mathbf{r})]. \tag{12}$$

The coherence radius $\mathbf{r}_c$ is defined as the value of $\boldsymbol{\rho}'_\perp$ for which $\Gamma = 1/e$. It is the root of the equation

$$d(\mathbf{r}_c) = (\pi k_0^2 x')^{-1}. \tag{13}$$

In this paper, it is assumed that the main contribution to the index-of-refraction fluctuations comes from turbulent velocity fluctuations. This approximation is usually a very reasonable one for the atmosphere, particularly for neutral conditions.[16] As a result, $\mu \simeq v_i/c_0$, where v_i is the turbulent velocity fluctuation in the direction of propagation.[15] Hence we can replace the correlation function for μ with $R_{ii}(\mathbf{r})/c_0^2$ (no summation of repeated indices implied), where $R_{ij}(\mathbf{r}) = \langle v_i(\mathbf{0}) v_j(\mathbf{r}) \rangle$ is the cross-correlation function between v_i and v_j. Our final equations for the mean pressure and coherence are

$$\langle p(x', \mathbf{r}'_\perp) \rangle = p_0(x', \mathbf{r}'_\perp) \exp\left[-\frac{\pi}{c_0^2} k_0^2 x' b_{ii}(\mathbf{0}) \right], \tag{14}$$

and

$$\Gamma(x', \mathbf{r}'_\perp) = \exp\left[-\frac{\pi}{c_0^2} k_0^2 x' d_{ii}(\mathbf{r}'_\perp) \right], \tag{15}$$

where $b_{ii}(\mathbf{r})$ is the 2-D correlation function of the velocity fluctuation in the direction of propagation and $d_{ii}(\mathbf{r})$ is the corresponding 2-D structure function.

According to the two previous equations, we must calculate the 2-D correlation (and structure) functions of the turbulence to determine the acoustic extinction and coherence. However, it is not always convenient to compute the 2-D correlations directly from their definitions in terms of the 3-D correlation function, because the turbulence models are usually developed in the wave number spectral domain rather than in the spatial domain. Hence it is worthwhile to develop some relationships that give the 2-D correlation directly in terms of the spectra. Such relationships can be derived on the basis that the 3-D correlations R_{ij} and spectral densities Φ_{ij} constitute a Fourier transform pair:

$$R_{ij}(\mathbf{r}) = \int \Phi_{ij}(\mathbf{k}) \exp(i\mathbf{k}\cdot\mathbf{r})\, d^3k, \tag{16}$$

$$\Phi_{ij}(\mathbf{k}) = \frac{1}{(2\pi)^3} \int R_{ij}(\mathbf{r}) \exp(-i\mathbf{k}\cdot\mathbf{r})\, d^3r. \tag{17}$$

By Fourier transforming Eq. (16) with respect to r_1 and then setting $k_1 = 0$, we find

$$b_{ij}(\mathbf{r}_\perp) = \int \Phi_{ij}(\mathbf{k}_\perp) \exp(i\mathbf{k}_\perp \cdot \mathbf{r}_\perp)\, d^2k_\perp. \tag{18}$$

In the general case of anisotropic turbulence, the 2-D correlations depend on the direction of the propagation as well as the direction of the sensor displacement $\mathbf{r}'_\perp$. But let us consider for a moment the case of isotropic turbulence, for which the 3-D spectra can be determined from the energy spectrum $E(k)$ using the following equation:[17]

$$\Phi_{ij}(\mathbf{k}) = \frac{E(k)}{4\pi k^2} \left(\delta_{ij} - \frac{k_i k_j}{k^2} \right). \tag{19}$$

By substituting Eq. (18) into (16), setting $i = j$, and rewriting the integration in cylindrical coordinates, we find

$$b_{ii}(r_\perp) = \frac{1}{2} \int_0^\infty \frac{E(k_\perp)}{k_\perp} J_0(k_\perp r_\perp)\, dk_\perp, \tag{20}$$

where J_0 is the cylindrical Bessel function. Note that in isotropic turbulence, the 2-D structure function depends only on the magnitude of $\mathbf{r}_\perp$.

In the next section of this paper, several anisotropic turbulence models will be considered that are based on a suggestion due to Kristensen *et al.*[11] According to this suggestion, the 3-D spectral tensor in anisotropic turbulence can be modeled approximately with the equation

$$\Phi_{ij}(\mathbf{k}) = \sum_{m=1}^{3} A_m(k) \left(\delta_{mi} - \frac{k_m k_i}{k^2} \right) \left(\delta_{mj} - \frac{k_m k_j}{k^2} \right). \tag{21}$$

The A_m's are three independent scalar energy functions. When $A_1(k) = A_2(k) = A_3(k) \equiv A(k)$, the equation for the 3-D spectra reduces to the one for isotropic turbulence, with $E(k) = 4\pi k^2 A(k)$. In general, $E(k) = \frac{4}{3}\pi k^2 [A_1(k) + A_2(k) + A_3(k)]$. If one assumes validity of the Kristensen *et al.* spectral tensor, the 2-D correlation becomes

$$b_{ii}(r_\perp) = 2\pi \int_0^\infty A_i(k_\perp) J_0(k_\perp r_\perp) k_\perp\, dk_\perp. \tag{22}$$

This result implies $b_{ii}(r_\perp)/2\pi$ and $A_i(k_\perp)$ are a Hankel-transform pair. Also note that the Kristensen *et al.* equation for the 3-D spectral tensor causes the 2-D correlation to be independent of the direction of sensor separation $\mathbf{r}'_\perp$, as in isotropic turbulence. However, the 2-D correlation *does* depend on the orientation of the propagation path when the Kristensen *et al.* tensor is used, unlike the case of isotropic turbulence. It needs to be stressed that the Kristensen *et al.* tensor for the 3-D spectra does not constitute a fully general description of anisotropic turbulence. As mentioned above, the 2-D correlation in anisotropic turbulence will depend, in general, on the direction of $\mathbf{r}'_\perp$.

II. MODELS BASED ON THE KRISTENSEN *ET AL.* ANISOTROPIC TENSOR

The turbulence models derived in this section are all based on previous suggestions made by Kristensen *et al.*[11] In my view, their paper weaves together three particularly significant ideas, which can be considered separately for the purposes of this paper. The first of these ideas hypothesizes a particular equation for the 3-D spectral density tensor, given above as Eq. (21). Although the Kristensen *et al.* spectral density tensor does represent a reasonable first step toward

incorporating anisotropy, it also has some shortcomings. For example, it predicts zero covariance between the along-wind and vertical velocity fluctuations, although this covariance is intrinsically nonzero in a shear layer.

The second main idea in the Kristensen *et al.* paper is a mathematical procedure for determining the three scalar energy functions from 1-D spectral densities, such as can be observed by spatially fixed wind sensors (anemometers). This procedure will be discussed in more detail shortly. The third idea is a versatile three-parameter equation used to model the observed 1-D spectral densities.

A total of three different statistical models for anisotropic turbulence will be considered in this section. All are developed using the Kristensen *et al.* 3-D spectral density tensor, along with their procedure for determining the three scalar energy functions from the 1-D spectra. However, for the first and second models (the anisotropic von Kármán and Gaussian models), the equations used for the 1-D spectra are simpler than the Kristensen *et al.* equation, containing two parameters instead of three. My reason for considering anisotropic versions of the von Kármán and Gaussian models is that the isotropic forms of these models have been employed extensively in atmospheric acoustics; therefore, it is interesting to see how they can be generalized. The third model considered uses the Kristensen *et al.* 1-D spectral equation verbatim and hence is exactly the same as their model for neutral surface-layer turbulence. It is simply repeated here (in condensed form) for convenience. No isotropic version of the full Kristensen *et al.* model has been employed previously in wave propagation studies.

A. Anisotropic von Kármán model

Derivation of an anisotropic model, which reduces to the popular von Kármán model in the isotropic limit, is outlined in this section. The reader may wish to refer to Wilson[18] or Kristensen *et al.*[11] to fill in some of the details. We start by considering the family of 1-D turbulence velocity spectra having the wave number axis parallel to the direction of the mean wind. These spectra can be measured by recording time series with an anemometer fixed to a tower and then converting the time series to an approximate spatial series by invoking Taylor's ''frozen turbulence'' hypothesis.[19] The Fourier transform of the approximate spatial series can then be used to determine the spatial spectra. The spectrum of the velocity component aligned with the direction of the mean wind, called the ''longitudinal'' spectrum, is modeled by the equation[20]

$$F_L(k)=\frac{1}{B(\frac{1}{2},\frac{1}{3})}\frac{\sigma_1^2\ell_1}{(1+k^2\ell_1^2)^{5/6}}, \tag{23}$$

where k is the turbulence wave number, $B(x,y)=\Gamma(x)\Gamma(y)/\Gamma(x+y)$ is the beta function, σ_1^2 is the variance of the longitudinal velocity, and ℓ_1 is a length scale parameter. The coordinate system has the x_1 axis aligned with the mean wind, and the x_3 axis vertical. In isotropic turbulence, the ''transverse'' or ''crosswind'' (horizontal and perpendicular to the mean wind) spectrum $F_T(k)$ and the ''vertical'' spectrum $F_V(k)$ are equal to[19]

TABLE I. Values for the turbulent velocity variances σ_i^2 used in the isotropic von Kármán model and the anisotropic models based on Kristensen *et al.*'s spectral tensor. The variances are normalized by u_*^2, the square of the friction velocity.

Direction	Isotropic von Kármán model	Anisotropic models
	σ_i^2/u_*^2	σ_i^2/u_*^2
Along wind ($i=1$)	2.97	4.77
Crosswind ($i=2$)	2.97	2.68
Vertical ($i=3$)	2.97	1.46

$$F_T(k)=F_V(k)=\frac{1}{2}\left[F_L(k)-k\frac{dF_L(k)}{dk}\right]. \tag{24}$$

Since

$$F_L(k)-k\frac{dF_L(k)}{dk}=\frac{1}{B(\frac{1}{2},\frac{1}{3})}\frac{\sigma_1^2\ell_1}{(1+k^2\ell_1^2)^{5/6}}\times\left(1+\frac{5}{3}\frac{k^2\ell_1^2}{1+k^2\ell_1^2}\right),$$

natural choices for $F_T(k)$ and $F_V(k)$ are

$$F_T(k)=\frac{1}{2B(\frac{1}{2},\frac{1}{3})}\frac{\sigma_2^2\ell_2}{(1+k^2\ell_2^2)^{5/6}}\left(1+\frac{5}{3}\frac{k^2\ell_2^2}{1+k^2\ell_2^2}\right) \tag{25}$$

and

$$F_V(k)=\frac{1}{2B(\frac{1}{2},\frac{1}{3})}\frac{\sigma_3^2\ell_3}{(1+k^2\ell_3^2)^{5/6}}\left(1+\frac{5}{3}\frac{k^2\ell_3^2}{1+k^2\ell_3^2}\right). \tag{26}$$

When the variances σ_i^2 are all equal, and the length scales ℓ_i all equal, Eqs. (23), (25), and (26) reduce to the 1-D spectra of the isotropic von Kármán model. By defining

$$F_0(\sigma,\ell,h,\nu;k)=\frac{\sigma^2\ell}{B(\frac{1}{2},\nu)}\frac{1}{(1+k^2\ell^2)^{\nu+1/2}}\left(1+\frac{hk^2\ell^2}{1+k^2\ell^2}\right), \tag{27}$$

we can conveniently abbreviate Eqs. (23), (25), and (26) as $F_L(k)=F_0(\sigma_1,\ell_1,0,\frac{1}{3};k)$, $F_T(k)=(\frac{1}{2})F_0(\sigma_2,\ell_2,\frac{5}{3},\frac{1}{3};k)$, and $F_V(k)=(\frac{1}{2})F_0(\sigma_3,\ell_3,\frac{5}{3},\frac{1}{3};k)$.

The parameters in the anisotropic von Kármán model can be selected by matching the variances and inertial-subrange asymptotes in the Kaimal *et al.*[21] empirical equations for neutral surface-layer turbulence. The procedure for doing so is straightforward and described in the Appendix, with the results given in Tables I and II. It should be pointed out that the requirement of isotropy in the inertial subrange ($k\ell_i\gg 1$) implies that only four of the six parameters in the anisotropic von Kármán model are independent. Specifically, we must have $\sigma_1^2\ell_1^{-2/3}=\sigma_2^2\ell_2^{-2/3}=\sigma_3^2\ell_3^{-2/3}$. The values in Tables I and II for the isotropic von Kármán model were chosen by setting $\sigma_{\text{avg}}^2=(\sigma_1^2+\sigma_2^2+\sigma_3^2)/3$, and ℓ from the requirement $\sigma_{\text{avg}}^2\ell^{-2/3}=\sigma_1^2\ell_1^{-2/3}$, etc. Note that the variances are all proportional to u_*^2, the friction velocity (defined in the Appendix), and the length scales are all proportional to z, the height. The 1-D spectra for the anisotropic

TABLE II. Values for the length scales and other parameters used in the various turbulence models. The length scales are normalized by z, the height from the ground.

Direction	von Kármán (isotropic)	von Kármán (anisotropic)	Gaussian (anisotropic)	Kristensen *et al.* (anisotropic)	
	ℓ_i/z	ℓ_i/z	L_i/z	l_i/z	μ_i
Along wind ($i=1$)	1.79	3.64	6.21	5.24	0.52
Crosswind ($i=2$)	1.79	1.53	3.59	2.52	0.49
Vertical ($i=3$)	1.79	0.617	0.774	0.59	0.68

von Kármán model are plotted in Fig. 1. In this figure, the curves labelled ''Kristensen *et al.*'' are nearly identical to the Kaimal *et al.* empirical equations. The von Kármán spectra therefore have sharper spectral peaks than the empirical results.

Determination of the extinction distance for propagation in the along-wind direction is a simple matter when the 1-D spectrum $F_L(k)$ is known. Using the Fourier transform relations, one can show that $b_{11}(\mathbf{0})=F_L(0)$, so $F_L(0)$ can be used in place of $b_{11}(\mathbf{0})$ in Eq. (14). But it is not true that $b_{22}(\mathbf{0})=F_T(0)$ or $b_{33}(\mathbf{0})=F_V(0)$. Therefore in the crosswind direction, we are forced to use Eq. (22), with $r_\perp=0$:

$$b_{22}(0)=2\pi\int_0^\infty A_2(k_\perp)k_\perp\,dk_\perp\,, \tag{28}$$

and similarly in the vertical direction. Now it is evident that we must calculate the scalar energy functions $A_2(k)$ and $A_3(k)$ to determine the extinction distances in the crosswind and vertical directions. It is necessary to find all of the $A_i(k)$ to calculate the 2-D structure functions needed for the MCF.

Fortunately Kristensen *et al.*[11] have devised a method for determining the $A_i(k)$ from $F_L(k)$, $F_T(k)$, and $F_V(k)$. Their method is based on the following equations, which they derive:

$$A_1(k)=\frac{k}{4\pi}\frac{d}{dk}\frac{1}{k}\frac{dF_L(k)}{dk}+\frac{1}{2\pi}[-\beta(k^{-2})-\zeta(k^{-2})], \tag{29}$$

$$A_2(k)=\frac{k}{4\pi}\frac{d}{dk}\frac{1}{k}\frac{dF_L(k)}{dk}+\frac{1}{2\pi}[\alpha(k^{-2})-3\beta(k^{-2})-\zeta(k^{-2})], \tag{30}$$

and

$$A_3(k)=\frac{k}{4\pi}\frac{d}{dk}\frac{1}{k}\frac{dF_L(k)}{dk}+\frac{1}{2\pi}[-\alpha(k^{-2})-3\beta(k^{-2})-\zeta(k^{-2})]. \tag{31}$$

(These equations are actually in a slightly different, but equivalent, form than the one given by Kristensen *et al.*[11] The function ζ was not defined in their paper.) The first term in Eqs. (29)–(31) represents the isotropic contribution. By differentiation of Eq. (23), this term is found to be

$$\frac{k}{4\pi}\frac{d}{dk}\frac{1}{k}\frac{dF_L(k)}{dk}=\frac{55\sigma_1^2}{36\pi B(\frac{1}{2},\frac{1}{3})}\frac{k^2\ell_1^5}{(1+k^2\ell_1^2)^{17/6}}. \tag{32}$$

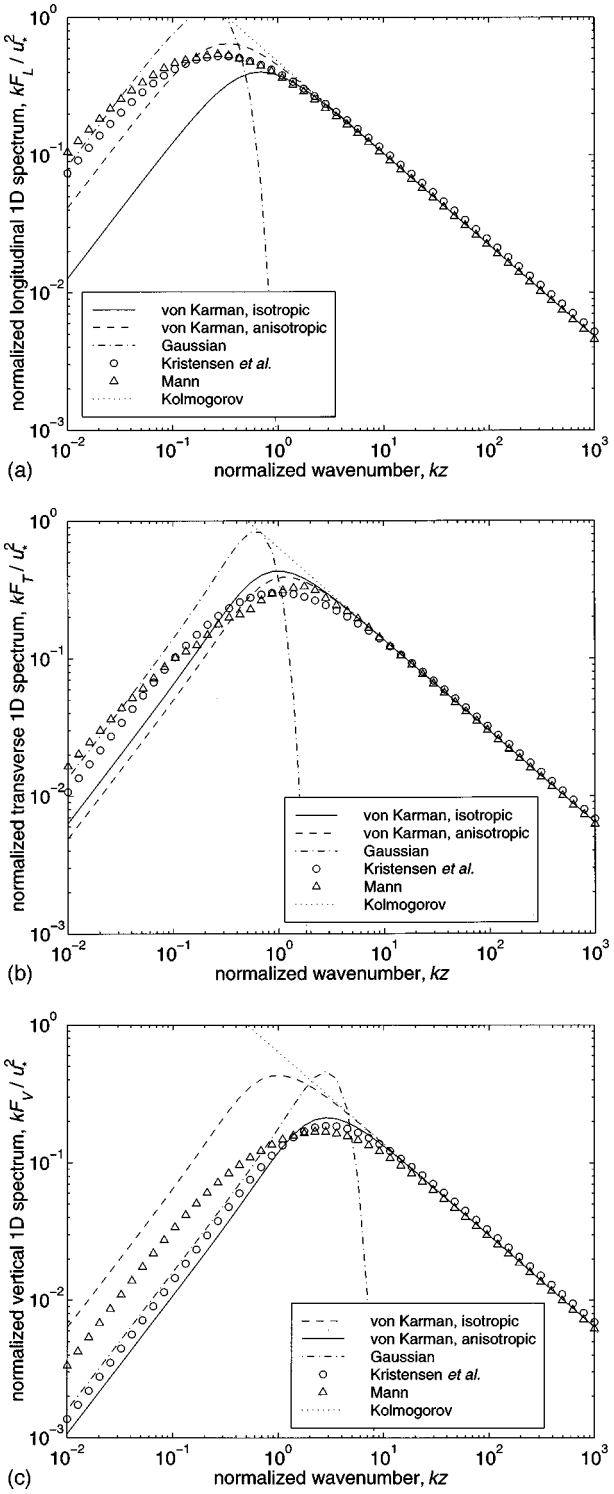

FIG. 1. (a) Modeled one-dimensional spectra for fluctuations of the along-wind velocity component, $F_L(k)$, for the various turbulence models. (b) Modeled one-dimensional spectra for fluctuations of the crosswind velocity component, $F_T(k)$. (c) Modeled one-dimensional spectra for fluctuations of the vertical velocity component, $F_V(k)$. In each plot the spectrum has been multiplied by k/u_*^2, where k is the wave number in the along-wind direction and u_* is the friction velocity.

Derivation of the terms in Eqs. (29)–(31) involving the functions $\alpha(s)$, $\beta(s)$, and $\zeta(s)$ begins by defining the ''residual'' functions

$$f(s)=[F_T(k)-F_V(k)]s^2 \tag{33}$$

and

$$g(s)=\{F_L(k)-kF_L'(k)-[F_T(k)+F_V(k)]\}s^2, \tag{34}$$

where $s\equiv k^{-2}$. From Eqs. (23)–(27), we find

$$f(s)=\frac{s^2}{2}[F_0(\sigma_2,\ell_2,\tfrac{5}{3},\tfrac{1}{3};s^{-1/2})-F_0(\sigma_3,\ell_3,\tfrac{5}{3},\tfrac{1}{3};s^{-1/2})] \tag{35}$$

and

$$g(s)=\frac{s^2}{2}[2F_0(\sigma_1,\ell_1,\tfrac{5}{3},\tfrac{1}{3};s^{-1/2})-F_0(\sigma_2,\ell_2,\tfrac{5}{3},\tfrac{1}{3};s^{-1/2}) -F_0(\sigma_3,\ell_3,\tfrac{5}{3},\tfrac{1}{3};s^{-1/2})]. \tag{36}$$

The functions $\alpha(s)$, $\beta(s)$, and $\zeta(s)$ in Eqs. (29)–(31) can be determined from the integrals[11]

$$\alpha(s)=\frac{s^{+1/\sqrt{2}}}{\sqrt{2}}\int_0^s t^{1-1/\sqrt{2}}f'''(t)\,dt - \frac{s^{-1/\sqrt{2}}}{\sqrt{2}}\int_0^s t^{1+1/\sqrt{2}}f'''(t)\,dt, \tag{37}$$

$$\beta(s)=\frac{s^{1/3}}{3}\int_0^s t^{2/3}g'''(t)\,dt, \tag{38}$$

and

$$\zeta(s)=-s^{-1}\int_0^s t^2 g'''(t)\,dt. \tag{39}$$

Hence we need to solve integrals of the form

$$I(\sigma,\ell,q;s)=\frac{qs^q}{2}\int_0^s t^{1-q}\frac{d^3}{dt^3}[t^2F_0(\sigma,\ell,\tfrac{5}{3},\tfrac{1}{3};t^{-1/2})]\,dt. \tag{40}$$

With this definition, we have

$$\alpha(s)=I\left(\sigma_2,\ell_2,\frac{1}{\sqrt{2}};s\right)-I\left(\sigma_3,\ell_3,\frac{1}{\sqrt{2}};s\right) +I\left(\sigma_2,\ell_2,-\frac{1}{\sqrt{2}};s\right)-I\left(\sigma_3,\ell_3,-\frac{1}{\sqrt{2}};s\right), \tag{41}$$

$$\beta(s)=2I(\sigma_1,\ell_1,\tfrac{1}{3};s)-I(\sigma_2,\ell_2,\tfrac{1}{3};s) -I(\sigma_3,\ell_3,\tfrac{1}{3};s), \tag{42}$$

and

$$\zeta(s)=2I(\sigma_1,\ell_1,-1;s)-I(\sigma_2,\ell_2,-1;s) -I(\sigma_3,\ell_3,-1;s). \tag{43}$$

It can be shown that

$$\frac{d}{dt}F_0(\sigma,\ell,h,\nu;t^{-1/2})=\frac{\nu(\nu-h+\frac{1}{2})}{\nu+\frac{1}{2}}\frac{\ell^2}{s^2} \times F_0\left(\sigma,\ell,\frac{h(\nu+\frac{3}{2})}{\nu-h+\frac{1}{2}},\nu+1;t^{-1/2}\right),$$

from which follows recursively the triple derivative needed in Eq. (40),

$$\frac{d^3}{dt^3}[t^2F_0(\sigma,\ell,\tfrac{5}{3},\tfrac{1}{3};t^{-1/2})] =-\frac{140}{27}\frac{\ell^6}{s^4}F_0\left(\sigma,\ell,-\frac{23}{15},\frac{10}{3};t^{-1/2}\right).$$

Using the definition of the incomplete beta function $B_z(a,b)$ [e.g., Eq. (6.6.1) in Abramowitz and Stegun[24]], we can now write the function I as

$$I(\sigma,\ell,q;k^{-2})=\frac{4675}{432}\frac{q\sigma^2\ell^3}{B(\frac{1}{2},\frac{1}{3})}(k\ell)^{-2q} \times[\tfrac{23}{15}B_{1/(1+k^2\ell^2)}(\tfrac{11}{6}-q,3+q) -B_{1/(1+k^2\ell^2)}(\tfrac{11}{6}-q,2+q)]. \tag{44}$$

Substitution of this result into Eqs. (41)–(43) yields the functions $\alpha(s)$, $\beta(s)$, and $\zeta(s)$, and hence the three scalar energy functions.

The 2-D correlation functions now follow by substituting the scalar energy functions into Eq. (22). The isotropic contribution to the 2-D correlation is found by integrating Eq. (32). This integration presents no great difficulties and we find

$$b_{iso}(\sigma_1,\ell_1;r)=\int_0^\infty\left[\frac{k^2}{2}\frac{d}{dk}\frac{1}{k}\frac{dF_L(k)}{dk}\right]J_0(kr)\,dk =\frac{2\sigma_1^2\ell_1}{\sqrt{\pi}\Gamma(\frac{1}{3})}\left(\frac{r}{2\ell_1}\right)^{5/6} \times\left[K_{5/6}\left(\frac{r}{\ell_1}\right)-\frac{r}{2\ell_1}K_{1/6}\left(\frac{r}{\ell_1}\right)\right]. \tag{45}$$

To find the anisotropic contributions, we need to calculate integrals of the form

$$\overline{I}(\sigma,\ell,q;r)=\int_0^\infty I(\sigma,\ell,q;k^{-2})J_0(kr)k\,dk, \tag{46}$$

in which $I(\sigma,\ell,q;s)$ contains incomplete beta functions. Not surprisingly, the integral has no solution in terms of common higher functions such as Bessel functions. One possible approach to solving the integral is to rewrite the incomplete beta functions as Meijer's G-functions. (Discussions of G-functions can be found in Erdélyi *et al.*[22] and Gradshteyn and Ryzhik.[23]) This can be done by first converting the incomplete beta function to a hypergeometric function having argument $-(k\ell)^{-2}$, using Eqs. (6.6.8) and (15.3.4) in Abramowitz and Stegun.[24] Next the hypergeometric function is recast as a G-function using Eq. (74), Sec. 5.6, and Eq. (9), Sec. 5.3, from Erdélyi *et al.*,[22] with result

$$B_{1/(1+k^2\ell^2)}(a,b)=\frac{(k^2\ell^2)^{-a-1}}{\Gamma(a+b)} \times G_{22}^{21}\left(k^2\ell^2\left|\begin{matrix}2,a+2\\ a+1,a+b+1\end{matrix}\right.\right). \tag{47}$$

It is now possible to calculate $\overline{I}(\sigma,\ell,q;r)$ using Eq. (7.822.1) in Gradshteyn and Ryzhik.[23] We find

$$\overline{I}(\sigma,\ell,q;r)=\frac{q\sigma^2\ell}{2\sqrt{\pi}\Gamma(\frac{1}{3})}\left(\frac{r}{2\ell}\right)^{11/3}\times\left[G_{42}^{22}\left(\frac{4\ell^2}{r^2}\middle|\begin{matrix}\frac{17}{6},2,\frac{23}{6}-q,\frac{17}{6}\\ \frac{17}{6}-q,\frac{35}{6}\end{matrix}\right)-\frac{5}{2}G_{42}^{22}\left(\frac{4\ell^2}{r^2}\middle|\begin{matrix}\frac{17}{6},2,\frac{23}{6}-q,\frac{17}{6}\\ \frac{17}{6}-q,\frac{29}{6}\end{matrix}\right)\right]. \tag{48}$$

The G-functions can be converted to a lower order using a recursion relation [Eq. (12), Sec. 5.3 in Ref. 22], and a reduction formula [Eq. (7), Sec. 5.3 in Ref. 22]. The result is

$$\overline{I}(\sigma,\ell,q;r)=\frac{q\sigma^2\ell}{2\sqrt{\pi}\Gamma(\frac{1}{3})}\left(\frac{r}{2\ell}\right)^{11/3}\times\left[G_{13}^{21}\left(\frac{r^2}{4\ell^2}\middle|\begin{matrix}q-\frac{11}{6}\\ -\frac{11}{6},-1,q-\frac{17}{6}\end{matrix}\right)-8G_{13}^{21}\left(\frac{r^2}{4\ell^2}\middle|\begin{matrix}q-\frac{11}{6}\\ -\frac{5}{6},-1,q-\frac{17}{6}\end{matrix}\right)+\frac{13}{2}G_{13}^{21}\left(\frac{r^2}{4\ell^2}\middle|\begin{matrix}q-\frac{11}{6}\\ \frac{1}{6},-1,q-\frac{17}{6}\end{matrix}\right)-G_{13}^{21}\left(\frac{r^2}{4\ell^2}\middle|\begin{matrix}q-\frac{11}{6}\\ \frac{7}{6},-1,q-\frac{17}{6}\end{matrix}\right)\right]. \tag{49}$$

[Equation (9), Sec. 5.3 in Ref. 22, was also used to derive this result.] For the 2-D correlation function in the along-wind direction, we now have from Eq. (29)

$$b_{11}(r)=b_{iso}(\sigma_1,\ell_1;r)-\overline{\beta}(r)-\overline{\zeta}(r), \tag{50}$$

where, from Eq. (42),

$$\overline{\beta}(r)=2\overline{I}(\sigma_1,\ell_1,\tfrac{1}{3};r)-\overline{I}(\sigma_2,\ell_2,\tfrac{1}{3};r)-\overline{I}(\sigma_3,\ell_3,\tfrac{1}{3};r). \tag{51}$$

Equations for $b_{22}(r)$, $b_{33}(r)$, $\overline{\alpha}(r)$, and $\overline{\zeta}(r)$ follow with obvious replacements.

Since routines for computing Meijer's G-functions are not widely available, it is often impractical to calculate the 2-D correlations by using Eq. (49).[25] Rather, they must be calculated by performing the integration in Eq. (46) numerically.

B. Anisotropic Gaussian model

Although it is rather unrealistic, the isotropic Gaussian model has proven quite popular. The main advantage of the isotropic Gaussian model is that the equations for the correlation and spectral functions are easily obtainable. The disadvantage is that it does not accurately describe the inertial subrange. In this section we explore how the isotropic Gaussian model can be generalized to the anisotropic case. The basic assumption is that the longitudinal correlation function has the form

$$R_L(r)=\sigma_1^2\exp\left(-\frac{r^2}{L_1^2}\right). \tag{52}$$

By Fourier transforming the correlation function, we find

$$F_L(k)=\frac{\sigma_1^2L_1}{2\sqrt{\pi}}\exp\left(-\frac{k^2L_1^2}{4}\right). \tag{53}$$

As mentioned previously, $F_T(k)=F_V(k)=(\frac{1}{2})[F_L(k)-kF_L'(k)]$ in isotropic turbulence. Hence a natural choice for $F_T(k)$ is

$$F_T(k)=\frac{\sigma_2^2L_2}{4\sqrt{\pi}}\left(1+\frac{k^2L_2^2}{2}\right)\exp\left(-\frac{k^2L_2^2}{4}\right), \tag{54}$$

and similarly for $F_V(k)$.

Since Gaussian models do not, by nature, have a realistic inertial subrange, it is reasonable to select the model parameters to obtain the best possible fit to spectral characteristics of the energy subrange, such as variances and integral length scales. A reasonable approach (described in the Appendix) is to select the parameters to reproduce the variances and integral length scales of the Kaimal *et al.*[21] empirical equations. The results are shown in Tables I and II, and the 1-D spectra are plotted and compared to other models in Fig. 1. As one would expect, the Gaussian spectra are satisfactory in the energy subrange ($kz\ll 1$), but very poor in the inertial subrange ($kz\gg 1$).

As for the von Kármán model, we determine the scalar energy functions A_i using Eqs. (29)–(31). For the Gaussian model, the isotropic term in those equations is

$$\frac{k}{4\pi}\frac{d}{dk}\frac{1}{k}\frac{dF_L(k)}{dk}=\frac{\sigma_1^2k^2L_1^5}{32\pi^{3/2}}\exp\left(-\frac{k^2L_1^2}{4}\right). \tag{55}$$

Using the same method as before to calculate $\alpha(s)$, $\beta(s)$, and $\zeta(s)$, we arrive at the residual functions

$$f(s)=\frac{s^2}{2}[G_0(\sigma_2,L_2;s^{-1/2})-G_0(\sigma_3,L_3;s^{-1/2})],$$

and

$$g(s)=\frac{s^2}{2}[2G_0(\sigma_1,L_1;s^{-1/2})-G_0(\sigma_2,L_2;s^{-1/2})-G_0(\sigma_3,L_3;s^{-1/2})],$$

where the function G_0, defined by

$$G_0(\sigma,L;k)=\frac{\sigma^2L}{2\sqrt{\pi}}\left(1+\frac{k^2L^2}{2}\right)\exp\left(-\frac{k^2L^2}{4}\right), \tag{56}$$

appears in place of F_0 in the von Kármán model. We again need to find integrals of the form given by Eq. (40), although with the function G_0 replacing F_0. It can be shown that

$$\frac{d^3}{dt^3}[t^2 G_0(\sigma,L;t^{-1/2})] = \frac{\sigma^2 L}{2\sqrt{\pi}}\left[\left(-\frac{5L^6}{64t^4}+\frac{L^8}{128t^5}\right)\times\exp\left(-\frac{L^2}{4t}\right)\right].$$

The integrals can be written as incomplete gamma functions [e.g., Eq. (6.5.1) in Ref. 24], with result

$$I(\sigma,L,q;s) = \frac{q\sigma^2 L^3}{8\sqrt{\pi}}\left(\frac{4s}{L^2}\right)^q\left[\Gamma\left(3+q,\frac{L^2}{4s}\right) - \frac{5}{2}\Gamma\left(2+q,\frac{L^2}{4s}\right)\right]. \quad (57)$$

The functions $\alpha(s)$, $\beta(s)$, and $\zeta(s)$ can now be determined using Eqs. (41)–(43).

The isotropic contribution to the 2-D correlation function is

$$b_{iso}(\sigma_1,L_1;r) = \frac{\sigma_1^2 L_1}{2\sqrt{\pi}}\left(1-\frac{r^2}{L_1^2}\right)\exp\left(-\frac{r^2}{L_1^2}\right). \quad (58)$$

[If only this isotropic contribution is used to calculate the 2-D correlation function, the results for the extinction and coherence can be shown to be equivalent to Eqs. (22) and (24) in Ostashev *et al.*[26]] Calculation of the anisotropic contributions to the 2-D structure function requires us to integrate the product of an incomplete gamma function and a Bessel function. This integration can be done by rewriting the incomplete gamma functions as confluent hypergeometric functions, using Eqs. (13.1.33) and (13.6.28) in Abramowitz and Stegun.[24] The relationship is $\Gamma(a,x) = e^{-x/2}x^{a/2-1/2}W_{a/2-1/2,-a/2}(x)$, where $W_{\kappa,\mu}(\bullet)$ is Whittaker's function. The integration can now be performed using Gradshteyn and Ryzhik's[23] Eq. (7.672.2), with result

$$\overline{I}(\sigma,L,q;r) = \frac{3q\sigma^2 L}{2\sqrt{\pi}(1-q)}\left[{}_2F_2\left(4,1-q;1,2-q;-\frac{r^2}{L^2}\right) - \frac{5}{4}\,{}_2F_2\left(3,1-q;1,2-q;-\frac{r^2}{L^2}\right)\right], \quad (59)$$

where ${}_2F_2(\bullet)$ is a generalized hypergeometric function. As was the case with the anisotropic von Kármán model, the Gaussian result for the 2-D correlation function again involves a higher function for which computational routines are not commonly available. Hence it is usually most practical to calculate the 2-D correlation function by numerically integrating Eq. (46). Even the simple Gaussian model, when generalized to the anisotropic case, eludes convenient solution for the 2-D correlation function.

C. Kristensen *et al.* model

Krasnenko *et al.*[27] have previously suggested using the Kristensen *et al.* model[11] to calculate statistics of acoustic field fluctuations. The Kristensen *et al.* model uses equations very similar to the von Kármán model, except that in place of F_0 [defined in Eq. (27)] we instead use the new function H_0, defined by

$$H_0(\sigma,l,\mu,h;k) = \frac{l\sigma^2}{\pi}\frac{1}{\{1+[kl/a(\mu)]^{2\mu}\}^{5/6\mu}}\times\left\{1+\frac{h[kl/a(\mu)]^{2\mu}}{1+[kl/a(\mu)]^{2\mu}}\right\}, \quad (60)$$

where $a(\mu)=\pi\mu/B(1/2\mu,1/3\mu)$. The 1-D spectra are

$$F_L(k) = H_0(\sigma_1,l_1,\mu_1,0;k), \quad (61)$$

$$F_T(k) = \tfrac{1}{2}H_0(\sigma_2,l_2,\mu_2,\tfrac{5}{3};k), \quad (62)$$

and

$$F_V(k) = \tfrac{1}{2}H_0(\sigma_3,l_3,\mu_3,\tfrac{5}{3};k). \quad (63)$$

The parameters l_i are integral length scales. The parameters μ_i control the sharpness of the spectral peak; larger values give a sharper peak. Setting the $l_i = a(\mu_i)\ell_i$ and $\mu_i = 1$ reproduces the anisotropic von Kármán model. Kristensen *et al.* chose the parameters in their model to approximate the empirical spectra of Kaimal *et al.*,[21] and the resulting values are shown in Tables I and II. Note that the μ_i's are significantly less than 1, indicating that the actual spectra have broader peaks than in the von Kármán model. The 1-D spectra from the Kristensen *et al.* model (Fig. 1) virtually match the empirical spectra determined by Kaimal *et al.*

Derivation of the scalar energy functions $A_i(k)$ proceeds much as it did in Sec. II A, except that the equations become somewhat more complicated due to the more complicated form for the 1-D spectra. The first term in Eqs. (29)–(31), representing the isotropic spectra, is found by differentiation of Eq. (61) to be

$$\frac{k}{4\pi}\frac{d}{dk}\frac{1}{k}\frac{dF_L(k)}{dk} = \frac{5\sigma_1^2}{12\pi^2 a^{2\mu_1}(\mu_1)}\times\frac{k^{2\mu_1-2}l_1^{2\mu_2+1}}{\{1+[kl_1/a(\mu_1)]^{2\mu_1}\}^{5/6\mu_1+2}}\times\{2-2\mu_1+\tfrac{11}{3}[kl_1/a(\mu_1)]^{2\mu_1}\}. \quad (64)$$

The remaining terms in Eqs. (29)–(31), involving the functions $\alpha(s)$, $\beta(s)$, and $\zeta(s)$, represent the anisotropic contributions. Since the reader can refer to Kristensen *et al.*[11] for the solution for these functions, only the final results will be repeated here:

$$\alpha(s) = \gamma_0\left(\frac{1}{\sqrt{2}},\sigma_{22},l_2,\mu_2;s\right) - \gamma_0\left(\frac{1}{\sqrt{2}},\sigma_{33},l_3,\mu_3;s\right) + \gamma_0\left(-\frac{1}{\sqrt{2}},\sigma_2,l_2,\mu_2;s\right) - \gamma_0\left(-\frac{1}{\sqrt{2}},\sigma_3,l_3,\mu_3;s\right), \quad (65)$$

$$\beta(s) = 2\gamma_0(\tfrac{1}{3},\sigma_1,l_1,\mu_1;s) - \gamma_0(\tfrac{1}{3},\sigma_2,l_2,\mu_2;s) - \gamma_0(\tfrac{1}{3},\sigma_3,l_3,\mu_3;s), \quad (66)$$

and

$$\zeta(s)=2\gamma_0(-1,\sigma_1,l_1,\mu_1;s)-\gamma_0(-1,\sigma_2,l_2,\mu_2;s)-\gamma_0(-1,\sigma_3,l_3,\mu_3;s). \tag{67}$$

The function γ_0 is given by

$$\gamma_0(q,\sigma,\ell,\mu;s)=\frac{1}{96\pi}\frac{q\sigma^2\ell^3}{\mu a^2(\mu)}\eta^q\sum_{n=1}^{4}C_n(\mu)B_{\eta^{\mu}/(1+\eta^{\mu})}\times\left(\frac{11}{6\mu}-\frac{q}{\mu},n+\frac{q-1}{\mu}\right), \tag{68}$$

where

$$\eta\equiv\frac{a^2(\mu)}{\ell^2}s, \tag{69}$$

and

$$\begin{aligned}C_1(\mu)&=40(1-\mu)(1-2\mu)(2-\mu),\\ C_2(\mu)&=\frac{140}{3}(1-\mu)(1-2\mu)(5+6\mu),\\ C_3(\mu)&=\frac{10}{9}(5+6\mu)(5+12\mu)(7-12\mu),\\ C_4(\mu)&=\frac{10}{27}(5+6\mu)(5+12\mu)(5+18\mu).\end{aligned} \tag{70}$$

To find the 2-D structure function, we need to solve the integral Eq. (22), with the scalar energy functions given by Eqs. (29)–(31). Integrals of the form

$$\overline{\gamma}_0(q,\sigma,L,\mu;r)=\int_0^{\infty}\gamma_0(q,\sigma,L,\mu;k^{-2})J_0(kr)k\,dk$$

must be calculated, where $\gamma_0(\bullet)$ incorporates incomplete beta functions with the wave number raised to fractional powers. I have been unable to find a method for calculating these integrals, even in terms of Meijer's *G*-functions, as was possible for the von Kármán model. Fortunately, it is not difficult to find the 2-D structure function by numerical integration.

III. MANN'S RAPID-DISTORTION MODEL

The Mann model[12] is based on *rapid distortion theory*, which models shear-induced distortions to eddies by using a linearized solution to the Navier–Stokes equations. A constant (height-independent) mean shear is assumed in the solution. A full discussion of rapid distortion theory and Mann's model is beyond the scope of this paper. However, the relevant equations will be summarized and applied to acoustic propagation. Mann's equations for the 3-D autospectra are

$$\Phi_{11}(\mathbf{k})=\frac{E(k_0)}{4\pi k_0^4}[k_0^2-k_1^2-2k_1k_{30}\zeta_1+(k_1^2+k_2^2)\zeta_1^2], \tag{71}$$

$$\Phi_{22}(\mathbf{k})=\frac{E(k_0)}{4\pi k_0^4}[k_0^2-k_2^2-2k_2k_{30}\zeta_2+(k_1^2+k_2^2)\zeta_2^2], \tag{72}$$

and

$$\Phi_{33}(\mathbf{k})=\frac{E(k_0)}{4\pi k^4}(k_1^2+k_2^2). \tag{73}$$

In these equations, $E(k)$ is the initial (before the onset of shear distortion) energy spectrum. The von Kármán spectrum is used for $E(k)$, which can be written in the form[20]

$$E(k)=\frac{55}{9B(\frac{1}{2},\frac{1}{3})}\frac{\sigma_M^2k^4\ell_M^5}{(1+k^2\ell_M^2)^{17/6}}, \tag{74}$$

where σ_M^2 and ℓ_M are the variance and length scale parameters, respectively. The initial wave number is

$$\mathbf{k}_0=(k_1,k_2,k_{30}), \tag{75}$$

where $k_{30}=k_3-\beta k_1$. The parameter β is called the nondimensional *eddy lifetime*. Mann's equation for β [Eq. (3.3) in Ref. 12] involves a hypergeometric function. However, β can also be expressed in terms of the incomplete beta function, which is sometimes more convenient since the incomplete beta function can be computed by using widely available routines:[18]

$$\beta=\frac{\sqrt{3}\Gamma}{k\ell_M}\left[B_{1/(1+k^2\ell_M^2)}\left(\frac{1}{3},\frac{5}{2}\right)\right]^{-1/2}. \tag{76}$$

The ζ_i are wave-number-dependent functions, given by the equations

$$\zeta_1=C_1-\frac{k_2}{k_1}C_2,\quad \zeta_2=\frac{k_2}{k_1}C_1+C_2, \tag{77}$$

where

$$C_1=\frac{\beta k_1^2(k_0^2-2k_{30}^2+\beta k_1k_{30})}{k^2(k_1^2+k_2^2)} \tag{78}$$

and

$$C_2=\frac{k_2k_0^2}{(k_1^2+k_2^2)^{3/2}}\arctan\left[\frac{\beta k_1(k_1^2+k_2^2)^{1/2}}{k_0^2-\beta k_{30}k_1}\right]. \tag{79}$$

In his initial paper, Mann[12] determined the free parameter Γ (not to be confused with the MCF) by a least-squares fit to two atmospheric data sets. The resulting values for Γ were 2.6 and 3.2. More recently, Mann[28] determined Γ by fitting his model to various empirical spectral models, and found Γ in the range 3.0 to 4.5. A somewhat simpler alternative method for determining Γ is used in this paper. Specifically, Γ is chosen such that the ratio σ_1^2/σ_3^2 matches the anisotropic models discussed earlier. From Table I, this ratio should be 4.77/1.46=3.27. The desired value of Γ, found using numerical integration, is 3.58.[18] To force σ_1^2 equal to $4.77u_*^2$ when $\Gamma=3.58$, we need to set[18]

$$\sigma_M^2=1.52u_*^2 \tag{80}$$

in the initial von Kármán spectrum. The length scale ℓ_M is obtained by setting the dissipation rate of turbulent kinetic energy to $u_*^3/\kappa z$, where $\kappa\simeq0.40$ is von Kármán's constant.[29] The result is[18]

$$\ell_M=0.587z. \tag{81}$$

TABLE III. Normalized values $\overline{\xi}$ of the extinction distance for several turbulence models. The normalized value must be multiplied by $c_0^2/(k_0^2 u_*^2 z)$ to obtain the actual distance ξ.

Model	$\overline{\xi}$, along wind	$\overline{\xi}$, crosswind	Cross/along-wind ratio
Kristensen *et al.*	0.0400	0.104	2.59
von Kármán, isotropic	0.252	0.252	1.00
von Kármán, anisotropic	0.0770	0.234	3.04
Gaussian, anisotropic	0.0381	0.0815	2.14
Mann	0.141	1.84	13.0
Wilson and Thomson	0.0332	0.245	7.40

The 1-D spectra for the Mann model must be determined numerically, by integrating over k_2 and k_3. For example,

$$F_L(k_1) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \Phi_{11}(\mathbf{k})\, dk_2\, dk_3 . \tag{82}$$

The 1-D spectra are plotted and compared to the other turbulence models in Fig. 1. On the whole, the Mann model agrees well with the Kristensen *et al.* model, the main distinction being that the energy-subrange levels for $F_V(k_1)$ are somewhat higher. This overall agreement is quite satisfactory considering that the Mann model has only three parameters, compared to nine in Kristensen *et al.*

The 2-D correlation functions can be found using Eq. (18). Since $\Phi_{ii}(\mathbf{k}_\perp)$ depends on the orientation of $\mathbf{k}_\perp$, the double integral cannot be reduced to a single one involving a Bessel function as in Eq. (22). However, if we restrict ourselves to sensor separations along just one of the orthogonal coordinate axes, Eq. (18) can be simplified somewhat. For example, if propagation is in the along-wind direction and the sensors are separated in the crosswind direction, the 2-D correlation function of interest is $b(r_2,0) = b_{11}(r_2,0)/c_0^2$, where

$$b_{11}(r_2,0) = \int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty} \Phi_{11}(0,k_2,k_3)\, dk_3\right] \exp(ik_2 r_2)\, dk_2 . \tag{83}$$

The advantage of this equation is that the full Fourier transform needs to be performed along just one axis. A simple numerical integration can be performed along the other axis.

Note that the 2-D structure functions in the Mann model depend on the direction of the displacement. This behavior distinguishes the Mann model from the ones in Sec. II based on the Kristensen *et al.* spectral tensor.

IV. RESULTS AND DISCUSSION

A. Extinction distance

Extinction distances calculated for the various turbulence models discussed in Secs. II and III are shown in Table III. Also shown are calculations for the isotropic von Kármán model, and the Wilson and Thomson model (retaining the second and third terms only).[8] ''Along wind'' is the x_1 direction, and ''crosswind'' is the x_2 direction. The values in the table are the actual extinction distance normalized by $c_0^2/(k_0^2 u_*^2 z)$. This normalization factor arises from Eq. (14), and the fact that the 2-D structure function $d_{ii}(\mathbf{r}_\perp)$ is proportional to $u_*^2 z$ for all of the shear-layer models considered in this paper. [The velocity variances are proportional to u_*^2 and the length scales to z. The function $d_{ii}(\mathbf{r}_\perp)$ therefore has dimensions of velocity variance times length.]

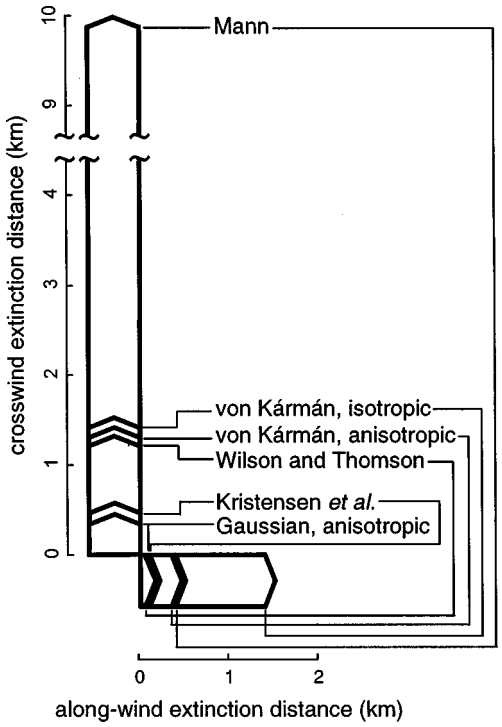

FIG. 2. Extinction distances for the various turbulence models. The calculations are for a frequency $f = 500$ Hz, height $z = 1$ m, friction velocity $u_* = 0.5$ m/s, and sound speed $c_0 = 340$ m/s. (Lengths of the arrows indicate the extinction distance.)

A graphical comparison of the model predictions is shown in Fig. 2, which is for the particular case $f = 500$ Hz, $z = 1$ m, $u_* = 0.5$ m/s, and $c_0 = 340$ m/s. The value for u_* is representative of moderately strong winds. Note that the relative *proportions* between the various distances plotted in Fig. 2 are *independent* of the particular values used for f, z, u_*, and c_0.

All of the anisotropic models predict an extinction distance in the along-wind direction that is much shorter than the isotropic von Kármán model. In the crosswind direction, the Mann model predicts an extinction distance much longer than the isotropic von Kármán model. Predicted distances from the anisotropic von Kármán, and Wilson and Thomson, models are just slightly shorter than the isotropic von Kármán model prediction in the crosswind direction. Predicted distances from the remaining models are all considerably shorter.

For all of the anisotropic models, the predicted extinction distance in the crosswind direction is longer than in the along-wind direction. The ratio of crosswind to along-wind extinction varies from 2.14 for the Gaussian model to 13.0 for the Mann model. In fact, all of the models based on the Kristensen *et al.* spectral tensor have ratios much less than the Mann model. This behavior could indicate that some of the assumptions regarding symmetry of the turbulence, which are inherent to the Kristensen *et al.* spectral tensor

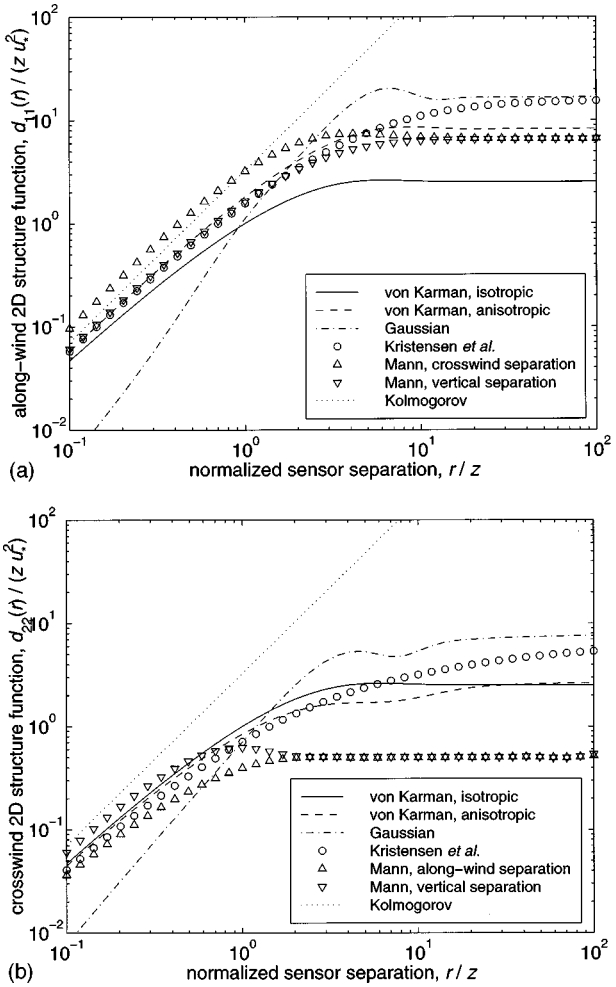

FIG. 3. Two-dimensional structure function as a function of sensor separation for the various turbulence models. (a) Along-wind propagation. (b) Crosswind propagation.

(but not to the Mann model), do not work well in this application.

B. Two-dimensional structure function

Predictions of the 2-D structure function for the various models are shown in Fig. 3. Also shown in the figures are predictions from the Kolmogorov (inertial subrange) model.[30] As discussed in Sec. I, the 2-D structure function of the turbulence determines coherence of the acoustic wave. The plots clearly show that the Kolmogorov model only works well when the ratio of the sensor separation to the height, r/z, is much less than 1. Convergence to the Kolmogorov prediction as r/z decreases is very slow. Conversely, the Gaussian model is reasonable only in the energy subrange, where r/z is much greater than 1. A peculiar (and probably unphysical) characteristic of the Gaussian model is the appearance of local peaks in the 2-D structure function, at $r/z \approx 6$ in the along-wind direction [Fig. 3(a)] and $r/z \approx 3$ in the crosswind direction [Fig. 3(b)].

In the along-wind direction [Fig. 3(a)], the energy-subrange 2-D structure function is larger for all of the anisotropic models than for the isotropic von Kármán model. The main reason for this behavior is that the anisotropic models all use a longer length scale for the along-wind direction. In the crosswind direction [Fig. 3(b)], the results are mixed. The 2-D structure function is larger for the Kristensen *et al.* and Gaussian models than for the isotropic von Kármán model; for the Mann model, the function is considerably smaller, equal to about 1/10 the Kristensen *et al.* model predictions for large r/z. The essential cause of this behavior is that the Mann model predicts a very small length scale for the crosswind velocity fluctuations in the crosswind direction. Symmetries inherent to the other anisotropic models, including the Kristensen *et al.* model, lead to larger values for this length scale.

For the Mann model, note that the structure functions for both horizontal and vertical separations are nearly the same for very small r/z (the inertial subrange), diverge for moderate separations, and then become equal again for large separations. The reason for the similarity in the inertial subrange is isotropy in that part of the spectrum. They become equal for large separations because $b_{ii}(r,0)$ and $b_{ii}(0,r)$ both approach zero for large r/z, so that the 2-D structure function in the two cases is $d_{ii}(r,0) \simeq d_{ii}(0,r) \simeq 2b_{ii}(0,0)$.

C. Coherence radius

In terms of the 2-D structure function for the turbulent velocities, the coherence radius [Eq. (13)] is the root of the equation

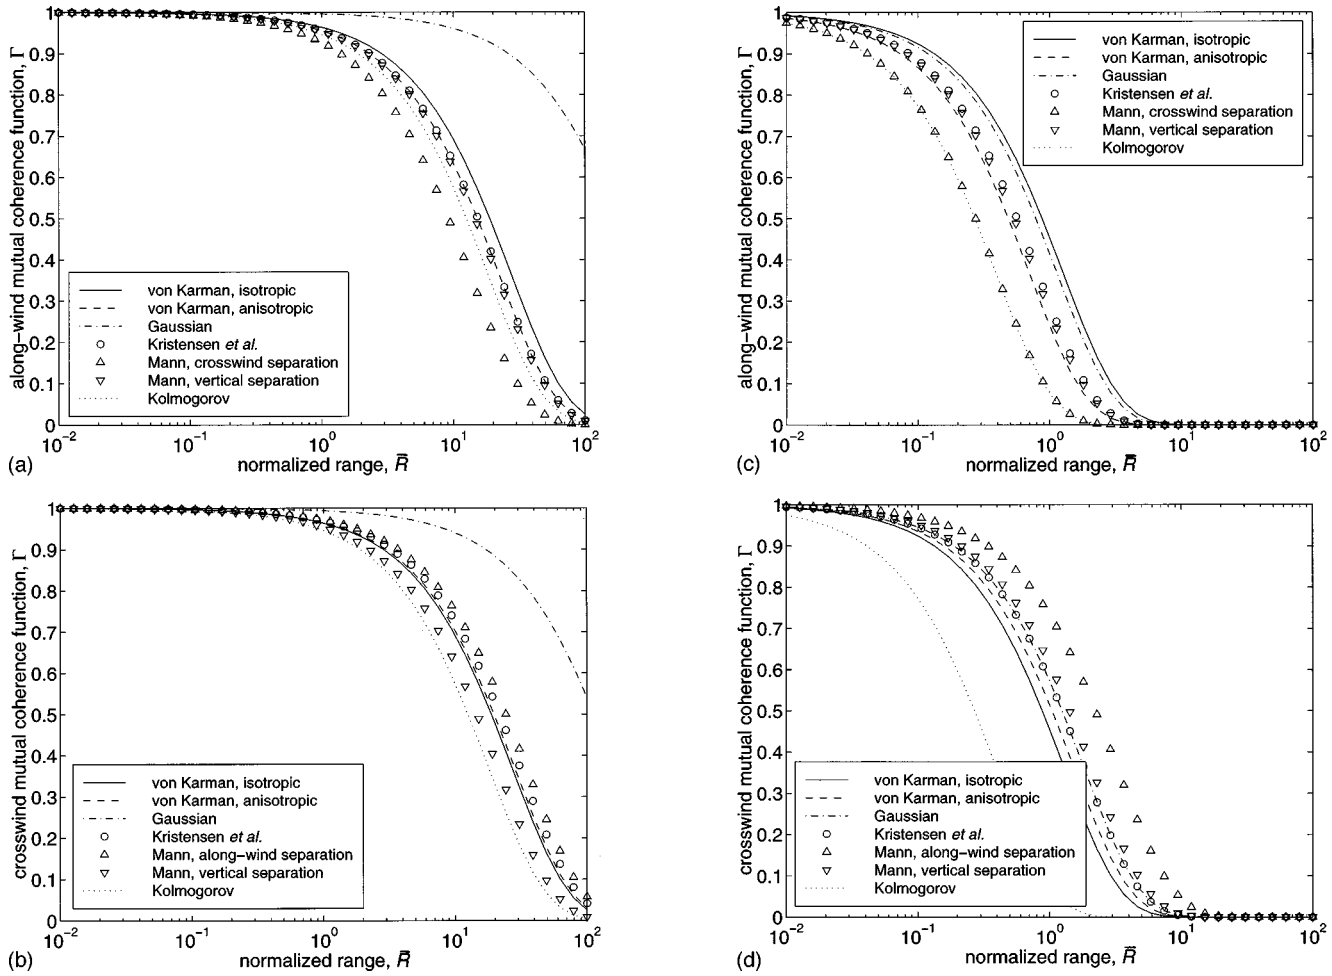

FIG. 5. Mutual coherence function (MCF) as a function of normalized range for the various turbulence models. (a) Along-wind propagation, ratio of sensor separation to height $r/z=0.1$. (b) Crosswind propagation, ratio of sensor separation to height $r/z=0.1$. (c) Along-wind propagation, ratio of sensor separation to height $r/z=1$. (d) Crosswind propagation, ratio of sensor separation to height $r/z=1$.

$$d_{ii}(\mathbf{r}_c)=c_0^2/(\pi k_0^2 x'). \tag{84}$$

Let us define a normalized 2-D structure function for the velocities as $\overline{d}_{ii}(\mathbf{r}_c)=d_{ii}(\mathbf{r}_c)/(zu_*^2)$. Then, if we also define a normalized propagation distance

$$\overline{R}=\frac{4x'k_0^2zu_*^2}{c_0^2}, \tag{85}$$

the equation to be solved becomes

$$\overline{d}_{ii}(\mathbf{r}_c)=4/(\pi\overline{R}). \tag{86}$$

The roots of this equation, as a function of $\overline{R}$, are plotted in Fig. 4(a) and (b), which shows the along-wind and crosswind directions, respectively.

When $\overline{R}$ exceeds 10, the Kolmogorov model works reasonably well in both directions. However, the Gaussian model is poor at these long ranges, because it does not have a realistic inertial subrange. For shorter ranges ($\overline{R}<1$) in the along-wind direction, the anisotropic models predict shorter coherence radii than the isotropic von Kármán model. In the crosswind direction, however, most of anisotropic models predict longer coherence radii than the isotropic von Kármán model. An exception is the Mann model for vertical separations, which predicts a coherence radius slightly less than the isotropic von Kármán model.

D. Mutual coherence function

Predictions of the mutual coherence function [MCF, Eq. (15)] for the various turbulence models, as a function of the normalized range $\overline{R}$, are shown in Fig. 5. Plots (a) and (b) are MCFs for the along-wind and crosswind directions with the sensor separation equal to 0.1 times the height; plots (c) and (d) are for the along-wind and crosswind directions with the separation equal to the height.

When $r/z=0.1$ [the case considered in Fig. 5(a) and (b)], all models except the Gaussian give fairly similar predictions. This is because inertial-subrange turbulence is most important for this small sensor separation, and all of the models except the Gaussian have a realistic inertial subrange. The Gaussian model predicts too little turbulent energy in the inertial subrange and therefore leads to a coherence that is unrealistically high. For the anisotropic von Kármán, Kristensen *et al.*, and Mann models, the predicted coherence in the along-wind direction is less than for the isotropic von Kármán model. The main reason for this behavior is that the

anisotropic models have a higher velocity variance in this direction. In the crosswind direction, the curve for the isotropic von Kármán model falls about midway between the various anisotropic models.

Differences between the models become more pronounced when $r/z=1$ [the case considered in Fig. 5(c) and (d)]. For this separation the energy-subrange characteristics become very important. The Kolmogorov model predicts much lower coherence than the others because it incorporates no ''roll-off'' in the energy spectrum for small wave numbers. Again, in the along-wind direction, the coherence predictions for the anisotropic models are less than for the isotropic von Kármán model. In the crosswind direction, all of the anisotropic models now predict higher coherence than the isotropic von Kármán model. The Mann model predicts the highest coherence in the crosswind direction, particularly for along-wind sensor separations.

V. CONCLUDING REMARKS

The effects of turbulence anisotropy on acoustic propagation were explored in this paper, using several rigorously derived models for the turbulence spectrum in a shear layer. Anisotropy effects were found to be very significant, sometimes resulting in order-of-magnitude corrections to predictions from an isotropic von Kármán model. Dramatic differences between along-wind and crosswind predictions were found in the anisotropic models: predictions of the extinction distance in the crosswind direction were about 2 to 13 times longer than in the along-wind direction, and coherence of the propagating wave persists over much longer distances in the crosswind direction than along-wind.

The various anisotropic turbulence models considered in this paper were found to yield very different propagation predictions, even though the parameters for the models were all chosen based on the same set of empirical spectra measured by Kaimal *et al.*[21] The three models derived from Kristensen *et al.*'s 3-D spectral density tensor (the anisotropic Gaussian, anisotropic von Kármán, and Kristensen *et al.* models) yielded less dramatic differences between the along-wind and crosswind characteristics than Mann's rapid distortion model. Furthermore, predictions from the three models based on Kristensen *et al.*'s spectral tensor differed significantly from each other, despite their underlying mathematical similarities. These results indicate that the predictions are very sensitive to the exact form of the energy-subrange model, so that it will probably be difficult to develop accurate quantitative predictions for energy-subrange effects on scattering.

The Mann model is likely the most realistic one available for an atmospheric shear layer, since it does not incorporate *ad hoc* assumptions about statistical symmetries of the turbulence field. Mann's model is also not much more difficult to apply than the ones based on Kristensen *et al.*'s spectral tensor.

Although the comparisons in this paper are a useful first step toward understanding the effects of anisotropic turbulence on acoustic propagation, field experiments are of course needed to establish and quantify its true importance. Application of the models in this paper is unfortunately hampered by ground reflections and atmospheric refraction. For example, the predictions cannot be expected to hold in a shadow region, since the ''line-of-sound'' scattering theory is invalid there. Hence it would be very worthwhile to include reflection and refraction in subsequent work on propagation through anisotropic turbulence. Other important topics for future research are incorporation of large-scale (buoyancy-driven) turbulence, and development of simpler turbulence models that retain the acoustically most significant features of the anisotropic turbulence.

APPENDIX: PARAMETER SELECTION FOR THE ANISOTROPIC VON KÁRMÁN AND GAUSSIAN MODELS

Velocity statistics in a neutral shear layer are typically scaled by the friction velocity u_*, which equals $\sqrt{\tau/\rho}$, τ being the Reynolds stress and ρ the fluid density.[19] The appropriate length scale is z, the height from the ground.[19]

Kaimal *et al.*[21] made extensive measurements of the 1-D spectra of atmospheric turbulence, and devised a set of empirical equations that fit their measurements for neutral conditions. Their equations are parametrized on the basis of u_* and z. I have chosen the parameters for the anisotropic von Kármán and Gaussian models to reproduce certain features of the Kaimal *et al.* empirical spectra. The spectral variances measured by Kaimal *et al.* are given in Table I, and these values were used for the variances in both the anisotropic von Kármán and Gaussian models.

The length scales in the von Kármán model were chosen to reproduce the inertial-subrange asymptote determined by Kaimal *et al.* Specifically, in the inertial subrange the following equation must hold:[21]

$$F_L(k)=\frac{\alpha}{2}\epsilon^{2/3}k^{-5/3}, \tag{A1}$$

where $\epsilon=u_*^3/\kappa z$ is the dissipation rate of turbulent kinetic energy, and α and κ are constants whose values are approximately 0.52 and 0.40, respectively.[29] Taking the limit of Eq. (23) for large $k\ell_1$, and solving for ℓ_1, we find

$$\ell_1=\left[\frac{2\sigma_1^2}{\alpha B(\frac{1}{2},\frac{1}{3})}\right]^{3/2}\frac{\kappa z}{u_*^3}\simeq 0.350\frac{\sigma_1^3 z}{u_*^3}\simeq 3.64z. \tag{A2}$$

The length scales ℓ_2 and ℓ_3 follow similarly by using the inertial-subrange relationship[19]

$$F_T(k)=F_V(k)=\tfrac{4}{3}F_L(k), \tag{A3}$$

with results given in Table II.

Because the Gaussian model does not possess an inertial subrange, some other method is needed for determining its length scale parameters. A reasonable method is to equate the integral length scales in the Gaussian model to those implied by the Kaimal *et al.*[21] measurements. Taking the

zero-wave-number limits of the Kaimal *et al.* empirical equations, we find $l_1 = 5.50z$, $l_2 = 1.59z$, and $l_3 = 0.343z$. Likewise taking the zero-wave-number limits of Eqs. (53) and (54), we have the relationships

$$l_1 = \frac{\sqrt{\pi}}{2} L_1, \quad l_2 = \frac{\sqrt{\pi}}{4} L_2, \quad l_3 = \frac{\sqrt{\pi}}{4} L_3.$$

The values given in Table II now follow.

Reverberation in waveguides with rough surfaces

David H. Berman
Department of Physics and Astronomy, University of Iowa, Iowa City, Iowa 52242

(Received 23 January 1998; accepted for publication 13 October 1998)

An impedance formalism for treating scattering at multiple rough boundaries in waveguides with depth-varying sound speeds is developed. The formalism is used to give a compact result for the time history of multiply scattered reverberant sound. In general, the multiple scattering contribution to reverbation decays more slowly than the single scattering contribution. When attenuation mechanisms other than surface scattering are small, the reverberant field has a diffusive character, and this leads to algebraic ($\sim 1/t$) decay of the reverberation of originally pulsed signals. As a by-product of the formalism, conventional reverberation models are derived from ''first principles.'' The derivation provides the precise form of the scattering strength used in such models. In addition, it shows that the mean field should be used for propagation to and from the scattering surface. Finally, the computations present the possibility of treating the scattering by two rough boundaries simultaneously. © *1999 Acoustical Society of America.* [S0001-4966(99)01602-1]

INTRODUCTION

Recent work by Maradudin and co-workers[1–3] has shown that multiple scattering from a surface that supports bound surface waves gives rise to the phenomenon of enhanced backscattering. Enhanced backscattering occurs not only from a surface which separates two half-spaces, but also from a surface which is one boundary of a bounded layer which supports guided waves. Enhanced backscattering is concerned with plane waves incident on these surfaces: what is enhanced is the plane wave scattering amplitude in the exact backscatter direction. The aim of present work is to examine what happens to waves from a point source which are incident on rough surfaces from within a waveguide.

Although it is not entirely explicit, the key to developing a multiple scattering formalism in Ref. 4 is the use of nonlocal impedance boundary conditions. Within a waveguide nonlocal impedance conditions can be satisfied on two surfaces simultaneously by using the analogs of plane waves: waves of a given horizontal wave vector, but with vertical dependence appropriate to the sound speed profile. Then the boundary conditions can be satisfied formally by superpositions of such waves. Using impedance boundary conditions circumvents the need to decompose waves in the waveguide into up- and downgoing components in order to use plane wave scattering amplitudes. (See, for example, Refs. 5–7.) The coefficients of the superposition depend on the source location and can be written formally in terms of an operator $g=1/(g_0^{-1}-Z)$, where Z is a random operator related to the impedances of the bounding surfaces and g_0 is a nonrandom operator involving known solutions of the wave equation in the waveguide, evaluated at the surfaces. The surface Green's function, g involves only quantities evaluated at the bounding surfaces. The treatment of random operators like g has been worked out in detail and is summarized in the appendix of Ref. 4. The field within the waveguide can be written in terms of g, or rather the related scattering operator $t=v/(1-g_0v)$ (where $v=Z-M$, and M is an effective impedance) and derivatives of the mean Green's function of the field in the waveguide evaluated at the surfaces. The result given below in Eq. (29) simply states that the fluctuation of the field within the waveguide is obtained by propagating to the interfaces from the source using the mean Green's function, scattering at the interfaces using t, and then propagating from the surfaces to the receiver again using the mean Green's function.

Multiple scattering enters the picture first in the computation of the mean Green's function which obeys boundary conditions involving an effective impedance. It was shown in Ref. 8 that when the correlation length of surface roughness is short compared to the skip distance between surface encounters, the effective impedance is well approximated by the effective impedance of the surface when it separates two homogeneous half-spaces.

However, the multiple scattering with which we are concerned here arises in computing the second moment of the Green's function. As pointed out by Kirkpatrick,[9] the infinite sum of certain scattering diagrams gives rise to diffusive behavior in the second moment, at least in the case of sound scattered by random volume inhomogeneities. In addition, there is another class of scattering diagrams, the maximally crossed diagrams, which can be summed and give rise to enhanced backscattering on the one hand, and on the other hand, to a sort of ''fossil'' sound which does not appear even to diffuse away from the source, at least in one and two dimensions. These same kinds of sums occur for surface scattering once it has been cast into a similar formalism. Furthermore, the layered waveguide we have in mind here is primarily two-dimensional. These effects require that the only attenuation mechanism is the scattering of the coherent field into the incoherent field. It seems unlikely that this is ever realistic for sound in the ocean, and the maximally crossed diagrams will not be treated here. However, even with other attentuation mechanisms present, the diffusive behavior leads to reverberation which decays more slowly in time than conventional treatments of reverberation[7] would predict.

In Sec. I we describe the impedance formalism. In Sec. II we discuss the Bethe–Salpeter equation and the computation of the second moment of fields scattered at boundaries of a waveguide. Note that the formalism allows the scattering from two bounding rough surfaces to be treated simultaneously. In Sec. III we present details of the computation of reverberation time histories of pulsed signals. The conventional, single scatter, result is contained in Eq. (84) while a multiple scattering contribution to reverberation is given in Eq. (90). The results apply to a fully three-dimensional environment with isotropic roughness. Other authors[10–12] have used ideas similar to those used here for treating multiple surface scattering, but I believe the final results here are both more explicit for reverberation and more concise.

I. IMPEDANCE FORMALISM

Consider a layer bounded by a rough interface just above $z=z_0$ and another interface just below $z=z_1<z_0$. Between z_0 and z_1 the medium has a sound speed profile $c=c(z)$ which depends only on the depth z. The effects of roughness can be described by nonlocal impedance boundary conditions on the flat imaginary surfaces at z_0 and z_1. By this we mean that if $G(\mathbf{R},z;\mathbf{R}_s,z_s)$ is the Green's function for sound in the layer (where $\mathbf{R}$ is a horizontal position and the subscript s refers to the source location), then on the flat surface $z=z_0$ all fields, including $G(\mathbf{R},z;\mathbf{R}_s,z_s)$, must satisfy

$$G(\mathbf{R},z_0;\mathbf{R}_s,z_s)=\int d\mathbf{R}'\, Z_0(\mathbf{R},\mathbf{R}')\partial_z G(\mathbf{R}',z_0;\mathbf{R}_s,z_s). \tag{1}$$

A similar condition must hold on the flat surface at z_1, but with the impedance Z_0 replaced by another impedance, $Z_1(\mathbf{R},\mathbf{R}')$, appropriate to the lower interface. It is more convenient to work with horizontal Fourier transforms of these functions since the sound speed is presumed independent of horizontal position. Then, in terms of horizontal wave vectors we write the boundary conditions as

$$G(\mathbf{Q},z_0;\mathbf{K},z_s)=\int d\mathbf{P}\, Z_0(\mathbf{Q},\mathbf{P})\partial_z G(\mathbf{P},z_0,\mathbf{K},z_s) \tag{2}$$

and

$$G(\mathbf{Q},z_1;\mathbf{K},z_s)=-\int d\mathbf{P}\, Z_1(\mathbf{Q},\mathbf{P})\partial_z G(\mathbf{P},z_1,\mathbf{K},z_s). \tag{3}$$

The minus in the last equation is for later convenience and the convention regarding factors of 2π is

$$G(\mathbf{Q},z_0;\mathbf{K},z_s)=\frac{1}{(2\pi)^2}\int \exp(-i\mathbf{Q}\cdot\mathbf{R}+i\mathbf{K}\cdot\mathbf{R}_s) \times G(\mathbf{R},z_0,\mathbf{R}_s,z_s)\, d\mathbf{R}\, d\mathbf{R}_s. \tag{4}$$

An argument for boundary conditions of this form is given in Appendix A, where it is also shown how the impedance is related to the scattering amplitude. In first-order perturbation theory, for example, if the surface at z_0 were Dirichlet, then $Z_0(\mathbf{Q},\mathbf{P})$ would be given by $-h(\mathbf{Q}-\mathbf{P})$ where $h(\mathbf{Q})$ is the Fourier transform of the surface profile, $z=h(\mathbf{R})=\int h(\mathbf{K})\exp(i\mathbf{K}\cdot\mathbf{R})\, d\mathbf{K}$.

The Green's function $G(\mathbf{Q},z;\mathbf{K},z_s)$ must satisfy the depth separated wave equation

$$\left[\partial_z^2+\left(\frac{\omega^2}{c(z)^2}-\mathbf{Q}^2\right)\right]G(\mathbf{Q},z;\mathbf{K},z_s) =-\delta(z-z_s)\,\delta(\mathbf{Q}-\mathbf{K}) \tag{5}$$

in addition to the boundary conditions. This Green's function can be conveniently constructed from canonical regular solutions, $e^{\pm}(\mathbf{Q},z)$, of the homogeneous depth separated wave equation and the Neumann Green's function $\Phi(\mathbf{Q},z;\mathbf{K},z_s)$ which satisfies Eq. (5) and the simple boundary conditions

$$\partial_z\Phi(\mathbf{Q},z_0;\mathbf{K},z_s)=\partial_z\Phi(\mathbf{Q},z_1;\mathbf{K},z_s)=0. \tag{6}$$

The canonical regular solutions of the homogeneous depth separated wave equation play the role of plane waves in the half-space problem. We will require $e^{\pm}$ to satisfy

$$e^+(\mathbf{Q},z_0)=1,\quad \partial_z e^+(\mathbf{Q},z_0)=0, \tag{7}$$

$$e^-(\mathbf{Q},z_1)=1,\quad \partial_z e^-(\mathbf{Q},z_1)=0. \tag{8}$$

The Neumann Green's function, in turn, can be constructed from these functions as follows:

$$\Phi(\mathbf{Q},z;\mathbf{K},z_s) =\begin{cases} \dfrac{-1}{W(\mathbf{Q})}e^+(\mathbf{Q},z)e^-(\mathbf{Q},z_s)\,\delta(\mathbf{Q}-\mathbf{K}), & z\geqslant z_s, \\ \dfrac{-1}{W(\mathbf{Q})}e^-(\mathbf{Q},z)e^+(\mathbf{Q},z_s)\,\delta(\mathbf{Q}-\mathbf{K}), & z<z_s. \end{cases} \tag{9}$$

Here $W(\mathbf{Q})$ is the Wronskian

$$W(\mathbf{Q})=\partial_z e^+(\mathbf{Q},z)e^-(\mathbf{Q},z)-e^+(\mathbf{Q},z)\partial_z e^-(\mathbf{Q},z) =\partial_z e^+(\mathbf{Q},z_1)=-\partial e^-(\mathbf{Q},z_0). \tag{10}$$

Now write the Green's function $G(\mathbf{Q},z;\mathbf{K},z_s)$ as a superpostion of $e^{\pm}$ and Φ

$$G(\mathbf{Q},z;\mathbf{K},z_s)=e^+(\mathbf{Q},z)\chi^+(\mathbf{Q},\mathbf{K};z_s) +e^-(\mathbf{Q},z)\chi^-(\mathbf{Q},\mathbf{K};z_s)+\Phi(\mathbf{Q},z;\mathbf{K},z_s). \tag{11}$$

The Neumann Green's function Φ accounts for the δ-function source. The coefficients $\chi^{\pm}$ are independent of receiver depth z but dependent on the source depth z_s and are to be chosen to account for the impedance boundary conditions. The boundary conditions provide two linear equations for the two unknown coefficients $\chi^{\pm}$ and these are most conveniently written as a matrix operator equation

$$[E(\mathbf{Q},\mathbf{P})-Z(\mathbf{Q},\mathbf{P}')\partial E(\mathbf{P}',\mathbf{P})]\chi(\mathbf{P},\mathbf{K};z_s) =-\phi(\mathbf{Q},\mathbf{K};z_s). \tag{12}$$

Integration over repeated wave vectors is implied as well as two-by-two matrix multiplication. The matrix operators here are given by

$$E(\mathbf{Q},\mathbf{P})=\delta(\mathbf{Q}-\mathbf{P})\begin{pmatrix} e^+(\mathbf{Q},z_0) & e^-(\mathbf{Q},z_0)\\ e^+(\mathbf{Q},z_1) & e^-(\mathbf{Q},z_1)\end{pmatrix}$$

$$=\delta(\mathbf{Q}-\mathbf{P})\begin{pmatrix} 1 & e^-(\mathbf{Q},z_0)\\ e^+(\mathbf{Q},z_1) & 1\end{pmatrix}, \tag{13}$$

$$\partial E(\mathbf{Q},\mathbf{P})=\delta(\mathbf{Q}-\mathbf{P})\begin{pmatrix} \partial_z e^+(\mathbf{Q},z_0) & \partial_z e^-(\mathbf{Q},z_0)\\ -\partial_z e^+(\mathbf{Q},z_1) & -\partial_z e^-(\mathbf{Q},z_1)\end{pmatrix}$$

$$=-\delta(\mathbf{Q}-\mathbf{P})W(\mathbf{Q})\begin{pmatrix} 0 & 1\\ 1 & 0\end{pmatrix}, \tag{14}$$

and

$$Z(\mathbf{Q},\mathbf{P})=\begin{pmatrix} Z_0(\mathbf{Q},\mathbf{P}) & 0\\ 0 & Z_1(\mathbf{Q},\mathbf{P})\end{pmatrix}. \tag{15}$$

In writing E and ∂E in this way the relation between derivatives obtained from the Wronskian in Eq. (10) has been used.

The remaining undefined quantities in Eq. (12) are

$$\phi(\mathbf{Q},\mathbf{K})=\begin{pmatrix}\Phi(\mathbf{Q},z_0;\mathbf{K},z_s)\\ \Phi(\mathbf{Q},z_1;\mathbf{K},z_s)\end{pmatrix}, \tag{16}$$

and

$$\chi(\mathbf{Q},\mathbf{K};z_s)=\begin{pmatrix}\chi^+(\mathbf{Q};\mathbf{K},z_s)\\ \chi^-(\mathbf{Q};\mathbf{K},z_s)\end{pmatrix}. \tag{17}$$

A formal solution to Eq. (12) is

$$\chi=\frac{1}{\partial E}\frac{1}{E/\partial E-Z}(-\phi)=\frac{1}{\partial E}\frac{1}{g_0^{-1}-Z}(-\phi), \tag{18}$$

where now E and ∂E; etc. denote the operators whose kernels are given above. In the case of flat surfaces for which Z is diagonal in wave vector, one can show that the modal poles associated with the original Neumann Green's function ϕ (the zeros of W) are replaced by poles arising from zeros of the determinant of $g_0^{-1}-Z$. These coincide with the solutions of the conventional dispersion relation,[13]

$$1-R_0R_1=0, \tag{19}$$

once the reflection amplitudes R are written in terms of impedances.

Equation (18) suggests defining a *surface* Green's function

$$g=\frac{1}{g_0^{-1}-Z} \tag{20}$$

in which all terms are evaluated on the bounding surfaces. Note, however, that the sound speed structure within the waveguide is built in to g via the function $e^-(\mathbf{Q},z)$. The surface Green's function can now be formally manipulated exactly as in Ref. 4. The average of g over an ensemble of rough bounding surfaces defines an effective impedance operator, M, which for a statistically stationary ensemble is diagonal in wave number, by

$$\langle g\rangle=\frac{1}{g_0^{-1}-M}. \tag{21}$$

The surface Green's function, g, before averaging, can be written using the averaged Green's function and a scattering operator t as

$$g=\langle g\rangle+\langle g\rangle t\langle g\rangle, \tag{22}$$

where t is given by

$$t=\frac{1}{1-v\langle g\rangle}v=v\frac{1}{1-\langle g\rangle v} \tag{23}$$

and

$$v=Z-M. \tag{24}$$

The effective impedance can be found iteratively by noting that the average of t must vanish.

The statistics of the field in the waveguide are the statistics the scattering operator t. To make this assertion we need to show explicitly how fluctuations of the field within the waveguide are related to t. From Eq. (11) the field within the waveguide is given by

$$G(\mathbf{Q},z;\mathbf{K},z_s)=[e^+(\mathbf{Q},z),e^-(\mathbf{Q},z)]\begin{pmatrix}\chi^+(\mathbf{Q},\mathbf{K},z_s)\\ \chi^-(\mathbf{Q},\mathbf{K},z_s)\end{pmatrix}+\Phi(\mathbf{Q},z;\mathbf{K},z_s)$$

$$=[e(z)]^T\frac{1}{\partial E}[\langle g\rangle+\langle g\rangle t\langle g\rangle](-\phi)+\Phi. \tag{25}$$

First take the mean of G, then take z derivatives and let z first approach z_0 and then z_1. Because Φ is constructed so that its derivatives vanish on z_0 and z_1 we find

$$\begin{pmatrix}\partial_z\langle G(\mathbf{Q},z_0;z_s)\rangle\\ \partial_z\langle G(\mathbf{Q},z_1;z_s)\rangle\end{pmatrix}=\sigma_3\langle g\rangle(-\phi). \tag{26}$$

The two-by-two constant matrix σ_3 is just

$$\sigma_3=\begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}. \tag{27}$$

It arises here because there is a $-\partial_z e^+(\mathbf{Q},z_1)$ in the definition of ∂E. Derivatives of $\langle G\rangle$ give rise to derivatives of $e^{\pm}$ producing a matrix ∂E which is cancelled by its inverse which appears in Eqs. (18) and (26).

We can also average G and take vertical derivatives from the right, that is on z_s, and then let z_s approach z_0 and z_1. The details are given in Appendix B with the result

$$[\langle G(\mathbf{Q},z;\mathbf{K},z_0)\rangle\overleftarrow{\partial}_{z_0},\langle G(\mathbf{Q},z;\mathbf{K},z_1)\rangle\overleftarrow{\partial}_{z_1}]$$

$$=-[e^+(\mathbf{Q},z),e^-(\mathbf{Q},z)]\frac{1}{\partial E}\langle g\rangle\sigma_3. \tag{28}$$

Also in Appendix B it is shown that the effective impedance, M, relates the mean field to its derivatives, just as Z relates a realization of the field to its derivatives. Equations (28) and (26) used in Eq. (25) show that the fluctuation of the field within the waveguide is given by

$$\Delta G=[\langle G\rangle\partial]^T\sigma_3 t\sigma_3\partial\langle G\rangle. \tag{29}$$

The scattered field is obtained by propagating to the interfaces with the mean field, scattering with t, and then propa-

gating from the interfaces to the receiver, again using the mean field. This result is reminiscent of the Helmholtz–Kirchhoff integral; the appearance of σ_3 is likely a reflection of the need to use both outward or both inward derivatives at the bounding surfaces.

One word of caution is necessary. The utility of this formalism for forming moments of the fluctuating field might depend on having the impedance, Z, be a Gaussian random field. This is because the algebra of resummation seems to require that all moments of Z factorize into second moments. If so, then the results here are limited to a first-order (in surface roughness) approximation for the impedance, and to roughness described by Gaussian statistics. If non-first-order approximations for Z are used, there is no guarantee that higher-order cumulants will not be significant.

II. SECOND MOMENT OF THE FLUCTUATING FIELD

The principal result of the last section, Eq. (29), means that if we want to find the incoherent contribution to the second moment of the fluctuating field

$$\langle|\Delta G(R,z,t;R_s=0,z_s,t_s=0)|^2\rangle$$
$$=\int d\omega_1\, d\omega_2 \int d\mathbf{Q}_1\, d\mathbf{Q}_2 \int d\mathbf{K}_1\, d\mathbf{K}_2 e^{i(\omega_1-\omega_2)t}$$
$$\times e^{i(\mathbf{Q}_1-\mathbf{Q}_2)\cdot\mathbf{R}}\langle\Delta G(\mathbf{Q}_1,\mathbf{K}_1,\omega_1)\Delta G(\mathbf{Q}_2,\mathbf{K}_2,\omega_2)\rangle,$$

in general, we must consider correlations of tt^* where t and t^* differ in frequency, outgoing horizontal wave vector, and incoming wave vector. Because we will always assume that surface roughness is statistically homogeneous, it is convenient to use sum and difference variables defined by

$$\Omega=(\omega_1+\omega_2)/2,\quad \omega=\omega_1-\omega_2,$$
$$\mathbf{Q}=(\mathbf{Q}_1+\mathbf{Q}_2)/2,\quad \mathbf{p}=\mathbf{Q}_1-\mathbf{Q}_2, \tag{30}$$
$$\mathbf{K}=(\mathbf{K}_1+\mathbf{K}_2)/2,\quad \mathbf{k}=\mathbf{K}_1-\mathbf{K}_2.$$

In this way we are naturally led to consider

$$\langle t(\mathbf{Q}+\mathbf{q}/2,\mathbf{K}+\mathbf{k}/2,\Omega+\omega/2)t^*(\mathbf{Q}-\mathbf{q}/2,\mathbf{K}-\mathbf{k}/2,\Omega-\omega/2)\rangle$$
$$=\tau_{\mathbf{Q},\mathbf{K}}(\mathbf{q}|\Omega,\omega)\,\delta(\mathbf{q}-\mathbf{k}), \tag{31}$$

where τ is defined by this equation and the δ-function follows from the assumed statistical homegeneity.

Fortunately, machinery for computing moments of this type has been described in a number of places.[4,9,14] What makes the present context somewhat distinctive is that there is multimodal propagation in a waveguide. In fact, we will make a pole approximation for both the mean surface Green's function, $\langle g\rangle$, and the mean Green's function $\langle G\rangle$ within the waveguide. The location of the poles is the same. We will therefore write

$$\langle G(\mathbf{P},z;\mathbf{Q},z_s)\rangle=G(\mathbf{P};z,z_s)\,\delta(\mathbf{P}-\mathbf{Q}) \tag{32}$$

with $G(\mathbf{P};z,z_s)$ given by

$$G(\mathbf{P};z,z_s)=\sum_m \frac{-u_m(z)u_m(z_s)}{P^2-(k_m+i\Delta_m)^2}. \tag{33}$$

The $u_m(z)$ are the normal modes of the mean field in the waveguide which satisfy the separated Helmholtz equation with sound speed profile $c(z)$ and ''effective'' impedance boundary conditions at z_0 and z_1. [Effective impedance boundary conditions are given by Eq. (B5) in Appendix B. What is a bit strange here is that, in general, M will have off-diagonal elements. This means that the value of u_m on z_0 is a linear combination, determined by the elements of the matrix M, of its derivatives on z_0 *and* on z_1, and, likewise, the value of u_m on z_1 is a different linear combination of its derivatives on z_0 *and* on z_1.] This expression for G used in Eq. (31) and then in Eq. (4) gives the following expression for the mean Green's function in spatial variables:

$$\langle G\rangle(\mathbf{R},z,\mathbf{R}_0,z_0,\Omega)$$
$$=(-i/4)\sum_m u_m(z)u_m(z_0)H_0^1[(k_m+i\Delta_m)|\mathbf{R}-\mathbf{R}_0|]. \tag{34}$$

The factor $(-i/4)$ is consistent with the right-hand side of Eq. (5). We will assume that the right-hand side depends on frequency, Ω, primarily through the frequency dependence of the modal wave numbers, $k_m=k_m(\Omega)$. The imaginary part of the modal wave number, Δ_m, gives the attenuation of the mth mode of the *mean* field.

Returning to Eq. (31), recall that t is a 2×2 matrix operator and that tt^* is the outer product of such operators. Were we to insert indices, $\tau_{\mathbf{Q},\mathbf{K}}$ would carry four discrete indices. [See Eq. (70) below.] Following Brown *et al.*,[4] τ is the reducible vertex function. It is related to the irreducible vertex function, U, by

$$\tau=U+U\mathcal{G}U. \tag{35}$$

Here $\mathcal{G}$ is the two-point surface Green's function defined by

$$\langle g_{i_1,j_1}(\mathbf{P}+\mathbf{p}/2,\mathbf{K}+\mathbf{k}/2,\Omega+\omega/2)g_{i_2,j_2}$$
$$\times(\mathbf{P}-\mathbf{p}/2,\mathbf{K}-\mathbf{k}/2,\Omega-\omega/2)^*\rangle$$
$$=\mathcal{G}^{i_1,i_2;j_1,j_2}_{\mathbf{P},\mathbf{K}}(\mathbf{p}|\Omega,\omega)\,\delta(\mathbf{p}-\mathbf{k}). \tag{36}$$

Indices in Eq. (31) are inserted similarly. The simplest contribution to the irreducible vertex function is the single-rung ladder diagram, which is a regular function of wave number and frequency.

Roughly speaking, the irreducible vertex function, U, describes multiple scattering which is statistically correlated, while the two-point Green's function $\mathcal{G}$ describes the whole sequence of correlated scattering followed by uncorrelated propagation, followed by correlated scattering, etc., as described in the Bethe–Salpeter equation[4,9]

$$[\langle g^*\rangle^{-1}-\langle g\rangle^{-1}]\mathcal{G}=[\langle g^*\rangle-\langle g\rangle](1+U\mathcal{G}). \tag{37}$$

Our strategy for computing τ is to approximate U, find $\mathcal{G}$ from Eq. (37), and then use the result in Eq. (35). Note that, in contrast to Brown *et al.*, $\langle g^*\rangle$ denotes the complex conjugate at frequency $\Omega-\omega/2$, while $\langle g\rangle$ refers to the surface Green's function at frequency $\Omega+\omega/2$, and these are both 2×2 matrix operators.

It is convenient to work in a basis in which $\langle g\rangle^{-1}$ is diagonal. Because of the assumed statistical homogeneity,

eigenstates are labeled by horizontal wave vectors, **P**. For each **P** there are two eigenstates and we will write

$$\langle g\rangle^{-1}\psi_s(\mathbf{P})=\lambda_s(\mathbf{P})\psi_s(\mathbf{P}), \tag{38}$$

for $s=1,2$. The subscript s distinguishes the two eigenstates, ψ_s, and corresponding eigenvalues, λ_s, both of which are frequency dependent. In this basis, the Bethe–Salpeter equation, Eq. (37), becomes

$$\begin{aligned}[\lambda_{s_1}(\mathbf{P}+\mathbf{q}/2)-\lambda^*_{s_2}(\mathbf{P}-\mathbf{q}/2)]&\mathcal{G}^{s_1,s_2;v_1,v_2}_{\mathbf{P},\mathbf{Q}}(\mathbf{q})\\ &=\left[\frac{1}{\lambda^*_{s_2}(\mathbf{P}-\mathbf{q}/2)}-\frac{1}{\lambda_{s_1}(\mathbf{P}+\mathbf{q}/2)}\right](\delta_{s_1,v_1}\delta_{s_2,v_2}\delta(\mathbf{P}-\mathbf{Q})\\ &\quad+U^{s_1,s_2;u_1,u_2}_{\mathbf{P},\mathbf{K}}(\mathbf{q})\mathcal{G}^{u_1,u_2;v_1,v_2}_{\mathbf{K},\mathbf{Q}}(\mathbf{q})).\end{aligned} \tag{39}$$

It is understood here that there is a sum over the indices u_i and integration over the intermediate wave vector, **K**. There is no sum on the indices s_i nor on v_i. Both $\mathcal{G}$ and the irreducible vertex function U depend on both Ω and ω.

As will be seen in the next section, at large times, reverberation is determined by the singularities of $\mathcal{G}$ as $\omega\to 0$. In turn, the singularities of $\mathcal{G}$ arise because for some values of the horizontal wave vector one of the eigenvalues vanishes. The wave vectors at which one of the eigenvalues vanishes, $|\mathbf{P}|=k_m+i\Delta_m$, $m=1,...,N$, are the modal horizontal wave numbers. In the vicinity of $k_m+i\Delta_m$ let λ_1 be the eigenvalue which vanishes at $k_m+i\Delta_m$. In finding $\mathcal{G}$, restrict attention to only the elements $\mathcal{G}^{1,1;1,1}$ and $U^{1,1;1,1}$; these presumably give the most singular part of $\mathcal{G}$ and determine long time reverberation. For the moment we can now drop the discrete indices with the understanding that we will always be concerned with indices only equal to one, corresponding to the vanishing eigenvalue.

Following the literature[1] we make a pole approximation for $1/\lambda(+)-1/\lambda(-)$ writing

$$\begin{aligned}&\frac{1}{\lambda(\mathbf{P}+\mathbf{q}/2,\Omega+\omega/2)}-\frac{1}{\lambda^*(\mathbf{P}-\mathbf{q}/2,\Omega-\omega/2)}\\ &\quad\approx\sum_{m=1}^{N}\frac{g_m}{(\mathbf{P}+\mathbf{q}/2)^2-(k_m(\Omega+\omega/2)+i\Delta_m)^2}\\ &\qquad-\frac{g_m}{(\mathbf{P}-\mathbf{q}/2)^2-(k_m(\Omega-\omega/2)-i\Delta_m)^2}\\ &\quad\approx\sum_{m=1}^{N}\frac{g_m}{(\mathbf{P})^2-(k_m(\Omega)+i\Delta_m)^2}-\frac{g_m}{(\mathbf{P})^2-(k_m(\Omega)-i\Delta_m)^2}\\ &\quad\approx\sum_{m=1}^{N}2\pi i g_m\delta(P^2-k_m^2).\end{aligned} \tag{40}$$

This sequence of approximations assumes first that $1/\lambda$ can be written as a sum of simple poles, that the residues, g_m, are real, that we are interested in small frequency differences ω and small wave vectors **p**, and that the damping of the coherent field is sufficiently small that $\mathcal{T}[1/(x-i\Delta)]\to\pi i\delta(x)$.

The δ-functions in Eq. (40) will drive the solution of the Bethe–Salpeter equation and they suggest the *ansatz*

$$\mathcal{G}_{\mathbf{K},\mathbf{Q}}(\mathbf{q})=\sum_{m,n}\delta(P^2-k_m^2)\phi_{k_m\hat{\mathbf{K}};k_n\hat{\mathbf{Q}}}(\mathbf{q})\delta(Q^2-k_n^2). \tag{41}$$

The term in square brackets on the left side of Eq. (39) can be expanded to first order in the difference frequency, ω, and in the difference wave vector, **q**, since we are interested in long times. Long times will force $|\mathbf{q}|$ to be small; after a long time sound will have diffused so that slowly varying spatial wave vectors dominate the distribution of sound. Substituting our *ansatz* for $\mathcal{G}$ and integrating $|\mathbf{P}|$ over a small neighborhood of k_m, and $|\mathbf{Q}|$ over a neighborhood of k_n gives the following set of coupled integral equations

$$\begin{aligned}[2i\,\mathrm{Im}\,\lambda(\hat{\mathbf{P}}k_m|\Omega)+\mathbf{q}\cdot\partial_{\mathbf{P}}\lambda(k_m\hat{\mathbf{P}}|\Omega)&\\ +\omega\partial_\Omega\lambda(k_m\hat{\mathbf{P}}|\Omega)]\phi_{k_m\hat{\mathbf{P}};k_n\hat{\mathbf{Q}}}(\mathbf{q})&\\ =-4\pi i g_m\delta_{m,n}\delta(\hat{\mathbf{P}}-\hat{\mathbf{Q}})-\pi i g_m&\\ \times\int\sum_{m'}d\theta_K\,U_{k_m\theta_P;k_{m'}\theta_K}(\mathbf{q})\phi_{k_{m'}\theta_K;k_n\theta_Q}(\mathbf{q}).&\end{aligned} \tag{42}$$

The angle θ_P is the angle $\hat{\mathbf{P}}$ makes with some axis, etc. The factor of 4 comes from $\delta(P^2-k_m^2)=\delta(P-k_m)/(2k_m)$ for positive P, and the analogous result for the δ-function in Q.

The imaginary part of λ arises both from intrinsic dissipative processes and from scattering of the mean field into the incoherent field. The Ward identity[1,4,14] implies

$$\begin{aligned}\mathrm{Im}\,\lambda(k_n)&=\frac{-2k_n(\alpha_n+\epsilon_n)}{g_n}\\ &=\frac{-2k_n\alpha_n}{g_n}-\pi^2\sum_m g_m U^{l=0}_{k_m,k_n}(\mathbf{0}|\Omega,0)).\end{aligned} \tag{43}$$

See Appendix C. The contribution to modal decay caused by scattering at the boundaries is ϵ_m; that caused by other dissipative mechanisms is α_m. The complex modal wave number is $k_m+i\Delta_m=k_m+i(\epsilon_m+\alpha_m)$.

Also shown in Appendix C are results for the derivatives of λ:

$$\partial_{\mathbf{P}}\lambda(k_m)=\frac{2k_m\hat{\mathbf{P}}}{g_m} \tag{44}$$

and

$$\partial_\Omega\lambda(k_m)=\frac{-2k_m}{g_m v_{gm}}, \tag{45}$$

where v_{gm} is the modal group velocity. In order to make the scattering in the Bethe–Salpeter equation self-adjoint, it is useful to absorb factors of g_m into ϕ by writing

$$\psi_{k_m\hat{\mathbf{P}};k_n\hat{\mathbf{Q}}}(\mathbf{q})=\frac{1}{g_m}\phi_{k_m\hat{\mathbf{P}};k_n\hat{\mathbf{Q}}}(\mathbf{q})\frac{1}{g_n}. \tag{46}$$

Then the Bethe–Salpeter equation for ψ can be written

$$\left[2k_m\alpha_m+i\mathbf{q}\cdot\hat{\mathbf{P}}k_m-i\omega\frac{k_m}{v_{gm}}\right]\psi_{k_m\theta_P;k_n\theta_Q}(\mathbf{q}|\Omega,\omega)$$
$$=2\pi\delta_{m,n}\delta(\theta_P-\theta_Q)+\int d\theta_K\sum_{m'}\Lambda_{m,\theta_P;m'\theta_K}$$
$$\times(\mathbf{q}|\Omega,\omega)\psi_{k_{m'}\theta_K;k_n\theta_Q}(\mathbf{q}|\Omega,\omega). \tag{47}$$

The left side of this equation can be recognized as a free-streaming operator: Fourier transformation with respect to **q**, calling the Fourier conjugate variable **R**, and with respect to ω, calling its conjugate variable time, t, gives

$$\left[2k_m\alpha_m-k_m\hat{\mathbf{P}}\cdot\nabla+\frac{k_m}{v_{gm}}\frac{\partial}{\partial_t}\right]\psi$$

for left-hand side of Eq. (47). If the right-hand side were zero, this equation would govern the free motion of a swarm of particles with velocities whose direction is random but whose magnitude is v_{gm}, the group velocity of the mth mode. (The term $2k_m\alpha_m$ represents a loss of particles of this type, independent of direction, i.e., absorption.) The right-hand side of Eq. (47) is analogous to the collision term in the Boltzmann equation. It describes the collisions of the particles initially having velocity $v_{gm'}\hat{\mathbf{K}}$ which after collision have velocities $v_{gn}\hat{\mathbf{P}}$.

The scattering operator, Λ, is given by

$$\Lambda_{m,\theta_P;m'\theta_K}(\mathbf{q}|\Omega,\omega)=\frac{\pi}{2}\left[g_mU_{k_m,\theta_P;k_{m'}\theta_K}(\mathbf{q}|\Omega,\omega)g_{m'}-\frac{4}{\pi}\delta_{m,m'}\epsilon_mk_m\right]. \tag{48}$$

Because of the Ward indentity (energy conservation), the scattering operator satisfies

$$\sum_{m'}\int d\theta_K\,\Lambda_{m,\theta_P;m'\theta_K}(0|\Omega,0)$$
$$=0=\sum_m\int d\theta_P\,\Lambda_{m,\theta_P;m'\theta_K}(0|\Omega,0). \tag{49}$$

When the α_m are small, the behavior of ψ as $\omega\to0$ and $\mathbf{q}\to0$ is dominated by the projection of ψ onto its isotropic and modal average. Using standard projection operator techniques[15] on Eq. (47) gives for the modal and angular average of ψ

$$\left[2\langle k\alpha\rangle-i\omega\left\langle\frac{k}{v}\right\rangle+q^2\frac{1}{2N}\sum_{m,n}k_m\left[\frac{1}{\Lambda^{(1)}}\right]_{m,n}k_n\right]\overline{\psi}(\mathbf{q}|\Omega,\omega)=1 \tag{50}$$

as ω and **q** tend to zero. To be precise, $\overline{\psi}$ is given by

$$\overline{\psi}(\mathbf{q}|\Omega,\omega)=\frac{1}{2\pi N}\int d\theta_P\,d\theta_Q\sum_{m,n=0}^{N}\psi_{k_m\theta_P;k_n\theta_Q}(\mathbf{q}|\Omega,\omega). \tag{51}$$

The matrix $\Lambda^{(1)}$ is given by

$$\Lambda^{(1)}_{m,n}=\int\frac{d\theta_P}{\sqrt{2\pi}}\frac{d\theta_Q}{\sqrt{2\pi}}e^{-i\theta_P}\Lambda_{k_m\theta_P;k_n\theta_Q}(\mathbf{q}|\Omega,\omega)e^{i\theta_Q}, \tag{52}$$

and

$$\left[\frac{1}{\Lambda^{(1)}}\right]_{m,n}$$

denotes the m,n element of the matrix inverse of $\Lambda^{(1)}$. The average of the ratio of wave number to group velocity is

$$\left\langle\frac{k}{v}\right\rangle=\frac{1}{N}\sum_{m=0}^{N}\frac{k_m}{v_{gm}}, \tag{53}$$

and

$$\langle k\alpha\rangle=\frac{1}{N}\sum_{m=0}^{N}k_m\alpha_m. \tag{54}$$

Comparing with Eq. 4.4 in Ref. 9 shows that the diffusion coefficient here should be identified as

$$D(\Omega)=\left(\frac{1}{\langle k/v\rangle}\right)\frac{1}{2N}\sum_{m,n}k_m\left[\frac{1}{\Lambda^{(1)}}\right]_{m,n}k_n. \tag{55}$$

The contribution of $\mathcal{G}$ to τ is given by the second term in Eq. (35). Using $\overline{\psi}$ and the δ-function ansatz for $\mathcal{G}$ gives

$$\mathcal{G}^{u_1,u_2;v_1;v_2}_{\mathbf{P},\mathbf{K}}(\mathbf{p})\approx\frac{1}{8\pi N}\sum_{m,n}\delta(P-k_m)\frac{g_m}{k_m}\overline{\psi}\frac{g_n}{k_n}$$
$$\times\delta(K-k_n)\delta_{u_1,1}\delta_{u_2,1}\delta_{v_1,1}\delta_{v_2,1}. \tag{56}$$

Filling in the details of the operator multiplication in $U\mathcal{G}U$ gives

$$(U\mathcal{G}U)^{\alpha,\beta;\gamma,\delta}_{\mathbf{Q},\mathbf{Q}'}(\mathbf{q}|\Omega,\omega)$$
$$=\frac{1}{8\pi N}\sum_{m,n}\int d\theta_P\,d\theta_K\,U^{\alpha,\beta;1,1}_{\mathbf{Q};k_m\hat{\mathbf{P}}}(\mathbf{q}|\Omega,\omega)g_m$$
$$\times\overline{\psi}g_nU^{1,1;\gamma,\delta}_{k_n\hat{\mathbf{P}};\mathbf{Q}'}(\mathbf{q}|\Omega,\omega). \tag{57}$$

The Ward identity (see Appendix C) can be written as

$$i\pi\sum_n\int d\theta_K\,g_nU^{1,1;\gamma,\delta}_{k_n\hat{\mathbf{K}};\mathbf{Q}'}(\mathbf{0}|\Omega,0)$$
$$=M_{\delta,\gamma}(\mathbf{Q}')-M^*_{\gamma,\delta}(\mathbf{Q}')\equiv2i\Sigma_{\delta,\gamma}(\mathbf{Q}'), \tag{58}$$

with a similar result for the transpose resulting from reciprocity. Using this and our result for $\overline{\psi}$ in Eq. (57) gives

$$(U\mathcal{G}U)^{\alpha,\beta;\gamma,\delta}_{\mathbf{Q},\mathbf{Q}'}(\mathbf{q}|\Omega,\omega)$$
$$=\frac{1}{\pi^2 2\pi N}\Sigma_{\beta,\alpha}(\mathbf{Q})\frac{i}{\langle k/v\rangle[\omega+i\xi+iq^2D(\Omega)]}\Sigma_{\delta,\gamma}(\mathbf{Q}'), \tag{59}$$

where $\xi=2\langle k\alpha\rangle/\langle k/v\rangle$, and where we let $\mathbf{q}\to0$ in $U(\mathbf{q}|\Omega,0)$. This is the expression for multiple scattering that will be used in the next section to compute long-time reverberation. Reference 16 shows how to relax the $\mathbf{q}\to0$, $\omega\to0$ limit in the case of resonant volume scattering.

It should be pointed out that the denominator in Eq. (59), when $\xi\to0$, is just the Fourier transform of the Green's function for the diffusion equation

$$\frac{\partial P}{\partial t}+D\nabla^2 P=-\delta(\mathbf{R})\,\delta(t).$$

Hence Eq. (59) is telling us that over long times sound diffuses between scattering events. In this approximation, the second moment has lost much of its wave character.

III. REVERBERATION

In this section the formalism described above will be applied to computing the second moment of pressure fluctuations arising from a point source in a layered medium with one rough interface. In the process, Ellis's model for reverberation will be rederived, but with some small differences. The advantage of the present derivation is that it can be seen from ''first principles'' what the scattering function must be. In addition, we will show that the multiple scattering contribution to reverberation has an algebraic decay with time, if intrinsic attenuations can be ignored. Even if intrinsic attenuations cannot be ignored, the multiple scattering contribution to reverberation decays more slowly in time than the single scattering contribution, and for long enough time will dominate the single scattering contribution.

A. Conventional reverberation

The starting point for the computation is Eq. (29), and the main mathematical issue is how to deal with the multidimensional integrations that are needed. The pressure at $(\mathbf{r},t)$ caused by a narrow-band pressure source at $\mathbf{r}_0=(\mathbf{R}_0,z_s)$ is

$$p(\mathbf{r},t)=\int\frac{d\omega}{2\pi}e^{-i\omega t}G(\mathbf{R},z;\mathbf{R}_0,z_s;\omega)\hat{a}(\omega), \tag{60}$$

where $\mathbf{r}=(\mathbf{R},z)$. The source function, $\hat{a}(\omega)$, is the Fourier transform of

$$a(t)=\mathrm{Re}\,e^{-i\omega_c t}b(t), \tag{61}$$

where $b(t)$, the complex envelope of the source signal,[17] is slowly varying with respect to the carrier wave, $e^{-i\omega_c t}$. Then

$$a(\omega)=[\hat{b}(\omega-\omega_c)+\hat{b}^*(-\omega-\omega_c)]/2. \tag{62}$$

The received pressure can also be written in terms of its complex envelope, $\tilde{p}(\mathbf{r},t)$, by

$$p(\mathbf{r},t)=\mathrm{Re}\,e^{-i\omega_c t}\tilde{p}(\mathbf{r},t), \tag{63}$$

with $\tilde{p}(\mathbf{r},t)$ given by

$$\tilde{p}(\mathbf{r},t)=\int\frac{d\omega}{2\pi}e^{-i\omega t}G(\mathbf{r},\mathbf{r}_0,\omega+\omega_c)\hat{b}(\omega). \tag{64}$$

The magnitude of $\tilde{p}$ is the quantity usually measured, and here we will be concerned with its fluctuations, in particular with

$$C(\mathbf{r},t)\equiv\langle\Delta\tilde{p}(\mathbf{r},t)\Delta\tilde{p}^*(\mathbf{r},t)\rangle. \tag{65}$$

The complex envelope of the emitted signal is related to the total acoustic energy generated by the source, E_0, by

$$E_0=\frac{1}{16\pi^2\rho_0 c_0}\int|\hat{b}(\omega)|^2\,d\omega. \tag{66}$$

Here ρ_0 and c_0 are the density and sound speed at the source, respectively.

To compute the mean square envelope fluctuation $C(\mathbf{r},t)$ we need to ''unpack'' Eq. (29) for ΔG to obtain

$$\begin{aligned}\Delta\tilde{p}(\mathbf{r},t)=\int\frac{d\omega}{2\pi}e^{-i\omega t}\frac{d\mathbf{P}}{2\pi}\frac{d\mathbf{K}}{2\pi}e^{i\mathbf{P}\cdot\mathbf{R}}e^{-i\mathbf{K}\cdot\mathbf{R}_0}(-1)^i\partial_{z_i}\\ \times\langle G(\mathbf{P},z,z_i,\omega+\omega_c)\rangle t^{i,j}(\mathbf{P},\mathbf{K};\omega+\omega_c)(-1)^j\partial_{z_j}\\ \times\langle G(\mathbf{K},z_j,z_s,\omega+\omega_c)\rangle\hat{b}(\omega).\end{aligned} \tag{67}$$

Here, z_i, $i=0,1$, refers to the level of the imaginary plane adjacent to either the upper or lower bounding rough surface while z_s is the source depth. There is an implicit sum over i and j and the factors $(-1)^i$ are just a simple way to incorporate the matrix σ_3. To understand this expression it is useful to replace the wave vector dependence of the mean fields by the corresponding spatial dependence using

$$\langle G(\mathbf{P},z,z_i,\omega+\omega_c)\rangle=\int d\mathbf{R}'\,e^{-i\mathbf{P}\cdot\mathbf{R}'}\langle G(\mathbf{R}',z,z_i,\omega+\omega_c)\rangle. \tag{68}$$

After translating the dummy variables of integration the fluctuation of the pressure becomes

$$\begin{aligned}\Delta\tilde{p}(\mathbf{r},t)=\int\frac{d\omega}{2\pi}e^{-i\omega t}\frac{d\mathbf{P}}{2\pi}\frac{d\mathbf{K}}{2\pi}d\mathbf{s}\,d\mathbf{s}'\\ \times(-1)^i\partial_{z_i}\langle G(\mathbf{R}-\mathbf{s},z,z_i,\omega+\omega_c)\rangle\\ \times e^{i\mathbf{P}\cdot\mathbf{s}}t^{i,j}(\mathbf{P},\mathbf{K};\omega+\omega_c)e^{-i\mathbf{K}\cdot\mathbf{s}'}(-1)^j\partial_{z_j}\\ \times\langle G(\mathbf{s}'-\mathbf{R}_0,z_j,z_s,\omega+\omega_c)\rangle\hat{b}(\omega).\end{aligned} \tag{69}$$

Results of this type were used by Ellis and Yang[7,18] and others to compute reverberant and scattered fields. The result here is distinctive in that (*a*) derivatives of the mean field are used to propagate to and from the scattering at the boundary, (*b*) there is a precise prescription for the scattering amplitude, t, in terms of the impedance even if t cannot be computed exactly, and (*c*) there are two rough bounding surfaces. This equation, Eq. (69), is still formally exact. However, the ninefold integral in Eq. (69) is daunting. The dimensionality will be reduced by expanding the phase difference of the Green's functions to first order in spatial separations and to first order in the deviation of the frequency from the carrier frequency.

Computing $C(\mathbf{r},t)$ doubles the number of integrations. The dummy variables of integration for $\Delta\tilde{p}$ will be denoted with subscripts ''1'' and the variables of integration giving $\Delta\tilde{p}^*$ with subscripts ''2.'' It will then be convenient to introduce sum and difference variables because the statistical homogeneity of t,

$$\begin{aligned}\langle t^{i_1,j_1}(\mathbf{P}_1,\mathbf{K}_1,\Omega+\omega/2+\omega_c)t^{i_2,j_2}(\mathbf{P}_2,\mathbf{K}_2,\Omega-\omega/2+\omega_c)^*\rangle\\ =\tau^{i_1,i_2;j_1,j_2}_{(\mathbf{P}_1+\mathbf{P}_2)/2_1(\mathbf{K}_1+\mathbf{K}_2)/2}(\mathbf{P}_1-\mathbf{P}_2|\Omega+\omega_c,\omega)\\ \times\delta(\mathbf{P}_1-\mathbf{P}_2-(\mathbf{K}_1-\mathbf{K}_2))\end{aligned} \tag{70}$$

is best expressed in these variables, and because, in expanding phases to first order in the difference variables, the error

is only of third order. Therefore, make the following changes of variable:

$$\Omega=(\omega_1+\omega_2)/2,\quad \omega=\omega_1-\omega_2,$$
$$\mathbf{P}=(\mathbf{P}_1+\mathbf{P}_2)/2,\quad \mathbf{p}=\mathbf{P}_1-\mathbf{P}_2,$$
$$\mathbf{K}=(\mathbf{K}_1+\mathbf{K}_2)/2,\quad \mathbf{k}=\mathbf{K}_1-\mathbf{K}_2, \tag{71}$$
$$\mathbf{R}_1=(\mathbf{s}_1+\mathbf{s}_2)/2,\quad \boldsymbol{\rho}_1=\mathbf{s}_1-\mathbf{s}_2,$$
$$\mathbf{R}_2=(\mathbf{s}_1'+\mathbf{s}_2')/2,\quad \boldsymbol{\rho}_2=\mathbf{s}_1'-\mathbf{s}_2'.$$

Using Eq. (70) eliminates one integral leaving

$$C(\mathbf{r},t)=\frac{1}{(2\pi)^6}\int d\Omega\, d\omega \int d\mathbf{P}\, d\mathbf{K}\, d\mathbf{p}\int d\mathbf{R}_1\, d\mathbf{R}_2\, d\boldsymbol{\rho}_1\, d\boldsymbol{\rho}_2 e^{-i\omega t}\partial_{z_{i_1}}\langle G(\mathbf{R}-\mathbf{R}_1-\boldsymbol{\rho}_1/2,z,z_{i_1},\Omega+\omega_c+\omega/2)\rangle$$
$$\times\partial_{z_{i_2}}\langle G^*(\mathbf{R}-\mathbf{R}_1+\boldsymbol{\rho}_1/2,z,z_{i_2},\Omega+\omega_c-\omega/2)\rangle e^{i\mathbf{P}\cdot\boldsymbol{\rho}_1}e^{i\mathbf{p}\cdot(\mathbf{R}_1-\mathbf{R}_2)}e^{-i\mathbf{K}\cdot\boldsymbol{\rho}_2}\tau^{i_1,i_2;j_1,j_2}_{\mathbf{P},\mathbf{K}}(\mathbf{p}|\Omega+\omega_c,\omega)(-1)^{i_1+i_2+j_1+j_2}$$
$$\times\partial_{z_{j_1}}\langle G(\mathbf{R}_2-\mathbf{R}_0+\boldsymbol{\rho}_2/2),z_{j_1},z_s,\Omega+\omega_c+\omega/2)\rangle\partial_{z_{j2}}\langle G^*(\mathbf{R}_2-\mathbf{R}_0-\boldsymbol{\rho}_2/2),z_{j_2},z_s,\Omega+\omega_c-\omega/2)\rangle$$
$$\times b(\Omega+\omega/2)b^*(\Omega-\omega/2). \tag{72}$$

This equation is still exact.

Assume that the source produces a pulse of finite duration. Then for long times after the pulse is emitted one can reasonably expect that only distant portions of the surface contribute to the integral. This means that the Green's functions, which are of the form shown in Eq. (34), can be evaluated asymptotically using

$$H_0^{(1)}(kR)\sim\sqrt{\frac{2}{\pi kR}}e^{-i\pi/4}e^{ikR}. \tag{73}$$

In the special case of a rough Dirichlet surface, to lowest order in the surface roughness, τ is simply the spectrum of surface heights,

$$\tau_{\mathbf{P},\mathbf{K}}(\mathbf{p}|\Omega,\omega)=S(\mathbf{P}-\mathbf{K}). \tag{74}$$

(Because to lowest order τ is the correlation of impedances, τ in this case does not involve vertical components of the wave vectors. This is one of the simplifying features of the impedance formalism.) Thus, in this case, τ is independent of $\mathbf{p}$, $\mathbf{P}+\mathbf{K}$, Ω, and ω. Integration over $\mathbf{p}$ will give a δ-function in $\mathbf{R}_1-\mathbf{R}_2$. Integration over $(\mathbf{P}+\mathbf{K})/2$ gives $\delta(\boldsymbol{\rho}_1-\boldsymbol{\rho}_2)$. Integration over $\mathbf{P}-\mathbf{K}$ will give the correlation function of surface heights, $C_h(\boldsymbol{\rho}_1+\boldsymbol{\rho}_2)=C_h(2\boldsymbol{\rho}_1)$. This means that the region of integration over $\boldsymbol{\rho}_1$ will be limited to a few correlation lengths of the surface roughness. Thus, for large time t we can expect

$$|\mathbf{R}-\mathbf{R}_1|\gg|\boldsymbol{\rho}_1|/2\approx L_c. \tag{75}$$

In fact, a reasonable estimate of $|\mathbf{R}-\mathbf{R}_1|$ is $|\mathbf{R}-\mathbf{R}_1|\approx v_g t$ where v_g is a typical modal group velocity. The upshot of this argument is that if $t\gg L_c/v_g$, then the phases of the Green's functions can be expanded as

$$e^{ik_m|\mathbf{R}-\mathbf{R}_1\pm\boldsymbol{\rho}_1/2|}\approx e^{ik_m|\mathbf{R}-\mathbf{R}_1|\pm ik_m(\widehat{\mathbf{R}-\mathbf{R}_1})\cdot\boldsymbol{\rho}_1/2}, \tag{76}$$

etc. It will simply be assumed that this same argument can be used in the case of more complicated expressions for τ. Be aware, however, that in the case of a fluid–fluid boundary, τ will contain vertical wave numbers and corresponding branch points. These may be problematic for modes near cut off. In any event, it is assumed that for long times the scattering takes place far from the source and receiver, and then at the scattering location, the incident field has a locally plane wave character. This is what it means to expand to first order in ρ_1 or ρ_2. In the phases, modal wave numbers will be expanded to first order in ω using

$$k_m(\Omega+\omega_c+\omega/2)\approx k_m(\Omega+\omega_c)+\omega/(2v_{gm}), \tag{77}$$

where v_{gm} is the group velocity of the mth mode at the center frequency $\Omega+\omega_c$. The narrow-band assumption limits ω and Ω to values much less than the center frequency. Outside of the phases only zeroth-order terms in these expansions will be used. Making all these approximations gives

$$C(\mathbf{r},t)=\frac{1}{(2\pi)^6 16(2\pi)^2}\sum_{m,n}\int d\Omega\, d\omega\int d\mathbf{P}\, d\mathbf{K}\, d\mathbf{p}\int d\mathbf{R}_1\, d\mathbf{R}_2\, d\boldsymbol{\rho}_1\, d\boldsymbol{\rho}_2\, e^{-i\omega t}\frac{u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_n(z_s)^2}{k_m k_n|\mathbf{R}-\mathbf{R}_1||\mathbf{R}_2-\mathbf{R}_0|}$$
$$\times(-1)^{i_1+i_2+j_1+j_2}\exp[-2\Delta_m|\mathbf{R}-\mathbf{R}_1|-2\Delta_n|\mathbf{R}_2-\mathbf{R}_0|-ik_m(\widehat{\mathbf{R}-\mathbf{R}_1})\cdot\boldsymbol{\rho}_1+ik_n(\widehat{\mathbf{R}_2-\mathbf{R}_0})\cdot\boldsymbol{\rho}_2]$$
$$\times\exp[i\mathbf{P}\cdot\boldsymbol{\rho}_1-i\mathbf{K}\cdot\boldsymbol{\rho}_2+i\mathbf{p}\cdot(\mathbf{R}_1-\mathbf{R}_2)]\tau^{i_1,i_2;j_1,j_2}_{\mathbf{P},\mathbf{K}}(\mathbf{p}|\Omega+\omega_c,\omega)$$
$$\times\exp[i\omega|\mathbf{R}-\mathbf{R}_1|/v_{gm}+i\omega|\mathbf{R}_2-\mathbf{R}_0|/v_{gn}]\hat{b}(\Omega+\omega/2)\hat{b}^*(\Omega-\omega/2). \tag{78}$$

There should really be a fourfold sum over mode numbers. However, terms such as $\exp[i(k_m-k_{m'})|\mathbf{R}+\mathbf{R}_1|$ have been dropped under the assumption that these will oscillate rapidly except when $m=m'$. The integral over $\boldsymbol{\rho}_1$ gives $(2\pi)^2\delta(\mathbf{P}-k_m\times(\widehat{\mathbf{R}-\mathbf{R}_1}))$ and over $\boldsymbol{\rho}_2$ gives $(2\pi)^2\delta(\mathbf{K}-k_n(\widehat{\mathbf{R}_2-\mathbf{R}_0}))$ giving

$$C(\mathbf{r},t)=\frac{(2\pi)^4}{(2\pi)^6 16(2\pi)^2}\sum_{m,n}\int d\Omega\, d\omega\int d\mathbf{p}\int d\mathbf{R}_1\, d\mathbf{R}_2(-1)^{i_1+i_2+j_1+j_2}\frac{u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_u'(z_{j_2})u_n(z_s)^2}{k_m k_n|\mathbf{R}-\mathbf{R}_1||\mathbf{R}_2-\mathbf{R}_0|}$$

$$\times\tau^{i_1,i_2;j_1j_2}_{k_m(\widehat{\mathbf{R}-\mathbf{R}_1}),k_n(\widehat{\mathbf{R}_2-\mathbf{R}_0})}(\mathbf{p}|\Omega+\omega_c,\omega)\exp[-2\Delta_m|\mathbf{R}-\mathbf{R}_1|-2\Delta_n|\mathbf{R}_2-\mathbf{R}_0|]\exp[+ip\cdot(\mathbf{R}_1-\mathbf{R}_2)]$$

$$\times\exp\{-i\omega[t-|\mathbf{R}-\mathbf{R}_1|/v_{gm}-|\mathbf{R}_2-\mathbf{R}_0|/v_{gn}]\}\hat{b}(\Omega+\omega/2)\hat{b}^*(\Omega-\omega/2). \tag{79}$$

We will assume that the bandwidth of the pulse is sufficiently small that Ω can be neglected relative to ω_c within τ and that the modal wave numbers k_m, modes $u_m(z)$, and group velocities v_{gm} are to be evaluated at ω_c.

To get conventional reverberation results such as in Ref. 7 consider only the contribution to τ from the irreducible vertex function and set $\mathbf{p}=0$ and $\omega=\Omega=0$ in $U_{\mathbf{P},\mathbf{K}}(\mathbf{p}|\Omega+\omega_c,\omega)$, assuming that U is well behaved in this limit. Then the integration over $\mathbf{p}$ gives $(2\pi)^2\delta(\mathbf{R}_1-\mathbf{R}_2)$. Furthermore, assume that the source and receiver are separated only vertically so that we can let $\mathbf{R}=\mathbf{R}_0=0$. Assume also that $U_{-k_m\widehat{\mathbf{R}}_1,k_n\widehat{\mathbf{R}}_1}$ is independent of the direction of $\widehat{\mathbf{R}}_1$. Then the mean square fluctuation of the pressure envelope is

$$C(\mathbf{r},t)=\frac{1}{(32\pi)}\sum_{m,n}\int_0^\infty RdR(-1)^{i_1+i_2+j_1+j_2}\frac{u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_n'(z_s)^2}{k_m k_n R^2}$$

$$\times U^{i_1,i_2;j_1,j_2}_{-k_m\hat{\mathbf{R}},k_n\hat{\mathbf{R}}}(\mathbf{0}|\omega_c,0)e^{-2(\Delta_m+\Delta_n)R}\int e^{-i\omega[t-R(1/v_{gm}+1/v_{gn})]}\hat{b}(\Omega+\omega/2)\hat{b}^*(\Omega-\omega/2)\,d\omega\,d\Omega, \tag{80}$$

where, again, k_m, ϵ_m, u_m, etc. are evaluated at the carrier frequency, ω_c.

Finally, suppose for the sake of concreteness, that $\hat{b}$ is Gaussian,

$$\hat{b}(\omega)=A\exp[-\omega^2/(2B^2)],$$

in order to see how things work out. The double frequency integral in Eq. (80) is

$$\int e^{-i\omega[t-R(1/v_{gm}+1/v_{gn})]}\hat{b}\left(\Omega+\frac{\omega}{2}\right)\hat{b}^*\left(\Omega-\frac{\omega}{2}\right)d\Omega\,d\omega$$

$$=A^2 2\pi B^2\exp\left[-\left(t-R\left(\frac{1}{v_{gm}}+\frac{1}{v_{gn}}\right)\right)^2B^2\right], \tag{81}$$

and the normalization of $\hat{b}$ in terms of the total energy gives

$$|A|^2\sqrt{\pi B^2}=16\pi^2\rho_0 c_0 E_0. \tag{82}$$

Hence $C(\mathbf{r},t)$ becomes

$$C(\mathbf{r},t)=\frac{16\pi^2\rho_0 c_0 E_0}{32\pi}\sum_{m,n}\int_0^\infty dR\,(-1)^{i_1+i_2+j_1+j_2}$$

$$\times\frac{u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_n(z_s)^2}{k_m k_n R}$$

$$\times U^{i_1,i_2;j_1,j_2}_{-k_m\hat{\mathbf{R}}+k_n\hat{\mathbf{R}}}(\mathbf{0}|\omega_c,0)$$

$$\times\exp[-2(\Delta_m+\Delta_n)R]\sqrt{4\pi B^2}$$

$$\times e^{-[t-R(1/v_{gm}+1/v_{gn})]^2B^2}. \tag{83}$$

This leaves just the range integral in Eq. (83). However, if $t\gg 1/B$, i.e., the observations take place at a time long compared to the duration of the pulse, and if the decay rate is small enough that

$$2(\epsilon_m+\epsilon_n)\frac{v_{gm}v_{gn}}{v_{gm}+v_{gn}}\frac{1}{B}\ll 1,$$

then the Gaussian behaves like a δ-function

$$\sqrt{4\pi B^2}e^{-(t-R(1/v_{gm}+1/v_{gn})B)^2}$$

$$\approx\frac{2\pi(v_{gm}+v_{gn})}{v_{gm}v_{gn}}\delta\left(R-t\frac{v_{gm}v_{gn}}{(v_{gm}+v_{gn})}\right).$$

Now the range integral can be done giving

$$C(\mathbf{r},t)=\pi^2\rho_0 c_0 E_0\sum_{m,n}(-1)^{i_1+i_2+j_1+j_2}$$
$$\times\frac{u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_n(z_s)^2}{k_m k_n t}$$
$$\times U^{i_1,i_2;j_1,j_2}_{k_m\mathbf{R},-k_n\hat{\mathbf{R}}}(\mathbf{0}|\omega_c,0)$$
$$\times\exp\left[-2(\Delta_m+\Delta_n)t\frac{v_{gm}v_{gn}}{(v_{gm}+v_{gn})}\right]. \tag{84}$$

This is basically Ellis' result. It differs only in some details. First, group velocities have replaced phase velocities. Second, instead of a somewhat ill-defined scattering strength, we use here the irreducible vertex function which in turn is expressed in terms of impedance fluctuations and in terms of horizontal wave vectors. It is this last fact that probably accounts for differences in numerical factors. The normal modes here are normalized so that for Dirichlet surfaces, $\int u_n(z)^2\,dz=1$ and the dimension of the normal modes here is $1/\sqrt{\text{Length}}$.

B. Reverberation with multiple scattering

We now compute the contribution to reverberation that comes from including the second term in $\tau=U+U\mathcal{G}U$. Starting again from Eq. (79), the pole structure of $\mathcal{G}$ means that it is not possible to ignore the $\mathbf{p}$ and ω dependence of the $U\mathcal{G}U$ contribution to τ. Using Eq. (59) gives, taking $\mathbf{R}=\mathbf{R}_0=0$,

$$C^{\text{mult.}}(\mathbf{r},t)=\frac{i(2\pi)^4}{((2\pi)^6 16(2\pi)^2)\pi^2\langle k/v\rangle 2\pi N}\sum_{m,n}\int d\Omega\,d\omega\,d\mathbf{p}\,d\mathbf{R}_1\,d\mathbf{R}_2(-1)^{i_1+i_2+j_1+j_2}$$
$$\times\frac{\Sigma_{i_1,i_2}(k_m)u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_n(z_s)^2\Sigma_{j_1,j_2}(k_n)}{k_m k_n R_1 R_2[\omega+i\xi+ip^2D(\omega_c)]}e^{-2\Delta_m R_1-2\Delta_n R_2}$$
$$\times\exp[-i\mathbf{p}\cdot(\mathbf{R}_1-\mathbf{R}_2)]e^{-i\omega(t-R_1/v_{gm}-R_2/v_{gn})}\hat{b}(\Omega+\omega/2)\hat{b}^*(\Omega-\omega/2). \tag{85}$$

Write the frequency denominator as

$$\frac{1}{[\omega+i\xi+ip^2D(\omega_c)]}=i\int_0^\infty dy\,e^{i[\omega+i\xi+ip^2D(\omega_c)]y}. \tag{86}$$

Then the $\mathbf{p}$ integral (two-dimensional) is Gaussian:

$$\int d\mathbf{p}e^{i\mathbf{p}\cdot(\mathbf{R}_2-\mathbf{R}_1)-p^2Dy}=\frac{\pi}{Dy}e^{-(\mathbf{R}_2-\mathbf{R}_1)^2/(4Dy)}. \tag{87}$$

The pressure fluctuation now becomes

$$C^{\text{mult.}}(\mathbf{r},t)=\frac{i(2\pi)^4}{((2\pi)^6 16(2\pi)^2)\pi^2\langle k/v\rangle 2\pi N}\sum_{m,n}\int d\Omega\,d\omega\int_0^\infty dy\,d\mathbf{R}_1\,d\mathbf{R}_2(-1)^{i_1+i_2+j_1+j_2}$$
$$\times\frac{\pi\Sigma_{i_1,i_2}(k_m)u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_n(z_s)^2\Sigma_{j_1,j_2}(k_n)}{k_m k_n R_1 R_2 Dy}e^{-2\Delta_m R_1-2\Delta_n R_2}$$
$$\times\exp[-(\mathbf{R}_2-\mathbf{R}_1)^2/(4Dy)]e^{i[\omega+i\xi]y}e^{-i\omega(t-R_1/v_{gm}-R_2/v_{gn})}\hat{b}(\Omega+\omega/2)\hat{b}^*(\Omega-\omega/2). \tag{88}$$

For large times t, we expect that only small values of ω will contribute to the integral. Hence, replace ω by 0 in b and b^*. The remaining ω integration gives $2\pi\delta(y-(t-|\mathbf{R}_1|/v_{gm}-|\mathbf{R}_2|/v_{gn}))$. This allows the y integral to be performed:

$$C^{\text{mult.}}(\mathbf{r},t)=\frac{i(2\pi)^4}{((2\pi)^6 16(2\pi)^2)\pi^2\langle k/v\rangle 2\pi N}\sum_{m,n}\int d\Omega\,d\mathbf{R}_1\,d\mathbf{R}_2(-1)^{i_1+i_2+j_1+j_2}$$
$$\times\frac{\pi(2\pi)\Sigma_{i_1,i_2}(k_m)u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_n(z_s)^2\Sigma_{j_1,j_2}(k_n)}{k_m k_n R_1 R_2 D(t-R_1/v_{gm}-R_2/v_{gn})}$$
$$\times e^{-2\Delta_m R_1-2\Delta_n R_2}\exp[-(\mathbf{R}_2-\mathbf{R}_1)^2/(4D(t-R_1/v_{gm}-R_2/v_{gn}))]e^{-\xi(t-R_1/v_{gm}-R_2/v_{gn})}\hat{b}(\Omega)\hat{b}^*(\Omega), \tag{89}$$

provided $(t-R_1/v_{gm}-R_2/v_{gn})\geqslant 0$. Because of the damping in $e^{-2\Delta_m R_1-2\Delta_n R_2}$, both R_1 and R_2 are restricted to values less than a few times $1/\Delta_m$. For t much larger than $(1/(v_{gm}\Delta_m)+1/(v_{gn}\Delta_n))$ we can replace $\exp[-(\mathbf{R}_2-\mathbf{R}_1)^2/(4D(t-R_1/v_{gm}-R_2/v_{gn}))]$ by unity and $1/(D(t-R_1/v_{gm}-R_2/v_{gn}))$ by $1/Dt$. Then the integrations over $\mathbf{R}_i$ can be done with the result

$$C^{\text{Mult.}}(\mathbf{r},t)=\frac{\rho_0 c_0 E_0}{2\pi N\langle k/v\rangle}\sum_{m,n}(-1)^{i_1+i_2+j_1+j_2}\frac{\Sigma_{i_1,i_2}(k_m)u_m^2(z)u_m'(z_{i_1})u_m'(z_{i_2})u_n'(z_{j_1})u_n'(z_{j_2})u_m(z_s)^2\Sigma_{j_1,j_2}(k_n)}{k_m k_n 4\Delta_m\Delta_n 2D(\omega_c)t}e^{-\xi t}. \tag{90}$$

In the limit of vanishing intrinsic attenuation, $\xi=0$, $C^{\text{Mult.}}\sim 1/t$; there is only algebraic, not exponential, decay of the reverberation. Also in this limit, Δ_m and $\Sigma(k_m)$ will be proportional for small roughness. $C^{\text{Mult.}}$ then vanishes as the scattering vanishes only because the diffusion constant, D, becomes infinite. For another instance of diffusive reverberation, see Ref. 19. It is claimed there that reverberation in the ocean was observed to follow a power law of the form

$$p^2\sim At^{-4}$$

for surface scattering according to Ref. 20. I am not sure that these observations have survived the test of time, and it is not clear why the decay is faster than that proposed here.

Even when $\xi\neq 0$, it can happen that α is smaller than any of the Δ_m, in which case, the decay of $C^{\text{Mult.}}$ will be slower than the single scatter (from U) contribution to $C^{\text{Mult.}}$. For example, suppose there is only a single propagating mode. Then Eq. (84) takes the form

$$C(\mathbf{r},t)\sim B\frac{e^{-2(\epsilon_1+\alpha_1)v_{g1}t}}{t},$$

while the multiple scattering contribution, Eq. (90), takes the form

$$C^{\text{Mult.}}(\mathbf{r},t)=A\frac{e^{-2\alpha_1 v_{g1}t}}{Dt}.$$

Recall that ϵ_m accounts for the modal attenuation caused by surface roughness, while α accounts for the modal attenuation caused by other mechanisms. Clearly the multiple and single scattering contributions to reverberation are qualitatively similar. However, it is also clear that the multiple scattering contribution decays more slowly than the single scatter contribution. At some time, depending on the various constants A, B, D, α, etc., multiple scattering will dominate single scattering. However, at such times, or at times sufficiently long so that these results for single and multiple scattering are valid, the reverberation signals might be too small to be actually detectable. Since these results concerning the relative size of the single and multiply scattered fields are evidently new, I suspect that no experiment has been designed to distinguish the two. More computation is required to determine the feasibility of such an experiment. In a realistic ocean setting, I would speculate that intrinsic attenuation, α, is so large that algebraic decay will never be observed. However, it seems important to know how to compute the decay rate for reverberation. Should one use α or $\epsilon+\alpha$? This can only be settled by experiment and by an actual computation of the magnitudes of the single and multiple scattering contributions.

IV. SUMMARY AND DISCUSSION

A first-principles computation of reverberation has been presented. Approximations needed to obtain conventional reverberation models have been delineated, resulting in some small corrections and in a better understanding of what function should be used to describe the scattering *per se*. The impedance formalism for describing scattering in a complicated environment has been shown to be a convenient starting point. The contribution of multiple scattering to reverberation has been shown to result in algebraic decay rather than exponential decay of the signal when there is little intrinsic attenuation. However, in general, both the single- and multiple-scattering contributions to reverbation involve a product of exponential and $1/t$ decay. The multiple-scattering contribution appears to decay more slowly than the single-scatter contribution.

The computations presented here are completely analogous to those presented in Refs. 9 and 16 for the scattering of scalar waves by volume inhomogeneities. They are distinct in (1) the treatment of multi-modal propagation and (2) in that the scattering occurs at boundaries. Similar ideas have been numerically implemented by Schmidt and Kuperman.[21] The results here provide an analytic baseline for those computations.

The principal approximations and assumptions for this computation are the following:

(1) Scattering can be described by a nonlocal impedance function for any one realization of an ensemble of rough surfaces. As indicated in Appendix A, this use of the impedance is reasonably well founded. It underlies not only this work, but is implicit in the work of Maradudin, as well.
(2) The computation cannot proceed without assuming statistical homogeneity. Is the ocean really statistically homogeneous? Probably only over limited scales.
(3) Equation (34) for τ and Eq. (37), the Bethe–Salpeter equation, are exact. However, when the irreducible vertex function, U, is approximated as a simple ladder diagram, these cease to be exact. It is difficult to assess the error incurred by using the ladder approximation. For a discussion in the context of electron localization see Ref. 14. The analysis there seems to indicate that when there is no intrinsic attenuation, in addition to ladder diagrams, the maximally crossed diagrams will be important.
(4) Liberal use was made of pole approximations both for the mean Green's function and for the two-point Green's function. For the mean field, this means that branch-cut contributions are ignored. This is normally a reasonable approximation for far-field computations. I assume that if I confine my interest to long times, I need only consider the far field.
(5) In the treatment of the Bethe–Salpeter equation it was assumed further that (a) only the most singular part of $\mathcal{G}$ is needed for long time results, and (b) that this most singular behavior is dominated by the vanishing eigenvalues of the free-streaming operator, i.e., the left side of

Eq. (37), and by the vanishing eigenvalues of the scattering operator, Λ. This is consistent with conventional treatments of transport phenomena derived from the Boltzman equation.[15]

(6) What is not clear is how large the elapsed time t needs to be for these assumptions and approximations to be valid. Computation of the next term in a systematic asymptotic expansion is required to address this issue. Perhaps it is possible to make mean-free-path arguments to assess the validity of these approximation, but that would be another paper.

(7) In computing the multiple integral in Eq. (72) the far-field assumption, Eq. (73), was used, and it was assumed that at the scattering events, the wave field is locally like a plane wave, at least horizontally. Furthermore, the bandwidth of pulses needs to be sufficiently narrow that only a low-order expansion of modal wave numbers in frequency is needed. In obtaining Ellis's result, the expression for U is unevaluated. One can use the ladder approximation, or try to infer U from measurement if the multiple scattering contribution can be neglected.

The multiple scattering result is necessarily more problematic than the single scattering result. However, once one accepts the idea of sound *intensity* diffusing between scattering events, Eqs. (89) and (90) become more understandable, if not more believable. First, the various modes and derivatives appear because the field propagates via the mean field from the source to the various surfaces in a wavelike fashion, and the field propagates from the surface to the receiver also in a wavelike fashion via the mean field. There is a pair of Green's functions for the former and a pair for the latter propagation. Each Green's function contains a sum of products of two modal functions. Hence there are eight modal functions.

The factor $\exp[-(\mathbf{R}_2-\mathbf{R}_1)^2/(4D(t-R_1/v_{gm}-R_2/\times v_{gn}))]/(D(t-R_1/v_{gm}-R_2/v_{gn}))$ in Eq. (89) describes the diffusion of the second moment between scattering events at $\mathbf{R}_1$ and $\mathbf{R}_2$. If the total round trip time is t, and the time to propagate from the source to $\mathbf{R}_2$ is determined by the group velocity v_{gn} and from $\mathbf{R}_1$ to the receiver by the group velocity v_{gm}, this leaves the time $(t-R_1/v_{gm}-R_2/v_{gn})$ to diffuse from $\mathbf{R}_2$ to $\mathbf{R}_1$. The factors $\exp(-2\Delta_m R_1-2\Delta_n R_2)$ describe the decay of the mean field first from the source to $\mathbf{R}_2$ and second from $\mathbf{R}_1$ to the receiver (here co-located with the source). The scattering allows all modes to contribute. The precise form of the diffusion constant, D, requires the detailed analysis leading to Eq. (54). The appearance of the decay constants Σ in Eq. (89) follows from Eq. (57) and the Ward identity–in effect from conservation of energy. All of which is to say that Eq. (89) is understandable, even if the approximations leading to it appear somewhat opaque.

Finally, we note again that the exponential decay rate for multiple scattering is controlled by mechanisms other than surface scattering; the decay arising from surface scattering is contained in ϵ_m and these disappeared from the Bethe–Salpeter equation when the scattering operator Λ was constructed in Eq. (48) and the Ward identity was applied in Eq. (49). The exponential decay rate for single scattering is controlled by a sum of surface scattering and other decay mechanisms.

I have not attempted to include the contribution of maximally crossed diagrams to the scattering. In the limit of no intrinsic scattering these will give rise to a signal that does not decay in time at all because, in this case the diffusion coefficient, D, is proportional to ω. This, means that the sound does not leave the region from which it was generated.[9] It is hard to believe that this can be a significant effect in underwater acoustics, so I have chosen not to investigate the maximally crossed diagrams here.

ACKNOWLEDGMENTS

The work was supported in part by the Office of Naval Reseach. It owes much (more than is indicated by the footnotes) to the clear presentations by A. A. Maradudin in the papers cited below.

APPENDIX A: NONLOCAL IMPEDANCE

This appendix discusses nonlocal impedance boundary conditions. Reference 22 shows that Green's functions, and hence arbitrary fields, in the presence of a single rough boundary can be represented as superpositions of scattering states of the form

$$\psi(\mathbf{R},z)=\int d\mathbf{K}\,d\mathbf{Q}e^{i\mathbf{Q}\cdot\mathbf{R}}[e^{-iq_z z}\delta(\mathbf{Q}-\mathbf{K}) + e^{iq_z z}T(\mathbf{Q}|\mathbf{K})]A(\mathbf{K}). \tag{A1}$$

Here $T(\mathbf{Q}|\mathbf{K})$ is the scattering amplitude for a downgoing plane wave of horizontal wave vector $\mathbf{K}$ to scatter into an upgoing plane wave of horizontal wave vector $\mathbf{Q}$. Impedance boundary conditions relate this field and its z derivative along a horizontal plane. If differentiation and integration can be interchanged, then the z derivative of the field ψ at z is given by

$$\frac{\partial\psi(\mathbf{R},z)}{\partial z}=\int d\mathbf{K}\,d\mathbf{Q}e^{i\mathbf{Q}\cdot\mathbf{R}}(-iq_z)[e^{-iq_z z}\delta(\mathbf{Q}-\mathbf{K}) - e^{iq_z z}T(\mathbf{Q}|\mathbf{K})]A(\mathbf{K}). \tag{A2}$$

Since the amplitudes $A(\mathbf{K})$ appear both in the field and its derivative, there is surely some direct relation between the two. To get at this relation, form the horizontal Fourier transform of the derivative of the field:

$$\frac{\partial\hat{\psi}(\mathbf{Q},z)}{\partial z}\equiv\frac{1}{(2\pi)^2}\int e^{-i\mathbf{Q}\cdot\mathbf{R}}\frac{\partial\psi(\mathbf{R},z)}{\partial z}d\mathbf{R} = \int d\mathbf{K}-iq_z[e^{-iq_z z}\delta(\mathbf{Q}-\mathbf{K}) - e^{iq_z z}T(\mathbf{Q}|\mathbf{K})]A(\mathbf{K}). \tag{A3}$$

For flat surfaces $T(\mathbf{Q}|\mathbf{K})$ is proportional to a δ function and it is a simple matter to solve for A in terms of the vertical derivative. For rough surfaces, in which T is not diagonal in horizontal wave vector, I *assume* that it is still possible to invert (A3) for A in terms of the z derivative of the field. The relationship is linear and must take the form

$$A(\mathbf{K})=\int f(\mathbf{K},\mathbf{Q})[e^{iq_z z}/(-iq_z)]\frac{\partial\hat{\psi}(\mathbf{Q},z)}{\partial z}d\mathbf{Q}. \quad \text{(A4)}$$

The function $f(\mathbf{K},\mathbf{Q})$ is the kernel of the inverse of the operator whose kernel is

$$\delta(\mathbf{Q}-\mathbf{K})-e^{2iq_z z}T(\mathbf{Q}|\mathbf{K}).$$

Formally we can write

$$A=\frac{1}{1-e^{2i\beta z}T}\left(\frac{e^{i\beta z}}{-i\beta}\right)\frac{\partial\hat{\psi}}{\partial z}. \quad \text{(A5)}$$

Substituting Eq. (A4) for A into Eq. (A1) and rearranging the order of integrations and using the inverse Fourier transform gives

$$\psi(\mathbf{R},z)=\int d\mathbf{K}\,d\mathbf{Q}\,d\mathbf{P}\Bigg\{e^{i\mathbf{Q}\cdot\mathbf{R}}[e^{-iq_z z}\delta(\mathbf{Q}-\mathbf{K}) + e^{iq_z z}T(\mathbf{Q}|\mathbf{K})]f(\mathbf{K},\mathbf{P})\frac{e^{ip_z z}}{-ip_z}e^{-i\mathbf{P}\cdot\mathbf{R}'}\Bigg\} \times\frac{\partial\psi(\mathbf{R}',z)}{\partial z}d\mathbf{R}'. \quad \text{(A6)}$$

In this way, the nonlocal impedance of Eq. (1) of the text can be identified as the integral over **K**, **Q**, and **P** of the expression in braces in the equation above. A more formal expression for the impedance is

$$Zi\beta=\frac{1+e^{i\beta z}Te^{i\beta z}}{1-e^{i\beta z}Te^{i\beta z}}. \quad \text{(A7)}$$

Here β is diagonal in horizontal wave vector and gives the vertical component of the wave vector, i.e., $\beta(\mathbf{Q})=\sqrt{\omega^2/c^2-\mathbf{Q}^2}$.

APPENDIX B: THE MEAN FIELD

In this appendix, Eq. (28) of the text is derived. Writing out some of the details of Eq. (25) gives

$$\begin{aligned}&\langle G(\mathbf{Q},z,z_s)\rangle\\ &=[e^+(\mathbf{Q},z),e^-(\mathbf{Q},z)]\frac{1}{\partial E}\langle g\rangle(-\phi)+\Phi(Q,z,z_s)\\ &=[e^+(\mathbf{Q},z),e^-(\mathbf{Q},z)]\frac{1}{\partial E}\langle g\rangle\frac{1}{W(\mathbf{Q})}\begin{pmatrix}e^-(\mathbf{Q},z_s)\\ e^+(\mathbf{Q},z_s)\end{pmatrix}\\ &\quad+\Phi(Q,z,z_s). \quad \text{(B1)}\end{aligned}$$

Here Eqs. (7) and (8) have been used to simplify ϕ. Taking the depth derivative with respect to z_s and first letting $z_s\to z_0$ and then $z_s\to z_1$ gives

$$\begin{aligned}&[\partial_{z_s}\langle G(\mathbf{Q},z,z_s)\rangle|_{z_s=z_0},\partial_{z_s}\langle G(\mathbf{Q},z,z_s)\rangle|_{z_s=z_1}]\\ &=[e^+(\mathbf{Q},z),e^-(\mathbf{Q},z)]\frac{1}{\partial E}\langle g\rangle\frac{1}{W(\mathbf{Q})}\\ &\quad\times\begin{pmatrix}\partial_{z_0}e^-(\mathbf{Q},z_0) & 0\\ 0 & \partial_{z_1}e^+(\mathbf{Q},z_1)\end{pmatrix}. \quad \text{(B2)}\end{aligned}$$

The derivatives of Φ vanish at $z_s=z_0$ and at $z_s=z_0$ because by construction Φ satisfies Neumann boundary conditions. Now Eq. (10) for the Wronskian, $W(\mathbf{Q})$, yields Eq. (28).

Now the role of the effective impedance can also be demonstrated. Equation (B1) can be evaluated first for $z=z_0$ and then for $z=z_0$ to give

$$\begin{pmatrix}\langle G(z_0;z_s)\rangle\\ \langle G(z_1;z_s)\rangle\end{pmatrix}=\left(-E\frac{1}{\partial E}\langle g\rangle+1\right)\phi, \quad \text{(B3)}$$

which we abbreviate as

$$\langle G\rangle=[1-g_0^{-1}\langle g\rangle]\phi. \quad \text{(B4)}$$

Equation (26) of the text allows us to write ϕ in terms of $\partial\langle G\rangle$ which, when combined with the last equation for $\langle G\rangle$, gives

$$\begin{aligned}\langle G\rangle&=-[1-g_0^{-1}\langle g\rangle]\langle g\rangle^{-1}\sigma_3\partial\langle G\rangle\\ &=[g_0^{-1}-\langle g\rangle^{-1}]\sigma_3\partial\langle G\rangle=M\sigma_3\partial\langle G\rangle. \quad \text{(B5)}\end{aligned}$$

Hence M is indeed the impedance operator for the mean field.

APPENDIX C: DERIVATION OF EQS. (43)–(45)

Derivations of Eqs. (43)–(45) of the text are presented here.

In the notation of this paper, the Ward identity given in Ref. 4 is

$$\sum_{\alpha,\beta}[\langle g\rangle_{\alpha,\beta}-\langle g\rangle^*_{\alpha,\beta}]U^{\alpha,\beta;\mu,\nu}=M_{\nu,\mu}-M^*_{\mu,\nu}. \quad \text{(C1)}$$

The Greek indices denote pairs consisting of a horizontal wave vector and a discrete index denoting the upper or lower scattering surface. Using such pairs in Eq. (C1) gives

$$\begin{aligned}&\int d\mathbf{P}\sum_{i_1,i_2}[\langle g\rangle_{i_1,i_2}(\mathbf{P}|\Omega)-\langle g\rangle^*_{i_2,i_1}(\mathbf{P}|\Omega)]\\ &\quad\times U^{i_1,i_2;j_1,j_2}_{\mathbf{P},\mathbf{Q}}(\mathbf{p}=\mathbf{0}|\Omega,0)\\ &\quad=M_{j_2,j_1}(\mathbf{Q}|\Omega)-M_{j_1,j_2}(\mathbf{Q}|\Omega)^*. \quad \text{(C2)}\end{aligned}$$

The difference wave vector **p** is forced to vanish because the mean surface Green's function, $\langle g\rangle$, is diagonal in wave vector. The irreducible vertex function, U, also has a δ function but this is the same as that attached to the full expression for the self-energy, M. The Ward identity requires that the impedance be Hermitian. For penetrable surfaces, for example, fluid–fluid interfaces, the impedance, in general, will not be Hermitian. Its non-Hermiticity reflects the possibility of energy loss to the exterior of the wave guide. If, however, we restrict attention to normal modes and large horizontal wave numbers, the corresponding part of the impedance will be Hermitian. It may be possible to account for the non-Hermitian part of the impedance in what is called intrinsic attenuation, α_m, below, but this is just speculation.

As in the text, it is useful to have the indices i_1 and i_2 refer to eigenvectors of $\langle g\rangle(\mathbf{P})$ rather than surfaces. This is accomplished by inserting an orthogonal transformation and redefining U. Again we argue that it is now the 1,1 elements

of $\langle g\rangle$ that dominate the sum on the left of Eq. (C2), i.e., $1/\lambda(\mathbf{P})$. If the pole approximation, Eq. (39), is used in Eq. (C2), then

$$i\pi\int d\theta_P \sum_m g_m U^{1,1;j_1,j_2}_{k_m,\theta_P;\mathbf{Q}}(\mathbf{0}|\Omega,0)=2i\Sigma_{j_2,j_1}, \tag{C3}$$

where

$$\Sigma_{j_2,j_1}(\mathbf{Q}|\Omega)=\frac{M_{j_2,j_1}(\mathbf{Q}|\Omega)-M_{j_1,j_2}(\mathbf{Q}|\Omega)^*}{2i}. \tag{C4}$$

It is also convenient to define

$$H_{j_2,j_1}(\mathbf{Q}|\Omega)=\frac{M_{j_2,j_1}(\mathbf{Q}|\Omega)+M_{j_1,j_2}(\mathbf{Q}|\Omega)^*}{2}. \tag{C5}$$

Both H and Σ are Hermitian matrices. Furthermore, from its definition, $g_0^{-1}=E(\partial E)^{-1}$, it can be seen that g_0^{-1} is Hermitian in the absence of intrinsic attenuation mechanisms.

We can relate Σ to the imaginary part of the modal wave numbers. Suppose that ψ_0 is an eigenvector of $g_0^{-1}-H$ with eigenvector λ_0. If ψ is the corresponding eigenvector of $\langle g\rangle=g_0^{-1}-M=g_0^{-1}-H-i\Sigma$ with eigenvalue λ, then if Σ is small,

$$\lambda\approx\lambda_0-i\langle\psi_0|\Sigma|\psi_0\rangle\approx\lambda_0-i\Sigma_{1,1}. \tag{C6}$$

Since $\Sigma_{1,1}$ is real, the correction to λ_0 is pure imaginary.

We are interested not so much in the eigenvalue λ as in the zeros of λ, because these are the modal wave numbers. Suppose that $k_m+i\alpha_m$ is a zero of λ_0,

$$\lambda_0(k_m+i\alpha_m)=0. \tag{C7}$$

We can expect a small imaginary part α if there is some small amount of intrinsic damping showing up in a non-Hermitian part of g_0^{-1}. For the zeros of the perturbed eigenvalue write

$$\lambda(k_m+i\alpha_m+i\epsilon_m)=0. \tag{C8}$$

Expanding to first order in ϵ_m gives

$$\lambda(k_m+i\alpha_m)+\frac{\partial\lambda(k_m+i\alpha_m)}{\partial k_m}i\epsilon_m$$

$$=0=-i\Sigma_{1,1}(k_m+i\alpha_m)+\frac{\partial\lambda(k_m+i\alpha)}{\partial k_m}i\epsilon_m, \tag{C9}$$

or

$$\epsilon_m=\frac{1}{\partial\lambda(k_m+i\alpha_m)/\partial k_m}\Sigma_{1,1}(k_m+i\alpha_m). \tag{C10}$$

Here ϵ_m represents the damping of the mth normal mode resulting from scattering of the coherent field at the boundaries of the waveguide. The derivative in Eq. (C10) can be related to other quantities by recalling that near a zero of λ we have written

$$\frac{1}{\lambda(Q)}=\frac{g_m}{Q^2-(k_m+i\Delta_m)^2}\approx\frac{g_m}{2k_m(Q-(k_m+i\Delta_m)}, \tag{C11}$$

where $\Delta_m=\alpha_m+\epsilon_m$. This means that

$$\frac{\partial\lambda(k_m+i\alpha_m)}{\partial k_m}=\frac{2k_m}{g_m}, \tag{C12}$$

and that the damping resulting from scattering is

$$\epsilon_m=\frac{g_m}{2k_m}\Sigma_{1,1}(k_m). \tag{C13}$$

Equation (C11) also gives

$$\mathrm{Im}\,\lambda(k_m)=-\frac{2k_m}{g_m}\Delta_m, \tag{C14}$$

as in the left side of Eq. (43).

Finally, Eq. (45) results from considering the full frequency dependence of the eigenvalue, $\lambda=\lambda(k_m(\Omega)|\Omega)$ absorbing the imaginary contributions into k_m. The condition that k_m be a modal wave number is

$$\lambda(k_m(\Omega)|\Omega)=0. \tag{C15}$$

If the frequency Ω varies, the eigenvector changes both through its explicit dependence on Ω and through the dependence of the wave number on Ω:

$$\frac{\partial\lambda}{\partial k_m}\frac{\partial k_m}{\partial\Omega}+\frac{\partial\lambda}{\partial\Omega}=0, \tag{C16}$$

which implies

$$\frac{\partial\lambda}{\partial\Omega}=\frac{-2k_m}{g_m v_{gm}}. \tag{C17}$$

In writing this last result the definition of the modal group velocity

$$v_{gm}=1/\frac{\partial k_m}{\partial\Omega} \tag{C18}$$

has been used.

(Received 17 January 1997; revised 8 October 1998; accepted 28 October 1998)

A complete energy conservation correction is derived to improve the accuracy of the elastic parabolic equation for range-dependent problems. The correction is complete in the sense that it is valid for problems involving a broad spectrum of horizontal wave numbers. It is a linear condition that associates the incident and transmitted fields on a vertical interface with arrays of point sources having the appropriate energy flux densities. It is a generalization of a complete energy conservation correction for the acoustic parabolic equation [J. Acoust. Soc. Am. **94**, 975–982 (1993)]. © *1999 Acoustical Society of America.* [S0001-4966(99)02002-0]

INTRODUCTION

The parabolic equation method is an efficient approach for solving range-dependent propagation problems.[1] Recent topics of interest in parabolic equation modeling include techniques for handling elastic layers[2–5] and conserving energy in range-dependent problems.[6–8] One of the key remaining goals is to develop an approach for accurately handling range-dependent problems involving fluid and elastic layers. In this paper, we resolve part of this problem by deriving a complete energy conservation correction for the elastic parabolic equation.

The parabolic equation method is based on factoring an operator to obtain an outgoing wave equation that can be solved efficiently as an initial value problem in range. The factorization is exact when the medium is range independent. Many range-dependent problems can be solved by approximating the medium as a sequence of range-independent regions, using the parabolic equation method to propagate the field through each region, and neglecting energy that is backscattered at the vertical interfaces between regions. Transmitted fields can be obtained using energy conservation[6–8] and single scattering[9,10] corrections. Energy conservation corrections have proven to be more effective for the acoustic case. The elastic case has not been fully resolved.

Since outgoing wave equations contain only one range derivative, their solutions cannot be forced to satisfy all of the conditions at a vertical interface. Accurate solutions can be obtained by conserving energy flux. An implementation based on the standard expression for this quantity would involve a nonlinear interface condition. Partial energy conservation corrections are linear conditions based on the assumption of a narrow horizontal wave number spectrum. They provide accurate solutions to many acoustics problems.[6,7] It is possible to obtain linear conditions without resorting to the narrow spectrum approximation. The complete energy conservation correction for acoustic media is a linear condition that handles a broad spectrum of horizontal wave numbers.[8]

A partial energy conservation correction has been derived for elastic media.[8] Since this approximation lacks robustness, we have derived a complete energy conservation correction for the elastic case. Although the derivation is based on approximations, the complete correction should be accurate for many range-dependent problems. For the acoustic case, the complete correction associates the incident and transmitted fields with arrays of point sources having the appropriate energy flux densities.[8] A similar interpretation applies to the complete correction for the elastic case. Before deriving the correction, we discuss the elastic parabolic equation, self-starter[11,12] (which is used to interpret the correction), and normal mode solution (which is used to derive the correction).

I. THE ELASTIC PARABOLIC EQUATION

We consider a two-dimensional problem and work in Cartesian coordinates, where z is the depth and the range x is the horizontal distance from a source. A range-dependent elastic waveguide is divided into a sequence of range-independent regions. The equations of motion are solved in each region with the elastic parabolic equation, which is derived in this section. A method for approximating transmitted fields at the vertical interfaces between regions is derived in Sec. IV. The wave speeds c_p and c_s are related to the density ρ and the Lamé parameters λ and μ by $\rho c_p^2 = \lambda + 2\mu$ and $\rho c_s^2 = \mu$. We work in the frequency domain and remove the factor $\exp(-i\omega t)$ from the dependent variables, where ω is the circular frequency and t is time.

The equations of motion,[5]

$$(\lambda+2\mu)\frac{\partial^2\Delta}{\partial x^2}+(\lambda+2\mu)\frac{\partial^2\Delta}{\partial z^2}+\rho\omega^2\Delta+2\frac{\partial\mu}{\partial z}\frac{\partial^2 w}{\partial x^2}+\omega^2\frac{\partial\rho}{\partial z}w+\left(\frac{\partial\lambda}{\partial z}+2\frac{\partial\mu}{\partial z}\right)\frac{\partial\Delta}{\partial z}+\frac{\partial}{\partial z}\left(\frac{\partial\lambda}{\partial z}\Delta\right)+2\frac{\partial}{\partial z}\left(\frac{\partial\mu}{\partial z}\frac{\partial w}{\partial z}\right)=0, \tag{1}$$

a)Electronic mail: collins@ram.nrl.navy.mil

$$\mu \frac{\partial^2 w}{\partial x^2} + \mu \frac{\partial^2 w}{\partial z^2} + \rho\omega^2 w + (\lambda + \mu) \frac{\partial \Delta}{\partial z} + \frac{\partial \lambda}{\partial z} \Delta + 2 \frac{\partial \mu}{\partial z} \frac{\partial w}{\partial z} = 0, \tag{2}$$

are valid in each range independent region, where Δ is the dilatation and w is the vertical displacement. The horizontal displacement u and stresses σ_{xx}, σ_{zz}, and σ_{xz} are related to Δ and w by the equations

$$\frac{\partial u}{\partial x} = \Delta - \frac{\partial w}{\partial z}, \tag{3}$$

$$\sigma_{xx} = (\lambda + 2\mu)\Delta - 2\mu \frac{\partial w}{\partial z}, \tag{4}$$

$$\sigma_{zz} = \lambda \Delta + 2\mu \frac{\partial w}{\partial z}, \tag{5}$$

$$-\frac{\partial \sigma_{xz}}{\partial x} = \frac{\partial \sigma_{zz}}{\partial z} + \rho\omega^2 w = \frac{\partial}{\partial z}(\lambda\Delta) + 2\frac{\partial}{\partial z}\left(\mu \frac{\partial w}{\partial z}\right) + \rho\omega^2 w. \tag{6}$$

The normal stress σ_{zz} and tangential stress σ_{xz} vanish at the boundaries $z=0$ and $z=H$. Placing the depth operators appearing in Eqs. (1) and (2) into the matrices L and M, we obtain

$$L \frac{\partial^2 \mathbf{U}}{\partial x^2} + M\mathbf{U} = \mathbf{0}, \tag{7}$$

$$\mathbf{U} = \begin{pmatrix} \Delta \\ w \end{pmatrix}. \tag{8}$$

The absence of a $\partial/\partial x$ term in Eq. (7) is an advantage for parabolic equation applications, which are based on factoring an operator. Since L and M commute with $\partial/\partial x$ in each range-independent region, we can factor the operator in Eq. (7) to obtain

$$\left(\frac{\partial}{\partial x} + iK\right)\left(\frac{\partial}{\partial x} - iK\right)\mathbf{U} = \mathbf{0}, \tag{9}$$

where $K = (L^{-1}M)^{1/2}$. The outgoing solution of Eq. (9) satisfies the parabolic equation,

$$\frac{\partial \mathbf{U}}{\partial x} = iK\mathbf{U}. \tag{10}$$

The implementation of Eq. (10) is based on the formula

$$\mathbf{U}(x + \Delta x) = \exp(iK\,\Delta x)\mathbf{U}(x), \tag{11}$$

a rational approximation of the operator $\exp(iK\,\Delta x)$, and numerical techniques.[13,14]

II. THE SELF-STARTER

The self-starter[11,12] is an efficient approach for obtaining an initial condition for Eq. (10). In this section, we generalize the self-starter to the case of an arbitrary source. The form of the self-starter provides a physical interpretation of the energy conservation correction. We first consider the case of a medium that consists of homogeneous layers. In each layer, we define the compressional potential ϕ and shear potential ψ so that

$$u = \frac{\partial \phi}{\partial x} - \frac{\partial \psi}{\partial z}, \tag{12}$$

$$w = \frac{\partial \phi}{\partial z} + \frac{\partial \psi}{\partial x}. \tag{13}$$

We place an arbitrary combination of compressional and shear sources at $x=0$. In each layer, the potentials satisfy

$$\frac{\partial^2}{\partial x^2}\begin{pmatrix} \phi \\ \psi \end{pmatrix} + \frac{\partial^2}{\partial z^2}\begin{pmatrix} \phi \\ \psi \end{pmatrix} + \begin{pmatrix} k_p^2 & 0 \\ 0 & k_s^2 \end{pmatrix}\begin{pmatrix} \phi \\ \psi \end{pmatrix} = 2\rho^{-1/2}\omega^{-2}\delta(x)\begin{pmatrix} -iA_p \\ A_s \end{pmatrix}, \tag{14}$$

where $k_p = \omega/c_p$, $k_s = \omega/c_s$, $A_p(z) = 0$ for a shear source, and $A_s(z) = 0$ for a compressional source.

Integrating Eq. (14) over an arbitrarily small range interval about $x=0$ and rearranging, we obtain

$$\lim_{x \to 0^+} \rho\omega^2 \frac{\partial}{\partial x}\begin{pmatrix} \phi \\ \psi \end{pmatrix} = \rho^{1/2}\begin{pmatrix} -iA_p \\ A_s \end{pmatrix}. \tag{15}$$

From Eqs. (2), (3), (12), (13), and (14), we obtain

$$\rho\omega^2 \frac{\partial \phi}{\partial x} = -(\lambda + 2\mu)\frac{\partial}{\partial x}\nabla^2 \phi = -(\lambda + 2\mu)\frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z}\right) = -(\lambda + 2\mu)\frac{\partial \Delta}{\partial x}, \tag{16}$$

$$\rho\omega^2 \frac{\partial \psi}{\partial x} = -\mu \frac{\partial}{\partial x}\nabla^2 \psi = \mu \frac{\partial}{\partial x}\left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}\right) = (\lambda + 2\mu)\frac{\partial \Delta}{\partial z} + \frac{\partial \lambda}{\partial z}\Delta + \rho\omega^2 w + 2\frac{\partial \mu}{\partial z}\frac{\partial w}{\partial z}. \tag{17}$$

The terms in Eq. (17) that involve derivatives of λ and μ apply to the general case involving inhomogeneous layers. Since there is a range derivative on the right side of Eq. (16) but not Eq. (17), we handle the compressional and shear components separately. Substituting Eqs. (16) and (17) into Eq. (15) and using Eq. (10) to replace the x derivative for the compressional case, we obtain

$$\rho^{-1/2} QK\mathbf{U}_p = \begin{pmatrix} A_p \\ 0 \end{pmatrix}, \tag{18}$$

$$\rho^{-1/2} Q\mathbf{U}_s = \begin{pmatrix} 0 \\ A_s \end{pmatrix}, \tag{19}$$

where $\mathbf{U} = \mathbf{U}_p + \mathbf{U}_s$ and

$$Q = \begin{pmatrix} \lambda + 2\mu & 0 \\ (\lambda + 2\mu)\dfrac{\partial}{\partial z} + \dfrac{\partial \lambda}{\partial z} & \rho\omega^2 + 2\dfrac{\partial \mu}{\partial z}\dfrac{\partial}{\partial z} \end{pmatrix}. \tag{20}$$

For the general case involving inhomogeneous layers, we rearrange Eq. (7) and place compressional and shear source terms on the right side to obtain

$$\frac{\partial^2 \mathbf{U}}{\partial x^2} + K^2 \mathbf{U} = 2i\delta(x) Q^{-1} \begin{pmatrix} \rho^{1/2} A_p \\ 0 \end{pmatrix} + 2i\delta(x) K Q^{-1} \begin{pmatrix} 0 \\ \rho^{1/2} A_s \end{pmatrix}. \tag{21}$$

Integrating Eq. (21) over an arbitrarily small range interval about $x=0$, we obtain

$$\lim_{x \to 0^+} \frac{\partial \mathbf{U}}{\partial x} = iQ^{-1} \begin{pmatrix} \rho^{1/2} A_p \\ 0 \end{pmatrix} + iKQ^{-1} \begin{pmatrix} 0 \\ \rho^{1/2} A_s \end{pmatrix}. \tag{22}$$

We obtain Eqs. (18) and (19) from Eq. (22) by using Eq. (10) to replace $\partial/\partial x$ on the left side and handling the terms on the right side separately. Rearranging Eqs. (18) and (19) and applying Eq. (11), we obtain

$$\mathbf{U}_p(x) = K^{-1} \exp(iKx) Q^{-1} \begin{pmatrix} \rho^{1/2} A_p \\ 0 \end{pmatrix}, \tag{23}$$

$$\mathbf{U}_s(x) = \exp(iKx) Q^{-1} \begin{pmatrix} 0 \\ \rho^{1/2} A_s \end{pmatrix}. \tag{24}$$

To avoid singularities at the source location, the self-starter can be implemented using Eqs. (23) and (24) at $x = x_0$, where x_0 is comparable to a wavelength. In cylindrical geometry, it is necessary to account for cylindrical spreading and apply the correction factor $K^{1/2}$ to the self-starter.[11,12] For this case, Eqs. (18) and (19) become

$$\rho^{-1/2} Q K^{1/2} \mathbf{U}_p = \begin{pmatrix} A_p \\ 0 \end{pmatrix}, \tag{25}$$

$$\rho^{-1/2} Q K^{-1/2} \mathbf{U}_s = \begin{pmatrix} 0 \\ A_s \end{pmatrix}. \tag{26}$$

III. THE NORMAL MODE SOLUTION

In this section, we describe the normal mode solution of Eq. (21). The properties of this solution and the projection operator associated with the normal modes are used to derive the energy conservation correction in the following section. The depth separated eigenvalue problem for Eq. (21) is

$$K^2 \mathbf{U}_j = k_j^2 \mathbf{U}_j, \tag{27}$$

$$\mathbf{U}_j = \begin{pmatrix} \Delta_j \\ w_j \end{pmatrix}, \tag{28}$$

where $\mathbf{U}_j$ and k_j^2 are the jth mode and eigenvalue.

The projection operator associated with the normal modes is defined in terms of the displacements and stresses.[15–17] From Eqs. (3), (4), and (6), we obtain

$$\begin{pmatrix} \sigma_{xx} \\ w \end{pmatrix} = R\mathbf{U}, \tag{29}$$

$$\frac{\partial}{\partial x} \begin{pmatrix} u \\ -\sigma_{xz} \end{pmatrix} = S\mathbf{U}, \tag{30}$$

$$R = \begin{pmatrix} \lambda + 2\mu & -2\mu \dfrac{\partial}{\partial z} \\ 0 & 1 \end{pmatrix}, \tag{31}$$

$$S = \begin{pmatrix} 1 & -\dfrac{\partial}{\partial z} \\ \dfrac{\partial}{\partial z}\lambda & 2\dfrac{\partial}{\partial z}\mu\dfrac{\partial}{\partial z} + \rho\omega^2 \end{pmatrix}. \tag{32}$$

The projection operator is defined by

$$(\mathbf{U}, \tilde{\mathbf{U}}) = \int_0^H (R\mathbf{U})^t S \tilde{\mathbf{U}}\, dz, \tag{33}$$

where $\mathbf{U}$ and $\tilde{\mathbf{U}}$ are arbitrary and the superscript t denotes the transpose. In the Appendix, we show that the projection operator is symmetric and that the modes can be normalized so that

$$(\mathbf{U}_i, \mathbf{U}_j) = \delta_{ij}, \tag{34}$$

for distinct eigenvalues.

Assuming continuous depth dependence and applying integration by parts to Eq. (33), we obtain

$$(\mathbf{U}, \tilde{\mathbf{U}}) = -2\mu w \left(\tilde{\Delta} - \frac{\partial \tilde{w}}{\partial z} \right) \Big|_0^H + \int_0^H \mathbf{U}^t T \tilde{\mathbf{U}}\, dz, \tag{35}$$

$$T = \begin{pmatrix} \lambda + 2\mu & -(\lambda + 2\mu)\dfrac{\partial}{\partial z} \\ \dfrac{\partial}{\partial z}(\lambda + 2\mu) & \rho\omega^2 \end{pmatrix}. \tag{36}$$

An arbitrary field can be expressed in terms of the normal modes as

$$\mathbf{U} = \sum_j a_j \mathbf{U}_j, \tag{37}$$

$$a_j = (\mathbf{U}, \mathbf{U}_j). \tag{38}$$

For the compressional line source $A_p(z) = \delta(z - z_0)$ in a homogeneous layer, it follows from Eqs. (23), (35), and (38) that

$$a_j = \omega^{-2} k_j \rho^{-1/2} (\lambda + 2\mu) \Delta_j \exp(ik_j x)\big|_{z=z_0}. \tag{39}$$

For the shear line source $A_s(z) = \delta(z - z_0)$, in a homogeneous layer it follows from Eqs. (24), (35), and (38) that

$$a_j = \omega^{-2} \rho^{-1/2} \left((\lambda + 2\mu) \frac{\partial \Delta_j}{\partial z} + \rho\omega^2 w_j \right) \exp(ik_j x) \Big|_{z=z_0}. \tag{40}$$

The quantities appearing on the right sides of Eqs. (39) and (40) are proportional to the entries of $Q\mathbf{U}_j$, which are the compressional and shear parts of the mode.

IV. ENERGY CONSERVATION

In this section, we derive a method for approximating transmitted fields across vertical interfaces. To simplify the derivation, we assume that the elastic parameters are sufficiently smooth so that integration by parts can be performed without introducing interface terms, range dependence occurs away from $z=0$ and $z=H$ so that only a small error is introduced by ignoring boundary terms that arise from integration by parts (i.e., the boundary terms are nearly equal on

each side of a vertical interface), and the imaginary parts of the Lamé parameters (which account for attenuation) are small perturbations.

The energy flux through a vertical interface[18] is proportional to

$$E = \mathrm{Im} \int_0^H (u^* \sigma_{xx} + w^* \sigma_{xz}) dz. \tag{41}$$

Rearranging Eq. (41), we obtain

$$E = -\mathrm{Im} \int_0^H (u \sigma_{xx}^* - w^* \sigma_{xz}) dz. \tag{42}$$

From Eqs. (10) and (30), we obtain

$$\begin{pmatrix} u \\ -\sigma_{xz} \end{pmatrix} = -iSK^{-1}\mathbf{U}. \tag{43}$$

From Eqs. (29), (42), and (43), we obtain

$$E = \mathrm{Re} \int_0^H (R\mathbf{U})^* SK^{-1}\mathbf{U}\, dz. \tag{44}$$

To further simplify the derivation, we assume that $\mathbf{U}$ is dominated by propagating modes. Since the attenuation is assumed to be small, the imaginary parts of these modes and the corresponding eigenvalues are perturbations that can be neglected. From the modal representation, the properties of the modes, and Eq. (44), we obtain

$$E = \int_0^H (RK^{-1/2}\mathbf{U})^* SK^{-1/2}\mathbf{U}\, dz. \tag{45}$$

Applying integration by parts to Eq. (45) and neglecting boundary terms, we obtain

$$E = \int_0^H (K^{-1/2}\mathbf{U})^* T(K^{-1/2}\mathbf{U}) dz. \tag{46}$$

To simplify the integrand in Eq. (46), we apply the factorization $T = \tilde{G}\, DG$, where

$$\tilde{G} = \begin{pmatrix} 1 & -(\lambda+2\mu)\dfrac{\partial}{\partial z}\dfrac{1}{\rho\omega^2} \\ 0 & 1 \end{pmatrix}, \tag{47}$$

$$D = \begin{pmatrix} (\lambda+2\mu)\left(1 + \dfrac{\partial}{\partial z}\dfrac{1}{\rho\omega^2}\dfrac{\partial}{\partial z}(\lambda+2\mu)\right) & 0 \\ 0 & \rho\omega^2 \end{pmatrix}, \tag{48}$$

$$G = \begin{pmatrix} 1 & 0 \\ \dfrac{1}{\rho\omega^2}\dfrac{\partial}{\partial z}(\lambda+2\mu) & 1 \end{pmatrix}. \tag{49}$$

Substituting the factorization into Eq. (46), performing integration by parts, and neglecting boundary terms, we obtain

$$E = \int_0^H (GK^{-1/2}\mathbf{U})^* D(GK^{-1/2}\mathbf{U}) dz. \tag{50}$$

To further simplify the derivation, we consider the limit of gradual depth dependence and neglect terms involving depth derivatives of the material properties to obtain

$$\Delta + \frac{\lambda+2\mu}{\rho\omega^2}\frac{\partial^2\Delta}{\partial z^2} = -\frac{\lambda+2\mu}{\rho\omega^2}\frac{\partial^2\Delta}{\partial x^2} = \frac{\lambda+2\mu}{\rho\omega^2}K^2\Delta, \tag{51}$$

where $K^\gamma\Delta$ and $K^\gamma w$ denote the entries of $K^\gamma\mathbf{U}$ and γ is arbitrary. From Eqs. (48), (49), (50), and (51), we obtain

$$E = \omega^{-2}\int_0^H (|A_p|^2 + |A_s|^2) dz, \tag{52}$$

$$A_p = \rho^{-1/2}(\lambda+2\mu)K^{1/2}\Delta, \tag{53}$$

$$A_s = \rho^{-1/2}\left((\lambda+2\mu)\frac{\partial}{\partial z}(K^{-1/2}\Delta) + \rho\omega^2 K^{-1/2} w\right). \tag{54}$$

Energy can be conserved across a vertical interface by conserving A_p and A_s across the interface. These quantities are closely related to the potentials. The quantity A_p reduces to the quantity conserved in the complete correction for the acoustic case.[8]

The implementation of the correction involves the solution of two boundary value problems. The incident field $\mathbf{U}_a$ propagates in region a. The transmitted field $\mathbf{U}_b$ propagates on the other side of the vertical interface in region b. We compute A_p and A_s using the equations

$$\begin{pmatrix} A_p \\ B_s \end{pmatrix} = \rho_a^{-1/2} Q_a K_a^{1/2}\mathbf{U}_a, \tag{55}$$

$$\begin{pmatrix} B_p \\ A_s \end{pmatrix} = \rho_a^{-1/2} Q_a K_a^{-1/2}\mathbf{U}_a. \tag{56}$$

We discard the quantities B_p and B_s, which are defined by Eqs. (55) and (56), and compute $\mathbf{U}_b = \mathbf{U}_p + \mathbf{U}_s$ using the equations

$$\rho_b^{-1/2} Q_b K_b^{1/2}\mathbf{U}_p = \begin{pmatrix} A_p \\ 0 \end{pmatrix}, \tag{57}$$

$$\rho_b^{-1/2} Q_b K_b^{-1/2}\mathbf{U}_s = \begin{pmatrix} 0 \\ A_s \end{pmatrix}. \tag{58}$$

As in the acoustic case,[8] the complete correction is related to the self-starter. Comparing Eqs. (57) and (58) with Eqs. (25) and (26), we observe that the field is associated with arrays of compressional and shear point sources that have the appropriate energy flux densities. This physical interpretation suggests that the complete correction should provide accurate solutions for many problems despite the assumptions that were made in the derivation. The solutions of Eqs. (57) and (58) can be obtained using the approach for implementing the self-starter.

Generalizations of partial corrections for the acoustic case can be obtained by making approximations in Eqs. (53) and (54). By applying the approximation $K \cong k_0$, which was used in Ref. 6 for the acoustic case, the conserved quantity is reduced to $\rho^{-1/2} Q\mathbf{U}$. A natural generalization of the approximation $K \cong k_p$, which was used in Ref. 7 for the acoustic case, is to conserve the quantities

$$\tilde{A}_p = \rho^{-1/2} c_p^{-1/2}(\lambda+2\mu)\Delta, \tag{59}$$

$$\tilde{A}_s = \rho^{-1/2} c_s^{1/2}\left((\lambda+2\mu)\frac{\partial\Delta}{\partial z} + \rho\omega^2 w\right). \tag{60}$$

The quantity $\tilde{A}_p$ is conserved in the partial correction of Ref. 8, which provides improved accuracy. The partial corrections do not require the approximation of the fourth root of an operator or the separate treatment of the compressional and shear components. The partial correction involving c_p and c_s should provide greater accuracy, as it does in the acoustic case.

V. CONCLUSION

We have derived a complete energy conservation correction for the elastic parabolic equation. With this improvement, the elastic parabolic equation should be accurate for many range-dependent problems. The correction is valid for problems involving a broad spectrum of horizontal wave numbers. As in the acoustic case, the incident and transmitted fields are associated with arrays of point sources having the appropriate energy flux densities. The correction is based on the assumption of gradual range dependence and predicts that energy does not couple between shear and compressional waves across a vertical interface in this limit. The next logical step in the development of the elastic parabolic equation is to implement the corrections derived in Sec. IV. This might require special rational approximations to avoid instabilities and a formulation in a different set of dependent variables[8] to facilitate the treatment of sloping interfaces.

APPENDIX: ORTHOGONALITY OF THE MODES

We show that the modes are orthogonal with respect to the projection operator for an arbitrary stratified elastic medium. We first show that the projection operator is symmetric for problems involving continuous depth dependence. From Eqs. (31), (32), and (33), we obtain

$$(\mathbf{U},\tilde{\mathbf{U}}) = \int_0^H \left\{ \left[(\lambda+2\mu)\Delta - 2\mu \frac{\partial w}{\partial z} \right] \left(\tilde{\Delta} - \frac{\partial \tilde{w}}{\partial z} \right) + w \left[\frac{\partial}{\partial z}(\lambda \tilde{\Delta}) + 2 \frac{\partial}{\partial z} \left(\mu \frac{\partial \tilde{w}}{\partial z} \right) + \rho \omega^2 \tilde{w} \right] \right\} dz. \tag{A1}$$

Expanding the terms in Eq. (A1) and rearranging, we obtain

$$(\mathbf{U},\tilde{\mathbf{U}}) = \int_0^H \left[(\lambda+2\mu)\Delta\tilde{\Delta} + \rho\omega^2 w\tilde{w} - 2\mu \left(\Delta \frac{\partial \tilde{w}}{\partial z} + \tilde{\Delta} \frac{\partial w}{\partial z} \right) + 2\mu \frac{\partial w}{\partial z} \frac{\partial \tilde{w}}{\partial z} - \lambda \Delta \frac{\partial \tilde{w}}{\partial z} + w \frac{\partial}{\partial z}(\lambda \tilde{\Delta}) + 2w \frac{\partial}{\partial z} \left(\mu \frac{\partial \tilde{w}}{\partial z} \right) \right] dz. \tag{A2}$$

Applying integration by parts to Eq. (A2), we obtain

$$(\mathbf{U},\tilde{\mathbf{U}}) = w \left(\lambda \tilde{\Delta} + 2\mu \frac{\partial \tilde{w}}{\partial z} \right) \Bigg|_0^H + \int_0^H \left[(\lambda+2\mu)\Delta\tilde{\Delta} + \rho\omega^2 w\tilde{w} - (\lambda+2\mu) \left(\Delta \frac{\partial \tilde{w}}{\partial z} + \tilde{\Delta} \frac{\partial w}{\partial z} \right) \right] dz. \tag{A3}$$

Since $\sigma_{zz}=0$ at $z=0$ and $z=H$, the boundary terms vanish in Eq. (A3). From the symmetry of the integrand in Eq. (A3), we conclude that $(\mathbf{U},\tilde{\mathbf{U}})=(\tilde{\mathbf{U}},\mathbf{U})$. Since the boundary terms in Eq. (A3) involve w and σ_{zz}, which are continuous across horizontal interfaces, we conclude that symmetry holds for problems involving piecewise continuous depth dependence.

To simplify the remaining analysis, we approximate (to arbitrary accuracy) a waveguide involving piecewise continuous depth variations in the elastic properties with a waveguide involving N homogeneous layers. In each layer, the ith normal mode satisfies

$$k_i^2 \Delta_i = \frac{d^2\Delta_i}{dz^2} + \frac{\rho\omega^2}{\lambda+2\mu}\Delta_i, \tag{A4}$$

$$k_i^2 w_i = \frac{\lambda+\mu}{\mu}\frac{d\Delta_i}{dz} + \frac{d^2 w_i}{dz^2} + \frac{\rho\omega^2}{\mu} w_i. \tag{A5}$$

Substituting two arbitrary modes into Eq. (35) and using Eqs. (A4) and (A5), we obtain

$$k_i^2(\mathbf{U}_i,\mathbf{U}_j) = -2\sum_{m=1}^{N-1} \left((\lambda+\mu)\frac{d\Delta_i}{dz} + \mu\frac{d^2 w_i}{dz^2} + \rho\omega^2 w_i \right) \left(\Delta_j - \frac{dw_j}{dz} \right) \Bigg|_{z_m}^{z_{m+1}} + \sum_{m=1}^{N-1} \int_{z_m}^{z_{m+1}} \left[\left((\lambda+2\mu)\frac{d^2\Delta_i}{dz^2} + \rho\omega^2\Delta_i \right) \times \left(\Delta_j - \frac{dw_j}{dz} \right) + \left(\frac{\lambda+\mu}{\mu}\frac{d\Delta_i}{dz} + \frac{d^2 w_i}{dz^2} + \frac{\rho\omega^2}{\mu} w_i \right) \left((\lambda+2\mu)\frac{d\Delta_j}{dz} + \rho\omega^2 w_j \right) \right] dz, \tag{A6}$$

where the mth layer lies within $z_m < z < z_{m+1}$.

Expanding the terms in Eq. (A6) and applying integration by parts, we obtain

$$k_i^2(\mathbf{U}_i,\mathbf{U}_j) = -\sum_{m=1}^{N-1}\left[\rho\omega^2 w_j\left(\Delta_i - \frac{dw_i}{dz}\right) + \left(\lambda\frac{d\Delta_i}{dz} + 2\mu\frac{d^2w_i}{dz^2} + 2\rho\omega^2 w_i\right)\left(\Delta_j - \frac{dw_j}{dz}\right)\right]\Bigg|_{z_m}^{z_{m+1}}$$

$$+\sum_{m=1}^{N-1}\int_{z_m}^{z_{m+1}}\left[\rho\omega^2\left(\Delta_i\Delta_j - \frac{dw_i}{dz}\frac{dw_j}{dz} + \frac{\rho\omega^2}{\mu}w_i w_j\right)\right.$$

$$\left.+(\lambda+2\mu)\left(\frac{d\Delta_i}{dz}\frac{d^2w_j}{dz^2} + \frac{d\Delta_j}{dz}\frac{d^2w_i}{dz^2} + \frac{\lambda}{\mu}\frac{d\Delta_i}{dz}\frac{d\Delta_j}{dz}\right) + \frac{(\lambda+2\mu)\rho\omega^2}{\mu}\left(w_i\frac{d\Delta_j}{dz} + w_j\frac{d\Delta_i}{dz}\right)\right]dz. \tag{A7}$$

We use the symmetry of the integrand in Eq. (A7) and a similar expression for $k_j^2(\mathbf{U}_j,\mathbf{U}_i)$ to obtain

$$k_i^2(\mathbf{U}_i,\mathbf{U}_j) - k_j^2(\mathbf{U}_j,\mathbf{U}_i) = \sum_{m=1}^{N-1}\left[\left(\lambda\frac{d\Delta_j}{dz} + 2\mu\frac{d^2w_j}{dz^2} + \rho\omega^2 w_j\right)\left(\Delta_i - \frac{dw_i}{dz}\right)\right.$$

$$\left.-\left(\lambda\frac{d\Delta_i}{dz} + 2\mu\frac{d^2w_i}{dz^2} + \rho\omega^2 w_i\right)\left(\Delta_j - \frac{dw_j}{dz}\right)\right]\Bigg|_{z_m}^{z_{m+1}}. \tag{A8}$$

The interface and boundary terms in Eq. (A8) involve the x derivatives of σ_{xz} and u. The interface terms cancel because σ_{xz} and u are continuous across interfaces. The boundary terms vanish because $\sigma_{xz}=0$ at $z=0$ and $z=H$. We therefore obtain

$$0 = k_i^2(\mathbf{U}_i,\mathbf{U}_j) - k_j^2(\mathbf{U}_j,\mathbf{U}_i)$$

$$= (k_i^2 - k_j^2)(\mathbf{U}_i,\mathbf{U}_j) \Rightarrow (\mathbf{U}_i,\mathbf{U}_j) = \delta_{ij}. \tag{A9}$$

The second equality in Eq. (A9) follows from the symmetry of the projection operator, which we demonstrated using the assumption that σ_{zz} and w are continuous across interfaces and that $\sigma_{zz}=0$ at $z=0$ and $z=H$. All of the interface and boundary conditions were therefore used to arrive at Eq. (A9).

Normal mode oscillation of a sphere with solid–gas–solid structure

H. Oda[a] and I. Suzuki
Department of Earth Sciences, Okayama University, Okayama 700, Japan

(Received 2 March 1998; revised 19 October 1998; accepted 20 October 1998)

A free oscillation study was made for a heterogeneous sphere with three-layered spherical shell structure composed of an inner spherical sample, middle gas, and outer solid layers in order to apply resonant sphere technique (RST) to elasticity measurements at high pressures. The spheroidal modes of the sphere are classified into ''sample,'' ''gas,'' and ''container'' modes, whose strain energy distributions are localized in the sample, gas, and outer layers, respectively. The sample modes, whose frequencies provide information about the elastic constants of the spherical sample, are more strongly excited than the gas and container modes when putting a vibrational source on the surface of spherical sample in the three-layered sphere and measuring the resonance spectrum on the sample sphere. The localization of strain energy is due to a large difference in acoustic impedance between gas and solid layers. All the resonant frequencies increase with increasing pressure in the gas layer, but the pressure derivatives of resonant frequencies of gas modes are larger than those of sample and container modes. Thus the pressure curves of gas modes frequently intersect those of sample and container modes. At pressures where the sample or container modes intersect the gas modes, modal interchange takes place only between spheroidal modes of ${}_nS_l$ and ${}_{n'}S_{l'}$ satisfying the conditions of $l=l'$ and $n-n'=\pm 1$. To avoid such an interchange, the gas layer should be kept thin. © *1999 Acoustical Society of America.* [S0001-4966(99)01202-3]

INTRODUCTION

The elastic constants of the Earth's materials provide us with important information regarding the structure and composition of the Earth's interior. It is especially important to investigate effects of pressure and temperature on the elastic constants in material science and earth science. Consequently, a number of methods have been developed and applied for measuring the elastic constants of solids. The resonance method is a technique to determine the elastic constants from the measured resonance spectrum of a vibrating solid. The method is classified into several kinds, depending on a specimen's shape used for the spectral measurements. In particular, the method using a spherical specimen, which is called ''resonant sphere technique'' (RST), has been successfully applied to elasticity measurements of anisotropic materials at room temperature and ambient pressure (e.g., Suzuki *et al.*, 1992; Oda *et al.*, 1994). The RST has merit in that it is amenable to quite small specimens, i.e., specimens with dimensions less than 1 mm. Furthermore, the ''buffer method'' was devised for applying the resonance method to the elasticity measurements at high temperatures (Goto and Anderson, 1988). This method has been employed to trace the temperature variations of elastic constants of solids by rectangular parallelepiped resonance (RPR) method (e.g., Isaak *et al.*, 1992). The first application of the buffer method to RST was made to measure the elastic constants of calcium oxide specimen up to 1200 K (Oda *et al.*, 1992). A more complete compendium of the available high-temperature elasticity data from the resonance technique is found in Anderson and Isaak (1995).

The cavity resonance method (CRM) was proposed by Ohno *et al.* (1991) for elasticity measurements of solids by RST at high pressures. In the CRM, a spherical specimen is placed in the center of a spherical container which is filled by pressurized gas to compress the specimen. The resonance spectrum of the spherical specimen is then measured under hydrostatic pressure. Recently Isaak *et al.* (1998) presented a method to evaluate the pressure effects on the rigidity modulus that take into account the finite viscosity of the pressurizing gas. Their study addressed only the pure toroidal modes. We assumed zero gas viscosity, but extend the theory to spheroidal modes where gas viscosity is less important. Thus our study provides the means by which pressure effects on compressional moduli may ultimately be obtained from RST.

In order to determine the elastic constants from resonant frequencies of a spherical sample vibrating in pressurized gas, it is necessary to account for frequency shifts due to small deformations of the spherical sample by hydrostatic pressure and due to exchange of vibrational energy from the spherical sample to the gas layer. The first effect on the frequencies can be easily evaluated, but the latter effect is more problematic. We treat the sample oscillation in a pressurizing gas as the free oscillation of a three-layered sphere in which an inner spherical solid specimen is surrounded by a high-pressure gas layer and an outer solid layer. Because it is possible to calculate the free oscillation frequencies for a radially heterogeneous sphere with solid–gas–solid configuration, the elastic constants are determined in the usual way by minimizing, in a least squares sense, the differences be-

[a]Electronic mail: lfee0688@cc.okayama-u.ac.jp

tween measured and computed frequencies of the sample mode oscillations of the three-layered sphere. However, the sample mode oscillations have not been studied in detail for a sphere with solid–gas–solid configuration. Since the configuration is similar to that of the deep Earth, inner core (solid)–outer core (fluid)–mantle (solid), our study is of broader interest than the immediate problem of using RST to determine the pressure effects of elasticity.

We investigate how the sample mode oscillations are affected by increasing pressure in the gas layer of the three-layered sphere, and discuss problems in identifying sample oscillation modes under pressure. Furthermore, we point out the optimal conditions for correctly measuring the resonance spectrum of the inner spherical specimen by CRM.

I. THEORETICAL BACKGROUND

Free oscillations of a radially heterogeneous sphere with isotropic elasticity are classified into toroidal and spheroidal modes, and their solutions are numerically obtained for each mode. Here we briefly review the theory to calculate the free oscillation frequencies of the elastically isotropic sphere with solid–gas–solid structure, assuming that the viscosity in gas layer is zero. According to Takeuchi and Saito (1972), the equation of motion of an elastic body in spherical coordinate (r,θ,ϕ) is given by

$$\boldsymbol{\rho}\frac{\partial^2\mathbf{u}}{\partial t^2}=(\operatorname{div}\mathbf{T}_r,\operatorname{div}\mathbf{T}_\theta,\operatorname{div}\mathbf{T}_\phi)+\frac{1}{r}(-T_{\theta\theta}-T_{\phi\phi},\ T_{r\theta}-T_{\phi\phi}\cot\theta,T_{\phi r}+T_{\theta\phi}\cot\theta), \tag{1}$$

where ρ is density, $\mathbf{u}$ is the displacement vector, and $\mathbf{T}_r$, $\mathbf{T}_\theta$, and $\mathbf{T}_\phi$ denote stress vectors acting across the planes normal to the r, θ, ϕ axes. When the origin of the spherical coordinates is at the center of a sphere, the displacement vector $\mathbf{u}$ and stress vector $\mathbf{T}_r$ of the freely oscillating sphere can be expressed by

$$\begin{aligned}\mathbf{u}&=ry_1(r)\boldsymbol{\nabla}\times[\mathbf{r}Y_l^m(\theta,\phi)],\\ \mathbf{T}_r&=ry_2(r)\boldsymbol{\nabla}\times[\mathbf{r}Y_l^m(\theta,\phi)]\end{aligned} \tag{2}$$

for toroidal modes and

$$\begin{aligned}\mathbf{u}&=y_1(r)[\mathbf{r}Y_l^m(\theta,\phi)]+ry_3(r)\boldsymbol{\nabla}[Y_l^m(\theta,\phi)],\\ \mathbf{T}_c&=y_2(r)[\mathbf{r}Y_l^m(\theta,\phi)]+ry_4(r)\boldsymbol{\nabla}[Y_l^m(\theta,\phi)]\end{aligned} \tag{3}$$

for spheroidal modes, where $Y_l^m(\theta,\phi)$ is the spherical harmonic function specified by angular order, l, and azimuthal order, m, and $\mathbf{r}$ is the unit vector in the radial direction. The symbol ''$\times$'' denotes cross product of two vectors and $\boldsymbol{\nabla}$ is defined by

$$\boldsymbol{\nabla}=\left(\frac{\partial}{\partial r},\frac{1}{r}\frac{\partial}{\partial\theta},\frac{1}{r\sin\theta}\frac{\partial}{\partial\phi}\right). \tag{4}$$

Therefore the problem is to find radial eigenfunctions $y_1(r)$, $y_2(r)$, $y_3(r)$, and $y_4(r)$ satisfying the equation of motion.

Equation (1) gives the motion for the radially heterogeneous sphere and can be expressed in a simple form by using $y_1(r)$, $y_2(r)$, $y_3(r)$, and $y_4(r)$:

$$\frac{d\mathbf{y}}{dr}=\mathbf{A}(r)\mathbf{y}(r). \tag{5}$$

The motion-stress vectors $\mathbf{y}(r)$ are given by

$$\begin{aligned}\mathbf{y}(r)&=[y_1(r),y_2(r)]^t,\\ \mathbf{y}(r)&=[y_1(r),y_2(r),y_3(r),y_4(r)]^t\end{aligned} \tag{6}$$

for toroidal and spheroidal modes, respectively, and ''t'' means the transpose of the matrix. The coefficient matrix $\mathbf{A}(r)$ is written as

$$\mathbf{A}(r)=\begin{bmatrix}\dfrac{1}{r} & \dfrac{1}{\mu}\\ \dfrac{\mu(l-1)(l+2)}{r^2}-\omega^2\rho & -\dfrac{3}{r}\end{bmatrix} \tag{7}$$

for toroidal modes, and

$$\mathbf{A}(r)=\begin{bmatrix}-\dfrac{2\lambda}{(\lambda+2\mu)r} & \dfrac{1}{\lambda+2\mu} & \dfrac{\lambda l(l+1)}{(\lambda+2\mu)r} & 0\\ -\omega^2\rho+\dfrac{4\mu(3\lambda+2\mu)}{(\lambda+2\mu)r^2} & \dfrac{-4\mu}{(\lambda+2\mu)r} & -\dfrac{2\mu(3\lambda+2\mu)l(l+1)}{(\lambda+2\mu)r^2} & \dfrac{l(l+1)}{r}\\ -\dfrac{1}{r} & 0 & \dfrac{1}{r} & \dfrac{1}{\mu}\\ -\dfrac{2\mu(3\lambda+2\mu)}{(\lambda+2\mu)r^2} & -\dfrac{\lambda}{(\lambda+2\mu)r} & -\omega^2\rho+\dfrac{4\mu(\lambda+\mu)l(l+1)}{(\lambda+2\mu)r^2}-\dfrac{2\mu}{r^2} & -\dfrac{3}{r}\end{bmatrix} \tag{8}$$

for spheroidal modes, where ω is angular frequency, and λ and μ are Lame's constants depending on the r coordinate.

The motion-stress vectors $\mathbf{y}(r)$ can be obtained for a given value of ω by solving Eq. (5) by means of the conventional Runge–Kutta–Gill's method. When the spherical surface $(r=a)$ is stress-free, we must find the free oscillation frequency ω for which the solutions of $\mathbf{y}(r)$ satisfy the boundary condition $y_2(a)=0$ in the case of toroidal mode oscillation or $[y_2(a),y_4(a)]=0$ in the case of spheroidal mode oscillation. This is a typical boundary value problem

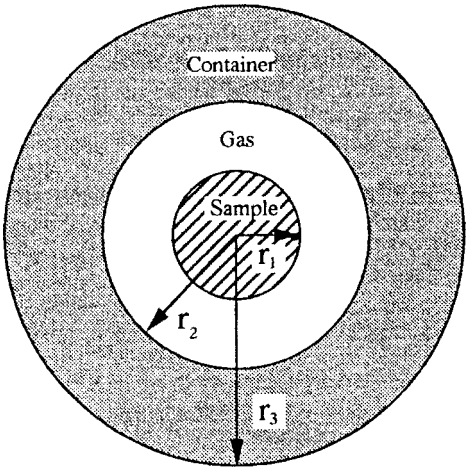

FIG. 1. Model of spherical shell structure which is composed of sample (Fe), gas (He), and container (WC) layers. Radii of sample, gas, and container layers are denoted by r_1, r_2, and r_3, respectively. The elastic constants, density and other parameters of each layer are given in Table I.

and the practical procedures to find their solutions are presented in detail by Saito (1988).

II. FREE VIBRATION OF A THREE-LAYERED SPHERE

Figure 1 shows a three-layered sphere composed of an inner spherical sample of iron (Fe), middle layer of helium gas (He) and outer layer of tungsten carbide (WC). The elastic constants, density, and other parameters of each layer are given in Table I. The helium gas is used as a pressure medium to compress the spherical sample. Such a model is called ''cavity model.''

The numerical solution of free oscillation of the three-layered sphere was obtained by solving Eq. (5) using the computer program ''Disper80'' (Saito, 1988). In order to examine characteristics of the normal mode of the three-layered sphere, we investigated the distribution of strain energy in the sphere. The strain energy can be expressed as

$$W=\int \varepsilon_{ij}T_{ij}\,dv, \tag{9}$$

where ε_{ij} and T_{ij} are strain and stress tensors, respectively, and the summation convention is assumed for repeated indices. Integration of Eq. (9) is performed over the entire volume of the sphere. Calculating the stress and strain tensors from the displacement solutions of Eqs. (2) and (3) and substituting them into (9), we have

$$W=\int_0^a E(r)dr, \tag{10}$$

where the strain energy density function $E(r)$ is defined by

$$E(r)=\frac{(ry_2)^2}{\mu}+(l-1)(l+2)\mu(y_1)^2 \tag{11}$$

for toroidal modes and

$$\begin{aligned}E(r)&=E_\mu(r)+E_K(r)\\&=\frac{1}{\lambda+2\mu}(ry_2)^2+l(l^2-1)\\&\quad\times(l+2)\mu(y_3)^2+\frac{l(l+1)}{\mu}(ry_4)^2\\&\quad+\frac{\mu(3\lambda+2\mu)}{\lambda+2\mu}\{2y_1-l(l+1)y_3\}^2\end{aligned} \tag{12}$$

for spheroidal modes. The $E_\mu(r)$ and $E_K(r)$ are strain energy densities to which the rigidity and bulk moduli contribute, respectively.

When a vibration source is put on the surface of the inner sample, the strain energy of toroidal modes is confined only to the inner sphere because the toroidal displacements are not excited in the gas layer in the case of zero gas viscosity. Isaak *et al.* (1998) consider the effect of finite gas viscosity on the toroidal vibrations, and they show that when the pressurizing gas is helium the effects are small. Thus, to a close approximation, the toroidal oscillations of the inner spherical sample may be regarded as ''sample modes.'' In contrast to the toroidal oscillation, spheroidal mode displacements are excited over the entire space of the three-layered sphere. Nevertheless, strain energy localization is seen in the spheroidal modes. Figure 2 shows the distribution of strain energy density of three spheroidal modes. We find three characteristic modes called ''sample,'' ''gas,'' and ''container'' modes, whose strain energy distributions are localized in sample, gas, and container layers, respectively. Such a localization of strain energy is due to a large difference in acoustic impedance between gas and solid layers.

III. PRESSURE DEPENDENCE OF FREE OSCILLATION FREQUENCIES

Free oscillation frequencies of the three-layered sphere were calculated with changing pressure in the gas layer. Pressure changes in density and elastic constants of the three layers and a slight decrease in sample volume due to confining pressure were accounted for when calculating the free oscillation frequency spectrum. The pressure derivatives of the elastic constants in each layer are listed in Table I. The elasticity and density data of the helium gas at high pressures are from Nishitake and Hanayama (1975). Another spectrum was calculated for a single iron sphere under the same hydrostatic pressure condition by assuming no transfer of vibrational energy from the iron sphere and that the density, radius, and elastic constants of the iron sphere and their pressure changes are the same as those of the inner specimen of the three-layer configuration.

Frequency spectra of the three-layered sphere and the single iron sphere at 0.1 MPa pressure are shown in Fig. 3 by classifying the vibration modes into sample, gas, and container modes. In a given frequency range there are many more gas and container modes than sample modes. At low pressure, the spectrum of the sample does not vary so much when going from the single sphere to the sample mode of the three-layer configuration. Figure 4 depicts the pressure dependencies of a sample mode and its equivalent mode for the

TABLE I. Parameter values of cavity model.

	Density (g/cm^3)	Radius (mm)	Elastic constants (GPa) K	μ
Sample Fe	7.789	2.384	165.0	79.5
Gas He	$2.5E-04$	5.0	$2.4E-04$	⋯
Container WC	15.1	8.5	391.0	219.0
			$\partial K/\partial P$	$\partial\mu/\partial P$
Sample Fe			5.0	1.9
Gas He			[a]	
Container WC			6.0	2.5

[a]Pressure variation of sound velocity α (km/s) in gas layer is expressed by $\alpha=0.99239+5.4467P-24.270P^2+80.028P^3$.

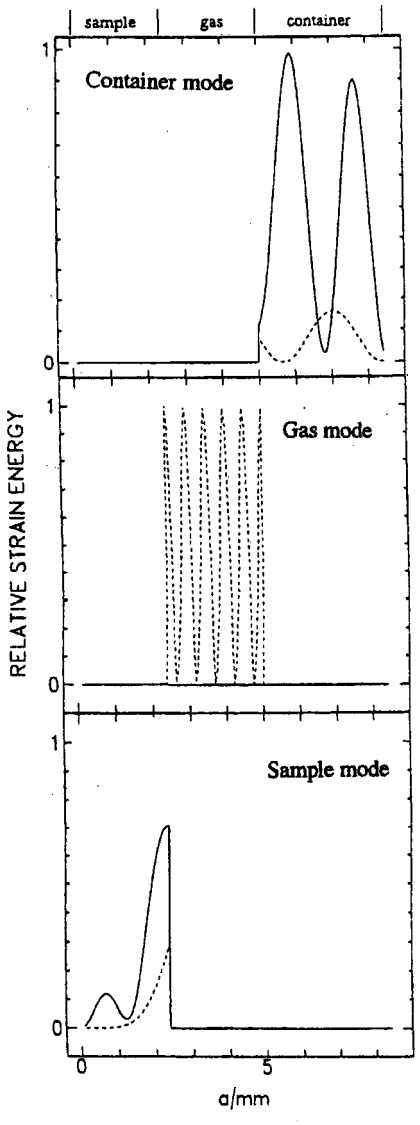

FIG. 2. Distribution of strain energy density of spheroidal modes of the three-layered sphere. The horizontal axis indicates distance measured from the center of the sphere. The strain energy density normalized by the maximum value of $E(r)$ is shown by dividing into two parts, $E_\mu(r)$ (solid line) and $E_k(r)$ (dashed line), to which the rigidity and bulk moduli contribute [see Eq. (12)].

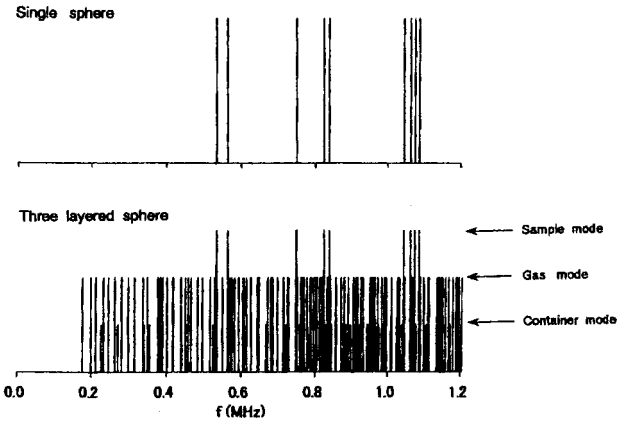

FIG. 3. Comparison between resonance spectra of the three-layered sphere and the single iron sphere at pressure of 0.1 MPa. Sample, gas, and container modes are indicated by long, intermediate, and short bars, respectively.

single sphere. In both cases the frequencies become larger with increasing pressure. The increase in frequencies is attributed to changes in elastic constants, density, and volume for the single sphere and to those in each layer for the three-layered sphere. The sample mode frequency is nearly equal to the resonant frequency of the single sphere at low pressure, but diverges from the single sphere frequency as pressure increases. The difference in acoustic impedance between gas and solid layers decreases as pressure increases, thus allowing vibrational energy to more readily transfer from the solid sphere to the gas layer. Consequently, the sample mode frequency deviates from the resonant frequency of the single sphere and the pressure derivatives of frequencies for the two cases are not equal. If the frequency difference is evaluated and accounted for, we obtain the resonant frequencies of a single sphere from spectral measurements on the three-layered sphere. We emphasize, however, that determining the frequency shifts due to vibrational energy transfer implies that the elastic constants of the sample are already known at elevating pressure. In order to avoid such complications, we recommend evaluating the sample's elastic constants from a least squares fit of the measured and calculated spectra for the full three-layered system. In this

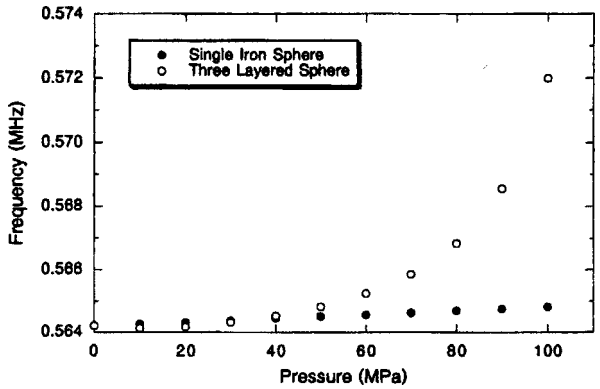

FIG. 4. Pressure dependence of resonant frequencies of the single sphere (solid circles) and sample mode (open circles) of the three-layer configuration. The oscillation mode is ${}_0S_2$ for the single sphere and ${}_5S_2$ for the sample mode, and both modes are equivalent.

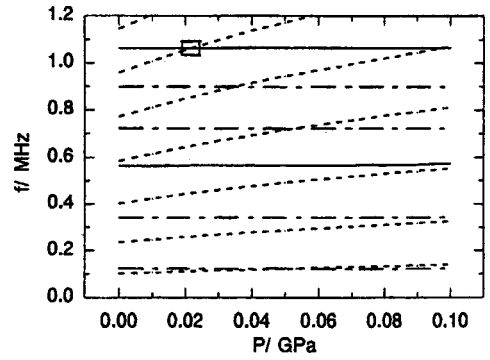

FIG. 5. Pressure dependence of resonant frequencies of sample (solid line), gas (dashed line), and container (dotted and dashed line) modes, which are equivalent to the ${}_nS_2$ modes. A small rectangular region is magnified in Fig. 6.

case care is required in order to identify what modes of spheroidal oscillations are equivalent to measured sample modes. Therefore we investigate the behavior of the sample modes in response to elevating pressure in a gas layer.

Figure 5 shows the pressure dependence of frequencies of spheroidal modes, ${}_nS_2$, where ''n'' and ''2'' are radial and angular order numbers, respectively. Each of these modes belongs to one of sample, gas, and container modes. All the free oscillation frequencies increase with increasing pressure. The gas modes show the largest increase in frequencies against a pressure increase because of the larger compressibility of gas. Thus their pressure curves frequently intersect those of sample and container modes (Fig. 5). In order to observe details of the intersection between the pressure curves of resonant frequencies, a small rectangular region containing an intersection between sample and gas modes is magnified in Fig. 6 (see Fig. 5). The frequencies of ${}_{10}S_2$ and ${}_{11}S_2$ modes gradually approach as the confining pressure increases up to the intersection pressure and separate above the pressure. Thus the sample mode is equivalent to the ${}_{11}S_2$ mode below the intersection pressure, but to the ${}_{10}S_2$ mode above the pressure. This result means that an interchange from ${}_{11}S_2$ mode to ${}_{10}S_2$ mode takes place in the vicinity of the intersection on the pressure curve of the sample mode. Reverse interchange also occurs on the pressure curve of gas mode. Therefore the intersection between the pressure curves of sample and gas modes is interpreted as interchange from ${}_{11}S_2$ to ${}_{10}S_2$ on the sample mode and from ${}_{10}S_2$ to ${}_{11}S_2$ on the gas mode. Such an interchange occurs only between the spheroidal modes, ${}_nS_l$ and ${}_{n'}S_{l'}$, satisfying the conditions of $l=l'$ and $n-n'=\pm 1$, and the modal interchanges do not take place in the case of single sphere oscillation. This result means that one should be aware of change

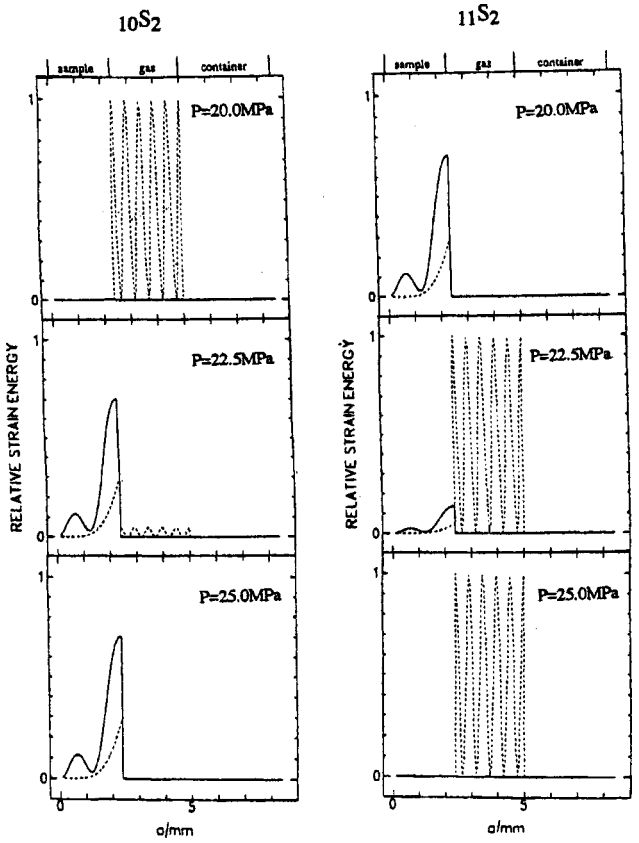

FIG. 7. Strain energy distribution of ${}_{10}S_2$ and ${}_{11}S_2$ modes at three confining pressures, 20, 22.5, and 25 MPa. See the caption of Fig. 2 for the solid and dashed lines.

in radial order numbers of spheroidal modes when tracing sample mode frequencies against pressure.

Figure 7 shows the strain energy distribution of the ${}_{10}S_2$ and ${}_{11}S_2$ modes under different confining pressures. As the pressure increases, the distribution shows that the ${}_{10}S_2$ mode changes from gas mode to sample mode and the ${}_{11}S_2$ mode changes reversely. The resonance modes in the vicinity of the intersection are intermediate between sample and gas modes. In general, a spheriodal mode of a three-layered sphere with solid–gas–solid structure shows the feature of the sample, gas, or container mode at a confining pressure, but the mode changes into other modes as the confining pressure increases.

IV. DISCUSSION AND CONCLUSION

As seen in Figs. 5 and 6, intersection between the pressure curves of resonant frequencies may make it difficult to identify spheroidal oscillation modes measured in the vicinity of the intersection. The misidentification of resonance modes is a source of errors in the elastic constants determined from the resonant frequencies. In order to avoid problems in mode identification, it is necessary to either not use frequencies measured at the intersection of pressure curves in the elasticity inversion analysis or use a configuration for which the number of gas modes is minimized. The pressure dependencies of resonant frequencies of gas modes were calculated for different thicknesses of gas layer in order to find optimal conditions for identifying sample mode frequencies. As seen in Fig. 8, the frequency interval between adjacent gas modes increases as the thickness of gas layer is reduced. Thus, the possibility of misidentification of sample modes in the resonance spectrum is lessened in the case of a three-layered sphere with a thinner gas layer.

Because there are a number of resonance modes in the free oscillation of a three-layered sphere with solid–gas–solid structure, knowing the relative amplitudes of the resonance modes is useful for extracting the sample modes from the resonance spectrum. Assuming the same situation as the cavity resonance experiment where a pair of source and receiver is set at opposite poles on the surface of the spherical sample, we synthesized waveforms of elastic waves generated by the point source and then calculated amplitude spectra of the synthesized waveforms. The synthesis of the elastic

waves was carried out at ambient pressure by means of normal mode superposition method (Gilbert and Dziewonski, 1975), where the eigenfunctions of 550 modes including 12 sample modes were used. Figures 9 and 10 depict the synthesized waveforms and their amplitude spectra, respectively. The amplitude spectra show several clear peaks that correspond to the sample modes, but no spectral peaks of gas and container are found. This result indicates that the excitation of gas and container modes are sufficiently weak on the surface of the sample in comparison with that of sample mode. Thus even if the resonance spectrum of the three-layered sphere is complicated because a large number of gas and container modes are excited, sample modes can be easily identified in the resonance spectrum measured on the spherical sample.

In summary we have addressed problems related to the use of RST for elasticity measurements under high pressure. We investigated normal mode oscillation of a sphere with spherical shell structure composed of three layers: solid spherical sample, gas, and solid container shell. The results obtained are summarized as follows.

(1) The resonance modes of a sphere with solid–gas–solid structure are classified into sample, gas, and container modes, whose strain energy distributions are localized into sample, gas, and container layers, respectively.
(2) All resonant frequencies increase with increasing gas pressure and the increase in frequency of gas mode is largest. When tracing the pressure change of resonant frequencies, a spheroidal mode shows feature of sample, gas, or container mode at one hydrostatic pressure, but changes into other modes as pressure increases.
(3) At a pressure where a pressure curve of sample or container mode intersects that of gas mode, modal interchange takes place only between spheroidal modes of ${}_nS_l$ and ${}_{n'}S_{l'}$ satisfying the conditions of $l=l'$ and $n-n'=\pm 1$. Thus it is very important to identify what modes of spheroidal oscillation correspond to measured sample modes. The interchange may be an origin for misidentification of resonance mode measured in the vicinity of the intersection pressure. To avoid occurrence of the modal interchange, the gas layer should be thinned.
(4) Sample modes are much more strongly excited than those of gas and container modes when the resonance spectrum is measured on the surface of the inner sample and a vibrational source is put on the sample surface.

Backscattering enhancements due to retroreflection of ultrasonic leaky Rayleigh waves at corners of solid elastic cubes in water

Karen Gipson[a] and Philip L. Marston[b]
Department of Physics, Washington State University, Pullman, Washington 99164-2814

(Received 11 August 1998; revised 2 November 1998; accepted 2 November 1998)

Backscattering enhancements can be important for interpreting acoustical images of scatterers. Experiments were performed on a solid stainless steel cube in water in order to investigate a significant mechanism for producing a large backscattered signal. Enhanced high-frequency backscattering is observed when the block is rotated such that the incident acoustic wave strikes one of its flat surfaces in the vicinity of the coupling angle for launching a leaky Rayleigh wave at the steel–water interface. This enhancement can be explained as a retroreflection of the leaky wave at a corner of the block, which results in a reversal of the incident wave vector and thus produces a large backscattered signal. The magnitude of the peak backscattered pressure is approximated using a convolution formulation [P. L. Marston, J. Acoust. Soc. Am. **97**, 34–41 (1995)]. Observed backscattering enhancements support the validity of the convolution formulation to approximate the general magnitude of the peak pressure, as well as being consistent with the dephasing predicted by that theory as the block is rotated away from the coupling angle. Tilting the block while maintaining the coupling angle reduces the backscattered amplitude because of changes in the reflection coefficients at the corner as well as increased attenuation.

INTRODUCTION

The scattering characteristics of certain canonical shapes, such as spheres and infinite cylinders, have been studied using analytical solutions expressed as a partial-wave series.[1,2] However, many scatterers are not amenable to analytical solutions; even an object as simple as an elastic rectangular parallelepiped precludes a partial-wave solution, since the wave equation is not separable for such a geometry. Hence, other methods must be employed to predict or explain the scattering properties of such shapes. Chinnery *et al.*[3] and Thorne *et al.*[4] have recently analyzed the scattering by cubes at low frequencies; however, different scattering mechanisms are expected to dominate at high frequencies. Ray methods have proven useful for describing high-frequency scattering for a variety of cases,[5,6] and such methods are heuristically appealing because they provide visualization of specific physical processes that may contribute to scattering. In the present work we investigate a specific high-frequency backscattering enhancement observed for a solid stainless steel cubical block that is submerged in water. It is noteworthy that related manifestations of the retroreflection process discussed herein may be relevant to a variety of elastic objects with corner truncations and that such enhancements may be important for interpreting the sonar images of objects with corners.

A leaky Rayleigh wave is launched on a fluid-loaded flat elastic surface when an acoustic wave is incident on the flat surface such that the incident acoustic wave vector's component along the interface matches the wave vector of the Rayleigh wave on the interface.[7] The incident angle for which such wave coupling occurs is called the Rayleigh angle and is commonly expressed by the trace velocity matching condition $\theta_R = \sin^{-1}(c/c_R)$, where c is the speed of sound in the water and c_R is the phase velocity of the leaky Rayleigh wave. Since c_R is supersonic with respect to c, the Rayleigh wave will leak radiation into the water; by reciprocity we see that radiation leaks into the water at the Rayleigh angle. If the cubical block of this investigation is rotated such that the acoustic wave in water is incident on one of the flat faces of the block in the vicinity of the Rayleigh angle, a leaky Rayleigh wave is launched on the face. When this wave reaches the edge of the face, part of it is reflected and propagates to the adjacent edge forming the corner, where part of it is reflected again. A ray diagram of the process of interest is shown in Fig. 1. This process is termed retroreflection: for a 90° corner, the final result is that the wave vector of the leaky Rayleigh wave is reversed. Since the outgoing wavefront associated with this leaky radiation is locally flat[5] and directed back toward the source, the retroreflection process can result in a large contribution to the farfield backscattered pressure.

For an elastic object with flat surfaces and corners, significant backscattering can occur from the process described above or from specular reflection off one of the flat faces. However, specular reflection requires that two of the Euler angles of the surface normal be narrowly constrained.[8] In contrast, the requirements for the retroreflection process to contribute to backscattering are (a) that a leaky Rayleigh wave be launched on the surface, and (b) that this wave

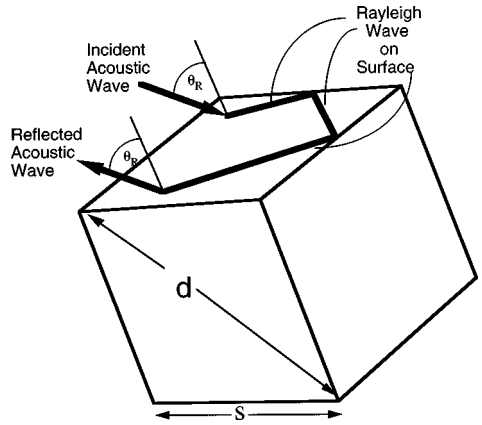

FIG. 1. The retroreflection process. If the acoustic wave is incident in the vicinity of the Rayleigh angle, a leaky Rayleigh wave will be launched on the flat surface of the block. When the associated ray reaches the corner, it will be partially reflected at each edge, with the result that the wave vector is reversed as shown. The Rayleigh wave will thus retroreflect acoustic radiation in the backscattering direction with a flat wavefront. Other rays parallel to the one shown contribute to the flat wavefront. The radiation due to subsequent reflections of the leaky waves is neglected due to the damping rate at the high frequencies under consideration.

survive the successive reflections at the edges of the solid. The former requirement narrowly constrains one of the Euler angles: the acoustic wave must be incident near the Rayleigh angle. In Sec. I we present the experimental methods and observations that confirm the existence of the retroreflected backscattered signal for incidence near the Rayleigh angle when conditions are favorable for satisfying the second requirement, and the angular width associated with rotation is found to be relatively broad. In addition, it is observed that the second requirement places only weak restrictions on a second angle, which can be connected to the tilt angle of the block. This suggests that the mechanism under investigation is more likely to be observed than specular reflection from one of the flat faces of the block; we will see in Sec. III that the experiments and theory of this investigation substantiate that idea.

The theoretical analysis of the retroreflected wave in Sec. II is based on a convolution formulation discussed by Marston,[9–11] specialized to the present case of leaky Rayleigh waves. The dependence of the result of Sec. II on the rotation and tilt angles of the block are derived in Appendices A and B, respectively. In Appendix C we explain the modifications required to account for the finite launch region, while a correction to plane wave incidence due to the finite nature of the separation distance of the transducer and the target is given in Appendix D. (Other corrections to and justifications of some of the approximations in the theory are presented in Ref. 12.) In Appendix E we discuss the normalization of the data, and comparisons between the theoretical predictions and the experimental observations appear in Sec. III.

I. OBSERVATION OF THE RETROREFLECTED SIGNAL

The experiments were performed in a redwood tank of 12-ft diam and 8-ft depth, which held approximately 6500

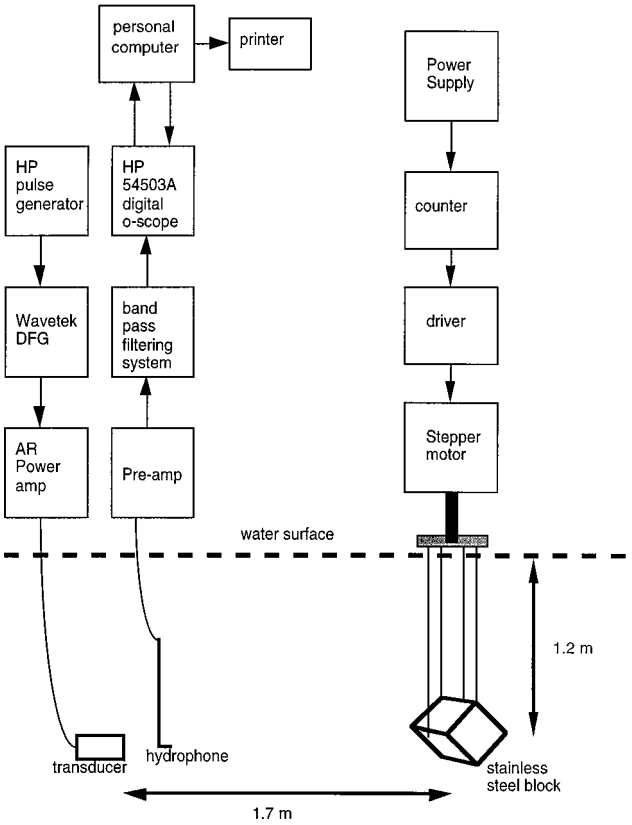

FIG. 2. The experimental setup for measuring the dependence of backscatter on rotation and tilt.

gallons of water. The experimental setup and associated electronics are shown in Fig. 2. The experiment was centered in the tank, with the source and target separated by a distance of approximately 1.7 m in order to ensure uniform ensonification across the target while isolating the signals backscattered by the target from those reflected from the tank walls. The source was a 0.95-cm diam piston transducer (Panametrics model V309), which was driven with 1.5-MHz five-cycle sine wave bursts generated by the Wavetek digital function generator and gated by a Hewlett-Packard pulse generator. A small bent-tip hydrophone was positioned a distance of 50 cm in front of the source (between the source and the target) to detect the backscattered signal, which was amplified and filtered before being sent to the Hewlett-Packard digital oscilloscope. The data were averaged over many identical events by the HP scope and manually time windowed to isolate the peak signal at each angular step before being recorded by a computer.

The target was a solid stainless steel 303 cubic block 6.00 cm on a side. The material parameters of the target were measured from a sample of the material from which the target was constructed; the relevant material parameters and those of the surrounding water are shown in Table I and are needed to calculate the Rayleigh velocity and attenuation.[7,11] The size of the target was chosen so that its dimensions would be somewhat larger than the Rayleigh wave attenuation length of 2.88 cm for the frequency used in the experiments but not so large as to significantly compromise plane wave illumination within the constraints of the scattering

TABLE I. Material parameters for the experiment. The parameters for the block and surrounding water are used to determine the Rayleigh angle, and the parameters for the calibration sphere are used to determine the magnitude of the specular contribution to its form function in the backscattering direction.

facility. The block was suspended from the rotary stage by four thin stainless steel wires in order to inhibit it from swinging after being rotated; care was taken to preserve the reflecting surface of the block when attaching the suspension wires. (See Appendix E.) The tilt angle was varied by adjusting the lengths of two of the suspension wires and was determined to the nearest 0.1° by measuring the deflection of a laser beam reflected from a mirror mounted on the top surface of the block. The rotary stage was driven by a stepper motor, which enabled the rotation angle to be incremented by 0.05°. The high inertia of the target motivated manual collection of the data to ensure that the block was motionless during the signal averaging process.

In the first set of experiments, the block was suspended such that its diagonal was level, so that a surface wave on the block would strike each of the edges forming the retroreflecting corner at a 45° angle. For this orientation the horizontal incident wave vector, the normal to the illuminated face, and a diagonal of that face all lie in a horizontal plane. (This is termed the untilted block for reasons to be explained subsequently.) The block was then rotated about a vertical axis through its center using the rotary stage, which varied the angle at which the incoming rays were incident on the front face of the block. In this manner, the dependence of the backscattered signal on the rotation angle θ was investigated. Examples of the farfield signals are shown in Fig. 3; the large signal near 35 μs in Fig. 3(a) corresponds to the predicted time for the first return from the mechanism under consideration. Due to the relatively high rate of radiation damping at high frequencies, subsequent returns from multiple reflections are not expected to contribute significantly to backscattering in the high-frequency regime. Therefore the pressure magnitude at a given angle was determined from an average over several cycles of the first return. The pressure magnitudes were normalized as discussed in Appendix E to produce the backscattering form function as a function of θ plotted in Fig. 4. (The dotted and dashed curves in Fig. 4 are theoretical dephasing relationships derived in Appendix A by the convolution method to be discussed subsequently.) The data in Fig. 4 confirm that the backscattered signal has a maximum for incidence near the Rayleigh angle and decreases as the angle of incidence differs from the region of the Rayleigh angle, supporting the hypothesis that a leaky Rayleigh wave is launched on the surface of the block and retroreflected around the corner to yield a large backscattering contribution.

In the second set of experiments, the block was held at

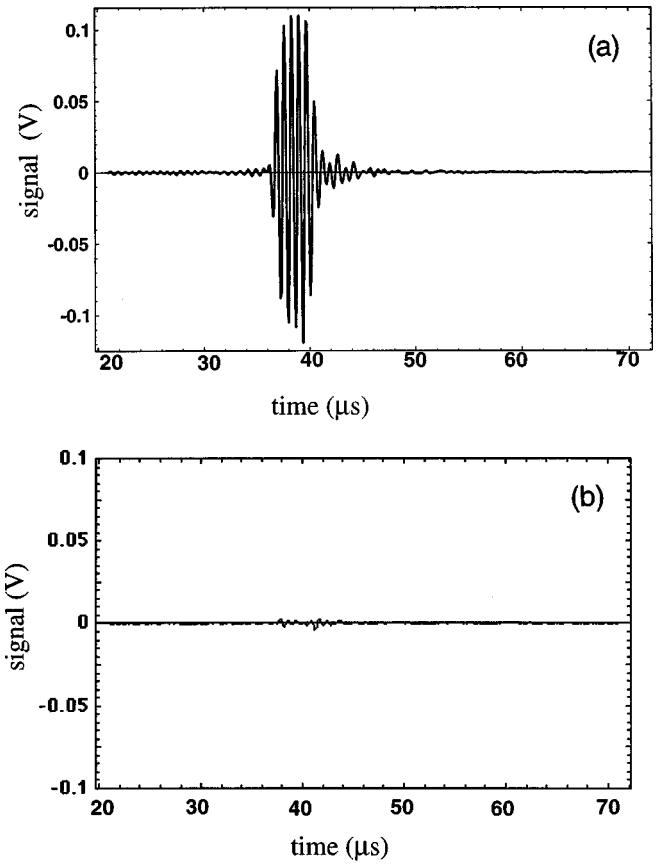

FIG. 3. Examples of backscattered signals, with time $t=0$ set to correspond to the specular reflection from the face of the block. (a) The backscattered signal from the block for $\theta=29.9$ degrees, and (b) the corresponding signal for $\theta=32.0$ degrees. The signal is significantly greater in (a) than in (b) due to the excitation of the ray shown in Fig. 1.

the Rayleigh angle (the experimentally determined maximum in the absence of tilt) while the tilt angle was varied such that the diagonal of the block's ensonified surface was no longer horizontal. As shown in Fig. 5, tilting the block by an angle γ causes the Rayleigh wave to strike the edges forming the corner at complementary angles $\gamma \pm 45°$. Since

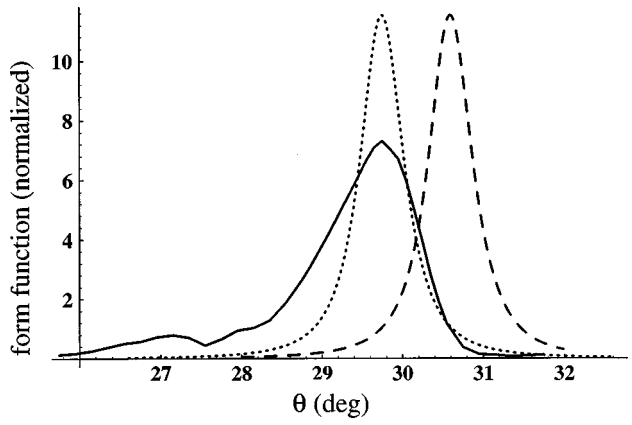

FIG. 4. The backscattering form function magnitude as a function of the rotation angle. The solid curve shows the data, the dashed curve is the theoretical dephasing relationship derived in Appendix A, and the dotted curve is the theoretical dephasing curve taking the rotation angle as an adjustable parameter. The form function is normalized as discussed in Appendix D.

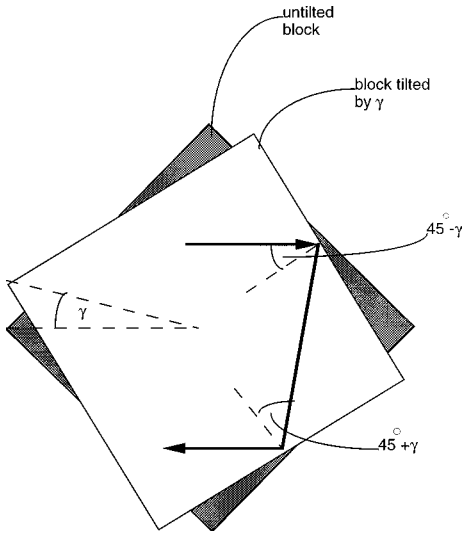

FIG. 5. The effects of block tilt on Rayleigh wave propagation on the block's face. Tilting the block causes the Rayleigh wave to strike each of the edges forming the corner at different angles as well as resulting in a longer pathlength across the corner.

edge reflection coefficients depend on the angle of incidence, the angles $\gamma \pm 45°$ are expected to have different reflection coefficients than the 45° angles of the untilted case. In addition, tilting the block results in increased attenuation due to a longer pathlength as the surface wave travels across the corner. In Appendix B we demonstrate that the product of the two reflection coefficients with the attenuation factor will be largest when the Rayleigh wave strikes each of the edges at a 45° angle. This elucidates why having the diagonal level is considered the untilted block: the backscattered pressure should decrease as the block is tilted away from that orientation. Figure 6 displays the backscattered pressure as a function of tilt angle γ. The dots representing the data are normalized with respect to the value at $\gamma = 0$ and clearly confirm the expectation that the backscattered pressure decrease as the block is tilted away from $\gamma = 0$. (The solid curve in Fig. 6 is the theoretical tilt degradation curve derived in Appendix B by quantifying the above considerations, and will be discussed in more detail in Sec. III.)

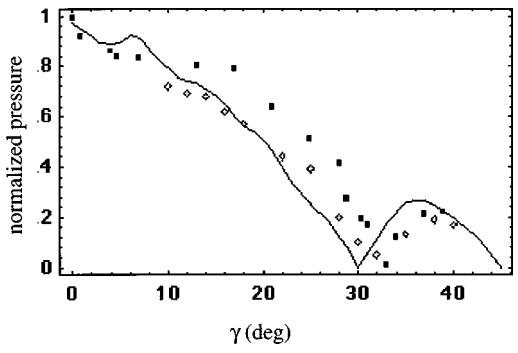

FIG. 6. Backscattered pressure as a function of tilt angle. The dots and boxes represent two sets of data, while the solid curve is the theoretical tilt degradation relationship derived in Appendix B. Both the data and the theory have been normalized with respect to backscattered pressure for the untilted block.

II. DEVELOPMENT OF AN APPROXIMATE MODEL

Following the development of Marston *et al.*,[10] an approximation for the backscattered pressure can be obtained by expressing the outgoing leaky wave field near the scatterer as a spatial convolution of the incident pressure and a function describing the response of the scattering surface to a spatially localized pressure, employing the concept of an image block to account for the reflection at the corner, and then using the Rayleigh–Sommerfeld propagation integral[5] to construct the farfield amplitude. Time harmonic waves are assumed; an $\exp(-i\omega t)$ time dependence is suppressed throughout the development. The initial calculation is performed for the maximum backscattering case: the acoustic wave is incident on the untilted block at the Rayleigh angle. In addition, the block is initially approximated as a semi-infinite corner. After obtaining an expression for the magnitude of the backscattered pressure for this idealized case, a correction accounting for the finite size of the block is introduced. (The details of that correction are presented in Appendix C.) The resulting expression gives an approximate prediction of the peak farfield backscattered pressure due to the retroreflection process under investigation, Eq. (8). As mentioned in the Introduction, the dependence of the backscattered pressure on rotation and tilt angles is analyzed in Appendices A and B, respectively. These results are discussed in Sec. III.

Due to the two edge reflections of the Rayleigh wave associated with the retroreflection process (see Fig. 1), the prediction of the pressure amplitudes relies on an approximation of the magnitude of the two amplitude reflection coefficients. We use the Rayleigh wave reflection coefficients calculated by Gautesen using a numerical transform method for Rayleigh wave reflections on an elastic quarter-space bounded by a vacuum.[13] The value of Poisson's ratio used in Gautesen's calculation ($\frac{1}{3}$) is sufficiently close to the calculated value for the stainless steel block (0.289) that the discrepancy can be neglected for the present purpose of testing the ability of the analysis to explain the general magnitude of the observed signal. However, we note that using Gautesen's coefficients neglects any effects of radiation on the reflection coefficient product B introduced in Eq. (4); the presence of fluid loading will decrease the actual reflection coefficients somewhat since some energy can leak into the fluid.

For the case of the untilted block, the leaky Rayleigh wave strikes each of the edges forming the corner at a 45° angle, which corresponds to the angular region of the largest product of the edge reflection coefficients. We begin the convolution formulation by approximating the scatterer as an elastic half-space, which is a reasonable approximation for the present case of high-frequency acoustic waves incident on a flat face of the block. In addition, the response of the surface is assumed to be uniform in a direction transverse to the propagation of the leaky wave. This allows the surface response to be approximated as a convolution with a spatial *line* response given by a one-dimensional integral.[9] Although such an approximation does not fully represent the reflecting corner, the error it introduces to the final result is ameliorated by attenuation effects, as shown in Ref. 12 by applying the more complicated approximation method of Ref. 11 in a spe-

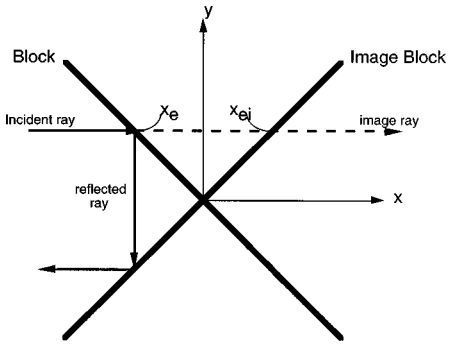

FIG. 7. Image plane depiction of the retroreflection process. The reflection around the corner may be viewed as propagation onto the image block as shown, with an appropriate factor accounting for energy losses at each reflecting edge. For the case of the untilted block shown, the Rayleigh wave strikes each edge at a 45 degree angle, so that $x_e=-y$ and $x_{ei}=y$.

cial case. Defining x to be the initial (horizontal) propagation direction of the leaky Rayleigh wave on the surface of the block, the leaky wave contribution to pressure field at a point x' relative to a line source at a surface coordinate $x=0$ can be expressed as a convolution of the spatial line response with the incident pressure:

$$p_{\mathrm{R}}(x')=\int_{-\infty}^{x'} p_i(x)h(x'-x)dx, \tag{1}$$

where the subscript R denotes that this is the pressure contribution due to leaky Rayleigh waves, and the one-sided spatial line response $h(x)$ can be written as[9]

$$h(x\geqslant 0)\approx -2\alpha\exp(-\alpha x)\exp(ik_R x+i\varphi_b), \tag{2}$$

where k_R and α are the real and imaginary components of the complex leaky wave number, associated with Rayleigh wave propagation and attenuation, respectively, and φ_b is a background phase constant. In the experiments, plane wave incidence is assumed; thus, we write the incident pressure as $p_i(x)=p_0\exp(ik_x x)$, where p_0 is taken to be real.

Next, we consider propagation of the Rayleigh wave around the corner as propagation onto an image block, as shown in Fig. 7. We assume for the time being that the acoustic wave is incident at the Rayleigh angle, so that $k_x=k_{\mathrm{R}}$, resulting in a phase matching of the incident pressure and response function terms in the convolution integral of Eq. (1). This allows the magnitude of the leaky pressure field in the $x'=0$ plane to be expressed as

$$|p_{\mathrm{R}}(0)|=p_0\int_{-\infty}^{x_e}|h(-x)|dx, \tag{3}$$

where x_e is the x coordinate of the position at which the propagating Rayleigh wave strikes the edge of the infinite corner. The integration is truncated at x_e because the illumination ends there. Since we are currently considering the case of a 90° corner with 45° incidence of the Rayleigh wave, we see from Fig. 7 that $x_e=-y$, and Eq. (3) simplifies to $2p_0\exp(-\alpha y)$. The retroreflected leaky Rayleigh wave will experience attenuation as it propagates in the x direction, as well as losing energy in the reflection processes at each of the edges forming the corner. The magnitude of the outgoing pressure field at an arbitrary point on the surface in the image quadrant is thus

$$|p_{\mathrm{R}}(x,y)|=2p_0B\exp(-\alpha x)\exp(-\alpha|y|), \tag{4}$$

where B is the product of the edge reflection coefficients, which depend on the angles at which the leaky Rayleigh wave impinges on the reflecting edges. For the purpose of approximating the modulus of the backscattered amplitude, it is not necessary to show the cumbersome expressions for the phase in Eq. (4). This is because the outgoing wavefront is locally flat within the relevant radiating portion of the block's surface, so that there is no ambiguity as to any variation of phase along coordinates transverse to a given backscattered ray that is radiated from the block's surface.

The ray analysis is only used near the block; the far-field backscattered pressure is subsequently determined by substituting Eq. (4) for the leaky pressure field at the surface of the block into the Rayleigh propagation integral,[5]

$$p_{lsca}(x_s,y_s,z_s)=-\frac{1}{2\pi}\int\int_{-\infty}^{\infty}dx'\,dy'\,p_{\mathrm{R}}(x',y',0)\times\frac{\partial}{\partial z_s}\left(\frac{\exp(ikr')}{r'}\right), \tag{5}$$

where (x_s,y_s,z_s) is the far-field observation point and $r'=[(x_s-x')^2+(y_s-y')^2+z_s^2]^{1/2}$. The plane over which the integration is performed, called[5] the ''exit plane,'' is defined so as to approximate p_{R} as constant in phase, and therefore corresponds to a plane of the leaky wavefront leaving the surface. Since the Rayleigh wave is attenuated by radiation damping as it travels along the block's surface, the maximum contribution to the backscattered pressure will come from a point just after reflection at the corner of the block; we therefore define the origin of the exit plane to correspond to the point of that maximum contribution. The wave field is propagated geometrically from the block to the adjacent exit plane which touches the corner of the block. We choose the coordinates of the exit plane such that its y axis coincides with the y axis previously defined for the image block's surface, while its x axis is rotated about the y axis by θ_{R}. Thus, a point (x_i,y_i) on the image block is projected to the point (x',y') on the exit plane according to

$$x'=x_i\cos\theta_{\mathrm{R}}; \tag{6a}$$

$$y'=y_i. \tag{6b}$$

The exit plane is considered to be semi-infinite; its lower boundaries are determined by the edges forming the corner of the block. Since the radiation leaks only from the surface of the block, the outgoing wavefront is bounded by the projection of the ray that leaves the edge of the block. Letting x_{ei} denote the image of x_e, this projection is given by $x'_e=x_{ei}\cos\theta_{\mathrm{R}}$. From Fig. 7 we see that $x_{ei}=y_i$ for the present case of a 90° corner with 45° incidence, and using Eq. (6b) we obtain $x'_e=y'\cos\theta_{\mathrm{R}}$. Since $\cos\theta_{\mathrm{R}}\leqslant 1$, we see that the projection of the corner of the block onto the image plane is thus larger than the physical corner.

The propagation integral of Eq. (5) is simplified by restricting attention to far-field observation points using the Fraunhofer approximation of the phase,[5] which is applicable because the effective dimensions of the radiating region are limited by the length L discussed below. Since the phase of p_R is constant in the exit plane, the phase of the integrand is constant for the backscattering case of $x_s = y_s = 0$. From symmetry, we see that the integration has equal contributions from two regions; showing only one of these and introducing a factor of 2 to account for the other integration region, Eq. (5) thus becomes

$$|p_{\text{scat}}| = \frac{4p_0 B}{\lambda r} \int_0^\infty dy' \int_{x_e'}^\infty dx' \exp(-\alpha y') \times \exp(-\alpha x' (\cos\theta_R)^{-1}), \tag{7}$$

where $x_e' = y' \cos\theta_R$, as previously discussed, and $\lambda = 2\pi/k$ is the wavelength of the acoustic wave in water. We define the Rayleigh wave attenuation length as $L = \alpha^{-1}$. (With this definition the Rayleigh wave experiences $1/e$ attenuation for $x = L$.) The integration of Eq. (7) thus yields

$$|p_{\text{scat}}| = \frac{2BL^2}{\lambda r} p_0 g \cos\theta_R, \tag{8}$$

where the integration result has $g = 1$. The integration result is supplemented by introducing a geometrical correction factor $g \leqslant 1$ in order to account for the finite size of the block. The derivation of g is presented in Appendix C.

Using the normalization convention discussed in Appendix E allows Eq. (8) to be rewritten as a form function, which elucidates its dependence on frequency. Applying Eq. (E4) to Eq. (8) eliminates the dependence on r and p_0 while introducing a factor of $1/s\sqrt{3/(2\pi)}$, where s is shown in Fig. 1. The frequency dependence of the resulting form function is thus seen to be embedded in the terms L, λ, and g. (The frequency dependence of the geometrical correction factor g arises from its dependence on L.) In order to explicitly determine the form function's dependence on k, we can use $\lambda = 2\pi/k$ and $L = 1/\alpha$, and rewrite the latter expression in terms of k by noting that α can be written as $\alpha = (\alpha/k_R) \times (k_R/k)k$, where the parenthetical factors are constants. The term k_R/k is simply equal to $\sin\theta_R$, and we can define a new variable $\beta = \alpha/k_R$ to represent the first term. (For the parameters in Table I, $\beta = 0.011$.) The resulting form function is

$$|f_{\text{cube}}| = \left(\frac{2B\cos\theta_R}{\sqrt{6\pi}(\beta \sin\theta_R)^2} \right) \frac{g}{ka_{\text{cube}}}, \tag{9}$$

where the bracketed terms do not depend on frequency, and $a_{\text{cube}} = s/2$ is the half-width of the cube, defined so that ka_{cube} is a dimensionless frequency. Figure 8 shows a plot of $|f_{\text{cube}}|$ as a function of ka_{cube}. The decrease of $|f_{\text{cube}}|$ for low frequencies arises from the decrease in g, while the decrease for high frequencies arises from the $1/k$ dependence evident in Eq. (9). Note that the increase of L at very low frequencies may result in resonances, but Eq. (9) predicts only the contribution for the first retroreflected return. The frequency used in this experiment corresponds to $ka_{\text{cube}} = 190$, which is approximately the optimum frequency predicted by Eq. (9). The attenuation length L is sufficiently small that any contributions to the backscattering due to the Rayleigh waves transmitted across the faces of the cube beyond the reflecting edges have been neglected in our analysis.

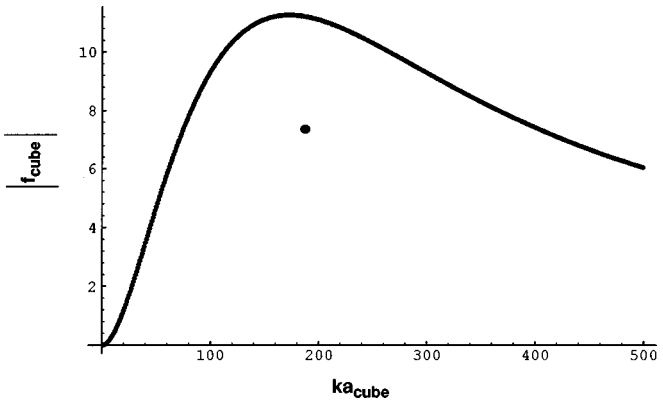

FIG. 8. Frequency dependence of the form function. The curve above is plotted from Eq. (9) to elucidate the frequency dependence of the backscattered return. The experimental parameters correspond to $ka_{\text{cube}} = 190$, and the dot indicates the observed form function at that frequency. At low ka_{cube}, the assumption that subsequent Rayleigh wave reflections are negligible breaks down and the form function is expected to exhibit structure due to resonances.

III. DISCUSSION

The Rayleigh angle and attenuation length are calculated from elasticity theory using the shear and longitudinal speeds of the block, its density, and the density and sound speed of the surrounding water.[14] The parameters in Table I predict a Rayleigh speed of 2.908 mm/μs, with an attenuation length L of 2.88 cm. Using the trace velocity matching condition, the theoretical prediction for the Rayleigh angle is thus 30.6°. The geometric factor g for the experimental parameters is determined to be 0.688 (see Appendix C), and the wavelength λ is determined from the water temperature to be 0.986 mm for the frequency used. The specular contribution[5] to the form function for the calibration sphere is determined from the parameters in Table I to have a magnitude of 0.938. Thus, we find that for the untilted block the peak backscattering form function magnitude is predicted from Eqs. (E2) and (E5) to be 11.5. Experimentally, the peak retroreflected form function for the data shown in Fig. 4 was approximately 7.3. These results are in relatively good agreement; the elevated theoretical prediction is consistent with the elevated values of the reflection coefficients (due to neglecting the effects of fluid loading) and the effects of assuming a transversely uniform wave on the surface. In addition, the size of the scattering facility prevented a sufficient separation distance to ensure that the farfield conditions assumed in the theory were rigorously satisfied.

Figure 4 is a plot of the normalized backscattering form function versus the incident angle. The solid data curve clearly shows that the backscattered pressure has a local maximum; the experiments place this maximum at an average angle of 30.0°. The dashed curve in Fig. 4 was determined by evaluating the theoretical dephasing relationship of Eq. (A6) at 0.01° steps over an 8° interval and normalizing to

the peak form function predicted by Eqs. (E2) and (E5). The dotted curve is a shifted version of the dashed curve, offset by the 0.6° discrepancy between the measured and predicted Rayleigh angles in order to facilitate comparison between the experimental results and the theoretical predictions. The justification of this angular shift is based on the finite distance between the source and the target, as discussed in Appendix D. It is seen in Fig. 4 that the theory describes the general features of the data. The observed peak magnitude is of the same order of magnitude as that predicted by the theory, and the width of the data curve is also in general agreement with the theoretical width based on the dephasing of the incident acoustic wave with respect to the Rayleigh surface wave. Ray tracing with diffraction predicts a backscattering angular width of order λ/L, corresponding to approximately 2° for the experimental parameters of this study; the data and theory curves in Fig. 4 substantiate that prediction. The structure visible in the 26°–28° range of the data curve in Fig. 4 is visible in every dataset, but is unaccounted for by the present (approximate) theory.

Figure 6 is a plot of the normalized backscattered pressure as a function of tilt angle when the acoustic wave is incident at the Rayleigh angle. The theory curve was determined from the degradation factor of Eq. (B4), using the appropriate reflection coefficients to determine B for each value of g, and was normalized to the experimental value for $\gamma=0$. Again, we note general agreement between the theory and observations, and it is noteworthy that the signal degrades relatively slowly with block tilt. The observed dip in the data appears to be associated with a zero of the Rayleigh wave reflection coefficient predicted by Gautesen's calculations[13] to occur at $\gamma=30°$ for a Poisson's ratio of $\frac{1}{3}$. The slight discrepancy in the observed angle of the dip may be due to the slight dissimilarity of the Poisson's ratio of the block (0.289) from the assumed value of $\frac{1}{3}$.

Although the necessity for incidence at the Rayleigh angle narrowly constrains one of the Euler angles, Fig. 6 demonstrates that the effect is observable for almost any tilt of the block, placing very weak restrictions on a second angle. The symmetry inherent in tilting the block downward instead of upward allows Fig. 6 to be reflected about $\gamma=0°$, and the symmetry of the four corners of the face allows the resulting 90° curve to be periodically extended to create a 360° curve. Since the 360° curve has so few nulls, we can approximate the solid angle associated with retroreflection as $(\lambda/L)\sin\theta_R$. In contrast, the solid angle for high-frequency backscattering due to specular reflection is of order $(\lambda/d)^2$, where d is shown in Fig. 1. For metal objects in water, the Rayleigh angle is typically 28°–30°.[15] Thus, we see that for high-frequency underwater scattering, elastic objects with corner truncations that satisfy the simple requirement $d>L$ will be more likely to produce detectable backscattered signals through the retroreflection process described in this paper than through specular reflection.

As mentioned in the Introduction, the convolution formulation presented in Sec. II also has an application to other shapes of scatterers. For example, this method has been applied to backscattering due to the retroreflection of Lamb waves by corner truncations on plates.[10,16] Geometrical ray tracing predicts that any corner truncation of angle $180°/n$, where n is an even integer, will exhibit the retroreflection process.[10] Although the present work focused on 90° corners, Dodd observed retroreflective contributions to backscattering for plates having both 45° and 90° corner truncations, and the observed peak backscattered pressure ratio was in good agreement with a theoretical prediction from a one-dimensional analysis analogous to that presented in Sec. II.[16] Though we are not aware of the publication of sonar images demonstrating enhanced target visibility from this mechanism, images have been published for other situations where the visibility of the edge of a target is enhanced due to reflection of a leaky wave.[17]

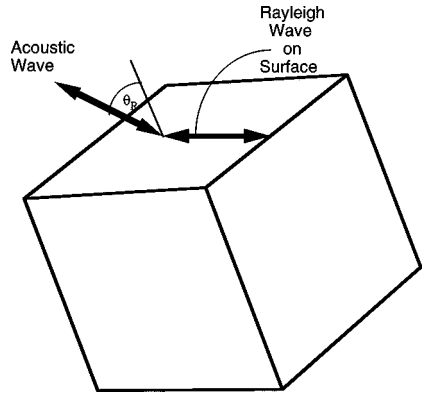

FIG. 9. Single-bounce edge reflection. Backscattering can also occur when the block is tilted such that its edges are level ($\gamma=45$ degrees) so that only one edge is involved in the reflection process. The signal from this type of reflection has a larger amplitude but a smaller angular width than the corner retroreflection which is the main topic under investigation.

It is also noteworthy that the tilt degradation experiments of the present investigation revealed a very large signal for $\gamma=45°$, which was omitted from the data displayed in Fig. 6 because it corresponds to a slightly different mechanism. That mechanism is depicted in Fig. 9 and may be termed a single-bounce edge reflection. Since the mechanism shown in Fig. 9 requires that γ lie close to 45°, it is relatively unlikely to be observed for a randomly oriented cube; its analysis is outside the scope of the present paper.

This research was supported by the Office of Naval Research. Portions of related research on the scattering by the corners of plates (Refs. 10 and 16) were carried out while one of the authors (P.L.M.) was a Visiting Scientist at the Applied Research Laboratories of University of Texas and was supported by the ARL:UT Independent Research and Development Program.

APPENDIX A: DEPHASING OF BACKSCATTERED PRESSURE WITH INCIDENT ANGLE

Equation (8) represents the backscattered pressure when the acoustic wave is incident at the Rayleigh angle. For incidence at other angles, the phase terms in the convolution integral do not cancel but instead lead to a transverse phase

dependence on the block's surface and a modified prefactor. If the incident pressure has $k_x \neq k_R$, then the pressure for $x=0$ and $y \geqslant 0$ is found from Eq. (1) to be

$$p_R(0,y) = -2p_0 \frac{\alpha}{\alpha + i\,\Delta k} \exp(-i\,\Delta k\, y + i\varphi_b) \times \exp(-\alpha y), \tag{A1}$$

where $\Delta k = k_x - k_R$. To account for propagation and attenuation of the Rayleigh wave on the image plane and its reflection at the edges, Eq. (A1) is multiplied by $B\exp(ik_R x)\exp(-\alpha x)$. The constant phase surfaces on the image block are thus no longer oriented in the y direction, but instead are found to be given by lines of slope $k_R/\Delta k$. The phase dependence can be viewed as a skewing of the rays at the edge of the block, before propagation onto the image block. The rays that correspond to the direction of propagation of the wavefronts are described by lines of slope $-\Delta k/k_R$; these make an angle φ with the x axis, where φ is given by

$$\tan\varphi = \frac{-\Delta k}{k_R} = \frac{k_R - k_x}{k_R}, \tag{A2}$$

where the fact that $\tan\varphi$ is an odd function means that Eq. (A2) retains the information of whether k_x is greater or less than k_R, so that both cases may be analyzed simultaneously.

A simple method of approximating the skewing uses a parameter $\beta = -\tan\varphi$, with φ defined as in Eq. (A2). Taking the exit plane along the block's surface, the leaky wave pressure for $y \geqslant 0$ on the surface is obtained from Eq. (A1) by allowing for paraxial propagation along x and by using $\Delta k = \beta k_R$ in the y term:

$$p_R(x,y) = -2p_0 \frac{\alpha B}{\alpha + i\,\Delta k} \exp(-i\beta k_R y - \alpha y + i\varphi_b) \times \exp(i(k_R + i\alpha)x). \tag{A3}$$

The leaky wave contribution to the far-field pressure is then found using the far-field form of the Rayleigh–Sommerfeld propagation integral [see our Eq. (5) and Eq. (6) of Ref. 5]:

$$p_{ff} = \frac{-ik}{2\pi r}\cos\theta \exp(ikr) \int_{-\infty}^{\infty}\int_{x_b}^{\infty} p_R(x,y) \times \exp(-ikx\sin\theta)\,dx\,dy, \tag{A4}$$

where r is the distance from the point (0,0) on the block's surface to the far-field evaluation point, and the lower integration limit of x, $x_b = x_b(y)$, depends on the edge of the block. Substituting Eq. (A3) into Eq. (A4) and evaluating the integral gives the magnitude of the far-field pressure as

$$|p_{ff}| = \frac{4p_0 B}{\lambda r}\cos\theta \left|\frac{\alpha}{\alpha + i\,\Delta k}\right| \frac{1}{|\alpha + i\,\Delta k|} \frac{1}{|2\alpha + i\beta k_R + i\,\Delta k|}, \tag{A5}$$

using summetry for $y<0$. Note that for $\theta = \theta_R$, Eq. (A5) reduces to Eq. (8), as expected. Furthermore, Eq. (A5) gives the ratio of the result for $\theta \neq \theta_R$ to the result for $\theta = \theta_R$ as

$$\left|\frac{p_{scat}(\theta \neq \theta_R)}{p_{scat}(\theta = \theta_R)}\right| = \frac{\cos\theta}{\cos\theta_R} F_1 F_2; \tag{A6a}$$

$$F_1 = \frac{1}{1 + (kL)^2(\sin\theta - \sin\theta_R)^2}; \tag{A6b}$$

$$F_2 = \frac{1}{\sqrt{1 + (jkL)^2(\sin\theta - \sin\theta_R)^2}}, \tag{A6c}$$

where j is a parameter accounting for the wavefront skew on the block's surface: taking $j = \frac{1}{2}$ ($\beta = 0$) neglects the effects of wavefront skew while $j = 1$ ($\beta = \Delta k/k_R$) includes the effects. (As seen in Ref. 12, the results are very similar for the two cases.) The main consequence of dephasing is through the terms Δk in (A5). The theoretical dephasing curve plotted in Fig. 4 was generated by evaluating Eq. (A6) with $j = \frac{1}{2}$ for 0.01° steps over an 8° interval, normalizing the results to the peak pressure magnitude predicted by Eq. (E2), and using Eq. (E5) to express the results in terms of a dimensionless form function.

APPENDIX B: SIGNAL DEGRADATION WITH BLOCK TILT

The calculations in Sec. II are for an untilted block; backscattering will decrease when the block is tilted for two reasons: (a) the Rayleigh wave will strike the reflecting edges at different angles, which have different reflection coefficients; and (b) the Rayleigh wave will travel a greater distance as it cuts across the corner of the block, resulting in increased attenuation. If the block is tilted by an angle γ, the Rayleigh wave will be incident on one reflecting edge at $45° + \gamma$ and the other at $45° - \gamma$ (see Fig. 5), so that both the reflection coefficients contributing to the product B in Eq. (8) are altered. Approximating the Rayleigh wave reflection coefficients for the case under investigation as the corresponding values on an elastic quarter-space bounded by a vacuum, as determined by Gautesen,[13] it is found that the *product* of the two reflection coefficients is greatest in the angular region near $\gamma = 0°$. Any tilt away from that angle will therefore tend to decrease the amplitude of the wave after retroreflection and subsequently decrease the backscattered pressure.

The increased attenuation will also tend to decrease the backscattered pressure; this effect can be quantified by geo-

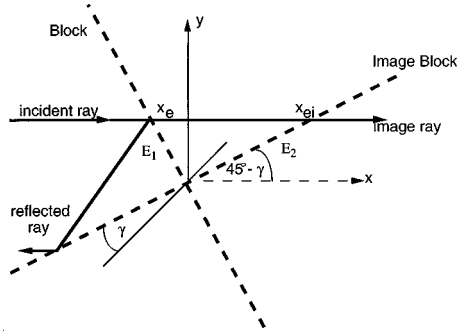

FIG. B1. Image plane for the tilted block. The distance across the corner is the same as the distance $X_c = x_{ei} - x_e$, which can be determined from the triangle with sides X_c, E_1, and E_2, as discussed in the text. X_c is longer than the corresponding distance for the untilted block, resulting in a decrease in amplitude due to extra attenuation.

metrical analysis of the change in pathlength resulting from tilting the block. From Fig. 7 we can see that for the untilted block the pathlength across the corner is $2y$. Figure B1 shows the corresponding figure when the block is tilted by an angle γ. From the figure we can see that the path across the corner, $X_c = x_e - x_{ei}$, is the hypotenuse of a triangle having the edges of the corner labeled by E_1 and E_2 as its other two sides, where E_1 and E_2 are given by

$$E_1 = \frac{y}{\cos(45° - \gamma)}; \tag{B1}$$

$$E_2 = \frac{y}{\sin(45° - \gamma)}. \tag{B2}$$

Substituting Eqs. (B1) and (B2) into the Pythagorean theorem and making trigonometric simplifications shows the pathlength across the corner to be a function of y and γ:

$$X_c(y, \gamma) = 2y \frac{1 + (\tan \gamma)^2}{1 - (\tan \gamma)^2}. \tag{B3}$$

Repeating the steps leading to Eq. (8) with the geometry shown in Fig. B1 shows that after the integration over x', the integrand $\exp(-2\alpha y')$ is replaced by $\exp(-\alpha X_c(y', \gamma))$. The subsequent integration over y' gives increased attenuation from the increased pathlength, which results in an amplitude factor of

$$K(\gamma) = \frac{1 - (\tan \gamma)^2}{1 + (\tan \gamma)^2}. \tag{B4}$$

The above analysis may be repeated for a block tilted by $-\gamma$, in which case the arguments of Eqs. (B1) and (B2) are replaced by $45° + \gamma$. Such substitutions result in Eq. (B3) for the pathlength so that Eq. (B4) is the correct tilt degradation factor, regardless of the direction of tilt.

The dephasing curve shown in Fig. 6 was generated by discretizing Gautesen's graphical presentation of Rayleigh wave reflection coefficients, multiplying the tilt degradation factor $K(\gamma)$ by the product of the coefficients at $45° + \gamma$ and $45° - \gamma$ for each value of γ in 1° steps over the interval plotted, and normalizing with respect to the measured amplitude at $\gamma = 0$. The curve may be reflected about $\gamma = 45°$ and $\gamma = 0°$ as desired to generate a tilt degradation curve valid for the complete 360° tilt range of the block. It is noteworthy that the retroreflected signal is detectable for almost any tilt of the block. The weak local maximum predicted near γ of 7° in Fig. 6 is the result of features of the reflection coefficient calculated by Gautesen.

APPENDIX C: CORRECTION TO THE APPROXIMATION OF A SEMI-INFINITE BLOCK

To represent the finite nature of the block, the lower limit of integration in Eq. (3) and both the upper and lower integration limits in Eq. (5) are modified. Letting d represent the block diagonal, Fig. C1 shows that for the untilted case we can write the lower limit of the x integration on the block in Eq. (3) as $x_0 = -(d - x_e) = -d + y$, while the upper limits on the image block become $x_{oi} = d - x_{ei} = d - y$ for the x integration and $d/2$ for the y' integration. The modifications to Eq. (3) give the pressure on the image block as

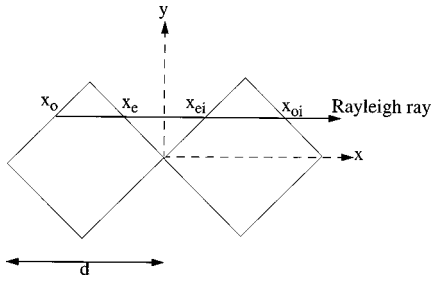

FIG. C1. Integration limits for the finite block. As seen from the sketch, the x integration limits on the block are x_0 to x_e, and on the image block they are x_{ei} to x_{oi}. The y integration extends from $-d/2$ to $d/2$. Evaluating Eqs. (5) and (7) with these corrected limits gives Eq. (C3).

$$|p_R(x,y)| = 2Bp_0 \exp(-\alpha x)\exp(-\alpha y) \times [1 - \exp(-\alpha d)\exp(2\alpha y)], \tag{C1}$$

where the bracketed factor modifies the result of Eq. (4) for the infinite corner. Substituting this result into Eq. (5) with the appropriate modifications to the integration limits discussed above and defining the dimensionless parameter $\zeta = d/L$, gives the far-field pressure as

$$|p_{scat}| = \frac{2BL^2 p_0 \cos \theta_R}{\lambda r}[1 - 2\zeta \exp(-\zeta) - \exp(-2\zeta)]. \tag{C2}$$

Comparing Eq. (C2) to Eq. (9) yields the geometrical correction factor g:

$$g(\zeta) = 1 - 2\zeta \exp(-\zeta) - \exp(-2\zeta). \tag{C3}$$

For these experiments, $d = 8.48$ cm and $L = 2.88$ cm so that $g = 0.688$.

APPENDIX D: ESTIMATION OF ANGULAR UNCERTAINTY DUE TO FINITE SEPARATION DISTANCE

In this Appendix we analyze the effect that the finite distance between the source and target has on the angle at which the incident wave strikes the corner of the block. Because of radiation damping, the largest contribution to backscattering will come from leaky rays with a detachment point very near the launch point, i.e., those launched just prior to the retroreflection around the corner. Therefore, the peak backscattered pressure will occur at the angle associated with incidence on the block's corner rather than at its center. The situation is illustrated in Fig. D1, where it can be seen that the angle of incidence on the corner is larger than the angle of incidence at the block's center by δ. Since the experimental angle θ is measured at the center of the block, the peak backscattered signal is expected to occur at the angle $\theta - \delta$. The present analysis approximates the transducer as a point source, so that the results give only an upper bound on δ rather than an exact value.

Letting C represent the distance from the transducer to the center of the block and d represent the diagonal of the block, it is found that $\tan \delta = a/c = A/C$, with a and A defined as in Fig. D1. Reference to the figure shows that c

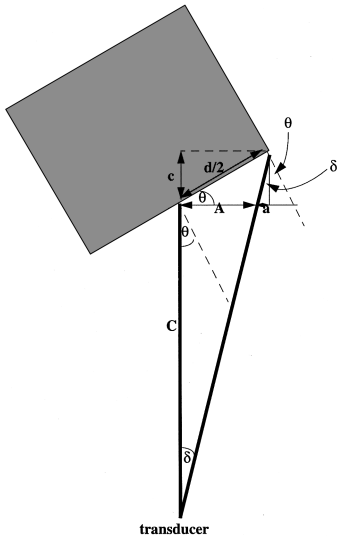

FIG. D1. Geometrical analysis of the effect of the finite separation distance on the incident angle. From the sketch it can be seen that if θ is the angle of incident at the center of the block, then the angle of incidence on the corner is $\theta+\delta$.

$=(d/2)\sin\theta$ and $A+a=(d/2)\cos\theta$. Solving this system of equations yields $\delta=\arctan[(\tan\theta(1+(2C)/(d\sin\theta)))^{-1}]$. Substituting in the measured values of $d=8.48\,\text{cm}$, $C=170\,\text{cm}$, and $\theta=29.9°$ from the experiment gives a predicted shift of $-1.21°$. The measured angular discrepancy of $-0.7°$ is well within this upper bound. Therefore, the angular shift of the theoretical dephasing curves in Fig. 4 is justified on the basis of the finite distance between the source and the target.

APPENDIX E: NORMALIZATION OF DATA

In this Appendix we explain how the measured pressure amplitudes are converted to form function magnitudes (such as plotted in Fig. 4). The target was a solid stainless steel 303 cubic block 6.00 cm on a side and was suspended from the rotary stage by four thin stainless steel wires, as shown in Fig. E1. The measured pressure amplitudes were initially

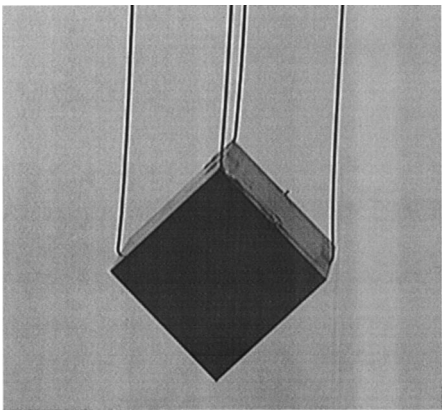

FIG. E1. Photograph of the cubical target. The target was a solid stainless cube 6.00 cm on a side and was suspended by four thin stainless steel wires. The wires were welded to the top face of the cube so as not to affect the reflecting surface, which was the front face of the block. The wires attached to the apex were fixed, and the tilt of the block was adjusted by changing the lengths of the two side wires.

calibrated to the measured specular return from a calibration sphere for each experiment.[5] The calibration sphere used in these experiments was a solid sphere of radius 3.49 cm composed of stainless steel 440c. After each dataset, the block was removed from the water and replaced by the sphere, with time traces ensuring that the front surface of the sphere was at the same location as the block's reflecting surface. Using p_0 to represent the magnitude of the incident pressure, the magnitude of the pressure backscattered to a far-field observation point a distance r from a sphere of radius a is known to be expressible as[5]

$$|p_{\text{sph}}|=p_0\frac{a|f_{\text{spec}}|}{2r}, \tag{E1}$$

where f_{spec} is the specular form function of the sphere. In the high-frequency limit the magnitude of f_{spec} can be approximated as $|\rho_E c_L-\rho c|/|\rho_E c_L+\rho c|$, where ρ_E and c_L are the density and longitudinal wave speed of the elastic solid and ρ and c are the density and speed of sound in the surrounding water. Using parameters in Table I, we find that $|f_{\text{spec}}|\cong 0.938$ for the experiments of this chapter. From Eq. (8) we can see that calibrating the data in this way eliminates the dependence of the backscattering amplitude on incident pressure and observation point; specifically, Eq. (8) yields

$$\frac{|p_{\text{scat}}|}{|p_{\text{sph}}|}=\frac{4BL^2g\cos\theta_{\text{R}}}{\lambda a|f_{\text{spec}}|}. \tag{E2}$$

A form function for the cube was subsequently defined by normalization with respect to a reference sphere of the same projected area, as introduced by Chinnery *et al.* for scattering by cubes in the low-frequency regime.[3] We have chosen to follow Chinnery's form function convention, despite the fact that the scattering pattern in the low-frequency regime includes resonances that are not relevant to our high-frequency tone burst measurements. A generic form function is defined from power considerations to be[3]

$$|f|=\sqrt{\frac{4\pi r^2}{A}}\frac{|p_{\text{scat}}|}{|p_0|}, \tag{E3}$$

where A is the projected cross-sectional area of the scatterer. Note that for a sphere, $A=\pi a^2$, so that Eq. (E3) gives the same result as Eq. (E1). However, for a cube, the projected cross-sectional area will depend on the orientation of the cube; therefore the average projected cross-sectional area $\langle A\rangle=3s^2/2$ is used. This gives the form function of the cube as

$$|f_{\text{cube}}|=\frac{2r}{s\sqrt{3/(2\pi)}}\frac{|p_{\text{scat}}|}{|p_0|}. \tag{E4}$$

Since Eq. (E4) has the structure of a form function of a sphere of radius $a_{\text{ref}}=s\sqrt{3/(2\pi)}$, the form function can be interpreted as referenced to a sphere having the same projected area as the cube. Equation (E1) can be used to eliminate the dependence on r and p_0, yielding an expression for the form function of the cube in terms of the ratio of the pressure magnitude backscattered by the cube to the pressure magnitude of the specular return from the calibration sphere. The result is

$$|f_{\text{cube}}| = \frac{a|f_{\text{spec}}|}{s\sqrt{3/(2\pi)}} \frac{|p_{\text{scat}}|}{|p_{\text{sph}}|}. \tag{E5}$$

This normalization is applied to both the measured pressure ratios and the theoretical pressure ratio given by Eq. (E2). In the experiments of this chapter, $a = 1.75\,\text{cm}$, $s = 6.00\,\text{cm}$, and $|f_{\text{spec}}| = 0.938$, so that the prefactor is found to be 0.790.

Acoustic recovery of lost power in pulse tube refrigerators

G. W. Swift, D. L. Gardner, and S. Backhaus
Condensed Matter and Thermal Physics Group, Los Alamos National Laboratory, Los Alamos, New Mexico 87545

(Received 18 May 1998; accepted for publication 21 October 1998)

In an efficient Stirling-cycle cryocooler, the cold piston or displacer recovers power from the gas. This power is dissipated into heat in the orifice of an orifice pulse tube refrigerator, decreasing system efficiency. Recovery of some of this power in a pulse tube refrigerator, without sacrificing the simplicity and reliability inherent in a system with no cold moving parts, is described in this paper. In one method of such power recovery, the hot ends of both the regenerator and the pulse tube are connected to the front of the piston driving the refrigerator. Experimental data is presented demonstrating this method using a thermoacoustic driver instead of a piston driver. Control of time-averaged mass flux through the refrigerator is crucial to this power recovery, lest the refrigerator's cooling power be overwhelmed by a room-temperature mass flux. Two methods are demonstrated for control of mass flux: a barrier method, and a hydrodynamic method based on turbulent irreversible flow. At $-55\,^{\circ}\mathrm{C}$, the refrigerator provided cooling with 9% of the Carnot coefficient of performance. With straightforward improvements, similar refrigerators should achieve efficiencies greater than those of prior pulse tube refrigerators and prior standing-wave thermoacoustic refrigerators, while maintaining the advantages of no moving parts. © *1999 Acoustical Society of America.* [S0001-4966(99)00802-4]

INTRODUCTION

As illustrated in Fig. 1(a) and (b), the orifice pulse tube refrigerator[1] (PTR) may be regarded as a Stirling refrigerator in which the cold moving parts have been replaced by stationary components. A reduction in efficiency may accompany this simplification in hardware, for a number of reasons. The most obvious cause of reduced efficiency is that work is absorbed and dissipated into waste heat in the orifice of the orifice PTR, whereas it is recovered at the cold piston of the Stirling machine and delivered back to the hot end of the system, either directly (via a displacer) or indirectly (via a crankshaft). Kittel[2] has shown that this orifice dissipation, regarded as a loss inherent to the orifice PTR, causes the coefficient of performance COP (i.e., the efficiency) of orifice PTRs to be bounded by T_C/T_H, significantly less than the Carnot COP $T_C/(T_H-T_C)$ which bounds Stirling refrigerators. (T is temperature and the subscripts C and H refer to cold and hot, respectively.) This inherent loss is most severe for $T_C \sim T_H$, thus far preventing practical use of orifice PTRs in noncryogenic applications such as food refrigeration and air conditioning. Orifice dissipation loss is also important in cryogenic systems: In one large orifice PTR with which we are familiar,[3,4] having 2 kW of cooling power at 125 K, orifice dissipation comprises 30% of the entropy generation and lost available work[5] in the refrigeration system (excluding losses in its thermoacoustic driver).

Acoustic transmission lines and inertances can pass acoustic power with little dissipation, while shifting the magnitude and phase of oscillatory pressure dramatically. This suggested to us that they could perform the work-recovery function of the Stirling's cold piston, while preserving the PTR's no-moving-parts advantage. This can be accomplished by at least two methods, illustrated schematically in Fig. 1(c) and (d) for a piston-driven pulse tube refrigerator. In the first method, an acoustic transmission line replaces the orifice, inertance, and compliance, connecting between the hot heat exchanger of the pulse tube and the back side of the drive piston. Most of the power that would previously have been dissipated in the orifice travels along the transmission line to the back side of the piston, helping move the piston and hence reducing the power required of the motor. In the second method, an inertance (or short transmission line) and a compliance between the piston and the aftercooler produce substantial amplitude and phase shifts between them, with the hot heat exchanger of the pulse tube connected at the *front* of the piston. In this method, the power previously dissipated in the orifice is delivered directly to the *front* of the piston and thereby added to the power supplied by the piston, reducing the power required of the motor. Thus, for both methods, system efficiency can be greater than for conventional orifice PTRs.

The fundamental idea behind these methods (and others) was fully anticipated over ten years ago by Ceperley,[6] whose early publications on ''traveling wave heat engines'' (including refrigerators) inspired the beginnings of thermoacoustics research here at Los Alamos. Ceperley realized that the essence of Stirling equipment is a regenerator in which the pressure and volumetric velocity oscillations are substantially in phase, and that an acoustic network with essentially toroidal topology [e.g., in our Fig. 1(c) or (d)] containing the Stirling heat-exchange components can provide such phasing. He showed that efficiencies near 80% of the Carnot efficiency are, in principle, possible with such configurations.

However, Ceperley did not discuss two features that we find are vital for practical operation of such refrigerators and

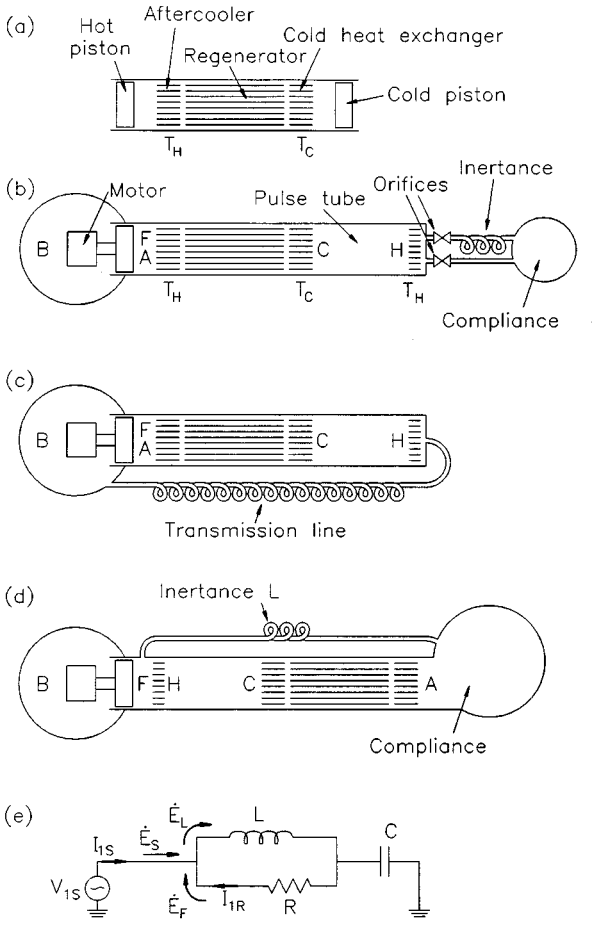

FIG. 1. Schematics of (a) Stirling cycle refrigerator (omitting details such as motor, crankshaft, etc.), (b) orifice pulse tube refrigerator, in which the cold piston of the Stirling cycle refrigerator is replaced by passive components, (c) pulse tube refrigerator with transmission-line feedback, and (d) pulse tube refrigerator with lumped boost configuration. To avoid confusion with the pulse tube's hot heat exchanger, the heat exchanger at the hot end of the regenerator is called the aftercooler. Capital letters in (b) through (d) label locations in the refrigerators: B—back of piston; F—front of piston; A—aftercooler; C—cold heat exchanger; H—hot heat exchanger; and L—inertance. The pistons move sinusoidally in time; the gas velocity in the regenerator is generally from aftercooler to cold heat exchanger while the pressure is high and generally in the opposite direction while the pressure is low. (e) Electric circuit crudely analogous to the acoustic network of (d).

engines. First, a thermal insulation column, namely the pulse tube itself in PTR practice, must insulate the ''remote'' heat exchanger (cold for refrigerators, hot for engines) from ambient temperature. The heat leak along a pulse tube can be as small as 5% of the cooling power of a PTR[7] using a tapered[8] pulse tube, although 15%–40% is typical.[9] Second, something must be done to prevent significant time-averaged mass flow from circulating around the torus. Gedeon[10] has discussed causes of such mass flow and the large heat flux it can carry.

To discuss these concepts quantitatively and in more detail, we take the essential physics to be spatially one-dimensional, with x specifying the coordinate along the direction of oscillatory gas motion. We use the conventional counter-clockwise phasor notation, so that time-dependent variables are expressed as

$$\xi(x,t)=\xi_m(x)+\mathrm{Re}[\xi_1(x)e^{i\omega t}], \tag{1}$$

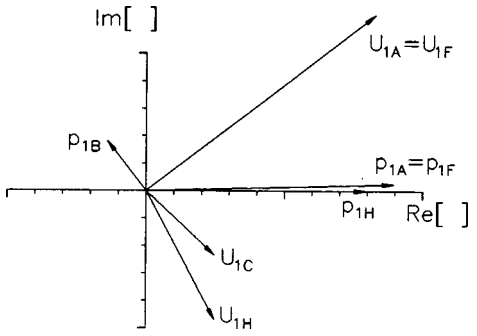

FIG. 2. Typical phasor diagram. Cryogenic pulse tube refrigerators with sufficient power to employ inertances have phasors similar to these, with p_1 in the pulse tube slightly smaller in magnitude than at the aftercooler, and usually lagging in phase; and with U_1 leading pressure at the aftercooler and lagging at both ends of the pulse tube. Pressure phasors are plotted as p_1/p_m, with each mark on the axes representing 0.01. Velocity phasors are plotted as U_1/Sa, where S is pulse tube area and a is sound speed, with each mark on the axes representing 0.001.

with the mean value ξ_m real, and with $\xi_1(x)$ complex to account for both the magnitude and phase of the oscillation. We adopt an acoustical point of view,[11] using the vocabulary of acoustic resistance, inertance, compliance, and transmission line to discuss the lumped and distributed impedances associated with the components of the PTR. This approach has been successful previously, even within regenerators.[12–15] In a minor departure from most prior PTR literature, which has focused on pressure p_1 and mass flux $\dot{M}_1$ as the oscillatory quantities of most interest, we will generally use the conventional acoustic variables p_1 and volumetric velocity U_1; the latter is related to mass flux simply via $\dot{M}_1=\rho_m U_1$, where ρ is the mass density. We take x and U_1 positive in the direction of positive acoustic power flow, for example to the right through the regenerators and pulse tubes in Fig. 1(a)–(c), and to the left through the transmission line in Fig. 1(c).

Some very general, almost unavoidable features of phasor diagrams for efficient cryogenic orifice PTRs are shown in Fig. 2, where the extra, capitalized subscripts on p_1 and U_1 correspond to the location labels in Fig. 1(b). We adopt the arbitrary convention that the phase of the pulse tube pressure is zero, so p_{1H} falls on the real axis. Typically the pressure drop along the pulse tube itself is immeasurably small, and that across the heat exchangers is negligible compared to that across the regenerator, which is in turn small compared to $|p_1|$, so $p_{1C}\cong p_{1H}$ and p_{1A} must lie close to p_{1H}, as shown in Fig. 2. Typically the time-averaged energy flux through the regenerator is small.[16] Applying energy conservation to the cold heat exchanger then shows that the cooling power $\dot{Q}_C$ is approximately equal to the total power flowing away from the cold heat exchanger in the pulse tube. The open nature of the pulse tube suggests that this total power flowing along it is the acoustic power $\frac{1}{2}\mathrm{Re}[p_1\tilde{U}_1]$, where the tilde signifies complex conjugation; in fact, heat can flow from hot to cold in the pulse tube, so the acoustic power is an upper bound of the cooling power:

$$\dot{Q}_{C,\mathrm{gross}}\leqslant \tfrac{1}{2}\mathrm{Re}[p_{1C}\tilde{U}_{1C}]. \tag{2}$$

Hence, in Fig. 1(a)–(d) acoustic power must flow in the di-

rection we have defined as positive x, so U_{1A}, U_{1C}, and U_{1H} must lie in the right half-plane in Fig. 2. An idealized refrigerator might be imagined with negligible entrained gas volume, so that U_1 would be independent of x in the pulse tube, $\rho_m U_1$ would be independent of x in the regenerator, and in particular the phase of U_1 would be constant throughout the refrigerator. As is well known,[1] nonzero gas volume causes x dependence in U_1, proportional to the compliance of the components and to $i\omega p_1$. This leads to a spread in phase of U_1 through the system, with U_1 at small x (i.e., toward the aftercooler) leading. The most efficient regenerator operation is achieved for the phase of p_1 falling somewhere between the phases of U_1 at the two ends of the regenerator. In orifice PTRs, this can be achieved using inertance[17,18] or a double inlet.[19] Viscous pressure drop occurs throughout the regenerator, so $p_{1A}-p_{1C}\cong p_{1A}-p_{1H}$ must be in phase with (parallel to) some weighted average of U_1 in the regenerator. Both $|U_1|$ and viscosity are highest at the regenerator's hot end, so the weighted average is dominated by U_{1A}, generally ensuring that p_{1H} lags p_{1A}. Finally, to the extent that the volume V_B on the back side of the piston is simply a compliance,

$$p_{1B}=j\frac{\gamma p_m}{\omega V_B}U_{1F}, \tag{3}$$

so p_{1B} must lead $U_{1F}=U_{1A}$ by 90°. Often the gas volume on the back side is large enough that $|p_{1B}|$ is much smaller than $|p_{1F}|$. These features are also illustrated in Fig. 2.

As discussed in the first paragraph, in an orifice PTR, the acoustic power

$$\dot{W}_H=\frac{\omega}{2\pi}\int_0^{2\pi/\omega}p(t)U(t)dt=\frac{1}{2}\mathrm{Re}[p_{1H}\tilde{U}_{1H}] \tag{4}$$

exiting the hot end of the pulse tube is lost, dissipated into heat in the orifice. This is typically nearly equal to the gross cooling power given in Eq. (2). To recover this acoustic power, thereby bringing the inherent efficiency limit of PTRs up to the Carnot limit, we can incorporate either of two low-loss acoustic connections shown in Fig. 1(c) and (d). The first method is described briefly in the next section: As shown in Fig. 1(c), a transmission line feeds the power recovered from the hot end of the pulse tube to the back side of the drive piston at p_{1B}. In Sec. II, we describe the second, more interesting method, shown in Fig. 1(d), in which the pulse tube delivers the recovered power directly to the front of the driver at p_{1F}, while the inertance delivers the drive power to the aftercooler. To convey the generality of the two methods, we describe them qualitatively for a piston driver in Secs. I and II, but we present experiments based on the second method using a thermoacoustic driver in Secs. III, IV, and V. In common with the double-inlet PTR,[19] both of these methods unfortunately permit second-order mass streaming through the refrigerator; in Sec. V we discuss our progress toward simple control of this important effect. Finally, in Sec. VI we present some conclusions and challenges for future development.

The idea that acoustic power will naturally circulate clockwise through the networks of Fig. 1(c) and (d) seems surprising, until we consider the LRC circuit of Fig. 1(e), a textbook electrical circuit crudely analogous to the acoustic network of Fig. 1(d). Many of us have derived expressions for the ac currents in each component of this circuit, but seldom do we consider the time-averaged electric power flows $\dot{E}$. By energy conservation, the time-averaged power $\dot{E}_S=\frac{1}{2}\mathrm{Re}[V_{1S}\widetilde{I_{1S}}]$ flowing from the voltage source into the circuit must equal the time-averaged power $\dot{E}_L-\dot{E}_F$ dissipated in the resistor. (In this idealized circuit, no time-averaged power can be absorbed in the dissipationless inductor L nor flow into the dissipationless capacitor C.) Ordinary ac circuit analysis easily yields the fed-back power

$$\dot{E}_F=\frac{1}{2}\mathrm{Re}[V_{1S}\widetilde{I_{1R}}]=\frac{|V_{1S}|^2}{2R}\frac{\omega^2LC(1-\omega^2LC)}{(1-\omega^2LC)^2+(\omega L/R)^2}, \tag{5}$$

with the sign convention as shown in the figure. Hence, whenever $\omega^2LC<1$, the directions of time-averaged power flow are as shown in the figure; positive electric power $\dot{E}_F$ flows *out* of the end of the resistor closest to the voltage source!

I. ACOUSTIC POWER RECOVERY

A. Transmission line configuration

Figure 1(c) illustrates an acoustic transmission line connecting the hot end of the pulse tube with the back side of the drive piston. A transmission line[20] obeys the equations

$$p_1(x)=p_{1i}\cos kx-i\frac{\rho_m a}{S}U_{1i}\sin kx, \tag{6}$$

$$U_1(x)=U_{1i}\cos kx-i\frac{S}{\rho_m a}p_{1i}\sin kx, \tag{7}$$

which show how p_1 and U_1 evolve with x along the transmission line, given their initial values p_{1i} and U_{1i} at $x=0$. The cross-sectional area of the transmission line is S, and a is the sound speed. [We omit the subscript m on variables such as a which, in principle, should be expressed as in Eq. (1) but whose oscillatory parts are of no interest in this work.] If the wave vector k is real, these equations describe a lossless transmission line, with $\frac{1}{2}\mathrm{Re}[p_1\tilde{U}_1]$ independent of x; losses in the transmission line (due to viscosity and thermal conductivity) can be included by using complex k.

From Eq. (6), a transmission line can connect the hot end of the pulse tube with the back side of the piston if its length l and area S are chosen such that

$$p'_{1B}=p_{1H}\cos kl-i\frac{\rho_m a}{S}U_{1H}\sin kl, \tag{8}$$

with the new value of p'_{1B} determined by a modified version of Eq. (3), accounting for the volumetric velocity flowing into V_B from the end of the transmission line:

$$p'_{1B}=j\frac{\gamma p_m}{\omega V_B}\left(U_{1F}-U_{1H}\cos kl+i\frac{S}{\rho_m a}p_{1H}\sin kl\right). \tag{9}$$

Because Eqs. (8) and (9) are complex, they represent four real equations in the four unknowns l, S, $\mathrm{Re}[p'_{1B}]$, and $\mathrm{Im}[p'_{1B}]$, so they will generally have a solution. The curves

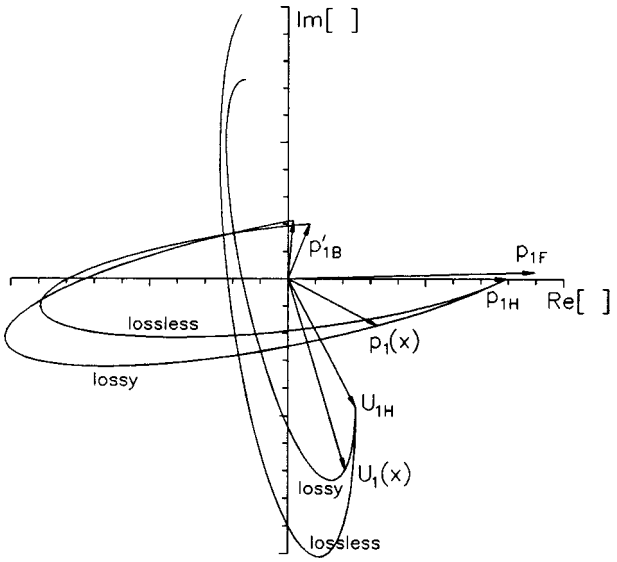

FIG. 3. Typical phasor diagrams for lossless (inner curves) and lossy (outer curves) transmission lines connected between pulse tube and back of piston. The transmission line's initial phasors p_{1H} and U_{1H} are the same as in Fig. 2.

in Fig. 3 illustrate Eqs. (6) and (7) when l and S are chosen correctly for the PTR whose phasors were shown in Fig. 2. The phasors are functions of x, following ellipses for the idealized, lossless (real k) transmission line; p_{1H}, U_{1H}, and S determine the eccentricity and orientation. The realistic, lossy transmission line yields similar curves, almost ellipses if the losses are sufficiently small, as shown in Fig. 3. Even for the lossy line, a substantial fraction of the acoustic power exiting the hot end of the pulse tube is delivered to the back of the drive piston, as shown by the reduction of the pressure difference across the piston from $p_{1F}-p_{1B}$ in Fig. 2 to $p_{1F}-p'_{1B}$ in Fig. 3. These figures are based on preliminary design calculations for a 100 K, helium-filled PTR having a gross cooling power of a few kW, which is typical of the cooling power we have been considering for liquefaction of natural gas.[3]

Although we decided to discuss this configuration here because it is easy to understand, we did not pursue it experimentally, because the more compact layout of the ''boost'' configuration discussed below was so appealing.

B. Lumped boost configuration

A second method to feed acoustic power from the hot end of the pulse tube back to the driver is illustrated in Fig. 1(d). The hot end of the pulse tube is connected directly to the front of the piston, while the aftercooler is connected through an acoustic network comprising an inertance and a compliance. We call this the ''lumped boost'' configuration because lumped acoustic impedances are used to boost $|p_{1A}|$ slightly above $|p_{1F}|$. (A ''distributed boost'' configuration, in which a short transmission line replaces the inertance and compliance, is also feasible.) In the lumped boost configuration, we will no longer neglect the flow resistance of the pulse tube's hot heat exchanger; its resistance R_H must be such that

$$p_{1H}-p_{1F}=R_H U_{1H}. \tag{10}$$

The compliance ensures that the volumetric velocity U_{1L} through the inertance differs from that at the aftercooler:

$$U_{1L}=U_{1A}+j\frac{\omega V_A}{\gamma p_m}p_{1A}, \tag{11}$$

where V_A is the volume of the compliance, so that the pressure difference across the inertance is

$$p_{1F}-p_{1A}=j\omega\frac{\rho_m l}{S}\left(U_{1A}+j\frac{\omega V_A}{\gamma p_m}p_{1A}\right), \tag{12}$$

where l and S are the length and area of the inertance. Taking the phasors at H and A to be given and combining Eqs. (10) and (12) to eliminate p_{1F}, we obtain a single complex equation in the unknowns R_H, V_A, l, and S, often with many possible solutions. Phasors for one such solution are shown in Fig. 4, where the refrigerator's end-point phasors are again the same as in Fig. 2.

The drive power is of course $\frac{1}{2}\,\mathrm{Re}[(p_{1F}-p_{1B})\widetilde{U_{1F}}]$ in both Fig. 1(b) and (d). If the compliance on the back side of the piston can be considered lossless, $\mathrm{Re}[p_{1B}\widetilde{U_{1F}}]=0$, so the drive power is simply $\frac{1}{2}\,\mathrm{Re}[p_{1F}\widetilde{U_{1F}}]$. In the lumped-boost case, $|U_{1F}|=|U_{1L}-U_{1H}|$ is rather large—much larger in Fig. 4 than in Fig. 2—so the amplitude of the piston motion in Fig. 1(d) must be much greater than in Fig. 1(b) or (c). Nevertheless, the power required of the piston is much less in Fig. 1(d) than in Fig. 1(b), because the phase angle between p_{1F} and U_{1F} is so large. Furthermore, the large magnitude of $|U_{1F}|$ presents no problem whatsoever if a pistonless thermoacoustic engine is used to drive the refrigerator.

II. APPARATUS

Encouraged by all these ideas, we proceeded to experiments with the lumped boost configuration. To use an existing driver[21] to power the experimental refrigerator, and to avoid the expense of building large hardware, we chose to test these ideas with a scale-model PTR that was approximately *similar*, in the technically strict sense of the word, to what would be required for a kW helium design. We built a ''half-scale'' PTR, filled with 2.4 MPa argon and operated at 23 Hz. It can be shown[22,23] that this is *similar* to a full-scale, 40-Hz, 3-MPa helium system, as long as the temperatures are high enough that argon can be regarded as an ideal gas. The physical phenomena and dimensionless combinations of variables in the half-scale argon PTR are all the same as at full scale in helium, just as a scale-model airplane in a wind tunnel and a full-sized airplane in flight share the same aerodynamics. The primary advantage of our half-scale argon model is that all powers are reduced by a factor of 16.7. A disadvantage is that we should keep this PTR's cold temperature greater than about 200 K, so that the argon is approximately an ideal gas. (Argon's critical point is 151 K, 4.9 MPa. At 2.4 MPa, it liquefies at 134 K.) Hence, our experiments can be regarded both as an easy exploration of some phenomena involved in acoustic recovery of otherwise

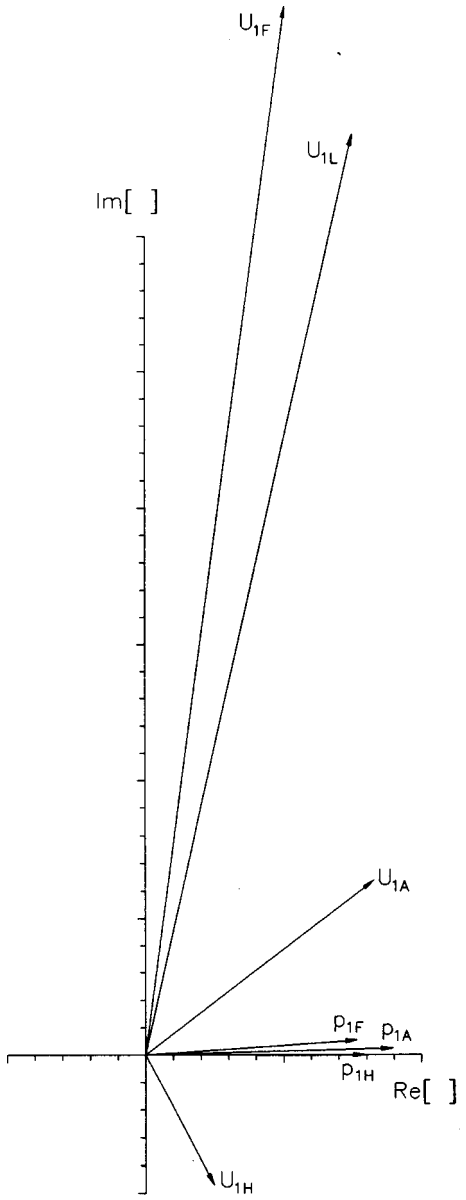

FIG. 4. Typical phasor diagrams for lumped boost configuration. The endpoint phasors p_{1H}, U_{1H}, p_{1A}, and U_{1A} are the same as in Fig. 2. The simple lumped impedances cause $p_{1H}-p_{1F}$ to be in phase with U_{1H}, $U_{1A}-U_{1L}$ to lag p_{1A} by 90°, and $p_{1F}-p_{1L}$ to lead U_{1L} by 90°.

lost power in PTRs, and as testing of an accurate scale model of a particular large refrigerator, with scaling details given in Table I.

In designing this hardware, we often sacrificed expected performance for versatility, ease of construction, and speed of design, because we correctly anticipated having to make many modifications in order to understand the behavior of such a novel apparatus. The system we built, illustrated in Fig. 5, is based on the lumped boost configuration of Fig. 1(d), but driven by a thermoacoustic engine instead of a piston and motor.

The heart of the refrigerator, its regenerator, was made of a 2.1-cm-thick stack of 400-mesh (i.e., 400 wires per inch) twilled-weave stainless-steel screens punched at 6.1-cm diameter. The total weight of the screens in the regenerator was 170 g. We calculated the hydraulic radius[24,25] of this

TABLE I. Scale factors to convert experimental data obtained with argon in this paper to numbers relevant to a larger helium-filled refrigerator. Multiply experimental data in this paper by the number in the table to obtain the expected result for the larger refrigerator. (Heat leaks that depend on the thermal conductivity of air, metal, or plastic do not scale.)

Variable	Multiplier
length	2
temperature	1
frequency	1.58
pressure	1.32
velocity	3.16
volumetric velocity	12.6
power	16.7

regenerator to be approximately 12 μm, based on its geometry and weight; in thermoacoustic calculations presented throughout the rest of this paper, we use 11 μm because this value gave the best agreement with our preliminary experiments in the ''traditional PTR'' configuration discussed below. The hydraulic radius is much smaller than the argon's thermal penetration depth (100 μm at 300 K), as required of a good regenerator. The stainless-steel pressure vessel around the regenerator had a wall thickness of 1.4 mm.

The pulse tube was a simple open cylinder, 3.0-cm id and 10.3 cm long, with 0.8-mm wall thickness. Its diameter is, of course, much greater than the argon's viscous penetration depth (90 μm at 300 K), and its length is greater than the 1-cm gas displacement amplitude in it at a typical operating point near $|p_1|/p_m \sim 0.1$. At each end, a few 35-mesh copper screens served as simple flow straighteners, to help maintain something resembling oscillatory plug flow in the pulse tube. We expected that argon's high density (relative to helium, which is almost universally used in PTRs) enhances the gravitational stability of this plug flow, so that careful flow straightening and tapering[8] would be unnecessary. This need for gravitational stability dictated the orientation of the refrigerator assembly with respect to vertical.

The cold heat exchanger between the regenerator and pulse tube was a 1.8-Ω length of NiCr ribbon wound zigzag on a fiberglass frame. Wires from the heater and a thermometer passed axially along the pulse tube to leak-tight electrical feedthroughs at room temperature. The two water-cooled heat exchangers (aftercooler and hot heat exchanger) were of shell-and-tube construction, with the Reynolds number of order 10^4 at $|p_1|/p_m \sim 0.1$ in the argon inside the 1.7-mm-diam, 18-mm-long tubes. The aftercooler had 365 such tubes, and the hot heat exchanger had 91.

The inertance was a simple metal tube with 2.2-cm id and 21-cm length, with 7-degree cones as shown in Fig. 5 at both ends to reduce turbulent end effects. The inertance and the refrigerator components were sealed to the flat plates above and below by rubber O-rings to enable easy modifications. The flat plates were held at a fixed separation by flange extensions and a cage of stout tubes through which long bolts passed, not shown in the figure. The compliance was half an ellipsoid with 2:2:1 aspect ratio, with a volume of 950 cm^3.

For simplicity, we insulated the cold parts of the apparatus with fiber-foam water-pipe insulation from the local

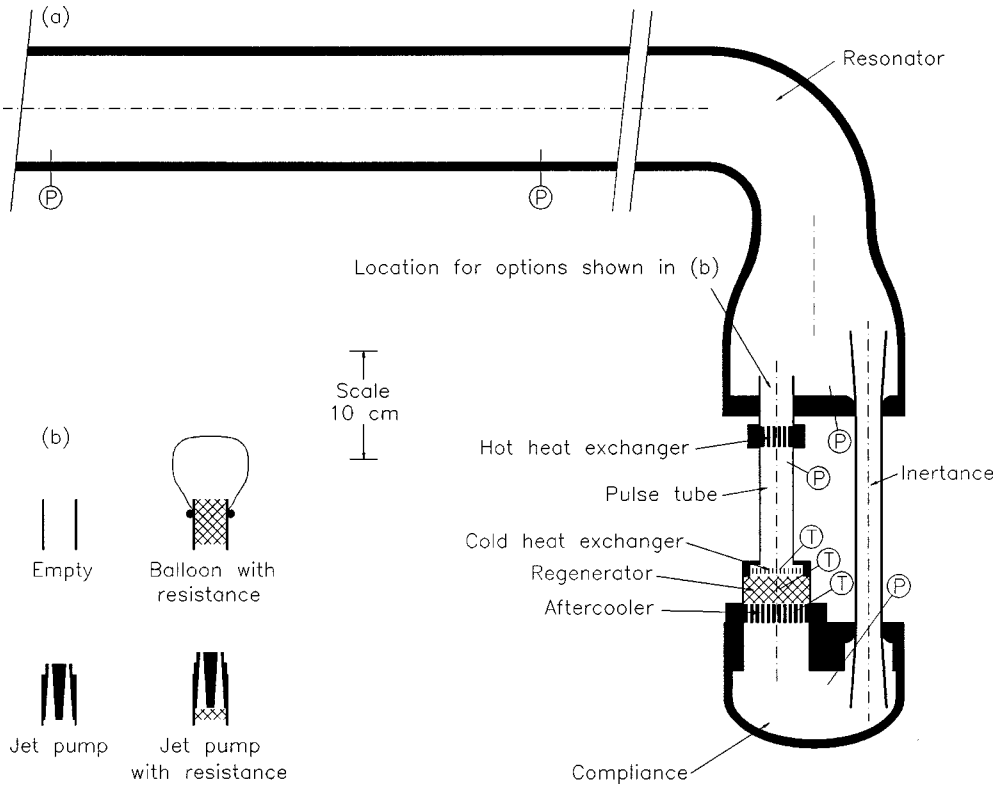

FIG. 5. (a) Drawing of the apparatus, in the inertance-boost configuration of Fig. 1(d). The dash–dot lines show local axes of cylindrical symmetry. Acoustic power circulates clockwise through the inertance and refrigerator part of the apparatus. ''P'' shows the location of a pressure sensor, and ''T'' the location of a temperature sensor. The heavy flanges around the aftercooler and hot heat exchanger contain water jackets. O-rings, most flanges, and bolts are omitted for clarity. The inside boundaries of the pressure vessel are to scale. (b) In the course of the measurements, these four options were used above the hot heat exchanger in (a). In each of the two cross-sectional views of the jet pump, two of the four tapered holes are shown.

hardware store. Type-K thermocouples measured temperatures in and near the regenerator. The 1.6-mm-diam thermocouple probe used to measure T_H was in the aftercooler, in the argon in one of the 365 tubes, touching the tube wall. The 0.8-mm-diam thermocouple probe used to measure T_C was standing freely in the argon between the cold heat exchanger and the flow straightener at the cold end of the pulse tube. Because of the different attachments of the T_C and T_H thermocouples, we believe that T_C represents the average temperature of the cold gas while T_H approximates the metal surface temperature in the aftercooler. The 0.8-mm-diam thermocouple probe whose temperature we will call T_{mid} was inserted into the very center of the regenerator, in a well that was drilled radially through the pressure-vessel wall and the screens. (Additional thermocouples outside the pressure vessel near the cold heat exchanger and the middle of the regenerator were used to confirm the internal temperature measurements.) Three piezoresistive pressure sensors (Endevco) in the compliance, pulse tube, and upper flat plate detected p_{1A}, p_{1H}, and p_{1F}, respectively, and two more sensors in the middle of the resonator were used to measure the acoustic power[26] flowing down the resonator from the thermoacoustic driver to the refrigerator. All pressure signals were detected with a lock-in amplifier.

A. First measurements

Preliminary measurements checked our implementation of the two-microphone acoustic-power measurement method[26] using the two sensors in the middle of the resonator. In these measurements, the PTR at the end of the resonator was replaced by a simple variable acoustic load comprising an adjustable valve R and a compliance C. Pressure sensors on either side of the valve allowed determination of the power dissipated in this RC network.[26] Figure 6 shows measurements of the two-microphone power as a function of dissipation in the RC network, at two pressure amplitudes in the resonator. The slopes in Fig. 6 are unity, demonstrating consistency between the RC and two-microphone methods. The region of large scatter in the measurements plotted in

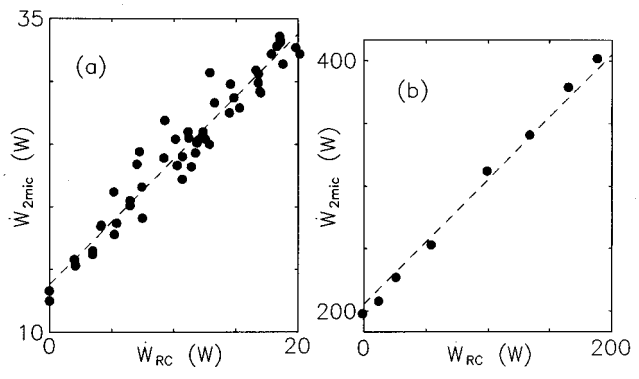

FIG. 6. Points show measured acoustic power $\dot{W}_{2\mathrm{mic}}$ passing the two-microphone location in the resonator, as a function of measured acoustic power $\dot{W}_{\mathrm{RC}}$ dissipated at the end of the resonator. For these preliminary measurements, an RC network replaced the refrigerator, inertance, and compliance of Fig. 5. The lines have slopes unity. (a) $|p_{1F}|/p_m = 0.038$ and (b) $|p_{1F}|/p_m = 0.094$.

Fig. 6(a) is due to thermoacoustic engine instability.[27] Fortunately, this instability was not encountered when the refrigerator was in place.

In Fig. 6(a) and (b), the offsets at zero RC dissipation are measures of the dissipation of acoustic power in that portion of the resonator between the two-microphone location and the RC network. This dissipation is up to four times greater than would be calculated for laminar acoustic dissipation, and is consistent with the turbulent dissipation calculations[28,29] of `DeltaE` Versions 3 and 4, assuming a pipe roughness factor of 1×10^{-3} for the resonator. This roughness factor is used in calculations of dissipation in the resonator and the inertance in the remainder of this paper.

To gain experience with our refrigerator, we made preliminary measurements with our PTR components (the regenerator, pulse tube, and three associated heat exchangers in Fig. 5) in the traditional PTR configuration shown in Fig. 1(b). Although PTR impedance networks at the hot end of the pulse tube are sometimes as simple as a single adjustable orifice and a compliance,[1] or a fixed lossy inertance and a compliance,[18] we used the configuration shown in Fig. 1(b), with two adjustable orifices (valves) and a fixed inertance in series with the compliance. The two valves allow independent control of both the magnitude and phase of the network's acoustic impedance.[21] In this traditional configuration, the refrigerator's performance was roughly as we had expected. At $|p_{1H}|/p_m=0.06$, the refrigerator cooled to $-115\,^{\circ}\mathrm{C}$ and had 20 W of net cooling power at $-50\,^{\circ}\mathrm{C}$; at $|p_{1H}|/p_m=0.08$ this cooling power was 40 W. Measurement of p_1 in the compliance and pulse tube, and knowledge of the gas volume in each component, allowed[21,28] us to infer U_1 throughout the refrigerator. The measured cooling power at $-50\,^{\circ}\mathrm{C}$ was about 10 W less than the inferred gross cooling power $\mathrm{Re}[p_{1H}\widetilde{U_{1C}}]/2$. We estimate that external heat leak contributes approximately half of this difference, with the balance due mostly to heat transport through the regenerator. In these preliminary measurements with the PTR in the traditional configuration, the most efficient operating points approached 5% of Carnot's coefficient of performance, using the net cooling power (i.e., electric resistance heater power, uncorrected for heat leak) and the two-microphone acoustic power in the calculations.

Next, we configured the refrigerator in the lumped boost configuration as shown in Fig. 5(a) [with the ''empty'' option of Fig. 5(b) installed above the pulse tube's hot heat exchanger]. The results were immediately disappointing: The refrigerator did not cool below 19 °C, essentially the temperature of the cooling water supplied to the water-cooled heat exchangers that day. (The aftercooler temperature $T_H=26\,^{\circ}\mathrm{C}$ for these measurements.) However, the pressure phasors seemed to be close to our expectations and the refrigerator's disappointing ''cold'' temperature was very strongly independent of heat load applied to the ''cold'' heat exchanger—e.g., at $|p_{1H}|/p_m=0.07$ an applied load of 70 W raised T_C to only 35 °C, as shown by the half-filled circles in Fig. 7. We concluded that the acoustic phenomena and gross cooling power were substantially as planned. Thus, we suspected that extremely vigorous streaming was effectively keeping the cold heat exchanger thermally anchored to the aftercooler, overwhelming the otherwise satisfactory thermoacoustic cooling power.

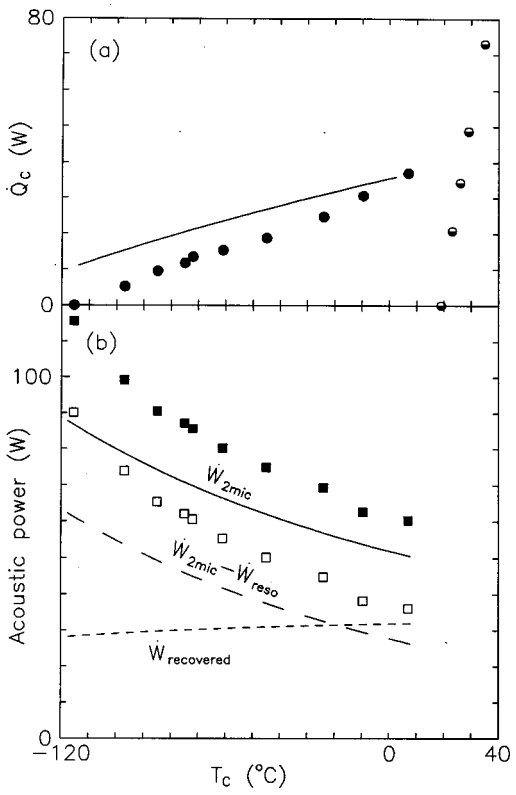

FIG. 7. Powers as a function of cold temperature T_C. The half-filled circles show measured cooling power with no balloon or other attempt to mitigate streaming ($|p_{1H}|/p_m=0.068$). The filled symbols and lines are with the balloon blocking streaming, at $|p_{1H}|/p_m=0.054$. (a) Cooling power. The experimental points show the electric power applied to the cold heat exchanger to maintain a given T_C. The line is the corresponding calculation. (b) Acoustic powers. The experimental points show measurements at the two-microphone location in the resonator; the solid line is the corresponding calculation. The open squares show the inferred acoustic power delivered to the refrigerator network, obtained by subtracting the calculated resonator dissipation from the measured two-microphone power. The long-dash line is the corresponding calculation. The short-dash line shows calculated values of recovered power (i.e., the acoustic power passing through the balloon).

III. SUPPRESSION OF STREAMING

A. Barrier method

It is essential that the time-averaged mass flow $\dot{M}$ through a PTR be near zero, to prevent a large steady energy flux $\dot{M}c_p(T_H-T_C)$ from flowing to the cold heat exchanger (where c_p is the gas' isobaric specific heat per unit mass). Such a steady energy flux would add an unwanted thermal load to the cold heat exchanger. In a traditional PTR configuration such as shown in Fig. 1(b), $\dot{M}$ is exactly zero; otherwise, mass would accumulate (or deplete, depending on sign) steadily in the compliance as a function of time. Gedeon[10] has discussed how nonzero $\dot{M}$ can arise in Stirling and pulse-tube cryocoolers whenever a closed-loop path exists for steady flow. Our lumped boost configuration clearly provides such a path; hence, we must understand and minimize $\dot{M}$.

Henceforth, we extend the complex notation introduced in Eq. (1) to second order by writing time-dependent variables as

$$\xi(x,t)=\xi_m(x)+\mathrm{Re}[\xi_1(x)e^{i\omega t}] + \xi_{2,0}(x)+\mathrm{Re}[\xi_{2,2}(x)e^{i2\omega t}]. \quad (13)$$

The final term, which oscillates at angular frequency 2ω, is of no interest here, but the time-averaged second-order term, with subscript ''2,0,'' is of great interest.

Gedeon argues that the second-order time-average mass flow

$$\dot{M}_2=\tfrac{1}{2}\mathrm{Re}[\rho_1\tilde{U}_1]+\rho_m U_{2,0} \quad (14)$$

is of primary concern. In acoustics, such second-order mass flow is known as streaming.[30] Gedeon shows that $\frac{1}{2}\mathrm{Re}[\rho_1\tilde{U}_1]=\rho_m\dot{W}_2/p_m$ in a regenerator, where $\dot{W}_2=\frac{1}{2}\mathrm{Re}[p_1\tilde{U}_1]$ is the acoustic power passing through the regenerator. Hence, $\frac{1}{2}\mathrm{Re}[\rho_1\tilde{U}_1]$ *must* be nonzero, and efficient regenerator operation requires that

$$U_{2,0}=-\tfrac{1}{2}\mathrm{Re}[\rho_1\tilde{U}_1]/\rho_m=-\dot{W}_2/p_m. \quad (15)$$

The consequences of ignoring this requirement can be severe. If $\dot{M}_2>0$, an undesired, streaming-induced heat load

$$\dot{Q}_{\mathrm{loss}}\sim\dot{M}_2 c_p(T_H-T_C) \quad (16)$$

flows from hot to cold through the regenerator. (If $\dot{M}_2<0$, such heat flows from hot to cold through the pulse tube, with equally harmful effect.) For $U_{2,0}=0$, the ratio of $\dot{Q}_{\mathrm{loss}}$ to the ordinary regenerator loss $\dot{H}_{\mathrm{reg}}$ is of the order of

$$\frac{\dot{Q}_{\mathrm{loss}}}{\dot{H}_{\mathrm{reg}}}\sim\frac{\gamma}{\gamma-1}\frac{(T_H-T_C)}{T_H}\frac{\dot{W}_H}{\dot{H}_{\mathrm{reg}}} \sim\frac{\gamma}{\gamma-1}\frac{(T_H-T_C)}{T_C}\frac{\dot{Q}_{C,\mathrm{gross}}}{\dot{H}_{\mathrm{reg}}}, \quad (17)$$

where $\dot{W}_H$ is the hot-end acoustic power and $\dot{Q}_{C,\mathrm{gross}}$ is the gross cooling power [see Eq. (2)]. In the third expression, each of the three fractions is >1 for cryocoolers; hence their product is $\gg 1$, and the unmitigated streaming-induced heat load would be much greater than the ordinary regenerator loss.

The steep slope $d\dot{Q}_C/dT_C$ shown in the half-filled circles in Fig. 7 provides an estimate of $\dot{M}_2$ in our refrigerator's ''empty'' configuration. Over the narrow temperature range of these data, gross cooling power and all other acoustic phenomena should be approximately constant and regenerator loss should be small, so the slope of the data should reflect Eq. (16): $-d\dot{Q}_{\mathrm{loss}}/dT_C=\dot{M}_2 c_p$. The experimental data yield $\dot{M}_2=9$ g/s. With Eq. (14) and our estimate that $\rho_m\dot{W}_2/p_m\sim 1$ g/s, this suggests that $\rho_m U_{2,0}$ was an order of magnitude larger than $\frac{1}{2}\mathrm{Re}[\rho_1\tilde{U}_1]$ for these measurements.

To quickly confirm our suspicion that the initial poor refrigerator performance shown as half-filled circles in Fig. 7 was due to such streaming, we installed a large rubber balloon (from a party-supplies store) above the pulse tube's hot heat exchanger, with the balloon protruding up into the resonator, as shown in Fig. 5(b). We rolled the balloon's collar completely up its neck and partly onto its body, so that tension in the rubber could not hold the balloon's surface against the sharp upper edge of the 3.1-cm-diam tube over which it was stretched. The balloon's limp volume was about 100 cm^3. We expected that this limp balloon would be acoustically transparent, but would block streaming flow completely.

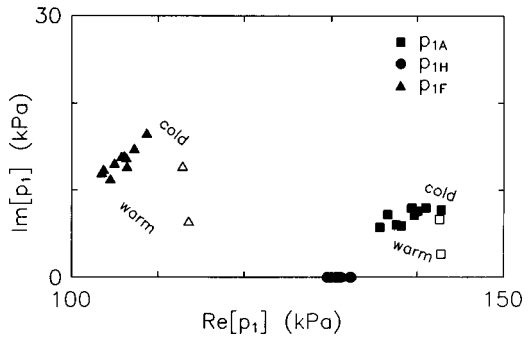

FIG. 8. Pressure phasors for measurements with balloon blocking streaming, at $|p_{1H}|/p_m=0.054$. The zero of phase has been chosen to set the phase of p_{1H} to zero, consistent with the other figures in this paper. The traditional phasor lines from the origin to each phasor have been eliminated to avoid clutter. Note the suppressed zero. The filled symbols are measurements; open symbols are calculations at the extreme values of T_C, with p_{1H} matched to the experimental values. The uppermost or rightmost symbols correspond to T_C near $-115\,^\circ$C; the lowermost or leftmost symbols correspond to T_C above $0\,^\circ$C.

At the same time, we installed extra resistance above the hot heat exchanger as shown in Fig. 5(b), because our earlier ''empty'' measurements had indicated that a larger flow resistance there was needed to make the phase of p_{1A} lead that of p_{1H}. The resistance comprised 130 g of 60 mesh copper screen packed into a volume 3 cm in diameter and 4 cm long. During fabrication, this screen was accidentally flattened and crushed to a higher density than expected, thereby providing more resistance than we wanted. Hence, we are uncertain of its hydraulic radius, which would otherwise have been approximately 100 μm. Fortunately, the system-performance calculations described below are not very sensitive to details in this component. We selected 60 μm as a reasonable estimate of the as-built hydraulic radius of this component, using this value in all calculations.

With the balloon in place, the refrigerator performed well, much like it had in the traditional PTR configuration described above, confirming our suspicion that enforcing $\dot{M}\equiv 0$ is the key to successful operation of this type of thermoacoustic system. The balloon survived without visible damage for 36 h of operation at $|p_{1H}|/p_m$ ranging from 0.04 to 0.10, more than enough time to obtain measurements.

In one set of measurements, we kept $|p_{1H}|/p_m=0.054$, while varying T_C from $-115\,^\circ$C to $7\,^\circ$C by adjusting the electric heater power $\dot{Q}_C$ at the cold heat exchanger. ($T_H=13\,^\circ$C throughout.) Figure 7 shows the resulting experimental cooling power and acoustic power requirements and Fig. 8 shows the experimental pressure phasors, together with some calculations of these and other variables. The calculations use `DeltaE`,[28] with geometry, mean pressure, fre-

TABLE II. The essential sequence of segments used in the DeltaE calculations described in this paper. (Free targets have been omitted for clarity.) The shooting-method guesses include T_m, complex p_1, and complex U_1 at the beginning, the complex branch impedance at the ''tbranch,'' and the heat flows at the aftercooler and cold heat exchanger. The shooting-method targets include T_H (at both aftercooler and hot heat exchanger), T_C, complex p_{1H}, the complex p_1 matching condition at the union, and the complex impedance at the ''hardend.''

quency, p_{1H}, T_H, and T_C set to experimental conditions. (For those who are interested, Table II shows the sequence of DeltaE segments used in the calculations.)

In Fig. 8, p_{1F} and p_{1A} lead p_{1H}, with $|p_{1F}|<|p_{1H}|<|p_{1A}|$, consistent with the discussion leading up to Fig. 4. The measured and calculated phasors are in reasonably good agreement, showing that we understand the overall acoustic behavior of this network. Indeed, we can regard the complex differences $p_{1A}-p_{1H}$, $p_{1H}-p_{1F}$, and $p_{1F}-p_{1A}$ as indications of the impedances of the intervening components and the volumetric velocities through them [cf. Eqs. (10) and (12)]. From this viewpoint, the agreement between measured and calculated p_{1A} might be taken to indicate, for example, that we understand U_1 through the regenerator to within 10%–30% in magnitude and 10°–40° in phase.

In Fig. 7, the cooling power drops and the two-microphone acoustic power rises as T_C decreases. The calculations, which are in reasonable agreement with the experiments, provide insight to the main causes of these trends. First, the calculated gross cooling power $\dot{W}_C = \frac{1}{2}\mathrm{Re}[p_{1C}\tilde{U}_{1C}]$ is nearly constant at 40 W, independent of T_C, for these measurements. As discussed near Eq. (2), under the most ideal circumstances this would be the cooling power. The decrease in calculated $\dot{Q}_C$ below 40 W as T_C decreases is nearly proportional to T_H-T_C and is almost entirely due to heat flux through the regenerator. The difference between measured and calculated $\dot{Q}_C$ is also proportional to T_H-T_C, rising to 10 W at $T_C=-120\,°\mathrm{C}$. This could easily be due to a combination of ordinary heat leak through our insulation and streaming- or jet-driven convection in the pulse tube. Second, under the most ideal circumstances—with 40 W of cooling power and with Carnot's COP$=T_C/(T_H-T_C)$—the required net acoustic power would be $\dot{W}=(40\ \mathrm{W})(T_H-T_C)/T_C$, which rises from zero at $T_C=T_H$ to 35 W at $T_C=-120\,°\mathrm{C}$. This accounts for most of the 40 W rise in calculated $\dot{W}_{2\mathrm{mic}}$ with falling T_C in the figure. The measurements of $\dot{W}_{2\mathrm{mic}}$ exceed calculations by roughly 20%, for unknown reasons. Some 25 W of $\dot{W}_{2\mathrm{mic}}$ can be attributed to dissipation in the resonator between the two-microphone location and the refrigerator; this has been subtracted to yield the open squares and associated dashed line. Approximately 5 W of acoustic power is dissipated in the flow resistance under the balloon, 15 W is lost due to viscosity in the regenerator and adjacent heat exchangers, and 10 W is dissipated in the inertance.

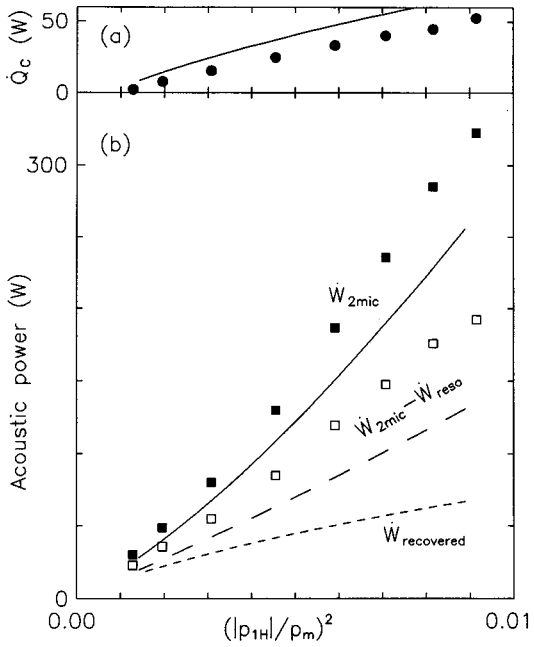

FIG. 9. Powers at $T_C=-60\,°\mathrm{C}$, as a function of pressure amplitude. (a) Cooling power. (b) Acoustic powers. The symbols have the same meaning as in Fig. 8.

If this were a traditional orifice PTR, $\dot{W}_C=40$ W would be dissipated in the orifice. In Fig. 7, the calculated fedback acoustic power $\dot{W}_{\mathrm{recovered}}$, which is of primary interest in this investigation, is near 30 W; hence, approximately 75% of $\dot{W}_C$ is recovered, fed back into the resonator. Note that, at the highest temperatures, $\dot{W}_{\mathrm{recovered}}$ is comparable to $\dot{W}_{2\mathrm{mic}}-\dot{W}_{\mathrm{reso}}$; in other words, at these temperatures feedback reduces the acoustic power delivered from the resonator to the refrigerator by roughly half.

In a second set of measurements with the balloon blocking streaming, we varied $|p_{1H}|$ while holding T_C constant near $-60\,°\mathrm{C}$. Unsurprisingly, the pressure phasors resembled those of Fig. 8 in phases and in degree of agreement between measurement and calculation. Cooling power and acoustic powers are displayed in Fig. 9. Again, calculations are in reasonably good agreement with experiment. Cooling power is proportional to $|p_{1H}|^2$, as expected. The difference between calculated and measured cooling power is roughly 5 W at the lowest amplitudes, consistent with the corresponding difference in Fig. 7; this difference increases at higher

amplitudes, for unknown reasons. The measurements of $\dot{W}_{2\mathrm{mic}}$ exceed calculations by roughly 20%, as they did in Fig. 7. At the highest amplitudes, resonator dissipation is a large fraction of $\dot{W}_{2\mathrm{mic}}$; subtracting resonator dissipation from $\dot{W}_{2\mathrm{mic}}$ leaves both calculated and measured $\dot{W}_{2\mathrm{mic}}$ proportional to $|p_{1H}|^2$, as expected. Again, the calculated $\dot{W}_{\mathrm{recovered}}$ is somewhat larger than the cooling power, is most of $\dot{W}_C$, and is large enough that in its absence the acoustic power $\dot{W}_{2\mathrm{mic}}-\dot{W}_{\mathrm{reso}}$ delivered from the resonator to the refrigerator would have to be significantly larger.

B. Hydrodynamic method

The measurements with the balloon convinced us that the acoustic aspects of the lumped-boost network were functioning as expected. However, we feared that the balloon would not be reliable enough for long-term practical use, so we returned our attention to the more challenging issue of streaming suppression. From among several options (including series bellows, fans, and parallel check valves) we chose to investigate asymmetry in hydrodynamic end effects to suppress streaming.

Gedeon[10] shows that $\dot{M}_2$ will be zero only if a nonzero $\Delta p_{2,0}$ exists across the regenerator, consistent with, and causing, the viscous flow of the correct $U_{2,0}$ in the regenerator. In a simple orifice PTR, this pressure difference appears automatically, because the topology imposes $\dot{M}_2=0$. However, when a regenerator is connected with other components in a ''loop'' topology, such as shown in Fig. 1(c) or (d) or such as in a double-inlet PTR, the topology does not ensure $\dot{M}_2=0$; rather, it ensures that $\oint(dp_{2,0}/dx)dx=0$ around the loop. To obtain the correct $U_{2,0}$ in the regenerator in ''loop'' systems, we must design the other components of the loop so that they impose the correct $\Delta p_{2,0}$ across the regenerator.

The required $\Delta p_{2,0}$ can be estimated using the low-Reynolds-number limit of Fig. 7-9 of Kays and London[25]

$$\frac{dp}{dx}\simeq-\frac{6U\mu}{Sr_h^2} \tag{18}$$

for the pressure gradient in a screen bed of cross-sectional area S and hydraulic radius r_h, where U is the volumetric velocity and μ is the viscosity. (The numerical factor depends weakly on the volumetric porosity of the bed.) With Eq. (15) for U, this yields

$$\Delta p_{2,0}\simeq\frac{6}{Sr_h^2p_m}\int_{\mathrm{reg}}\mu_m(x)\dot{W}_2(x)dx \tag{19}$$

for the pressure difference across the regenerator when $\dot{M}_2\equiv0$. (The viscosity's x dependence is due to the temperature gradient.) For our apparatus at typical operating conditions, $\Delta p_{2,0}$ is of the order of a few hundred Pa.

In the limit of low viscosity or large tube diameters and in the absence of turbulence, $p_{2,0}$ would be described by some acoustic version of the Bernoulli equation. This suggests that an acoustically ideal loop connecting the two ends of the regenerator would impose across the regenerator a pressure difference of the order of $\Delta[\rho_m u_1\tilde{u}_1]$, where u_1 is the complex velocity amplitude. (Such an ideal loop might include a pulse tube, transmission line, and compliance, without heat exchangers or other components with small passages.) This pressure difference is typically much smaller than the $\Delta p_{2,0}$ given in Eq. (19) that is required for $\dot{M}_2=0$. Hence, to produce the required $\Delta p_{2,0}$, we need an additional physical effect or structure in the loop, relying on turbulence, viscosity, or some other physical phenomenon not included in the Bernoulli equation.

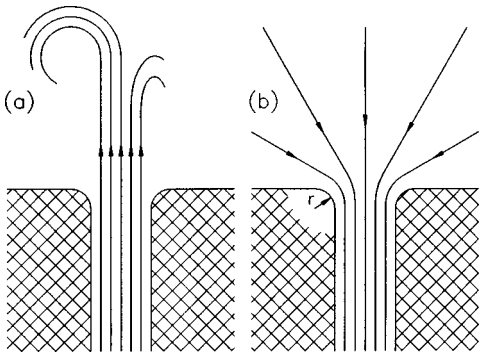

FIG. 10. Illustration of asymmetric flow at high Reynolds number at the transition between a small tube and open space. (a) Outflow. (b) Inflow, for which the radius r of rounding of the lip is important.

Asymmetry in hydrodynamic end effects can produce this required $\Delta p_{2,0}$. In a tapered transition between a small-diameter tube, where $|u_1|$ is large, and a large-diameter tube, where $|u_1|$ is small, turbulence would be avoided and Bernoulli's equation would hold if the taper were sufficiently gentle. At the opposite extreme, for an abrupt transition, we expect large $|u_1|$ to generate significant turbulence, and further we expect the oscillatory pressure drop across the transition to reflect the phenomena known as ''minor losses''[31] in high-Reynolds-number steady flow. If the gas displacement amplitude is much greater than the tube diameter, we also expect that the flow would at any instant have little memory of its past history, so that the acoustic behavior can be deduced from careful time integration of the steady-flow phenomena.

Ideally, the pressure at each instant of time could be described by the ordinary, steady-flow Bernoulli equation. At abrupt transitions, deviations of the pressure from this ideal are called ''head loss'' or ''minor loss'' in steady flow, with the lost pressure Δp_{ml} given by

$$\Delta p_{ml}=K\,\tfrac{1}{2}\rho u^2, \tag{20}$$

where K is the minor-loss coefficient, which is well known[31,32] for many transition geometries, and u is the velocity. For our purposes, the most important fact about K is that it depends strongly on the direction of flow through the transition. In the example shown in Fig. 10, a small tube is connected to an essentially infinite open space. When the gas (at velocity u inside the tube) flows out of the tube, a jet occurs, and kinetic energy is lost to turbulence downstream of the jet; $K_{\mathrm{out}}=1$. In contrast, when gas flows into the tube, the streamlines in the open space are widely and smoothly dispersed; K_{in} varies from 0.5 to 0.04, with smaller values for larger radius r of rounding of the edge of the entrance.

If $u=|u_1|\sin\omega t$, we can calculate the time-averaged pressure drop by integrating Eq. (20) in time:

$$\overline{\Delta p_{ml}}=\frac{\omega}{2\pi}\left(\int_0^{\pi/\omega}K_{\rm out}\frac{1}{2}\rho|u_1|^2\sin^2\omega t dt - \int_{\pi/\omega}^{2\pi/\omega}K_{\rm in}\frac{1}{2}\rho|u_1|^2\sin^2\omega t dt\right)$$
$$=\tfrac{1}{8}\rho|u_1|^2(K_{\rm out}-K_{\rm in}). \quad (21)$$

This is the source of $\Delta p_{2,0}$ that we will use. Such simple control of $\dot{M}_2$ is not without penalty, however; acoustic power is dissipated at a rate

$$\dot{E}=S\frac{\omega}{2\pi}\int_0^{2\pi/\omega}\Delta p_{ml}u dt$$
$$=S\frac{\omega}{2\pi}\left(\int_0^{\pi/\omega}K_{\rm out}\frac{1}{2}\rho|u_1|^3\sin^3\omega t dt - \int_{\pi/\omega}^{2\pi/\omega}K_{\rm in}\frac{1}{2}\rho|u_1|^3\sin^3\omega t dt\right)$$
$$=\frac{1}{3\pi}\rho|u_1|^2|U_1|(K_{\rm out}+K_{\rm in}) \quad (22)$$
$$=\frac{8}{3\pi}\overline{\Delta p_{ml}}|U_1|\frac{K_{\rm out}+K_{\rm in}}{K_{\rm out}-K_{\rm in}}, \quad (23)$$

where S is the area of the small tube. Equation (23) shows that the best way to produce a desired $\overline{\Delta p_{ml}}$ is to insert the device at a location where $|U_1|$ is small, and to shape it so that $K_{\rm out}-K_{\rm in}$ is as large as possible.

In our refrigerator, $|U_1|$ is smallest at the cold heat exchanger, but that is an unsuitable location for adding a dissipative structure. The hot heat exchanger has only slightly larger $|U_1|$, and already requires some extra dissipation to ensure that p_{1A} leads p_{1H} slightly, so we chose the space above the hot heat exchanger, previously occupied by the balloon and extra resistance, as the location for our experiments on asymmetry in end effects for streaming control. We installed what we call the ''jet pump,'' a brass block bored through with four identical tapered holes, each 5.3 cm long, 10 mm diam at the lower end, and 4 mm diam at the upper end, as shown in Fig. 5(b). We expected that end effects at the small ends of the holes would be strongly asymmetric, causing the desired $\overline{\Delta p_{ml}}$, while the velocities at the large ends of the holes would be small enough that minor losses would be negligible and the tapers joining the ends would be gradual enough to prevent minor losses in between.

To investigate the control of $\overline{\Delta p_{ml}}$ through the dependence of $K_{\rm in}$ on the radius r of rounding of the entrance, we made a series of temperature measurements with the jet pump in our refrigerator, at $|p_{1H}|/p_m\simeq 0.06$ with no heat applied at the cold heat exchanger, with each measurement having a different entrance rounding at the small ends of the tapered holes in the jet pump. At this pressure amplitude, the Reynolds number of the oscillatory flow was 2×10^5 and the gas displacement amplitude $|U_1|/\omega S\sim 0.2$ m at the jet. The results of this series of temperature measurements are shown

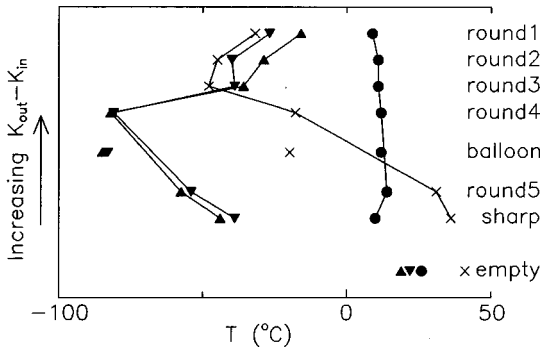

FIG. 11. Temperatures in and near the regenerator as the hardware above the hot heat exchanger was changed. Circles, aftercooler temperature T_H; ×, mid-regenerator internal temperature $T_{\rm mid}$; erect triangles, cold heat exchanger internal temperature T_C; inverted triangles, cold heat exchanger external temperature. Lines link the six jet-pump data sets, which are arranged vertically in order of increasing strength of jet pump. Measurements under comparable conditions with the balloon and with no attempt to mitigate streaming (''empty'') are inserted into the sequence at appropriate vertical locations.

in Fig. 11. We began this tedious process with sharply machined edges (''sharp'' in Fig. 11) at the small ends of the four holes. Next, we rounded and polished the edges of the holes to $r\sim 0.5$ mm (''round1''), and then we proceeded to machine away ~ 0.1 mm at a time from the flat upper end of the jet pump (''round2'' through ''round5''), thus removing ever more of the rounded edges and returning the entrances ever closer to ''sharp.'' Also shown for comparison in the figure are data from the balloon measurements and from our preliminary measurements with no attempt to mitigate streaming [corresponding to the ''empty'' configuration of Fig. 5(b) and the lowest half-filled circle in Fig. 7].

Figure 11 is qualitatively consistent with the discussion of streaming and its control presented above, and in particular with the expected increase of $\overline{\Delta p_{ml}}$ with decreasing $K_{\rm in}$ as determined by the radius of rounding of the entrances. With no attempt to control streaming (''empty''), the cold and hot temperatures T_C and T_H were nearly equal, and the temperature $T_{\rm mid}$ in the middle of the regenerator was 20° warmer than the others. In this circumstance, $\dot{M}$ was large and positive (i.e., flowing through the regenerator from hot to cold). With such large $\dot{M}$, the middle of the regenerator was thermally tied to the average gas temperature on the hot end of the regenerator (which happened to be about 20° warmer than the aftercooler metal surface temperature T_H), and this warm gas flowing up through the regenerator delivered a large heat load to the cold heat exchanger, as implied by Eq. (17), keeping T_C high. With the ''sharp'' and ''round5'' versions of the jet pump, a nonzero $\overline{\Delta p_{ml}}$ reduced $\dot{M}$, thereby lowering the temperatures. With the ''round4'' version of the jet pump, we were fortunate to arrive at the value of $K_{\rm in}$ that generated exactly the $\overline{\Delta p_{ml}}$ needed to force $\dot{M}\simeq 0$, so the temperatures were very nearly equal to those we observed when the balloon enforced $\dot{M}\equiv 0$. More well-rounded versions of the jet pump (''round3'' through ''round1'') reduced $K_{\rm in}$ and hence generated even greater $\overline{\Delta p_{ml}}$, causing $\dot{M}<0$; in these cases, the cold heat exchanger was loaded by warm gas flowing down through the pulse tube, and the mid-

regenerator temperature felt the thermal influence of gas flowing steadily from the cold end of the regenerator.

Furthermore, the phase of p_{1A} increased steadily from ''round1'' through ''round5'' and ''sharp,'' consistent with the increase in the effective resistance to U_1 of the jet pump with increasing K_{in} that we expect based on Eq. (22).

Hoping that we understood all the important features of this apparatus, we made final modifications. We upgraded our computer model of the apparatus to incorporate the minor losses of Eq. (22), both at the small end of the jet pump and at both ends of the inertance. The model results suggested that system performance would be improved if we added some extra resistance above the hot heat exchanger, so we inserted 25% of our copper screen resistance under the jet pump; together with the resistance of the jet pump itself, this provided a total resistance that left p_{1A} nearly in phase with p_{1H} and yielded calculated performance superior to that we had observed with the balloon. We rounded and polished the jet pump hole entrances again, repeating abbreviated measurements of temperatures and iteratively smoothing the entrances until we returned to temperatures comparable to ''round4'' in Fig. 11. We then proceeded with more extensive measurements.

In one set of measurements with this final jet-pump configuration, we kept $|p_{1H}|/p_m = 0.054$ while varying T_C by adjusting the electric heater power $\dot{Q}_C$ at the cold heat exchanger. These conditions are comparable to those for the ''balloon'' and ''empty'' data shown in Fig. 7. The results are shown in Fig. 12. The mid-regenerator temperature was 20 °C for $T_C = -80$ °C, indicating that the jet pump was too weak, with nonzero $\dot{M}$ flowing from hot to cold through the regenerator. Nevertheless, the cooling power is far greater than it was for the ''empty'' data, showing that the jet pump was far better than nothing at suppressing streaming. At high T_C the calculated and measured cooling powers are in good agreement; here, a small nonzero $\dot{M}$ has less effect on the net cooling power. At lower T_C the measured cooling power is significantly lower than the calculated values (and lower than the balloon measurements), as the small nonzero $\dot{M}$ consumes a significant fraction of the cooling power. The acoustic powers are negligibly affected by small $\dot{M}$, so the agreement between measured and calculated $\dot{W}_{2\text{mic}}$ is as good as it was for the balloon measurements. Both calculated cooling power and calculated $\dot{W}_{2\text{mic}}$ are better than for the balloon case, because of the better choice of total flow resistance above the hot heat exchanger discussed in the previous paragraph.

In a second set of measurements, we varied $|p_{1H}|$ while holding T_C constant near -55 °C; these conditions are comparable to the balloon measurements shown in Fig. 9. The results are shown in Fig. 13. In Fig. 13(a), the experimental cooling power exhibits interesting structure, which we believe is due to nonzero $\dot{M}$. A local maximum in $\dot{Q}_C$ occurs at $(|p_{1H}|/p_m)^2 = 0.0025$, for which $T_{\text{mid}} = 10$ °C as shown in Fig. 13(c). This value of T_{mid} is comparable to that we observed with the balloon at this T_C, suggesting that $(|p_{1H}|/p_m)^2 = 0.0025$ happens to obtain $\dot{M} \simeq 0$ with this jet

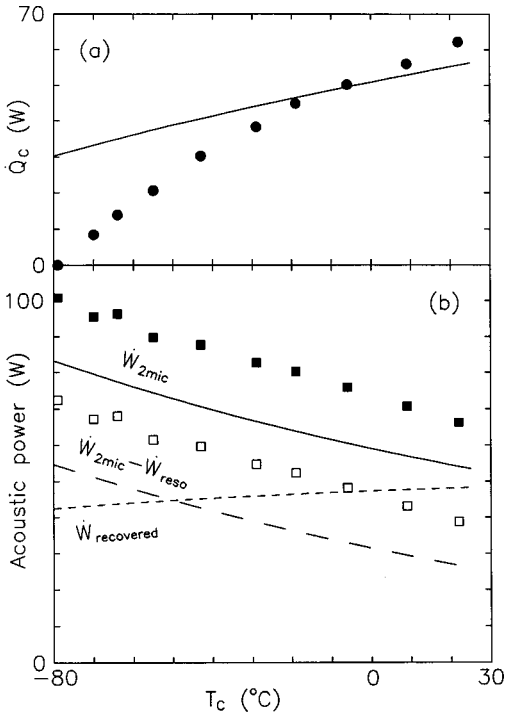

FIG. 12. Powers as a function of cold temperature T_C, with final configuration with jet pump and small extra resistance, at $|p_{1H}|/p_m = 0.054$. $T_H = 12$ °C throughout. (a) Cooling power. The experimental points show the electric power applied to the cold heat exchanger to maintain a given T_C. The line is the corresponding calculation. (b) Acoustic powers. The experimental points show measurements at the two-microphone location in the resonator; the solid line is the corresponding calculation. The open squares show the inferred acoustic power delivered to the refrigerator network, obtained by subtracting the calculated resonator dissipation from the measured two-microphone power. The long-dash line is the corresponding calculation. The short-dash line shows calculated values of the recovered power (i.e., the acoustic power passing through the balloon).

pump r. At lower $|p_{1H}|$, the T_{mid} measurements imply $\dot{M} < 0$; at higher $|p_{1H}|$, they imply $\dot{M} > 0$. In both cases, cooling power is reduced significantly by this streaming. The experimental acoustic power $\dot{W}_{2\text{mic}}$ in Fig. 13(b) is in reasonable agreement with calculations over the whole range of $|p_{1H}|$, with no obvious feature near the $\dot{M} \simeq 0$ amplitude, again confirming our expectation that nonzero $\dot{M}$ has little effect on purely acoustic phenomena.

However, the dependence of $\dot{M}$ on amplitude implied by Fig. 13 suggests that our understanding is incomplete: Eq. (19) for the pressure difference required across the regenerator and Eq. (21) for the pressure difference produced by the jet pump are both quadratic in amplitude, so if they conspire to make $\dot{M} \simeq 0$ at one amplitude, then they should do so at all amplitudes. Furthermore, there is a significant difference between the results of these two equations. Using calculated powers and velocities at $(|p_{1H}|/p_m)^2 = 0.0025$ in Fig. 13, Eq. (19) yields 200 Pa while Eq. (21) yields 2 kPa (assuming $K_{\text{out}} - K_{\text{in}} \sim 0.7$). Rough estimates show that a large number of other components and phenomena in the apparatus may each contribute tens to hundreds of Pa to $\oint (dp_{2,0}/dx)dx$. Representative examples include the gravitational head due to the cold gas in the cold components, minor losses at the inertance ends, boundary-layer streaming in the inertance,

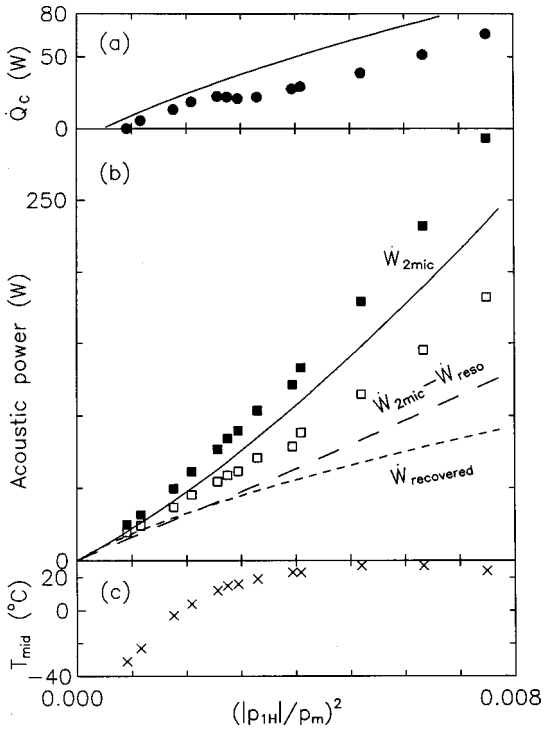

FIG. 13. Powers and mid-regenerator temperature at $T_C = -55\,^{\circ}\mathrm{C}$, as a function of pressure amplitude, with final configuration with jet pump and small extra resistance. $T_H = 13\,^{\circ}\mathrm{C}$ throughout. The symbols have the same meaning as in Fig. 12. (a) Cooling power. (b) Acoustic powers. (c) Mid-regenerator temperature.

and Gedeon's streaming in the extra resistance below the jet pump. Additional evidence that such components are contributing significantly to streaming is provided by the steep slope $d\dot{Q}_C/dT_C$ observed in our original, ''empty'' configuration and discussed below Eq. (17), which suggests that the ''empty'' configuration had a large nonzero $\Delta p_{2,0}$ across the regenerator, with its sign driving $U_{2,0}$ in the same direction as $1/2\,\mathrm{Re}[p_1 \tilde{U}_1]$.

The sensitivity of $\dot{M}$ to small details, illustrated in Figs. 11 and 13(a), suggests that practical use of a jet pump to suppress streaming in this type of refrigerator will require convenient adjustability in the jet pump or in some other $\dot{M}$-controlling part of the acoustic network.

IV. CONCLUSIONS

The $\dot{M} \simeq 0$ operating points in Fig. 13 are the most efficient operating points observed in these measurements. At the points near the relative maximum in cooling power in Fig. 13(a), the experimental coefficient of performance $\mathrm{COP} = \dot{Q}_C/\dot{W}_{2\mathrm{mic}} = 0.29$, so that the second-law efficiency is 9%. [The second-law efficiency is $\mathrm{COP}/\mathrm{COP}_{\mathrm{Carnot}}$, where $\mathrm{COP}_{\mathrm{Carnot}} = T_C/(T_H - T_C)$.] This is not as high as today's best traditional orifice PTRs[17] (10%–20% of Carnot) or standing-wave thermoacoustic refrigerators[33] (20% of Carnot), but it is high enough to show that this type of refrigerator has promise. If we deduct the calculated resonator dissipation from the experimental $\dot{W}_{2\mathrm{mic}}$, we obtain a second-law efficiency of 13%. We are confident that we can design much more efficient systems, based on the lessons we've described in this paper. For example, in our present refrigerator the inertance should have had a larger diameter and more streamlined ends; constraints of our existing hardware prevented such apparently straightforward modifications. Even simple improvements to our thermal insulation and use of a tapered pulse tube[8] could improve performance significantly, by increasing net cooling power with no cost to acoustic power.

We have discovered no reasons to doubt Ceperley's conclusion that efficiencies much greater than half of Carnot's are possible; we believe he was correct to suggest that traveling-wave refrigerators offer the potential for excellent performance with the simplicity of no moving parts. However, in addition to following Ceperley's ideas, it is vital to suppress time-averaged mass flux through such a refrigerator, and to use a thermal buffer column such as the pulse tube of a traditional PTR.

These same principles also apply to engines, which will be the subject of a paper in the near future.

Much more overall exploration remains to be done. Here, we have investigated the transmission-line configuration briefly, and the lumped boost configuration in more detail. It seems likely that other traveling-wave configurations can be discovered; they may offer advantages in efficiency or size. We used a balloon and a jet pump to suppress streaming; again, it seems likely that other, possibly better methods remain to be discovered. Quantitative understanding of all the sources of $\Delta p_{2,0}$ in the network will also be challenging.

In addition to these general research issues, considerable engineering effort will be required to determine how such techniques might impact specific applications such as cryogen liquefaction, cooling of superconducting electronics, or food refrigeration.

[22] Briefly, similitude requires that reduction of all dimensions of the apparatus by a factor of 2 is accompanied by a reduction of all thermophysical length scales in the gas by a factor of 2. Here, the relevant thermophysical length scales are the acoustic wavelength $\lambda=a/f$ and the viscous penetration depth $\delta_\nu=\sqrt{\mu/\pi f\rho}$. Reducing these lengths by a factor of 2 determines the frequency and pressure necessary to make argon in the half-scale apparatus *similar* to helium in the full-scale apparatus. Sensitivity measurements of piezoelectric polymer hydrophones from 0.2–2 MHz using a broadband-pulse technique

Gerald R. Harris and Paul M. Gammell
Food and Drug Administration, Center for Devices and Radiological Health, Rockville, Maryland 20850

(Received 12 August 1998; accepted for publication 23 October 1998)

It is widely recognized that the sensitivity of hydrophones used to measure medical diagnostic ultrasound fields should be uniform over several octaves above the center frequency (i.e., above the mean of the upper and lower −3 dB frequencies in the transmitted acoustic-pressure spectrum). However, a bandwidth extending to at least ten times *below* the diagnostic pulse-center frequency is needed for accurate (error ≈5%) measurement of the peak rarefactional pressure. Since at present it is not common for manufacturers of medical-use hydrophones to provide sensitivity information below 1–2 MHz, a study was undertaken to determine these low-frequency sensitivities. The technique uses broadband, plane-wave pressure pulses generated by electrical short-pulse excitation of a thick piezoelectric ceramic disk. The hydrophone response is calculated from measurements of the source transducer and hydrophone-voltage waveforms. The frequency responses of both needle-type and spot-poled membrane polymer hydrophones were measured using this technique. The spot-poled membrane hydrophones had −3-dB bandwidths extending below 0.2 MHz, the lower limit for the calibration technique. The needle-type hydrophones studied, however, all exhibited a response roll-off of greater than 3 dB in the frequency range studied. Therefore, given the above bandwidth criterion as a function of diagnostic pulse-center frequency, the sensitivity to at least 0.2 MHz should be established for diagnostic-use hydrophones, because a uniform response below 1 MHz cannot be assumed. INTRODUCTION

Recent work has shown that the low-frequency response of medical-use hydrophones may be important for accurate pulse measurements, particularly of the peak rarefactional pressure, an important quantity for assessing the likelihood of cavitation onset.[1] However, frequency-response data below 1–2 MHz typically are not provided for commercial hydrophones designed for measurements in medical ultrasound fields. A technique for generating broadband-pressure pulses was therefore applied as an efficient means to measure the low-frequency response of miniature hydrophones used in biomedical ultrasonics.

Both needle-type and spot-poled membrane piezoelectric polymer hydrophones were studied. These hydrophones are described below, followed by a discussion of the calibration technique. Then the frequency-response measurements are presented and discussed, with special attention given to the results for the needle-type hydrophones, which display a low-frequency roll-off in response that appears to be due primarily to diffraction at the needle tip.

I. DESCRIPTION OF HYDROPHONES

Both the needle-type and spot-poled membrane hydrophones had the piezoelectric polymer polyvinylidene fluoride (PVDF) as the sensitive element. In the basic needle-type hydrophone design, a circular piece of poled, metal-coated PVDF film, usually 25 μm or less in thickness and 1 mm or less in diameter, is attached to the end of a hollow metal tube of similar diameter. In the spot-poled membrane design, a sheet of PVDF film is stretched across a support frame several centimeters or more across. Only a small central region of the film, typically 1 mm or less in extent, is rendered piezoelectrically active by a spot-poling procedure. Electrodes (covering the poled spot) and contiguous electrical leads are vacuum deposited onto the film. A common variation is the bilaminar membrane design, in which two identical film layers are glued together and the outer surfaces are metal coated to provide an electrical shield.

Eleven hydrophones were included in the study. Six were needle-type hydrophones from four commercial sources, and three were spot-poled membrane hydrophones from three commercial sources. Two other spot-poled membrane hydrophones made in the authors' laboratory also were included. The five membrane hydrophones consisted of three single-layer and two bilaminar types, and in two of the single-layer designs, the polymer film had a soft rubber backing.

Table I lists the designations and geometrical diameters of the hydrophones; that is, the diameters defined by the dimensions of the active elements of the hydrophones. All hydrophone signals except for N1 and N6 were fed to an amplifier having a nominal gain of 40 dB, an input impedance of 500 kΩ, and a −3-dB bandwidth of 10 kHz to 20 MHz. Integral preamplifiers were used with hydrophones N1, N3, N6, M1, and M3. Preamplifier −3-dB bandwidths extended from less than 30 kHz to greater than 20 MHz.

TABLE I. Geometrical diameters of hydrophones.

Hydrophone ID N=Needle M=Membrane	Geometrical diameter (mm)
N1	1.0
N2	1.0
N3	0.6
N4	0.4
N5	0.5
N6	0.2
M1	1.0
M2	1.0
M3	0.5
M4	0.6
M5	0.2

II. MEASUREMENT TECHNIQUE

The frequency response was measured using a technique for generating broadband, plane-wave acoustic pulses in water via short-pulse excitation of a thick piezoelectric transducer.[2] Figure 1 contains a diagram of the source transducer, electrical pulse generator, and hydrophone under test. If the applied voltage pulse has a duration that is short compared to the acoustic transit time through the transducer, two distinct planar stress waves are radiated from each face. The amplitudes of these pressure pulses are determined by the magnitudes of the mechanical-load impedances relative to that of the transducer. For the materials shown, the wave radiated into the air backing is negligibly small.

The source used for these measurements was a 6.35-cm-diam, 2.54-cm-thick, lead zirconate titanate transducer (Navy type I). In Ref. 2 it was shown that for this transducer type and thickness, the spectra of the radiated front-face pressure pulse, $P_I(f)$, and the electrical excitation pulse, $V_T(f)$, [related respectively to temporal pressure and voltage pulses $p_I(t)$ and $\nu_T(t)$] are proportional for frequencies above approximately $f=0.2$ MHz. For this restricted frequency range, $F(s)$ in Eq. (1) of Ref. 2 can be dropped, giving

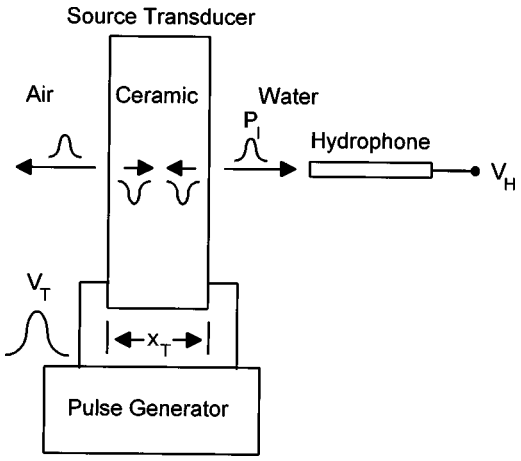

FIG. 1. Diagram of source transducer, electrical pulse generator, and hydrophone.

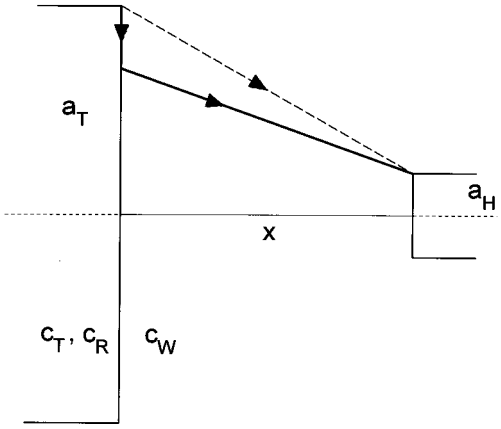

FIG. 2. Diagram of waves traveling from the source transducer boundary to the hydrophone. −−− propagation path of edge wave; ——— propagation path of head wave.

$$P_I(f)=\frac{h_{33}\epsilon_{33}^{s}z_W}{x_T(z_W+z_T)}\cdot V_T(f)=\frac{e_{33}z_W}{x_T(z_W+z_T)}\cdot V_T(f)$$
$$=KV_T(f), \tag{1}$$

where the negative sign in Ref. 2 has been ignored for convenience. Here, h_{33} and e_{33} are piezoelectric constants, ϵ_{33}^{s} is the clamped dielectric permittivity, and z_W and z_T are the water and transducer specific acoustic impedances. (For the relationship $e_{33}=h_{33}\epsilon_{33}^{s}$, see, e.g., Ref. 3.)

For Eq. (1) to be useful in practice, the front-face plane-wave pulse radiated into water, $p_I(t)$, must be isolated in time from the other components of the radiated field, most notably the pulse from the back face of the source transducer, and waves originating at the source boundary. By proper selection of the source dimensions and hydrophone location, such temporal isolation is possible. To see this, first consider only the pulse from the back face (i.e., neglect for the moment source-boundary effects). In this case, Eq. (1) is valid until the pulse radiated from the back face of the source transducer reaches the hydrophone. That is, if the source transducer and hydrophone are separated by axial distance x, and if the source is excited at time $t=0$, then Eq. (1) is valid for times $t<t_{\max}$, where

$$t_{\max}=t_M+x/c_W<x_T/c_T+x/c_W. \tag{2}$$

Here, c_T and c_W are the longitudinal wave velocities in the source transducer and water, respectively, and t_M is the desired temporal-measurement window, which can be no greater than x_T/c_T, the transit time through the source transducer. (Also, t_M is greater than the duration of the source-transducer excitation pulse.)

Now considering source-boundary effects, further temporal restrictions regarding Eq. (1) are related to the arrival at the hydrophone of edge and head waves that originate at the source boundary.[4,5] The hydrophone distance x must be small enough so that these waves arrive at the hydrophone after time $t_{\max}$. To determine the limiting values on x, consider each of these waves separately, as depicted in Fig. 2.

Edge waves: Edge waves arise due to diffraction at the source boundary. The time, t_E, that the edge wave takes to first reach the perimeter of a coaxially aligned hydrophone is

$$t_E = \frac{\sqrt{x^2 + (a_T - a_H)^2}}{c_W}, \tag{3}$$

where a_T and a_H are the source transducer and hydrophone radii, respectively. For t_E to be greater than $t_{\max}$, the limiting value of x, x_{Elim}, is

$$x_{\text{Elim}} < \frac{(a_T - a_H)^2 - (c_W t_M)^2}{2 c_W t_M}. \tag{4}$$

Head waves: As described in Refs. 4 and 5, radial modes excited in the source transducer give rise to lateral waves that originate at the source perimeter. As the lateral waves propagate inward along the transducer–water interface, head waves are radiated into the water. Two lateral waves are launched at the interface, traveling at the longitudinal and shear-wave velocities of the source transducer. For this analysis, only the longitudinal wave need be considered because of its greater velocity. This velocity, c_R, differs from c_T in that c_T is the velocity of the longitudinal wave traveling parallel to the polar axis of the transducer, whereas c_R is measured perpendicular to the polar axis.

Equation (4) in Ref. 4 can be solved for the time of arrival of the nearest head wave at the perimeter of a coaxially aligned hydrophone [cf. Ref. 5, Eq. (16)]

$$t_H = \frac{a_T - a_H + x\sqrt{(c_R^2/c_W^2 - 1)}}{c_H}. \tag{5}$$

It is assumed that $c_R > c_W$. For t_H to be greater than $t_{\max}$, the limiting value of x, x_{Hlim}, is

$$x_{\text{Hlim}} < \frac{c_W(a_T - a_H - c_R t_M)}{c_R - \sqrt{c_R^2 - c_W^2}}. \tag{6}$$

Equation (6) is valid in the conical region whose base is the circular source-transducer surface and whose apex is the axial point $x_{\text{Hmax}} = a_T[(c_H/c_W)^2 - 1]^{0.5}$. In theory, head waves cease to exist on axes beyond this point, although in practice the transition is more gradual.[4,5]

For the source transducer used in this study, $a_T = 3.18$ cm, $x_T = 2.54$ cm, $c_T = 0.46$ cm/μs, and $c_R = 0.39$ cm/μs. Taking $c_W = 0.149$ cm/μs, $t_M = 5.0$ μs, and a maximum a_H of 0.05 cm from Table I gives $x_{\text{Elim}} = 6.2$ cm, $x_{\text{Hlim}} = 5.9$ cm, $x_{\text{Hmax}} = 7.6$ cm, and $x_T/c_T = 5.5$ μs. For the $x < x_{\text{Hmax}}$ region considered, x_{Hlim} is always less than x_{Elim}. Using $x = x_{\text{Hlim}}$ in Eq. (2) gives $t_{\max} = 44$ μs.

In the actual measurements, the hydrophones were located on the source-transducer axis between $x = 1.5$ cm and $x = 6$ cm. As expected, no discernable position-dependent differences were found in the pulses measured with the hydrophones throughout this range over the 5-μs measurement interval.

Because axial points are equidistant from the circular-source perimeter, the edge- and head-wave components arrive in phase. Therefore, positioning the hydrophones on the axis was easily accomplished by spatially maximizing these pulse components. However, it should be noted that positioning is not critical to the measurements because of the plane-wave nature, and therefore position independence, of $p_I(t)$ over a large portion of the paraxial field of the source transducer.[4] (The attenuation of water can be neglected for frequencies below 2 MHz.)

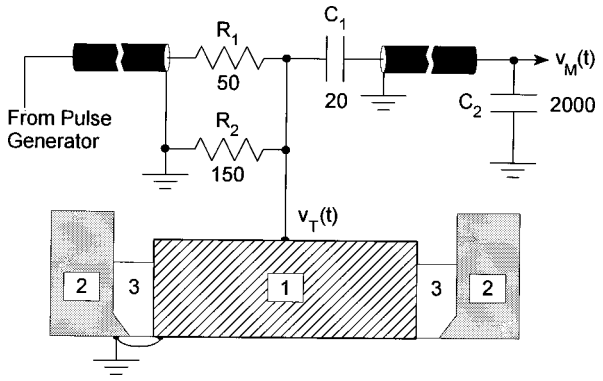

FIG. 3. Source-transducer schematic with partial view of transducer and housing in cross section. (1) 6.35-cm diameter by 2.54-cm thick, piezoelectric ceramic source transducer (Navy type I), (2) metal housing; (3) silicone rubber. Resistance and capacitance values are in ohms and picofarads, respectively. The two coaxial-cable symbols represent the cable connections between R_1 and C_1 (both located inside the transducer housing along with R_2) and the pulse generator and C_2, respectively.

Having established the measurement conditions under which Eq. (1) is valid, the hydrophone sensitivity can be determined. The hydrophone sensitivity at frequency f, $M(f)$, is the ratio of the hydrophone-voltage spectrum, $V_H(f)$, to the incident pressure pulse, $P_I(f)$. Using Eq. (1),

$$M(f) = V_H(f)/KV_T(f), \tag{7}$$

again, for $f > 0.2$ MHz. Thus, with Eq. (7) a broadband hydrophone-sensitivity response can be computed from measurements of $\nu_T(t)$ and the hydrophone's output voltage, $\nu_H(t)$, in response to $p_I(t)$. As mentioned above, since $p_I(t)$ is largely position independent, spatial averaging by the hydrophone is not an issue, and no spatial-averaging correction factors need be calculated and applied to $M(f)$ unless a_H approaches a_T.

A schematic of the source transducer is shown in Fig. 3. The separation between the cylindrical-transducer surface and the housing was approximately 0.8 cm. The unipolar-voltage pulse from the pulse generator (model 605B, Cober Electronics) had a maximum amplitude of 2200 V into 200 Ω, and a variable pulse width down to a minimum of 0.1–0.2 μs (-6 dB). Resistive divider R_1–R_2 helped match the source and load, thus minimizing both pulse ringing and fall time. Noninductive power resistors were used (MS Series, Caddock Electronics.)

Source-transducer voltage $\nu_T(t)$ was monitored using the capacitive divider C_1–C_2. C_1, an rf high-voltage ceramic capacitor (UFP1 Series, Murata Electronics), was mounted inside the transducer housing along with R_1 and R_2. C_2, comprising two 1000-pF silvered mica capacitors in parallel, was located externally to minimize rf pick-up. If the attenuation of the capacitive divider is denoted A, then the monitored voltage, $\nu_M(t)$, is

$$\nu_M(t) = A\nu_T(t) = \frac{C_1}{C_1 + C_2 + C_C + C_{\mathrm{IN}}}\nu_T(t), \tag{8}$$

where C_C is the capacitance of the 1-m coaxial cable connecting the source transducer to C_2, and C_{IN} is the input capacitance of the waveform analyzer used to record $\nu_M(t)$ (Tektronix DSA602 with 11A34 amplifier).

With $V_M(f) = AV_T(f)$, Eq. (7) is

$$M(f) = \frac{AV_H(f)}{KV_M(f)}. \tag{9}$$

From impedance analyzer measurements of capacitance (Hewlett-Packard model 4192A), the ratio A was determined to be 0.0103. Also, from published transducer material values in Ref. 6, $e_{33} = 15.1\,\mathrm{C/m^2}$ and $z_T = 34.5\times10^6\,\mathrm{N\cdot s/m^3}$. With $z_W = 1.49\times10^6\,\mathrm{N\cdot s/m^3}$, $K = 24.6\,N/(\mathrm{V\cdot m^2})$, which gives

$$M(f) = 4.19\times10^{-4}\frac{V_H(f)}{V_M(f)}\,\mathrm{V/Pa}, \tag{10}$$

or,

$$M_{\mathrm{dB}}(f) = 20\log\frac{V_H(f)}{V_M(f)} - 187.6\ \ \mathrm{dB}\ \ re:\ \ 1\ \ \mathrm{V/\mu Pa}. \tag{11}$$

Note that the sensitivity in Eq. (11) is referred to the output of the 40-dB amplifier mentioned in Sec. I. Voltages $\nu_H(t)$ and $\nu_M(t)$ were recorded using the waveform analyzer for the 11 hydrophones, and spectra were calculated from 0.2 to 2 MHz for use in Eq. (11). Measurements were made in water having a temperature of $21.0\pm1.0\,^\circ\mathrm{C}$ and an electrical conductivity of $2.0\pm1.0\ \mu\mathrm{S/cm}$.

Five microseconds of temporal data were recorded; i.e., $t_M = 5\ \mu\mathrm{s}$. Over this 5-μs interval, 512 data points were taken. Before performing the fast Fourier transforms (FFT), the waveforms were windowed to suppress any truncation effects, as discussed in Ref. 2. Then the waveform-data arrays were zero filled to achieve a record length of 4096 points, resulting in an FFT-frequency resolution of 25 kHz.

III. RESULTS

Example plots of the monitored voltage $\nu_M(t)$ and hydrophone voltage $\nu_H(t)$ for hydrophones N2 and M1 are shown in Fig. 4(a) and (b). For comparative purposes the plots are normalized to a peak amplitude of 1. The maximum value of $\nu_M(t)$ in Fig. 4 was 7 V. Taking $p_I(t)$ as $K\nu_T(t) = (K/A)\nu_M(t)$, a monitored voltage of 7 V corresponds to a temporal-peak pressure of about 17 kPa, a pressure amplitude much less than these hydrophones typically measure. Therefore, waveform averaging of the hydrophone signals (up to 512 averages using the waveform analyzer) was performed for noise reduction. The rise time and -6-dB pulse duration of $\nu_M(t)$ in Fig. 4 are 48 and 113 ns, respectively. As stated above, $t_M = 5\ \mu\mathrm{s}$. However, only 3 μs are shown in Fig. 4 for easier viewing and comparison of the pulses.

Figures 5 and 6 contain the magnitude responses for the needle-type and spot-poled membrane hydrophones, respectively. Equation (11) was used, but, except for N1 and N6, the 40-dB gain of the hydrophone amplifier was subtracted, so the sensitivities plotted are referred to the input of this amplifier. Also, 20 dB was subtracted from the sensitivity of N1 in Fig. 5 to decrease the size of the vertical scale.

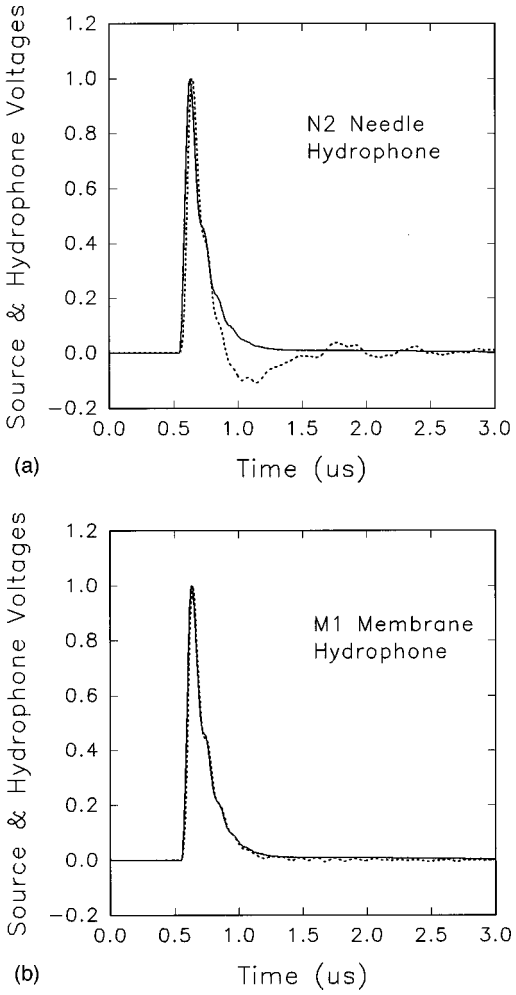

FIG. 4. The monitored source-transducer voltage, $\nu_M(t)$, and the hydrophone voltage, $\nu_H(t)$, for (a) needle-type hydrophone N2 and (b) spot-poled membrane hydrophone M1; ——— $\nu_M(t)$, ····· $\nu_H(t)$. Each plot is normalized to a peak amplitude of 1.

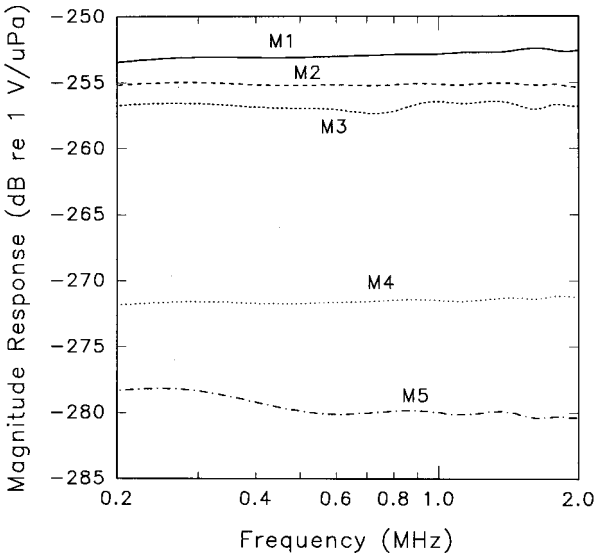

FIG. 6. Sensitivity versus frequency plots for the spot-poled membrane hydrophones.

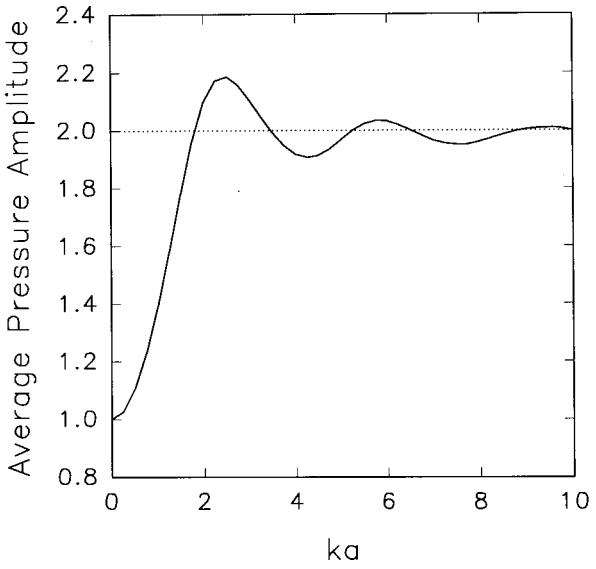

FIG. 7. Acoustic pressure spatially averaged over the end of a rigid, semi-infinite cylindrical rod vs *ka* for sound normally incident on the end of the cylinder. For the plot, it is assumed that the amplitude of the incident wave, p_i, is unity.

IV. DISCUSSION

A. Low-Frequency sensitivity

The low-frequency sensitivity of piezoelectric receivers usually is assumed to be limited by the RC time constant associated with the loading (e.g., amplifier) resistance and total capacitance of the receiver, cable, and amplifier.[7] For typical hydrophones such as those used in medical ultrasound exposimetry, this limit is less than 50 kHz. From the spot-poled membrane hydrophone results in Fig. 6, this simple electrical analysis seems to be adequate, since no significant deviations from a flat, uniform response are seen. For the needle-type hydrophones, however, this model is insufficient to explain the low-frequency roll-offs observed in Fig. 5.

Theoretical models have shown that other factors associated with the needle-type hydrophone's geometry and construction can affect the low-to-mid-range frequency response, including surface waves in the backing material,[8] and, more importantly in the present study, diffraction effects at the needle tip.[9–11] To illustrate this latter effect, consider the plot in Fig. 7. This plot, constructed from calculations in Ref. 11, shows the acoustic pressure spatially averaged over the end of a rigid, semi-infinite cylindrical rod vs ka, where k is the wave number ($2\pi/\lambda$), λ is the acoustic wavelength in the propagation medium (e.g., water), and a is the cylinder radius. The sound is incident normal to the end of the rod. Modeling the needle-type hydrophone as this rod, the acoustic field at the needle tip can be considered to comprise the incident pressure wave with amplitude p_i, and a wave diffracted at the edge of the circular tip. When λ is much smaller than the needle-tip diameter (high-frequency or large-ka case), the diffracted wave averages to zero over the tip, and the pressure at the tip is twice the incident pressure due to total reflection of the incident wave from the end of the rigid surface. As λ becomes large compared to the tip diameter, the diffracted component vanishes and the average pressure at the tip approaches that of the incident pressure. In between these two extremes, when the wavelength and tip diameter are similar, diffraction-induced interference effects produce the oscillatory behavior seen in Fig. 7. Here, the pressure amplitude averaged over the tip rises with frequency from its initial value of p_i, reaching a peak of $2.18p_i$ at $ka=2.4$, and then eventually settling to the final value of $2p_i$. This theoretical response passes through the -3-dB point ($re{:}2p_i$) at $ka=1.03$. Thus, the larger the needle diameter, the lower in frequency the response extends.

To examine the needle-type hydrophone results in light of this model, the sensitivities in Fig. 5 were replotted on a linear scale in Fig. 8, with each plot normalized to unity at $ka=1.81$, the value at which the average pressure in Fig. 7 first reaches 2.0. With a sound speed of 1.49 mm/μs, this ka value corresponds to $fd=0.86$, where f is in MHz and d

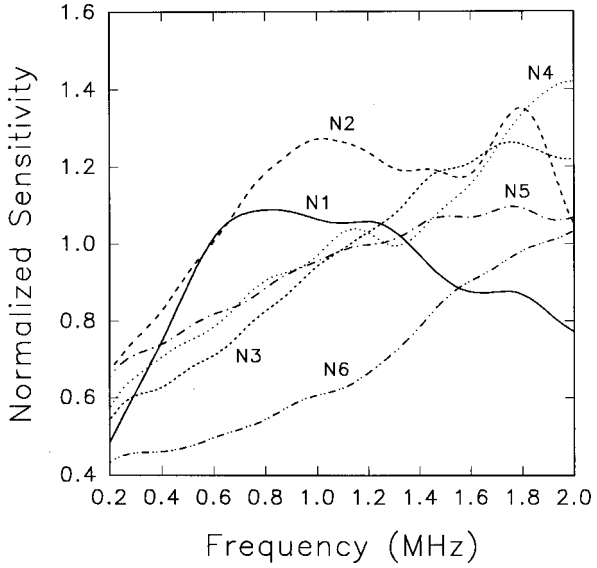

FIG. 8. Normalized sensitivity vs frequency plots for needle-type hydrophones.

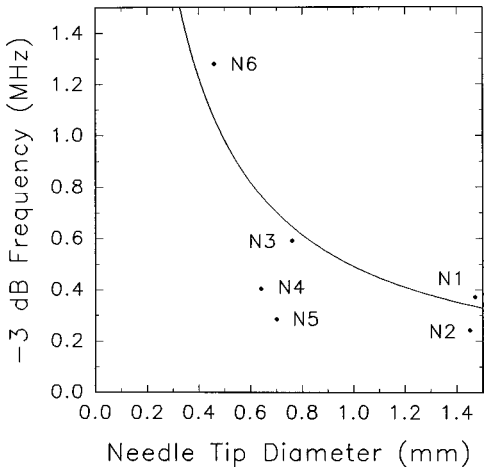

FIG. 9. −3-dB frequencies relative to the response at $f=0.86/d$. The solid curve is the theoretical result for the pressure spatially averaged over the end of a rigid, semi-infinite cylindrical rod (i.e., $f=0.49/d$). The individual points are taken from the experimental results for the six needle-type hydrophones.

$=2a$ is in mm. Figure 9 contains the −3-dB frequencies relative to the value at $f=0.86/d$ for the six needle-type hydrophones, d being the needle-tip diameters (which are, of course, larger than the geometrical diameters given in Table I). At the −3-dB point, $ka=1.03$ corresponds to $fd=0.49$; also plotted in Fig. 9 is the function $f=0.49/d$, the theoretical −3-dB result for the rigid-rod model. Points to the left of this curve would represent hydrophones having a broader low-frequency response than that predicted by the model.

Regarding comparisons with the model, needle-type hydrophones typically are hollow cylinders (rather than rigid rods) containing the center conductor as well as backing materials and coatings of unspecified acoustic impedances. Also, the geometrical and needle-tip diameters differ. Furthermore, the needle diameter of N4 increases to 1 mm about 2 mm from the tip, and for both N3 and N5 the needle body near the tip is tapered. In addition, the tip of N5 is rounded rather than flat, as with the other hydrophones (which also made determining d more difficult). Thus, while direct comparisons are hampered by these deviations from the rigid-rod model, based on the needle-type hydrophones studied it appears that an enhanced low-frequency response may be achieved by altering the size, shape, or composition of the hydrophone near the tip. Increasing the geometrical diameter would, of course, exacerbate errors due to spatial averaging.

B. Calibration accuracy

The main sources of error in the sensitivity results presented in Figs. 5 and 6 come from the systematic uncertainties associated with the factors in Eq. (9), along with the gain accuracy of the 40-dB amplifier used.

Capacitive-divider attenuation, A: The overall error in determining this capacitive ratio is estimated to be ±5%, the main component being the stray capacitance associated with mounting C_1.

Transducer constant, K: The piezoelectric and dielectric transducer properties are subject to batch fluctuations and aging.[6] However, it is implied in Ref. 6 that the reported value of the piezoelectric constant e_{33} should vary by no more than approximately ±10%. Assuming that the combined uncertainties of the specific acoustic impedances and transducer thickness contribute no more than ±5%, an error of ±15% can be assigned to K.

Hydrophone and monitored-voltage spectra, $V_H(f)$ and $V_M(f)$: Here, the error depends not on the accuracy of the waveform analyzer used to record $\nu_H(t)$ and $\nu_M(t)$, but on the precision of the input attenuators, since a voltage ratio is being measured. This error should be less than ±5%.

Amplifier gain: The gain of the rated 40-dB amplifier was measured to be 39.87±0.03 dB from 0.2 to 2.0 MHz, for an error of less than ±0.5%.

Following the calculation procedure in Ref. 12, the estimated systematic uncertainty in the absolute-sensitivity data due to the above factors is ±19% (at the 95%-confidence level). It should be noted that if the data in Figs. 5 and 6 are considered as only relative responses, then a sensitivity measurement at a single frequency by an independent (and possibly more accurate) calibration technique may be used to obtain the broadband absolute response. In this regard, for single-frequency calibrations, laser interferometry has been used above about 400 kHz,[9] and three-transducer reciprocity has been used up to 500 kHz.[13]

With regard to the lower limit of 0.2 MHz, this limit applies only if Eq. (1) is used to compute $P_I(f)$. If a substitution method using the thick-transducer technique is employed, in which the spectral response of the hydrophone under test is compared to that of a reference hydrophone having known frequency response, then the lower-frequency limit, as well as calibration accuracy, will be determined by the response data available for the reference hydrophone. Furthermore, if $p_I(t)$ is measured directly, such as by interferometric means, as reported in Ref. 14, then the theoretical considerations used in Ref. 2 to calculate the lower-frequency limit do not apply.

V. CONCLUSIONS

The objective of this investigation was to use a thick-transducer, short-pulse technique to measure the low-frequency sensitivity of piezoelectric polymer hydrophones currently used in biomedical ultrasound exposimetry. With regard to the measurement technique, a chief advantage was the ability to obtain broadband calibration data in a single measurement, as opposed to the more time-consuming single-frequency techniques based on reciprocity or interferometry. Also, because of the plane-wave nature of the pulses, there was no need for precise source-hydrophone positioning or corrections for hydrophone spatial averaging. However, sensitivity was poor since the source transducer was neither focused nor operated in a resonant mode, so hydrophone-signal amplification and waveform averaging were necessary. Although not of concern for the present study, it may be noted that hydrophone-phase response also is available in addition to the amplitude-response results presented.

For the spot-poled membrane hydrophone sensitivities, no significant deviation from a flat, uniform response was seen. The needle-type hydrophones, on the other hand, all displayed a roll-off in low-frequency response at frequencies

considerably higher than that due to the RC time constant. The roll-off frequency was affected by the size and shape of the needle tip, an outcome in qualitative agreement with a diffraction-based model for the spatially averaged pressure on the end of a rigid, semi-infinite cylindrical rod.

Needle-type hydrophones have advantages over spot-poled membrane hydrophones in several practical instances, such as when measuring close to the source transducer. However, a roll-off in response calls the use of these devices into question when accurate knowledge of the pressure waveform is required, particularly with regard to measuring the peak rarefactional pressure in pulsed waveforms displaying significant finite-amplitude distortion. Therefore, altering the shape or composition of the needle to improve the low-frequency response could be an important design consideration.

This paper presents the results of an analytic and numerical investigation of flexural vibration of a finite plate clamped to an infinite baffle in mean flow. Attention of the present paper is focused on: (1) the physical mechanisms that lead to unstable conditions for a clamped plate in mean flow; (2) the effects of mean flow, plate aspect ratio and length to thickness ratio, and the structural nonlinearities on the instabilities; and (3) the onset of bifurcation and chaos in plate flexural vibration beyond critical mean flow speeds. In carrying out these analyses, the plate flexural displacements are solved by the Galerkin method. The critical mean flow speeds are determined by a general stability theory and the Routh algorithm. Results show that the instabilities of a baffled plate are mainly caused by an added stiffness due to acoustic radiation in mean flow, but controlled by the structural nonlinearities. The added stiffness is shown to be negative and increase quadratically with the mean flow speed. Hence, as the mean flow speed approaches a critical value, the added stiffness may null the overall stiffness of a plate, leading to an unstable condition. Note that without the inclusion of the structural nonlinearities, the plate has only one equilibrium position, namely, its undeformed flat position. Under this condition, the amplitude of plate flexural vibration would grow exponentially in time everywhere, known as absolute instability. With the inclusion of structural nonlinearities, the plate may possess multiple equilibria. When the mean flow speed exceeds the critical values, the plate may be unstable around all equilibria, jumping from one equilibrium position to another. Since this jumping is random, the plate flexural vibration may seem chaotic. This chaotic behavior disappears, however, when viscous damping is introduced. Accordingly, the plate settles down to a ''buckled-down'' position owning to the hydraulic fluid-loading effect. [S0001-4966(99)01902-5]

INTRODUCTION

Analyses of dynamic and acoustic responses of fluid-loaded structures in subsonic and supersonic flows have long been topics of great interest.[1–6] Applications of these studies can be found in the designs of aircraft fuselage and underwater vehicles. Previous studies have shown that the characteristics of the dynamic and acoustic responses of an elastic structure may be quite different when there is mean flow. The most significant change is the onset of instabilities, such as those depicted by Brazier-Smith and Scott[7] for an infinite plate subject to a time-varying external excitation. Using the causality principle, Brazier-Smith and Scott demonstrated numerically that the response of an infinite plate could become unstable in mean flow. When the mean flow speed is below a critical value, the plate response may be convectively unstable if the excitation frequency is below the upper limit of the spatial instability. Here convective instability is defined as an exponential growth in the plate flexural vibration amplitude as the disturbance propagates in the downstream direction. When the mean flow speed exceeds the critical value, the plate response may become absolute unstable. Namely, the amplitude of plate vibration may grow exponentially in time at any point under any excitation frequency.

Brazier-Smith and Scott's numerical analyses were confirmed by Crighton and Oswell's asymptotic analysis.[8] In particular, Crighton and Oswell shed light on the onset of convective instability: an infinite plate may draw energy from mean flow to sustain the growth in the amplitude of plate flexural vibration. Also, they derived an analytic formulation for depicting the critical mean flow speed beyond which absolute instability would occur. This critical mean flow speed is shown to depend on fluid/structure density ratio and compressional wave speeds ratio. According to Crighton and Oswell's formula, absolute instability may occur for an infinite steel plate in water, disregarding its thickness, when the mean flow speed exceeds 14.9 m/s. For the same plate in air, absolute instability may occur when the mean flow speed exceeds merely 0.02 m/s! These predictions are indeed startling. However, Crighton and Oswell's analysis[8] provides no explanations to the onset of absolute instability.

Actually, the phenomenon of absolute instability described above[7,8] may have little practical significance, because, first of all, an infinite plate is nonexistent and second, no one has ever observed it in reality. Nonetheless, this phenomenon has fascinated the first author of the present paper. The lack of physical explanation to such a phenomenon has motivated him to look further into this problem.

In two recent papers,[9,10] it has been found that absolute

instability may be attributable to an added stiffness effect due to acoustic radiation in mean flow. This added stiffness is negative and its value increases quadratically with the mean flow speed. As the mean flow speed approaches a critical value, the added stiffness may null the overall stiffness of a plate, thus leading to an unstable condition.

The objective of the present paper is to give a more detailed and in-depth analysis of the characteristics of plate flexural vibration around critical mean flow speeds. Since an infinite plate does not exist in reality, a finite plate is considered. To simplify the problem, the plate is assumed to be clamped to an infinite baffle, and to be in contact with a fluid on one side but in vacuum on the other side. Also taken into account is the effect of the structural nonlinearities induced by in-plane forces and shearing forces due to stretching of plate bending motion.

It is emphasized that the inclusion of the structural nonlinearities are not meant for analyzing large-amplitude vibrations, but rather for keeping the amplitude of plate flexural vibration from growing unboundedly. The inclusion of the nonlinearities also allows one to gain valuable insight into the characteristics of plate flexural vibration, for example, bifurcation and chaos, which cannot be acquired from the analysis of a linear system.

Attention of this paper is focused on: (1) the physical mechanisms leading to unstable conditions of a baffled plate in mean flow; (2) the effects of mean flow speed, plate aspect and length to thickness ratios, and the structural nonlinearities on the instabilities; and (3) the onset of bifurcation and chaos in plate flexural vibration beyond critical mean flow speeds. Section I presents the basic equations of motion for a fluid-loaded plate in mean flow. Section II gives the approximate solutions to plate flexural vibration by using Galerkin's method. The effect of mean flow on stability of a baffled plate is analyzed in detail in Sec. III. Section IV depicts stability charts of a baffled plate under various aspect ratios, length to thickness ratios, and fluid to structure density ratios. Section V illustrates the numerical results of transition of plate flexural vibration from stable to unstable conditions when the mean flow speed exceeds the critical values. In particular, it shows that this transition may be random and plate flexural vibration may be chaotic.

It is worth pointing out that while absolute instability has never been observed in reality, chaos in flexural vibration of a clamped plate has been observed experimentally.[11] This random vibration has a direct impact on resulting acoustic radiation. The studies of the instability mechanisms of a clamped plate in mean flow may eventually lead to a better understanding of why there is a sudden increase in the overall sound pressure level beyond certain mean flow speed.[12]

I. FUNDAMENTAL EQUATIONS

Consider a finite plate of length L, width b, and thickness h that is clamped to an infinite and rigid baffle (see Fig. 1). In analyzing flexural vibration, it is assumed that: (1) the plate is in contact with fluid of density ρ and sound speed c on one side ($z>0$) and in vacuum on the other side; (2) the fluid moves at a uniform, constant speed U in the x-axis direction; and (3) the amplitude of plate flexural vibration remains small at all times such that it does not alter significantly the steady flow pattern.

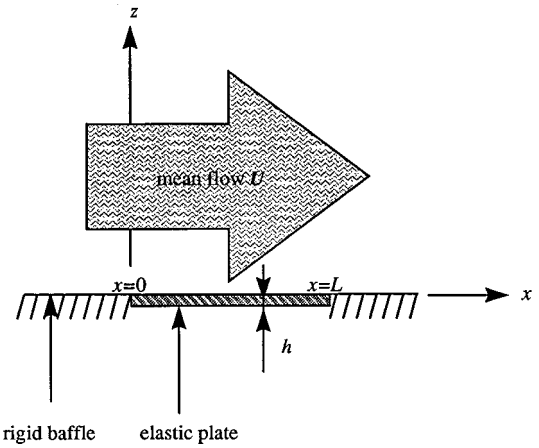

FIG. 1. Schematic of a baffled plate in mean flow.

Under these assumptions, the equation that governs plate flexural vibration can be written as[9,10]

$$\mathcal{L}_1\{w(x,y,t)\}-\mathcal{L}_2\{w(x,y,t)\}-\mathcal{L}_3\{w(x,y,t)\} = P\left(x,y,\frac{h}{2},t\right), \tag{1}$$

where w is the plate flexural displacement in the z-axis direction, P represents any external pressure excitation, and $\mathcal{L}_j$, $j=1$ to 3, are differential and integral operators operating on w.

Physically, the operator $\mathcal{L}_1$ represents the sum of plate stiffness, inertia, and damping forces per unit area, $\mathcal{L}_2$ stands for the effect of in-plane forces and shearing forces per unit area due to stretching of plate bending motion, and $\mathcal{L}_3$ describes the fluid-loading effect that acts back on the plate surface. Mathematically, these operators are defined by

$$\mathcal{L}_1 = D\nabla^4+\rho_p h\frac{\partial^2}{\partial t^2}+d\frac{\partial}{\partial t}, \tag{2a}$$

$$\mathcal{L}_2 = N_x\frac{\partial^2}{\partial x^2}+N_y\frac{\partial^2}{\partial y^2}+2N_{xy}\frac{\partial^2}{\partial x\,\partial y}, \tag{2b}$$

$$\mathcal{L}_3 = \rho\left(\frac{\partial}{\partial t}+U\frac{\partial}{\partial x}\right)\int_0^L\int_0^b\left[\mathrm{G}(\vec{r}|\vec{r}_o)\left(\frac{\partial}{\partial\tau}+U\frac{\partial}{\partial x_o}\right)\right]_\tau dx_o\,dy_o, \tag{2c}$$

where $D=Eh^3/12(1-\nu^2)$, is the plate flexural rigidity, here E and ν are the Young's modulus and the Poisson's ratio, respectively, ρ_p is the plate density, d is the plate viscous damping coefficient per unit area, N_x and N_y are the stress resultants in the x- and y-axis directions, respectively, and N_{xy} is the projection of the shearing forces in the z axis.[13] Because of the inclusion of N_x, N_y, and N_{xy}, Eq. (1) is nonlinear containing cubic nonlinearities.

The symbol $[\,]_\tau$ in Eq. (2c) implies that the quantities inside the square brackets are to be evaluated at the retarded time, $\tau=t-\Delta t$, and G represents the Green's function which for a subsonic mean flow speed can be written as[9,14]

$$G(\vec{r}|\vec{r}_o)=-\frac{1}{2\pi\sqrt{(x-x_o)^2+(1-M^2)[(y-y_o)^2+z^2]}}, \tag{3}$$

where M is the mean flow Mach number and Δt is the time required for the signal to travel from the source to receiver,

$$\Delta t=\frac{M(x-x_o)+\sqrt{(x-x_o)^2+(1-M^2)[(y-y_o)^2+z^2]}}{c\sqrt{1-M^2}}. \tag{4}$$

At the joints with the baffle, the plate satisfies the clamped boundary conditions

$$\begin{aligned} &w(0,y,t)=w(L,y,t)=w(x,0,t)=w(x,b,t)=0,\\ &\left.\frac{\partial w}{\partial x}\right|_{x=0}=\left.\frac{\partial w}{\partial x}\right|_{x=L}=\left.\frac{\partial w}{\partial y}\right|_{y=0}=\left.\frac{\partial w}{\partial y}\right|_{y=b}=0. \end{aligned} \tag{5}$$

II. APPROXIMATE SOLUTIONS VIA THE GALERKIN METHOD

Equation (1) represents a nonlinear, partial differential/integral equation. Because of the complexities involved in this equation, analytic solutions cannot be found. Hence, the Galerkin method is used to derive approximate solutions. Since in this paper we are interested in the effect of mean flow on the characteristics of the plate flexural vibration responses, it is sufficient to examine the homogeneous solutions of Eq. (1). Accordingly, we set the forcing function P on the right side of Eq. (1) to zero.

For convenience sake, let us first nondimensionalize variables in Eq. (1),

$$\begin{aligned} &(\bar{x},\bar{x}_o)=\frac{(x,x_o)}{L},\quad (\bar{y},\bar{y}_o)=\frac{(y,y_o)}{b},\quad \bar{t}=\frac{1}{\phi^2}\left(\frac{c_0 t}{h}\right),\\ &\phi=\frac{L}{h},\quad \eta=\frac{b}{L},\quad \sigma=\frac{\rho}{\rho_p},\\ &\xi=\phi^2\left(\frac{d}{\rho_p c_0}\right),\quad \zeta=\sigma^{1/2}\phi^{3/2}\left(\frac{U}{c_0}\right), \end{aligned} \tag{6}$$

where a bar over a variable implies a dimensionless quantity, ϕ represents the plate length to thickness ratio, η stands for the plate aspect ratio, σ describes the fluid/plate density ratio, ξ indicates the viscous damping ratio, ζ depicts the dimensionless mean flow speed, and $c_0=c_p/\sqrt{12}$ represents a scaled compressional wave speed, where c_p is the plate compressional wave speed.[15]

Next, the plate flexural displacement is expanded in terms of n normal modes in the $\bar{x}$-axis direction (longitudinal modes) and m normal modes in the $\bar{y}$-axis direction (lateral modes),[13]

$$\bar{w}(\bar{x},\bar{y},\bar{t})=\sum_{i=1}^{n}\sum_{j=1}^{m} W_i(\bar{x})W_j(\bar{y})\bar{C}_{ij}(\bar{t}), \tag{7}$$

where $W_i(\bar{x})$ and $W_j(\bar{y})$ satisfy the prescribed boundary conditions (5), and $\bar{C}_{ij}(\bar{t})$ are the dimensionless time-dependent coefficients for coupling of the ith longitudinal mode to the jth lateral mode.

Substitute Eq. (7) into (1), multiply the resultant equation by $W_k(\bar{x})$ ($k=1$ to n) and then integrate it over $\bar{x}$ from 0 to 1. Next, multiply the resultant equation by $W_l(\bar{y})$ ($l=1$ to m) and integrate it over $\bar{y}$ from 0 to 1. This process yields a set of homogeneous, nonlinear, second-order ordinary differential equations, which can be written in an indicial form as[14]

$$\Phi_{klij}\ddot{\bar{C}}_{ij}(\bar{t})+\Psi_{klij}\dot{\bar{C}}_{ij}(\bar{t})+\chi_{klij}\bar{C}_{ij}(\bar{t})+\Xi_{klij}\bar{C}_{ij}(\bar{t})=0, \tag{8}$$

where Φ_{klij}, Ψ_{klij}, and χ_{klij} represent the effects of plate inertia, viscous damping, and stiffness, respectively, and Ξ_{klij} stands for the effect of structural nonlinearities and contains quadratic powers of the unknown coefficients $\bar{C}_{ij}(\bar{t})$.

To facilitate integrations in Eq. (2c), the symmetry property of the Green's function G is utilized to replace $\partial G(\vec{r}|\vec{r}_o)/\partial x$ by $-\partial G(\vec{r}|\vec{r}_o)/\partial x_o$. Next, the chain rule is employed to transfer the derivative of G with respect to x_o to $w(x_o,y_o,\tau)$. Finally, the clamped boundary conditions (5) are used to eliminate w and its first derivative evaluated at the edges. If we further limit ourselves to the case in which the time required for an acoustic signal to traverse the characteristic dimension of the plate is much less than the characteristic period of the signal, then the time delay Δt in Eq. (2c) can be neglected. Such a compactness condition is justifiable for low Mach number flows[16] ($M\ll 1$), which is the case under consideration in the present paper.

Note that the above procedures are valid for clamped boundary conditions only. For other boundary conditions such as simply-supported conditions, the slope of the flexural displacement will be discontinuous at the edges of the plate. Accordingly, the Dirac delta function should be used to account for the contributions from these discontinuities along the edges. Evaluations of the integral in Eq. (2c) can then be facilitated by using this delta-type function and the corresponding boundary conditions at the edges.

Once this is done, the expressions of Φ_{klij}, Ψ_{klij}, χ_{klij}, and Ξ_{klij} for a subsonic flow can be written as

$$\Phi_{klij}=\delta_{ik}\delta_{jl}+\frac{\eta\sigma\phi}{2\pi\sqrt{1-M^2}}\Theta^{(0)}_{klij}, \tag{9a}$$

$$\Psi_{klij}=\xi\delta_{ik}\delta_{jl}+\frac{\eta\zeta\sqrt{\sigma\phi}}{\pi\sqrt{1-M^2}}\Theta^{(1)}_{klij}, \tag{9b}$$

$$\chi_{klij}=\left[\lambda_i^4+\frac{\lambda_j^4}{\eta^4}\right]\delta_{ik}\delta_{jl}+\frac{2}{\eta^2}\theta_{ik}\theta_{jl}+\frac{\eta\zeta^2}{2\pi\sqrt{1-M^2}}\Theta^{(2)}_{klij}, \tag{9c}$$

$$\begin{aligned} \Xi_{klij}=6(1-\nu^2)\bar{C}_{pq}(\bar{t})\bar{C}_{rs}(\bar{t})[&\theta_{pr}\theta_{ik}\beta_{jlqs}\\ &+\theta_{qs}\theta_{jl}\beta_{ikpr}-\gamma_{pr}\gamma_{sq}\gamma_{ik}\gamma_{jl}], \end{aligned} \tag{9d}$$

where δ_{ij} represent the Kronecker delta, λ_i is the eigenvalue of the ith normal mode, and θ_{ik}, γ_{ik}, β_{jlqs}, and $\Theta^{(\nu)}_{klij}$ are defined by

$$\theta_{ik}=\int_0^1 \frac{\partial^2 W_i(\bar{x})}{\partial \bar{x}^2} W_i(\bar{x}) W_k(\bar{x})\, d\bar{x}, \tag{10a}$$

$$\gamma_{ik}=\int_0^1 \frac{\partial W_i(\bar{x})}{\partial \bar{x}} W_k(\bar{x})\, d\bar{x}, \tag{10b}$$

$$\beta_{jlqs}=\int_0^1 W_j(\bar{y}) W_l(\bar{y}) W_q(\bar{y}) W_s(\bar{y})\, d\bar{y}, \tag{10c}$$

$$\Theta_{klij}^{(\upsilon)}=\int_0^1\int_0^1 W_k(\bar{x}) W_l(\bar{y})\, d\bar{x}\, d\bar{y} \times \int_0^1\int_0^1 \frac{W_j(\bar{y}_o)[\partial^{(\upsilon)} W_i(\bar{x}_o)/\partial x_0^{(\upsilon)}]}{\sqrt{(\bar{x}-\bar{x}_o)^2+\eta^2(1-M^2)(\bar{y}-\bar{y}_o)^2}}\, d\bar{x}_o\, d\bar{y}_o, \tag{10d}$$

where the superscript (υ) in Eq. (10d) indicates the order of derivatives with respect to x_o ($\upsilon=0$, 1, and 2).

Physically, the terms on the right side of Eq. (9a) represent the effect of mass for each mode of the plate and that of the added mass due to fluid loading, respectively. The terms on the right side of Eq. (9b) describe the effect of viscous damping associated with each mode and that of the added damping induced by acoustic radiation in the presence of mean flow, respectively. The square-bracketed term on the right side of Eq. (9c) indicates the sum of stiffness of the ith longitudinal mode and that of the jth lateral mode; the second term implies the stiffness due to coupling between the longitudinal and lateral modes; and the last term depicts the added stiffness due to acoustic radiation in mean flow. The terms on the right side of Eq. (9d) stand for the effect of added stiffness due to structural nonlinearities.

Thus, by using the Galerkin method the nonlinear, partial differential/integral equation (1) is reduced a set of coupled, nonlinear, second-order ordinary differential equations. If only the first longitudinal and lateral modes are considered, then Eq. (8) becomes a standard Duffing-type equation. The approximate solution to such an equation using multiple scales or averaging method has been documented extensively.[17–20] For an arbitrary number of longitudinal and lateral modes, however, analytic solutions cannot be obtained even for the first-order approximation. Under this circumstance, numerical solutions can be obtained by using the Gear method.[21]

III. MEAN FLOW EFFECTS ON PLATE FLEXURAL VIBRATION

To examine how mean flow changes the plate flexural vibration responses, we need first to determine the equilibrium positions around which a plate vibrates. One such equilibrium coincides with the plate's original undeformed position. The inclusion of structural nonlinearities, however, generates new equilibria. These additional equilibrium positions are derived explicitly in this section, which enables us to determine the critical mean flow speeds and to understand the mechanisms that govern the plate stabilities.

In the preceding section, we have derived the characteristic equation (8) for a baffled plate in mean flow. As an example of analyzing the plate stability, let us consider one lateral mode ($m=1$) and two longitudinal modes ($n=2$). Accordingly, Eq. (8) can be rewritten as a set of two homogeneous, nonlinear, second-order ordinary differential equations. To facilitate the analysis, we introduce an auxiliary set of variables Y_i to replace these two equations by four first-order, ordinary differential equations

$$Y_1=\bar{C}_{11}(\bar{t}), \tag{11a}$$

$$Y_2=\dot{\bar{C}}_{11}(\bar{t}), \tag{11b}$$

$$Y_3=\bar{C}_{21}(\bar{t}), \tag{11c}$$

$$Y_4=\dot{\bar{C}}_{21}(\bar{t}). \tag{11d}$$

This transformation results in a phase space[22] defined by Y_i and $\dot{Y}_i$,

$$\dot{Y}_1=Y_2, \tag{12a}$$

$$\dot{Y}_2=-\frac{\alpha_1}{\alpha_{01}}Y_1-\frac{\xi}{\alpha_{01}}Y_2-\frac{\alpha_3}{\alpha_{01}}Y_4-\frac{\alpha_4}{\alpha_{01}}Y_1^3-\frac{\alpha_5}{\alpha_{01}}Y_1Y_3^2, \tag{12b}$$

$$\dot{Y}_3=Y_4, \tag{12c}$$

$$\dot{Y}_4=-\frac{\alpha_2}{\alpha_{02}}Y_3-\frac{\xi}{\alpha_{02}}Y_4+\frac{\alpha_3}{\alpha_{02}}Y_2-\frac{\alpha_5}{\alpha_{02}}Y_1^2Y_3-\frac{\alpha_6}{\alpha_{02}}Y_3^3, \tag{12d}$$

where the coefficients α_{ij} are given by

$$\alpha_{01}=1+\frac{\eta\sigma\phi}{2\pi}\Theta_{1111}^{(0)}, \tag{13a}$$

$$\alpha_{02}=1+\frac{\eta\sigma\phi}{2\pi}\Theta_{2121}^{(0)}, \tag{13b}$$

$$\alpha_1=\lambda_1^4+\frac{2\theta_{11}^2}{\eta^2}+\frac{\lambda_1^4}{\eta^4}+\frac{\eta\zeta^2}{2\pi}\Theta_{1111}^{(2)}, \tag{13c}$$

$$\alpha_2=\lambda_2^4+\frac{2\theta_{11}\theta_{22}}{\eta^2}+\frac{\lambda_1^4}{\eta^4}+\frac{\eta\zeta^2}{2\pi}\Theta_{2121}^{(2)}, \tag{13d}$$

$$\alpha_3=\frac{\eta\zeta\sqrt{\sigma\phi}}{\pi}\Theta_{1121}^{(1)}, \tag{13e}$$

$$\alpha_4=6(1-\nu^2)\left(1+\frac{1}{\eta^4}\right)\beta_{1111}\theta_{11}^2, \tag{13f}$$

$$\alpha_5=6(1-\nu^2)\left(\beta_{1111}\theta_{11}\theta_{22}+\frac{3}{\eta^4}\beta_{1122}\theta_{11}^2\right), \tag{13g}$$

$$\alpha_6=6(1-\nu^2)\left(\beta_{1111}\theta_{22}^2+\frac{1}{\eta^4}\beta_{2222}\theta_{11}^2\right). \tag{13h}$$

Equation (12) allows us to use a general stability theory[23] to examine the stabilities at the fixed points or equilibrium positions determined by setting the right side of Eq. (12) to zero, namely,

$$Y_2=0, \tag{14a}$$

$$(\alpha_1+\alpha_4 Y_1^2+\alpha_5 Y_3^2)Y_1=0, \tag{14b}$$

$$Y_4=0, \tag{14c}$$

$$(\alpha_2+\alpha_5 Y_1^2+\alpha_6 Y_3^2)Y_3=0. \tag{14d}$$

Solutions to Eq. (14) are given by

$$\tilde{Y}_1=\tilde{Y}_2=\tilde{Y}_3=\tilde{Y}_4=0, \tag{15a}$$

$$\tilde{Y}_2=\tilde{Y}_3=\tilde{Y}_4=0, \quad \tilde{Y}_1=\pm\sqrt{-\frac{\alpha_1}{\alpha_4}}, \tag{15b}$$

$$\tilde{Y}_1=\tilde{Y}_2=\tilde{Y}_4=0, \quad \tilde{Y}_3=\pm\sqrt{-\frac{\alpha_2}{\alpha_6}}, \tag{15c}$$

$$\begin{aligned}&\tilde{Y}_2=\tilde{Y}_4=0, \quad \tilde{Y}_1=\pm\sqrt{\frac{\alpha_2\alpha_5-\alpha_1\alpha_6}{\alpha_4\alpha_6-\alpha_5^2}},\\ &\tilde{Y}_3=\pm\sqrt{\frac{\alpha_1\alpha_5-\alpha_2\alpha_4}{\alpha_4\alpha_6-\alpha_5^2}},\end{aligned} \tag{15d}$$

where the symbol $\tilde{Y}$ implies a fixed point or an equilibrium position. Note that solutions given by Eqs. (15) must be real in order for these equilibria to be meaningful.

Clearly, the equilibrium position given by Eq. (15a) corresponds to the plate's original undeformed position, and the rest are induced by structural nonlinearities. The stabilities around each of these equilibria can now be examined.

Taking the derivative of Eqs. (14) with respect to time, we obtain

$$\mathcal{J}(Y)\{\dot{Y}\}=0, \tag{16}$$

where $\mathcal{J}(Y)$ is a Jacobian matrix. Assume a form of solution to Eq. (16) as

$$\{Y\}=\{|Y|\}e^{\Lambda\bar{t}}, \tag{17}$$

where Λ represents the eigenvalues of the system and $\{|Y|\}$ stands for the amplitude of $\{Y\}$. Substituting Eq. (17) into (16) leads to the following characteristic equation,

$$\sum_{n=0}^{4}\Omega_n\Lambda^n=0, \tag{18}$$

where Ω_n are given by

$$\Omega_0=\Gamma_1\Gamma_2-4\alpha_5^2\tilde{Y}_1^2\tilde{Y}_3^2, \tag{19a}$$

$$\Omega_1=\xi(\Gamma_1+\Gamma_2), \tag{19b}$$

$$\Omega_2=\xi^2+\alpha_3^2+\alpha_{01}\Gamma_2+\alpha_{02}\Gamma_1, \tag{19c}$$

$$\Omega_3=\xi(\alpha_{01}+\alpha_{02}), \tag{19d}$$

$$\Omega_4=\alpha_{01}\alpha_{02}, \tag{19e}$$

where $\Gamma_{1,2}$ are given by

$$\Gamma_1=\alpha_1+3\alpha_4\tilde{Y}_1^2+\alpha_5\tilde{Y}_3^2, \tag{20a}$$

$$\Gamma_2=\alpha_2+\alpha_5\tilde{Y}_1^2+3\alpha_6\tilde{Y}_3^2. \tag{20b}$$

The stability theorem for linear systems[24] states that a system is stable if and only if the roots of the characteristic equation all lie in the left-half Λ plane, excluding the imaginary axis. This theorem is also applicable to the system under consideration. One way of determining whether the roots of the polynomial equation (18) all lie in the left-half Λ plane without actually solving Eq. (18) is via use of the Routh algorithm,[24] which yields the following inequalities:

$$\Omega_0>0, \quad \Omega_1>0, \quad \Omega_2>0, \quad \Omega_3>0, \quad \Omega_4>0, \tag{21a}$$

$$\Omega_2\Omega_3-\Omega_1\Omega_4>0, \tag{21b}$$

$$\Omega_1(\Omega_2-\Omega_1\Omega_4)-\Omega_0\Omega_3^2>0. \tag{21c}$$

Substituting Eq. (19) into Eq. (21) then leads to the following conditions,

$$\xi>0, \quad \alpha_{01}>0, \quad \alpha_{02}>0, \quad \Gamma_1>0, \quad \Gamma_2>0, \tag{22}$$

which must all be satisfied in order for the system defined by Eq. (12) to be stable.

Equation (22) may shed light on the mechanisms that govern the instabilities of a finite plate in the presence of mean flow. The first inequality in Eq. (22) requires that the damping ratio ξ be positive. This condition is automatically satisfied because the damping coefficient d is positive. In the special case of an undamped system, $\xi=0$, the roots of the polynomial equation all lie on the imaginary axis and the system is marginally stable, if other conditions in Eq. (22) are satisfied. The second and third inequalities in Eq. (22) require that α_{01} and α_{02} be positive. From Eqs. (13a) and (13b), we see that these quantities consist of the plate aspect ratio, the fluid/structure density ratio, and the added mass due to fluid loading, which are all positive. Therefore these two conditions are satisfied automatically.

The last two inequalities in Eq. (22) require both Γ_1 and Γ_2 be positive. Substituting the plate's undeformed equilibrium position given by Eq. (15a) into (20), we obtain $\Gamma_1=\alpha_1$ and $\Gamma_2=\alpha_2$. The quantities $\alpha_{1,2}$ represent the effect of the stiffness and that of the added stiffness due to acoustic radiation in mean flow [see Eqs. (13c) and (13d)], respectively. The former is positive, while the latter is negative because $\Theta^{(2)}_{1111}$ and $\Theta^{(2)}_{2121}$ are negative [see Eq. (10)]. This is obvious because for a plate with clamped boundary conditions, we have $\partial^2 W_i(\bar{x})/\partial\bar{x}^2=-\lambda_i^2 W_i(\bar{x})$.[9,10] Hence the values of $\Theta^{(2)}_{klij}$, which involve integrations of the product of $\partial^2 W_i(\bar{x})/\partial\bar{x}^2$ and $W_i(\bar{x})$, are always negative.

Without mean flow, the added stiffness is identically zero. Hence α_1 and α_2 are always positive, which means $\Gamma_1>0$ and $\Gamma_2>0$ and the plate is stable around its undeformed equilibrium position. When there is mean flow and when the mean flow speed is low, the effect of the added stiffness is small. Therefore α_1 and α_2 are positive, $\Gamma_1>0$ and $\Gamma_2>0$, and the plate is still stable. However, the values of α_1 and α_2 decrease quadratically with the increase of the mean flow speed. When the mean flow speed exceeds the critical values such that the added stiffness overpowers the plate's own stiffness, then α_1 and/or α_2 may be negative and the plate may become unstable.

The plate aspect and length to thickness ratios have a direct impact on the overall stiffness. The larger the plate

aspect and length to thickness ratios are, the smaller the plate overall stiffness is and the more unstable the plate tends to be.

The critical mean flow speeds can be determined by setting Γ_1 and Γ_2 to zero, which is equivalent to setting α_1 and α_2 to zero. From Eqs. (13c) and (13d), we obtain

$$u_{\mathrm{cr},1}=c_0\sqrt{-\frac{2\pi}{\eta\sigma\phi^3\Theta^{(2)}_{2121}}\left(\lambda_2^4+\frac{2\theta_{11}\theta_{22}}{\eta^2}+\frac{\lambda_1^4}{\eta^4}\right)}, \quad (23a)$$

$$u_{\mathrm{cr},2}=c_0\sqrt{-\frac{2\pi}{\eta\sigma\phi^3\Theta^{(2)}_{1111}}\left(\lambda_1^4+\frac{2\theta_{11}^2}{\eta^2}+\frac{\lambda_1^4}{\eta^4}\right)}. \quad (23b)$$

Note that the number of critical mean flow speeds is determined by that of normal modes selected in the characteristic equation (8) or, equivalently, the order of matrix in Eq. (8). In this particular case, the order of matrix in Eq. (8) is two, thus leading to two critical speeds.

Suppose that $u_{\mathrm{cr},1}<u_{\mathrm{cr},2}$. Then at the first critical mean flow speed $U=u_{\mathrm{cr},1}$, we have $\alpha_1>0$ and $\alpha_2=0$. The plate's original equilibrium position remains unchanged. At this equilibrium position [see Eq. (15a)], $\Gamma_1=\alpha_1>0$ and $\Gamma_2=\alpha_2=0$. The last inequality in Eq. (22) is marginally satisfied and the plate is stable.

When $u_{\mathrm{cr},1}<U<u_{\mathrm{cr},2}$, we have $\alpha_1>0$ and $\alpha_2<0$. In this case, a new equilibrium position given by Eq. (15c) emerges in addition to the original equilibrium position given by Eq. (15a). However, the plate is unstable at the original equilibrium position because $\Gamma_1=\alpha_1>0$ and $\Gamma_2=\alpha<0$ there, while stable at the new equilibrium position because $\Gamma_1=\alpha_1-\alpha_2\alpha_5/\alpha_6>0$ and $\Gamma_2=-2\alpha_2>0$. [Note that in order for the equilibrium position given by Eq. (15c) to exist, α_6 must be positive. In fact, Eqs. (10) and (13) show that α_4, α_5, and α_6 are all positive.] When $U=u_{\mathrm{cr},2}$, we have $\alpha_1=0$ and $\alpha_2<0$. In this case, the equilibrium position given by Eq. (15c) co-exists with the original equilibrium position. Once again, the plate is unstable at the original equilibrium position because $\Gamma_1=\alpha_1=0$ and $\Gamma_2=\alpha_2<0$ there, but stable at the new equilibrium position because $\Gamma_1=-\alpha_2\alpha_5/\alpha_6>0$ and $\Gamma_2=-2\alpha_2>0$.

When the mean flow speed exceeds both critical values, $U>u_{\mathrm{cr},1}$ and $U>u_{\mathrm{cr},2}$, then both α_1 and α_2 are negative. Under this condition, there are three equilibria given by Eqs. (15a), (15b), and (15c), respectively. The equilibrium position given by Eq. (15d) cannot be realized. This is because Eq. (15d) requires either of the following sets of inequalities to hold,

$$\begin{cases}\alpha_2\alpha_5>\alpha_1\alpha_6,\\ \alpha_4\alpha_6>\alpha_5^2,\end{cases} \text{ and } \begin{cases}\alpha_1\alpha_5>\alpha_2\alpha_4,\\ \alpha_4\alpha_6>\alpha_5^2,\end{cases} \quad (24a)$$

or

$$\begin{cases}\alpha_2\alpha_5<\alpha_1\alpha_6,\\ \alpha_4\alpha_6<\alpha_5^2,\end{cases} \text{ and } \begin{cases}\alpha_1\alpha_5<\alpha_2\alpha_4,\\ \alpha_4\alpha_6<\alpha_5^2.\end{cases} \quad (24b)$$

Since $\alpha_1<0$ and $\alpha_2<0$, the conditions of Eq. (24a) lead to

$$\alpha_5^2<\alpha_4\alpha_6, \quad (25a)$$

while those of Eq. (24b) result in

$$\alpha_5^2>\alpha_4\alpha_6, \quad (25b)$$

which are contradictory to each other.

Under this mean flow speed the plate is unstable around its original equilibrium position given by Eq. (15a) because $\Gamma_1=\alpha_1<0$ and $\Gamma_2=\alpha_2<0$. At the equilibrium position given by Eq. (15b), we have $\Gamma_1=-2\alpha_1>0$ and $\Gamma_2=\alpha_2-\alpha_1\alpha_5/\alpha_4$. In order for the plate to be stable, Γ_2 must be positive, namely, $\alpha_2>\alpha_1\alpha_5/\alpha_4$. On the other hand, at the equilibrium position given by Eq. (15c), we have $\Gamma_1=\alpha_1-\alpha_2\alpha_5/\alpha_6$ and $\Gamma_2=-2\alpha_2>0$. The stable condition (22) requires $\Gamma_1>0$, which yields $\alpha_1>\alpha_2\alpha_5/\alpha_6$. These two inequalities may be satisfied depending upon the values of α_1, α_2, α_4, α_5, and α_6, which represent the effects of the plate stiffness and the added stiffness due to acoustic radiation in mean flow. In most situations, however, the plate cannot be stabilized permanently at either one of these two equilibrium positions. Instead, it vibrates at one equilibrium position for a while and then jumps to another. Consequently, plate flexural vibration may seem unstable, yet its amplitude is always bounded.

It must be pointed out that these instabilities are caused by structural nonlinearities. Without the inclusion of structural nonlinearities, there is only one equilibrium position, i.e., the undeformed flat position. Under this condition, the amplitude of plate vibration would grow exponentially in time when the mean flow speed exceeds the critical value. With the inclusion of structural nonlinearities, the overall amplitude of vibration is bounded, but the plate may vibrate at the equilibrium positions other than its original one. In particular, when the mean flow speed exceeds certain critical values, plate vibration may become so unstable that it jumps from one equilibrium position to another. Further, this jumping may be random and plate vibration may seem to be chaotic.

IV. STABILITY CHARTS FOR FINITE PLATES IN MEAN FLOW

In the preceding section, we have derived explicit formulations for predicting critical mean flow speeds $u_{\mathrm{cr},i}$ for a baffled plate. These critical speeds are shown to be correlated to the plate stiffness and the added stiffness due to acoustic radiation in mean flow. Specifically, the values of $u_{\mathrm{cr},i}$ depend on the plate aspect ratio, length to thickness ratio, and fluid/structure density ratio. To acquire a better understanding of these correlations, we present in this section the stability charts for different types of elastic plates under different flow conditions.

As before, let us consider a finite plate with clamped boundary conditions. Under this condition, the plate normal modes are given by[13]

$$W_k(x)=\sigma_k\left[\sin\left(\frac{\lambda_k x}{L}\right)-\sinh\left(\frac{\lambda_k x}{L}\right)\right]+\left[\cos\left(\frac{\lambda_k x}{L}\right)-\cosh\left(\frac{\lambda_k x}{L}\right)\right], \quad (26a)$$

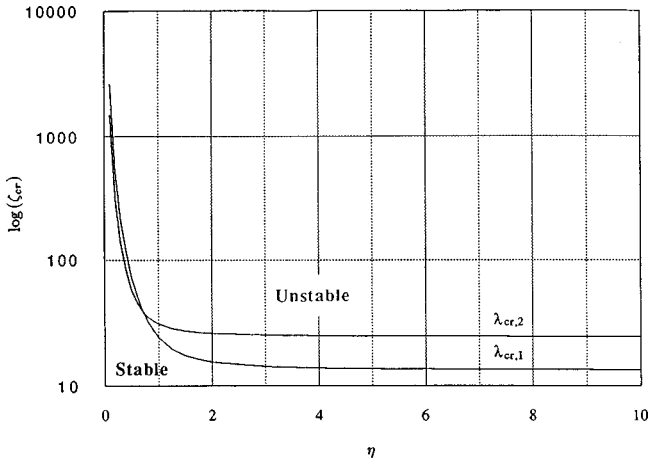

FIG. 2. Dimensionless mean flow speeds versus the plate aspect ratio.

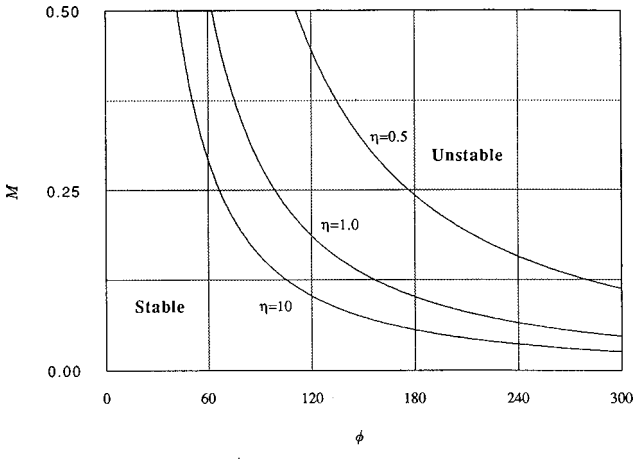

FIG. 3. Stability chart of a steel plate in contact with water on one side and vacuum on the other side at fixed plate aspect ratios.

$$W_i(y)=\sigma_i\left[\sin\left(\frac{\lambda_i y}{b}\right)-\sinh\left(\frac{\lambda_i y}{b}\right)\right]+\left[\cos\left(\frac{\lambda_i y}{b}\right)-\cosh\left(\frac{\lambda_i y}{b}\right)\right], \tag{26b}$$

where σ_i represents the ith modal ratio

$$\sigma_i=\frac{\sin\lambda_i+\sinh\lambda_i}{\cos\lambda_i-\cosh\lambda_i}, \tag{27}$$

where λ_i is the ith eigenvalue determined by $\cos\lambda_i\cosh\lambda_i=1$. The first three eigenvalues are given by $\lambda_1=4.73\,004$, $\lambda_2=7.8532$, and $\lambda_3=10.9956$. Accordingly, the first three modal ratios are -0.9825, -1.0008, and $-0.99\,997$. For a large value of i, $\lambda_k\to(2k+1)\pi/2$ and $\sigma_i\to-1$.

Note that the normal modes $\{W(x)\}$ and $\{W(y)\}$ are orthogonal to each other

$$\int_0^L W_k(x)W_l(x)\,dx=\begin{cases}L & \text{for } k=l,\\ 0 & \text{for } k\neq l;\end{cases}$$
$$\int_0^b W_i(y)W_j(y)dy=\begin{cases}b, & \text{for } i=j,\\ 0, & \text{for } i\neq j.\end{cases} \tag{28}$$

However, the products of $\{W(x)\}$ or $\{W(y)\}$ and their derivatives are not necessarily orthogonal.

The dimensionless mean flow speed ζ is defined in Eq. (6). Using the critical mean flow speeds given by Eq. (23), we can write

$$\zeta_{\mathrm{cr},1}=\sqrt{-\frac{2\pi}{\eta\Theta^{(2)}_{2121}}\left(\lambda_2^4+\frac{2\theta_{11}\theta_{22}}{\eta^2}+\frac{\lambda_1^4}{\eta^4}\right)}, \tag{29a}$$

$$\zeta_{\mathrm{cr},2}=\sqrt{-\frac{2\pi}{\eta\Theta^{(2)}_{1111}}\left(\lambda_1^4+\frac{2\theta_{11}^2}{\eta^2}+\frac{\lambda_1^4}{\eta^4}\right)}. \tag{29b}$$

The values of $\Theta^{(2)}_{1111}$ and $\Theta^{(2)}_{2121}$ can be evaluated numerically using the standard Gaussian quadrature techniques by substituting the normal modes given by Eq. (26) into Eq. (10).

Figure 2 depicts the curves of critical dimensionless mean flow speeds [expressed as $\log(\zeta_{\mathrm{cr},i})$] versus the plate aspect ratio η, which defines the stability boundaries of a finite plate in mean flow. The area below both curves represents the stable region where the plate vibrates around its undeformed equilibrium position. The area between the curves indicates the region where the plate vibrates around the equilibrium positions other than its original undeformed one. The area above both curves implies the region where the plate is unstable.

Figure 2 demonstrates that the larger the plate aspect ratio is, the more unstable the plate tends to be, while the smaller the plate aspect ratio is, the more stable the plate becomes in the presence of mean flow. This is because a large aspect ratio ($\eta\geqslant 1$) tends to reduce the stiffness of the lateral modes and those of coupling between the longitudinal and lateral modes [see Eq. (9c)]. Meanwhile, it increases the added stiffness induced by acoustic radiation in mean flow, which always works against the plate's own stiffness. As a result, the overall stiffness is reduced and the plate becomes less stable. On the other hand, a small aspect ratio ($\eta\leqslant 1$) tends to increase the stiffness of the lateral modes and those of coupling between the longitudinal and lateral modes, while it decreases the added stiffness due to acoustic radiation in mean flow. Consequently, the overall stiffness is enhanced and the plate becomes more stable in mean flow.

Also, Fig. 2 shows that the critical mean flow speeds approach constant values at large aspect ratios. Numerical results demonstrate that $\zeta_{\mathrm{cr},1}=13.4$ at $\eta=10$, and $\zeta_{\mathrm{cr},1}\to 13.33$ as $\eta\to\infty$. This implies that for a finite length but infinitely wide plate, the vibration responses may be unstable when the dimensionless mean flow speed exceeds $\zeta_{\mathrm{cr},1}=13.33$. Note that the square of $\zeta_{\mathrm{cr},1}$ is

$$\zeta^2_{\mathrm{cr},1}=13.33^2=177.68, \tag{30}$$

which is in excellent agreement with the analytic solution[6] of the critical value, $\zeta^2_{\mathrm{cr}}=177$, obtained by using the Galerkin method with a single mode approximation for a two-dimensional panel in mean flow.

The formulations derived in this paper also enable us to examine the correlations between mean flow speeds and fluid/structure density ratio, plate length to thickness ratio, and plate aspect ratio. Figures 3 and 4 illustrate the stability charts for a steel plate in water with a fluid/structure density ratio $\sigma=0.1282$ and that for an aluminum plate in water with

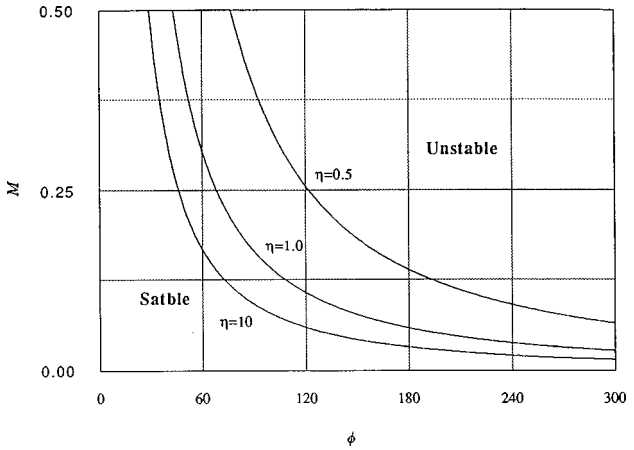

FIG. 4. Stability chart of an aluminum plate in contact with water on one side and vacuum on the other side at fixed plate aspect ratios.

$\sigma=0.3704$, respectively. Results show that for a fixed aspect ratio η and fluid/structure density ratio σ, the thinner the plate (i.e., the larger the value of $\phi=L/h$), the lower the critical mean flow Mach number, and the more unstable the plate. On the other hand, for a fixed length to thickness ratio ϕ and fluid/structure density ratio σ, the larger the aspect ratio η, the lower the critical mean flow Mach number, and the more unstable the plate. Finally, for a fixed length to thickness ratio ϕ and aspect ratio η, the larger the value of fluid/structure density ratio σ, the more unstable the plate.

V. BIFURCATION AND CHAOS IN PLATE VIBRATION IN MEAN FLOW

In this section, we demonstrate numerical results of the flexural displacements of a baffled plate in mean flow. In particular, we display transition of plate vibration from a stable condition to an unstable one as the mean flow speed exceeds its critical values.

First, we consider a steel plate in water with a mass density $\rho_p=7800(\mathrm{kg/m^3})$, a length $L=2.5$ (m), a width $b=1.25$ (m), and a thickness $h=0.003$ (m). Accordingly, the plate aspect ratio $\eta=0.5$, the length to thickness ratio $\phi=833.3$, and the fluid/structure density ratio $\sigma=0.1282$,

Substituting these values into Eq. (6) yields a dimensionless mean flow speed $\zeta=8288.36M$, where M is typically below 0.01 for most engineering applications. Accordingly, Eq. (29) gives the dimensionless critical mean flow speeds $\zeta_{\mathrm{cr},1}=57.97$ and $\zeta_{\mathrm{cr},2}=74.23$. In what follows, we calculate the amplitudes of plate flexural vibration at a fixed point with $M=0.005$, 0.008, and 0.01, or equivalently, $\zeta=41.44$, 66.31, and 82.99, which corresponds to the dimensionless mean flow speed regimes, $\zeta<\zeta_{\mathrm{cr},1}<\zeta_{\mathrm{cr},2}$, $\zeta_{\mathrm{cr},1}<\zeta<\zeta_{\mathrm{cr},2}$, and $\zeta_{\mathrm{cr},1}<\zeta_{\mathrm{cr},2}<\zeta$, respectively.

As in all nonlinear systems, the responses are sensitive to the initial conditions. In this paper, we choose to give the plate an initial displacement with a zero initial velocity, namely, $Y_1(0)=Y_3(0)=0.05$, and $Y_2(0)=Y_4(0)=0$. The plate flexural vibration responses subject to these initial conditions are obtained by solving (12) using the Gear method.[21]

Figure 5 displays the time history of the dimensionless plate flexural displacement and the corresponding phase

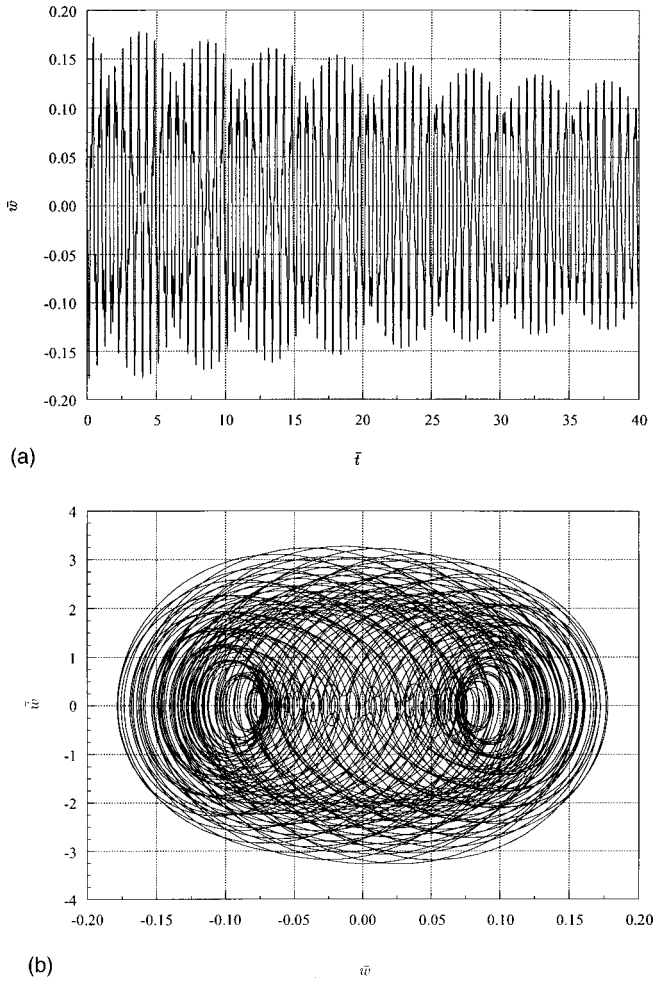

FIG. 5. Responses of flexural vibration for a steel plate with $\eta=0.5$, $\xi=0.5$, and $M=0.005$, i.e., $\zeta<\zeta_{\mathrm{cr},1}<\zeta_{\mathrm{cr},2}$. (a) Time history. (b) Phase plane.

plane evaluated at $\bar{x}=0.75$ and $\bar{y}=0.5$ with a damping ratio $\xi=0.5$ and a mean flow Mach number $M=0.005$, or $\zeta=41.44$. Since the mean flow speed is below the critical values ($\zeta<\zeta_{\mathrm{cr},1}<\zeta_{\mathrm{cr},2}$), the plate is stable around its undeformed equilibrium position, and vibrational motion is pseudo-periodic.

Here the effect of structural nonlinearities on plate flexural vibration is clearly visible. Without the inclusion of structural nonlinearities, the response would consist of contributions from the selected lateral and longitudinal modes only, which are coupled through the stiffness matrix and fluid loading. With the inclusion of structural nonlinearities, the responses include contributions not only from the selected modes, but also from their harmonics. Also, the amplitude of plate vibration is damped out by the viscous damping.

Next, we increase the Mach number to $M=0.008$, or $\zeta=66.31$. Since $\zeta_{\mathrm{cr},1}<\zeta<\zeta_{\mathrm{cr},2}$, the plate is unstable at its undeformed equilibrium position, but stable at a new equilibrium position. The time history of plate flexural vibration and the corresponding phase plane at $\bar{x}=0.75$ and $\bar{y}=0.5$ with a viscous damping ratio $\xi=0.5$ are illustrated in Fig. 6.

In this case, the main characteristics of plate flexural vibration remain essentially unchanged, namely, motion is

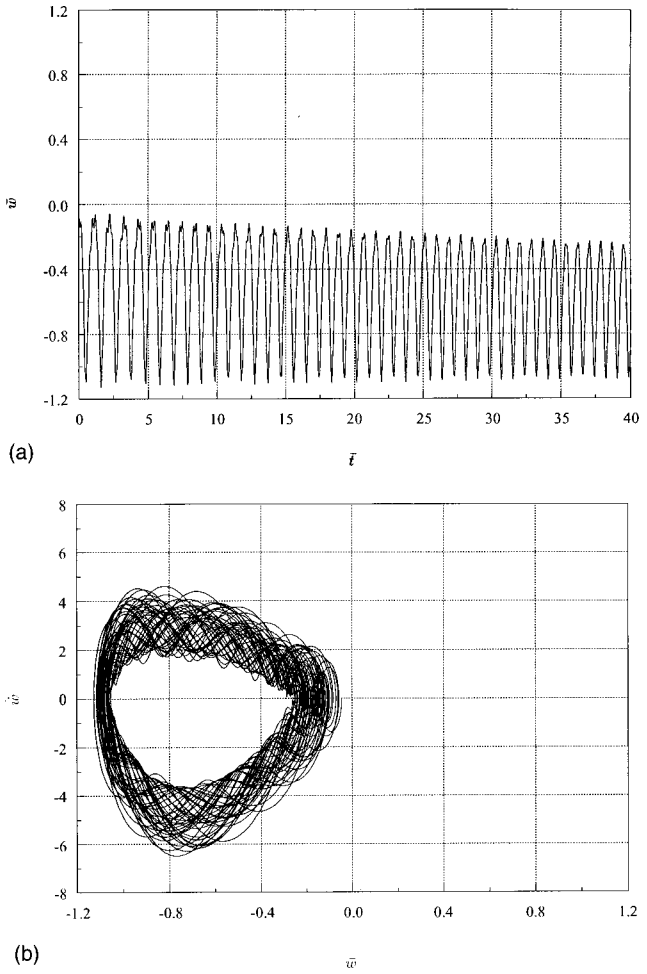

FIG. 6. Responses of flexural vibration for a steel plate with $\eta=0.5$, $\xi=0.5$, and $M=0.008$, i.e., $\zeta_{cr,1}<\zeta<\zeta_{cr,2}$. (a) Time history. (b) Phase plane.

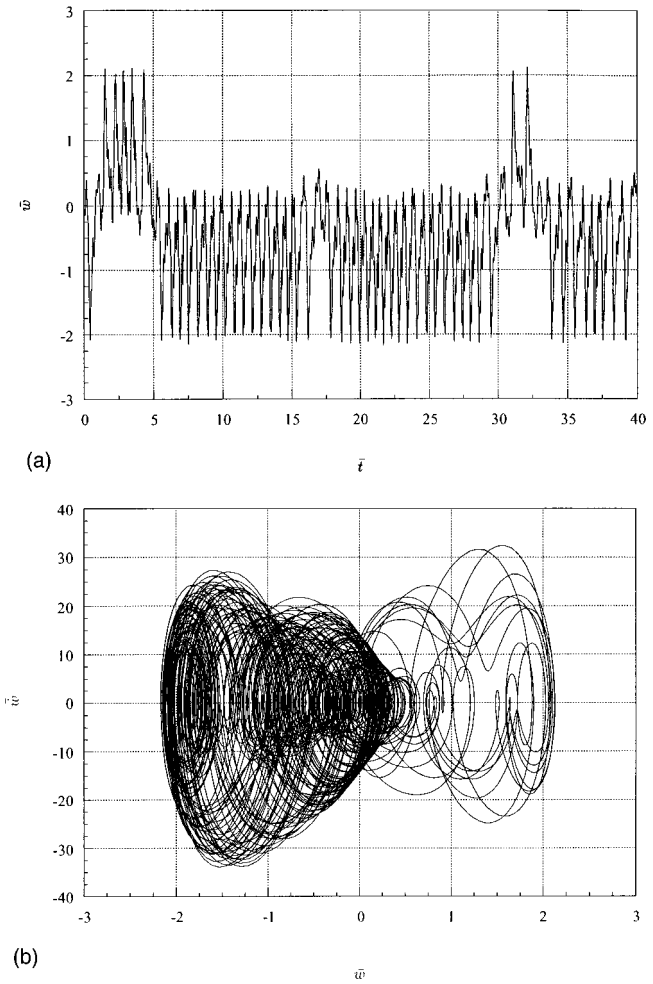

FIG. 7. Responses of flexural vibration for an undamped steel plate with $\eta=0.5$, $\xi=0.0$, and $M=0.01$, i.e., $\zeta_{cr,1}<\zeta_{cr,2}<\zeta$. (a) Time history. (b) Phase plane.

pseudo-periodic and consists of contributions from both the selected modes and their harmonics. The most striking differences are the change of the equilibrium position and the increase in the vibration amplitudes. Note that even without viscous damping, the plate can still be stabilized at a buckled-down equilibrium position owing to the fluid-loading effect.

When the Mach number is raised to $M=0.01$, or $\zeta=82.88$, the dimensionless mean flow speed exceeds both critical values, $\zeta>\zeta_{cr,2}>\zeta_{cr,1}$. Under this condition, the plate has three equilibrium positions given by Eqs. (15a), (15b), and (15c), respectively. However, the plate cannot be stabilized at any equilibria in an undamped situation. Figure 7(a) demonstrates that when $\xi=0$, plate flexural vibration becomes unstable, jumping from one equilibrium position to another. Moreover, these jumps are purely random and therefore flexural vibration is chaotic. This chaotic behavior is confirmed in the corresponding phase plate [see Fig. 7(b)]. Under this circumstance, the viscous damping may become a stabilizing factor. Figure 8 shows that when viscous damping is introduced, say, $\xi=0.5$, the jumping among the equilibria disappears and the plate settles down to a buckled-down position.

To better understand the chaotic behavior of a baffled plate in mean flow, we now calculate the dimensionless vertical displacements of the equilibria as the mean flow Mach number increases. As an example, we consider an undamped steel plate ($\xi=0$) with $\eta=0.5$, $\phi=833.3$, and $\sigma=0.1282$.

Figure 9 indicates that at very low Mach numbers ($\zeta<\zeta_{cr,1}<\zeta_{cr,2}$), the dimensionless vertical displacement of the

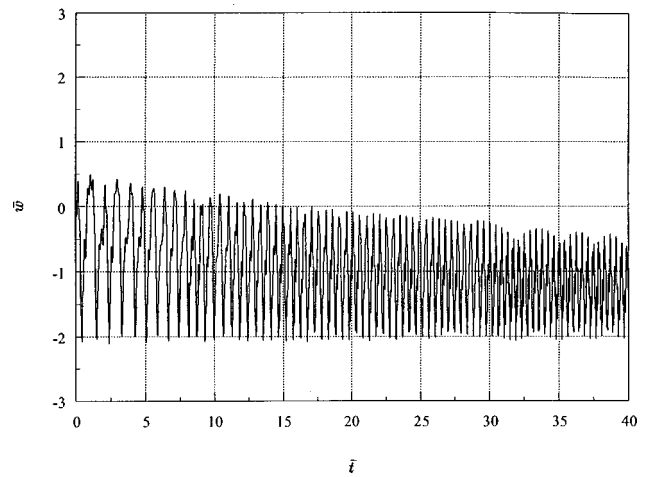

FIG. 8. Time history of plate flexural vibration for a damped steel plate with $\eta=0.5$, $\xi=0.5$, and $M=0.01$, i.e., $\zeta_{cr,1}<\zeta_{cr,2}<\zeta$.

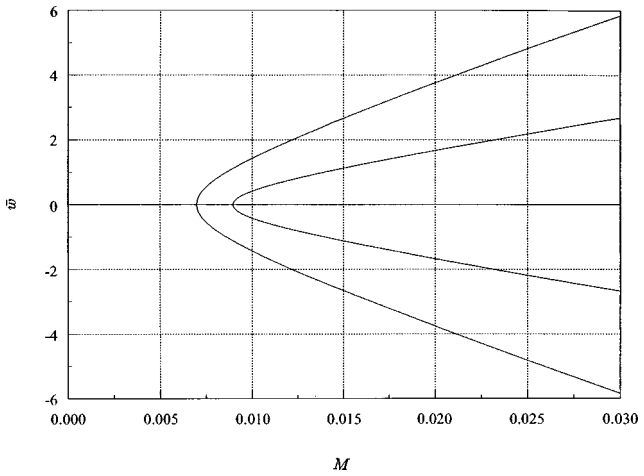

FIG. 9. Bifurcations in equilibria for a steel plate with $\sigma=0.1282$, $\phi=833.3$, and $\eta=0.5$.

equilibrium position is identically zero. This represents the stable situation in which the plate vibrates around its undeformed equilibrium position. When the mean flow Mach number exceeds a critical value, $\zeta_{cr,1}<\zeta<\zeta_{cr,2}$, the vertical displacements of the equilibria bifurcate to a symmetric pair. Mathematically, this corresponds to the situation in which the plate can vibrate around either a buckled-up or buckled-down position. However, the former is unstable because of the fluid loading effect which exerts a downward pressure on the plate surface. Hence the plate ends up with a buckled-down position. The buckling displacement increases monotonically with the Mach number M. When M exceeds a second critical values, $\zeta_{cr,1}<\zeta_{cr,2}<\zeta$, another bifurcation emerges and the plate has two pairs of equilibria. However, the plate cannot be stabilized permanently at any of the equilibria. Instead, it jumps from one equilibrium position to another in a random manner and flexural vibration may seem chaotic.

Figures 10 and 11 demonstrate similar bifurcation phenomena for a baffled plate with the same length to thickness ratio ϕ and fluid/structure density ratio σ, but larger aspect ratios at $\eta=1$ and $\eta=10$, respectively. As pointed out earlier, the larger the plate aspect ratio, the more unstable the plate. This trend is reflected in Figs. 10 and 11 in that bifurcations occur at lower Mach numbers as η increases.

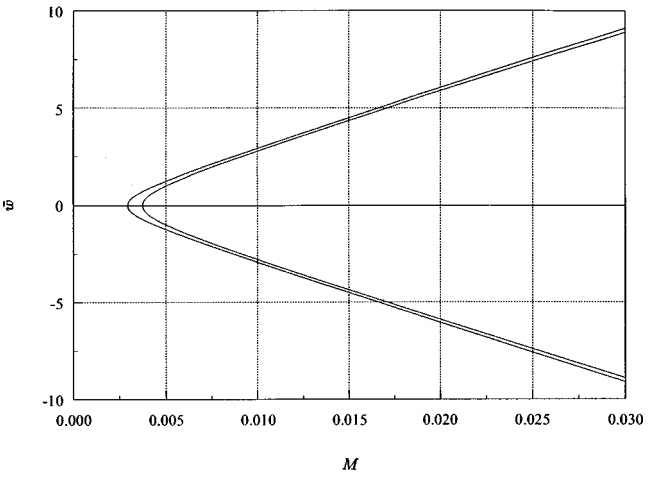

FIG. 10. Bifurcations in equilibria for a steel plate with $\sigma=0.1282$, $\phi=833.3$, and $\eta=1$.

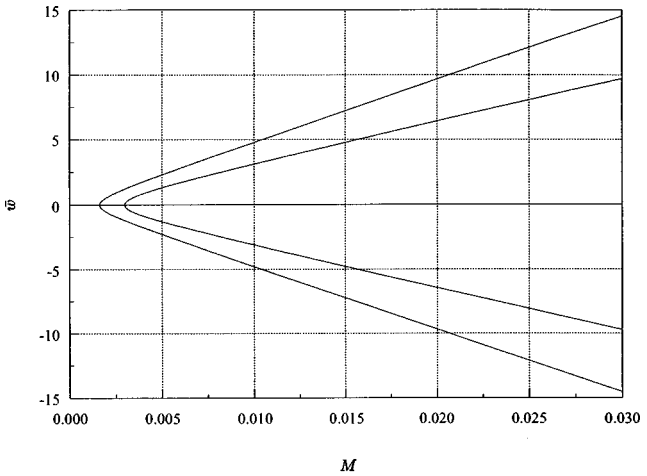

FIG. 11. Bifurcations in equilibria for a steel plate with $\sigma=0.1282$, $\phi=833.3$, and $\eta=10$.

For a plate with a fixed aspect ratio η and fluid/structure density ratio σ, the stability increases with the decrease of the length to thickness ratio ϕ. Figure 12 displays the bifurcation curves when ϕ is reduced by half to 416.7 or, equivalently, the thickness is doubled. Comparing the results of Fig. 12 to those of Fig. 10, we see clearly a delay in bifurcations as the mean flow speed increases. On the other hand, when the plate thickness is halved or the length to thickness ratio ϕ is doubled to 1666.7, bifurcations occur at a much lower Mach number (see Fig. 13). Accordingly, the plate becomes less stable in the presence of mean flow.

VI. CONCLUSIONS

The free responses of a baffled, clamped rectangular plate wetted on one side by a fluid moving at a constant, uniform velocity (and in vacuum on the other side) is investigated. The equations of motion for the plate flexural displacement are solved, taking into account the fluid-loading effect on the wetted side, as well as nonlinear inplane forces

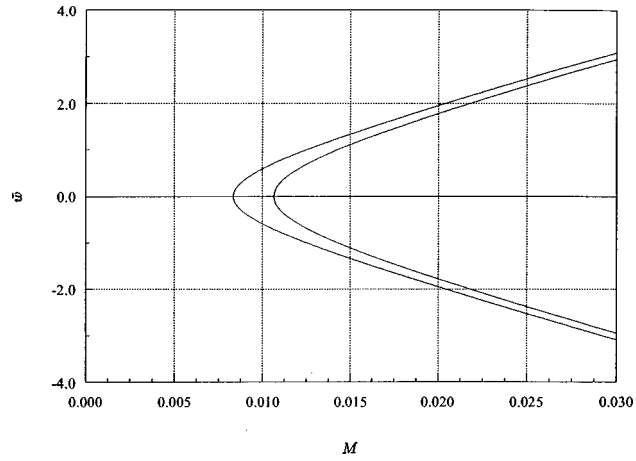

FIG. 12. Bifurcations in equilibria for a steel plate with $\sigma=0.1282$, $\phi=416.6$, and $\eta=1$.

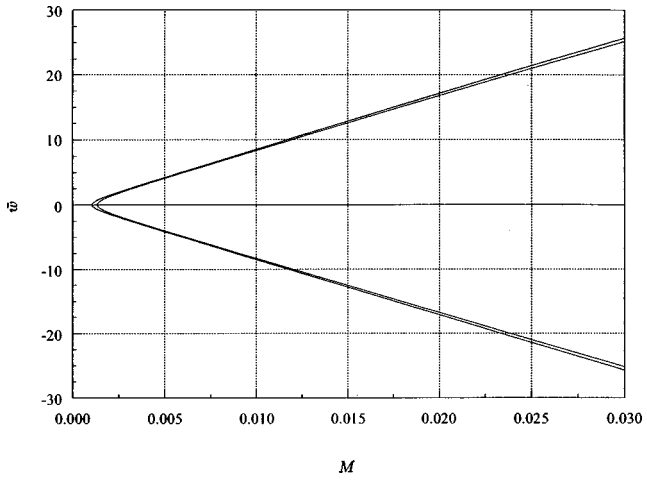

FIG. 13. Bifurcations in equilibria for a steel plate with $\sigma=0.1282$, $\phi=1666.7$, and $\eta=1$.

and share stresses. It is shown that ideal plates with these boundary conditions have more than one equilibrium positions, and the plate flexural vibration may become unstable under certain mean flow speeds. When the mean flow speed exceeds a critical value, the plate may be unstable around its original undeformed position, but stable around a buckled-down position with a larger amplitude. When the mean flow speed exceeds all the critical values, the plate may become unstable around all equilibria. Under this condition, the plate may jump randomly from one equilibrium position to another. This chaotic behavior disappears, however, when viscous damping is introduced. Note that without the inclusion of the structural nonlinearities, the plate has only one equilibrium position. Under this circumstance, the amplitude of plate flexural vibration would grow exponentially in time everywhere as the mean flow speed exceeds a critical value, known as absolute instability. With the inclusion of the nonlinearities, the plate may possess multiple equilibria, but may not be stable at all equilibrium positions beyond certain mean flow speeds. Under this condition, plate flexural vibration may become chaotic. Nonetheless, the overall amplitude is always bounded.

Aeroelastic structural acoustic control

Robert L. Clark and Kenneth D. Frampton
Department of Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina 27708-0300

(Received 4 March 1998; accepted for publication 27 October 1998)

Static, constant-gain, output-feedback control compensators were designed to increase the transmission loss across a panel subjected to mean flow on one surface and a stationary, acoustic half-space on the opposite surface. The multi-input, multi-output control system was based upon the use of an array of colocated transducer pairs. The performance of the static-gain, output-feedback controller was compared to that of the full state-feedback controller using the same control actuator arrays, and was found to yield comparable levels of performance for practical limitations on control effort. Additionally, the resulting static compensators proved to be dissipative in nature, and thus the design varied little as a function of the aeroelastic coupling induced by the fluid–structure interaction under subsonic flow conditions. Several parametric studies were performed, comparing the effects of control-effort penalty as well as the number of transducer pairs used in the control system. [S0001-4966(99)01302-8]

LIST OF SYMBOLS

$\mathbf{A},\mathbf{B},\mathbf{C},\mathbf{D}$	state space matrices
a	panel length (chord)
a_a	external speed of sound
b	panel width (span)
D	$EI/(1-\nu^2)$, stiffness
D_{mn}	aerodynamic influence coefficient
$H_{mn}(t)$	aerodynamic influence function
$I_{mn}(t)$	aerodynamic influence function
M	Mach number
M_n	mass matrix
N	number of plate expansion modes
$p^a(x,y,z,t)$	aerodynamic pressure
$p^{\text{tbl}}(x,y,z,t)$	TBL pressure
$q_n(t)$	plate generalized coordinate
$Q_n^a(t)$	aerodynamic generalized force
$Q_n^c(t)$	cavity generalized force
$Q_n^{\text{tbl}}(t)$	TBL generalized force
s	tU_a/a
S	plate surface
S_{mn}	aerodynamic influence coefficient
t	time
U_a	free-stream velocity
$w(x,y,t)$	panel displacement
x,y,z	Cartesian coordinates
ξ_s	structural-damping ratio
Λ_m	cavity modal volume
$\Psi_n(x,y)$	plate modal expansion functions
$\phi^a(x,y,z,t)$	aerodynamic velocity potential
ρ_a	external fluid density
ρ_s	plate density

INTRODUCTION

The active control of low-frequency sound transmission to the interior of modern aircraft is of particular interest for stochastic noise sources such as that presented by the turbulent boundary layer (TBL). In a recent study, Clark and Frampton (1996) demonstrated the importance of including aeroelastic coupling for predicting the resulting sound radiation in the presence of mean flow. Thomas and Nelson (1995) investigated linear quadratic regulator (LQR) theory and linear quadratic Gaussian (LQG) theory for the control of panels subjected to stochastic noise sources shaped in frequency to capture the dynamics of TBL noise. However, the aeroelastic coupling was not considered in this earlier study. The current study combines the analysis of a panel including aeroelastic coupling and the use of static compensation for the active control of sound transmission across a panel subjected to a stochastic noise source.

The purpose and contribution of this work is to detail the performance which can be achieved in active structural acoustic control of aeroelastic systems through the use of static (constant-gain, output-feedback) compensation on square (equal inputs and outputs) systems with colocated transducers. The dual Levine–Athans method (Toivonen, 1985; Makila and Toivonen, 1987) was implemented to design a static compensator which was optimal with respect to a frequency-weighted cost function and chosen control-effort penalty. The system model was based upon a panel with pinned-boundary conditions, residing within an infinite baffle, and subjected to mean flow on one surface and a stationary acoustic half-space on the opposite. Radiation filters were designed to predict the rms sound power radiated into the half-space as outlined by Baumann *et al.* (1991), and linearized potential-flow theory was used in the aerodynamic model. The aeroelastic coupling was created as detailed by Frampton and Clark (1996), which provided a means for constucting a state-variable model of the aeroelastic, structural acoustic system.

The work presented herein provides a comparison be-

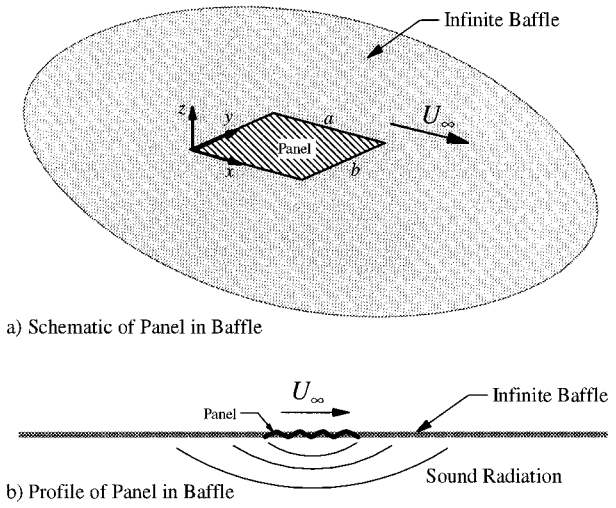

FIG. 1. Schematic diagram of aeroelastic, structural acoustic system.

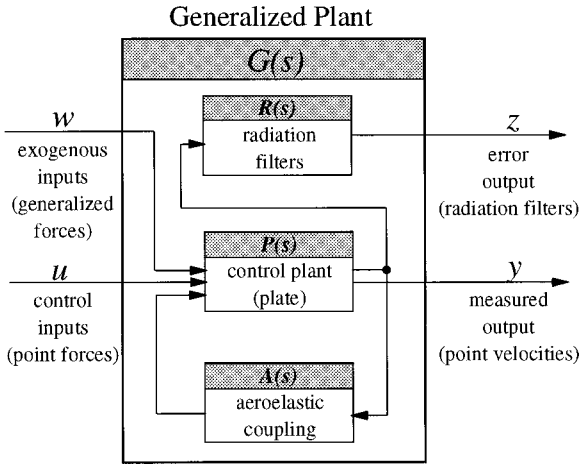

FIG. 2. Block diagram of generalized plant.

tween direct output-feedback control with static compensation (constant-gain feedback) and full state-feedback control (LQR). The LQR design for state feedback was computed to provide an upper bound on the performance which can be expected given the locations of the control actuators chosen. In all cases, for reasonable levels of control-effort penalty, active control systems incorporating static compensation yield performance which is comparable to that achieved with full state feedback. A parametric study is performed in this work, comparing the control system performance as a function of dynamic pressure under subsonic flow conditions. Additionally, the effect of control-effort penalty, the number of colocated control actuators used, and implementation of controllers designed for alternative flow conditions were studied. Results from this study indicate that a single, static, dissipative compensator can be designed to operate over all dynamic pressures corresponding to subsonic flow, increasing the transmission loss across the panel. Advantages of static compensation are less complexity in the control system implementation and the ease of generating a dissipative controller which is robust to model uncertainty.

I. MODEL DEVELOPMENT

A schematic diagram of the system is illustrated in Fig. 1. As depicted in Fig. 1(a), the panel is positioned within an infinite baffle, and air with mean velocity U_∞ flows over the surface of the panel in the x-direction. The panel has dimensions a and b in the x- and y-direction, respectively, with out-of-plane displacement occurring in the z-direction. As illustrated in Fig. 1(b), the opposite side of the panel is subject to a zero mean velocity (no-flow) condition, and the sound power radiated to this half-space is computed through the implementation of radiation filters derived from the Rayleigh integral.

A block diagram of the coupled system is illustrated in Fig. 2. Central to the block diagram are the panel dynamics, $P(s)$, which in this study were obtained from an assumed modes approach (Meirovitch, 1967). As illustrated, the output of the panel dynamics, $P(s)$, is coupled through the aerodynamic system, $A(s)$, which constitutes the aerodynamic response to the panel. This feedback through the fluid couples the panel modes and can potentially lead to divergence at Mach numbers less than 1 or flutter at Mach numbers greater than 1 in extreme cases. The dynamic coupling of the panel to the fluid influences the sound power radiated to the interior, as was demonstrated previously by Clark and Frampton (1996). The velocity of the panel in generalized coordinates is also coupled to the radiation filters, $R(s)$, which can be used to predict the sound power radiated as illustrated in Fig. 2. The generalized plant, $G(s)$, is the combination of all dynamics required for the design and synthesis of the control system.

The description of the aeroelastic, structural acoustic system can be divided into three sections: (1) panel model, $P(s)$; (2) aerodynamic model, $A(s)$; and (3) radiation-filter model, $R(s)$. Each of these models will be discussed in the following subsections.

A. Panel model

The partial differential equation of motion describing a thin, uniform panel including external-fluid loading and TBL loading can be expressed as follows:

$$\rho_s \frac{\partial^2 w(x,y,t)}{\partial t^2} + D\left[\frac{\partial^4 w(x,y,t)}{\partial x^4} + \frac{\partial^4 w(x,y,t)}{\partial x^2\,\partial y^2} + \frac{\partial^4 w(x,y,t)}{\partial y^4}\right] + p^a(x,y,z=0,t) + p^{\mathrm{tbl}}(x,y,z=0,t) = 0. \quad (1)$$

The coordinate system for the panel and associated flow was illustrated in Fig. 1. Note that the dynamic effect of the stationary, acoustic half-space is not considered in the model of the structural dynamic response of the panel.

A separable expansion solution is assumed using the *in vacuo* orthogonal panel eigenfunctions and generalized coordinates of the form

$$w(x,y,t) = \sum_{n=1}^{N} \Psi_n(x,y) q_n(t). \quad (2)$$

Substituting Eq. (2) into Eq. (1), multiplying by an arbitrary expansion function, $\Psi_m(x,y)$, and integrating over the domain yields a set of ordinary differential equations of the form

$$M_n[\ddot{q}_n(t)+\omega_n^2 q_n(t)]+\rho_a U_a^2 Q_n^a(t)+Q_n^{\mathrm{tbl}}(t)=0, \tag{3}$$

where the aerodynamic generalized forces are

$$Q_n^a(t)=\int_0^b\int_0^a \frac{p^a(x,y,z=0,t)}{\rho_a U_a^2}\Psi_n(x,y)dx\,dy, \tag{4}$$

and the turbulent boundary layer generalized forces are

$$Q_n^{\mathrm{tbl}}(t)=\int_0^b\int_0^a p^{\mathrm{tbl}}(x,y,z=0,t)\Psi_n(x,y)dx\,dy. \tag{5}$$

For the purpose of this study, $Q_n^{\mathrm{tbl}}(t)$ was chosen to be spectrally white and was used to excite each structural mode of the panel uniformly with stochastic independence. The desire was to place greater emphasis on characterizing the maximum transmission loss which could be achieved with the active control system, as opposed to detailing the operation with a frequency-shaped disturbance.

B. Aerodynamic model

Recent efforts by Frampton *et al.* (1996) and Frampton and Clark (1996) have been devoted to the development of reduced-order models of aerodynamics associated with full potential-flow theory cast in state-variable form. Clark and Frampton (1996) also detailed the implications of aeroelastic coupling on structural acoustic radiation. A brief overview of the aeroelastic model is presented herein and greater detail can be found in the references provided.

1. Transform solution to the linearized potential-flow generalized forces

Consider the case of a simply supported panel with the following eigenfunctions:

$$\Psi_n(x,y)=\sin\left(\frac{n\pi}{a}x\right)\sin\left(\frac{m\pi}{b}y\right). \tag{6}$$

The aerodynamic generalized forces, $Q_n^a(t)$, are found by solving the partial differential equation describing the velocity potential in an inviscid, irrotational fluid moving parallel to the *x*-axis

$$\nabla^2\phi^a-\frac{1}{a_\infty^2}\left[\frac{\partial^2\phi^a}{\partial t^2}+2U_a\frac{\partial^2\phi^a}{\partial x\,\partial t}+U_a^2\frac{\partial^2\phi^a}{\partial x^2}\right]=0. \tag{7}$$

subject to the boundary conditions for a panel embedded in an infinite baffle

$$\left.\frac{\partial\phi^a}{\partial z}\right|_{z=0}=\begin{cases}\dfrac{\partial w}{\partial t}+U_a\dfrac{\partial w}{\partial x}, & \text{on the plate,}\\ 0, & \text{off the plate,}\end{cases} \tag{8}$$

and a finiteness or radiation condition as *z* approaches infinity.

The solution can be obtained by taking a Laplace transform with respect to time and a double-Fourier transform with respect to the *x* and *y* spatial coordinates. The transformation is applied to Eqs. (7), (8), and Bernoulli's equation

$$p^a=-\rho_a\left[\frac{\partial\phi^a}{\partial t}+U_a\frac{\partial\phi^a}{\partial x}\right], \tag{9}$$

while incorporating Eq. (2). Details of the solution are discussed by Dowell (1967, 1975).

The solution yields the generalized aerodynamic forces on the panel which are given here as

$$Q_n^a(t)=\sum_{m=1}^{N} Q_{mn}^a(t), \tag{10}$$

where $Q_{mn}^a(t)$ is the force on the *n*th panel mode due to motion of the *m*th panel mode such that

$$Q_{mn}^a(t)=q_m(t)S_{mn}+\dot{q}_m(t)D_{mn}+\int_0^t q_m(\tau)H_{mn}(t-\tau)d\tau+\int_0^t \dot{q}_m(\tau)I_{mn}(t-\tau)d\tau, \tag{11}$$

where

$$S_{mn}=\frac{1}{M}\int_0^a\int_0^b\frac{\partial\Psi_m}{\partial x}\Psi_n\,dy\,dx, \tag{12}$$

$$D_{mn}=\frac{1}{MU_a}\int_0^a\int_0^b\Psi_m\Psi_n\,dy\,dx, \tag{13}$$

$$H_{mn}(t)=-\frac{U_a}{4\pi^2M^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}G_{mn}i\alpha\sqrt{\alpha^2+\gamma^2}\times e^{-i\alpha U_a t}J_1[a_\infty t\sqrt{\alpha^2+\gamma^2}]d\alpha\,d\gamma, \tag{14}$$

$$I_{mn}(t)=-\frac{1}{4\pi^2M^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}G_{mn}\sqrt{\alpha^2+\gamma^2}\times e^{-i\alpha U_a t}J_1[a_\infty t\sqrt{\alpha^2+\gamma^2}]d\alpha\,d\gamma, \tag{15}$$

and

$$G_{mn}=\int_0^a\int_0^b\Psi_m(x,y)e^{-i(\alpha x+\gamma y)}dy\,dx\int_0^a\int_0^b\Psi_n(x,y)\times e^{i(\alpha x+\gamma y)}dy\,dx. \tag{16}$$

More information on this modeling technique may be found in the reference by Frampton *et al.* (1996). A method of approximating the generalized forces and constructing the reduced-order model for the aeroelastic coupling can be found in the references by Clark and Frampton (1996) and Frampton and Clark (1996).

A plot of the aeroelastic response of the panel as a function of Mach number is presented in Fig. 3. The results presented were computed from the H_2 norm of the system, consisting of inputs corresponding to forces in generalized structural coordinates and outputs corresponding to velocities in generalized structural coordinates. The frequency response depicted in Fig. 3 represents the rms power associated with the system outputs when driven by independent, stochastic noise sources. (Greater detail of system norms can be found in the reference by Boyd and Barratt, 1991.) As illustrated, the dynamics of the aeroelastic system vary significantly as a function of Mach number, and significant energy dissipation due to the fluid-structure coupling is noted near Mach 0.9.

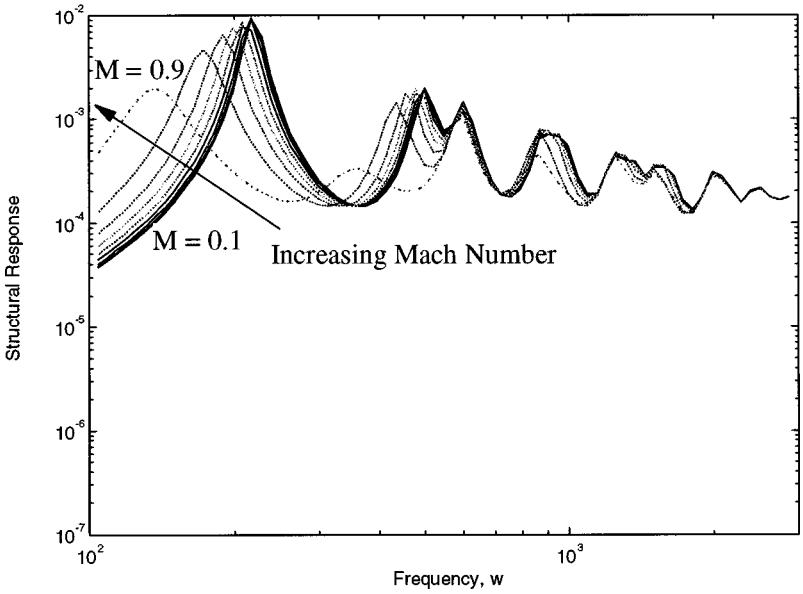

FIG. 3. rms structural response of an aeroelastic system.

C. Radiation filter model

Radiation filters were originally introduced by Baumann *et al.* (1991) for active structural acoustic control such that the dynamic response of the system could be augmented to incorporate additional states (radiation modes) which provide a measure of sound power radiated. The objective of the work was to produce a cost functional in the LQR/LQG formulation which, when minimized, would guarantee optimal performance with respect to structural acoustic control as opposed to structural control. The augmentation of system dynamics in the formulation of a ''frequency-shaped'' cost was originally proposed and detailed by Gupta (1980) and was extended to other exemplary applications. Thomas and Nelson (1995) also utilized the radiation filters for their feedback control-system realization, and the basic formulation for the filters can be found in their paper and that of Baumann *et al.* (1991).

For the infinite baffle, a frequency-dependent expression for the power radiated can be rendered by integrating an expression for the acoustic intensity over the hemisphere. Since the pressure can be obtained from Rayleigh's integral, the far-field acoustic intensity in the half-space is easily obtained. The form of the radiated power is

$$\Pi = \frac{1}{\pi}\int_0^\infty \mathbf{V}^H(j\omega)\mathbf{M}(j\omega)\mathbf{V}(j\omega)d\omega, \tag{17}$$

where Π is the total radiated power, $\mathbf{V}(j\omega)$ is matrix of the Fourier transform of modal velocities, and $\mathbf{M}(j\omega)$ represents the frequency-dependent interaction between structural modes required to compute the radiated power. The self- and mutual-radiation efficiencies of the structural modes can be readily obtained from this matrix as outlined by Lomas and Hayek (1977), and more recently by Cunnefare (1991).

If the Laplace domain equivalent of the matrix $\mathbf{M}(j\omega)$ is expressed as $\mathbf{M}(s)$, then one can express the matrix in terms of a filter and its parahermitian conjugate

$$\mathbf{M}(s) = \mathbf{R}^T(-s)\mathbf{R}(s), \tag{18}$$

where $\mathbf{R}(s)$ is the radiation filter as detailed by Baumann *et al.* (1991). This filter can be obtained through spectral factorization, as outlined by Francis (1986), and a state-variable model for the filter can be used to augment the system dynamics. The time-averaged sound power radiated from the structure when driven by a white-noise excitation can thus be computed from the output of these augmented states. For greater detail of the design of radiation filters, the reader is referred to the work of Baumann *et al.* (1991).

The radiation filters used in the work presented herein were compared against the self- and mutual-radiation efficiencies for several exemplary structural modes in the prior work by Clark and Frampton (1996). In Fig. 4, the rms sound power is plotted as a function of frequency. As in the previous section, the inputs correspond to independent, stochastic forces in generalized coordinates. However, for this case, the output of the generalized plant, $G(s)$, corresponding to the rms sound power is presented. Again, the effect of energy dissipation due to aeroelastic coupling is evident, and less sound power is radiated with increasing Mach number for the same level of forcing input. It should be noted that the response results presented here are normalized by the forcing input or TBL pressure-fluctuation levels. In reality, these pressure fluctuations are proportional to dynamic pressure or (for a fixed altitude) Mach number squared (Dowell, 1975). Hence, the dimensional or actual responses will increase with Mach number relative to those normalized responses shown here. For example, as one goes from $M=0.1$ to $M=0.9$, the increase will be by a factor of $(0.9/0.1)^2=81$. This may be important in practice, if the control authority of the actuators is limited (see Sec. II). Details of the plate and fluid properties used to generate the results presented are documented in Sec. III.

II. CONTROLLER SYNTHESIS

For the purpose of comparison, two different types of control laws, state feedback and output, constant-gain feedback, were investigated. Both sought to minimize a linear

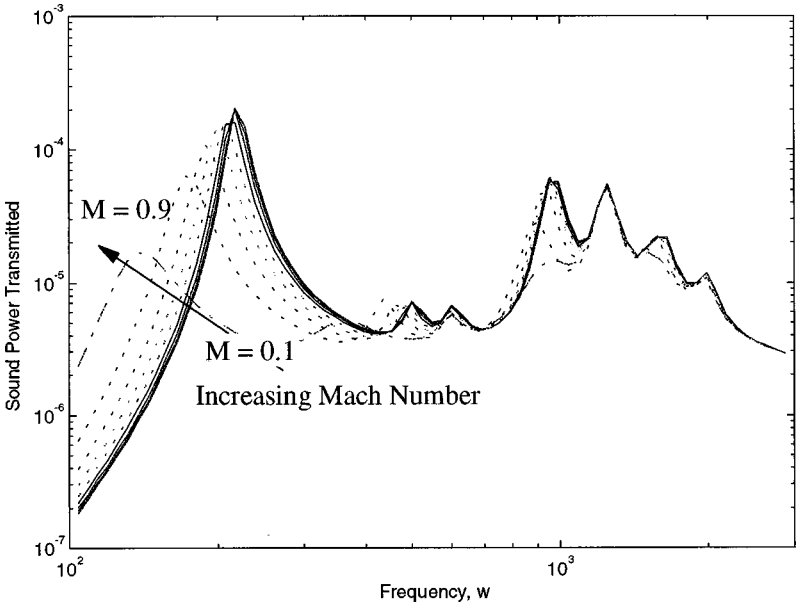

FIG. 4. rms structural acoustic response of an aeroelastic system.

quadratic cost function which balanced performance with control effort. State-feedback methods are well suited for this problem and optimal LQR gains provide an upper bound to obtainable performance. However, the same problem can be posed with constraints such that the control action consists of a matrix of constant gains applied to the sensor signals. Although this type of control is far more restrictive than state feedback, the ease of implementation makes its consideration important.

A. State-feedback control

The optimal control problem for the system,

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}_c\mathbf{u}_c, \tag{19}$$

$$\mathbf{y}_p = \mathbf{C}_p\mathbf{x}, \tag{20}$$

is to find the input signal, $\mathbf{u}_c$, which minimizes the cost function

$$J = \int_0^\infty \mathbf{y}_p^T\mathbf{Q}\mathbf{y}_p + \mathbf{u}_c^T R\mathbf{u}_c\, dt, \tag{21}$$

where $\mathbf{Q}$ is a semipositive definite performance weighting, R is the positive definite control-effort penalty, $\mathbf{y}_p$ is the performance output, and $\mathbf{u}_c$ is the actuator-control signal. The performance output is a weighted measure of the acoustic radiation and can be written as a linear function of the augmented states, i.e., $\mathbf{y}_p = \mathbf{C}_p\mathbf{x}$. Therefore, Eq. (21) can be written

$$J = \int_0^\infty \mathbf{x}^T\tilde{\mathbf{Q}}\mathbf{x} + \mathbf{u}^T R\mathbf{u}\, dt, \tag{22}$$

where $\tilde{\mathbf{Q}} = \mathbf{C}_p^T\mathbf{Q}\mathbf{C}_p$. For state feedback, the input is of the form $\mathbf{u} = -\mathbf{K}\mathbf{x}$, and the minimization of Eq. (21) yields the well-known linear quadratic regulator [Kalman *et al.* (1963); Anderson *et al.* (1990)]. This approach is often used for generating an optimal linear-control law, and its application to structural acoustic problems has been detailed elsewhere [Baumann *et al.* (1991); Thomas and Nelson (1995)].

Implementation of a state feedback-control law requires full knowledge of the state, which typically must be estimated from a limited set of measurements. When employing radiation filters, especially those derived from curve fitting, the augmented plant can become very high order. This makes practical implementation of a state estimator difficult. Nevertheless, the state-feedback gains provide an upper bound for the performance of the simpler constant-gain controllers. They are computed here for comparison and closed-loop results are derived assuming perfect state information is available.

B. The dual Levine–Athans algorithm

The minimization of Eq. (21) can also be carried out under the assumption that $\mathbf{u} = \mathbf{G}\mathbf{y}_s = \mathbf{G}\mathbf{C}_s x$, where $\mathbf{y}_s$ is the output signal from available measurements. This implies that the control signal is generated as a constant-gain matrix times the sensor signals. This choice of control input forms a parametric LQ problem, and several techniques of obtaining the optimal controller have been investigated (Makila and Toivonen, 1987). However, unlike the state-feedback case, there is still no guaranteed unique solution. The approach taken here is a variation on the method proposed by Levine and Athans (1970), and its development follows Toivonen (1985). It has the advantage of being globally convergent to a solution from a stabilizing initial guess, and the solution satisfies the necessary conditions for optimality.

Consider the cost function in Eq. (21); by letting $\mathbf{u} = \mathbf{G}\mathbf{C}_s\mathbf{x}$ we can write

$$J = \int_0^\infty \mathbf{x}^T(\tilde{\mathbf{Q}} + \mathbf{C}_s^T\mathbf{G}^T R\mathbf{G}\mathbf{C}_s)\mathbf{x}\, dt. \tag{23}$$

This cost function depends on initial conditions of the state. Given random initial conditions with $E[\mathbf{x}(0)^T\mathbf{x}(0)] = \mathbf{P}$, the cost can then be expressed using the trace operator as

$$J = \mathrm{tr}[(\tilde{\mathbf{Q}} + \mathbf{C}_s^T\mathbf{G}^T R\mathbf{G}\mathbf{C}_s)\mathbf{L}] = \mathrm{tr}(\mathbf{K})\mathbf{P}, \tag{24}$$

where $\mathbf{K}$ and $\mathbf{L}$ satisfy the equations

$$0 = \mathbf{K}\mathbf{A}_c + \mathbf{A}_c^T\mathbf{K} + \mathbf{C}_s^T\mathbf{G}^T R\mathbf{G}\mathbf{C}_s + \tilde{\mathbf{Q}}, \tag{25}$$

$$0 = \mathbf{L}\mathbf{A}_c + \mathbf{A}_c^T\mathbf{L} + \mathbf{P}, \tag{26}$$

with $\mathbf{A}_c = \mathbf{A} - \mathbf{B}\mathbf{G}\mathbf{C}_s$. The gain

$$\mathbf{G}_{\text{opt}} = R^{-1}B^T\mathbf{K}\mathbf{L}\mathbf{C}_s^T(\mathbf{C}_s\mathbf{L}\mathbf{C}_s^T)^{-1}, \tag{27}$$

is a stationary point on the loss function, i.e., $dJ/d\mathbf{G} = 0$. Therefore, $\mathbf{G}_{\text{opt}}$ satisfies the necessary conditions for optimality.

The procedure for calculating $\mathbf{G}_{\text{opt}}$ involves first determining an initial gain matrix, $\mathbf{G}_0$, which stabilizes the system. Equation (27) is then solved for $\mathbf{L}$, and the nonlinear equations

$$0 = \mathbf{K}\mathbf{A}_c + \mathbf{A}_c^T\mathbf{K} + \mathbf{C}_s^T\mathbf{G}^T R\mathbf{G}\mathbf{C}_s + \tilde{\mathbf{Q}}, \tag{28}$$

$$\mathbf{G} = \mathbf{G}_0 + \theta(R^{-1}\mathbf{B}^T\mathbf{K}\mathbf{L}\mathbf{C}_s^T(\mathbf{C}_s\mathbf{L}\mathbf{C}_s^T)^{-1} - \mathbf{G}_0), \tag{29}$$

must be solved for $\mathbf{G}$ and $\mathbf{K}$. The scalar parameter θ is constrained to $0 < \theta < 1$, and can be adjusted downward to ensure that $J(\mathbf{G}) < J(\mathbf{G}_0)$. The numerical algorithm proceeds by iterating on Eqs. (26), (28), and (29), and updating $\mathbf{G}$ until $|\mathbf{G}_{i+1} - \mathbf{G}_i| < \epsilon$. In practice, $\mathbf{G}_0 = 0$ was used as the initial stabilizing gain matrix and $\mathbf{P}$ was chosen to be $\mathbf{B}_d^T\mathbf{B}_d$, where $\mathbf{B}_d$ described a disturbance input influence matrix. Convergence of the algorithm on the 281-state model typically occurred within 25 iterations.

III. DESCRIPTION OF MODEL

The following parameters were used to construct the model used in this study: $a = 0.60$ m, $b = 0.51$ m, $h_s = 0.0022$ m, $E_s = 7.1 \times 10^{10}$ Pa, $\rho_s = 2700$ kg/m^3, $\xi_s = 0.05$, $\rho_a = 0.42$ kg/m^3, and $a_a = 300$ m/s. The plate modes included in the structural model correspond to the first 30 modes of the structure (ordered by natural frequency). However, only the first ten modes and the structural acoustic interaction of these modes were included in the model of the radiation filters. As detailed by Clark and Cox (1996), more modes are required in the structural model to compute the optimal static compensator and predict realistic closed-loop performance. However, fewer modes are required to accurately predict the sound power radiated over the desired bandwidth of emphasis for structural acoustic control. Additionally, the aerodynamic coupling between the structure and the fluid was limited to the first ten modes, as the influence is most significant over the desired bandwidth for these modes.

The material properties of the panel correspond to that of aluminum and the aerodynamic properties correspond to an altitude of 10 km. It should be noted that a realistic estimate of the damping ratio $\xi = 0.05$ was incorporated in the model to provide reasonable predictions of performance for actual aircraft panels.

The number of disturbance inputs equaled the number of structural modes included: 30. The disturbance path corresponded to independent excitation of all structural modes concurrently in generalized coordinates with a spectrally white input, which effectively assumes a uniform spatial distribution of the TBL pressures over the panel. While it can be argued that this method of excitation ignores the frequency-shaped weighting which would result from realistic TBL noise sources, it does serve to isolate the aeroelastic, structural acoustic coupling of the panel and provide a means for evaluating the active insertion loss (AIL) as detailed by Smith and Clark (1996).

FIG. 5. Schematic diagram of structure with corresponding transducer-pair locations.

The number of colocated transducer pairs used in the closed-loop system was varied between one and five. Point force and colocated point-velocity sensors were selected for this preliminary study due to the positive real behavior of such colocated transducer pairs. The locations of the control forces were selected randomly so as not to emphasize the control of any particular structural mode. The positions are displayed in the schematic diagram presented in Fig. 5. In addition to the displayed locations of the actuators in physical coordinates, the locations are tabulated in percent of the structure length in the *x*- and *y*-dimensions, respectively. The transducer pairs are numbered, and when one pair is used for control, the transducer pair labeled 1 is used, when three pairs are used for controls, transducer pairs labeled 1, 2, and 3 are used.

IV. RESULTS

Results presented in this section detail the performance of static compensation and compare this with state-feedback control for a single-input, single-output (SISO), three-input, three-output (3I3O), and five-input, five-output (5I5O) control system with colocated transducers. For the cases considered here, the augmented model has 281 states: 60 structural states, 55 aerodynamic states, and 166 states for the radiation filters. Clearly, state estimation for this *reduced-order* model of the system is not reasonable. However, closed-loop performance using static compensation is compared to full state feedback to provide a means of evaluating the performance of a practical implementation of the active structural acoustic control system. The dimension of the colocated array, the control effort penalty, and the effect of variation in Mach number (dynamic pressure) are studied parametrically to provide insight into the physics and practical implementation issues such as robustness to variation in plant dynamics. For each test case presented, the rms sound power radiated by the structure and the rms structural response to a random excitation are plotted as a function of frequency. These values represent the sum of the square of the singular values at each frequency for the MIMO transfer function from disturbance to acoustic power and modal velocity, respectively. Addi-

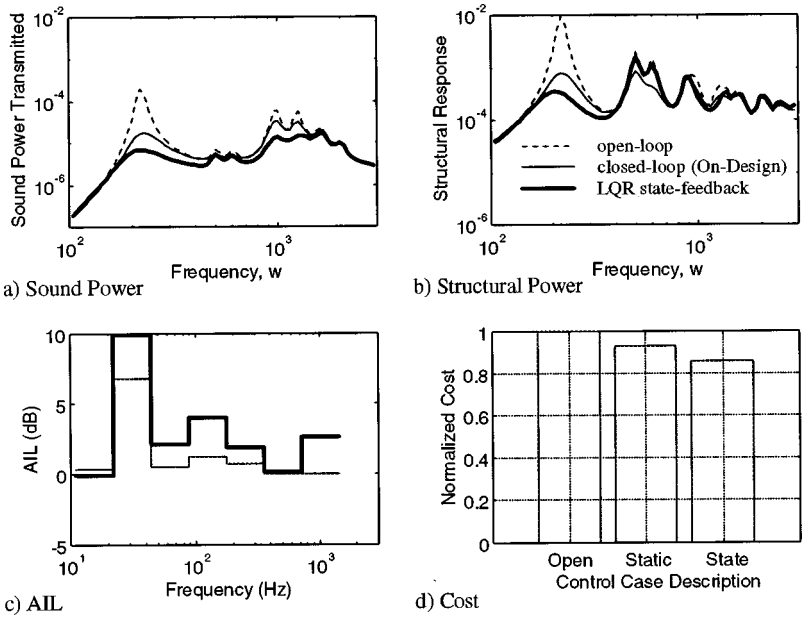

FIG. 6. Comparison of open- and closed-loop response for static and state-feedback control utilizing three colocated transducer pairs and a control-effort penalty of $R=10^{-5}$ for a flow condition of Mach 0.1.

tionally, the normalized cost function (ratio of closed loop to open loop) are plotted as is the active insertion loss (AIL) (Smith and Clark, 1996) for each active control system implementation.

A. Typical result

All of the results presented in this section will follow the general format outlined in this typical result. As illustrated in Fig. 6, results summarizing the (a) sound power transmitted, (b) the structural response, (c) the AIL, and (d) the normalized cost for a Mach number of 0.1 are presented. In Fig. 6(a), the static compensator is compared to full state feedback with the same performance and control-effort penalty ($R=10^{-5}$). Three colocated point-force actuators and point-velocity sensors as illustrated in Fig. 5 and described in Sec. III were used for the case presented. As illustrated in Fig. 6(a), significant levels of attenuation are achieved near the fundamental mode of the panel. Additionally, the results presented in Fig. 6(b) indicate that the static compensator is dissipative, as the response of the out-of-bandwidth structural modes are not increased. The AIL is presented in Fig. 6(c), and as indicated, as much as 9 dB of attenuation is achieved in the octave band containing the fundamental panel mode. The AIL decreases with increasing frequency as is expected for an active structural acoustic control (ASAC) system. The normalized cost illustrated in Fig. 6(d) demonstrates that the state-feedback controller results in better overall performance, but for the given control-effort penalty, results achieved with static compensation are acceptable.

Test cases at higher subsonic Mach numbers were selected and are presented in the following subsections. However, rather than discuss each case independently, the results of various parametric cases are compared.

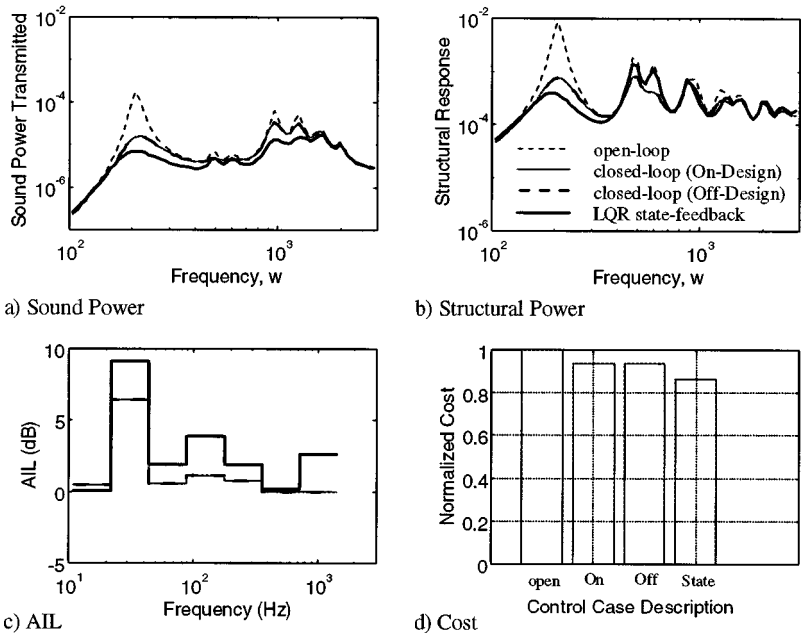

FIG. 7. Comparison of open- and closed-loop response for static and state-feedback control utilizing three colocated transducer pairs and a control-effort penalty of $R=10^{-5}$ for a flow condition of Mach 0.5, including an off-nominal design.

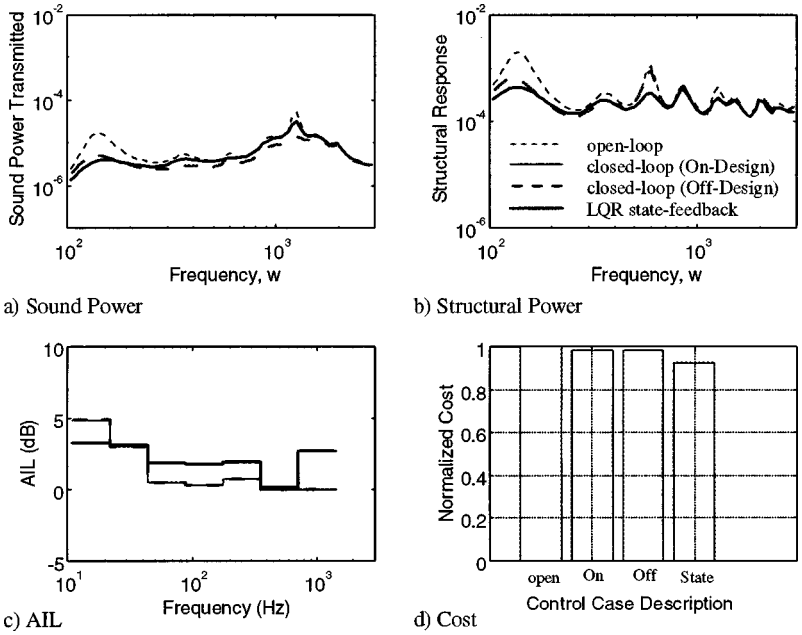

FIG. 8. Comparison of open- and closed-loop response for static and state-feedback control utilizing three colocated transducer pairs and a control-effort penalty of $R=10^{-5}$ for a flow condition of Mach 0.9, including an off-nominal design.

B. Variation in the Mach number and off-nominal design

In the following test cases, the control-effort penalty was maintained at $R=10^{-5}$; however, in addition to presenting the results for the optimal state-feedback controller and the optimal static compensator for each Mach number, the static compensator designed for operation at $M=0.1$ was also implemented for comparison of an *off-nominal design* and to provide a measure of robustness. As in the previous test case presented, three colocated transducer pairs were used to control the system. While the test cases presented are limited to Mach numbers of 0.5 and 0.9, additional test cases at Mach numbers ranging from 0.1 to 0.9 in increments of 0.1 were studied with similar results. For the results presented in Fig. 7, the Mach number was increased to 0.5. As illustrated in Fig. 7(a), the sound power transmitted in proximity to the resonant frequency corresponding to the fundamental mode was attenuated significantly. Due to the dissipative nature of the controller, spillover into higher-order structural modes was not a problem, and as much as 8 dB of AIL was achieved in the octave band containing the fundamental resonance. Additionally, one observes that the closed-loop response corresponding to the *off-nominal* design case yielded performance virtually identical to that achieved with the optimal static compensator. Thus, while the increase in Mach number altered the resonant behavior of the system, the static compensator design was relatively insensitive to this change in dynamics.

The Mach number was increased to 0.9, nearing the speed of sound, and as was illustrated in Figs. 3 and 4, the dynamics of the resonant behavior and inherent damping of the system were radically modified. An optimal static compensator was designed for this flow condition, and the closed-loop performance is compared to that of the off-

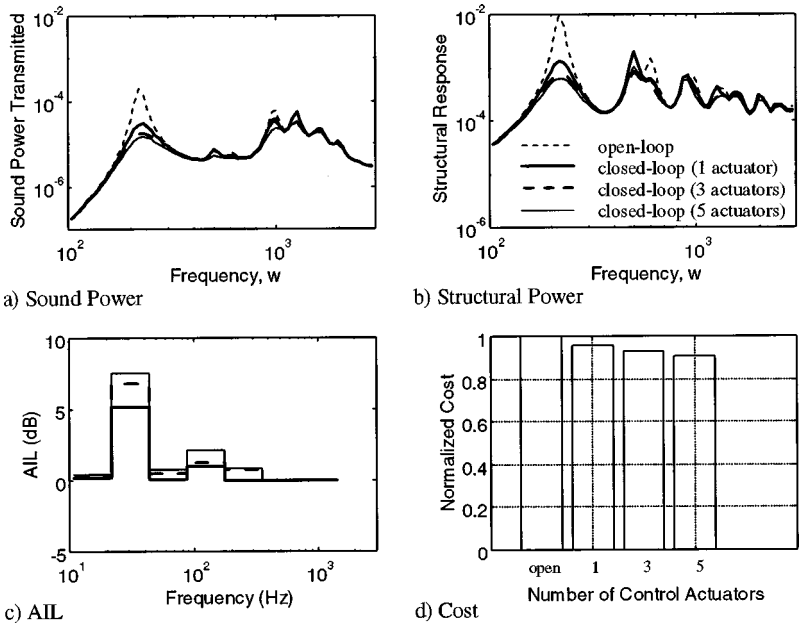

FIG. 9. Comparison of open- and closed-loop response for static compensation and variation in the number of transducer pairs implemented with a control-effort penalty of $R=10^{-5}$ and a flow condition of Mach 0.1.

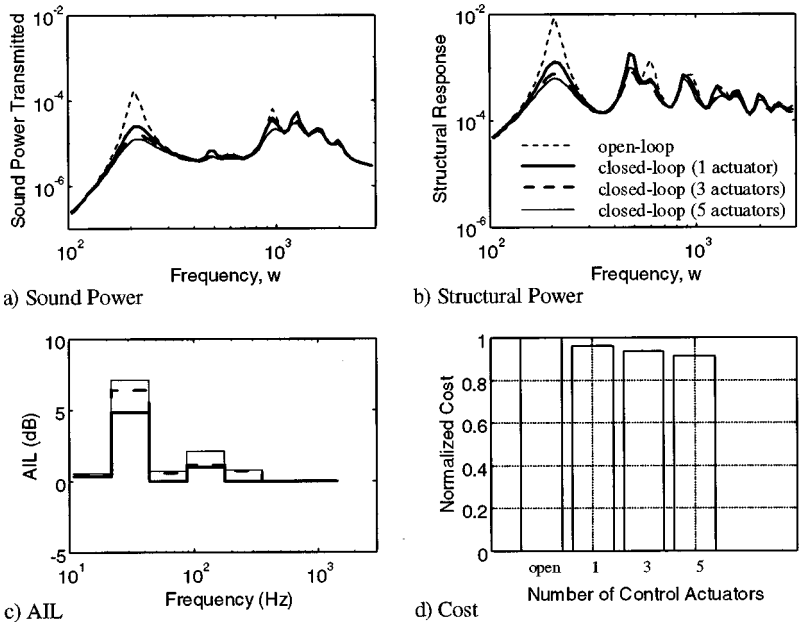

FIG. 10. Comparison of open- and closed-loop response for static compensation and variation in the number of transducer pairs implemented with a control-effort penalty of $R=10^{-5}$ and a flow condition of Mach 0.5.

nominal design and the optimal state-feedback controller in Fig. 8. As illustrated in Fig. 8(c), the AIL reaches a maximum of 5 dB in the octave band containing the fundamental mode. It is of interest to note that the static compensator performs better in this octave band than the state-feedback controller. This result is most likely due to the fact that the static compensator cannot modify the dynamics as a function of frequency, and thus couples most efficiently to the volumetric mode of the panel. Alternatively, the added-input impedance due to the aerodynamics decreases the performance penalty associated with the response in the octave band of the fundamental mode, hence, the state-feedback controller expends less effort at low frequency and more effort at high frequency. As in the results presented for the previous test case, the static compensator designed for operation at $M=0.1$ resulted in nearly identical performance to that of the static compensator designed for $M=0.9$. Due to the dissipative nature of the static compensators designed, spillover into higher-order structural modes was not a problem for the nominal or off-nominal control-system designs.

While the coefficients of the static compensators differed by 2% or 3%, the overall performance of the closed-loop system varied little as a function of Mach number or dynamic pressure for subsonic flow, including the test cases not presented in this article.

C. Variation in number of colocated transducer pairs

For the results presented in this section, the radiation filters were used to generate the performance penalty and the control-effort penalty was set to $R=10^{-5}$. This level of control-effort penalty was chosen since it provided reasonable control gains and associated control forces. The number

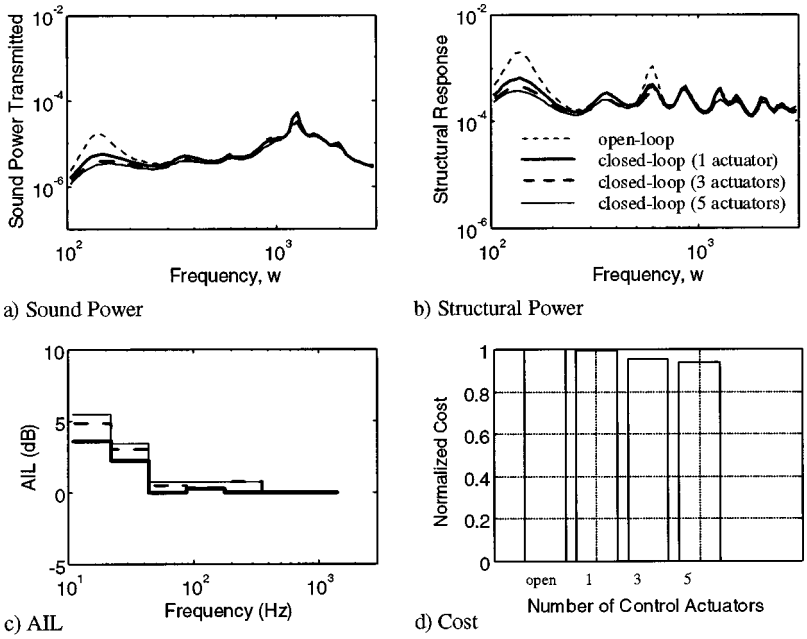

FIG. 11. Comparison of open- and closed-loop response for static compensation and variation in the number of transducer pairs implemented with a control-effort penalty of $R=10^{-5}$ and a flow condition of Mach 0.9.

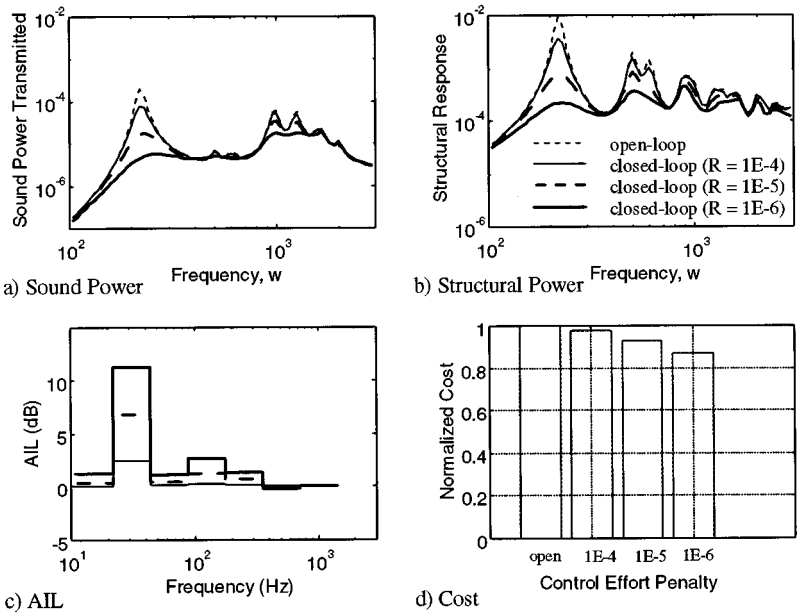

FIG. 12. Comparison of open- and closed-loop response for static compensation and variation in the control-effort penalty for a structure configured with three colocated transducer pairs and a flow condition of Mach 0.1.

of colocated transducer pairs was varied to demonstrate the effect of increasing transducer-pair order on performance.

In Figs. 9, 10, and 11, the closed-loop performance of static compensators for Mach numbers of 0.1, 0.5, and 0.9, respectively, are presented. Results from test cases corresponding to compensators incorporating 1, 3, and 5 colocated transducer pairs positioned on the panel as described in the previous section and illustrated in Fig. 5 are compared. Rather than discuss each test case and figure independently, general trends observed in all three figures are discussed concurrently. As indicated in (a) and (c) of Figs. 9, 10, and 11, the performance of the closed-loop system for decreasing the sound power transmitted increases with increasing order of colocated transducer pairs used in the control system for each Mach number. However, one should also recognize that the frequency-dependent characteristic of the controller does not change significantly with increasing transducer order. For example, the AIL of the control system improves in each octave band; however, the general trend in each octave band is the same. Additionally, as indicated in (b) of Figs. 9, 10, and 11, spillover into higher-order structural modes was not a problem. This result is again due to the dissipative nature of the controller.

D. Variation in the control-effort penalty

In the final set of comparisons, the variation in control-effort penalty is compared. For each of the test cases presented, the number of colocated transducer pairs was fixed at 3, and the Mach numbers used were 0.1, 0.5, and 0.9. The trends of the results presented in Figs. 12, 13, and 14, are discussed concurrently.

As was the case with increasing the number of transducer pairs used to control the aeroelastic, structural acoustic system, decreasing the control-effort penalty also results in improved performance. Although not shown graphically, the

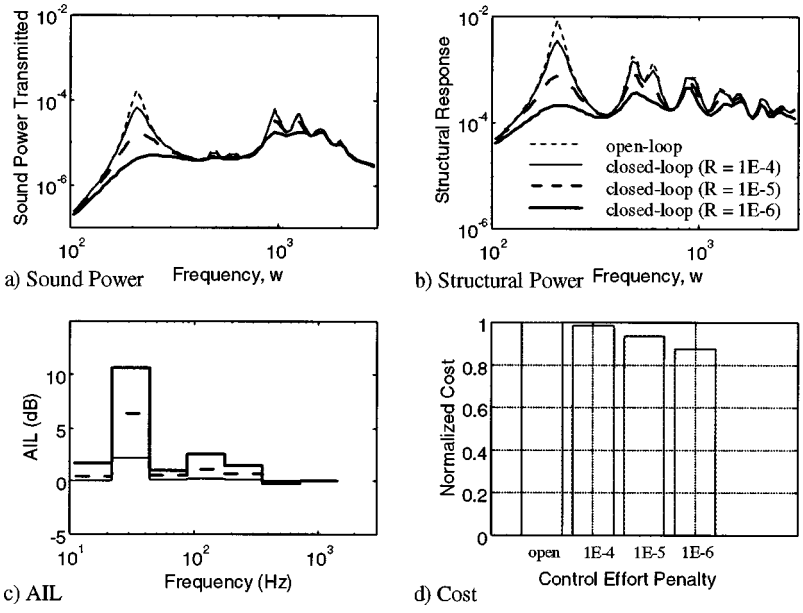

FIG. 13. Comparison of open- and closed-loop response for static compensation and variation in the control-effort penalty for a structure configured with three colocated transducer pairs and a flow condition of Mach 0.5.

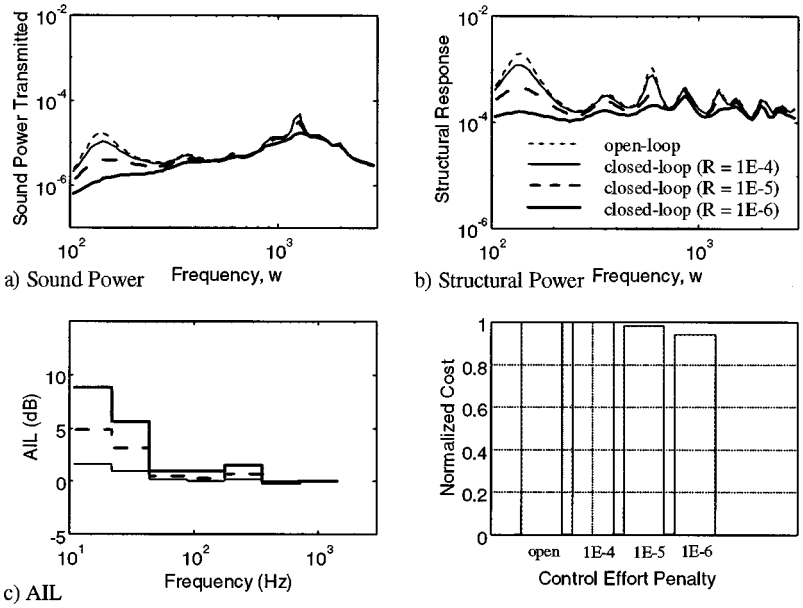

FIG. 14. Comparison of open- and closed-loop response for static compensation and variation in the control-effort penalty for a structure configured with three colocated transducer pairs and a flow condition of Mach 0.9.

ratio of control energy to disturbance energy was computed as a function of frequency. For a control-effort penalty of $R=10^{-4}$, the ratio of the control energy to disturbance energy is much less than 1, by more than an order of magnitude at any given frequency. For $R=10^{-5}$, the ratio is one order of magnitude less, which upon considering the performance achieved is an acceptable level of control effort. However, for $R=10^{-6}$, the ratio of control energy to disturbance energy is of the same order of magnitude over portions of the bandwidth. In general, a ratio less than 1 is desired for practical implementation. Using feedback control generally results in an increase in the input impedance of the system and a corresponding decrease in the control effort required. For practical reasons, one would not choose to implement a controller which requires as much energy as the disturbance imposes. However, for sake of comparison, the performance of a system implementing such a controller is presented (corresponding to $R=10^{-6}$). As illustrated in Figs. 12(c), 13(c), and 14(c), the AIL increases as the control-effort penalty is decreased. The legend for the lines is illustrated in (a) of each figure. All of the resulting static compensators were dissipative and the performance improved as the control-effort penalty was decreased. For reasons previously outlined, the static compensator resulting from a control effort penalty of $R=10^{-5}$ would be selected for practical implementation due to the relative performance achieved and the fact that the ratio of control energy to input energy is less than unity for this case.

V. CONCLUSIONS

A method of designing static-gain compensators for direct, output-feedback control of aeroelastic, structural acoustic systems was presented. Results from this work demonstrate that the sound transmission across a panel subjected to mean flow on one surface and a stationary half-space on the other can be decreased significantly through the use of colocated transducer pairs and simple static-gain, output-feedback control.

Further, results from this study demonstrate that the static-gain compensator design is relatively insensitive to variations in dynamic pressure (Mach number for fixed fluid properties), and thus a controller designed to operate at low subsonic speeds (Mach 0.1) is equally effective at higher subsonic speeds (Mach 0.9). The resulting controller is thus robust to variations in plant dynamics associated with aeroelastic coupling when multi-input, multi-output, colocated rate-feedback control is employed. While state-feedback control was shown to be more effective over the bandwidth, considering the order of the dynamic system, state estimation does not provide a practical alternative. For control systems designed with reasonable levels of control energy, the closed-loop performance of the static-gain compensator compared well with the full state-feedback control system design.

Future work will be devoted to the practical realization of the proposed control system. Additionally, the use of distributed piezoelectric transducers will also be considered.

This paper describes a method for measuring the vibrational velocity of the solid skeleton of a flexible porous sound-absorbing material. The method is based on a simple electromagnetic principle, involving a thin conductor that is structurally connected to the frame of the absorbent and placed in a magnetic field. The sample test results that are presented here demonstrate that links may be established between acoustic data and frame velocity measurements. In the presence of a high-amplitude sound field, measurements showed that the velocity of the frame exhibits very nonlinear properties, which cannot be explained by nonlinearities in the airborne sound wave. © *1999 Acoustical Society of America.* [S0001-4966(99)04001-1]

INTRODUCTION

Porous media have many applications in acoustics, mainly as sound absorbents. One such use is in dissipative mufflers, where structural motion of the solid frame of the absorbent can—at certain frequencies—have a significant effect on the sound-absorbing properties of the material. There has recently been interest in frame motion effects in porous media[1–3] and this work continues.

As a part of a theoretical, numerical, and experimental study[4,5] of the interaction between high-intensity sound and lightweight flexible porous media, we carried out measurements of the structural motion of the frame of the material as well as of sound pressure and acoustic particle velocity, up to frequencies of several hundred Hertz. Clearly, even small accelerometers cannot be used to measure frame motion in lightweight media such as glass fiber or plastic foams because of the mass-loading effect, and some alternative method must be employed. Laser methods might seem attractive, but they could only be used to measure the vibrational motion of the surface of the material and would also require the use of transparent walls in a duct containing the porous material. An alternative method was devised in the present investigation, involving the use of a thin metallic wire passing through the porous material and placed normal to a magnetic field. The electromotive force between the ends of the wire then gave a measure of the average vibrational velocity of the material along the length of the wire, normal to the axis of the wire and to the direction of the magnetic field. This method is the antithesis of remote sensing methods such as laser techniques, in that the sensing element is actually built into the test structure. The present method can, in principle, also be applied at levels of acoustic excitation lower than those employed in the present study.

In this paper, the above experimental technique for the measurement of frame vibration is outlined, the experimental apparatus is described and some experimental results are presented and discussed.

I. A NEW METHOD OF MEASUREMENT OF THE FRAME VELOCITY

A. Principles of the method and sources of error in the measurements

For the sake of simplicity it will be assumed that a one dimensional sound wave passes through a flexible porous medium and that the structural motion is also one dimensional, in the x direction, as illustrated in Fig. 1.

The motion of the frame of the porous medium will be driven by the oscillatory fluid motion via the fluid/structural coupling mechanism involving both viscous and (at high acoustic levels) inertial forces. A magnetic field is applied to the porous medium and is assumed to be uniform and directed normally to the x axis. A thin, flexible, metallic wire having a thin surface layer of adhesive is threaded through the pores of the material (which is assumed to be of a sufficiently open structure so as to permit this without any significant distortion of its structure), and runs normal to the x axis and to the direction of the magnetic field.

In general, the electromotive force (emf) over a length L of the wire will be given by

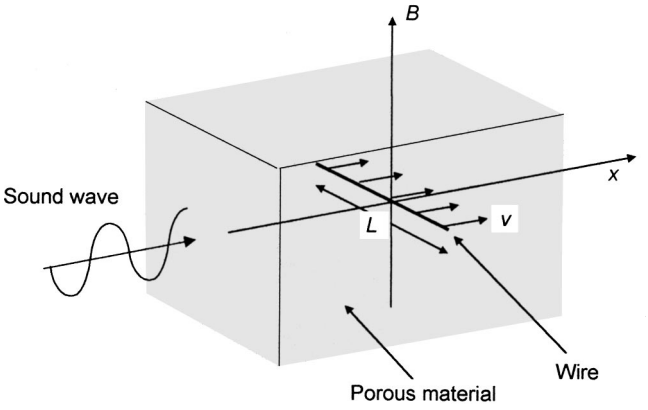

FIG. 1. Orientation of sound propagation, wire, and magnetic field.

$$E = \int_L (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{L}, \tag{1}$$

where **v** is the velocity vector of the wire at any point, **B** is the magnetic field vector at the same point, and $d\mathbf{L}$ is the relative position vector between the ends of an element of wire having length dL. In the present case, if **v**, **B**, and $d\mathbf{L}$ are assumed always to be normal to one another and $|\mathbf{B}|$ is assumed constant, we may write Eq. (1) simply as

$$E = \int_L v B \, dL = \langle v \rangle B L, \tag{2}$$

where $\langle v \rangle$ is the average of v along the length of the wire. Provided B—the magnitude of the magnetic field strength—is known, the emf E, developed along the length of the wire embedded in the porous medium, gives a measure of the average vibrational velocity of the wire along its length.

For Eq. (2) to give a measure of the vibrational velocity of the solid frame of the porous medium in the *absence* of the wire, it must be assumed that the wire has the same vibrational velocity as the frame and furthermore that the presence of the wire does not affect the frame motion. A detailed analysis of this problem is beyond the scope of the present investigation and would involve the solution of the equations of motion of the frame and wire in two dimensions, including both compressional and shear wave effects in the frame. Instead, we rely here on experimental data indicating that there is no significant dependence of the measured frame velocity on the diameter of the wire, for a given wire material. The experimental arrangement is described in Sec. II, but it is only the experimental data, taken for two differing thicknesses of wire, that are of interest at this point. The test material was ''Bulpren'' foam of 72 pores per inch (ppi) (see Sec. II for further details), and the wires used were of tinned copper, 40 and 140 μm diameter. These wires were threaded through the absorbent by using a fine needle. Two notionally identical, but different, samples of foam were employed in the tests and the wires were inserted at the same position in both samples. Two separate samples were used because it was assumed that the damage incurred to the sample by insertion of the wire would render the sample useless for further tests once the wire had been removed. The test frequency was 120 Hz, and—for identical incident sound fields in the two cases—the rms velocity amplitude of frame vibration was found to differ by 5% between the two tests. This small difference could have been attributable to variations in mechanical properties between the two samples of foam as much as to the effect of the mass of the wire, and in any case was taken to signify that, for the range of wire thickness and for materials similar to those used in the tests, there was no significant mass-loading effect of the wire on the absorbent. Time constraints precluded the repetition of these tests at higher frequencies, but it is thought that the wire and frame velocities would be closely similar up to at least 1 kHz, particularly in the case of the 40-μm wire. Any inertial effects caused by the wire—likely to be significant only at high frequencies—could be minimized by the use of a smaller diameter wire.

It is almost inevitable that there would be ''end effects'' in this method of measurement of the frame velocity, caused by small lengths of wire moving in the magnetic field but not embedded in the porous medium, since the ends of the wire would need to bend at some point in order to accommodate the motion of the wire. These can be minimized by careful design and should, in any case, be small. Some idea of their magnitude is given in the following subsection on calibration.

A further possible source of error, that could, in principle, be of concern at higher frequencies, relates to any structural resonance effects that might occur in the unsupported lengths of wire within the absorbent, between the points at which it is in contact with the solid frame of the porous medium. Again, a detailed treatment of this effect is hardly possible unless comprehensive information is available concerning the effective boundary conditions at the contact points and the distribution of unsupported lengths of wire. We can, however, make order-of-magnitude estimates of the resonance frequencies. The 140-μm-diam wire was used in the great majority of the experimental tests in view of its relative robustness and ease of handling, so we base our estimates on this. The coarser of the two foam sound-absorbing materials used in the experiments had 42 ppi, so that a typical pore dimension was about 0.6 mm. Supposing the wire was effectively simply supported every five pore dimensions, we may now estimate[6] the fundamental resonance of an unsupported length of wire—in isolation from the rest of the wire—as $f_1 = (\pi/2l^2)\sqrt{EI/\rho A}$, where l is the

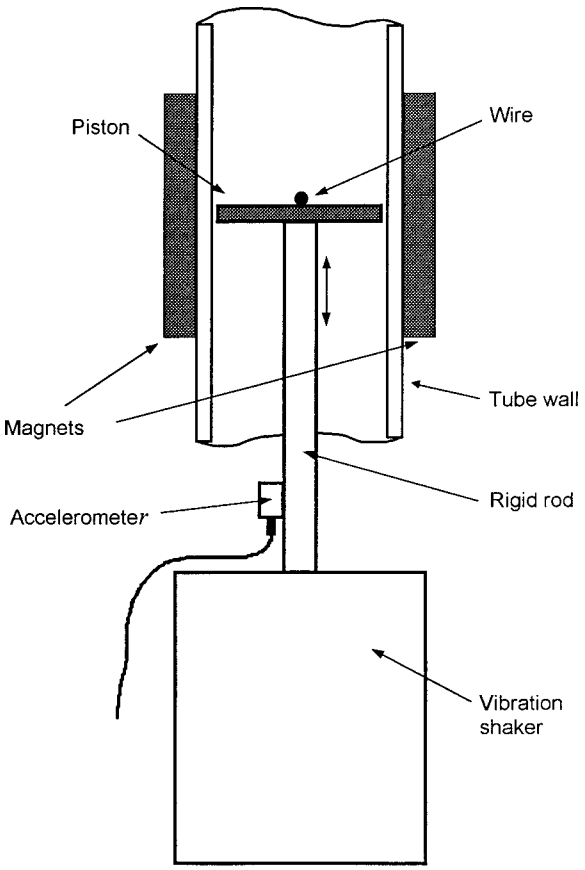

FIG. 2. Calibration arrangement.

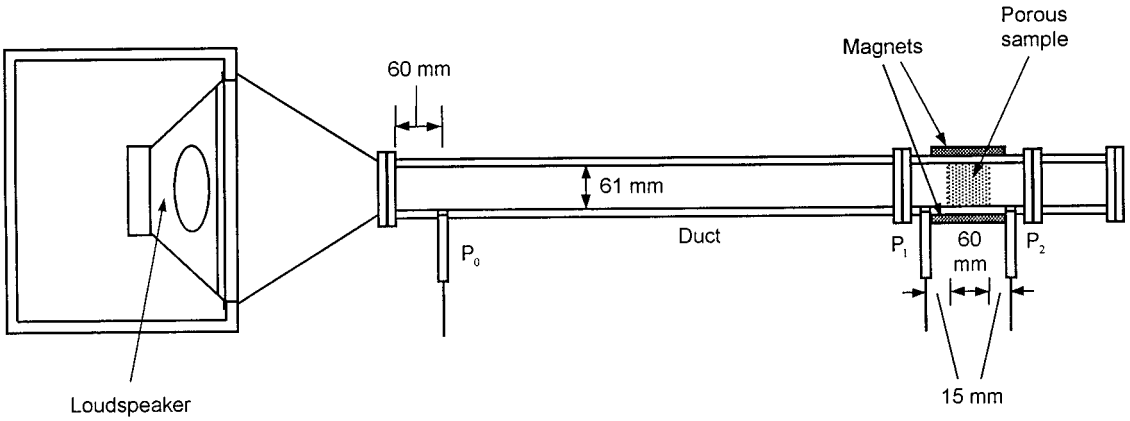

FIG. 3. Experimental apparatus.

length of the wire between supports, E is the Young's modulus of the wire material, ρ its density, I its second moment of area about the neutral plane, and A its cross-sectional area. For a copper wire as above with $l=3$ mm, we find $f_1 \approx 22$ kHz, which is well above the frequency range of interest. It is likely that l has been overestimated here, but even if the wire were supported only every ten pore dimensions, we should have $f_1 \approx 4.5$ kHz, which is still safely clear of the upper frequency of interest. It therefore seems unlikely that resonance effects in the wire should be of any concern.

B. Calibration of the system

The magnetic field in the experimental apparatus was provided by two identical ferrite permanent magnets, measuring $100\times151\times25$ mm. These were clamped firmly to opposite sides of a perspex tube with 19-mm walls and an internal cross section of 61×61 mm (see Sec. II for details). The distance between the opposite faces of the magnets was therefore 99 mm. The magnetic field strength at the position of the wire was measured by means of a Gauss meter with a Hall probe, and was found to vary between 0.05856 and 0.0602 Tesla along the length of the wire, the average value being 0.0596 Tesla. This figure is accurate to about 1%.

Although the emf measured at the ends of the wire should be proportional to the frame velocity via a coefficient which can be directly calculated from a knowledge of the magnetic field strength and length of the wire (see Sec. I A), a separate test was carried out in order to assess the magnitude of any extraneous effects that might cause departures from the theoretical estimates of frame velocity.

A rod of nonferromagnetic plastic material was attached to a Brüel & Kjær (B&K) vibration exciter type 4809 and placed in the section of the rectangular tube in which the porous samples were tested. A conducting wire, 140 μm in diameter, was glued to a square piston of side 55 mm, which was attached to the upper end of the rod as shown in Fig. 2. The length of the (aluminum) rod was such that no axial vibrational resonance effects occurred within the frequency range of the calibration experiments.

Because the voltage to be detected was very low it was necessary to amplify the signal, and accordingly an amplifier with a gain of 1300 was built. The amplifier was battery powered and had a very high input impedance in order to reduce noise caused by possible ground loops and extraneous induction effects. The voltage signal from the wire was fed to the amplifier through conducting wires that were glued to the tube walls in order to eliminate spurious signals caused

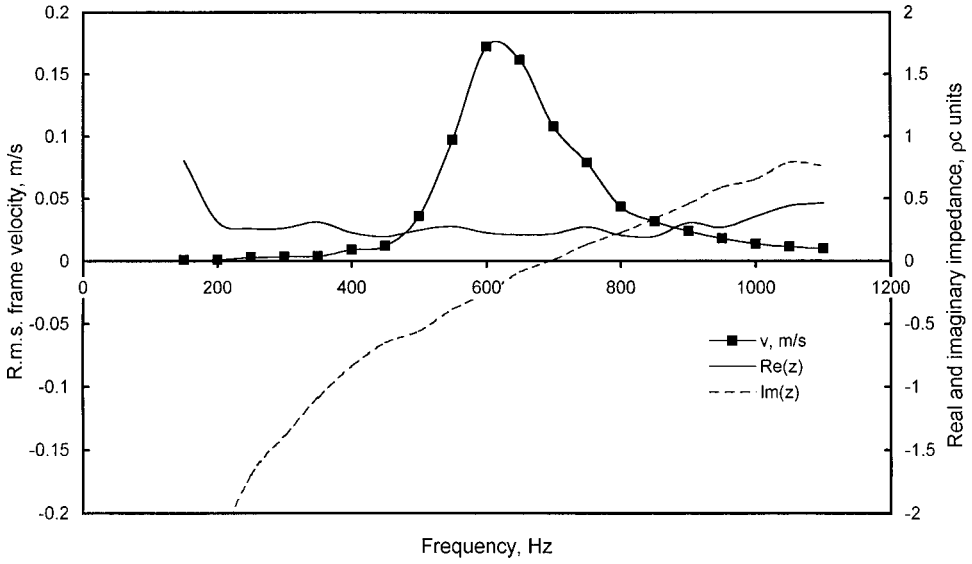

FIG. 4. Filtren, 40-mm cavity, 140 dB: impedance and frame velocity.

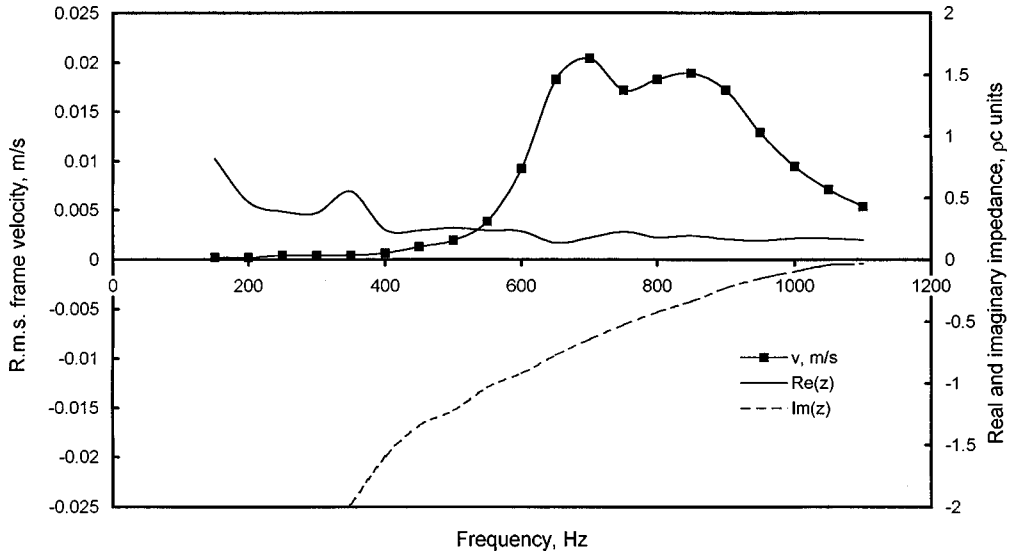

FIG. 5. Filtren, hard wall, 140 dB: impedance and frame velocity.

by vibration. A twisted pair of conducting wires was used away from the vicinity of the magnets in order to minimize the picking up of electromagnetic noise. The sensing wire passed through very small holes in opposite walls of the tube, from the sample to the exterior, and was soldered to the conducting wires.

The voltage signal from the wire was compared to the integrated signal from the accelerometer (B&K type 4332, with B&K charge amplifier type 2635) over a range of frequencies from 120 to 300 Hz, appropriate factors being applied to yield the inferred rms velocity signals. These velocity signals were in good agreement, the maximum discrepancies being about 2.5%, which could be accounted for by the small inaccuracy in measuring the amplifier gain, end effects leading to a small uncertainty in the length of the wire (see Sec. I A) and errors in measurement of the magnetic field strength. Tests were not carried out at lower or higher frequencies, but there was no reason to suppose that the resulting data would have shown any different trends.

II. THE EXPERIMENTAL APPARATUS

Figure 3 shows a test apparatus consisting of a JBL 2206H 300-mm-diam cone loudspeaker, mounted in an enclosure and coupled by means of a square-section conical horn to a perspex tube of 61×61 mm internal cross section and 19-mm wall thickness, as mentioned in Sec. I B. The two identical ferrite magnets of dimensions 100×151×25 mm were secured by an aluminum G-clamp to the outer surfaces of opposite walls of the perspex tube. To reduce possible distortion of the magnetic field, only nonmagnetic nylon bolts were used in the tube structure, in the neighborhood of the test section. Three microphones were used to detect the sound field at certain points in the tube; all were B&K

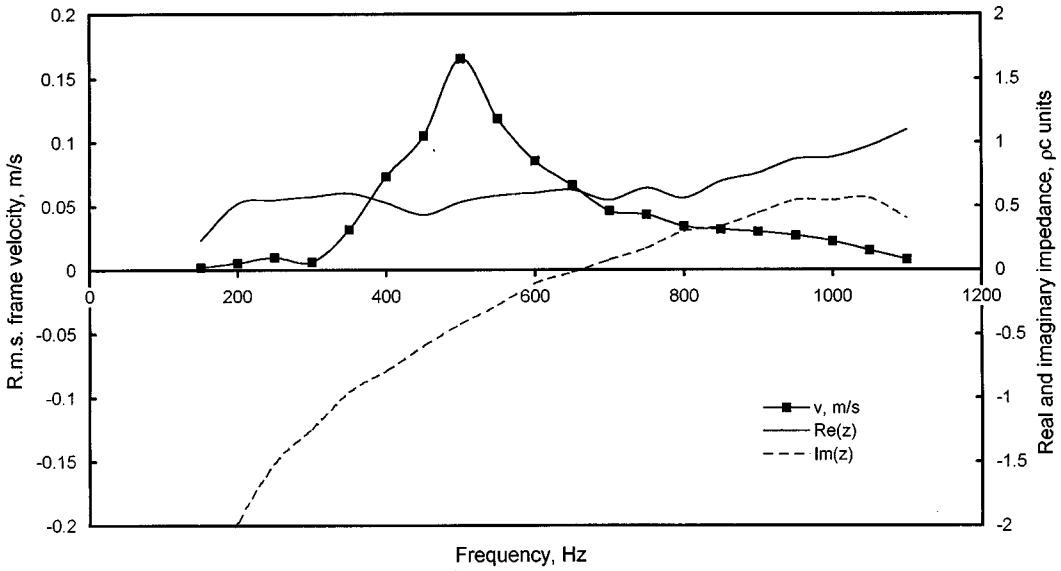

FIG. 6. Bulpren, 40-mm cavity, 140 dB: impedance and frame velocity.

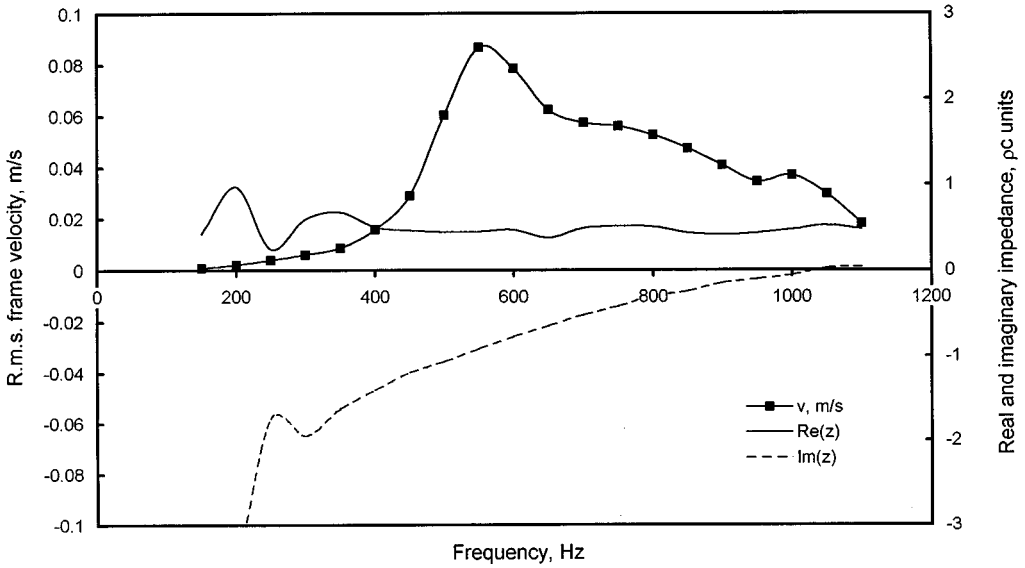

FIG. 7. Bulpren, hard wall, 140 dB: impedance and frame velocity.

1/4-in. condenser microphones, type 4136. Microphones P_1 and P_2, positioned in the side walls approximately 15 mm on either side of the sample, were used to measure sound-pressure level (SPL) in front of and behind the sample. Microphones P_0 and P_1 were used to measure the impedance of the sample and cavity or termination behind the sample by using a two-microphone technique.[7] All tests were conducted with discrete frequency excitation.

The possibility of flanking transmission across the test sample, via bending waves in the walls, needs to be considered here. Cummings[8] has studied internal/external sound transmission through the walls of flexible rectangular section ducts and has shown that wall vibration is only important near and above the lowest transverse structural resonance frequency of the duct walls. Below about half this frequency, the walls are effectively rigid and flanking can be neglected. This lowest resonance, in the case of plane waves in a square duct, may be approximated by that of a Euler beam made from a strip of the wall material, clamped at both ends and with a length equal to the transverse internal wall width. Thomson's[6] table of frequency formulas for Euler beams with various boundary conditions was again used here to estimate the lowest structural resonance frequency of the duct walls. Published data on the mechanical properties of perspex, together with the wall thickness and width for the experimental tube, yield a fundamental wall frequency of 9460 Hz, which is 8.6 times higher than the upper limit of the measured data in the present investigation (1100 Hz). Therefore, the tube walls may be assumed rigid and flanking transmission can be neglected.

The experiments were carried out with two types of porous materials: ''Bulpren'' S75 5734 foam with 72 ppi and ''Filtren'' 2145 foam with 42 ppi. The foam samples had dimensions of $60\times61\times61$ mm. Both these materials were fully reticulated polyurethane foams. The samples were cut to fit snugly within the tube.

A series of tests was carried out with the two types of sample: (i) with a cavity and (ii) with a rigid termination. The arrangement shown in Fig. 3 shows a cavity behind the sample. When the tests involved a rigid termination, microphone P_2 was removed. To test the consistency of the results, three wires were embedded in each sample: one centrally positioned and two displaced 10 mm to the right and left, respectively, in the x direction. The frame velocity data presented later in this paper were taken from the centrally placed wire; the two adjacent wires typically gave almost the same signal, indicating that the frame velocity in the central part of the sample was not very sensitive to x.

III. SOME EXPERIMENTAL RESULTS

The principal aim of the experiments was to test the experimental technique and to study the behavior of frame motion at different frequencies and sound-pressure levels. During the experiments the following quantities were measured: (i) velocity of the frame at the position of the wire, (ii) sound-pressure signal in front of and behind the porous sample (the latter in cases where there was a cavity behind the sample), (iii) impedance at the surface of the sample facing the sound source.

The rms value of the frame velocity was measured for sound-pressure levels in front of the sample (at microphone P_1) equal to 130 and 140 dB and in the frequency range from

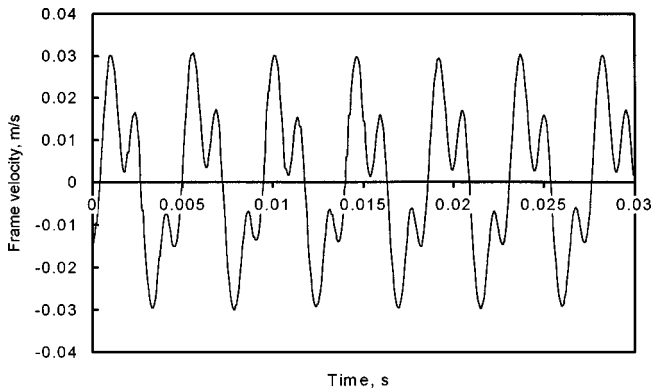

FIG. 8. Filtren, 80-mm cavity, 155 dB, 220 Hz: frame velocity versus time.

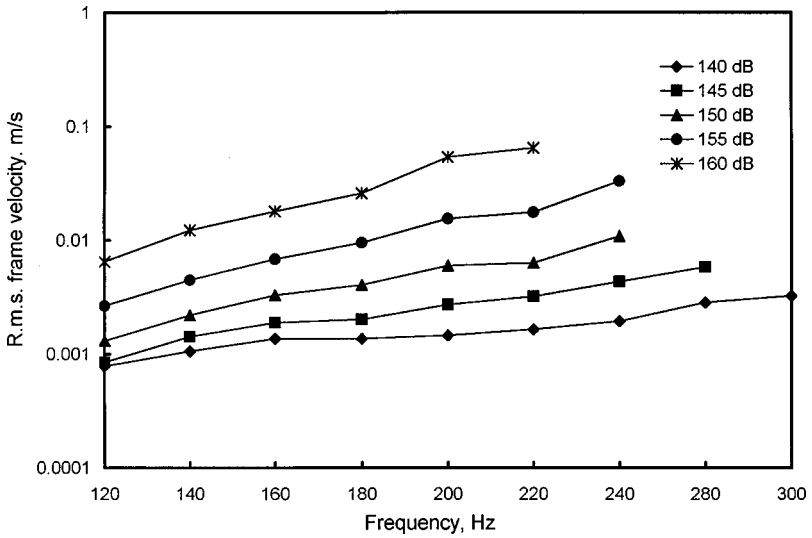

FIG. 9. Filtren, 80-mm cavity, 220 Hz: rms frame velocity at different sound-pressure levels.

150 to 1100 Hz. Additional data included values of impedance at the surface of the sample, measured by the use of the two-microphone method. Plots of rms frame velocity, together with the real and imaginary parts of the impedance at the surface of the sample facing the sound source, are shown in Figs. 4–7, for Filtren and Bulpren with both a 40-mm backing cavity and a rigid termination, at a sound-pressure level (at microphone P_1) of 140 dB. The Filtren sample with the cavity (Fig. 4) shows a maximum in the frame velocity at a slightly lower frequency than the first resonance frequency of the sample/cavity system. This might represent a structural resonance of the sample, weakly coupled to the resonance of the fluid phase of the system, or simply a peak in the structural response caused by the enhanced particle velocity in the sample near the fluid resonance frequency. Since there are no distinct features in the impedance curves near the structural velocity peak, it can be assumed that structural/fluid coupling is weak.

The Filtren plots (Fig. 5) with a rigid backing show a higher fluid resonance frequency (as expected) and a broader and lower structural velocity peak, at a rather higher frequency than that in Fig. 4. These data might suggest the forcing of a structural mode by the fluid motion, again with no evidence of strong structural/acoustic coupling. The Bulpren plots (Figs. 6 and 7), with and without a backing cavity, show similar features, overall, to those exhibited in Figs. 4 and 5, though both structural and fluid resonance frequencies are a little lower than those observed in the case of Filtren.

At higher incident sound levels, significant third harmonic distortion was evident in the frame motion. Figure 8 shows an example of a frame velocity/time history, with a Filtren sample and an 80-mm cavity, at 220 Hz and a sound-pressure level at microphone P_1 of 155 dB. Although—at these high sound-pressure levels—some harmonic distortion of the acoustic signal was present, it was clear from the experimental data that the frame itself exhibited significantly nonlinear dynamic structural behavior. The rms frame velocity versus frequency is shown in Fig. 9 for a range of incident sound levels (again at microphone P_1), and some evidence of a ''softening spring'' behavior is evident, since the spacing of the curves on the logarithmic velocity scale increases with equal increments in sound level. Studies of the static behavior of fully reticulated plastic foams (see, for example, the book by Gibson and Ashby[9]) show an initially linear elastic behavior of the frame in tension—with eventual stiffening at higher strains—and an initially linear behavior

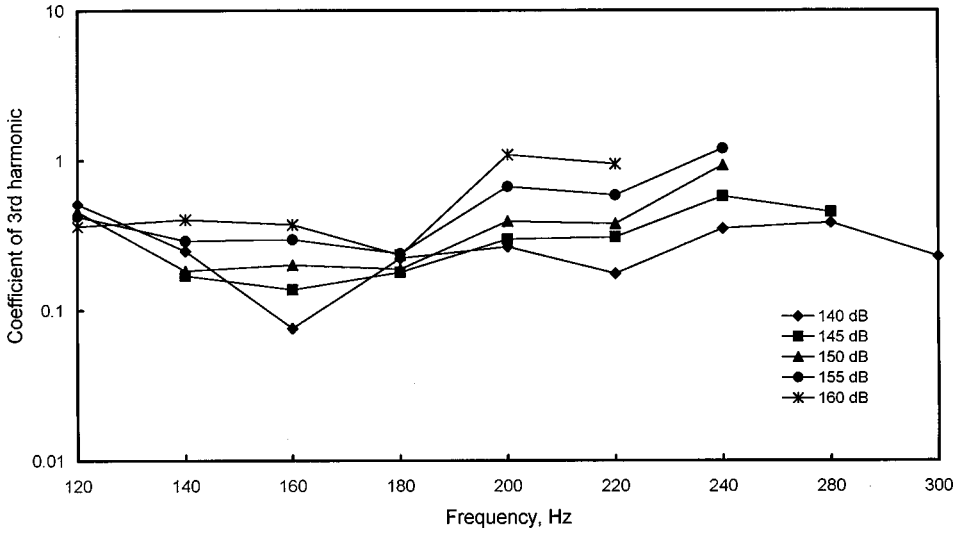

FIG. 10. Filtren, 80-mm cavity, 220 Hz: coefficient of third harmonic of frame velocity at different sound-pressure levels.

in compression, soon followed by a softening characteristic caused by frame buckling, and eventual stiffening. It is thought that dynamic frame buckling may be responsible for the softening spring characteristics apparent in Fig. 9.

In Fig. 10, the third harmonic amplitude coefficient for Filtren with an 80-mm cavity, at 220 Hz, is shown as a function of frequency at various incident sound levels. It can be seen that there is a general increase in third harmonic coefficient as the sound level increases, and that it can exceed unity at certain frequencies, when the sound level is 155–160 dB.

The experimental data presented in Figs. 4–10 are all, of course, dependent on the structural boundary conditions imposed by the walls of the tube on the sides of the test sample. These boundary conditions would depend on whether the sample was loose or tight fitting in the tube or whether it was glued in place. In the present case, where the purpose of the experiments was mainly to demonstrate the experimental technique, the precise nature of the boundary conditions was not very important. In cases where *in situ* data (for example, the vibration levels of the absorbent in dissipative mufflers) were required, representative structural boundary conditions for the porous material would have to be preserved.

IV. CONCLUSIONS

The main point of this paper has been to describe a simple method of measuring the vibrational velocity of the solid frame of a flexible porous material. This method is quite robust, with an accuracy that is fairly easy to establish; in the present case, this is estimated to be approximately $\pm 3\%$. The method has several desirable features: (i) it does not involve the use of any device (such as an accelerometer) that would mass load the material, (ii) the velocity can be measured in regions of the material away from the surface, (iii) the method does not require penetration of laser light into the inner regions of the porous medium, and (iv) it yields a space average of the vibrational velocity along the length of a wire that is embedded in the material (thereby avoiding any spurious local variations in velocity amplitude). Its main disadvantages would seem to be that magnets have to be placed on either side of the wire and that the measurement of a three dimensional vibrational velocity field could involve a cumbersome arrangement of wires and magnets. While these drawbacks could create difficulty in some circumstances, skillful design of the apparatus could enable the ready measurement of two-dimensional velocity fields in many situations.

The experimental data presented were taken at fairly high sound-pressure levels, and significant structural nonlinearity of the test samples was noted.

A boundary integral formulation for the prediction of acoustic scattering from periodic structures

Y. W. Lam
University of Salford, Salford M5 4WT, United Kingdom

(Received 3 March 1998; revised 16 September 1998; accepted 5 October 1998)

The scattering of sound by reflecting surfaces is an important feature in room acoustics. The boundary element method has been shown in the past to be an accurate method to calculate the scattering pattern of complex surfaces. However, this numerical method is expensive to use on large surfaces where a large number of elements is required. This paper proposes a method of reducing the number of boundary elements required to model large, but periodic, structures. The method is based on a consideration of the relationship between the field variables at two points exactly one period apart. The problem is reduced to the modeling of just one period of the structure. In cases of plane-wave incidence, the prediction using this method agrees very well with the prediction obtained by modeling the complete structure. With the point source in the near field of the surface, the incidence field is no longer periodic and the assumption of a constant periodic factor does not hold. In this case, it is shown that the method can still be used with a simple modification to the periodic formulation, and produces good agreements with the full structure predictions and with measurements. © *1999 Acoustical Society of America.* [S0001-4966(99)05301-1]

INTRODUCTION

Scattering surfaces play an important role in room acoustics and are often used to promote the diffusion of sound. The ability to characterize the scattering property of these surfaces is highly desirable in the design of room acoustics. The prediction of the scattering pattern or polar response of the surface can provide the acoustic designers with information to judge the sound field distribution. One may also use the scattering pattern to derive a single figure coefficient, much like the well-established absorption coefficient, to rank the diffusion performance of surfaces. Although a universally accepted formulation of such a single figure coefficient is still not available, efforts are being made to achieve this goal.[1,2]

The boundary element method has been shown by previous research to be an accurate and effective method for the prediction of scattering from complex surfaces.[3] The method is flexible enough to handle virtually any arbitrarily shaped, regular and locally reacting surface. It is also highly adaptable and can be modified to take advantage of specific features of a problem, such as the two-dimensional, thin panel, and axisymmetric formulations.[4,5] However, one limitation of the boundary element method is the large number of elements required to model large surfaces. In room acoustics, the scattering surfaces are usually quite large. The two-dimensional and thin panel formulations can be used to reduce the size of the problems on a large variety of surfaces, but it is still not practical to model very large surfaces that are formed by periodic structures. Examples are the quadratic diffusers used in concert halls, which often consist of a combination of several periods of a prime quadratic sequence, and profiled metal cladding walls, which are commonly used in industrial and leisure buildings.

The modeling of periodic structures using the boundary element method has been carried out by M. Heckel[6] to calculate the radiation from a vibrating profiled cladding. Her formulation uses a superposition of plane waves at discrete angles with the cladding acting as an acoustic diffraction grating. There was, however, no evidence to suggest how successful the formulation was. We also note that, in practical scattering problems, the number of periods in a periodic structure is finite, and it seems more intuitive and efficient to formulate the problems in terms of geometrical periods rather than superimposed plane waves. This paper outlines such a formulation. To limit the scope of the investigation, the formulation is carried out for two-dimensional problems. The extension to three dimensions should be a straightforward procedure. Predictions using this periodic formulation will be compared with predictions using the usual formulation to model the full structure, and with measurements performed on both small and large periodic structures.

I. PERIODIC FORMULATION

The boundary integral equations can be written as follows:[4]

$$\int_S \left[p(\mathbf{r}_q) \frac{\partial G(\mathbf{r}_p|\mathbf{r}_q)}{\partial \mathbf{n}_q} - \frac{\partial p(\mathbf{r}_q)}{\partial \mathbf{n}_q} G(\mathbf{r}_p|\mathbf{r}_q) \right] dS = \begin{cases} p(\mathbf{r}_p) - p_{\text{inc}}(\mathbf{r}_p), & \mathbf{r}_p \in V_{\text{ext}}, \\ \frac{1}{2} p(\mathbf{r}_p) - p_{\text{inc}}(\mathbf{r}_p), & \mathbf{r}_p \in S, \\ -p_{\text{inc}}(\mathbf{r}_p), & \mathbf{r}_p \in V_{\text{int}}, \end{cases} \tag{1}$$

where $p(\mathbf{r}_q)$ is the pressure on the surface at point $\mathbf{r}_q$, $\mathbf{n}_q$ is the outward normal, $p_{\text{inc}}(\mathbf{r}_p)$ is the incident pressure at receiver position $\mathbf{r}_p$, V_{int} is the interior volume enclosed by the surface S, and V_{ext} is the volume external to S. The Green's function for the two-dimensional problem is

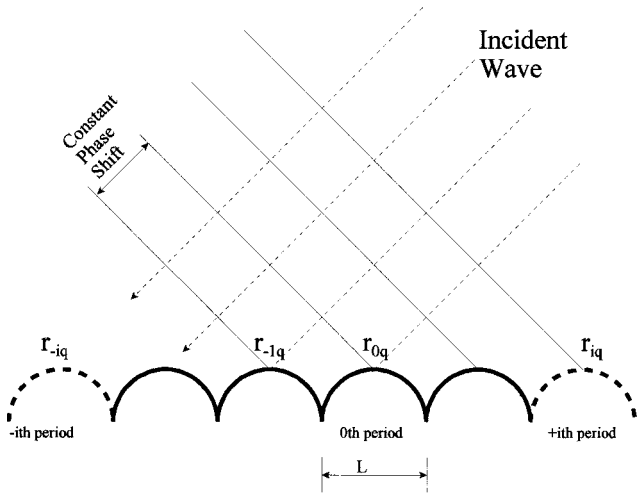

FIG. 1. Plane-wave incidence on a periodic structure.

$$G(\mathbf{r}_p|\mathbf{r}_q)=\frac{j}{4}H_0^{(2)}(k|\mathbf{r}_p-\mathbf{r}_p|),$$

where $H_0^{(2)}$ is the Hankel function of order zero. The integral equation can be solved if the surface impedance is known. Here the scattering surface is assumed to be hard, i.e., $\partial p(\mathbf{r}_q)/\partial \mathbf{n}_q=0$ inside the integral.

For the periodic structure shown in Fig. 1, the integral equation with the receiver position $\mathbf{r}_{0p}$ on the 0th period of the surface can be written as

$$\sum_{i=-\infty}^{\infty}\int_{S_i}\left[p(\mathbf{r}_{iq})\frac{\partial G(\mathbf{r}_{0p}|\mathbf{r}_{iq})}{\partial \mathbf{n}_{iq}}\right]dS=\frac{1}{2}p(\mathbf{r}_{0p})-p_{\mathrm{inc}}(\mathbf{r}_{0p}). \quad (2)$$

For free waves in a periodic structure, Bloch's theorem[7] states that all field quantities at two points exactly one period apart are related by the same factor. For excited waves, the variation in the field quantities will be modulated by the excitation. In the case of plane-wave incidence, the incident wave between two points exactly one period apart (periodic points) differs by a constant phase factor, but the relationship between the *total* pressure at periodic points will be modified by the scattered wave. The scattered wave can be considered in two parts. The first is the image reflection of the incident wave as if the surface were flat, rigid, and of infinite extent. This part has the same periodic phase shift as the incident wave on the surface. The second part is the additional wave field created by the surface variations that deviate from the flat, rigid, and infinite conditions. If this second part of the scattered wave is weak, the relationship between the total pressure at periodic points will still be dominated by the corresponding variation of the incident field. An example is the scattering from finite-size rigid plane surfaces for which Kirchhoff's approximation, that the total surface pressure is given by the doubling of the incident pressure, often produces good predictions. The validity of this assumption in this context will be thoroughly tested in later sections.

Assuming that the surface pressure on the periodic structure at two periodic points, i.e., points that are exactly one period apart, is related by a constant factor $e^{\gamma L}$, where γ is generally complex, then

$$p(\mathbf{r}_{0q})=e^{\gamma L}p(\mathbf{r}_{1q})=e^{2\gamma L}p(\mathbf{r}_{2q})=\cdots=e^{i\gamma L}p(\mathbf{r}_{iq}), \quad (3)$$

where i indexed the ith period. Here the constant factor is determined by the ratio of the incident pressure between any two periodic points,

$$e^{\gamma L}=\frac{p_{\mathrm{inc}}(\mathbf{r}_{iq})}{p_{\mathrm{inc}}(\mathbf{r}_{(i-1)q})}. \quad (4)$$

The integral equation (2) with the $\mathbf{r}_{0p}$ on the surface can now be written as

$$\int_{S_0}\left[p(\mathbf{r}_{0q})\sum_{i=-\infty}^{\infty}e^{i\gamma L}\frac{\partial G(\mathbf{r}_{0p}|\mathbf{r}_{iq})}{\partial \mathbf{n}_{0q}}\right]dS$$
$$=\tfrac{1}{2}p(\mathbf{r}_{0p})-p_{\mathrm{inc}}(\mathbf{r}_{0p}), \quad (5)$$

which can be discretized and solved in the usual way. Note that since the structure is periodic, the normal vectors are the same at corresponding periodic points. Hence the vector $\mathbf{n}_{iq}$ can be replaced by $\mathbf{n}_{0q}$ in the integral.

Since the asymptotic form of the two-dimensional Green's function (given by the Hankel function) at a large distance is inversely proportional to the square root of the distance, it may be expected that the summation inside the integral should converge quickly. In practice, since all structure must be finite and have a finite number of periods, one may conveniently choose the physical number of periods to be the limit of the summation. The effect on the accuracy of having only a finite number of periods will be tested later on a surface that has only a small number of periods.

A further reduction of the problem can be achieved if we assume that the thickness of the scattering object is small. This is often true, since most reflectors in room acoustics are constructed from thin panels. Also, when the surface is large, the effect of its rear side is small and modeling it as a rigid, thin object should not introduce significant errors. With the thin panel assumption, Eq. (5) can be further reduced to[4]

$$\int_{S_{01}}\left[(p(\mathbf{r}_{0q1})-p(\mathbf{r}_{0q2}))\sum_{i=-\infty}^{\infty}e^{i\gamma L}\frac{\partial^2 G(\mathbf{r}_{0p}|\mathbf{r}_{iq})}{\partial \mathbf{n}_{0q}\partial \mathbf{n}_{0p}}\right]dS$$
$$=-\frac{\partial p_{\mathrm{inc}}(\mathbf{r}_{op})}{\partial \mathbf{n}_{0p}}, \quad (6)$$

where the additional subscripts 1 and 2 index the front and back faces of the thin object, and the integral is now over just the front face S_{01} of one period of the structure. The exterior pressure, with $\mathbf{r}_p$ in the exterior region V_{ext}, is calculated by

$$p(\mathbf{r}_p)=\int_{S_{01}}\left[(p(\mathbf{r}_{0q1})-p(\mathbf{r}_{0q2}))\sum_{i=-\infty}^{\infty}e^{i\gamma L}\frac{\partial G(\mathbf{r}|\mathbf{r}_{iq})}{\partial \mathbf{n}_{0q}}\right]dS$$
$$+p_{\mathrm{inc}}(\mathbf{r}_p). \quad (7)$$

II. PLANE-WAVE INCIDENCE

The above formulation, represented by Eqs. (6) and (7), is applied to a periodic structure consisting of 21 half-cylinders, as shown in Fig. 1. Each cylinder has a diameter of 0.115 m, which is about 1.7 wavelengths at the highest test frequency of 5000 Hz used in this study. The half-

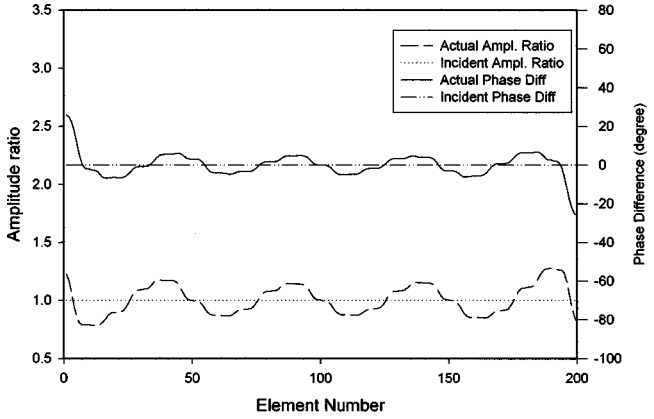

FIG. 2. Relationship between points one period apart. Normal incidence plane wave at 630 Hz. The amplitude ratios and phase differences are calculated according to Eq. (8).

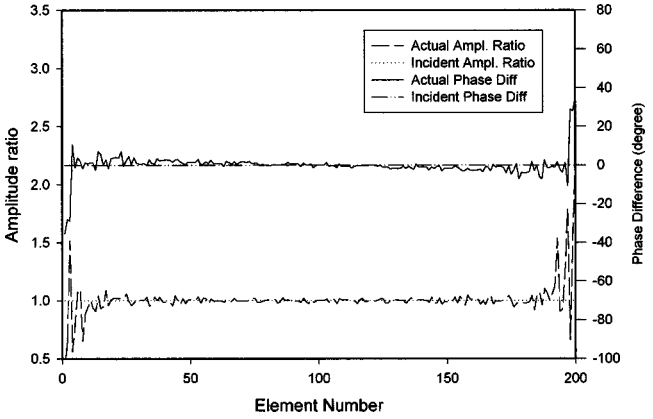

FIG. 3. Relationship between points one period apart. Normal incidence plane wave at 5000 Hz. The amplitude ratios and phase differences are calculated according to Eq. (8).

cylinders are placed side by side without gaps. The configuration corresponds to an experimental setup which will be discussed in the next section.

The source is located sufficiently in the far field so that plane-wave incidence can be assumed on the surface. The pressure difference across the front and back faces, $p(\mathbf{r}_{oq1}) - p(\mathbf{r}_{oq2})$, was calculated by the periodic formulation, Eq. (6), and by applying the full boundary integral formulation, Eq. (2), to the full structure of all 21 cylinders. The equations were solved by dividing the surface of integration into discrete boundary elements in the usual way. In this study, ten elements were used for each half-cylinder, giving a element size of about 1/4 wavelength at the highest test frequency of 5000 Hz. This is considered to be the maximum size that can be tolerated before the constant pressure assumption that is used to discretize the boundary integral into elements is seriously violated. With this mesh resolution, 210 elements were required in the full model but only 10 were required in the periodic model. The solution time for the surface pressure at a single frequency was 23 s for the full model and about 1 s for the periodic model on a Pentium II 300-MHz desktop computer.

The amplitude ratio and phase difference between points one period apart in successive periods are calculated from the full structure formulation as follows:

$$\text{Amplitude Ratio} = \left| \frac{p(\mathbf{r}_{(-1)q1}) - p(\mathbf{r}_{(i-1)q2})}{p(\mathbf{r}_{iq1}) - p(\mathbf{r}_{iq2})} \right|, \tag{8}$$

$$\text{Phase Difference} = \text{Phase Angle of} \left(\frac{p(\mathbf{r}_{(i-1)q1}) - p(\mathbf{r}_{(i-1)q2})}{p(\mathbf{r}_{iq1}) - p(\mathbf{r}_{iq2})} \right).$$

The result for normal incidence is shown in Figs. 2 and 3 for the 630- and 5000-Hz case. The ''element number'' used to label the x-axis corresponds to the numbering index of the boundary elements used in the model. The elements are numbered sequentially from one end of the structure to the other. Element 1 is at the source end of the structure when the source is offset from the center line (oblique incidence). Since ten elements were used for each period, each set of consecutive ten elements corresponds to a period of the structure.

For a plane incident wave, the amplitude ratio is 1 and at normal incidence the phase difference is 0. The constant factor $e^{\gamma L}$, determined from the incident wave by Eq. (4), is therefore equal to 1 in this case. These figures therefore show the deviation in the actual structure from this assumption. At high frequencies, such as in Fig. 3, the deviation is generally small except at the edges of the structure. At low frequencies, such as in Fig. 2, the deviation is higher throughout the entire panel because the size of the panel in relation to the wavelength is smaller and edge effects become more important. In these cases, the deviation can be as high as 10° in the middle of the panel. The effect of the deviations in the phase of the surface pressure on the prediction of the exterior far-field sound field is, however, small, as can be seen in the far-field polar responses in Figs. 4 and 5 for a receiver at far field (100 m). The dB values of the scattered pressure shown in these and subsequent figures are normalized to the incident pressure at 0°. The periodic and full structure predictions agree well. This is not surprising since, at normal incidence, the excitation is identical over each period. Therefore both the structure and the excitation are periodic with the same period. The surface pressure over each period should therefore be the same except for the variation created by the

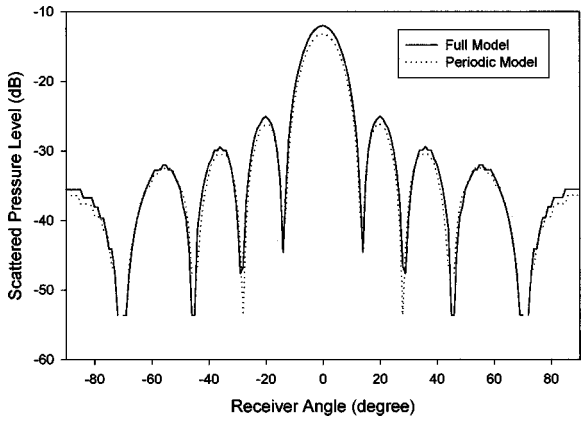

FIG. 4. Predicted far-field polar responses. Normal incidence plane wave at 630 Hz.

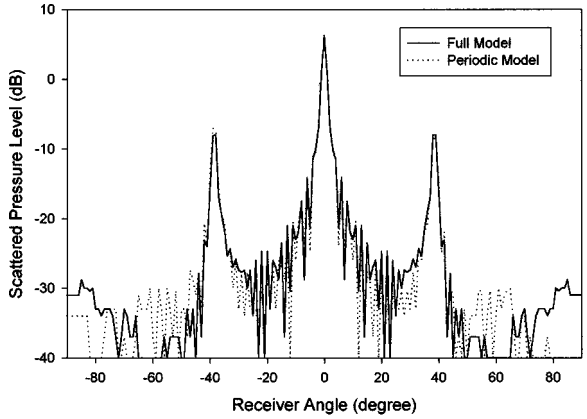

FIG. 5. Predicted far-field polar responses. Normal incidence plane wave at 5000 Hz.

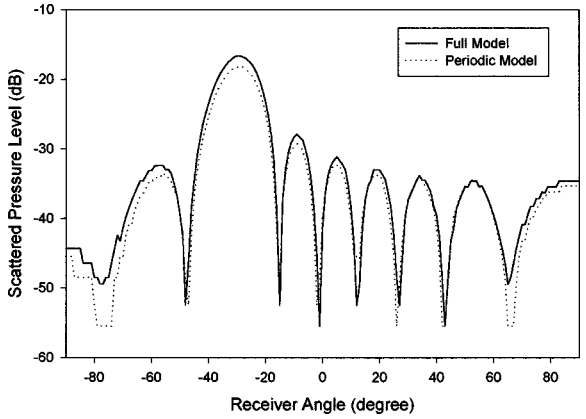

FIG. 7. Predicted far-field polar responses. 30° incidence plane wave at 630 Hz.

finite-size edge diffraction effect. The assumption of the periodic formulation is mostly satisfied with $e^{\gamma L}=1$. The periodic prediction should therefore agree with the full structure prediction, as is indeed the case.

The next set of results shows the surface pressure relationship between periods for a plane-wave incidence at 30° to the normal. At oblique incidence, the excitation created by the incident wave no longer has the same period as that of the structure. There is a constant phase shift in the incident wave at points that are exactly one structural period apart. The assumption that the surface pressures at periodic points are related by the same constant factor as that of the incident wave can be further tested in this result.

Figure 6 shows the total surface pressure and incident pressure relationships between periodic points. They are very similar to the normal incidence case except that the phase difference is now shifted from zero. Again the deviation from the incident pressure relationship is generally small. The agreement between the polar response predicted by the periodic formulation and that by the full structure model is also very good, as can be seen in Fig. 7. This result strongly suggests that the relationship of the incident wave over successive periods can be used successfully to represent the relationship between the surface pressure, at least in the case of plane-wave incidence.

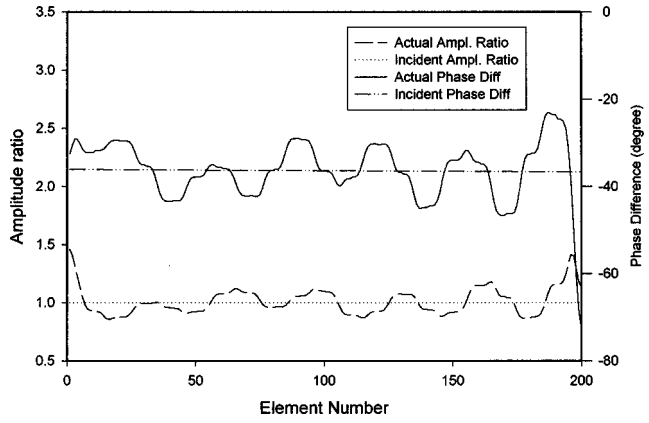

FIG. 6. Relationship between points one period apart. 30° incidence plane wave at 630 Hz. The amplitude ratios and phase differences are calculated according to Eq. (8).

The periodic formulation is also successful in the prediction of near-field polar responses. Figure 8 shows the case with a receiver at 1-m radius. The periodic prediction agrees very well with that predicted by the full integral formulation. An under-prediction of 1–2 dB in the sound-pressure level is seen in this case. Generally both over- and under-predictions occur in other cases and the error margins are similar to that observed here.

III. NEAR-FIELD SOURCE AND EXPERIMENTAL RESULTS

When the source is located in the near field of the surface, the incident wave is no longer a plane wave. In the two-dimensional case, the wave will be cylindrical and an additional phase and amplitude variation will be introduced by the cylindrical curvature, as can be seen in Fig. 9, which shows the general source, receiver, and object geometries of a near-field configuration used in this study. In this case, the incident pressure is no longer related by a constant factor at periodic points on the surface. Under such circumstances, the simple assumption of a constant relating factor for the surface pressure cannot hold; see Fig. 10, which shows the amplitude and phase relationship between successive periodic points on the 21 half-cylinder structure with the source at 2 m, normal incidence. The periodic formulation using this assumption produces significant errors in the calculation of

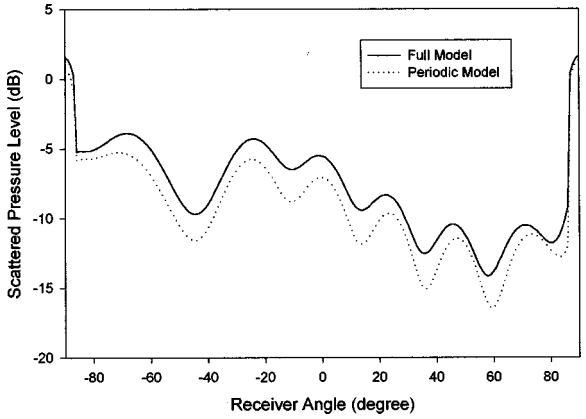

FIG. 8. Predicted near-field polar responses. 30° incidence plane wave at 630 Hz.

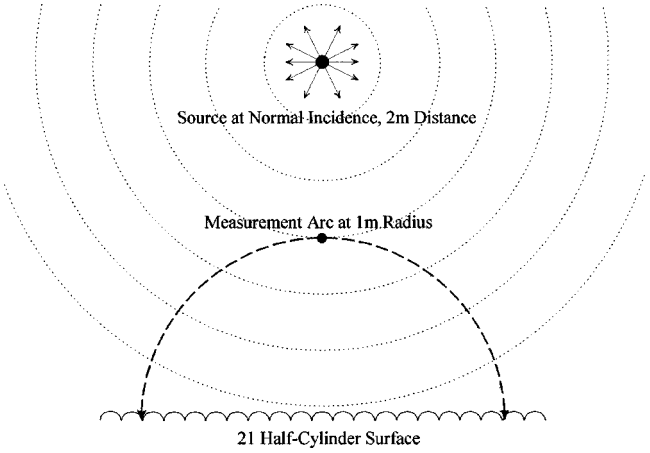

FIG. 9. Source, receiver, and scattering surface geometries for the near-field study.

the external pressure, as shown clearly in Figs. 11 and 12 for 0 and 30° incidence, respectively. The data predicted by this constant factor periodic formulation are labeled ''Constant Periodic'' in the figures. As can be seen, its predictions of the shapes of the polar responses, especially in the 30° case, are not in agreement with those predicted by the full structure model. Given the large deviation of the surface pressure phase factor from a constant factor, as shown in Fig. 10, this is hardly surprising.

The near-field source configuration is nevertheless an important case to consider since most laboratory measurements of large surfaces, due to limitation in space, will have the source not too far from the surface. The experimental setup, which produced the measured results shown in Figs. 11 and 12, and later figures, has the source at a radius of 2 m from the surface and a receiver radius of 1 m. Even at the lowest measuring frequency of 630 Hz, the 2-m source radius is less than the minimum far-field distance of 2.7 m, estimated from the usual formula of $W^2/4\lambda$,[8] where W is the total width of the surface, which is equal to 21×0.115 m in this case. To deal with this problem, we observe from Fig. 10 that, although the phase factor is not a constant, it follows almost exactly the phase shift of the incident pressure. This agrees with our assumption of weak nonimage scattering,

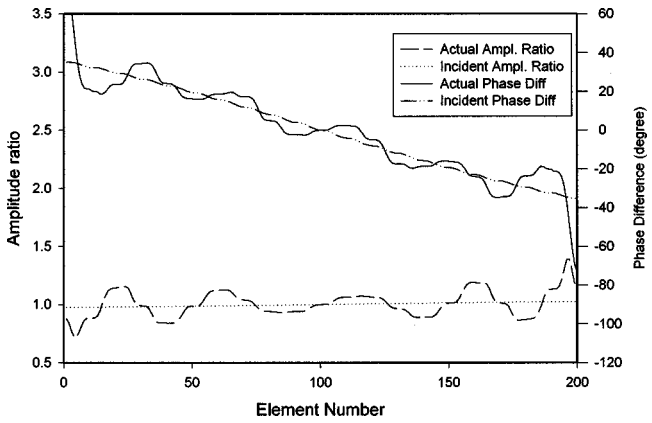

FIG. 10. Relationship between points one period apart. Near-field normal incidence at 630 Hz. The amplitude ratios and phase differences are calculated according to Eq. (8).

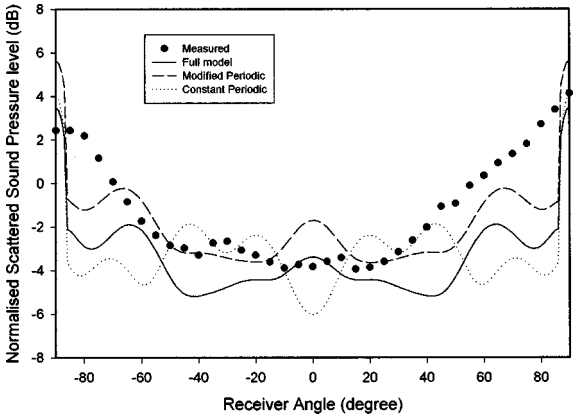

FIG. 11. 1/3-octave near-field polar responses at 1 m at 630 Hz. Near-field source at 2 m, normal incidence.

that the surface pressure relationship between successive periodic points is imposed predominantly by the incident field. It seems therefore appropriate to modify the constant factor periodic formulation by introducing a variable factor that is determined by the incident field at the points of interest. The surface integral equation (6) is modified accordingly, to give

$$\int_{S_{01}}\left[(p(\mathbf{r}_{0q1})-p(\mathbf{r}_{0q2}))\sum_{i=-\infty}^{\infty}\Lambda_{0i}\,\frac{\partial^2 G(\mathbf{r}_{0p}|\mathbf{r}_{iq})}{\partial\mathbf{n}_{0q}\partial\mathbf{n}_{0p}}\right]dS$$

$$=-\frac{\partial p_{\mathrm{inc}}(\mathbf{r}_{0p})}{\partial\mathbf{n}_{0p}}, \tag{9}$$

where

$$\Lambda_{0i}=\frac{p_{\mathrm{inc}}(\mathbf{r}_{iq})}{p_{\mathrm{inc}}(\mathbf{r}_{0q})}$$

and the integral equation (7) for the exterior pressure is similarly modified by replacing the factor $e^{i\gamma L}$ by the factor Λ_{oi}.

The result of applying this modification can be seen in Figs. 11 and 12. The data labeled ''Modified Periodic'' are predicted by this modified periodic formulation. The improvement in the prediction is obvious. The shapes of the polar scattered patterns predicted by the modified formulation are almost identical to those predicted by the full model, although there is a shift in the absolute amplitude of about 2 dB in the normal incidence case.

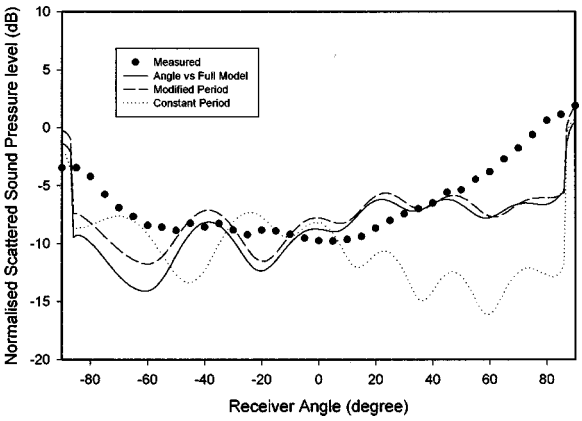

FIG. 12. 1/3-octave near-field polar responses at 1 m at 630 Hz. Near-field source at 2 m, 30° incidence.

The measured data shown in the figures were obtained by RRG Diffusor Systems, Inc., using an array of microphones located at a 1-m radius and separated at 5° intervals. The scattering surface was laid on a hard baffle and measurements were performed in 1/3-octave frequency bands. The polar scattering with the scattering sample in place and with no scattering sample (the background measurement) were measured. The background data were then subtracted from the scattering data to remove the direct sound and the room effect. The fast Fourier transform (FFT) of this response was divided by the 1/distance scaled loudspeaker response, which is measured 37 times with the loudspeaker in the scattering sample position on axis to each microphone. The deconvolved scattered data were then windowed to isolate them from any remaining interference. The subtraction and deconvolution procedure, however, introduces residue noise into the data. Measured data are therefore less reliable when the scattered energy is low (at receiver angles far away from the geometrical reflection angles), and also when the microphone is close to the surface or baffle (at large receiver angles). In most cases this affects the measured data at (absolute) receiver angles greater than 60°.

To allow comparisons in 1/3-octave bands, predictions were made at five single frequencies in each 1/3-octave band at logarithmically equal intervals. The scattered pressures were then energy averaged to give the 1/3-octave results. The use of five frequency points for the averaging was enough to smooth out most of the single-frequency specific interferences.

Unfortunately, precise information on the normalization used to generate the measured data was not clear and we cannot compare directly the absolute amplitudes of the predicted and measured scattering patterns. Nevertheless, the shapes of the patterns can be compared. This is not a serious problem in our work, since ultimately the shape of the scattering pattern is what characterizes the distribution of the scattered energy and hence the diffusion performance of the surface. In Figs. 11 and 12, and subsequent figures that show the measured data, the absolute amplitudes of the predicted scattering patterns are, as before, normalized to the incident pressure at 0°. The measured polar patterns are referenced to give dB values similar to the predicted patterns at 0°. However, since this normalization of the measured data is not precisely the same as the predictions, the measured data should not be used to judge the relative accuracy in the *amplitudes* of the predictions. For example, both the modified and the constant periodic predictions may seem to have better agreement with the measured data in terms of amplitude than the full model within the angular ranges of -50 to $-10°$ and 10 to 40° in Fig. 11, but this is purely because the measured data were normalized to give a similar amplitude at exactly 0° to that predicted by the full model. If the normalization were changed to shift the measured data down by 2 dB, then the full model data would have far better agreement with the measured data. The result in Fig. 12 is more clear-cut. The modified periodic and the full model predictions clearly agree well with each other and have much better agreement with the measured data than the constant periodic model.

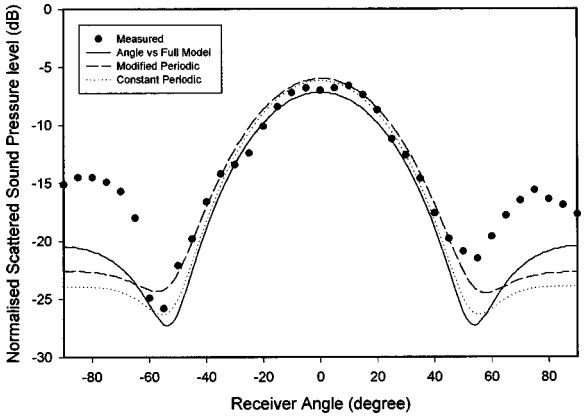

FIG. 13. 1/3-octave polar response of a surface with six half-cylinders at 630 Hz, normal incidence.

Overall, the predicted scattering patterns agree fairly well with the measured results except at near grazing angles when the receiver is close to the surface.

A second, smaller scattering surface with six periodic half-cylinders was also measured. The experimental setup is again the same as that for the 21-cylinder surface: the source is at 2-m normal incidence and the receivers are at 1-m radius. With this smaller surface, the estimated minimum far-field distance is 1.7 m at 5000 Hz, and the source is therefore in the far field even at 5000 Hz. The receiver distance, however, changes from near to far field depending on the frequency and angle. The purpose of this test is to determine if the periodic formulation can adequately model structures that have only a small number of periods and therefore have stronger influence from the edges.

Figures 13 and 14 show the predicted and measured scattering patterns at 630 and 5000 Hz, respectively. The agreement between both predictions and measurement is very good at the lower frequency when the source is well in the far field. At the higher frequency, the agreement is good near the main scattering beam from about -30 to 30°. Significant deviations develop at higher scattering angles where the scattering energy is low. Surprisingly, the modified periodic formulation agrees slightly better with the measurement at these angles than the full structure model. This is, however, more likely to be caused by the background or residue

noise in the measurement that was discussed earlier.

Interestingly, in Fig. 14, both the full model and the less accurate constant periodic model predicted large interference dips in the scattering pattern while the modified periodic model did not. It should, however, be noted that the surface under investigation here has only six periods. With such a small number of periods, edge diffractions will have a significant effect on the accuracy of both periodic formulations. Within the main scattering beam, from about -30 to 30°, the modified periodic model still has much better accuracy than the constant periodic model and agrees very well with the full model. At larger angles both periodic models are significantly affected by the edge effect and are both in error. Results from all the frequencies tested on this surface indicated that the modified model has a slight tendency to predict less sharp interference dips than the full model, but the difference is generally not as large as that shown in Fig. 14. Figure 13 is a more typical result.

IV. DIFFUSION COEFFICIENTS

As mentioned earlier in the Introduction, it is desirable to be able to calculate from the polar pattern a single figure coefficient, which one may call the diffusion coefficient, to describe the diffusion performance of a surface. A number of procedures for such a coefficient have been proposed in the past but all have certain difficulties which need to be resolved.[9,10] There are yet no universally accepted definitions for the diffusion coefficient, although efforts are being made to develop one.[1,2] Here we choose a simple procedure to calculate a diffusion coefficient from the polar response as a means of investigating the accuracy of the prediction methods in determining a single figure coefficient. The physical meaning of the chosen coefficient is based on the angular energy distribution and is considered sufficient to give an adequate representation of the diffusion performance.

The calculation is again based on the two-dimensional approach. Let the energy at each polar receiver angle be E_i, and the total energy summing over all the receiver angles be E_T, then an indication of how the scattering pattern deviates from an ideal uniform scattering can be calculated as

$$d=1-\frac{\Sigma_i^N|(E_i-E_T/N)|}{E_T}, \tag{10}$$

where N is the total number of receivers positioned at a constant angular interval $\Delta\theta$. This will give a value of 1 for a uniform scattering field. However, when the field is totally specular, i.e., the energy is concentrated within a specular angle range $\theta_s=n_s\cdot\Delta\theta$ such that $E_i=E_s$ within θ_s, but otherwise is equal to 0, then the total energy $E_T=E_s\cdot n_s$ and the equation gives

$$d=1-\frac{n_s(E_s-n_sE_s/N)+(1-n_s)(n_sE_s/N)}{n_sE_s}$$

$$=1-2\left(1-\frac{n_s}{N}\right), \tag{11}$$

which is negative when the specular angle is smaller than $N/2$. To obtain a coefficient that gives a value of 0 for totally specular reflection, one can normalize the summation term of the equation by the factor indicated by the totally specular case,

$$d=1-\frac{\Sigma_i^N|(E_i-E_T/N)|}{E_T2(1-n_s/N)}. \tag{12}$$

This definition works well in the far field when the specular angle range is small. In the near field it will work if the specular energy is uniformly distributed over the specular angle range. Unfortunately, in practice this is seldom the case and the normalization gives rise to negative values when n_s is large. To avoid this complication, we choose to remove the $(1-n_s/N)$ term from the normalization, so that

$$d=1-\frac{\Sigma_i^N|(E_i-E_T/N)|}{2E_T}. \tag{13}$$

The result will be similar to that using the full normalization in the far field when the specular angle range is small. In the near field the specular angle range is large and the scattering pattern is ''flatter'' than in the far field. Without the $(1-n_s/N)$ term in the normalization, the value of d will always be larger in the near field. The coefficient is bound between 0 and 1.

Using the above definition, the diffusion coefficients of the 6- and 21-cylinder surfaces were calculated from the polar responses. The result is summarized in Tables I and II. The modified periodic formulation was used to calculate the coefficients in the columns labeled ''Periodic.''

The results are consistent with the findings on the polar responses. With plane-wave incidence, the periodic formulation and the full structure model results are very similar. The changes in the values of the diffusion coefficient with the source and receiver configurations agree particularly well.

Measured data were only available in the near field (Table II). Even here the two predictions generally agree well with each other, and their diffusion coefficient values

5000	0.54	0.42	0.60	0.36	0.78	0.74	0.68	0.82	0.80	0.64	0.62	0.72

are also close to those calculated from the measured responses. The trend of variations in the coefficient is again well predicted. As expected, the value of the coefficient increases as the receiver moves into the near field of the surfaces. The differences between the predicted and measured values are generally within 0.15 and in most cases less than 0.1. Even in cases where the deviation is high (e.g., in the six-cylinder results), the corresponding polar responses do not seem to be significantly different (Figs. 13 and 14) except at large scattering angles where the scattered energy is low. Overall the coefficients calculated from the modified periodic formulation are as accurate as those calculated from the full model prediction in both the near and far fields and for both the small and large periodic surfaces.

Also shown under the columns labeled ''Constant'' in Table II are the coefficients calculated by the constant periodic model. Generally the constant periodic model shows slightly larger deviations from the full model and measurements than the modified model. Its prediction of the frequency dependence of the coefficient in the 21-cylinder case is also poor.

V. CONCLUSIONS

A boundary element method formulation that uses the periodic property of a structure has been developed. The formulation is based on the assumption that the surface pressure at two points exactly one period apart on a periodic structure is related by a factor that can be determined from the incident sound field. For plane-wave incidence, the factor is constant and is given by the phase shift between the incident pressure at the two periodic points. When the source is in the near field, the factor is not constant but can still be calculated from the individual ratio of the incident pressure at each pair of periodic points. This formulation has been shown to have an accuracy similar to that obtained by modeling the full structure in the prediction of the near- and far-field scattering patterns of both large and small periodic structures, except at scattering angles where the scattered energy is low. The prediction also compares well with measurements.

The predicted and measured scattering patterns were used to calculate a coefficient that can be used to describe the scattering performance of a surface. Again the agreement between the coefficients calculated from predictions and measurements is good. The trend of variations is particularly well predicted. The deviations in the absolute values are mostly within 0.1. However, further work is required to judge the significance of such a difference in values.

The multiple half-cylinder surfaces used in this study are smooth except at the joints between cylinders. In other scattering surfaces such as the quadratic residue diffusers (QRDs), there can be more sharp edges on the surface. Diffractions from these sharp edges may affect the weak non-image scattering assumption that is essential to the periodic formulation. An indication of the validity of applying the assumption to QRDs can be obtained from the work of Cox and Lam.[3] It was shown in their work that the scattering surface of a QRD can be represented satisfactorily by a flat surface with variable admittance in a boundary element model. The admittance of a well can be derived simply from the phase change of plane waves propagating up and down the well. This suggests that diffractions from the well edges can be ignored. One should therefore be able to apply the periodic formulation to a series of QRDs with each QRD modeled as a flat surface with variable admittance. Further work is required to confirm this suggestion.

ACKNOWLEDGMENTS

Transient-evoked otoacoustic emissions (TEOAE) were used to characterize linear and nonlinear cochlear transduction using a new system-identification procedure. In this technique, a computational model of the system is first developed. From the measured stimulus and response records, spectral-density functions and multiple coherence functions are calculated. The coherence functions allow the characterization of linear/nonlinear processes as a function of frequency. Summations of linear and nonlinear coherences provide a goodness-of-fit of the chosen model. Finite impulse response pulses with a bandwidth of 1–8 kHz were used to evoke otoacoustic emissions. Eleven adults with normal hearing served as subjects. Third- and fifth-order polynomial models were used to model the data, and the results indicate that the fifth-order model is a better fit to the TEOAE data. The results of this study suggest that this system-identification procedure can be successfully applied to model cochlear transduction using a broadband stimulus. Most importantly, coherence functions provide useful insights into linear and nonlinear cochlear processes and have the potential to be developed as a clinical measure for monitoring changes in cochlear status. INTRODUCTION

The auditory system, like most biological systems, is nonlinear. The nature of auditory nonlinearities has been examined at various levels of the auditory system using a variety of approaches. One approach has been to examine distortion products or combination tones generated in the cochlea when stimulated with a two-tone complex signal. The most easily detected and well-studied combination tones are distortion products of the form $2f1-f2$, and $f2-f1$, where $f1$ and $f2$ are frequencies of the primary tones of a two-tone complex, with $f1<f2$. Distortion products have been examined in cochlear microphonics (Dallos, 1973), in the nerve discharges of the auditory-nerve fibers (Goldstein and Kiang, 1968), from basilar-membrane vibrations (Robles *et al.*, 1991), and more recently, using evoked otoacoustic emissions recorded from the outer ear canal (Kemp, 1979; Probst *et al.*, 1991).

Evoked otoacoustic emissions are acoustic energy generated in the cochlea in response to acoustic stimulation and are measured from the ear canal of humans and animals. Acoustic distortion products evoked using a two-tone complex stimulus, also known as distortion-product otoacoustic emissions (DPOAE), have provided strong evidence for the existence of nonlinear active mechanical processes in the cochlea (Kemp, 1979; Kim *et al.*, 1980). Emissions evoked with a transient, such as a click, also exhibit nonlinear behavior (Kemp, 1978), which is evident from the nonlinear growth of the input/output (I/O), function. Numerous studies have since linked the outer-hair cells (OHC) of the cochlea as the source of the active nonlinear processes that generate otoacoustic emissions (Mountain, 1980; Zurek *et al.*, 1982; Brownell, 1983; Lonsbury-Martin *et al.*, 1987; Brown *et al.*, 1989; Veuillet *et al.*, 1991; Moulin *et al.*, 1993).

In recent years, DPOAE amplitude and I/O growth functions have been used to examine nonlinear processes of the cochlea. Although DPOAE I/O functions can provide information about cochlear transduction, they are difficult to interpret because they vary as a function of such factors as $f2/f1$ ratio, primary level of the stimuli, and primary frequency, even in normal-hearing subjects (Nelson and Kimberley, 1992; Lasky *et al.*, 1994). Therefore, to completely characterize cochlear transduction for all frequencies at once, or to monitor changes in its nonlinear processes, it would be necessary to obtain I/O functions for DPOAEs over a multitude of stimulus parameters. A technique that could characterize the properties of the transduction process for all frequencies of interest would provide new insights into the linear and nonlinear processes of signal transduction in the cochlea.

A recent development in the field of random data analysis is a linear/nonlinear system-identification technique (Bendat, 1990) that is well suited for characterizing nonlinear systems, such as cochlear transduction, using a broadband

input. In this system-identification technique, a computational model of the system consisting of nonlinear elements in series with unknown linear filters is first developed. From the measured input and output data, spectral-density functions and multiple coherence functions are calculated. The cumulative coherence functions provide a goodness-of-fit of the model to the data. The coherence functions may be further examined to characterize linear/nonlinear processing as a function of frequency. Filters that optimally characterize the nonlinear system are calculated using statistical techniques related to regression analysis. The identification of the system can be accomplished using either Gaussian or transient signals, and is performed in the frequency domain.

There are several advantages to applying this system-identification technique to nonlinear systems. First, as the analysis is done in the frequency domain, the results are presented as single-dimensional functions of frequencies that are easier to interpret than the multidimensional results of the time-domain, kernel-based approaches (Wickesberg *et al.*, 1984; Wickesberg and Geisler, 1984; Shi and Hecox, 1991; Dijk *et al.*, 1993). The potential for developing this technique into a clinical diagnostic procedure lies in the advantage that the outputs from this procedure are functions of frequency that are easy to interpret.

Second, with this technique, nonlinear systems may be modeled as arbitrary linear systems in parallel with arbitrary nonlinear systems. Any number of nonlinear paths may be in parallel with the linear system. This flexibility in the use of numerous nonlinear paths allows us to approximate system nonlinearities using polynomial equations of any order. This is important because accurate modeling of the nonlinear properties of cochlear transduction will require polynomials greater than third order (Weiss and Leong, 1985). Furthermore, this procedure yields *uncorrelated* outputs from the different paths in the model. From these uncorrelated outputs, coherence measures can be computed which reveal the relative contributions of energy from the various nonlinear paths to the overall response, e.g., otoacoustic emissions. In contrast, kernel-based approaches are computationally complex for orders higher than two, and kernels of consecutive orders are not mutually independent (Shi and Hecox, 1991). Finally and most importantly, a broadband signal, such as a transient signal, can be used as input to the cochlea. This allows stimulation of the entire length of the cochlea simultaneously, providing us with a complete characterization of the cochlea. It has been shown that emissions evoked with a transient, such as a click, have nonlinear I/O growth function (Kemp, 1978). However, the nonlinearities in transient-evoked emissions have not been characterized, mainly due to the lack of analytical techniques that are computationally manageable. The coherence functions obtained from this procedure may be used to characterize the nonlinear components of TEOAE. Besides, we need to have a better understanding of the responses of the cochlea to other types of signals, such as noise and clicks. As de Boer (1993) has rightly stated, ''There is no reason why the field of nonlinear studies cannot be extended to encompass other phenomena or other cases such as noise or click responses.''

The chief goal of this study is to determine the feasibility of using this system-identification technique to describe the relationship between the input: a transient signal, and the output: evoked otoacoustic emissions. Bendat's system-identification technique has been used to characterize the auditory system of Mongolian gerbils using cochlear microphonic data (Chertoff *et al.*, 1994; Chertoff *et al.*, 1996).

The goals of this study were to demonstrate the applicability of this system-identification technique to study cochlear processing to broadband input. Specifically, the linear and nonlinear components of TEOAEs will be studied using coherence measures.

I. SYSTEM-IDENTIFICATION PROCEDURE

A. Goals and procedure

The primary goal in system identification is to decipher the properties of an unknown system given the input and output measured from the system. The first step is to model the unknown system based on reasonable assumptions about the system and its nonlinear components. One such model is illustrated in Fig. 1(a). This is a single input/single output system with a linear system in parallel with finite-memory nonlinear systems. a_1, a_2, and $a_3 \ldots a_n$ are linear filters and $g_2[x(t)]$ and $g_3[x(t)] \cdots g_n[x(t)] \cdots$ are zero-memory nonlinear systems. The cascade of a zero-memory nonlinearity and a linear filter results in a more general class of nonlinearities, called a finite-memory nonlinearity.

For our purpose we defined a third-order polynomial model where the $g_2(x)$ and $g_3(x)$ were defined to be a squarer and a cuber followed by filters, a_2 and a_3, respectively. In the frequency-domain representation, $X_1(f)$, $X_2(f)$, and $X_3(f)$ are the Fourier transforms of $x(t)$, $x^2(t)$, and $x^3(t)$, respectively. This frequency-domain representation can be extended to any arbitrary number of $g_n[x(t)]$ as $X_n(f)$ followed by the corresponding $A_n(f)$. The fifth-order polynomial model is an extension of the third-order model, with a fourth-order and fifth-order zero-memory nonlinear systems which are in series with corresponding filters. The nonlinear model shown in Fig. 1(a) can be replaced by multi-input/single-output model and represented in the frequency domain as shown in Fig. 1(b). The derivation of frequency-domain formulas and the demonstration of the equivalence of single-input/single-output models to multiple-input/single-output models are presented in detail in Bendat (1990) and will not be dealt with here. Figure 1(b) shows the representation of the *n*-th order polynomial model as multi-input/single-output model in the frequency domain. Capitalized variables, $X_1(f), X_2(f), X_2(f), \ldots, X_n(f)$; $A_1(f), A_2(f), A_3(f), \ldots, A_n(f)$; $Y_1(f)$, $Y_2(f)$; $Y_3(f), \ldots, Y_n(f)$; $Y(f)$ and $N(f)$ are Fourier transforms of their associated time-domain waveforms, $x(t), x^2(t), x^3(t), \ldots, x^n(t)$; $y_1(t), y_2(t), y_3(t), \ldots, y_n(t)$; $y(t)$ and $n(t)$, respectively. The inputs from the different paths are correlated. The purpose of the analysis is to estimate the unknown systems, $A_1(f), A_2(f), A_3(f), \ldots, A_n(f)$. The system properties are estimated from simultaneous measurements of the input, $X(f)$ and output, $Y(f)$, so that the noise term, $N(f)$ is minimized. The term $N(f)$ accounts for the joint effects of measurement noise and modeling error. The estimation of the A filters requires the calcu-

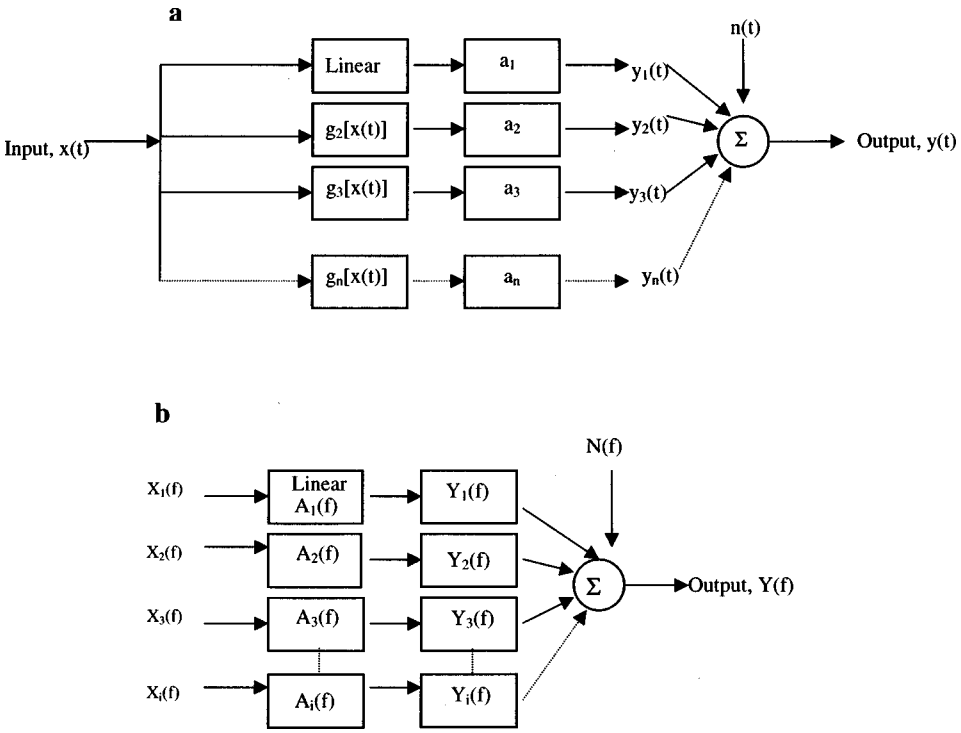

FIG. 1. (a) A time-domain model of a single-input/single-output system with a linear system in parallel with a finite memory nonlinear system. The linear filters are represented by $a_1, a_2, a_3, \ldots, a_n$. The zero-memory nonlinear systems are represented by $g_2[x(t)]$ and $g_3[x(t)]\cdots g_i[x(t)]$. $y_1(t), y_2(t), y_3(t), \ldots, y_n(t)$ are outputs from the different paths. $Y(t)$ is the summated output and $n(t)$ represents the noise term. (b) A frequency-domain model of a multi-input/single-output model which is equivalent to the single-input/single-output model shown in Fig. 1(a). The terms, $X_1(f), X_2(f), X_3(f), \ldots, X_n(f)$ are the spectrum of respective time-domain signals for the different paths. $A_1(f), A_2(f), A_3(f), \ldots, A_n(f)$ are the corresponding filters in the frequency domain. $Y_1(f), Y_2(f), Y_3(f), \ldots, Y_n(f)$ are the output spectra from the different paths. $Y(f)$ is the summated output spectrum of the system. $N(f)$ is the noise spectrum.

lation of autospectral (S_{xx}, S_{yy}) and cross-spectral (S_{xy}) density functions between inputs and outputs of the various paths. The next step is to uncorrelate the multiple inputs by using an ordered set of ''conditioned,'' or what are known statistically as ''residual,'' input records. Coherence measures, $\gamma^2_{u_i y}(f)$, are then computed from the uncorrelated input and the output spectral-density functions. It is important to understand that the coherence measures have been computed after uncorrelating the multiple inputs. This means, for example, that the third-order coherence is an indicator of how much of the output can be explained by the third-order path after subtracting the effects of the first- and second-order path. Thus, the third-order coherence function reflects only third-order distortions ($2f1-f2$, $2f2-f1$, $3f1$,... etc.) and not lower-order distortion products. To summarize, an *n*th-order polynomial does indeed generate distortion products lower than *n*th order, but an *n*th-order coherence function reflects only *n*th-order distortion products (since the effects of the lower-order distortion products have been subtracted out during the uncorrelation process). This, in fact, is the strength of this procedure as it allows us to use coherence functions as a measure of distortion from the different nonlinear paths. Coherence values lie between 0 and 1, and their magnitude is related to the degree of association between the input of a path and the total output. The coherence functions are summed algebraically to yield a cumulative coherence function that provides a measure of the model's overall goodness-of-fit. The closer the cumulative coherence is to 1, the better the fit. The goodness-of-fit with which the system under consideration can be identified depends largely on the zero-memory nonlinearity one chooses for the model and the amount of noise in the measurements (Bendat, 1990; Bendat and Piersol, 1993). Formulas for calculating spectral-density functions, estimation of *A* filters and coherence functions are not provided here, as they are available in Bendat (1990) and Bendat and Piersol (1993).

B. Selection of models

It is generally agreed that the outer-hair-cell transduction process plays a central role in the generation of cochlear nonlinearities that are observed in evoked otoacoustic emissions (Anderson and Kemp, 1979; Kim, 1980; Kemp, 1982; Zwicker, 1983; Brown, McDowell, and Forge, 1989; Patuzzi *et al.*, 1989). Although the exact nonlinearity is still unknown, researchers are in agreement that the OHC transduction function is a general compressive nonlinearity. Cody and Russell (1987) have shown that the I/O function for OHCs exhibits saturation. The saturation effects may be modeled by the function, x^α with values of α between 0 and 1 (Smoorenburg, 1972). Zwicker (1986), for his ''preprocessing'' model, assumed a power function with an exponent of 0.4 (up to levels of 40 dB SPL).

Simulation experiments were done to test whether or not the polynomial models would adequately model a compressive nonlinearity of the type x^α, where α was set to 0.4. A system composed of the compressive nonlinearity x^α followed by a Butterworth filter with a low-pass cutoff of 4 kHz and a rolloff of 18 dB/octave was simulated. The input, $x(t)$, was an ensemble of 30 records. The input $x(t)$ was passed through the nonlinear system and the corresponding output $y(t)$ was obtained. Both third-order and fifth-order polynomial models were used to analyze the simulated $x(t)$ and $y(t)$. Bendat's procedure was used to identify the filters in the linear and the nonlinear paths. These calculated filters were used to derive the original Butterworth filter that was cascaded with the x^α nonlinearity. The derived Butterworth filters were then compared with the original Butterworth filter to see how well the third- and fifth-order polynomials-

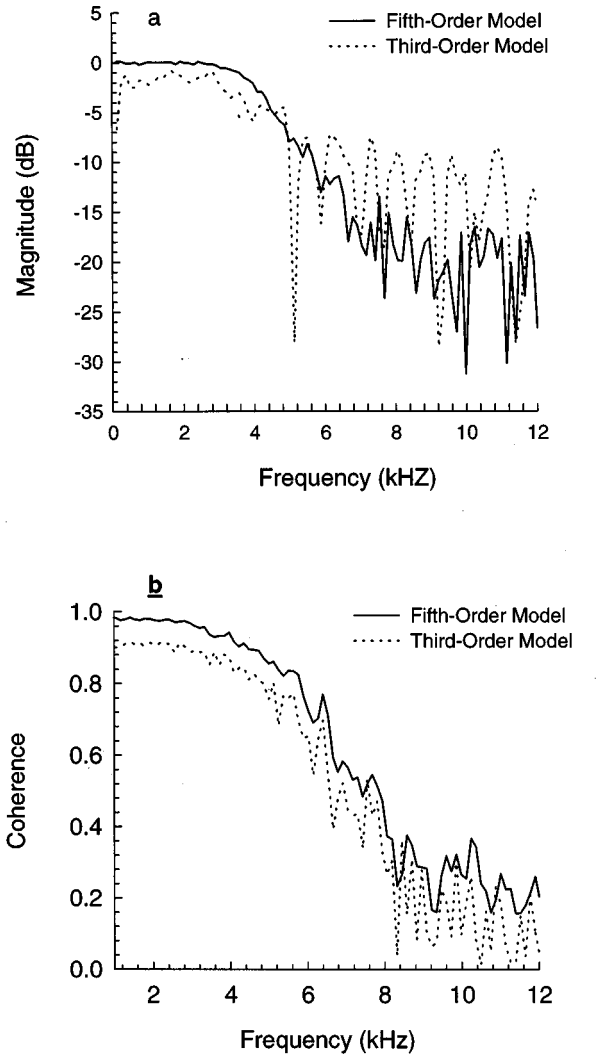

FIG. 2. (a) Estimated filters using the fifth- and third-order polynomial model for the simulation experiment where the x^{α} nonlinearity was low-pass filtered using a Butterworth filter with a 4-kHz cutoff and a rolloff of 18 dB/octave. The dotted line represents the estimated filter from the third-order model and the solid line represents the filter from the fifth-order model. (b) Cumulative coherence function from the third- and fifth-order models for the simulation experiment. The dotted line represents third-order cumulative coherence and the solid line represents fifth-order cumulative coherence.

could model the compressive nonlinearity x^{α}. The filter cutoff and rolloff from the fifth-order model [Fig. 2(a)] corresponded with the actual Butterworth filter, whereas the third-order model estimate did not yield the appropriate cutoff frequency and rolloff of the filter. Furthermore, the cumulative coherence was used to measure the goodness-of-fit of the two models. The cumulative coherence functions from the third-order and the fifth-order polynomial models are shown in Fig. 2(b). There was an increase in mean cumulative coherence, from 89% for the third-order to 96% for the fifth-order model. The increase in coherence, although seemingly small, was accompanied by better approximation of the original filter with the fifth-order polynomial. These results suggest that a compressive nonlinearity of the type x^{α} can be adequately modeled with a polynomial of sufficiently high order.

In a previously reported study, using Bendat's procedure, we modeled TEOAE data using a third-order polynomial function (Krishnan and Chertoff, 1995). In this paper, both third-order and fifth-order polynomial functions are fit to TEOAE data and the results from the two polynomial models are compared. Bendat's technique is not limited to using polynomial models. Any nonlinear function can be used for the $g(x)$ term. However, in this study, polynomials were chosen to model the compressive nonlinearity for two reasons: First, any general nonlinearity such as the power function with an exponent between 0 and 1 can be expanded into a Taylor or Laurent infinite series which converges over a limited range. Therefore, by using a sufficiently high-order polynomial model, we can model any arbitrary nonlinearity over a limited range of input amplitudes. In this study, the range is for input amplitudes up to 92 dB SPL (p–p) which is the peak-to-peak value of the finite impulse response (FIR) pulse used to evoke the emissions. Second, recent studies have found differences in the suppressive effects on odd-order and even-order distortion products in response to ipsilateral and contralateral stimulation to tones and broadband noise. These differences have been attributed to different sources of nonlinearities within the cochlear partition (Kirk and Johnstone, 1993; Chang and Norton, 1997), and more specifically, to the properties of the receptor potentials of the OHCs (Chang and Norton, 1997). The power spectrum of TEOAE of guinea pigs also show changes corresponding to the frequency of the signal used for overstimulation (Ueda *et al.*, 1997). The proposed procedure in this study will allow a detailed examination of the effects of such overstimulation on the linear and nonlinear components of TEOAEs. Our long-term goal is to use coherence measures to examine the effects of drug and noise exposure in animal models and humans. The choice of a polynomial model has some clear advantages in that the changes in the nonlinear coherence functions can be examined for the different orders. This could be potentially used as a clinical and research tool for monitoring the cochlea when normal functioning is disrupted. The coherence functions that are obtained from a polynomial model from the different nonlinear paths provide a measure of proportion of energy from the different nonlinear paths relative to total output. That is, we will be able to examine the contributions of the odd-order and even-order distortions to the output. On the other hand, if a general nonlinear function is used for the $g(x)$ term, we could only obtain the coherence function for the linear path and the nonlinear path. Furthermore, the use of a compressive function requires that we specify values for a number of parameters. For example, if the nonlinearity is modeled with x^{α}, then the model needs to be tested for a range of values of α. If a hyperbolic tangent function is used to model the nonlinearity, then various rectification factors need to be tested. With the use of a polynomial model, the system parameters are derived from the procedure. One disadvantage is that we may need to increase the order of the polynomial model to improve the fit. It should be emphasized that although the approach under investigation is strictly functional, having no structural implications, it will allow us to describe the system transfer characteristics that transform a broadband stimulus into a response.

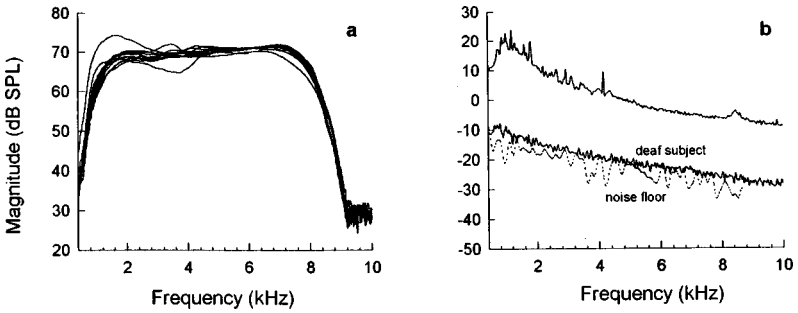

FIG. 3. (a) Input spectral-density function (S_{xx}) for 11 subjects. (b) Mean output spectral-density functions (S_{yy}) averaged across subjects. The bottom-most plot shows the output spectrum for the control subject who is deaf (solid line). The dotted line in the same panel marks the noise floor.

II. GENERAL METHODS

A. Subjects

Eleven normal-hearing adults between the ages of 18 and 40 years served as subjects. Subjects were included in the study if their pure-tone thresholds were 15 dB HL or better for octave frequencies between 250 and 8000 Hz. Tympanograms showed normal middle-ear function. All subjects had a negative history of extreme exposure to noise or use of ototoxic drugs and familial hearing loss. One subject with profound deafness served as a control.

B. Stimulus generation

The transient stimulus for evoking otoacoustic emissions consisted of a band-limited signal (1000 to 8000 Hz) that was generated by a finite impulse response (FIR) filter. The stimulus (2404 points) was generated in MATLAB (The Mathworks, 1993) and uploaded to an array processor (AP2, Tucker-Davis Technologies). The D/A output sampled at 65.536 kHz was sent to an attenuator (PA4, Tucker-Davis technologies) and delivered to a transducer (Knowles BP 1712). The stimulus was measured in each individual ear canal with a microphone (Knowles EK 3133). The signal had a flat frequency spectrum with an overall sound-pressure level of 70 dB across frequencies.

C. Data acquisition

Otoacoustic emissions were recorded with a custom-built probe that housed the transducer and microphone. The output of the microphone was high-passed at 400 Hz (Krohn-Hite) and low-passed at 10 kHz (Stanford, SR560), and amplified with a gain of 10 000 (Stanford, SR560). The amplifier was off for the first 3 ms after stimulus onset to prevent saturation of the amplifier. The signal was routed to an A/D converter (Tucker-Davis) for time-domain averaging, and an artifact reject routine rejected signals that saturated the A/D converter.

D. Experimental protocol

The first session for every subject included an audiological evaluation, which consisted of obtaining pure-tone thresholds, a tympanogram, and an otoscopic examination. The choice of a test ear was random, unless one ear was better than the other on audiological measures, in which case the better ear was chosen. Each subject was seated in a comfortable recliner in a sound-treated booth and allowed to relax during recording. Subjects were given breaks as needed. Test sessions lasted for 30–40 min.

A spectral-equalization procedure preceded recording of emissions. Details of this procedure are presented in Chertoff and Chen (1996). Briefly, this involved obtaining the ear canal's transfer function using an initial probe signal. The inverse of the transfer function was convolved with the desired signal, and the ''conditioned signal'' was obtained. The conditioned signal, when delivered into the ear canal of the individual, resulted in a flat frequency response. This flat-spectrum signal was then used to evoke otoacoustic emissions. The beginning of emissions was set at 4.5 ms from time zero. The actual energy in the FIR pulse begins 0.75 ms after time zero. So, emission responses measured from 4.5 ms from time zero are actually 3.75 ms from stimulus onset. Each recording was done for 30 ms.

A total of 30 stimulus/response records was obtained for each subject. Each emission record was obtained with 500 averages. A break occurred during recording if the stimulus changed drastically, due to displacement of the probe or if the subject needed a break. Following such breaks, the spectral-equalization procedure was repeated prior to additional data collection.

E. Models for system identification

System identification was performed using two models. The first was a third-order polynomial model. The second was an extension of the third-order model, with the addition of fourth- and fifth-order nonlinear paths [Fig. 1(a) and (b)]. The analyses were performed on 30 stimulus and 30 emission records for each of the 11 subjects and one control subject, who was profoundly deaf. Spectral-density functions were computed from fast Fourier transforms of 2048 points. From the input and output spectral-density functions, the frequency response and the phase response were obtained. Coherence measures were obtained for each path, and the cumulative coherence was calculated to test the models' goodness-of-fit. The coherence measures obtained for the two models were compared.

III. RESULTS

A. Spectral-density functions

Otoacoustic emissions were present for all 11 normal subjects in response to FIR pulse. In Fig. 3(a), the autospectral-density function for the stimulus (S_{xx}) is shown

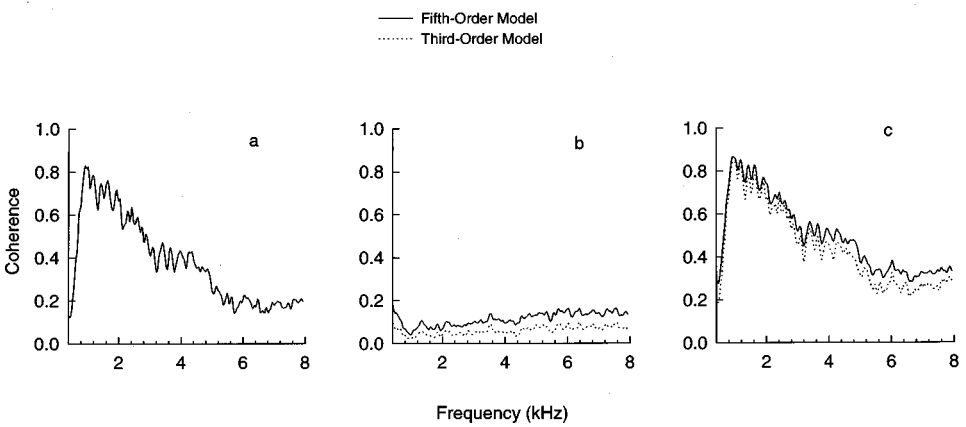

FIG. 4. Dotted lines represent coherence estimates from the third-order model. Solid lines represent coherence estimates from the fifth-order model. (a) Mean linear coherence. (b) Mean nonlinear coherence. (c) Mean cumulative coherence.

for each of these subjects. The spectral equalization resulted in a flat spectrum for most subjects for frequencies between 1 and 8 kHz. Figure 3(b) shows the mean autospectral-density function (S_{yy}) of the response averaged across subjects. The bottom curve shows the autospectral-density function of the response for the control subject with profound deafness, which coincided with the noise floor. This comparison shows that the responses from the 11 subjects were biological and above the noise floor.

B. Comparison of third- and fifth-order models

Figure 4(a)–(c) show the two models' mean coherence functions averaged across all normal subjects. The linear coherence function [Fig. 4(a)] is identical for both models. Figure 4(b) shows that the total nonlinear coherence from the fifth-order model is higher than that from the third-order model. Figure 4(c) shows that the cumulative coherence function from the fifth-order model is higher than that from the third-order model. There was an increase in the mean cumulative coherence of approximately 10% from the third- to the fifth-order model. This suggests that the fifth-order model provides a better fit to the otoacoustic emissions data. This increase of 10% is important, as the results of the simulation experiment suggests that small increases (7% in simulation experiment) are accompanied by a more accurate estimation of the properties of the original filter.

C. Coherence functions

The linear coherence functions for all subjects are presented in Fig. 5. These plots were obtained from the fifth-order model analysis. The nonlinear coherences are grouped according to even order (Fig. 6) and odd order (Fig. 7). From each of the coherence functions, the proportion of energy was averaged across frequency bands (1–2, 2–4, 4–6, and 6–8 kHz). The mean coherence as a function of frequency bands is shown in Fig. 8(a)–(e). The proportion of energy in these bands was examined and compared with the results reported in the acoustic distortion-product literature.

1. Linear coherence

For most subjects, linear coherences of at least 0.75 are seen for frequencies up to 1–2 kHz, as seen in Fig. 5. This trend is clearly seen in Fig. 8(a). Individuals show varying rates of decline in coherence values. For example, some subjects show a gradual decline in coherence from 2 to 4 kHz (e.g., S1), while for others, the decline is more abrupt (e.g., S4), and the bandwidth for which relatively high coherence values are present differs among individuals. The last panel of Fig. 5 (S12) shows the linear coherence function for the subject with profound deafness. It is near zero, indicating no degree of linear relation between input and output.

2. Even-order coherence

The second- and fourth-order coherence functions are shown for all subjects in Fig. 6. Second-order coherence functions reveal relatively high coherence values for a narrow frequency region below 1 kHz for most subjects. This may reflect second-order distortion-product terms of the form $f2-f1$, generated in the second-order path.

3. Odd-order coherence

The third- and fifth-order coherence functions are shown in Fig. 7 for all subjects. One consistent pattern among subjects is that the third-order coherence increases steadily for all subjects for frequencies between 1 and 8 kHz [Fig. 8(c)] This is perhaps due to the distortion-product terms of the form $3f1$, $2f1+f2$, or $2f2+f1$ generated in the third-order path. The fifth-order coherences are generally lower than the third-order coherences. However, there are exceptions. For example, S2 has a large peak in the fifth-order coherence function below 2 kHz, and the corresponding third-order coherence measures for that frequency region are lower. Similar to the third-order coherence, the fifth-order coherence also shows an increase from 1–2 and 6–8 kHz [Fig. 8(e)].

IV. DISCUSSION

A. Cochlear processing of broadband input

This analysis provides strong evidence that nonlinearities higher than third order are generated in the cochlea and that they can be detected in TEOAEs. In addition to second- and third-, fourth- and fifth-order nonlinearities were found for all 11 subjects.

Although the most commonly and easily detected distortion-product emissions to two-tone stimulation are third order, there is now evidence that the nonlinear cochlear

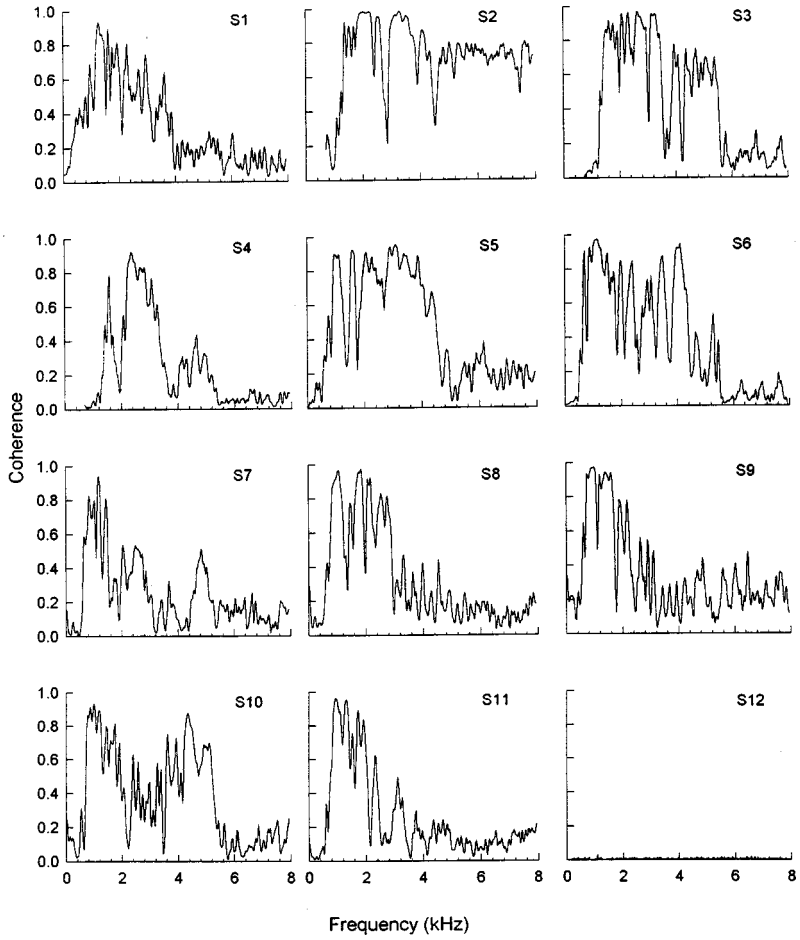

FIG. 5. Linear coherence functions shown for all subjects. The last panel (S12) shows linear coherence function that is close to zero for the control subject, who is profoundly deaf. This coincides with the noise floor.

transduction requires a model that is higher than third order. Weiss and Leong (1985), for example, have used a hyperbolic tangent function to model the channel conductance of the OHCs as a function of angular displacement of the stereociliary tuft. Patuzzi *et al.* (1989) have used a ninth-order polynomial to model the mechanical-to-electrical OHC transduction. More recently, Evans *et al.* (1991) fitted the voltage-length change function of the OHCs using a second-order Boltzmann equation. For the same data, they also reported that a fifth-order polynomial function did not adequately describe the saturation at extreme voltages. The data presented here also is in support of this, as the cumulative coherence does not equal 1, even for the fifth-order model. These nonlinear relations of the different but related cochlear processes indicate that a complete characterization of the nonlinear transduction has to include nonlinearities of orders higher than fifth. Although the fifth-order polynomial is a better fit than the third-order model to the TEOAE data presented here, future work in the use of this procedure should focus on higher-order polynomial models or other nonlinear functions to completely characterize cochlear transduction, and thereby improve the cumulative coherence.

Fifth- and higher-order DPOAEs have been reported in two-tone experiments in rabbits (Lonsbury-Martin *et al.*, 1987), gerbils, guinea pigs, and humans (Brown and Williams, 1993; Brown and Gaskill, 1990). However, the most commonly detected DPOAE in two-tone stimulation experiments under a variety of stimulus conditions in humans is the $2f1-f2$ frequency (Probst *et al.*, 1991). One possible explanation for the differences in detecting distortion products of higher orders using broadband stimuli, as seen in this study and in two-tone experiments, is that the cochlea responds differently to the different types of signals. With broadband stimulation there is a greater opportunity for interactions among frequencies, whereas, with two-tone stimuli the interactions are much less. This is an important difference between the distortion products evoked with two-tone stimuli and broadband stimuli. Interactions can also occur between numerous primary frequencies, between distortion products and primaries resulting in the generation of higher-order distortion products. Interactions between the various spectral components can actually result in the enhancement or attenuation of certain frequencies depending on individual system properties and phase relations between the forward- and backward-traveling waveforms. It has been noted that $2f1-f2$ and $3f1-2f2$ DPOAEs were larger in amplitude, and hence easily measured, when the stimuli were close in frequency (Gaskill and Brown, 1990). The closeness of frequencies in broadband input can result in detectable higher-order nonlinearities. With the use of broadband input, the level of fifth-order nonlinearities may be higher than two-tone DPOAEs due to enhancement of certain spectral components, consequently resulting in better signal/noise ratio.

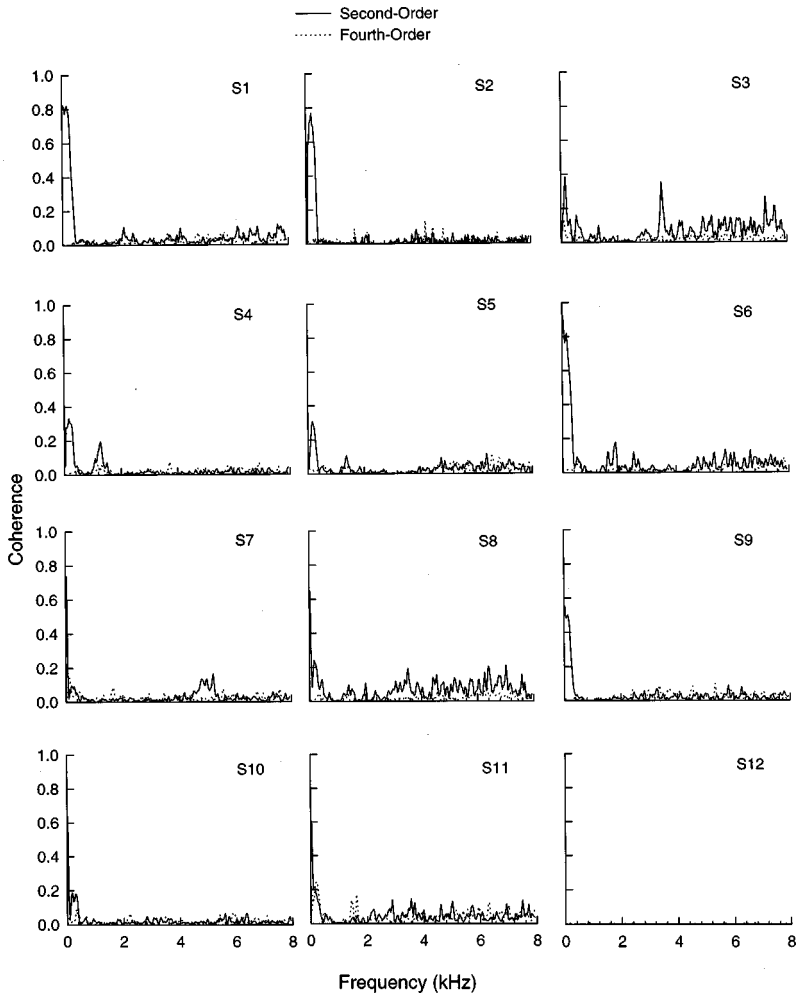

FIG. 6. Even-order coherence functions shown for all subjects. The second-order coherence functions are shown as solid lines and the fourth-order functions are shown as dotted lines.

B. Coherence functions: Further insights into linear and nonlinear processes

The coherence values reflect the proportion of energy from each path relative to the total energy of the response. Comparisons of linear and nonlinear coherence between frequency bands reveal interesting trends. For most subjects, the linear coherence was relatively high below 4 kHz, and decreased above 4 kHz. This is evident from the linear coherence functions.

The study's observations of an increase in third-order nonlinear coherence between 4 and 6 kHz are consistent with the two-tone $2f1-f2$ DPOAEs. In a recent study, Lonsbury-Martin *et al.* (1990) reported a substantial increase in the level of $2f1-f2$ DPOAEs in the frequency region between 4 and 6 kHz. They examined the level of DPOAEs as a function of the geometric mean frequencies of the primaries. An increase in $2f1-f2$ amplitude of approximately 10 dB between 1 and 6 kHz for stimulus levels of 75 and 85 dB SPL was reported. Similar increases were reported by Gaskill and Brown (1990) for $2f1-f2$ levels as a function of the primary frequency, $f1$. As noted by Lonsbury-Martin *et al.* (1990), this increase in the distortion-product levels for high frequencies, despite the possible attenuation by the middle ear, implies that at high frequencies the levels of distortion products are likely to be very large within the cochlea. These observations are supported by our results on the increase in the nonlinear coherences between 1 and 6 kHz and the corresponding decline in the mean linear coherences. The notable increase in total nonlinear coherence for the higher frequencies, 4–6, and 6–8 kHz, compared to 1–2 kHz observed in the present study, suggests that cochlear processing is more nonlinear for this frequency range compared to 1–2 kHz. Based on these findings, it is reasonable to conclude that a considerable amount of high-frequency energy in evoked emissions is due to distortions from nonlinear processes.

There are anatomical and physiological characteristics that distinguish the high-frequency (basal) and the low-frequency (apical) regions of the cochlea. *In vivo* studies suggest differences in tuning curves of the nerve fibers innervating the basal and apical ends of the cochlea. Fibers with high characteristic frequencies are more sharply tuned than those with low characteristic frequencies (Kiang *et al.*, 1965). Much of the differences between the high- and the low-frequency tuning appear to be related to differences in OHCs at the base and apex of the cochlea. One significant difference is that basal OHCs receive greater efferent input than the apical cells (Spoendlin, 1969, 1979). It is well known that contralateral stimulation, which presumably excites the efferent system, reduces the level of acoustic distortion products (Puel and Rebillard, 1990; Veuillet *et al.*, 1991). Furthermore, while the loss of basal cells has an im-

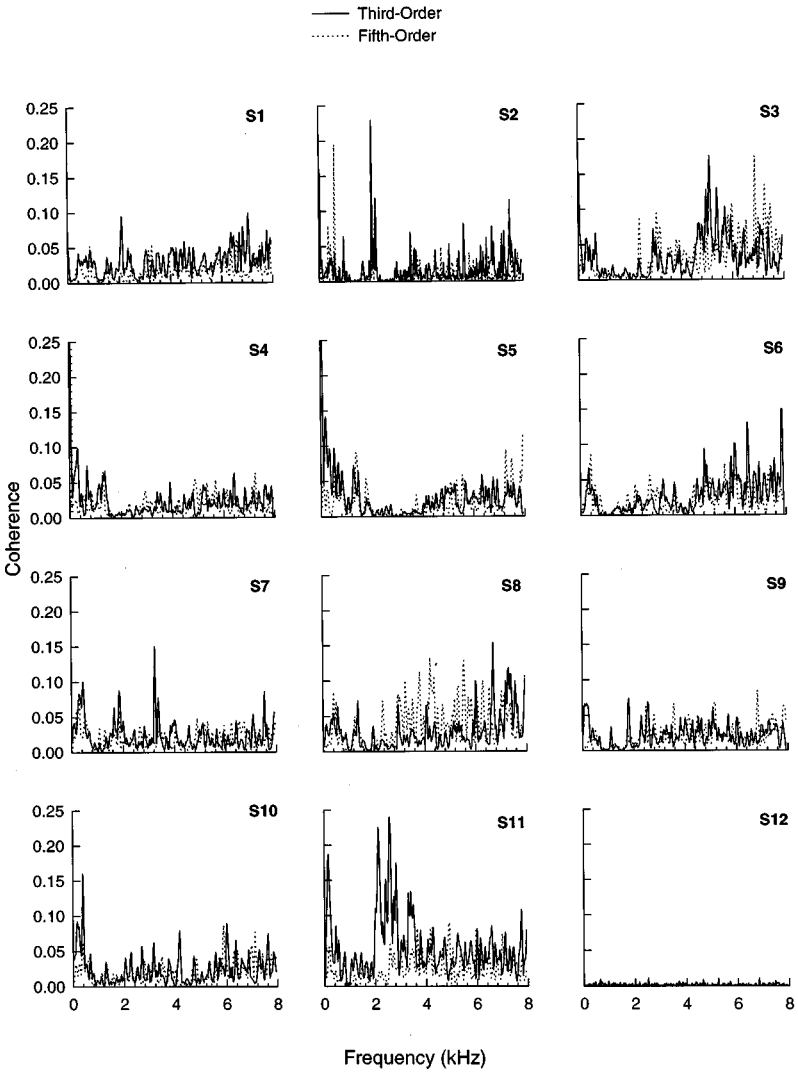

FIG. 7. Odd-order coherence functions for all subjects. The cubic coherence functions are shown as solid lines and the fifth-order functions are shown as dotted lines.

mediate effect on frequency sensitivity, the loss of apical cells is not necessarily reflected in threshold shifts (Altschuler *et al.*, 1992). Thus, the inherent sharper tuning and higher sensitivity of the basal cells may result in the generation of distortions of higher levels for high frequencies, compared to the low frequencies. Two other explanations are possible. First, the higher density of OHCs in the basal region compared to the apical region may also render the basal region relatively more sensitive, and consequently generate distortions of higher levels. Second, the stimulus used in this study had a flat spectrum that could result in relatively greater energy in the high-frequency region, resulting in greater stimulation and more distortion in the basal region of the cochlea. Comparisons of linear and nonlinear coherence functions have provided some insights into linear and nonlinear cochlear processing of broadband input.

It is difficult, however, to compare absolute distortion-product levels with nonlinear coherence measures because they measure different quantities. For example, levels of $2f1-f2$ cannot be directly compared with third-order coherence values. Third-order coherence reflects the percentage of all third-order distortions that are not statistically correlated to the first and second orders. The point that needs to be emphasized is that coherence functions provide a new and different measure of nonlinear processes. They are a measure of distortion that indicates the amount of uncorrelated energy added from the nonlinear paths to the output. The relative changes in the odd- and even-order coherences in response to changes in the cochlear status can, however, be compared with relative changes in the even- and odd-order DPOAEs. Future investigations along this line will likely provide a better understanding of the source of generation of the two types of emissions.

V. CONCLUSIONS

The primary goal of this study was to use a system-identification technique to understand linear and nonlinear processing in the cochlea for broadband input. The most important outcome of this study is the demonstration that Bendat's system-identification technique can be usefully applied to the study of linear and nonlinear properties of cochlear transduction. Furthermore, the coherence measures that are obtained through this procedure offer insights into linear and nonlinear cochlear processing of broadband signals. The coherence functions are functions of frequency, from which we can obtain frequency-specific information, and this information can be related to the localized status of the cochlea.

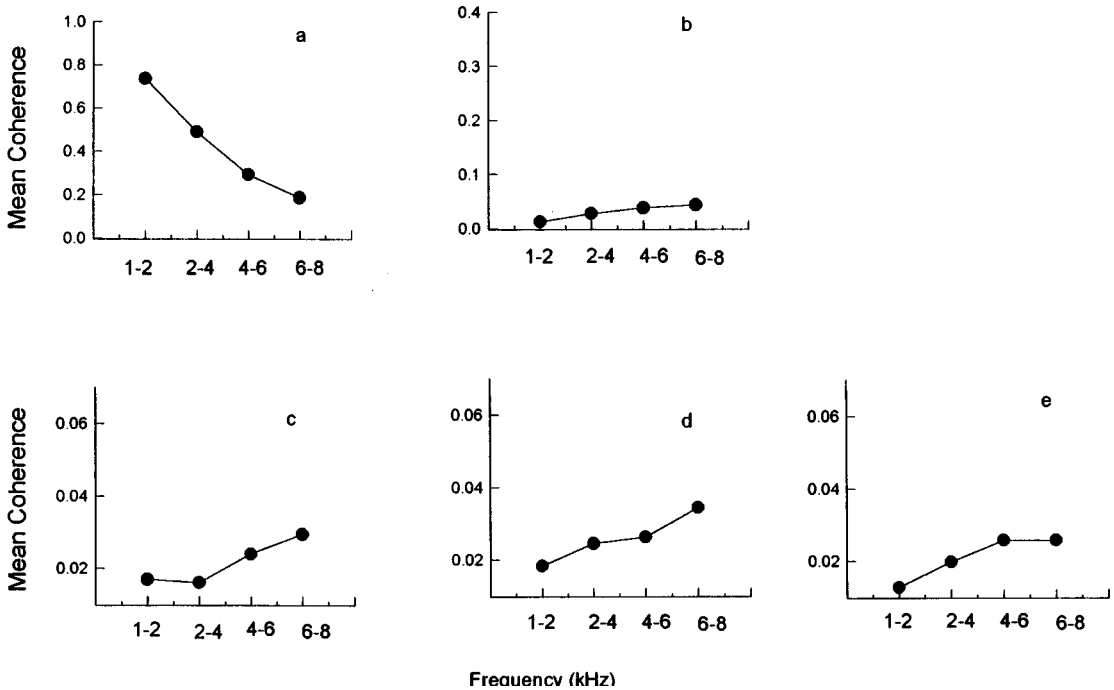

FIG. 8. (a) Mean linear coherence averaged across subjects shown as a function of frequency bands. (b) Mean second-order coherence averaged across subjects shown as a function of frequency bands. (c) Mean third-order coherence averaged across subjects shown as a function of frequency bands. (d) Mean fourth-order coherence averaged across subjects shown as a function of frequency bands. (e) Mean fifth-order coherence averaged across subjects shown as a function of frequency bands.

Additionally, these functions provide a measure of goodness-of-fit of the chosen model. In this study, third-order and fifth-order polynomial models were used to find the least-squares fit to the I/O relations, and the cumulative coherence showed that the fifth-order model is a better fit than the third-order model to the otoacoustic emissions data, evoked using a broadband FIR pulse. At this time, the characterization of the properties of the cochlear transduction is by no means complete. The total coherence for the fifth-order model is still less than 1 and this suggests that further improvement in the model is in order. One such improvement would be to use other nonlinear functions such as the hyperbolic tangent function, Boltzmann equation, or a polynomial model of a higher order for the zero-memory nonlinearity. Additionally, improvement in the cumulative coherence may also occur with reduction in the noise term. This may be possible if the number of input/output records used in the computation was increased.

Most importantly, coherence measures which are functions of frequency are useful indices of linear and nonlinear processes: It is conceivable that changes in the cochlear status due to different causes will show differences in coherence functions from the different nonlinear paths. Changes in trends as well as relative changes in coherence from the different paths may prove to be relevant factors in the clinical monitoring of cochlear status. The application of Bendat's system-identification procedure is by no means limited to otoacoustic emissions data. Physiological responses obtained using other techniques can be subjected to a similar analysis and the linear and nonlinear properties of responses can be characterized. For example, cochlear microphonic responses may also be obtained using broadband input and the linear/nonlinear processes involved in evoking these responses may be characterized and compared with those obtained using otoacoustic emissions.

Bendat's system-identification procedure offers an opportunity to compare TEOAE analysis with DPOAEs evoked with two-tone signals. For example, one study that is underway examines the effects of aspirin on DPOAEs and the relative changes in coherences of different orders. Currently, there is a lack of consensus on whether or not TEOAEs and DPOAEs are generated by a common source. A comparative analysis of relative changes in DPOAEs and the nonlinear components of TEOAEs, in a given model, such as guinea pigs or humans, will undoubtedly shed more light on this issue.

The focus of this paper has been on the coherence function, because of its potential as a clinical tool. Other outputs of this procedure are the spectral-density functions, and the A filters. The spectral-density functions are calculated for the set of stimulus and response records (please see Sec. I: System identification technique). The phase plot of the spectral-density function obtained from the response records can be potentially useful in the development of a measure of latency of emissions. The A filters can be used to predict system responses to other stimuli or stimulus conditions. These are just some of the avenues that are open for future work using this technique.

Last, this procedure is computationally feasible and provides us with a coherence measure, which is a potential clinical tool. A full understanding of the cochlear processes can be more successfully attained through the blending of several approaches and cross-validating empirical findings through different analytical techniques.

ACKNOWLEDGMENTS

This research was done at the University of Kansas, School of Allied Health, Department of Hearing and Speech, Kansas City, Kansas, and is based on part of the doctoral thesis by Geetha Krishnan. We wish to thank John Belmont, John Ferraro, of the University of Kansas Medical Center, and Christopher Schweitzer of Audiologic, Boulder, Colorado, for their helpful discussions and comments. We also thank several participants at the third joint meeting of the ASA and ASJ (Dec. 1996 in Honolulu, Hawaii) who demonstrated interest in this paper and provided very helpful comments. We would also like to thank the reviewers for their comments and suggestions.

Evoked otoacoustic emissions arise by two fundamentally different mechanisms: A taxonomy for mammalian OAEs

Christopher A. Shera[a] and John J. Guinan, Jr.
Eaton-Peabody Laboratory of Auditory Physiology, Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, Massachusetts 02114 and Department of Otology and Laryngology, Harvard Medical School, Boston, Massachusetts 02115

(Received 2 June 1998; accepted for publication 27 October 1998)

Otoacoustic emissions (OAEs) of all types are widely assumed to arise by a common mechanism: nonlinear electromechanical distortion within the cochlea. In this view, both stimulus-frequency (SFOAEs) and distortion-product emissions (DPOAEs) arise because nonlinearities in the mechanics act as ''sources'' of backward-traveling waves. This unified picture is tested by analyzing measurements of emission phase using a simple phenomenological description of the nonlinear re-emission process. The analysis framework is independent of the detailed form of the emission sources and the nonlinearities that produce them. The analysis demonstrates that the common assumption that SFOAEs originate by nonlinear distortion requires that SFOAE phase be essentially independent of frequency, in striking contradiction with experiment. This contradiction implies that evoked otoacoustic emissions arise by two fundamentally different mechanisms within the cochlea. These two mechanisms (linear reflection versus nonlinear distortion) are described and two broad classes of emissions—reflection-source and distortion-source emissions—are distinguished based on the mechanisms of their generation. The implications of this OAE taxonomy for the measurement, interpretation, and clinical use of otoacoustic emissions as noninvasive probes of cochlear function are discussed. [S0001-4966(99)02202-X]

INTRODUCTION

During the 20 years since Kemp's (1978) discovery, otoacoustic emissions (OAEs) have become widely used, both as research tools and as clinical diagnostic and screening aids (e.g., Kemp *et al.*, 1986; Norton and Stover, 1994; Whitehead *et al.*, 1996a; Robinette and Glattke, 1997). Interpretation of measured otoacoustic responses is grounded on an underlying picture of the origin of evoked OAEs. All categories of evoked OAEs are commonly regarded as originating in nonlinear distortion, presumably through the electromotile responses of outer hair cells (Brownell, 1990). These nonlinearities in cochlear mechanics are thought to act as ''sources'' of backward-traveling waves (Kemp, 1978; de Boer, 1983; Allen and Neely, 1992). Kemp (1997) describes the physical mechanism—often simply abstracted as ''nonlinear stimulus re-emission'' by cellular ''emission generators''—in a recent review:

> ''The model of the phenomenon adopted at that time [circa 1978] is still relevant. It is that ... a nonlinearity at the peak of the traveling wave turns around or scatters back some of the traveling wave energy, and returns both stimulus frequency and intermodulation signals back to the middle ear.''

We epitomize in Table I the major elements of this ''common view''—and the nonlinear-distortion model that underlies it—as culled from the literature (e.g., Kemp, 1980, 1998; Probst *et al.*, 1991; Allen and Neely, 1992; Allen and Lonsbury-Martin, 1993; Patuzzi, 1996; Hartmann, 1997).[1]

In this paper, *we argue that the common view cannot be correct*. For although the nonlinear-distortion model accounts for distortion products, it cannot explain stimulus-frequency or transiently evoked emissions, in particular their phase, which rotates rapidly with frequency at low sound levels. Although considerably elaborated, our central argument is similar in spirit to that first used by Kemp and Brown (1983a) and later formalized by others (Strube, 1989; Shera and Zweig, 1993b; Zweig and Shera, 1995) to distinguish ''wave-'' and ''place-fixed'' emission mechanisms. By combining our argument with data on emission phase, we conclude that at low sound levels stimulus-frequency and transiently evoked emissions must arise by mechanisms fundamentally different from pure distortion products.[2] We therefore distinguish two classes of emissions—reflection- and distortion-source emissions—based on the mechanisms of their generation. Our mechanism-based taxonomy has important implications for the measurement, interpretation, and use of otoacoustic emissions as noninvasive probes of cochlear function.[3]

I. DEFINITIONS AND BACKGROUND

Otoacoustic emissions are typically classified according to the stimulus waveform and related details of the measurement paradigm (e.g., Zurek, 1985). Initially, we follow suit by distinguishing two classes of evoked emissions based on the relationship between the emissions and the stimuli used to elicit them:[4]

[a]Electronic mail: shera@epl.meei.harvard.edu

TABLE I. Synopsis of the ''common view'' of evoked emissions presented in the literature.

Common view of evoked emissions
• Evoked otoacoustic emissions arise through nonlinear stimulus ''re-emission'' by cellular ''emission generators'' (e.g., outer hair cells). • Stimulus re-emission occurs because electromechanical nonlinearities—principally those near the peak of the traveling-wave envelope—act as ''sources'' of backward-traveling waves. • SFOAEs and DPOAEs both arise through nonlinear distortion (e.g., SFOAEs can be thought of as ''zeroth-order'' DPOAEs arising from distortion at the first harmonic).

(i) Echo emissions comprise stimulus-frequency and transiently evoked emissions (SFOAEs and TEOAEs), grouped together because they occur at the frequency (or frequencies) of stimulation, whether the stimulus is a pure tone or an acoustic transient.

(ii) Distortion-product emissions (DPOAEs) occur at frequencies not present in the evoking stimulus (e.g., at the frequency $2f_1-f_2$ in response to stimulus tones at frequencies f_1 and f_2).

Our use of the distortion-product nomenclature is standard, and we introduce the term ''echo emissions'' simply as a convenient shorthand. In the common view these two classes of evoked emission both arise from nonlinear electromechanical distortion within the cochlea. Preparatory to further analysis, we review basic properties of echo emissions at low sound levels.

A. Characterizing echo emissions at low levels

As one sweeps the frequency of an acoustic stimulus tone, the pressure in the human ear canal, P_{ec}, varies as shown in Fig. 1. As the stimulus level is lowered, a regular oscillatory component appears superposed on a more smoothly varying ''background'' response. Whereas the shape of the background depends on the acoustics of the ear canal and middle ear, the oscillatory component represents an acoustic interference pattern created by the superposition of the stimulus tone and a second tone at the same frequency originating from within the cochlea (Kemp, 1978, 1979a,b). The relative amplitude of the oscillatory component grows as the stimulus level is reduced, until, at the sound levels near threshold shown in Fig. 2 ($\lesssim$5 dB SL), the interference pattern becomes approximately independent of sound level, indicating that stimulus and response are linearly related (Zwicker and Schloth, 1984; Shera and Zweig, 1993a). Similar quasi-periodic oscillations appear in the frequency spectra of the responses to low-level acoustic transients (e.g., Zwicker and Schloth, 1984).[5] At frequencies near 1500 Hz, the frequency spacing Δf_{OAE} between adjacent spectral maxima is approximately 100 Hz in human ears.

1. Interpretation using the cochlear traveling-wave reflectance, R

We interpret evoked emissions as indicating the presence of backward-traveling waves within the cochlea. To characterize their properties, we define the *cochlear traveling-wave reflectance*, *R*, as the complex ratio of the out-going (or emitted) pressure wave to the in-going (or stimulus) wave at the basal end of the cochlea near the stapes (Shera and Zweig, 1993a):[6]

$$R(f;A)\equiv\left.\frac{P_{\text{out-going}}}{P_{\text{in-going}}}\right|_{\text{stapes}}, \tag{1}$$

where *R* depends on both the frequency, *f*, and amplitude, *A*, of the stimulus. The cochlear reflectance provides a phenomenological characterization of the emission process as seen from the base of the cochlea.[7]

By regarding the intervening middle ear as a linear, two-port network, one can relate the cochlear reflectance, *R*, to measurements of ear-canal pressure, P_{ec} (Shera and Zweig, 1993a). When the emission amplitude is small relative to the stimulus ($|R|\ll 1$), the relation reduces to the simple formula[8]

$$\frac{P_{ec}(f;A)}{P_{ec}(f;A_{ref})}\approx\frac{A}{A_{ref}}[1+m(f)R(f;A)], \tag{2}$$

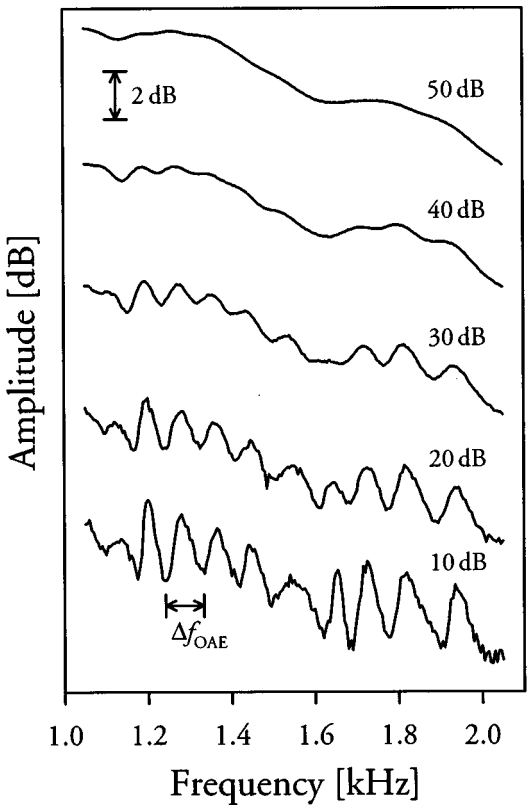

FIG. 1. Frequency dependence of ear-canal pressure and its variation with sound level in a normal human ear. The curves, offset vertically from one another for clarity, represent the normalized amplitude of the ear-canal pressure, P_{ec}, measured with a constant voltage applied to the earphone driver (Shera and Zweig, 1993a). The approximate sensation level of the stimulus tone at 1300 Hz is indicated on the right. At the highest level the pressure amplitude varies relatively smoothly with frequency. As the stimulus level is lowered, sound generated within the cochlea combines with the stimulus tone to create an oscillatory acoustic interference pattern that appears superposed on the smoothly varying background seen at high levels. Near 1500 Hz, the frequency spacing Δf_{OAE} between adjacent spectral maxima is approximately 100 Hz. Data from Shera and Zweig (1993a).

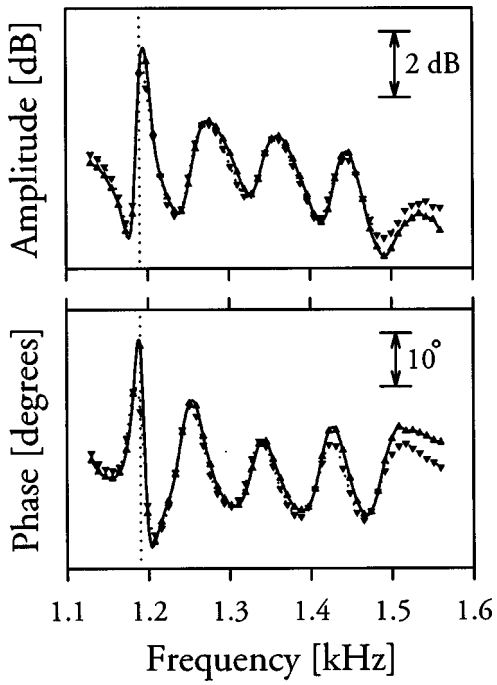

FIG. 2. Linearity at low levels manifest by measurements of the ear-canal pressure, P_{ec}, normalized by the amplitude of the earphone-driver voltage, at sound levels of 5 dB SL (▲) and 0 dB SL (▼) relative to threshold at 1300 Hz. The vertical dotted line marks the frequency of a known spontaneous emission. Aside from a small drift in the background—probably the result of slow changes in middle-ear cavity pressure and/or variations in the temperature of the recording microphone—the two functions nearly superpose, indicating that the response appears linear at these near-threshold levels. Adapted from Fig. 6 of Shera and Zweig (1993a).

where A is the stimulus amplitude and A_{ref} is a high-level reference amplitude at which the relative amplitude of the emissions is negligible (e.g., in humans $A_{ref} \approx 60$ dB SPL). The complex function $m(f)$ characterizes round-trip middle-ear transmission and varies relatively slowly with frequency (Shera and Zweig, 1993a).

At sound levels near threshold, R becomes independent of level, indicating that the emitted wave varies linearly with the stimulus. Solving Eq. (2) for mR using measurements of P_{ec} yields a function of slowly varying amplitude and rapidly rotating phase (Shera and Zweig, 1993a). Typical results, obtained from the measurements of Fig. 2 in the low-level linear regime, are shown in Fig. 3. Although the function $m(f)$ characterizing middle-ear transmission is not known in detail, middle-ear transfer functions vary relatively slowly with frequency compared to the oscillations in the ear-canal pressure spectrum (e.g., Puria *et al.*, 1997; Puria and Rosowski, 1997). The frequency dependence of the product mR is therefore primarily that of the reflectance R. Reference to Fig. 3 shows that[9]

$$\text{Emission measurements} \Rightarrow \begin{cases} |R| \approx \text{slowly varying} \\ \angle R \approx \text{locally linear with } f. \end{cases} \tag{3}$$

Over frequency intervals corresponding to a few oscillations in the pressure spectrum (i.e., over intervals a few times the size of Δf_{OAE}), the reflectance R has the approximate form[10]

$$R(f) \approx |R| e^{-2\pi i f \tau}, \tag{4}$$

where the amplitude $|R| \approx$ constant and $\tau \approx 10$ ms near 1500 Hz. Whereas the amplitude of the reflectance varies slowly, its phase rotates rapidly, circling one full period over the frequency interval $\Delta f_{OAE} \approx 1/\tau$. Since the largest contributions to the emission are believed to originate near the peak of the forward-traveling wave, the approximate constancy of $|R|$ suggests—via the cochlear mapping between frequency and position—that all points along the cochlear partition are about equally effective at reflecting the traveling wave. The linear variation of $\angle R$ with frequency suggests the presence of a delay (in this case, of about 10 ms).

Although deduced from measurements of stimulus-frequency emissions, Eq. (4) can be reinterpreted in the time domain to provide a description of transiently evoked emissions valid in the low-level linear regime: The echo evoked by a narrow-band tone burst is a scaled (by a factor $|R|$) and delayed (by τ seconds) version of the stimulus waveform (e.g., Wilson, 1980; Norton and Neely, 1987).[11] Having characterized the properties of echo emissions at low levels, we next consider whether they can originate through nonlinear distortion.

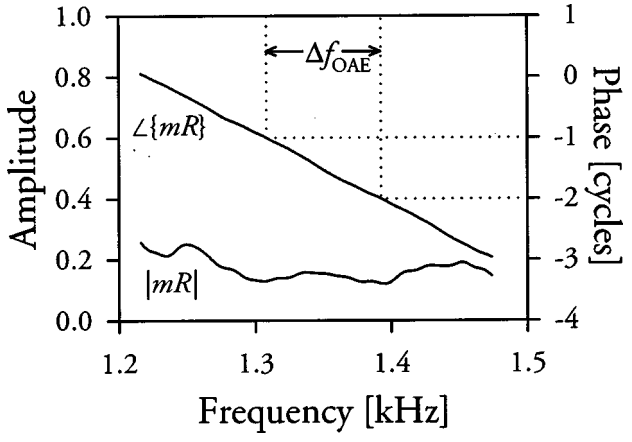

FIG. 3. Amplitude and phase of mR versus frequency computed from a subset of the data in Fig. 2 that avoids the spontaneous emission (Shera and Zweig, 1993a). The curves indicate that R has a slowly varying amplitude and a locally linear phase (assuming m is slowly varying). The frequency interval Δf_{OAE} between spectral maxima in ear-canal pressure corresponds to a full rotation of the phase of R. Data from Shera and Zweig (1993a).

II. DO ECHO EMISSIONS ARISE BY NONLINEAR DISTORTION?

A. The nonlinear-distortion model

The nonlinear-distortion model that underlies the common view of evoked emissions is illustrated schematically in Fig. 4. When the cochlear response is nonlinear, traveling waves can induce spatial distortions in the mechanics that act as ''sources'' of backward-traveling waves. In addition to accounting for distortion-product emissions, the model also appears to provide a natural explanation for echo emissions. For example, the observation that $|R| \approx$slowly varying—that is, that all points ''reflect'' about equally—might be naturally explained by supposing that the sources that generate the backward-traveling wave are induced by the wave itself through nonlinearities in the mechanics (Kemp, 1978, 1979a;

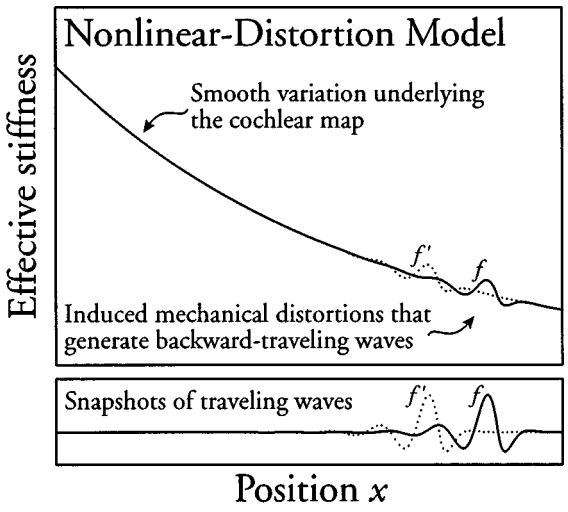

FIG. 4. Mechanical distortions induced by pure-tone stimulation. When the cochlear response is nonlinear, the traveling wave (bottom panel) is presumed to induce distortions in the mechanics (top panel) that act as sources of backward-traveling waves. In the example shown here, the traveling wave induces distortions in the effective stiffness of the cochlear partition (e.g., via nonlinearities in the mechanisms of force generation by outer hair cells). The dotted line shows how the region of induced mechanical distortion moves with the wave envelope as the stimulus frequency is increased from f to f'.

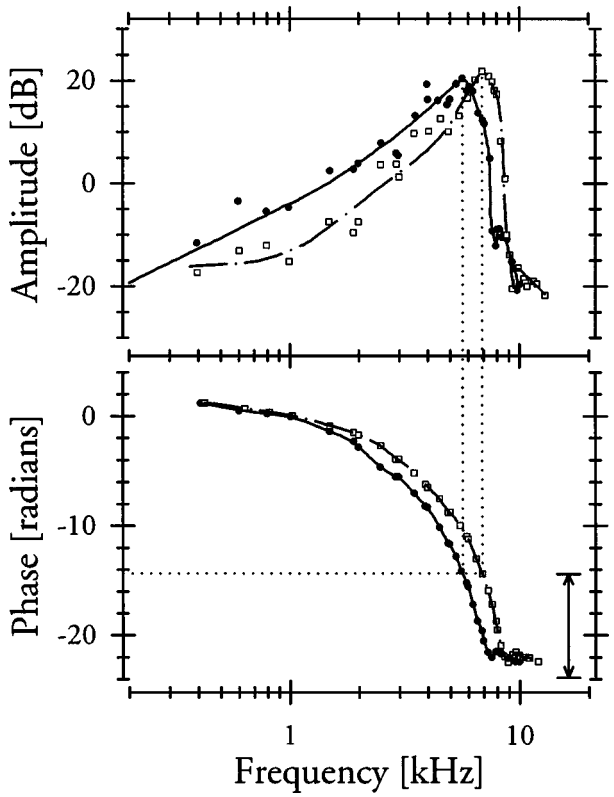

FIG. 5. Constancy of phase accumulation at the peak of the wave envelope. The figure shows Rhode's (1971, Fig. 8) measurements of basilar-membrane transfer functions (i.e., basilar membrane to malleus displacement ratios) at two nearby positons along the basilar membrane ($\Delta x \approx 1.5$ mm). As indicated by the dotted lines, the total phase accumulation at the peak of the transfer function (horizontal line) is not a strong function of frequency (vertical lines). The scale bar (double-headed arrow) in the lower right-hand corner provides an estimate of the relative phase accumulation necessary to account for the rapid rotation of $\angle R$ (see footnote 12). Relative to the scale bar, the observed difference in phase accumulation is negligible.

de Boer, 1983; Allen and Neely, 1992). And, since the phase of R has the form of a delay, it is natural to associate that delay with wave travel to and from the site of generation of the re-emitted wave.

An attractive feature of the nonlinear-distortion model is its implicit unification of echo and distortion-product emissions through a common origin in cochlear nonlinearity. Intuitively, the model seems to account naturally for both striking features of the frequency dependence of R (i.e., $|R| \approx$slowly varying, since the induced sources depend on the form and strength of cochlear nonlinearities, which presumably vary relatively slowly with position; and $\angle R \approx$locally linear with frequency, due to the round-trip traveling-wave delay between the stapes and the site of re-emission).

In what follows, we analyze the model more carefully and show that *the nonlinear-distortion model*—despite its apparent virtues—*actually predicts a constant reflectance phase, in striking contradiction with experiment*.

B. Can the nonlinear-distortion model account for $\angle R$?

To simplify the analysis of the model without sacrificing any essential feature, we assume that the forward-traveling wave is re-emitted by a nonlinear source induced at the *peak* of the traveling wave. Recall that $\angle R$ represents the accumulated phase shift between the out- and in-going waves at the stapes. In our simplified nonlinear-distortion model, this phase shift can be written as the sum of three components:

$$\angle R = \Delta\theta_{\text{forward-travel}} + \Delta\theta_{\text{re-emission}} + \Delta\theta_{\text{reverse-travel}}, \qquad (5)$$

representing phase shifts due to forward and reverse wave propagation (i.e., between the stapes and the site of re-emission at the peak of the wave envelope) and any phase shift due to the re-emission process itself. Consistency with the data of Fig. 3 requires that the sum of these phase shifts rotate rapidly with frequency. Does the model agree with experiment?

1. Phase shifts due to wave travel cannot account for $\angle R$

First, we consider phase shifts due to wave travel. Does $\Delta\theta_{\text{forward}}$ rotate rapidly with frequency? Figure 5 answers this question using measurements of basilar-membrane motion. The figure shows the phase accumulated by the forward-traveling wave as it propagates from the stapes to the peak of its envelope at its characteristic place. Perhaps surprisingly, the phase accumulation at the peak of the wave envelope is almost independent of frequency:

$$\underset{\text{measurements}}{\text{Basilar-membrane}} \Rightarrow \Delta\theta_{\text{forward-travel}} \approx \text{constant}. \qquad (6)$$

For comparison, the scale bar in Fig. 5 illustrates the phase shift necessary to account for the estimated change in $\angle R$ over the same frequency range.[12] Relative to the scale bar, the observed difference in the phase accumulation is negligible.

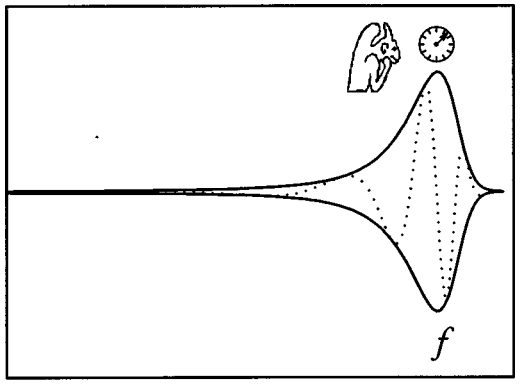

FIG. 6. The demon emitter. Charged with generating emissions by pushing and pulling on the basilar membrane, the demon needs to determine the stimulus frequency in order to create a backward-traveling wave with the correct relative phase. To determine the stimulus frequency the demon must compare the period of basilar-membrane vibration with the ticking of a ''clock.'' The only clock available, however, is the local resonator that determines the characteristic frequency.

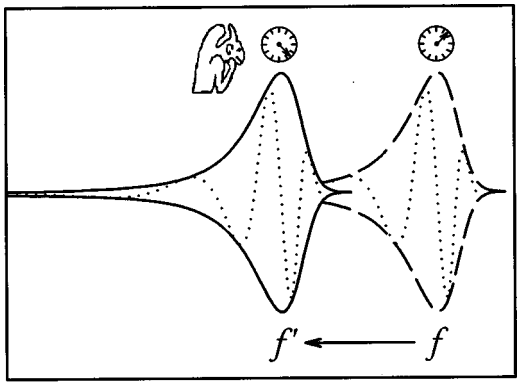

FIG. 7. When the stimulus frequency is changed (e.g., from $f \rightarrow f'$), the envelope of the traveling wave shifts along the basilar membrane. Because the demon moves with the wave, changing the stimulus frequency changes the demon's local time reference correspondingly. As a result, the demon cannot detect changes in stimulus frequency and thus cannot generate backward-traveling waves whose phase depends on that frequency.

The constancy of $\Delta\theta_{\text{forward}}$ is an immediate consequence of the approximate local scaling symmetry (Zweig, 1976; Siebert, 1968; Sondhi, 1978) manifest by basilar- and tectorial-membrane transfer functions (Rhode, 1971; Gummer *et al.*, 1987; Rhode and Cooper, 1996) and neural tuning curves (e.g., Kiang and Moxon, 1980; Liberman, 1978). Local scaling symmetry implies that rather than depending on position and frequency independently, basilar-membrane transfer functions depend on the two variables x and f only in the single combination $f/f_{\text{cf}}(x)$, where $f_{\text{cf}}(x)$ is the cochlear position-frequency map. When the cochlear map is exponential, the symmetry implies that traveling-wave envelopes are locally ''shift-similar,'' with the number of wavelengths in the traveling wave nearly independent of frequency. Compared to the higher frequency wave, the lower frequency wave travels further along the cochlea and requires a longer time to reach its peak. But *both waves travel the same number of wavelengths*, and the total phase accumulation is therefore the same.

Although we have no direct measurements of the phase shift $\Delta\theta_{\text{reverse}}$,[13] standard cochlear models[14] predict that

$$\Delta\theta_{\text{reverse-travel}} \approx \Delta\theta_{\text{forward-travel}}. \tag{7}$$

Consequently,[15]

$$\begin{matrix}\text{Measurements} \\ \text{and models}\end{matrix} \Rightarrow \Delta\theta_{\text{round-trip}} \approx \text{constant}. \tag{8}$$

For the nonlinear-distortion model of echo emissions to agree with experiment, the phase rotation of $\angle R$ must originate in $\Delta\theta_{\text{re-emission}}$. To test whether this is possible, we consider the thought-experiment of the demon emitter.

2. Phase shifts due to re-emission cannot account for $\angle R$

Rather than bog ourselves down in the model-dependent—and, for our purposes, irrelevant—details of a particular nonlinear re-emission mechanism, we argue more generally by imagining that emissions are generated within the cochlea by a tiny demon who ''surfs'' the peak of the envelope of the traveling wave, where the effects of nonlinear distortion are presumably greatest (see Fig. 6).[16] The demon, agent for nonlinear distortion, is charged with launching backward-traveling waves by pushing and pulling on the basilar membrane. In the process, the demon introduces the phase shift $\Delta\theta_{\text{re-emission}}$. Can the demon supply the frequency dependence necessary to produce the observed form of $\angle R$?

At first sight, the answer appears to be ''Yes.'' For example, when the ear is stimulated with a pure tone the demon simply determines the stimulus frequency and consults a formula he keeps in his pocket that tells him how to compute, as a function of frequency,[17] the phase with which he must push and pull (relative to the local motion of the basilar membrane) in order to produce the appropriate value of $\Delta\theta_{\text{re-emission}}$.[18]

How does the demon determine the stimulus frequency?[19] From his position atop the traveling-wave envelope the demon counts the number of times the basilar membrane rises and falls and compares that number with the ticking of a ''clock.'' But what clock does he have available? The demon's time reference is the local ''resonator'' that determines the characteristic frequency, f_{cf}, at his location.[20] The demon's clock therefore ticks at intervals proportional to $1/f_{\text{cf}}$,[21] counting out time in units appropriate to his position along the cochlear partition.

Suppose that we fix the stimulus frequency at some value, f. Because the demon sits at the peak of the traveling wave (i.e., at the characteristic place corresponding to frequency f), he sees the basilar membrane undergo one oscillation for every tick of his clock (since $f/f_{\text{cf}}=1$). The demon concludes that the stimulus has unit frequency (in units of cycles/clock-tick) and, after evaluating his formula, pushes and pulls on the basilar membrane appropriately. For example, at unit frequency the demon might push downwards on the basilar membrane during every upwards zero-crossing of its local motion.

Now suppose that we increase the stimulus frequency to the value f' as illustrated in Fig. 7. By increasing the fre-

quency, we shift the envelope of the traveling wave basalwards towards the stapes. And the demon, because he surfs the envelope, is carried along with the wave (just as the sources induced by nonlinear distortion move with the wave; cf. Fig. 4). Again the demon determines the stimulus frequency by counting the number of basilar-membrane oscillations per clock tick. But note that *because he moved with the wave, the demon now uses a different clock*. He now uses the local resonator corresponding to his new location, and that resonator ticks at time intervals of $1/f'_{\rm cf}$. Thus, once again, the demon measures a frequency of 1 cycle/clock-tick (since $f'/f'_{\rm cf}=1$) and, after consulting his formula, pushes and pulls with the same relative phase that he did for frequency f.

Although the stimulus frequency changes ($f\rightarrow f'$), the demon's clock changes correspondingly ($f_{\rm cf}\rightarrow f'_{\rm cf}$). As a result, the demon cannot detect the change and so pushes and pulls with the same relative phase at all stimulus frequencies. The demon—a proxy for nonlinear distortion, or, indeed, any emission mechanism that moves with the wave envelope—cannot generate backward-traveling waves with a phase shift that depends on frequency:[22]

$$\underset{\text{experiment}}{\text{Thought}} \Rightarrow \Delta\theta_{\text{re-emission}} \approx \text{constant}. \tag{9}$$

As suggested by the appearance in the thought-experiment of the relative frequency $f/f_{\rm cf}(x)$, this conclusion can be understood, equivalently, as a consequence of local scaling symmetry (Shera and Zweig, 1993b; Zweig and Shera, 1995).

By combining the predicted phase shifts due to wave travel and reflection we conclude that *the nonlinear-distortion model predicts a constant reflectance phase, in striking contradiction with experiment*:

$$\underset{\text{distortion model}}{\text{Nonlinear}} \Rightarrow \angle R \approx \text{constant}. \tag{10}$$

Although the measured $\angle R$ varies rapidly with frequency, the nonlinear-distortion model predicts a constant value for each of the three component phase shifts in Eq. (5). *This contradiction effectively rules out nonlinear distortion as the origin of echo emissions at low levels.*

Note that our analysis of the nonlinear-distortion model is independent of the detailed form of the emission sources and the nonlinearities that produce them. Made above for simplicity, the assumption that emissions originate from a single point (e.g., from the peak of the wave envelope) is not critical to the conclusion. The argument is easily generalized—by considering many demons surfing many different parts of the wave—to include emissions created over a broad region of the cochlea.

C. Testing the predictions of the thought-experiment using DPOAEs

Our analysis of the nonlinear-distortion model can be tested experimentally by measuring the frequency dependence of emission phase under circumstances where the generation mechanism is *known* to be scaling-symmetric nonlinear distortion. Central to the argument is the notion that changing the stimulus frequency simply shifts the resulting wave pattern (and thus any nonlinear emission sources) along the basilar membrane. As a consequence of local scaling symmetry, this shift corresponds to a simple frequency rescaling that results in approximate constancy of both $\Delta\theta_{\text{round-trip}}$ and $\Delta\theta_{\text{re-emission}}$. Note, however, that similar arguments should apply to *any* measurement paradigm for which an approximate frequency scaling of the stimulus is maintained.

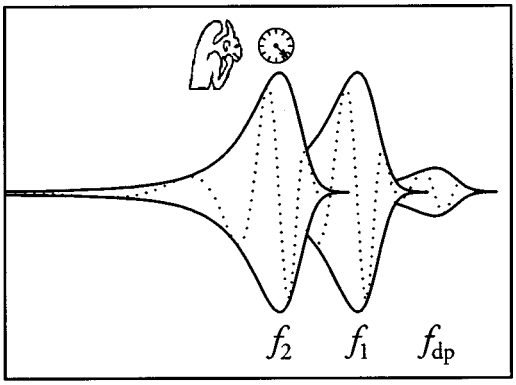

FIG. 8. The demon, responsible here for generating DPOAEs, generates the $2f_1-f_2$ distortion product from his position near the peak of the f_2 traveling wave. When the primary frequency ratio f_2/f_1 is held constant during the frequency sweep, the stimulus and distortion-product wave patterns are simply translated along the cochlear partition. As before, the demon is unable to detect changes in the stimulus frequencies and, consequently, generates a DPOAE with constant phase.

Specifically, the analysis should apply to the generation of distortion-product otoacoustic emissions when the primary-frequency ratio, f_2/f_1, is held fixed (see Fig. 8).[23] When the cochlear position-frequency map is exponential, a constant frequency ratio corresponds to a constant distance along the basilar membrane; the constant ratio f_2/f_1 thus fixes the spatial separations and relative phase relationships (referenced to stapes motion) of the primary traveling waves.[24] So imagine, for example, that the demon—responsible now for generating distortion-products—surfs the peak of the envelope of the f_2 traveling wave. Since the local resonator ticks at a rate proportional to f_2, the demon measures the primary frequencies as f_1/f_2 and 1, values that do not change as the two-tone complex is swept along the cochlea (since the frequency ratio f_2/f_1 is held constant).[25] The analysis thus predicts that for fixed f_2/f_1, the demon emitter should be unable to detect changes in the primary frequencies. Consequently, the resulting emission phase should be roughly constant.

Figure 9 provides a test of this prediction in the human ear. The figure shows the phase of the cubic distortion product $2f_1-f_2$ measured[26] at fixed $f_2/f_1=1.2$. As predicted, the emission phase is essentially independent of frequency,[27] varying by less than half a cycle over most of the nearly three octave range of the figure.[28] In contrast, SFOAE phase measured in the same subject varies by more than 30 cycles over the same frequency range.[29] Measurements in other subjects (total $n=3$) are consistent with these results, and Kemp and Brown have reported similar findings (Kemp and

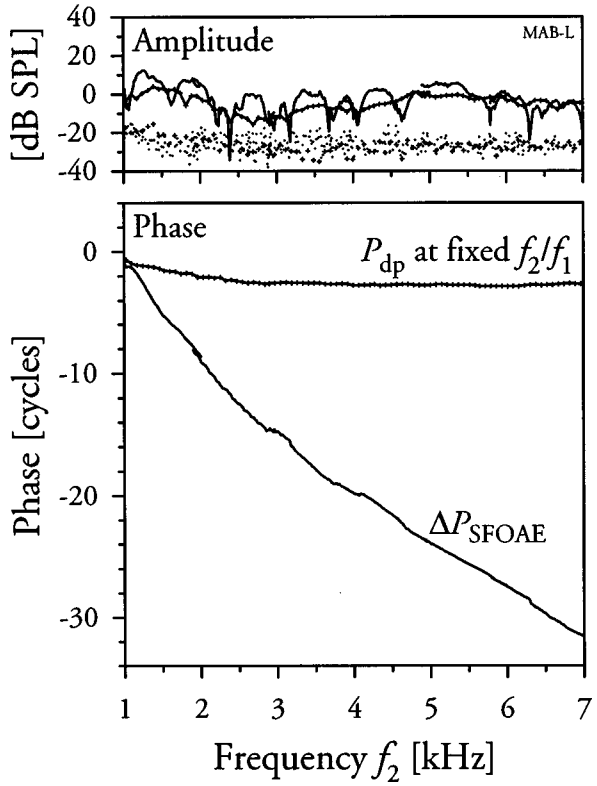

FIG. 9. Constancy of ''frequency-scaled'' DPOAE phase. The solid curves with small crosshairs (+) show the amplitude and phase of P_{dp}, the human $2f_1-f_2$ cubic distortion product measured while holding the ratio of the primary frequencies fixed (at $f_2/f_1=1.2$ with primary levels $\{L_2,L_1\}=\{40,50\}$ dB SPL). With the ratio f_2/f_1 fixed, the primary traveling waves maintain an approximately constant separation along the basilar membrane. To reduce the confounding effects of reflection-source emissions (see Sec. IV C below), the DPOAE was measured in the presence of a 55-dB SPL suppressor tone near $2f_1-f_2$ (e.g., Kemp and Brown, 1983b; Heitmann *et al.*, 1998). (Although the suppressor tone substantially reduced the DPOAE fine structure, it had little effect on the secular variation of the phase important here.) Shown for comparison are measurements in the same subject of ΔP_{SFOAE}, the stimulus-frequency emission obtained using a variant of the suppression method (e.g., Guinan, 1990; Kemp *et al.*, 1990) with probe and suppressor levels of {40,55} dB SPL, respectively. The dotted lines in the upper panel show the approximate measurement noise floor. Note that the data shown here were obtained over several measurement sessions; as a consequence of variations in system calibration, small discontinuities are sometimes visible near session boundaries. Detailed methods for both measurements are presented in the Appendix.

Brown, 1983b; Kemp, 1986). Our abstract thought-experiment thus correctly predicts the striking frequency independence of the phase of emissions generated by frequency-scaled (or ''scaling-symmetric'') nonlinear distortion.[30]

This result supports the argument of Sec. II B—and its contrast with the frequency dependence of echo-emission phase rules out nonlinear distortion as the origin of echo emissions at low levels. If echo emissions and distortion products shared a common origin in cochlear nonlinearity, echo-emission phase, like the phase of $2f_1-f_2$ measured at fixed f_2/f_1, would be essentially independent of frequency. But instead, echo-emission phase rotates rapidly. Contrary to the common view, echo emissions apparently arise by mechanisms fundamentally different from distortion products. When measured with comparable paradigms (i.e., stimuli that preserve the approximate frequency scaling of the stimulus wave pattern characterizing the measurement of stimulus-frequency emissions), echo and distortion-product emissions manifest profound differences in the frequency dependence of their phase that contradict the notion, succinctly expressed by Brass and Kemp (1993), that ''SFOAEs can be thought of as zero-order DPs, and thus as part of the DP series.''

III. ECHO EMISSIONS ARISE BY COHERENT REFLECTION

If echo emissions do not arise by nonlinear distortion, how do they originate? The (mistaken) prediction of the nonlinear-distortion model that $\angle R \approx$ constant hinges on the essential feature that the emission sources move with the wave. The resulting contradiction with experiment suggests that rather than ''surfing'' the wave envelope like the demon, the perturbations that reflect the wave may instead be fixed in space. Thus, rather than being ''re-emitted'' by ''emission generators'' induced through nonlinear distortion, the traveling wave simply scatters off pre-existing irregularities in the mechanics.

The recent theory of coherent reflection filtering (Shera, 1992; Shera and Zweig, 1993b; Zweig and Shera, 1995) characterizes this scattering and indicates that at low stimulus levels echo emissions arise via coherent reflection from the ''random'' impedance perturbations characteristic of cochlear anatomy (Engström *et al.*, 1996; Bredberg, 1968; Wright, 1984; Lonsbury-Martin *et al.*, 1988). Although the impedance perturbations may be densely and randomly distributed along the cochlear partition, the tall, broad peak of the traveling wave localizes the effective scattering to a region spanning the peak of the wave envelope. Most scattered wavelets combine out of phase and cancel one another out. But a simple analog of Bragg's law[31] from x-ray crystallography (Brillouin, 1946) enables a subset of scattered wavelets to combine coherently and form a large reflected wave having the characteristics of echo emissions observed experimentally. In this model, wavelets scattered over an extended region of the cochlea interfere with one another to create a region of coherent reflection that sweeps along the cochlear partition as the frequency is varied. This interference between multiple scattered wavelets precludes the representation of $\angle R$ as a simple sum of phase shifts due to wave propagation and reflection [e.g., along the lines of Eq. (5)]. Nevertheless, the theory predicts that the delay parameter τ—which characterizes the local average phase slope of R in Eq. (4)—equals twice the peak group delay of the basilar-membrane transfer function. Details of the theory, including its many predictions and applications, are presented elsewhere (e.g., Zweig and Shera, 1995; Talmadge *et al.*, 1998a).

IV. DISCUSSION

The arguments we present here demonstrate that the ''common view''—which attributes all otoacoustic emissions, both echo emissions and distortion products, to nonlinear distortion—cannot be correct. Although many argue that otoacoustic emissions share a common origin in co-

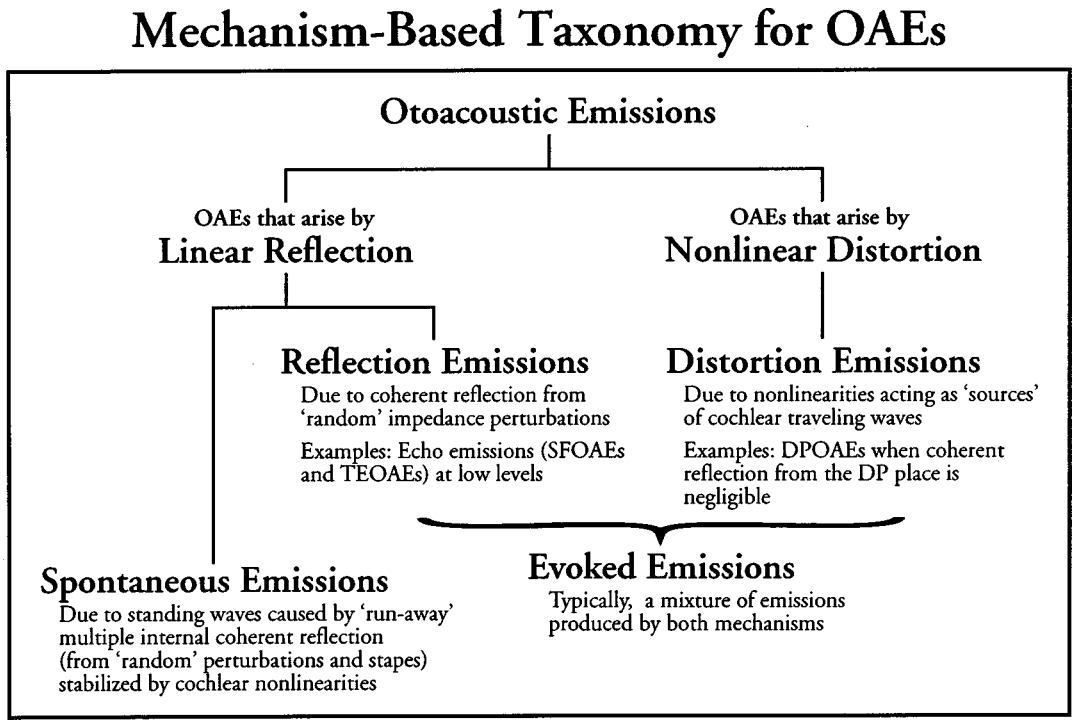

FIG. 10. Proposed mechanism-based taxonomy for mammalian otoacoustic emissions. For conciseness, the names ''reflection-source'' and ''distortion-source'' emissions are here shortened to ''reflection'' and ''distortion'' emissions, respectively.

chlear nonlinearity—that, as Kemp (1997) puts it, ''nonlinearity is at the heart of OAE generation''—we argue that OAEs arise by two fundamentally different mechanisms (i.e., linear coherent reflection[32] versus nonlinear distortion).

A. A mechanism-based taxonomy for otoacoustic emissions

To codify this fundamental distinction we propose a taxonomy for mammalian otoacoustic emissions based on the mechanisms of their generation. This OAE taxonomy, the simplest consistent with current data, is presented in Fig. 10.

Our mechanism-based taxonomy divides evoked otoacoustic emissions into two broad classes:

(i) *Reflection-source emissions*, in which backward-traveling waves arise through the linear (coherent) reflection of forward-traveling waves by pre-existing perturbations in the mechanics (e.g., echo emissions such as SFOAEs and TEOAEs measured at low sound levels); and

(ii) *Distortion-source emissions*, in which backward-traveling waves arise through sources induced by nonlinear distortion (e.g., pure DPOAEs[2]).

Whereas distortion-source emissions would not occur in the absence of cochlear nonlinearities, the coherent reflection responsible for reflection-source emissions is a linear process. The taxonomy is thus consistent with the observations (cf. Fig. 2) that at sound levels near threshold echo-emission amplitude grows linearly with the amplitude of the stimulus (e.g., Kemp and Chum, 1980; Wit and Ritsma, 1979; Wilson, 1980; Zwicker and Schloth, 1984; Shera and Zweig, 1993a) and the principle of superposition holds (Zwicker, 1983). These observations would be more difficult to explain if echo emissions arose through nonlinear distortion.[33]

The conclusion that reflection-source emissions arise through linear coherent reflection may appear to conflict with the well-known level dependence of stimulus-frequency and transiently evoked emissions, which exhibit a nonlinear growth in amplitude at all but the lowest sound levels (cf. Figs. 1 and 2). We emphasize, however, that nonlinear growth with level does not imply that reflection-source emissions arise by a nonlinear process. Rather, the theory of coherent reflection filtering suggests that the nonlinear growth should be understood as a consequence of the level-dependent amplification of forward and reverse traveling waves (Zweig and Shera, 1995), as schematized in Fig. 11. Since the outer hair cells are limited in the forces they can

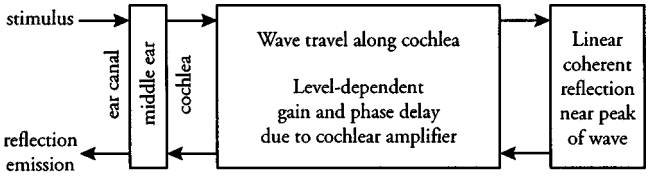

FIG. 11. Simplified conceptual model for the generation of reflection-source emissions. Reflection-source emissions arise from a region of linear coherent reflection near the peak of the traveling-wave envelope. Incident and reflected waves undergo level-dependent gains and phase delays while traveling to, from, and within the scattering reigon. At medium and high stimulus levels, reflection-source emissions therefore exhibit a nonlinear growth with sound level. Note that although they appear separated here for clarity, the regions of coherent reflection and maximal gain overlap within the cochlea. Figure 12 fleshes out this conceptual model (by including phase shifts due to wave propagation) and extends the model to illustrate the mixing of reflection- and distortion-source emissions that occurs during the generation of DPOAEs.

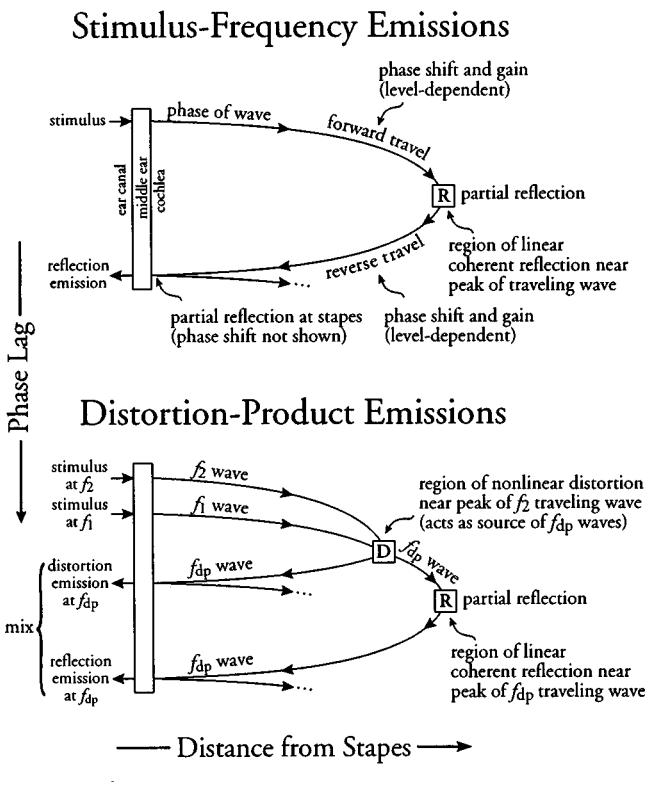

FIG. 12. Schematic diagrams illustrating the generation of stimulus-frequency (top) and distortion-product emissions (bottom) at low sound levels. Both diagrams show phase lags relative to stimulus phase (lag increasing downward) of forward- and backward-traveling waves versus distance from the stapes. At low levels, SFOAEs arise from a region of coherent reflection (**R**) near the peak of the traveling-wave envelope. Stimulus and reflected waves undergo level-dependent gains and phase delays while traveling to and from the scattering region. The generation of low-level DPOAEs is more complicated and involves the mixing of reflection and distortion emissions in the ear canal. A region of nonlinear distortion (**D**) near the peak of the f_2 wave generates waves at frequency f_{dp} that propagate in both directions: The backward-traveling wave propagates to the ear canal as a distortion-source emission; the forward-traveling wave undergoes partial coherent reflection (**R**) near the peak of its wave envelope, generating a second backward-traveling wave that propagates to the ear canal as a reflection-source emission. The DPOAE measured in the ear canal is thus a mixture of emissions arising not just from two spatially distinct regions, but from two fundamentally different mechanisms. Backward-traveling waves arriving at the stapes are partially reflected, creating new forward-traveling waves (arrows with three dots) that subsequently undergo partial coherent reflection themselves. The resulting (infinite) series of multiple internal reflections is truncated for clarity. Note that possible phase shifts due to reflection are not shown.

produce, traveling-wave amplitudes are compressive functions of sound level, with the greatest compression occurring near the peak of the wave envelope, where scattering is maximal. Although the propagation of traveling-wave energy is a nonlinear function of sound level, the physical mechanisms responsible for reversing the direction of that propagation (i.e., coherent reflection from perturbations in the mechanics) are essentially linear.

In our taxonomy, spontaneous emissions are grouped with reflection-source emissions. As originally suggested by Kemp (1980), spontaneous emissions may result from a process of ''run-away'' multiple internal reflection stabilized by cochlear nonlinearities. In the view espoused in the taxonomy, multiple cycles of propagation, amplification, and coherent reflection[34] create narrow-band cochlear standing waves measurable in the ear canal (Zweig and Shera, 1995; Talmadge and Tubis, 1993; Talmadge *et al.*, 1997).

When we argue that reflection- and distortion-source emissions arise by different mechanisms, we mean that the processes responsible for creating backward-traveling waves differ for the two emission types. For example, although the backward-traveling waves created by nonlinear distortion may arise, at least in part, through the action of nonlinear cellular demons (OHCs) pushing and pulling on the basilar membrane, reflection-source emissions do not result directly from OHC forces. Rather, we argue that reflection-source waves arise by the linear, ''passive'' scattering of the forward-traveling wave off more or less random perturbations in the mechanics. Although the waves created by this scattering may then be amplified through the collective action of the ''cochlear amplifier,'' the backward-traveling waves themselves are not fundamentally the product of nonlinear force generation by outer hair cells.

Once generated, however, backward-traveling waves produced by either mechanism propagate basally to the stapes (from which they may be partially reflected), through the middle ear, and out into the ear canal. While propagating, emissions of both types undergo delays, phase shifts, and gains (e.g., due to the cochlear amplifier or reverse middle-ear transmission), as illustrated in Fig. 12. Thus, although their mechanisms of generation are fundamentally different, both emission types traverse a similar pathway on their way to the ear canal, and both are potentially vulnerable to modifications or disruptions of this pathway (e.g., to changes in outer-hair-cell function, middle-ear transfer characteristics, etc.). Although a common dependence on propagation pathways from cochlea to ear canal presumably introduces correlations in reflection- and distortion-source emission amplitude, the taxonomy emphasizes that their respective mechanisms of generation—and hence their dependence on underlying parameters of cochlear mechanics—remain fundamentally distinct.

Although identifying what we suggest are the two principal branches of the OAE family tree, our taxonomy makes no attempt to adumbrate the sub-branches. For example, in some species (e.g., rodents and rabbits), considerable evidence suggests that distortion-source emissions can be usefully divided into subtypes, conventionally designated the ''active or low-level component'' and the ''passive or high-level component'' (e.g., Norton and Rubel, 1990; Mills and Rubel, 1994; Whitehead *et al.*, 1992a,b, 1995; Whitehead, 1998).[35] The differential vulnerability of these two distortion components to physiological insult suggests that they arise from different mechanisms within the cochlea.[36] And although coherent reflection from ''random'' mechanical perturbations appears to be the dominant reflection mechanism in the normal primate ear, reflection by other mechanisms may contribute in some circumstances. For example, incoherent reflection from large punctate perturbations may dominate in certain pathologies or in specialized cochleae, such as in the ''auditory fovea'' of the CF-FM bat (e.g., Kössl and Vater, 1995), in which the mechanical properties of the cochlear partition change rapidly with position. When

coupled with knowledge of the underlying mechanisms, a more complete identification of the different emission subtypes could presumably prove of considerable value in the application of OAEs to noninvasive diagnostics.

B. Relation to the conventional classification of OAEs

As the taxonomy implies, we argue that backward-traveling waves originating by coherent reflection and nonlinear distortion constitute the elemental OAE ''building blocks'' that combine to form evoked emissions measured in the ear canal (i.e., echo emissions and DPOAEs). In any given measurement, the two types mix in varying degrees dependent on the species, the stimulus parameters, and the state of the cochlea. For example, although presumably arising largely by coherent reflection, echo emissions measured at medium and high stimulus levels may contain significant energy from distortion-source waves created by nonlinear distortion (e.g., Yates and Withnell, 1998; Withnell and Yates, 1998).

The OAE taxonomy thus provides a mechanism-based alternative to the conventional classification scheme, which classifies emissions based principally on the stimuli used to elicit them (e.g., TEOAEs, SFOAEs, and DPOAEs). *The mixing of reflection- and distortion-source emissions in the ear canal precludes any fixed correspondence between the two schema*. At low levels, however, echo emissions (i.e., TEOAEs and SFOAEs) arise predominantly through linear coherent reflection. And under circumstances when coherent reflection from the f_{dp} place can be neglected, DPOAEs arise predominantly from distortion-source waves due to nonlinear distortion. Thus, in these special cases, the division of evoked emission into ''echo emissions'' and ''distortion products''—a division made at the beginning of this paper based on the relative spectral content of the stimulus and the emission—corresponds to a fundamental difference in generation mechanism as well.[37] As commonly measured, however, evoked OAEs typically represent mixtures of the different emission types. We therefore find the conventional, stimulus-based emission nomenclature more confusing than helpful for understanding the origin and properties of OAEs.

C. An example of reflection- and distortion-source mixing

Our taxonomy and its identification of the fundamental OAE ''building blocks'' provides a framework that simplifies the often bewildering complexity of OAE phenomenology. The phenomenon of DPOAE fine structure, for example, can be understood in terms of the mixing of the two OAE ''building blocks.'' As originally suggested by Kim (1980), much of DPOAE fine structure apparently arises through the interference of two distinct sources located near the f_2 and f_{dp} places (e.g., Kim, 1980; Kemp and Brown, 1983b; Shera and Zweig, 1992). Although the ''two-source'' model for DPOAEs now appears well established (e.g., Gaskill and Brown, 1990; Brown *et al.*, 1996; Engdahl and Kemp, 1996; Brown and Beveridge, 1997; Talmadge *et al.*, 1997, 1998b; Heitmann *et al.*, 1997, 1998; Fahey and Allen, 1997; Siegel *et al.*, 1998), our taxonomy goes further and identifies these two sources as arising not simply from two distinct locations, but from *two different mechanisms*: a distortion source near the f_2 place and a coherent reflection from the f_{dp} place. (The combined process is illustrated in the bottom panel of Fig. 12, where the distortion- and reflection-source regions are denoted **D** and **R**, respectively.) Indeed, as our argument demonstrates for the frequency-scaled, fixed-f_2/f_1 paradigm, it is fundamentally this difference in emission-source *mechanism*—and *not*, as is often implied (e.g., Brown *et al.*, 1996), the difference in source *location*—that is ultimately responsible for the different frequency dependencies of the phase of the emissions arising from the two interfering sources. Thus, as commonly measured, *DPOAEs actually comprise a mixture of backward-traveling waves that arise by two fundamentally different mechanisms within the cochlea*. By matching measurements of DPOAE fine structure with predictions obtained using the model of coherent reflection filtering, Talmadge *et al.* (1999) provide elegant experimental corroboration of these ideas.

The relative mix of the two OAE ''building blocks'' measured in the ear canal presumably depends on stimulus parameters such as frequency and level. For example, Fig. 12 predicts that variations in the DPOAE mix should occur as a consequence of any change in the relative amplitudes of the net forward- and backward-traveling distortion-source waves emanating from **D**. Mechanisms that may produce such changes include suppression by the primaries (e.g., Kanis and de Boer, 1997; Shera and Guinan, 1997), nonlinearities in the effective forward and reverse ''load impedances'' (Shera and Zweig, 1991, 1992; Fahey and Allen, 1997), and phase-dependent interference between distortion-source wavelets within the DP source region (e.g., van Hengel, 1996; Neely and Stover, 1997; Kemp and Knight, 1999). Variations in the relative mix would also be expected as a result of any mechanism (e.g., suppression) that affects the cochlear amplifier in the region between **D** and **R** and thereby modifies the strength of the reflection-source emissions that scatter back from **R** (e.g., Kemp and Brown, 1983b; Kummer *et al.*, 1995; Heitmann *et al.*, 1998).

Several studies can be interpreted in this light as providing evidence for stimulus-dependent mixing. For example, the data of Fahey and Allen (1997) in cat suggest that the relative amplitude of the distortion- and reflection-source components varies with the primary level ratio, L_2/L_1. Similarly, Kemp's (1986) measurements in human ears suggest a dependence on the ratio f_2/f_1. At values of f_2/f_1 relatively close to one ($f_2/f_1 \lesssim 1.1$), the frequency dependence of the $2f_1-f_2$ DPOAE shows regular variations (nulls) in amplitude and a more rapidly rotating phase distinctly different from the nearly constant amplitude and phase obtained at larger values of f_2/f_1 (cf. Fig. 9). These features appear consistent with the view that the measured DPOAE arises from a variable f_2/f_1-dependent mix of waves from two distinct sources, and, furthermore, that these two sources—in accordance with their respective identities as sources of nonlinear distortion and coherent reflection—produce emissions with very different frequency dependence in their phase. Applying the reasoning of Sec. II B to emissions evoked by any frequency-scaled stimulus (e.g., fixed

f_2/f_1), we hypothesize that (1) a nearly frequency-independent phase implies that the OAE arises mainly by nonlinear distortion, whereas (2) a rapidly rotating phase implies that the OAE arises mainly by coherent reflection.

D. The taxonomy resolves OAE ''paradoxes''

The taxonomy provides a conceptual framework that helps resolve issues that appear paradoxical if all emissions are regarded as sharing a common origin in nonlinear distortion. For example, consider the observations that

(i) whereas primates tend to have large SFOAEs and TEOAEs, many SOAEs, and small DPOAEs, rabbits and guinea pigs have the relative amplitudes and/or prevalence of these emissions reversed (e.g., Zurek, 1985; Whitehead *et al.*, 1996a); and

(ii) whereas SFOAEs and SOAEs are abolished by aspirin administration, DPOAEs can remain almost unchanged (e.g., Martin *et al.*, 1988; Wier *et al.*, 1988).

In the common view these observations are largely unintelligible and, indeed, are often presented as paradoxes. For if all emissions shared a common origin in cochlear nonlinearity, their relative amplitudes would be expected to vary together, both between species and in response to aspirin or other ototoxic drugs.[38] Our taxonomy resolves these ''paradoxes'' by recognizing fundamental differences in the mechanisms of OAE generation. As shown below, when differences in their mechanisms of generation are taken into account, the observation that the different emission types can be ''decoupled,'' both between species and by certain experimental manipulations and/or pathologies, is no longer surprising (indeed, it is predicted).

First, consider species differences in OAE amplitude and prevalence. Whereas distortion-source emissions depend on the form and magnitude of cochlear nonlinearities (e.g., on the effective ''operating point'' along hair-cell displacement-voltage transduction functions), reflection-source emissions depend strongly on the size and spatial arrangement of micromechanical impedance perturbations (e.g., on variations in hair-cell number and geometry). In the light of these different dependencies, species differences between the two emission types no longer appear mysterious: They simply reflect differences across species in the respective factors underlying emission generation. Indeed, the theory of coherent reflection filtering provides an interesting hypothesis to explain the striking species differences in reflection-emission amplitudes (Zweig and Shera, 1995): The model predicts that disorderly patterns of impedance perturbations produce large reflections whereas orderly patterns produce only small reflections.[39] Correspondingly, in contrast to the cellular disorder characteristic of the primate organ of Corti, anatomical regularity constitutes an ''impressive feature'' of the rodent cochlea (e.g., Wright, 1984). Thus, the theory of coherent reflection filtering accounts naturally for the relative amplitudes of reflection emissions in humans (large) and guinea pig (small).[40]

Next, consider the effects of aspirin on OAEs. Once reflection- and distortion-source emissions are understood as separate emission types, a number of possible explanations for their differential responses arise. For example, the experiments of Martin *et al.* (1988) suggest that aspirin may somehow reduce the gain of the cochlear amplifier while preserving the nonlinearities responsible for generating distortion emissions. Although a reduction in the gain of the cochlear amplifier would be expected to have a dramatic effect on reflection emissions—which arise from scattering near the peak of the traveling wave, where the gain is presumably largest—the effect on distortion-source emissions could be significantly less. To see this, note that suppression studies indicate that distortion-source waves appear to be generated predominantly in the region of maximum overlap between the primaries near the peak of the f_2 traveling wave (e.g., Brown and Kemp, 1984; Kummer *et al.*, 1995). The region of nonlinear distortion (**D** in Fig. 12) is therefore often significantly basal to the f_{dp} place (near **R**). For example, the generation of cubic distortion products at the frequency $f_{dp}=2f_1-f_2$ at a primary-frequency ratio of $f_2/f_1\approx 1.25$ occurs at the frequency ratio $f_{dp}/f_2\approx 0.6$, corresponding to roughly three-quarters of an octave. At the low and medium sound-pressure levels for which the amplifier gain is significant, this frequency ratio corresponds to a distance from the f_{dp} place larger than the width of the traveling-wave envelope.[41] Thus, the distortion source lies basal to the region of maximal gain for the f_{dp} traveling wave (see Fig. 12), and, consequently, the backward-traveling distortion-source wave experiences relatively little amplification as it travels to the stapes. The resulting DPOAE would thus appear relatively insensitive to the gain of the cochlear amplifier at the distortion-product frequency.[42]

Note, however, that the analysis is complicated by possible mixing of the emission types, specifically by contributions to the measured DPOAE from reflection-source emissions scattered back from the f_{dp} place. Although aspirin may have little effect on the distortion source (**D**), the argument outlined above predicts a decrease in the magnitude of any concomitant reflection-source emissions (due to reductions in the f_{dp} amplifier gain near **R**) and thus significant changes in the resulting distortion-product microstructure. Unfortunately, the measurements reported by Martin *et al.* do not permit an evaluation of this prediction.[43] Nevertheless, the general idea that reflection-source emissions may be more sensitive to changes in the f_{dp} amplifier gain is consistent with the observation that the emission component from the f_{dp} place (i.e., the coherent reflection) is differentially diminished by presumed reductions in the amplifier gain due to efferent feedback evoked by contralateral noise (Brown and Beveridge, 1997).

E. Implications of the taxonomy for the use of OAEs

As a consequence of their different origins, reflection- and distortion-source emissions presumably manifest different dependencies on cochlear pathologies. However, the mixing of the two emission types confounds an understanding of their individual characteristics and clouds the assessment of their different utilities as clinical diagnostic and screening aids. As a result, it is of considerable theoretical and practical interest to isolate and characterize the properties of each emission type (and related subtypes) separately,

to understand the factors that control their mixing, and to determine their individual correlations with cochlear pathology.

Although some degree of mixing among the OAE ''building blocks'' may prove unavoidable, several existing measurement techniques hold promise for at least partially separating the two types of emissions. For example, reflection-source emissions can be studied at low sound levels using methods that do not cancel the low-level linear components of the response (e.g., Kemp and Chum, 1980; Shera and Zweig, 1993a). And in DPOAE measurements, the confounding contributions of reflection-source emissions can be substantially reduced by using a third primary tone with frequency near f_{dp} to suppress amplification of the reflection-source emissions that scatter back from this location (e.g., Kemp and Brown, 1983b; Heitmann *et al.*, 1998). Alternatively, the reflection- and distortion-source components of DPOAEs may be separable based on onset latency, either in the time (e.g., Whitehead *et al.*, 1996b; Talmadge *et al.*, 1998b) or the frequency domain (e.g., Brown *et al.*, 1996). Note that extracting or suppressing individual components of an evoked emission may be more difficult—and problems of interpretation correspondingly greater—when the respective regions of wave generation [e.g., the regions of nonlinear distortion (**D**) and coherent reflection (**R**) in Fig. 12] overlap extensively within the cochlea. For DPOAEs, significant overlap can be expected when using primary-frequency ratios close to one.

Our taxonomy predicts that reflection- and distortion-source emissions—when properly separated and studied—will manifest considerable differences in their correlations with particular cochlear pathologies. Clinical measurement of both types of evoked emissions will presumably be needed to maximize the power and specificity of OAEs as noninvasive probes of cochlear function.

ACKNOWLEDGMENTS

Talmadge, and George Zweig and thank John R. Iversen, M. Charles Liberman, William T. Peake, John J. Rosowski, and three anonymous reviewers for their helpful critical readings of and comments on the manuscript. The work was supported by NIDCD/NIH Grant Nos. DC00108, DC03494, DC00119, and DC00235.

APPENDIX: MEASUREMENT METHODS

This appendix outlines the methods used to obtain the distortion-product and stimulus-frequency emission data shown in Fig. 9. All measurements were performed with subjects comfortably reclined in a sound-proofed, vibration-isolated chamber (Ver *et al.*, 1975), well shielded from sources of electrical interference (Golka, 1994). Stimulus waveforms were generated and responses acquired and averaged digitally using a Spectrum Signal Processing PC/C31 DSP board with two Burr-Brown analog daughter modules providing eight channels of synchronized analog I/O. The hardware was computer controlled using a custom data-acquisition system implemented in LabVIEW and supplemented with hand-coded time-domain artifact-rejection and synchronous-averaging routines. Acoustic signals were transduced at sampling rates of 59.94 kHz using a calibrated Etymotic Research ER-10c DPOAE probe system supplemented with an ER-3A earphone whose sound-delivery tube was threaded through the ER-10c foam ear-tip. Measurement frequency resolution was always sufficient to resolve ambiguities due to phase unwrapping. Control experiments in a small cavity indicated that the measurement-system distortion was at or below the noise floor (typically less than -25 dB SPL). Treatment of human subjects was in accordance with protocols approved by the Human-Studies Committee at the Massachusetts Eye and Ear Infirmary.

Measurement of DPOAEs: To reduce reflection-source contributions to the measured emission (see Sec. IV C), DPOAEs were measured in the presence of a suppressor tone with frequency near $2f_1-f_2$ (e.g., Kemp and Brown, 1983b; Heitmann *et al.*, 1998). Although the suppressor tone substantially reduced the DPOAE fine structure, it had little effect on the more secular variation of the phase of primary interest in the context of this paper.

At each measurement frequency the acoustic stimulus had the form

$$\text{stimulus}=\underbrace{\langle XX\ldots X\rangle}_{\#\geqslant M}, \tag{A1}$$

where X represents a periodic 4096-sample ($\approx$68.33 ms) segment containing an integral number of periods of the stimulus waveform. The waveform consisted of three frequency components: a component at each of the two primary frequencies, f_1 and f_2, and a third component at the suppressor frequency, f_s, near $2f_1-f_2$. The phase of each component was adjusted to produce an upwards zero-crossing (sine-phase) at the beginning of each X segment. The respective stimulus levels $\{L_1,L_2,L_s\}$ were {50,40,55} dB SPL. To minimize artifactual distortion, the three component waveforms were delivered synchronously through separate earphones.

Measurements were made versus frequency by sweeping f_2 from high frequencies to low while varying f_1 to keep the primary-frequency ratio at the fixed value $f_2/f_1=1.2$. The suppressor frequency was also swept, with $f_s=2f_1-f_2+\Delta f_s$ and $\Delta f_s=43.9$ Hz.[44] The periodic segments X were presented repeatedly until a total of $M=32$ corresponding artifact-free responses[45] were collected; at each frequency the total stimulus duration was therefore $\geqslant 32\times 68.33$ ms $\approx$2.2 s. To reduce unwanted transients the waveform was ramped on and off by pre- and postpending two additional segments (indicated by the angled brackets $\langle$ and $\rangle$) with envelopes of half Blackman windows with 2.5-ms rise and fall times. After digitizing the resulting ear-canal pressure, responses to the segments X were averaged and the amplitude and phase of the $2f_1-f_2$ distortion component extracted using Fourier analysis.

Measurement of SFOAEs: Stimulus-frequency emissions were measured using a variant of the suppression method

(e.g., Guinan, 1990; Kemp *et al.*, 1990; Brass and Kemp, 1991, 1993; Souter, 1995). In this method, the emission is obtained as the complex (or vector) difference between the ear-canal pressure at the probe frequency measured first with the probe tone alone and then in the presence of a stronger suppressor tone at a nearby frequency.

At each measurement frequency the acoustic stimulus had the form

$$\text{stimulus}=\underbrace{\langle XX\ldots X\rangle}_{\#\geqslant M}, \tag{A2}$$

where X represents a periodic (5×4096)-sample ($\approx$341.66 ms) segment consisting of two components:

$$X=\begin{cases}\pi_1\Pi_2\Pi_3\pi_4\pi_5\Pi_6\Pi_7\pi_8 & \text{(probe earphone)},\\ o_1O_2O_3\langle_4\sigma_5\Sigma_6\Sigma_7\rangle_8 & \text{(suppressor earphone)}.\end{cases} \tag{A3}$$

Each component consisted of four long (uppercase) and four short (lowercase and angled brackets) intervals. The long intervals were each 4096 samples ($\approx$68.33 ms) in duration and contained an integral number of periods of the probe (Π_i), suppressor (Σ_i), and zero (O_i) waveforms, respectively. The short intervals were one-fourth the duration of the long intervals (i.e., 1024-samples or $\approx$17.08 ms) and did not, in general, contain an integral number of periods of the corresponding waveform. The short intervals π_i, σ_i, and o_1 allowed for response settling time and contained segments of the probe, suppressor, and zero waveforms, respectively. The short intervals $\{\langle_4,\rangle_8\}$ were used to ramp the suppressor tone {on,off} using the {first,second} half of the Blackman window. The two components of X were synchronized and presented simultaneously through separate earphones. Note that whereas the probe tone played continuously during the measurement, the suppressor tone cycled on and off repeatedly due to alternation of the zero and suppressor waveforms. The probe and suppressor levels $\{L_p,L_s\}$ were {40,55} dB SPL.

Measurements were made versus probe frequency by sweeping both probe and suppressor from high frequencies to low, with $f_s=f_p+\Delta f_s$ and $\Delta f_s=43.9$ Hz. The periodic segments X were played repeatedly until a total of $M=64$ corresponding artifact-free responses were collected; at each frequency the total stimulus duration was therefore $\geqslant64\times341.66$ ms$\approx$22 s. To reduce unwanted transients the probe waveform was ramped on and off by pre- and postpending two additional segments [indicated by the angled brackets $\langle$ and $\rangle$ in Eq. (A2)] with envelopes of half Blackman windows with 2.5-ms rise and fall times. After digitizing the resulting ear-canal pressure, responses to all probe-alone segments (i.e., all segments Π_2 and Π_3) were averaged to form Y_p; similarly, the responses to all probe+suppressor segments (i.e., all segments Π_6 and Π_7) were averaged to form Y_{p+s}. From these averaged response waveforms, the complex amplitudes of the f_p components of the ear-canal pressure, denoted $P_p(f_p)$ and $P_{p+s}(f_p)$, were extracted using Fourier analysis. The complex quantity $\Delta P_{SFOAE}(f_p)$ was then defined as

$$\Delta P_{SFOAE}(f_p)\equiv P_p(f_p)-P_{p+s}(f_p)e^{-2\pi i\Delta N\Delta T f_p}, \tag{A4}$$

where the complex exponential compensates for the phase shift in the probe due to the time interval, $\Delta N\Delta T$, between the probe-alone and probe+suppressor segments. Here, ΔT is the sampling interval (reciprocal of the sampling rate), and ΔN represents the total number of these intervals that separate the two segments:

$$\Delta N=\#\text{ samples }(\Pi_2\Pi_3\pi_4\pi_5)=2\tfrac{1}{2}\times4096=10\,240. \tag{A5}$$

Note that when the two segments are separated by an integral number of periods of the probe waveform, the phase shift modulo 2π is zero.

Due to the long averaging time and high-frequency resolution (the probe frequency was typically decremented in steps of approximately 15 Hz), Fig. 9 shows data obtained over several measurement sessions. Unwrapped phase curves from the different sessions were patched together by shifting them vertically by integer multiples of 2π to obtain a (nearly) continuous curve. As a consequence of variations in system calibration, small discontinuities are sometimes visible in both amplitude and phase at the ''seams'' near session boundaries.

[1]In the common view, stimulus-frequency emissions (SFOAEs) are regarded as ''zeroth-order'' distortion-products (DPOAEs) produced by the degenerate primary stimulus pair $f_1=f_2$ (e.g., Brass and Kemp, 1993; Kemp, 1998). Patuzzi (1996), for example, argues this point from an operational perspective:

> ''The nonlinear growth of ear canal sound pressure with stimulus level is easily explained by a nonlinear input admittance to the ear canal, due to the nonlinear input admittance of the cochlea. Because the sound level in the ear canal does *not* scale proportionately with the stimulus level, the sound level predicted at low stimulus levels on the basis of linear extrapolation from high stimulus levels does not agree with that actually measured. The difference between the expected and measured acoustic waveforms is often attributed to the presence of a 'stimulus frequency OAE,' when it is just as easily explained by a nonlinear cochlear input admittance and an error of extrapolation. The measurement of SFOAEs can be viewed as an analysis of the first harmonic of the nonlinear input admittance. [...] Just as the SFOAEs represent the nonlinear growth of the first harmonic of the cochlear input admittance, the DPOAEs can be viewed as two-tone interactions due to the nonlinearity of the cochlear input admittance.''

[2]We use the qualifier ''pure'' here because distortion products measured in the ear canal are often *mixtures* of emissions generated by both distortion- and reflection-source mechanisms. We elaborate on this point in Sec. IV below.

[3]A preliminary account of this work has been presented elsewhere (Shera and Guinan, 1998).

[4]In this paper, we focus on acoustically evoked otoacoustic emissions; emissions evoked by direct electrical stimulation of the organ of Corti are not considered.

[5]In a normal ear, the threshold hearing curve often manifests corresponding peaks and valleys (e.g., Elliot, 1958; Thomas, 1975; Long, 1984); at levels near threshold, a swept tone of constant driver level moves alternately into and out of perception (e.g., Kemp, 1979b; Cohen, 1982).

[6]The symbol ''$\equiv$'' denotes equivalence—it means that the quantity on the left (in this case, the cochlear reflectance) is defined by the quantity on the right (here, the complex ratio of forward- and backward-traveling pressure waves at the stapes).

[7]Although we later conclude that the terminology is physically appropriate, the term ''reflectance'' should not be understood to imply any tacit assumption of a particular emission mechanism.

[8]Equation (2) neglects terms proportional to $R^2,R^3,\ldots$ that arise due to multiple internal reflection within the cochlea (see Shera and Zweig, 1993a; Zweig and Shera, 1995). See also Fig. 12 of this paper.

[9]A wider range of emission data from humans (Shera and Zweig, 1993a) shows that there exist extended frequency regions well characterized by statements (3) punctuated by short ''anomalous regions'' in which the re-

flectance varies more rapidly (see also Fig. 9 and footnote 29).

[10]Over a wider frequency range, R varies roughly as

$$R \approx R_0 e^{-2\pi i N \ln(f/f_{\max})},$$

where $f_{\max}$ is the maximum frequency of hearing. Except near ''anomalous regions'' (see footnote 9), both the complex amplitude R_0 and the dimensionless parameter N generally vary slowly with frequency (Shera and Zweig, 1993a). By expanding $\angle R$ in a power series about an arbitrary reference frequency one can show that the effective ''delay,'' τ, appearing in Eq. (4) varies inversely with frequency as $\tau(f) = N/f$. The parameter N thus represents the delay measured in units of the stimulus period.

[11]For simplicity, we have ignored dispersive effects due to sound transmission through the middle ear. The echo described here is that which would be measured at the basal end of the cochlea near the stapes (i.e., at the point where the reflectance R is defined).

[12]We wish to compare the observed change in $\Delta\theta_{\text{forward}}$ with the value predicted using the assumption that $\angle R \approx 2\Delta\theta_{\text{forward}}$. [The factor of 2 arises from round-trip travel; see Eq. (7).] The change, $\Delta\{\angle R\}$, in the phase of R over the frequency interval Δf_{cf} between the characteristic frequencies of the two measurement points can be estimated as follows. Since $\angle R$ rotates through 2π radians over the interval Δf_{OAE} between spectral maxima, the interval Δf_{cf} between the characteristic frequencies of the two measurement points corresponds to a phase shift of roughly

$$\Delta\{\angle R\} \approx 2\pi \Delta f_{\text{cf}} / \Delta f_{\text{OAE}}.$$

Unfortunately, the frequency spacing Δf_{OAE} between emission spectral maxima has not been measured in the squirrel monkey. However, measurements of SFOAEs at frequencies of 1–2 kHz in the rhesus monkey (Lonsbury-Martin *et al.*, 1988) indicate that $\Delta f_{\text{OAE}}/f \approx \frac{1}{13}$—compared with roughly $\frac{1}{15}$ at similar frequencies in humans (Shera and Zweig, 1993a)—suggesting that species differences may be small among primates. Using the human value yields

$$\Delta\{\angle R\} \approx 2\pi 15 \Delta f_{\text{cf}}/f_{\text{cf}} \approx 6\pi,$$

where the ratio $\Delta f_{\text{cf}}/f_{\text{cf}} \approx |f_{\text{cf}}(x_1) - f_{\text{cf}}(x_2)| / \sqrt{f_{\text{cf}}(x_1) f_{\text{cf}}(x_2)} \approx \frac{1}{5}$ has been estimated from the data in Fig. 5. Under the assumption that $\angle R \approx 2\Delta\theta_{\text{forward}}$, the predicted change in $\Delta\theta_{\text{forward}}$ is $\frac{1}{2}\Delta\{\angle R\}$ (i.e., approximately 3π, as shown by the scale bar in Fig. 5). Note that human emission measurements suggest that the ratio $\Delta f_{\text{OAE}}/f$ decreases at higher frequencies (Zweig and Shera, 1995); our calculation based on the value of $\Delta f_{\text{OAE}}/f$ near 1 kHz may therefore underestimate the value of $\Delta\{\angle R\}$ at 6 kHz.

Alternatively, the value of $\Delta\{\angle R\}$ can be estimated directly from the data in Fig. 5 using the theory of coherent reflection filtering (see Sec. III), which predicts the relation $\Delta f_{\text{OAE}}/f \approx 1/2f\tau_{\text{group}}$, where τ_{group} is the transfer-function group delay measured at the characteristic frequency (Zweig and Shera, 1995). Calculating the slope of the transfer-function phase from the data in Fig. 5 yields the value $\Delta f_{\text{OAE}}/f \approx \frac{1}{8}$, an estimate that implies a value of $\Delta\{\angle R\}$ roughly half that obtained above. Because the transfer-function phase varies more rapidly when the amplitude response is sharper, the estimates of τ_{group} and $\Delta\{\angle R\}$ obtained here from Fig. 5 presumably underestimate the values characteristic of healthy preparations at low sound levels (cf. Zweig and Shera, 1995).

The obvious uncertainty in these various estimates notwithstanding, the value of $\Delta\{\angle R\}$ consistently appears many times greater than the observed change in $\Delta\theta_{\text{forward}}$.

[13]Direct determination of phase shifts due to reverse propagation may now be possible using careful measurements of OAEs evoked by focal electrical stimulation of the cochlear partition (e.g., Nakajima *et al.*, 1994, 1999).

[14]For nice reviews, see the series by de Boer (1980, 1984, 1991).

[15]Even if $\Delta\theta_{\text{forward}}$ and $\Delta\theta_{\text{reverse}}$ are not numerically equal, the constancy of $\Delta\theta_{\text{round-trip}}$ follows so long as $\Delta\theta_{\text{reverse}} \approx$ constant, as expected in an approximately scaling-symmetric cochlea.

[16]Our thought experiment alludes, of course, to ''Maxwell's demon'' (e.g., Maxwell, 1871; Leff and Rex, 1990), a ''very observant and neat-fingered being'' invented by Maxwell to illustrate the statistical character of the second law of thermodynamics. Compared to Maxwell's demon, our demon is rather myopic, but is capable of doing work.

[17]The demon's phase formula may depend not only on the frequency of basilar-membrane vibration, but also on its local amplitude. We focus here, however, on changes in stimulus frequency and assume, for simplicity, that the stimulus amplitude is held constant during the measurement (e.g., as it was during the frequency sweeps shown in Fig. 1).

[18]Of course, the demon must also determine, from his measurements of basilar-membrane displacement, how *hard* he must push in order to generate an emission with the correct relative amplitude, $|R|$.

[19]Despite an aptitude for pushing and pulling, the demon is no omniscient or omnipotent being. Rather, the demon is but a stand-in for unspecified biophysical mechanisms and, consequently, must make do with the tools he finds at hand.

[20]Every transverse section of the cochlear partition may exhibit, in addition to the macromechanical oscillator tuned to f_{cf}, various micromechanical oscillators, modes of vibration, or other processes with different resonant frequencies and/or characteristic time scales (e.g., tectorial-membrane resonances, membrane time constants, efferent feedback signals, etc.). At each location, the cochlear partition may therefore contain not one but multiple ''clocks;'' and these multiple clocks could, in principle, be arranged to enable the demon to detect changes in the stimulus frequency. However, so long as the emission process does not depend sensitively on the relative values of these additional resonant frequencies [e.g., because the micromechanical oscillators have nearly the same spatial dependence as $f_{\text{cf}}(x)$ (e.g., Allen and Fahey, 1993) and/or because the relevant time scales are either much larger or much smaller than $1/f_{\text{cf}}$], then each location along the cochlear partition can effectively be regarded as having a single independent clock. At low and moderate sound levels, this assumption is supported both by the existence of scaling symmetry and, most compellingly, by the measurements of emission phase presented in Sec. II C. These measurements suggest that even if additional clocks exist, the demon (i.e., the source of nonlinear distortion) does not consult them while generating distortion-product emissions.

[21]With no loss of generality we can take the proportionality constant to be unity.

[22]More precisely, the demon cannot generate backward-traveling waves with a phase shift that depends *reproducibly* on frequency. The demon could, however, generate a stochastic frequency dependence by pushing and pulling on the basilar membrane at random. Such a strategy would, of course, be at odds with the repeatability of the emission measurements.

[23]In the nonlinear-distortion model, stimulus-frequency emissions simply correspond to the limiting case $f_2/f_1 = 1$.

[24]A constant ratio f_2/f_1 fixes not only the spatial separation between the envelopes of the primary traveling waves, but also the distances between all resulting distortion-product waves whose frequencies fall in the exponential portion of the cochlear map. *Proof*: If $\alpha \equiv f_2/f_1 =$ constant, then

$$f_{\text{dp}}/f_2 = (nf_1 - mf_2)/f_2 = n/\alpha - m = \text{constant},$$

for all values of n and m.

[25]For simplicity, we have assumed here that the demon is able to separate the complex temporal waveform of basilar-membrane vibration into its component frequencies. To the demon sitting at the f_2 place, the two-tone complex might look like a sinusoid of frequency $\frac{1}{2}(1 + f_1/f_2)$, amplitude modulated at the frequency $\frac{1}{2}(1 - f_1/f_2)$, where frequencies are measured in the demon's local units (i.e., in units of f_2).

[26]Measurement methods are detailed in the Appendix.

[27]The near constancy of ''frequency-scaled'' DPOAE phase differs from the more rapid phase rotation obtained when DPOAEs are measured using a stimulus paradigm (e.g., fixed f_1, fixed f_2, or fixed $2f_1 - f_2$) for which the cochlear wave pattern is not simply translated along the cochlear partition (e.g., Kimberley *et al.*, 1993; O Mahoney and Kemp, 1995). The strong dependence of the observed phase gradient on the measurement paradigm argues against any naive equivalence between DPOAE phase gradients and ''wave travel times'' within the cochlea.

[28]The slow variation in DPOAE phase apparent in the data at frequencies less than roughly 3 kHz may reflect a gradual breaking of scaling symmetry in the apical turns of the cochlea. Deviations from scaling at similar frequencies are apparent in the shapes of cat auditory-nerve tuning curves (e.g., Kiang and Moxon, 1980; Liberman, 1978).

[29]Although we focus here on SFOAE phase, a few remarks about SFOAE amplitude may be helpful. In particular, we emphasize that the irregular variations in SFOAE amplitude, $|\Delta P_{\text{SFOAE}}|$, apparent in the top panel of Fig. 9 should not be confused with the quasi-periodic oscillations in ear-canal pressure amplitude, $|P_{\text{ec}}|$, seen in Figs. 1 and 2. Whereas oscillations in $|P_{\text{ec}}|$ arise due to acoustic interference between stimulus and emission caused by the quasi-periodic cycling of SFOAE phase (or, equivalently, the locally linear variation of $\angle R$) with frequency, the variations in

$|\Delta P_{\mathrm{SFOAE}}|$ result from changes in SFOAE amplitude (or, equivalently, changes in $|R|$). Frequency intervals where $|R|$ changes rapidly are known as ''anomalous regions'' (Shera and Zweig, 1993a; see also footnote 9). The theory of coherent reflection filtering accounts for the origin and properties of these irregular variations in $|R|$ with frequency (Zweig and Shera, 1995).

[30]The analysis here can be ''inverted'' by asking ''What constraint does the striking frequency independence of fixed-f_2/f_1 DPOAE phase place on cochlear mechanics?'' That constraint might reasonably be expected to take the form of a symmetry principle enforcing the empirical relation $\angle P_{\mathrm{dp}} \approx$ constant. The arguments presented here identify the underlying symmetry principle as local scaling symmetry.

[31]Bragg's law—formulated by English physicists W. H. Bragg and his son, W. L. Bragg—states that when monochromatic x rays are incident upon a crystal, diffracted beams of maximal intensity occur when the x rays that scatter back from different atomic layers within the crystal combine in phase with one another.

[32]It may be worth remarking that the principal and eponymous conclusion of this paper—namely, that mammalian OAEs arise by two fundamentally different mechanisms—while certainly consistent with the theory of coherent reflection filtering, is by no means logically dependent upon it. So far as the logic of the present paper is concerned, the existence of a plausible candidate theory for the origin of reflection-source emissions is no more than a happy coincidence.

[33]These observations are not conclusive of linearity both because the measurements have only limited precision and because *ad hoc* nonlinear systems can always be constructed that will mimic the response of a linear system to a finite collection of test signals.

[34]Just as with stimulus-frequency emissions, the forward-traveling wave scatters off perturbations in the mechanics of the cochlear partition located near the peak of the wave envelope. The backward-traveling wave reflects from the impedance mismatch at the stapes (Shera and Zweig, 1991, 1992).

[35]The extent to which these two components reflect actual distortion-source subtypes—as opposed to uncontrolled-for, level-dependent mixing of reflection- and distortion-source emissions (see Sec. IV C and Fig. 12 below)—remains an important open question.

[36]Two distortion components with differential sensitivity to acoustic trauma have also been identified in the alligator lizard (Rosowski *et al.*, 1984).

[37]To clarify the distinction we maintain between ''echo'' and ''reflection-source'' emissions: As defined in Sec. I, the term ''echo emissions'' is simply a convenient shorthand for stimulus-frequency and transiently evoked emissions; as defined by the taxonomy in Sec. IV A, the term ''reflection-source emissions'' refers to OAEs that arise by linear reflection. At low levels, echo emissions are examples of reflection-source emissions.

[38]Indeed, based on their observations Martin *et al.* (1988) suggested that SFOAEs and DPOAEs may arise by different mechanisms, a suggestion fleshed out by the taxonomy presented here.

[39]Orderly patterns of impedance perturbations typically do not contain significant components at the spatial frequencies for which scattering is coherent (Zweig and Shera, 1995).

[40]Concomitant with the small amplitudes of rabbit and rodent reflection-source emissions is the absence of pronounced DPOAE fine-structure (e.g., Whitehead *et al.*, 1992a; Whitehead, 1998). Both observations can be understood—with reference to Fig. 12—as a consequence of the relatively small amplitude of the reflection-source emission (**R**) scattered back from the f_{dp} place.

[41]At low sound-pressure levels, the width of the traveling-wave envelope can be approximated by using local scaling symmetry to convert the bandwidth of the basilar-membrane transfer function (or neural tuning curve) to a spatial distance using the cochlear map (e.g., Liberman, 1982; Greenwood, 1990). For comparison with the ratio $f_{\mathrm{dp}}/f_2 \approx 0.6$ calculated in the text, the upper-frequency $Q_{10\mathrm{dB}}$-point on the f_{dp} transfer function occurs at the frequency

$$f_{Q_{10}} \approx f_{\mathrm{dp}}(1+1/2Q_{10}).$$

For a realistic Q_{10} of order 10, this yields a frequency ratio of $f_{\mathrm{dp}}/f_{Q_{10}} \approx 0.95$, corresponding to a distance along the cochlear partition spanning less than a semitone in characteristic frequency.

[42]Of course, distortion amplitudes also depend on amplifier gains at the primary frequencies f_1 and f_2. However, because the amplifier gain saturates at high sound levels, these effects are likely to be small at the sound levels used by Martin *et al.* (i.e., 80 dB SPL).

[43]In addition, the high primary sound levels they employed may well have suppressed the gain of the f_{dp} amplifier, reducing the reflection component even in the absence of aspirin ototoxicity.

[44]To preserve the frequency scaling of the stimulus waveform, the suppressor frequency f_s should, ideally, be swept while maintaining a fixed frequency ratio f_s/f_{dp} rather than the constant frequency difference $\Delta f_s = f_s - f_{\mathrm{dp}}$ used here. However, the frequency-quantization constraints imposed by our use of digital stimulus generation and time-domain averaging precluded our use of a constant-f_s/f_{dp} paradigm. Nonetheless, control experiments suggest that the phase $\angle \Delta P_{\mathrm{dp}}$ is not especially sensitive to the precise value of f_s. Similar remarks apply to the measurement of SFOAEs discussed below.

[45]The time-domain responses Y_n and Y_{n+1} to stimulus segments X_n and X_{n+1} were judged to contain an artifact if

$$\max_i |Y_{n+1}[i] - Y_n[i]| > Y_{\mathrm{rejection}},$$

where $Y[i]$ represents the ith sample of Y, and $Y_{\mathrm{rejection}}$ is the rejection threshold (set on a per subject and per session basis). When an artifact was detected, both responses were discarded and neither Y_n nor Y_{n+1} added to the final average. We adopted this artifact-rejection scheme primarily because of the ease with which it could be implemented in real time (cf. Keefe and Ling, 1998).

Response phase: A view from the inner hair cell

M. A. Cheatham[a] and P. Dallos
Communication Sciences and Disorders, Audiology and Hearing Sciences, Hugh Knowles Center, Frances Searle Building, Northwestern University, Evanston, Illinois 60208-3550

(Received 2 June 1998; revised 9 October 1998; accepted 23 October 1998)

Inner hair cell (IHC) responses are recorded from the apical three turns of the guinea pig cochlea in order to define the relationship between hair cell depolarization and position of the basilar membrane. At low frequencies, inner hair cell depolarization is generally observed near basilar membrane velocity to scala vestibuli, reflecting the putative freestanding nature of the IHC's stereocilia. While this is consistent with previous IHC results, independent of location, and with neural responses for fibers with low best frequencies, it is inconsistent with single-unit results from the base of the cochlea, where response phase is associated with basilar membrane velocity to scala tympani. Results suggest that the temporal disparity between IHC and neural data from the base of the cochlea may relate to several factors that influence transmembrane voltage in IHCs. First, extracellular voltages (Ingvarsson, 1981; Sellick *et al.*, 1982; Russell and Sellick, 1983) can potentially affect low- and high-frequency regions differently because electrical interactions are more likely in the base of the cochlea than in the apex (Dallos, 1983, 1985). Second, waveform distortion and kinetic properties associated with voltage-dependent ion channels in the IHC's basolateral membrane can both influence response phase by adding harmonic components and lagging the receptor potential by as much as 90 deg. Third, the velocity dependence of IHCs in the apex appears to extend to higher frequencies than the velocity dependence demonstrated for IHCs in the base of the cochlea. These features, which influence the timing of discharges in the auditory nerve, are compared and evaluated.

INTRODUCTION

Auditory-nerve fibers with low best frequencies (BF) tend to generate spikes for low-level, low-frequency inputs during the time when the basilar membrane is moving to scala vestibuli (SV); i.e., when basilar membrane velocity is maximum in the direction of SV. Conversely, auditory-nerve fibers innervating the base of the cochlea tend to respond near scala tympani (ST) velocity. A transition separates these regions where preferred phase is easily designated. These general trends, defined by Ruggero *et al.* (1996), have been studied and/or replicated to varying degrees by several investigators in the chinchilla (Ingvarsson, 1981; Ruggero and Rich, 1983, 1987), guinea pig (Konishi and Nielsen, 1978; Maceri *et al.*, 1982; Oshima and Strelioff, 1983), gerbil (Sokolich *et al.*, 1976; Oshima and Strelioff, 1983), and cat (Cai and Geisler, 1996a). The state of the art on this subject, however, is reflected in the extensive recordings obtained by Ruggero and his colleagues (Ruggero *et al.*, 1996).

Although hair cell measurements are difficult and, therefore, much less extensive than those from auditory-nerve fibers, data from the apex of the cochlea demonstrate that IHCs depolarize at low frequencies near SV velocity (Dallos and Santos-Sacchi, 1983; Dallos, 1985; Cheatham, 1993). This is in harmony with neural records obtained in the chinchilla for fibers with low BFs. Interestingly, IHCs from the base of the cochlea also respond to SV velocity at low stimulus frequencies (Sellick and Russell, 1980; Nuttall *et al.*, 1981; Russell and Sellick, 1983; Patuzzi and Yates, 1987), which is difficult to reconcile with single-unit responses from the high-frequency region of the cochlea. In order to clarify the relationship between IHC and neural responses, this report provides additional data from IHCs in the apical three turns of the guinea pig cochlea. Results from third and fourth turns correspond to neural data obtained for fibers with low BFs. Data from the second turn, however, may provide insights into the temporal disparities between IHC and neural responses at more basal regions of the cochlea.

Ideally, it would be important to provide IHC data from the basal turn to compare with the results presented here. In other words, apply the lateral approach to hair cell recording (Dallos *et al.*, 1982) in all four cochlear turns. Unfortunately, this approach has not been successful in the high-frequency region of the cochlea. This may relate to position of the access window over scala media. In the basal turn, outer hair cells are short and a flatter electrode track is required to avoid disruption of the tectorial membrane. Consequently, the lower position of the window may interfere with attachment of the basilar membrane to the spiral ligament. Because of these difficulties, the results in this report from the apical three turns are compared with measurements from first-turn IHCs collected by other investigators using the scala tympani approach, which requires penetration of the basilar membrane (Sellick and Russell, 1980; Nuttall *et al.*, 1981; Russell and Sellick, 1983; Patuzzi and Yates, 1987; Cody and Mountain, 1989). Taken together, the experimental results may

[a]Electronic mail: m-cheatham@nwu.edu

further our understanding of how signals are processed prior to spike initiation in the auditory nerve.

I. METHODS

The cochlea is exposed in anesthetized guinea pigs using the traditional ventrolateral approach (Dallos *et al.*, 1982). Because it is practical to record from only one turn in any given preparation, a single window is made over scala media in turns 2, 3, or 4, where BFs are approximately 4000, 1000, and 250 Hz, respectively. After traversing the spiral ligament and the endolymphatic space, the recording electrode encounters Hensen cells at the edge of the organ of Corti (OC). Ideally, the electrode track is roughly parallel to but below the reticular lamina, thereby optimizing chances for hair-cell recordings. Additional details can be obtained from previous publications (Dallos, 1985; Cheatham and Dallos, 1992). All animal care procedures were approved by the National Institutes of Health and by Northwestern University's Institutional Review Committee.

In these experiments, receptor potentials are recorded from individual IHCs. These potentials are produced by the receptor current flowing through resistances associated with the cell's basolateral membrane. Stimulus-related responses are also measured in the organ of Corti fluid space. These measures reflect outer hair cell (OHC) receptor currents which are proportional to local basilar membrane displacement (Dallos, 1973; Nedzelnitsky, 1974; Dancer and Franke, 1980). Consequently, the voltages recorded from the OC fluid space are used to determine the position of the basilar membrane. In other words, the motion pattern of the basilar membrane is estimated locally in the same general area as the hair cell recordings and no corrections are required to compensate for traveling wave and/or synaptic delays. The OC measure is preferable to that at the round window for at least two reasons. First, there is usually a disparity between the round window location at which basilar membrane motion is estimated and the place along the cochlear partition where a nerve fiber innervates its hair cell target. Thus, traveling-wave delays must be estimated and compensated. Second, the electroanatomy in the hook region is complex (Weiss *et al.*, 1969; Dallos *et al.*, 1971), with the result that the CM suffers from phase cancellation (Whitfield and Ross, 1965) as local and remote hair cell generators interact. This electrical complication makes estimation of basilar membrane position from round window recordings less accurate when compared to measures from the OC fluid space. The organ of Corti potentials, made in the same general area as the hair cell recordings, are also preferable to those from perilymphatic scalae because the length constant within the organ may be shorter (Geisler *et al.*, 1990).

Stimuli are produced by a single earphone (Beyer DT-48) and the input sound pressure levels are measured in the ear canal utilizing a miniature microphone (Knowles BT-1751). Because the latter is nonlinear at high levels, distortion in the sound is determined in a coupler using a 1/2-in. Brüel & Kjaer condenser microphone (type 4134). Measurements are not made in the ear canal because of contamination by distortion products generated in the cochlea and fed back through the middle ear as otoacoustic emissions. At the highest levels used in these experiments, i.e., 75 dB, the second harmonic is at least 65 dB down from the fundamental at 40 Hz. Using this result, one can estimate harmonic response magnitudes due to distortion in the sound (Dallos *et al.*, 1969). When compared to these calculations, the physiological responses reported here for the 40 Hz fundamental are at least an order of magnitude greater than the predicted magnitude of the artifact. Even though distortion levels may be higher when measured in the ear canal (Ruggero *et al.*, 1996, Table 1), they are still estimated to be lower than the levels required to produce the results reported here.

Electrical measurements are made from individual IHCs and from the organ of Corti fluid space. Responses are amplified, low-pass filtered to control aliasing, and gain-controlled to avoid saturating the analog-to-digital converter. The averaged-response waveforms are plotted versus time relative to the beginning of the time window used in the averaging process. In order to emphasize detailed aspects of the responses, waveform segments are plotted for two stimulus periods. This procedure is clarified by using two abscissas: one in time, the other in periods.

In order to assay the magnitudes of individual components from distorted responses, averaged-response waveforms are digitally filtered off-line. These manipulations are performed using IGOR PRO (WaveMetrics, Lake Oswego, OR 97035) equipped with the Igor Filter Design Laboratory. In this program, filtered outputs appear in phase with the input because phase changes associated with the filter are removed. This in-phase or noncausal filtering allows small phase variations to be quantified. Design macros implement either low- or high-pass filters by using the McClellan–Parks–Rabiner technique. Attenuations in the reject band are at least 40 dB down from the passband, where rippling is less than ± 0.02 dB. In the low-pass case, the passband is 0–50 Hz, while in the high-pass case, the reject band is 0–50 Hz. IGOR PRO is also used to subtract OC from IHC waveforms, allowing the IHC's basolateral membrane potential to be determined (Russell and Sellick, 1983; Cody and Mountain, 1989). This is useful because the release of neurotransmitter is proportional to the potential difference across the presynaptic membrane (Katz and Miledi, 1967).

II. RESULTS

In this report, the term ''response phase'' refers to the time during a single period of a low-frequency sinusoid when the hair cell depolarizes, thereby inducing transmitter release and, presumably, increasing discharge rate (Flock, 1971). Consequently, IHC data are evaluated to determine when the voltage gradient across the cell's basolateral membrane becomes more positive relative to that in quiet, and to relate this to the instantaneous position of the basilar membrane. An IHC recording from the fourth turn is used to introduce these ideas and results.

A. Fourth turn

Figure 1 displays IHC and OC waveforms for a 100 Hz stimulus presented at 40 dB. Two cycles are displayed to demonstrate temporal aspects of the responses. Because the BF of this IHC is 270 Hz, the 100 Hz input produces a large

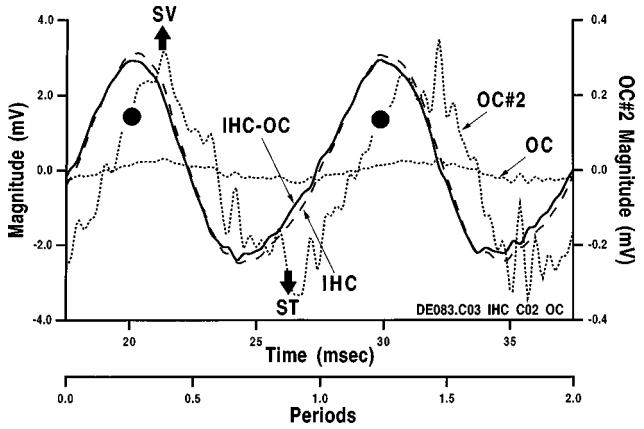

FIG. 1. Data in this figure were collected from fourth turn at 100 Hz (40 dB). Organ of Corti responses are plotted with dotted lines, the IHC response with dashed lines, and the subtracted IHC–OC response with solid lines. In this and subsequent figures, response magnitudes are plotted versus time relative to the beginning of the time window used in the averaging process. Although the second abscissa indicates only two periods of the stimulating sinusoid, the tone burst was 40 ms long. Symbols are placed on the OC waveform guided by eye to indicate when the IHC–OC potential is maximally positive relative to the position of the basilar membrane. The OC#2 response is plotted using the right ordinate so that temporal comparisons can be made between intracellular and extracellular measures. In this and all figures, sound pressure level is measured in dB *re*: 20 μPa.

ac receptor potential which exceeds that produced in the OC fluid space. Although the left ordinate applies to both IHC and OC responses, the OC waveform is replotted as OC#2 using the ordinate on the right, where an expanded scale facilitates temporal comparisons. The phase lead demonstrated here between IHC and OC potentials is thought to reflect the freestanding nature of the IHC stereocilia (Lim, 1972) and the consequent velocity dependence of the IHC input (Dallos *et al.*, 1972). The fourth waveform, plotted with solid lines, is obtained by subtracting the OC from the IHC response. Because of the large disparity in magnitude between intracellular and extracellular responses at this apical location, the IHC–OC curve is virtually identical to that for the IHC. In other words, intracellular ac responses recorded in the apex of the cochlea are much larger in magnitude than those measured nearby in the OC fluid space, with the result that the IHC transducer largely determines the transmembrane voltage.

In order to determine the timing of hair cell depolarizations relative to the position of the basilar membrane, the OC response is interpreted in the following way. The positive phase of this cochlear microphonic (CM) response is associated with basilar membrane displacement to SV; the negative phase with displacement to ST. This relationship is based on evidence suggesting that the CM reflects outer hair cell (OHC) receptor currents (Dallos and Cheatham, 1976), and that OHCs respond to basilar-membrane displacement (Békésy, 1960; Dallos *et al.*, 1972). Hence, the local CM also reflects basilar membrane displacement. Based on this association, one concludes that the IHC plotted in Fig. 1 depolarizes between basilar membrane velocity to SV and basilar membrane displacement to SV. This is indicated by the filled circles placed on the OC waveform at the time when the IHC–OC potential, which drives transmitter release, is maximally positive.

B. Third turn

An IHC response from third turn, where BF is 1000 Hz, is shown in Fig. 2. At the top, both IHC and OC response waveforms are displayed for a 200 Hz stimulus presented at 50 dB. The IHC–OC function is not included because it is virtually identical to the IHC response. As in Fig. 1, the input is below BF and the IHC response leads the potential recorded in the OC fluid space by ~45 deg. These temporal features are shown by comparing the OC response with that from the IHC. Waveforms are also included for higher frequency inputs, again presented at 50 dB. For 600 Hz (center), the IHC and OC responses are nearly in phase and the IHC depolarizes for basilar membrane displacements to SV similar to observations in first-turn IHCs (Sellick and Russell, 1980; Nuttall *et al.*, 1981; Russell and Sellick, 1983; Patuzzi and Yates, 1987; Cody and Mountain, 1989). This is because the velocity sensitivity of the IHC transducer is expressed only at low frequencies.

At the bottom of Fig. 2, the IHC waveform at 1200 Hz lags behind the OC response. This shift is thought to reflect low-pass filtering associated with the hair cell's basolateral membrane (Sellick and Russell, 1980; Dallos and Santos-Sacchi, 1983). Based on information collected from third-turn IHCs, the cutoff frequency of this filter is estimated to be ~470 Hz (Dallos, 1984). Therefore, IHC responses at high frequencies should decrease in magnitude by 6 dB/octave and the IHC phase should lag behind the OC response by 90 deg. The CM does not show a similar phase lag because this extracellular ac potential reflects OHC receptor currents and not OHC receptor potentials (Russell and Sellick, 1983; Dallos and Evans, 1995). Therefore, the OHC basolateral membrane does not act as a low-pass filter on the OC response.

C. Second turn

Because low-frequency response phase depends on the BF of single auditory-nerve fibers (Ruggero *et al.*, 1996) and presumably on their place of innervation along the cochlear spiral, it is helpful to examine this feature in hair cells with higher BFs. Information was, therefore, collected from second-turn IHCs where BFs are ~4000 Hz. In the top panel of Fig. 3, the IHC ac receptor potential at 150 Hz exceeds in magnitude and leads in phase the extracellular CM response. At 1200 Hz, however, the IHC and the IHC–OC responses both lag behind the OC measurement, consistent with filtering by the IHC's basolateral membrane (Sellick and Russell, 1980; Dallos and Santos-Sacchi, 1983). In other words, these patterns are qualitatively similar to those seen in Fig. 2. Because of the relatively larger OC response at 1200 Hz, the subtracted waveform differs from the IHC receptor potential. In fact, the temporal disparity is exaggerated when the IHC's basolateral membrane potential (IHC–OC) is compared with the OC response.

Although these measures from the second turn are consistent with those obtained elsewhere along the cochlear par-

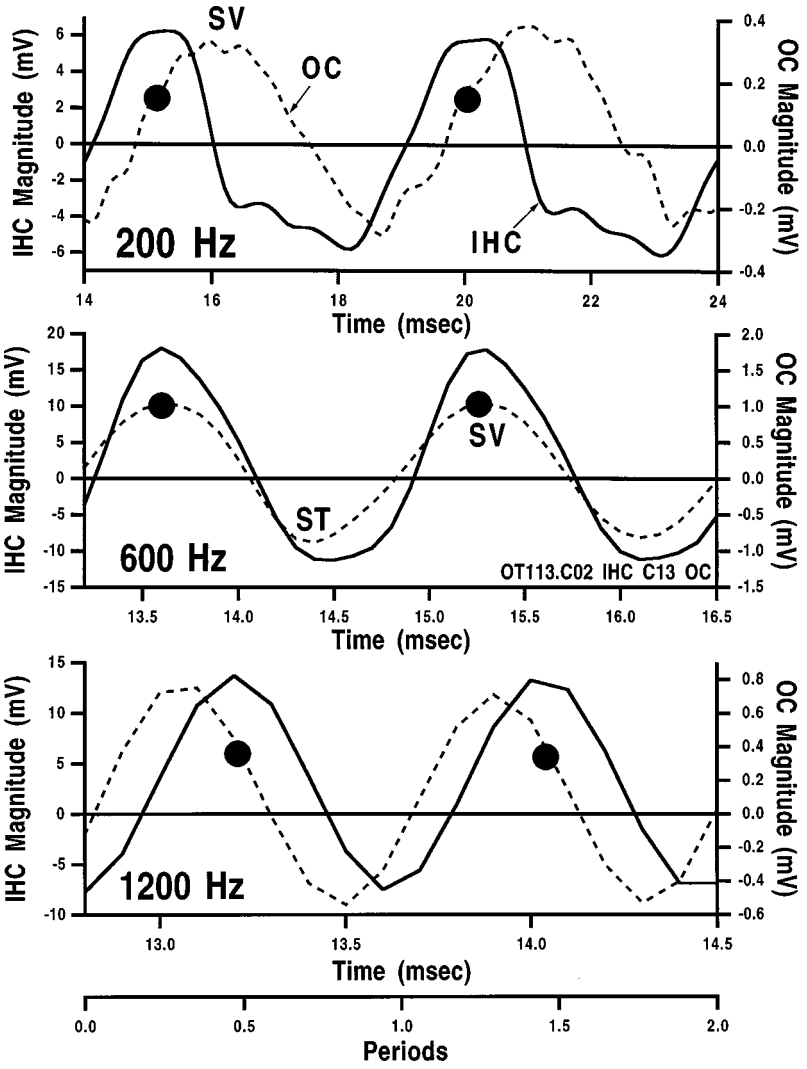

FIG. 2. Data are provided for IHC (solid lines) and OC (dotted lines) responses recorded in third turn at three different frequencies. All inputs were presented at 50 dB. A zero line is included for reference. Although only two stimulus periods are displayed, the tone burst duration was 40 ms.

tition, it is instructive to look for indications where this characterization might not apply. This is because single units with high BFs exhibit a response phase that differs from that for units with low BFs. Based on previous suggestions that extracellular voltages can influence transmitter release at very low frequencies (Ingvarsson, 1981; Sellick *et al.*, 1982; Russell and Sellick, 1983), a 40 Hz input was chosen to increase separation between the stimulus frequency and the cell's BF. These second-turn results, displayed in Fig. 4 for OC, IHC, and IHC–OC records, are not typical of the responses usually encountered at this location and plotted in Fig. 3. In fact, the IHC response (thin solid lines) at 40 Hz and 65 dB is slightly lagging behind that recorded in the OC fluid space (dotted lines). The response phase estimated from the difference potential, IHC–OC (bold solid lines), lies in the region between basilar membrane displacement to SV and basilar membrane velocity to ST. This is indicated by the symbol placed on the OC waveform. Although this is an unusual IHC response pattern, it is similar to responses recorded in single units with comparable BFs. For example, fibers in the chinchilla auditory nerve with BFs in the transition region express a response phase just leading ST velocity at low frequencies (Ingvarsson, 1981; Ruggero and Rich, 1989; Ruggero *et al.*, 1996).

Data collected from the same IHC at 40 Hz and 75 dB are plotted in Fig. 5. The IHC waveform (thin solid lines) indicates that depolarization occurs between SV displacement and ST velocity. However, when the OC response is subtracted from the intracellular response (bold solid lines), two positive peaks emerge. These data at 40 Hz indicate that only after subtracting the extracellular response are two occurrences of hair-cell depolarization expressed within the cycle. This is probably because the second peak of depolarization coincides with the ST phase of the cochlear microphonic. Because an extracellular negativity tends to depolarize IHCs, this is the excitatory phase of the CM response. Consequently, the timing of hair cell depolarizations is affected by the relative magnitudes of extracellular and intracellular voltages.

Because these responses are distorted at 75 dB, the waveforms were digitally filtered off-line and plotted in the center panel of Fig. 5 to reveal changes in response phase for the fundamental versus the higher-order harmonics. These filtered responses represent difference potentials (IHC–OC) obtained after both high- and low-pass filtering. This is done to indicate the ways in which extracellular and intracellular responses are integrated and filtered by the hair cell's basolateral membrane. The low-pass filtered OC waveform is ap-

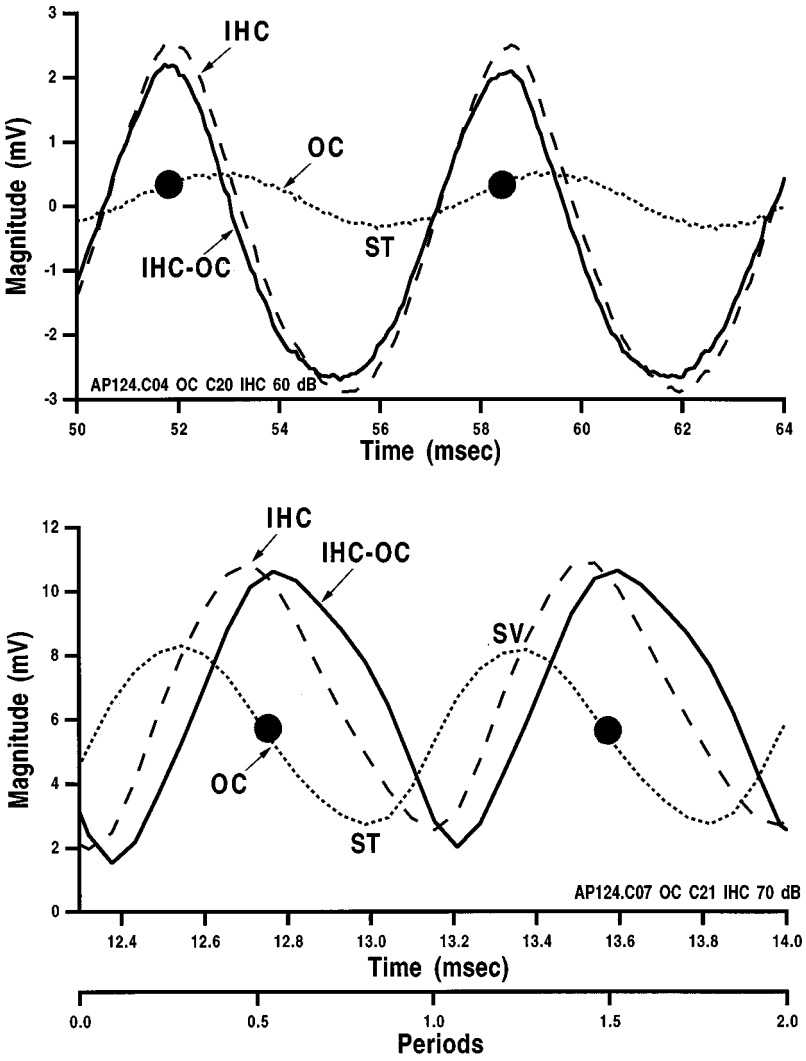

FIG. 3. This figure provides results from a second-turn IHC (dashed lines) and from the OC fluid space (dotted lines). The IHC–OC difference potential (solid lines) is also included to approximate the IHC's basolateral membrane voltage. Results at the top are for 150 Hz at 60 dB; those at the bottom for 1200 Hz at 70 dB. The OC response at 1200 Hz has been shifted vertically to facilitate comparisons with the IHC results (actually, the dc response in the extracellular space is small). The tone burst at 150 Hz (1200 Hz) was 50 (40) ms long. Although the first cycle at 1200 Hz is somewhat larger than the second, this is most likely due to noise, because only 40 presentations were averaged. In other words, this cell is not different from all other IHCs that do not exhibit adaptation.

pended to indicate position of the basilar membrane. Comparisons between the OCLP response and the subtracted low-pass waveform [(IHC–OC)LP] reflect phase differences between the IHC's basolateral membrane potential and the extracellularly recorded response at the fundamental (OCLP). The subtracted high-pass response [(IHC–OC)HP] reflects the harmonic content of the voltage gradient across the cell's basolateral membrane. The source of this nonlinearity is suggested in the lower panel, where low- and high-pass filtered IHC and OC waveforms are compared. In spite of the fact that the OC response at the fundamental is larger than the IHC response, the harmonic content of the intracel-

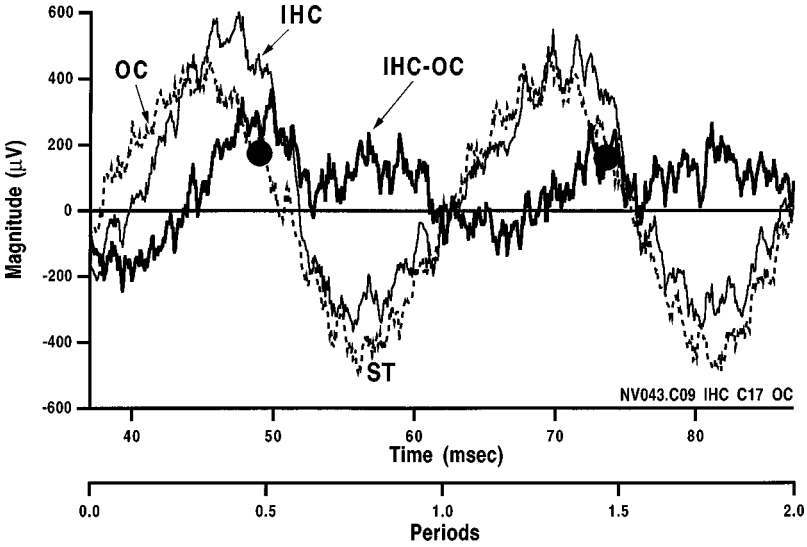

FIG. 4. Results from an unusual second-turn IHC are shown here for 40 Hz at 65 dB. Again waveforms are included for the IHC (thin lines), OC (dotted lines), and the IHC–OC (bold lines) responses. The OC response is used to designate position of the basilar membrane with the negative phase of the response indicating displacement to ST. The duration of the 40-Hz tone burst was 105 ms.

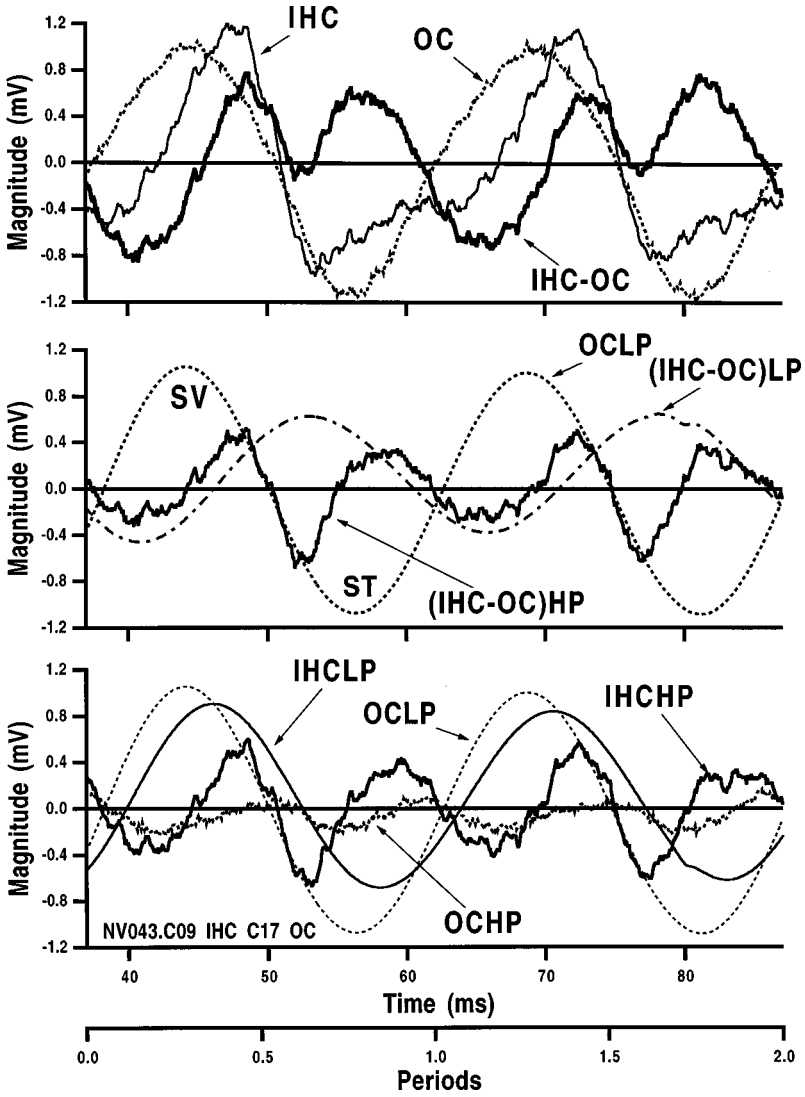

FIG. 5. These results are from the same IHC and the same level series as in Fig. 4. The data here, however, were collected at 75 dB. Line styles in the top panel are the same as those in Fig. 4. In the center panel, difference potentials are computed by subtracting IHC and OC responses and then high- and low-pass filtering the subtracted waveforms. The low-pass filtered OC waveform, plotted with dotted lines, is appended to indicate position of the basilar membrane. The bottom panel shows high- and low-pass filtered waveforms for both OC and IHC responses. The high- (low-) pass condition is plotted with thick (thin) lines.

lular response (IHCHP) exceeds that measured just outside the cell. In other words, the IHC response is more nonlinear than the one measured in the OC fluid space. Consequently, the more distorted intracellular response appears to reflect nonlinearities associated with voltage-dependent channels in the cell's basolateral membrane, as well as nonlinearities associated with the hair cell transducer. These harmonic components tend to produce an apparent phase lag of the depolarizing phase of the hair cell's basolateral-membrane potential (i.e., IHC–OC).

III. DISCUSSION

A. The frequency and level dependence of response phase

The single-unit literature indicates that response phase at low frequencies depends on BF. A preference for SV velocity is demonstrated, but only for neurons innervating the apex of the cochlea. Fibers targeting the base respond during basilar membrane velocity to ST (Ruggero *et al.*, 1996). This contrasts with results from IHCs, where depolarizations have generally been recorded near basilar membrane velocity to SV, independent of location (Sellick and Russell, 1980; Dallos and Santos-Sacchi, 1983; Patuzzi and Yates, 1987; Cody and Mountain, 1989). In order to deal with this discrepancy, it has been suggested that transmitter release could be driven by dominant, extracellular voltages with the result that single units would be expected to respond during ST displacement (Ingvarsson, 1981; Sellick *et al.*, 1982; Russell and Sellick, 1983). In this case, the voltage gradient across the IHC's basolateral membrane becomes relatively more positive during the negative phase of the CM response, which coincides with basilar membrane displacement to ST.

Data collected here in the apex of the cochlea indicate that IHC responses are larger and more nonlinear than those recorded outside the cell in the OC fluid space. This implies that extracellular voltages would not drive transmitter release (Dallos, 1983, 1985). However, in the base of the cochlea, gross extracellular responses at low frequencies are distorted (Ruggero *et al.*, 1986) and sometimes larger than IHC responses (Russell and Sellick, 1983). These differences may relate to the signal-to-BF ratio. Because this can be several octaves for single units with high BFs, thresholds on the tails of tuning curves are relatively high. Consequently, neural-response phase could lead ST displacement by as much as 90 deg, reflecting changes in wave shape as the CM response becomes more distorted. In other words, as the CM wave-

form becomes more square in shape, stimulation due to it occurs earlier in time. Because single units fire when their threshold is crossed, this may explain why neural phases lead ST displacement.

At somewhat higher levels, the IHC's receptor potential begins to dominate the transmembrane potential, with the result that a preference for SV velocity should be expressed. This transition has been demonstrated in the high-frequency region of the cochlea (Sellick *et al.*, 1982; Cody and Mountain, 1989), where IHCs respond near ST displacement at threshold levels, and near SV velocity at somewhat higher levels. These variations in response phase probably depend on differences between inner and outer hair cell excitation; specifically, the velocity dependence of the IHC input that serves to increase its threshold at low frequencies, thereby allowing extracellular voltages from OHCs to influence transmitter release.

Unfortunately, empirical determination of the degree to which extracellular voltages influence transmembrane potential is difficult to obtain. This is because penetration of the cell changes its electrical characteristics (Kros and Crawford, 1990; Kros, 1996; Zeddies and Seigel, 1995, 1996), making quantitative comparisons between IHC and OC responses difficult. Not only is the receptor potential decreased because the membrane resistance is reduced, but the basolateral membrane itself is linearized compared to its normal *in vivo* behavior. This makes it difficult to quantify the effect of phase shifts and nonlinearities produced by voltage-dependent ion channels in the IHC's basolateral membrane. Because of these complications, IHC and OC responses could appear similar in magnitude because of the leak associated with electrode penetration which is largely unavoidable in all sharp microelectrode recordings.

B. Simulation of response phase

A simple summation of sinusoids (i.e., not the solution of an elaborate hair cell model) is used to demonstrate that the addition of appropriate signals can produce a series of response patterns that is useful in deciphering the various phase shifts measured in the peripheral auditory system. In this effort, contributions are added as if they were produced by nonlinear cochlear elements, including the IHC transducer and voltage-dependent ion channels located in the cell's basolateral membrane. Extracellular voltages are also incorporated. The resulting changes in transmembrane voltage produced by pertinent combinations are provided in Fig. 6. In part (A), the IHC response (dashed lines) exceeds in magnitude and leads in phase the response measured in the OC fluid space (dotted lines) at low frequencies. This configuration reflects dominance by the IHC transducer, with the result that the voltage gradient across the cell's basolateral membrane, plotted with solid lines, is positive for SV velocity. This pattern, though idealized, is reasonably similar to those shown in Figs. 1, 2, and 3 and corresponds to that for nerve fibers with low BFs where discharge rate also increases near basilar membrane velocity to SV.

Part (B) of Fig. 6 depicts the case where the OC response exceeds that in the IHC with the result that the transmembrane potential depolarizes near displacement to ST. This simulation may apply to very low-frequency responses in the base of the cochlea, where the velocity dependence of the IHC transducer acts as a high-pass filter and reduces input to the cell (Sellick *et al.*, 1982; Russell and Sellick, 1983; Cody and Mountain, 1989). In this case, it is possible that single units with high BFs respond closer to ST velocity, reflecting a squaring of the OC waveform at moderate and high levels. Although this simulation depicts a much larger extracellular response, Russell and Sellick (1983) demonstrate that even when the IHC potential exceeds or is commensurate with the OC response, the extracellular voltage can influence the waveform of the transmembrane potential, as shown in Figs. 3 and 5. Thus, the voltage that drives transmitter release reflects a complex interaction between extracellular and intracellular responses. Although IHCs in the apex are also velocity dependent, electrical interactions are not likely here (Dallos 1983, 1985) because the CM is very small compared to the intracellular response. This is because low-frequency inputs are much closer to BF in the apex than in the base of the cochlea, with the result that cells respond in the ''tip region'' of the traveling wave.

Inner hair cell harmonic components also influence the timing of hair cell depolarizations and, ultimately, the timing of transmitter release. This is represented in Fig. 6(C), where interactions between the fundamental and the second harmonic result in two peaks of depolarization similar to the results plotted in Fig. 5. Depending on the relative phase between fundamental and harmonic components, and the degree to which they cancel and/or reinforce one another, one or multiple depolarizations can develop per cycle. In other words, the presence of harmonic components can influence the degree to which there is more than one preferred time for spikes to occur during a single period of a low-frequency input (Johnson, 1980; Ruggero and Rich, 1983; Horst *et al.*, 1990; Cai and Geisler, 1996a). Because the CM response is usually more linear than that recorded inside the cell (Fig. 5 and Cody and Mountain, 1989), the degree to which multiple peaks occur postsynaptically also depends on the relative magnitudes of intracellular and extracellular voltages. This was indicated in Fig. 5, where two peaks of depolarization emerge after the OC response is subtracted from that recorded inside the IHC. This possibility, that extracellular voltages influence postsynaptic responses, assumes that OC voltages will be significant, relative to IHC receptor potentials, even if the cell is not invaded by the microelectrode.

Although results from first-turn IHCs are not included here, it has been reported that the IHC ac receptor potential leads the CM by 90 deg at 40 Hz, after which it falls rapidly to zero degrees between 200 and 300 Hz (Sellick and Russell, 1980; Russell and Sellick, 1983). This suggests that the phase lead between IHC and OC responses is expressed in the base of the cochlea, but only at very low frequencies. In fact, another first-turn IHC (Russell and Sellick, 1983) did not exhibit a velocity dependence even at 30 Hz, where the ac receptor potential was in phase with the CM recorded in the OC. This indicates that the cell depolarized when the basilar membrane was displaced to SV. At 250 Hz, the ac receptor potential produced by this same cell was lagging behind the CM by ~45 deg. This phase lag is consistent with

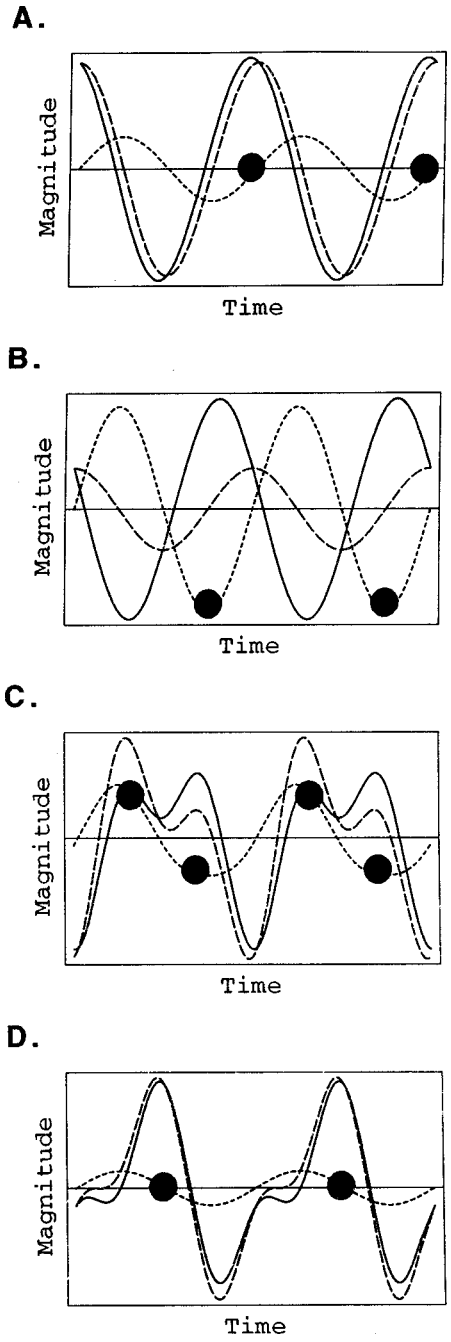

FIG. 6. Computer simulations demonstrate conditions where transmitter release is dominated by the IHC transducer [part (A)], the extracellular CM response [part (B)], and by IHC harmonic components [part (C)]. In all panels, two cycles are shown and the line styles are as follows: IHC, dashed; OC, dotted; transmembrane potential, solid. In part (A), the IHC transducer controls the voltage gradient across the cell's basolateral membrane with the result that the cell depolarizes for SV velocity, as indicated by the symbols. A similar response phase also characterizes single units with low BFs. In part (B), the extracellular CM, measured in the OC fluid space, controls transmitter release. The transmembrane potential is positive during basilar-membrane displacement to ST. For both panels (A) and (B), a phase lead of 90 deg for the fundamental component is incorporated. Contributions by IHC harmonic components, as in part (C), result in two depolarizations per cycle. This was achieved by adding 70% second harmonic, i.e., the second harmonic was 3 dB down from the fundamental. Finally, the simulation in panel (D) shows the fundamental component of the IHC response lagging behind the OC potential. This represents basal-turn responses at ~500 Hz where the IHC transducer responds to SV displacement and ion channels in the cell's basolateral membrane contribute a phase lag. Significant second-harmonic distortion (50%) is also assumed.

estimates (Zeddies and Siegel, 1995) of the kinetics of voltage-dependent ion channels. Based on these data obtained in the base of the cochlea, the simulation in panel (D) of Fig. 6 represents an input at ~500 Hz, where there is no velocity dependence. The simulation includes energy at the second harmonic and assumes a phase lag due to channel activity. In this case, maximum depolarization occurs near basilar membrane velocity to ST. This is evident in the records even when the OC response is not subtracted. This response phase is similar to that observed for single units in the base of the cochlea (Ruggero *et al.*, 1996; Cai and Geisler, 1996a).

The distortion and phase shift produced by voltage- and time-dependent channel activity should be considered when evaluating response phase. It is difficult, however, to quantify these contributions because all *in vivo* hair cell recordings invariably compromise channel kinetics. In fact, the receptor potential usually reflects the transducer impedance because of the leak that shunts the basolateral membrane when the electrode penetrates the cell. If this leak is relatively minor, then low-pass filtering by the membrane will shape the receptor potential and contribute a phase lag between intracellular and extracellular responses. Because IHC responses rarely reflect balanced contributions from both transducer and basolateral membrane impedances, the magnitude and phase changes, as well as the distortions contributed by channel activity, are not fully reflected in hair cell recordings.

C. Implications for postsynaptic responses

The schematic in Fig. 7 represents response phase plotted as a function of stimulus frequency and expressed relative to the motion pattern of the basilar membrane. Responses for the apex of the cochlea are presented in the top panel. Functions for the CM (dot–dashed lines), measured in the OC fluid space, indicate that the positive (negative) phase of this cochlear potential is associated with SV (ST) displacement throughout the frequency range depicted here. This is because the CM reflects OHC receptor currents (Dallos and Cheatham, 1976), and OHCs probably respond to basilar-membrane displacement at all frequencies (Dallos *et al.*, 1972). Thus, the phase changes on the right ordinate are plotted relative to basilar membrane displacement to SV. The function representing input to the IHC transducer (dashed lines) exhibits a velocity dependence for low frequencies with the result that IHC responses are measured near SV velocity. This preference reflects high-pass filtering associated with ciliary mechanics (Dallos and Cheatham, 1990). As stimulus frequency increases, IHC response phase changes to SV displacement, reflecting entrainment of the hair bundle (Freeman and Weiss, 1990) or possibly a loose contact between the IHC stereocilia and the overlying tectorial membrane. In other words, at higher frequencies, the IHCs can respond to basilar membrane displacement even when there is no firm attachment between the IHC stereocilia and the overlying tectorial membrane. The function plotted with solid lines combines high-pass filtering associated with the IHC transducer and low-pass filtering associated with the hair cell's basolateral membrane. As response phase moves

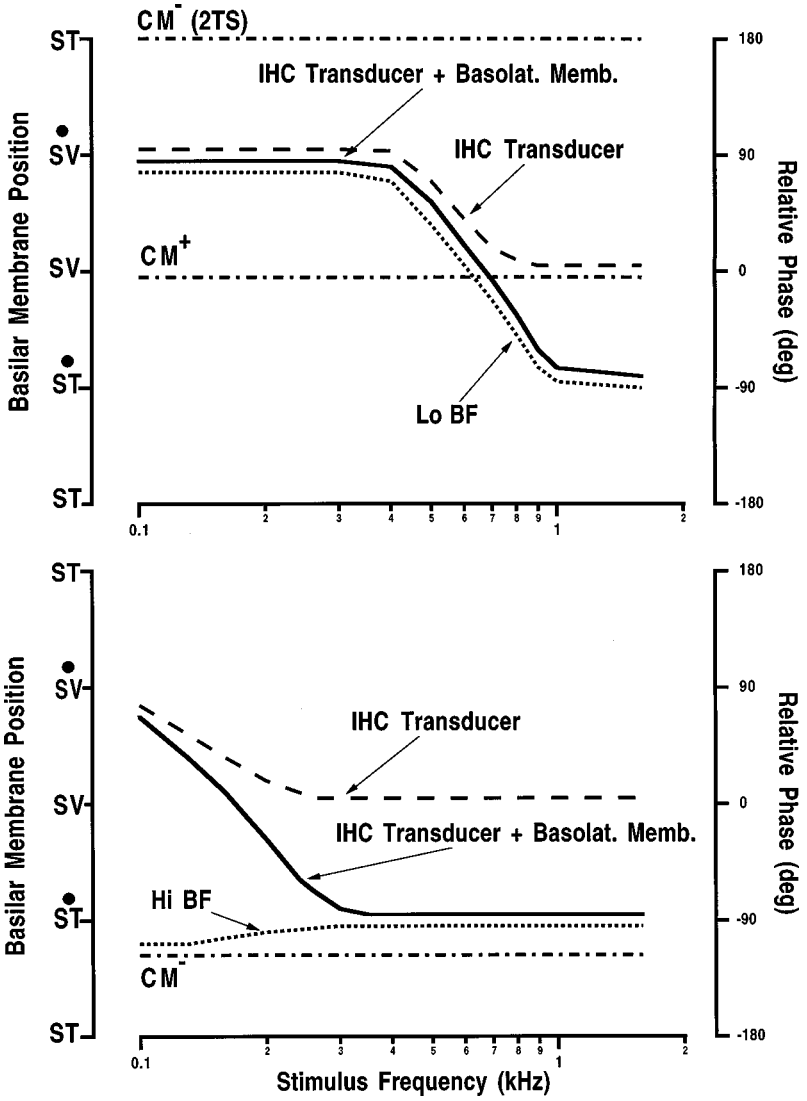

FIG. 7. These schematics are designed to summarize response phase for hair-cells and single-units in the apex (top panel) and base (bottom panel) of the cochlea. Because single-unit results in the chinchilla (Ruggero *et al.*, 1996) are the most extensive, they form the basis for these representations. The left ordinate represents basilar membrane position; the right, response phase plotted relative to SV displacement, with positive numbers indicating phase leads. The top panel indicates that the IHC transducer (dashed lines) responds to SV velocity at low frequencies. In other words, a 90 deg lead is expressed relative to the positive phase of the CM response (dot–dashed lines), which is associated with basilar membrane displacement to SV. As stimulus frequency increases, however, IHC excitation coincides with basilar membrane displacement to SV. In this case, the time of excitation is ~180 deg out of phase with the negative CM response. The phase of excitation for single units with low BFs (solid lines) indicates that they also respond to SV velocity at low frequencies. The IHC data reported here suggest that these neural responses should pass through SV displacement and finally settle at ST velocity as stimulus frequency increases. Above ~1000 Hz, the 1/4-cycle disparity between the single unit and the IHC transducer reflects the 90 deg phase lag associated with low-pass filtering by the IHC's basolateral membrane. For single units with high BFs, depicted at the bottom, a preference for ST velocity is demonstrated throughout the frequency range depicted here. The negative phase of the CM response is plotted near ST velocity to reflect nonlinearities associated with the high levels required to reach threshold for inputs well below BF.

from SV velocity to ST velocity (see also Figs. 2 and 3), the function displays a 90 deg lead at low frequencies and a 90 deg lag above ~1000 Hz, when measured relative to the positive phase of the CM response. This smooth transition is suggested by modeling efforts (Dallos, 1984) that show the corner frequencies of the low- and high-pass filters to be well matched. Finally, the function plotted with dotted lines represents the expected excitation phase for single units with low BFs, based on the IHC results. This function parallels that for the IHC transducer plus the basolateral membrane. These results imply that single units should respond to basilar membrane velocity but responses should be ~180 deg out of phase at 200 versus 1200 Hz. Predictions are not made for higher-frequency inputs because of the several stages of low-pass filtering associated with synaptic processes (Weiss and Rose, 1988a, b; Kidd and Weiss, 1990).

The bottom panel in Fig. 7 represents the basal, high-frequency region of the cochlea. Thus, these hair-cell and single-unit responses are obtained well below BF. The representation demonstrates that IHCs are velocity sensitive, but only at very low frequencies below ~200 Hz. This is why the IHC transducer function plateaus at SV displacement near 300 Hz, a lower frequency than in the apex. The combined function, for the IHC transducer plus the basolateral membrane, plateaus at ST velocity but, again, at lower frequencies than in the apex. The negative phase of the CM is also included because this phase of the extracellular response can induce transmitter release at very low frequencies. This function, however, is positioned closer to ST velocity, rather than ST displacement, to reflect a squaring of the CM waveform. This is done because the CM is distorted at the high levels required to reach threshold for inputs well below BF (Ruggero *et al.*, 1986). The function for single units with high BFs (dotted lines) is drawn to reflect control of transmitter release by the IHC transducer and basolateral membrane above ~300 Hz and control by the extracellular CM below ~200 Hz. In other words, the excitation phase at ST velocity probably reflects both intracellular and extracellular influences. The CM is not thought to control transmitter release at higher frequencies because it does not exceed the IHC receptor potential in magnitude (Russell and Sellick, 1983). Although single units in the apex also respond to

basilar membrane velocity, their responses at 200 and 1200 Hz are expected be ~180 deg out of phase. Consequently, the phases of excitation for high- and low-BF units should be in phase at 1200 Hz, but out of phase at 200 Hz.

It is emphasized that a preference for SV velocity is not exhibited in single units with high BFs. This may relate to observations where the phase lead associated with ciliary mechanics is only expressed at very low frequencies in IHCs with high BFs. For example, data obtained from first-turn IHCs (Sellick and Russell, 1980; Russell and Sellick, 1983) indicate that hair cell depolarizations occur for basilar membrane displacements to SV above ~200 Hz. Anatomical evidence is consistent with this possibility because the tallest stereocilia at the base of the cochlea are found on inner, rather than outer, hair cells (Lim, 1980; Wright, 1984). This observation is worth pointing out because it is the height of the stereocilia, in combination with the configuration of the subtectorial space, that determines input to the IHC. In spite of this caveat, the transition region where OHC stereocilia become shorter than IHC stereocilia occurs at a place along the cochlear partition (Eldredge *et al.*, 1981) that is similar to the place where response phase changes in the single-unit recordings (Ruggero *et al.*, 1996). It is, therefore, possible that the difference in response phase, for low- versus high-BF nerve fibers, relates to the wider frequency range over which the velocity dependence of the IHC transducer contributes to apical IHC responses. In fact, Dallos and Santos-Sacchi (1983) state that the median frequency producing an IHC phase lead of 45 deg, relative to the OC response, is 340 Hz. This is well above that for basal-turn IHC responses that are, on average, in phase with the OC response above ~200 Hz (Sellick and Russell, 1980; Russell and Sellick, 1983).

In addition to a spatial variation in the degree of coupling between the IHC stereocilia and the tectorial membrane (Ruggero and Rich, 1987), it is conceivable that ion-channel density for IHCs varies longitudinally along the cochlear spiral, as demonstrated for OHCs (Housley and Ashmore, 1992). This could influence the frequency at which a criterion phase lag is expressed, with the result that voltage-dependent ion channels could contribute a larger phase lag in the base versus the apex of the cochlea for a given low-frequency input. In other words, a 90 deg phase lag might occur at lower frequencies in the base of the cochlea. This implies that single units with high BFs would respond to ST velocity at lower frequencies than in the apex, as shown in Fig. 7.

It is also proposed that IHCs in the basal half of the cochlea may be more nonlinear than their apical counterparts. Even though a criterion ac receptor potential is produced at the same sound-pressure level in first- and third-turn IHCs, a 20 dB higher level is required to produce the same criterion dc response at the apical recording location (Russell and Sellick, 1978; Cheatham and Dallos, 1999). In other words, the IHCs are equally sensitive, but they differ in the degree of asymmetry exhibited in their transducer functions. Consequently, harmonic components may influence response phase to a greater degree in the high-frequency region of the cochlea.

D. The phase of excitation versus the phase of suppression

The frequency dependence of response phase depicted in Fig. 7 should be considered when evaluating the temporal relationships between single-tone excitation and two-tone suppression for low-frequency suppressors below BF. In contrast to reports demonstrating variations in the timing of excitation for single-tone inputs, the phase of two-tone suppression is relatively constant. Data indicate that the time of suppression, within a single cycle of a low-frequency suppressor, occurs near basilar membrane displacement to ST when the suppressor is introduced at its lowest effective level. This preference has been demonstrated in IHC ac receptor potentials (Patuzzi and Sellick, 1984; Cheatham and Dallos, 1997), in single-unit discharge rates (Ingvarsson, 1981; Patuzzi *et al.*, 1984a; Temchin *et al.*, 1997), and in cochlear mechanics (Patuzzi *et al.*, 1984b; Rhode and Cooper, 1993; Cooper, 1996). The association of suppression with basilar membrane displacement to ST, and with the negative phase of the CM response, is shown at the top of Fig. 7. It is thought to reflect asymmetries in the outer hair cell transducer, such that basilar membrane displacements to ST effectively bias the transducer in the off position (Geisler *et al.*, 1990; Cheatham and Dallos, 1997), thereby reducing the gain of the cochlear amplifier.

Confusion develops when the phase of suppression is compared with the phase of excitation for the low-frequency suppressor alone. In fact, the various temporal relationships observed between excitation and suppression could relate to the frequency and level dependence of response phase indicated here and well documented at the single-unit level (Ruggero *et al.*, 1996). Although not very common (Cai and Geisler, 1996b), there are instances where the phases of both excitation and suppression coincide with basilar membrane displacement to ST (Sachs and Hubbard, 1981; Sellick *et al.*, 1982). In this case, the most parsimonious explanation is that excitation for the low-frequency suppressor alone is related to the extracellular CM, as in Fig. 6(B). More often, however, the phases of suppression and excitation differ, suggesting that variations in response phase for single tones may underlie these differences. Representations in Fig. 7 indicate that, depending on BF, various temporal relationships can exist between the time of excitation for the low-frequency suppressor alone and the time of suppression in the two-tone case.

IV. SUMMARY

Simply characterizing the IHC transducer can sometimes reveal very little about how signals are conveyed to the auditory nerve. In fact, in order to understand this transfer of information, one must take into account contributions from ion channels located in the cell's basolateral membrane, which serves to integrate intracellular and possibly extracellular voltages. Data indicate that apical IHCs depolarize near SV velocity, reflecting the velocity dependence of the IHC transducer at low frequencies. However, as stimulus frequency increases, the time of depolarization shifts to SV displacement, reflecting the possibility of a visco–elastic cou-

pling between the hair bundle and the tectorial membrane. Although a similar pattern has been documented for first-turn IHCs, the transition between SV velocity and SV displacement appears to occur at lower frequencies than the transition demonstrated for apical IHCs. This suggests that the velocity dependence of the IHC transducer would be expressed in basal-turn responses, but only for very low-frequency inputs. Consequently, above ~200 Hz, IHCs with high BFs probably respond to SV displacement. This, coupled with waveform distortion and the kinetics of ion-channel gating in the cell's basolateral membrane, places the time of maximum transmitter release near ST velocity. Because IHCs in the base appear to be more asymmetrical than their apical counterparts, harmonic components influence the timing of hair-cell depolarizations to a greater degree in the high-frequency region of the cochlea. For frequencies below ~200 Hz, the difference in response phase between apex and base may well result from extracellular voltages that potentially influence transmitter release in the high-frequency region of the cochlea.

(Received 4 February 1998; revised 31 August 1998; accepted 29 October 1998)

An analog very large-scale integrated (VLSI) implementation of a model of signal processing in the auditory brainstem is presented and evaluated. The implementation is based on a model of amplitude-modulation sensitivity in the central nucleus of the inferior colliculus (CNIC) previously described by Hewitt and Meddis [J. Acoust. Soc. Am. **95**, 2145–2159 (1994)]. A single chip is used to implement the three processing stages of the model; the inner-hair cell (IHC), cochlear nucleus sustained-chopper, and CNIC coincidence-detection stages. The chip incorporates two new circuits: an IHC circuit and a neuron circuit. The input to the chip is taken from a ''silicon cochlea'' consisting of a cascade of filters that simulate basilar membrane mechanical frequency selectivity. The chip which contains 142 neurons was evaluated using amplitude-modulated pure tones. Individual cells in the CNIC stage demonstrate bandpass rate-modulation responses using these stimuli. The frequency of modulation is represented spatially in an array of these cells as the location of the cell generating the highest rate of action potentials. The chip processes acoustic signals in real time and demonstrates the feasibility of using analog VLSI to build and test auditory models that use large numbers of component neurons. [S0001-4966(99)03102-1]

INTRODUCTION

The complexity of auditory signal processing in the auditory periphery and brainstem requires sophisticated modeling techniques. Computational modeling of individual stages has already been shown to be a successful approach to characterizing the processes involved. However, when it is necessary to characterize the response of the system as a whole, even high-speed computers may require very long run times. There are approximately 10 000 inner-hair cells (IHCs), 30 000 afferent auditory-nerve (AN) fibers and tens of thousands of neurons in the cochlear nucleus alone. Very large-scale integrated (VLSI) circuitry offers the possibility of evaluating such complex models in real time. Below, we present an initial attempt to exploit analog VLSI technology to simulate a complex system involving inner-hair cells, ventral cochlear nucleus (VCN) sustained-chopping stellate cells, and coincidence-detecting neurons in the central nucleus of the inferior colliculus (CNIC). Although none of the individual cells is modeled in great detail by the electronic circuits, the VLSI system is nevertheless capable of implementing the signal-processing principles exploited by the biological system.

The highly parallel architecture of the auditory periphery and auditory brainstem is well suited to analog VLSI technology because of the case of replicating individual circuits once the design details of a single unit have been decided. For example, all IHCs appear to operate according to the same principles; it is only the input that differs between cells. If a suitable circuit can be designed to simulate their operation, they can be readily replicated in large numbers. The IHC and neurons to be described below occupy approximately the same area on the chip with a density of approximately 4000 neurons (or IHCs) per square centimeter. When IHCs and neurons are combined on a single chip, the response of large assemblies of neurons to complex stimuli is more easily evaluated in real time.

A number of seminal studies using analog VLSI technology have already attempted to simulate individual stages of mammalian auditory-signal processing. Lyon and Mead (1988) produced an early simulation of cochlear mechanical filtering, this has been followed by a number of other studies (Fragnière *et al.*, 1997; Lazzaro and Mead, 1989a; Lyon, 1991; Liu *et al.*, 1991; Sarpeshkar *et al.*, 1996; Watts *et al.*, 1992; Watts, 1993). Lazzaro (1992) has attempted to simulate mechanical-to-electrical transduction analogous to that occurring at the level of the IHC. Others (for example, Mahowald and Douglas, 1991; Mead, 1989; Rasche *et al.*, 1997; Sarpeshkar *et al.*, 1992) have developed models of neurons but only Lazzaro (Lazzaro and Mead, 1989b, 1989c; Lazzaro, 1991) appears to have used VLSI neurons to simulate aspects of auditory processing. In the study described below,

[a)]Present address: Auditory Neuroscience Lab., Dept. of Physiology, University of Sydney, NSW 2006, Australia.

we build upon these pioneering efforts to show how three different stages of auditory processing can be combined on a single chip to simulate the response of arrays of CNIC units to acoustic stimulation.

The circuit is based on a previous computer model of amplitude-modulation sensitivity of single neurons in the inferior colliculus (Hewitt and Meddis, 1994). The original model was able to simulate the rate response of a single CNIC unit as a function of the rate of amplitude modulation of sinusoidal signals. As such, it represented a testable model of the anatomical and physiological basis of the behavior of these cells as observed in animal preparations (Rees and Palmer, 1989; Langner and Schreiner, 1988). If, however, the model could be extended to represent the simultaneous activity of arrays of such cells, each with a different best-modulation frequency (BMF), its behavior might have relevance to psychoacoustic theories concerning the perception of pitch. Langner *et al.* (1998) have presented evidence that an orderly orthogonal arrangement of cells in the CNIC can be observed with respect to their best frequency (BF) for pure tones and their BMF for modulated tones. While such arrays of cells could be simulated using conventional digital computers, the required processing time can be prohibitive. This was seen as a suitable opportunity to explore the power of analog VLSI circuitry.

Section I summarizes the model as given by Hewitt and Meddis (1994). Section II contains the details of the hardware implementation of the model components. Section III evaluates the model in terms of its ability to represent the behavior of a single CNIC unit. Section IV shows how amplitude modulation may be represented across an array of hardware CNIC cells.

I. MODEL

As far as possible, the hardware was designed to simulate exactly the processing in the four-stage model described by Hewitt and Meddis (1994). This is represented in Fig. 1. Some compromises were necessary when designing the VLSI chip. These will be detailed when describing the hardware implementation in Sec. II. The description immediately below refers to the original software model that inspired the project.

Stage 1 is the mechanical filtering of the cochlea.

Stage 2 is a model of the functioning of an inner-hair cell in response to the mechanical stimulation of the basilar membrane. The model is based directly on that published earlier by Meddis (1986, 1988). The output of the cell is characterized as the probability of occurrence of an action potential in an auditory-nerve fiber synapsing with the cell. An important characteristic of the hair-cell model is that the response adapts over time to a constant stimulus. The output from the cell is half-wave rectified and has a low-pass frequency characteristic with a corner frequency in the region of 1 kHz.

Stage 3 simulates the activity of stellate cells in the VCN that show a sustained-chopping response to pure tones and are thought to have excitatory projections to the CNIC. Each cell receives inputs from a large number of hair cells with similar receptive fields. In the original version of the

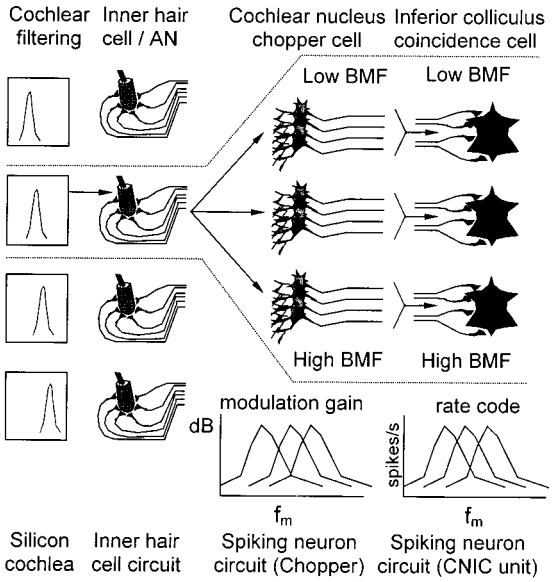

FIG. 1. Proposed neural circuit for amplitude-modulation sensitivity in the inferior colliculus. Abbreviations: BMF-best-modulation frequency. Adapted from Hewitt and Meddis (1994).

model, 60 inputs were used, but later studies (Meddis and O'Mard, 1997) have suggested that 30 might be a more appropriate number. The inputs to a VCN cell are in the form of spikes delivered by auditory-nerve (AN) fibers. They are thought to contact the receiving cell on its dendrites, where substantial low-pass filtering occurs. As a consequence, a continuous, high-frequency tone stimulus results in a steady input current that maintains a steady pressure on the membrane potential and causes it to rise regularly above threshold. The cell responds with a stream of action potentials at a rate determined mainly by its own membrane characteristics (Arle and Kim, 1990; Banks and Sachs, 1991; Hewitt *et al.*, 1992). This rate is its ''intrinsic frequency'' and varies from cell to cell. Detailed studies of models of this process show that these processes can be used to explain the tendency of these cells to synchronize their action potentials to the peaks of amplitude-modulated sinusoids when, and only when, the rate of modulation is close to the intrinsic frequency of the cell (Hewitt *et al.*, 1992).

Stage 4 simulates the observation that some cells in the CNIC respond with a firing-rate increase when the rate of amplitude modulation of a stimulus is close to a narrow range of frequencies characteristic of the particular cell. The model makes the assumption that certain cells in the CNIC receive input from a number of sustained-chopping cells in the VCN and respond only when a number of these inputs are simultaneously active. The inputs are assumed to come from VCN cells with similar intrinsic frequencies. Normally, the spike activity in these inputs will be random with respect to one another, and the CNIC cell will notice few coincidences. However, when the acoustic stimulus is amplitude modulated at a rate sympathetic to the VCN sustained-chopping cells, their activity will be synchronized as each cell spikes at the crest of the amplitude-modulation wave. As a result, the CNIC cell will receive many coincidental inputs and will respond with an increased rate of firing. This model has been shown to simulate rate-modulation functions ob-

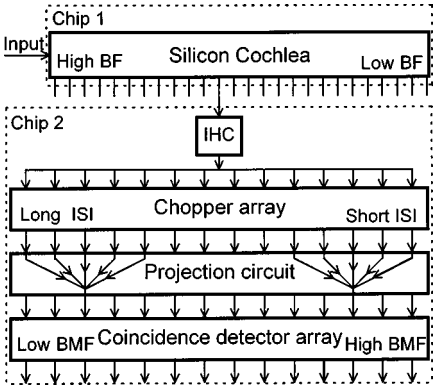

FIG. 2. Implementation of the amplitude-modulation sensitivity model.

served in cells in the inferior colliculus (Rees and Palmer, 1989) It is important to note that the rate–BMF of the CNIC cell depends upon the intrinsic frequencies of the VCN cells that are providing its input. It depends only weakly upon the membrane characteristics of the CNIC cell itself.

II. HARDWARE IMPLEMENTATION

The software implementation is based on carefully modeled individual cells. This would be very hard to achieve with the hardware implementation, since hardware implementations do not have the flexibility or the precision of software implementations. A detailed hardware model of an individual neuron can only be implemented with large and complex circuits (see, for instance, Rasche *et al.*, 1997), which would prohibit the implementation of a large number of these neurons on a single chip. The main advantage of a hardware implementation, however, is that it can simulate a model in real time, even when the number of elements and stages in the model becomes large. We have therefore kept the individual elements small and simple, under the hypothesis that the signal processing in the brain that we try to model depends more on the availability of a large number of neurons than on the exact details of operation of each individual neuron.

The hardware model (Fig. 2) aims to implement the signal processing performed at the different stages of the software model presented in the previous section, not the details of each element. In fact, we only use naming such as IHC, cochlear nucleus (CN) chopper and CNIC to allow the reader to compare the stages in the hardware with those in the original model. They do not imply that the hardware elements are detailed models of their biological counterparts.

The VLSI implementation uses two chips (Fig. 2). The first chip is an electronic simulation of the mechanical filtering of the cochlea and consists of series of bandpass filters corresponding to stage 1 in the model description above. This silicon cochlea has already been described in detail by van Schaik *et al.* (1995). This chip has a number of outputs, each simulating the response of the basilar membrane at a different point along its length. Only one output is fed to the second chip. As a consequence, each chip represents a single frequency-selective ''channel'' and additional chips will be required to represent the full range of channels. For all of the evaluations described below, the center frequency (CF) of the cochlear filter is set to 5 kHz.

The second chip contains the hardware implementation of stages 2–4 of the model: one inner-hair cell (IHC) circuit that models the average output of several IHCs from a small section along the basilar membrane and two arrays of the same spiking neuron circuit, simulating the signal processing of neurons in the VCN and the CNIC, respectively. The same spiking neuron circuit is used to simulate a sustained chopper (VCN) or a coincidence detector neuron (CNIC). Technical details concerning component values are given in the Appendix (see also van Schaik, 1997).

A. Inner-hair cell circuit

The IHC stage is implemented using three main circuit components (Fig. 3). The first component simulates the asymmetrical, saturating response of the IHC receptor potential to mechanical deflection of the stereocilia. It consists of two stages: a compressive function and a circuit to add a bias to the membrane potential. The bias also guarantees spontaneous activity in the absence of any input. The second component implements the low-pass filtering of the membrane potential. The third component introduces adaptation to constant stimulation. The output of the circuit is a continuous current, which can be interpreted as the instantaneous spike probability on a biological auditory nerve. Alternatively, we can interpret this output as the equivalent of the excitatory postsynaptic current generated in a chopper cell by a number of AN fibers from a small section along the basilar membrane that contact this chopper cell. The hardware implementation does not attempt to replicate the detailed mechanisms of the IHC model used in the original paper, but does simu-

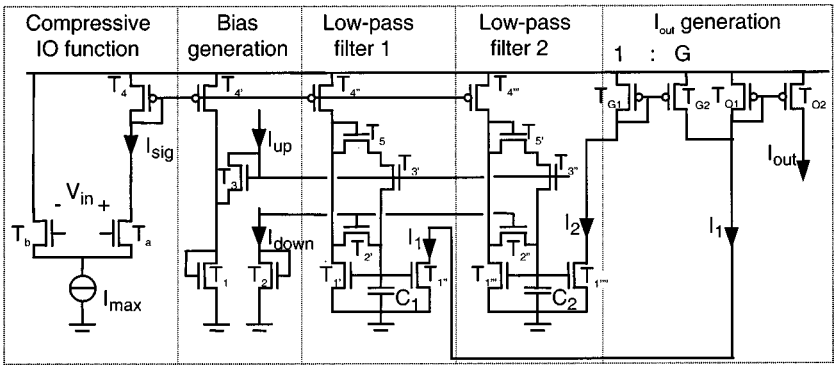

FIG. 3. Circuit diagram for the IHC stage.

late those features of the IHC response to acoustic stimulation that are important for the operation of the AM sensitivity model.

1. Static inner-hair cell voltage response

Hudspeth and Corey (1977) have shown that the relation between bundle deflection and the percentage of open-ion channels has a sigmoidal form with a certain offset, so that 20% of the channels are open at equilibrium. This can be easily modeled using two transistors T_a and T_b) as a differential pair (see Fig. 3) for which the current I_{sig} through transistor T_a is a sigmoidal function between 0 and $I_{\max}$ of the input voltage V_{in}, as we shall see in the measurement of Fig. 4(a). By using a differential pair with one transistor (T_b) four times as large as the other (T_a), only 20% of the bias current will flow through the smaller transistor (T_a) when V_{in} equals zero.

2. Dynamic IHC voltage response

The phase locking of the inner-hair cell can be modeled using a low-pass filter with a cutoff frequency of about 1 kHz (Rose *et al.*, 1967; Palmer and Russell, 1986). This implies a time constant equal to $\tau = 1/2\pi f = 0.16$ ms to model this effect. Obtaining such large time constants is one of the main problems in modeling comparatively slow brain elements with analog VLSI circuits. If the precision of the value of the time constant is not an important issue, then large time constants can be realized using the current mirror shown in the low-pass filter blocks in Fig. 3. This current mirror creates a nonlinear low-pass filter for which I_{up} controls the maximum rise speed and I_{down} sets the maximum fall speed of the voltage on the capacitor C_1. Using this circuit, the time constant will vary as a function of signal level for both the low-pass filter and the adaptation circuits. The time constant can be increased by as much as a factor of 3 for a 20-dB increase in signal level. This is a problem, and to avoid any difficulties in evaluating the later stages, all tests were made at the same signal levels.

3. IHC adaptation

A form of adaptation similar to the adaptation seen on the auditory nerve can be obtained in the IHC circuit by taking a weighted difference between I_1 and a second low-pass-filtered version of I_{sig}. When we use a larger capacitor in the second filter, its output I_2 will react more slowly to an onset of I_{sig} than I_1 does. In the circuit, the value $C_2 = 3C_1$ is used. The actual output current of the IHC circuit is given by $I_{\text{out}} = I_1 - GI_2 + I_{\text{spont}}$ and is created with two additional current mirrors, as shown in Fig. 3. The value G is the gain of this additional current mirror and controls the ratio between the peak response and the sustained response of the circuit. G should be smaller than 1 in order to keep a sustained response to the input signal. I_{spont} can be used to adapt the ''spontaneous rate of firing'' of the inner-hair-cell model independently of the signal levels of I_1 and I_2.

4. Test results

Figure 4(a) shows the measurements of the current I_1, which is the equivalent of the receptor potential in the real inner-hair cell, as a function of the input voltage. Comparison with the intracellular-voltage response to hair displacement as measured by Hudspeth and Corey (1977) shows good agreement. Although the differential pair has been designed to have an output current equal to 20% of the maximum current at zero input voltage, the measurement shows an output current equal to 30% of the maximum current in this case. This is probably due to the mismatch of the differential pair transistors.

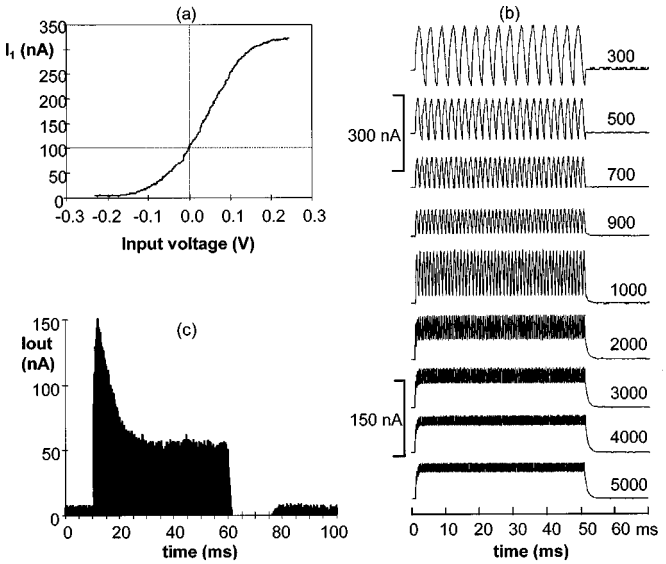

FIG. 4. IHC circuit output. (a) Static relation between I_1 and V_{in}, (b) variation of I_1 for pure-tone inputs at different frequencies, (c) Output current of the IHC circuit after weighted subtraction of I_2 from I_1.

Figure 4(b) shows the response of the current I_1 to pure-tone stimulation at frequencies between 300 Hz and 5 kHz. These results are comparable to those of Palmer and Russell (1986).

The final output current of the circuit in is given by $I_{\text{out}} = I_1 - GI_2 + I_{\text{spont}}$. Using I_{spont}, G, V_{up}, and V_{down} creates an output signal [Fig. 4(c)] similar to the post stimulus time histogram (PSTH) of a single auditory nerve when stimulated with a 5-kHz pure tone. The time constant of adaptation is around 10 ms.

5. Other IHC circuits

The only other analog VLSI implementation of an inner-hair cell known to the authors was implemented by Lazzaro (1992). The circuit is of a size and complexity comparable to the circuit presented here, but does not model the low-pass-filtering behavior of the IHC that causes a reduction in phase locking at frequencies above 1 kHz. This reduction of phase locking is essential for the operation of the AM sensitivity model.

B. Basic neuron circuit

The neuron implementation [Fig. 5(a)] has been kept as simple as possible in order to maximize the number of neurons that could be included on a single chip of size 5 mm^2. The circuit models the main features of a neuron needed to obtain chopping or coincidence-detecting behavior. It con-

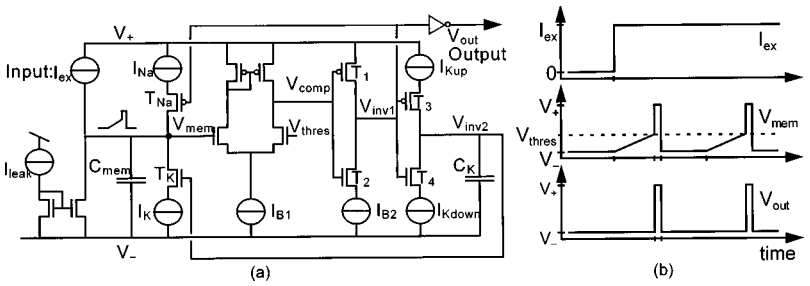

FIG. 5. (a) Circuit details of the VLSI neuron. (b) Example of the response of the membrane potential (V_{mem}) and the output signal (V_{out}) to a dc input current (I_{cx}).

sists of three main components corresponding to auditory-nerve input, membrane potential, and spike generation, respectively.

1. Neuron membrane potential

The membrane of a biological neuron is modeled by a membrane capacitance, C_{mem}; the membrane-leakage current is controlled by the current source, I_{leak}. In the absence of any input ($I_{\mathrm{ex}}=0$), the membrane voltage will be drawn to its resting potential (controlled by V_-) by this leakage current. Excitatory inputs simply add charge to the membrane capacitance. If an excitatory current larger than the leakage current is injected, the membrane potential will increase from its resting potential. This membrane potential, V_{mem}, is compared with a controllable threshold voltage, V_{thres}, using a basic transconductance amplifier driving a high-impedance load. If V_{mem} exceeds V_{thres}, an action potential will be generated [Fig. 5(b)].

2. Neuron-spike generation

The generation of the action potential in the neuron circuit is patterned after the biological neuron, in which an increased sodium conductance creates the upswing of the spike and in which the delayed blocking of the sodium channels plus delayed increase of the potassium conductance creates the downswing. The circuit model is as follows: If V_{mem} rises above V_{thres}, the output voltage of the comparator V_{comp} will rise to the positive power supply. The output of the following inverter V_{inv1} will thus go low, thereby making the *p*-channel metal oxide (PMOS) transistor $\mathrm{T_{Na}}$ conduct and thus allowing the current I_{Na} to pull up the membrane potential. At the same time, however, a second inverter will allow the capacitance C_K to be charged at a rate controlled by the current I_{Kup}. As soon as the voltage V_{inv2} on C_K is high enough to allow conduction of the *n*-channel metal oxide (NMOS) transistor T_K whose gate it controls, the current I_K will be able to discharge the membrane capacitance.

Two different time constants govern the spike-generation process. The current I_{Kup} which charges C_K controls the spike width, since the delay between the onset of conduction of $\mathrm{T_{Na}}$ and the onset of conduction of T_K is inversely proportional to I_{Kup}. If V_{mem} now drops below V_{thres} the output of the first inverter V_{inv1} will become high, blocking conduction of $\mathrm{T_{Na}}$ cutting off the current I_{Na}.

Furthermore, the second inverter will then allow C_K to be discharged by the current I_{Kdown}. If I_{Kdown} is small, the voltage on C_K will decrease only slowly, and as long as this voltage stays high enough to keep T_K conductive and allow I_K to discharge the membrane, it will be impossible to stimulate the neuron if I_{ex} is smaller than I_K. Therefore I_{Kdown} can be said to control the ''refractory period'' of the neuron.

Finally, I_{B1} and I_{B2} are two bias currents needed to limit the power consumption of the circuit; they do not influence the spiking behavior of the neuron in any major way.

3. Other neuron circuits

Several analog VLSI neurons have been published (for example, Mahowald and Douglas, 1991; Lazzaro and Mead, 1989a; Mead, 1989; Rasche *et al.*, 1997; Sarpeshkar *et al.*, 1992), and they can be divided into two categories. The first category, which contains the neuron circuit presented here, was started by Mead (1989). It uses a small circuit as a neuron model that tries to capture just the essentials needed for a given processing task. The goal in this case it to put a large number of these neurons on a chip to study their behavior as a group. Most of the neurons published in this group, however, are too simple for the AM sensitivity model, because they do not implement a refractory period, which is needed to control the intrinsic chopping rate of the choppers, nor do they include membrane leakage, which is needed to set the temporal selectivity of the coincidence-detector neuron. One neuron circuit, published by Sarpeshkar *et al.* (1992), is very similar to the neuron circuit presented here and could have been used for the AM sensitivity model. The circuit presented here is just slightly larger, but allows parameters such as the spiking threshold, spike width, and refractory-period duration to be controlled independently, which is not the case in Sarpeshkar's neuron. The second category of neuron circuits, started by Mahowald and Douglas (1991), tries to model a single neuron in great detail by implementing the hardware equivalent of Hodgkin–Huxley models. These neuron circuits, however, are not useful for the implementation of the AM sensitivity model because they are simply too big. For example, a recent publication of such a neuron by Rasche *et al.* (1997) describes a chip of the same size as our complete AM sensitivity model (4 mm^2), but the chip contains only a single neuron that emulates a cortical pyramidal cell.

C. VCN sustained-chopper model

The input to the neuron comes directly from the IHC and is a current representing the probability of an action potential in the afferent auditory-nerve fibers that contact a real VCN chopper neuron. Ideally, this should be in the form of discrete, stochastic spike events. Unfortunately, the generation of random events proved difficult using this technol-

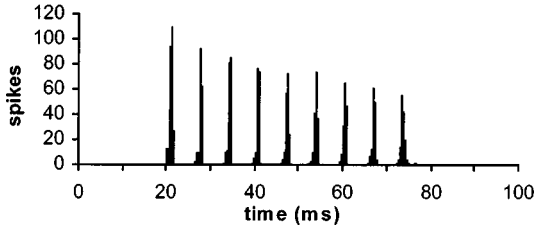

FIG. 6. Measured sustained-chopping response of a neuron on the chip.

ogy. The use of probabilities is not problematic for this particular application because the input to real cells comes from a large number of fibers and is strongly low-pass filtered at the cell dendrite. The net effect is roughly the same, but the electronic neuron remains more regular, i.e., sustains chopping longer, than its biological counterpart. The difficulty in generating random spikes will need to be overcome in the future, however, for other applications such as bushy cells. The neuron circuit described above (in conjunction with the IHC circuit) produces a sustained-chopping response when stimulated with a 5-kHz pure tone (Fig. 6). The rate at which the cell chops is controlled by the current I_{Kdown}, which is varied systematically across the array. The minimum- and maximum-chopping rates used for this project were 90 and 180 spikes per s, respectively.

D. VCN–CNIC projections

Each CNIC unit receives input from a range of VCN neurons at the previous level. The width of this range can be varied under operator control. The strongest input comes from the corresponding neuron in the VCN array. Inputs to the left and right are attenuated by a factor depending upon the distance from the CNIC unit to the VCN unit. The circuit that creates this connectivity, shown in Fig. 7, uses only two transistors, one input wire, and one output wire per CNIC neuron.

The operation of this circuit may be understood as follows: When a spike arrives at synapse 3, for instance, the current I_{syn3} will flow through the switch for the duration of the spike. Part of this current will flow directly through the transistor T_{G3}; the output current I_{ex3} will be equal to this

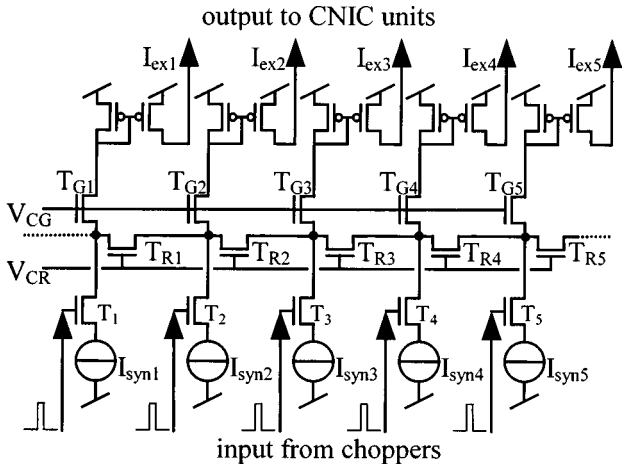

FIG. 7. The lateral-diffusion network circuit.

current. The rest of the current flows into the network to either side of the node which connects the different synapses laterally. If we assume that the network extends infinitely to the left and to the right, equal amounts of current will flow left and right. At the neighboring nodes these currents will split again, partially continuing to flow through the lateral transistors and the rest creating the output currents I_{ex2} and I_{ex1}. In this way, a current injected at a certain node in the network creates a symmetrical distribution of output currents; the largest output current occurs at the same node as the injection, and the amplitudes of the output currents decrease as the node gets farther away. It can be shown that when the transistors are operated in the weak inversion region, the distribution of currents is an exponential function given by:

$$\frac{I_{\mathrm{exj}}}{I_{\mathrm{syni}}} = \alpha e^{-d_{ij}/L}, \quad \alpha = \frac{1-e^{-1/L}}{1+e^{-1/L}}, \quad L = e^{(V_{CG}-V_{CR})/2nU_T}, \tag{1}$$

where d_{ij} is the distance in number of lateral transistors between output j and input i, n is the slope factor of the transistors (about 1.5), and U_T is the thermal voltage, which is 25 mV at room temperature. V_{CG} and V_{CR} are the bias voltages that are used to set L. In the experiments of this paper, a diffusion length L of about 3 has been used. Furthermore, since the circuit is completely linear in the current domain, we can apply the superposition principle, so that the current at a given output node is simply the sum of the individual effects of the input currents at the input nodes.

E. IC coincidence-detecting neuron model

The neuron circuit of Fig. 5 can also be used to create a coincidence-detecting neuron. In this case, the membrane time constant should be short, so that the neuron does not integrate its input over an extended period of time. If the input to the neuron consists of excitatory current spikes with an amplitude that ensures that no single spike can make the membrane potential reach the threshold voltage, multiple spikes will have to arrive simultaneously, or in very quick succession, in order to create output spikes. A way to reduce the membrane time constant is to reduce the membrane capacitance C_{mem}, which also saves considerable silicon area, since the capacitors are the largest structures on the chip. The second capacitor C_K can also be reduced in size to save space since the refractory period of the coincidence-detector cell does not play as important a role as it does for the chopper neuron.

III. SINGLE-UNIT SIMULATION

The output of the three types of units in the VLSI model has been characterized (Fig. 8) as a function of input-signal intensity, using a 5-kHz pure tone filtered by the silicon cochlea and taken at the output of the cochlear filter with a 5-kHz best frequency. The input intensity that just evokes spikes from the CN unit has been chosen as the 0-dB point. The IHC circuit does not actually generate spikes, but its current output is representative of a spike probability; in order to present it in the same graph, the current has been

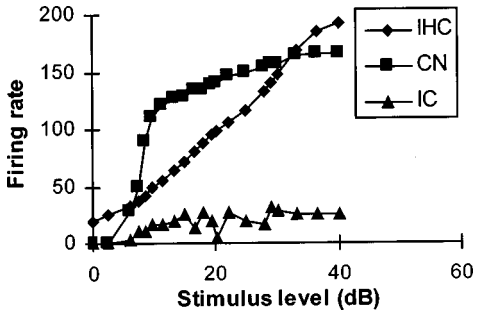

FIG. 8. Rate-intensity functions of the three types of units in the VLSI model for a 5-kHz pure-tone input. Stimulus intensity is given in dB relative to the spiking threshold of the CN unit.

converted into a spike rate, using an arbitrary scaling factor. Saturation of the IHC output, which is shown in Fig. 3(a), cannot be measured in the complete system, because the silicon cochlea cannot deal physically with sounds of such large amplitude. We do see in Fig. 8, however, that both the CN unit and the inferior colliculus (IC) unit saturate before the IHC unit does.

The spike activity of a chopper circuit will synchronize to the envelope of an amplitude-modulated, high-frequency tone. This will only occur, however, when the rate of AM is similar to the intrinsic rate of firing of the cell as controlled by the current I_{Kdown}. While synchronization is best at a particular frequency, it will still occur to a narrow range of frequencies above and below its best-modulation frequency. For any given rate of AM, some choppers will produce a stream of spikes synchronized with the amplitude modulation. As a result, the spikes produced by this group will be synchronized with each other and capable of driving a coincidence detector.

Synchronization of similar choppers by amplitude modulation at the appropriate modulation frequency can be seen in the oscilloscope traces of Fig. 9. When the input signal is either above or below BMF, the choppers do not synchronize to the input signal, and they therefore do not synchronize to each other either.

Activity in a coincidence-detector (CD) cell is generated by synchronized inputs from the chopper neurons. Pure-tone stimuli do not produce correlated activity across neighboring chopping cells, and they do not produce a rate rise in these CD units. Neighboring choppers with similar BMFs are connected to a single CD coincidence detector through the lateral-diffusion network. This network ensures that the CD unit is most strongly stimulated by a single chopper and that the neighbors of this chopper on either side stimulate the CD unit with a strength that falls off with distance. When this network is used with a diffusion length of about 3, then only three choppers on either side of the central chopper will have a noticeable effect on the CD unit. The CD input current will thus be maximal when these seven choppers spike simultaneously. The threshold of the CD unit can be set to require seven simultaneous input spikes using the I_{syni} current source (Fig. 7). When this is the case, the CD unit will only generate a spike if the inputs are perfectly correlated, i.e., when an appropriate modulation frequency is present. However, this setting would allow very little variation in the intrinsic chopping rate of the chopper units on the chip. In order to relax the constraints a little, the threshold has been adapted so that three neighboring chopper units spiking simultaneously are sufficient for reaching the threshold of firing of the CD cell. Furthermore, the oscilloscope trace in Fig. 9 shows very little noise on the IHC output. With such a deterministic IHC output, the synchronization will be far stronger than in biology at the BMF, and also disappear more quickly for frequencies above or below BMF. We have also observed very strong synchronization of the choppers to every second or third cycle of AM for modulation frequencies close to two or three times the BMF of the unit when this stimulus is used. In order to obtain a more biological behavior of both the chopper units and the CD units, we have explicitly added noise to the IHC output current. We have increased the noise level and measured the synchronization of the choppers to the signal [Fig. 10(a)], until the degree of synchrony to the stimulus envelope of the evoked activity of a chopper unit at different modulation frequencies roughly matches that of a biological chopper and of the computer model as presented by Meddis and O'Mard (1997). The sensitivity of the CD unit using these settings to amplitude modulation is shown in Fig. 10(b) for a single unit on the chip. Unfortunately, no data was available for a real IC neuron with a best-modulation frequency in the 130-Hz range. We have therefore plotted the data for a 52-Hz BMF unit from the Hewitt and Meddis' (1994) paper in the same figure (original data from Rees and Palmer, 1989). It can be seen that the VLSI CD unit has a more selective modulation-transfer function (MTF) than the IC neuron, but is of the same order of magnitude and shape.

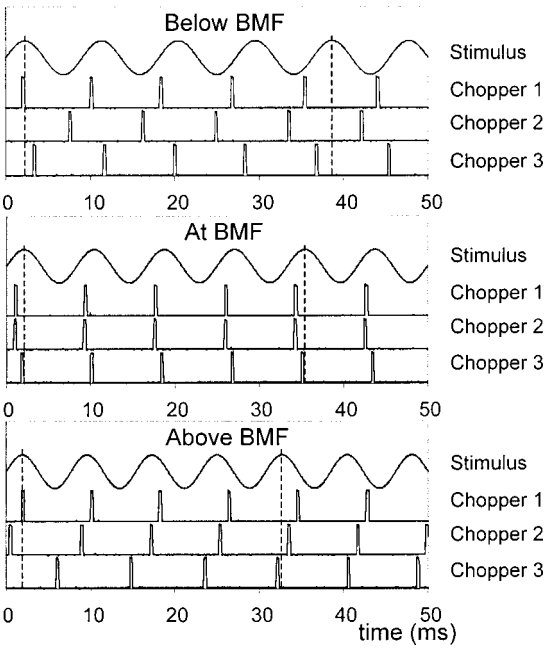

FIG. 9. Oscilloscope traces of the input signal to the IHC circuit and the output traces of three similar choppers on the chip; (a) below BMF, (b) at BMF, and (c) above BMF.

The degree of synchrony for the choppers has been measured from their period histograms using the vector-strength metric (Goldberg and Brown, 1969). Vector strength (r) is calculated as:

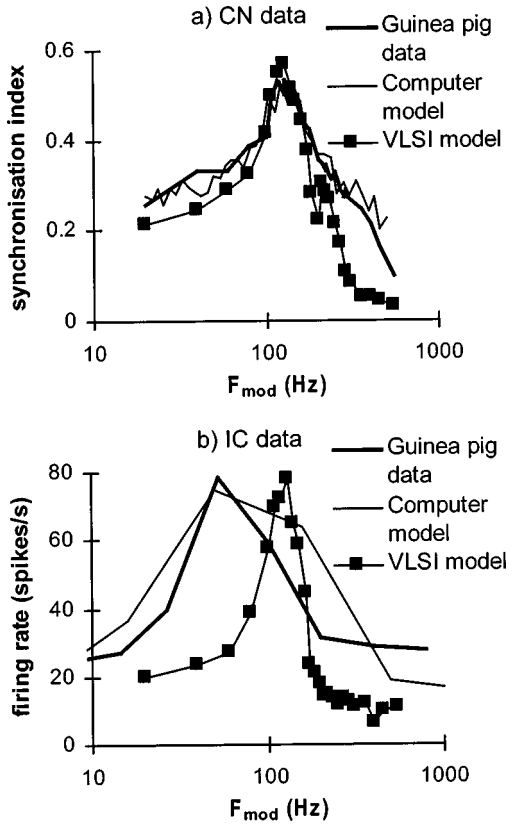

FIG. 10. (a) Vector strengths for the CN unit measured on guinea pig and Meddis' original computer model (Meddis and O'Mard, 1997) and the VLSI implementation. (b) AM sensitivity of an IC coincidence-detecting unit.

$$r = \frac{\sqrt{[\Sigma_0^{K-1} R_k \cos 2\pi(k/K)]^2 + [\Sigma_0^{K-1} R_k \sin 2\pi(k/K)]^2}}{\Sigma_0^{K-1} R_K}, \tag{2}$$

where K is the number of bins in the period histogram, and R_k is the magnitude of the kth bin.

IV. MULTIUNIT REPRESENTATION OF AM SENSITIVITY

While physiological studies are typically restricted to the measurement of the response of a single cell, the modeler can simulate the simultaneous response of large numbers of units. An overview of the operation of the chip as a whole is shown in Fig. 11, which illustrates measurements of the choppers and the coincidence detectors, respectively. In order to show the principle of operation clearly, a non-noisy output of the IHC circuit has been used for these measurements. Figure 11(a) shows the chopping rate of all choppers in the array when stimulated with a 5-kHz pure tone. The chopping rate increases along the array for a given stimulus intensity, due to the decreasing refractory period of the choppers in the array. Because of unavoidable component mismatch, the chopping rate, or intrinsic frequency of the cell, is a noisy function of the position in the array.

Figure 11(b) shows the spiking rate of the choppers when stimulated with a 5-kHz signal which is amplitude modulated at 120 Hz at 50% modulation depth. Most choppers are unaffected by the introduction of modulation, but those units whose intrinsic frequencies are close to 120 Hz

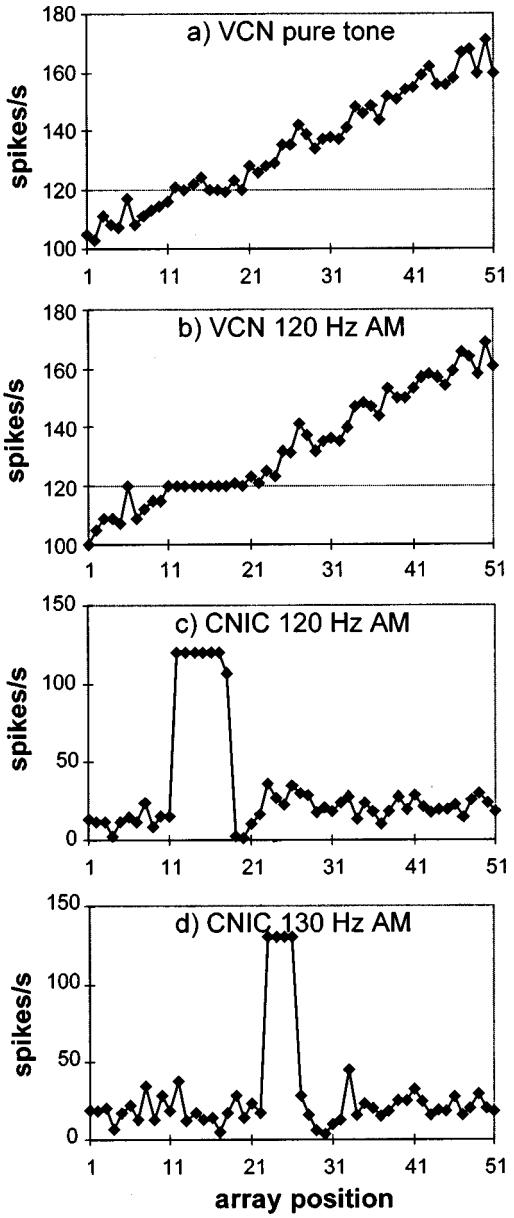

FIG. 11. (a) Average spiking rate of the choppers in the array in response to a pure-tone stimulus. (b) Average chopping rate in response to the pure-tone amplitude modulated at 120 Hz and 50% depth. (c) AM sensitivity of the coincidence-detecting neurons in response to the 120-Hz AM stimulus. (d) Response of the coincidence detectors to a 130-Hz AM stimulus. Note that only the central 51 of the 71 neurons in each array are shown.

are recruited to fire at the same rate as the modulation. It is also the case that these choppers fire at the same phase each modulation period, and are therefore phase locked to the modulation signal. The response of the CD neurons to the input from the choppers is summarized in Fig. 11(c). A small range of CD cells shows a high rate of firing. These are the cells that receive input from the choppers that are synchronized to the 120-Hz amplitude-modulated input signal. Figure 11(d) shows the response for a signal modulated at 130 Hz. The position of the responding CD unit moves to the right of the array. There are fewer CD neurons responding to the 130-Hz modulation than to the 120-Hz modulation, i.e., the peak in Fig. 11(d) is narrower than the peak in Fig. 11(c). This is caused by the random variations of component values

accidentally giving rise to more choppers with an intrinsic chopping rate closer to 120 than to 130 Hz. This fact may be checked in Fig. 11(a).

V. DISCUSSION

The primary goal of this project was to explore the feasibility of using VLSI technology to overcome the speed restrictions inherent in conventional computational modeling of signal processing in the auditory periphery and brainstem. The success of the project suggests that future modeling efforts should definitely consider using this approach. The pressure to use real-time, highly parallel architectures will increase as modelers reach beyond the IC to the thalamus and, eventually, the cortex. VLSI technology appears to have the capacity to meet the additional signal-processing needs. This is especially true for analog VLSI, continuous-time implementations, which operate per definition in real time.

The demonstration has many shortcomings. The project used only a very small chip incorporating one hair cell and 142 neurons. The difficulty experienced in obtaining physiologically accurate cochlear bandpass filters on the input chip restricted the stimuli to pure tones and AM tones that were not affected by this limitation. The IHC circuit has time constants that were dependent (unrealistically) on signal level. We have not been able to solve the problem of how to generate stochastic streams of spikes in the hardware implementation of inputs to the VCN chopper units. The hardware neurons were relatively primitive and only captured the simplest properties necessary to characterize the relevant characteristics of sustained chopping units. These problems will need to be solved before the technology can be used as a general-purpose modeling tool. Nevertheless, the present circuit has demonstrated the feasibility of an alternative approach to modeling complex signal processing in the brainstem.

In fact, the restraints imposed by the new technology did result in some unexpected new perspectives. First, the model works well without a stochastic input to the chopper cells, even though this was assumed to be essential to the success of the original computational model. The low-pass filtering of the dendritic inputs to real VCN choppers is likely, in any case, to attenuate much of the random fine-structure of the AN input. In the hardware model, the natural variation in intrinsic frequency of neighboring choppers is responsible for the decorrelation of spike activity that distinguishes steady-tone stimuli from amplitude-modulated tones. This may also be the case in the auditory nervous system. Second, in the original model, the chopper cells feeding the CNIC coincidence detectors were established as exclusive groups of choppers with identical intrinsic frequencies within a group. This was shown to be unnecessary by the VLSI model, which tolerated limited variation in intrinsic frequency and was able to use the output from one VCN chopper to feed a number of CD cells. This was a useful economy on our small VLSI chip and is a potential economy for the nervous system itself.

In the model, the best rate-modulation frequency of a CD unit is determined by the membrane characteristics of the chopping units that supply its input. The intrinsic chopping rate of the CD cell is not relevant. It is interesting, in this regard, that Rees *et al.* (1997) have recently found that CNIC cells with a highly regular (chopping) response to pure tones are not the cells that have the best response to amplitude modulation. The model described here would predict that a pronounced intrinsic regularity would impair the ability of the CNIC to respond to the intrinsic rhythms of the VCN chopping units, and is therefore consistent with the physiology.

The chip described above contained only 142 neurons. A 1-cm^2 chip could hold 4000 neurons. It is not known how many sustained-chopper cells there are in the VCN, but estimates of the number of multipolar cells (of which only some are sustained choppers) suggest something in the region of 28 000 in the cat (Liberman, 1990). If half of these are sustained choppers and half of the units on the chip are reserved for CNIC units, about eight identical chips would be required to represent a complete model of this AM sensitivity model using 1-cm^2 chips. If, say, 30 chips were used to represent a useful number of channels, each covering a small range of frequencies, there would be space to include other aspects of VCN functioning such as the response of bushy and octopus cells, known to be present in the human cochlear nucleus (Adams, 1996). Each chip would be identical except for the input, which would derive from a different filter tap in the silicon cochlea.

VI. CONCLUSIONS

An analog VLSI device has successfully implemented a model of the complex interaction of a large assembly of neurons in the auditory brainstem thought to be responsible for processing amplitude-modulated acoustic stimuli. The device prepares the way for large-scale implementations representing a similar number of neurons to those found in the mammalian brainstem.

APPENDIX

A. Implementation: Technical details

The chip described in this paper has been integrated in ES2's 1.0-μm CMOS technology ECPD 10.

The channel width-over-length ratios (W/L) of the transistors in the IHC circuit and the neuron circuit are given in Table AI and Table AII, respectively. For all measurements a 5-V power supply has been used.

The bias currents of the IHC circuit were determined as follows. $I_{\max}$ directly sets the maximum value of I_1 and has been set to 330 nA, as may be seen in Fig. 4(a). The adaptation gain G was about 2/3, so that the sustained output of the IHC circuit was about 1/3 of the maximum output at the onset of the stimulus, as may be seen in Fig. 4(c). Finally, I_{up}

C_2	15

and I_{down} have been adapted to obtain the output of I_1 for different input frequencies shown in Fig. 4(b) and are both on the order of 0.5 nA.

The design of the neuron has been kept very simple: all transistors that function as switches are 5 by 2 microns and all others are 5 by 5 microns (Table AII). The capacitors C_{mem} and C_K are 10 pF for the chopper implementation and 1 pF for the CD neuron implementation, respectively.

Different bias currents and voltages influence the behavior of the neuron. Some of the variables, however, have little influence, or influence only factors that can be easily fixed, such as the spike width. In order to generate a fixed-width, fixed-height spike, I_{Na} should be much larger than the leakage current I_{leak} or than the input current I_{ex}. In order to be able to bring the membrane potential back down at the end of the spike, I_K should in turn be larger than I_{Na}. The exact values of I_{Na} and I_K, however, are not critical. Both I_K and I_{Na} are currents in the 1-μA range, with I_K about twice as large as I_{Na}. The width of the spike depends almost exclusively on I_{Kup}, which has been adapted to yield a spike 0.3-ms wide. This yields a value for I_{Kup} of about 0.1 μA. The function of the bias currents I_{B1} and I_{B2} is only to limit the current flow through the threshold comparator, and through the first inverter. Their exact value is not important either, and has been set equal to I_K. The threshold voltage V_T influences the time the neuron needs to integrate a constant input from the end of the refractory period to the onset of the output spike. When both the input amplitude and the threshold voltage are doubled, the effective integration time will stay constant. In other words, doubling the threshold voltage is equivalent to reducing the input current by half. In the experiments in this paper, a threshold voltage of 3 V has been used.

The two remaining biases, I_{Kdown} and I_{leak}, have quite a large influence on the spiking behavior of the neuron. I_{Kdown} controls the duration of the refractory period of the neuron, and thereby sets the intrinsic chopping rate or limits the maximum spiking rate of the neuron. I_{Kdown} is made to vary along the chopper array, so that the intrinsic chopping rate of the neurons is 100 spikes per s at one end and 200 spikes per s at the other end. This means that, in either case, the refractory period is at least several ms. In order to create such long refractory periods, I_{Kdown} has to be small, on the order of 1 nA. For the coincidence-detecting neuron, I_{Kdown} is used to limit its maximum rate, which has been adjusted to about 200 spikes per s. The same I_{Kdown} as for the fastest chopper can thus be used for all coincidence-detector neurons.

I_{leak} plays an important role in creating the coincidence-detector behavior. The input to the coincidence-detector neuron is in the form of fixed-width, fixed-height current spikes which are passed through the lateral-diffusion network. The amplitude of the output-current spikes of the chopper and the lateral-diffusion length L are set, using I_{syni} and V_{CR} plus V_{CG}, respectively (Fig. 7), so that the input-spike current for the coincidence detector is larger than I_{leak} when the input comes from one of the seven most proximal chopper neurons only. I_{leak}, thus, limits the number of choppers that influence the coincidence detectors for a given setting of I_{syni}, V_{CR}, and V_{CG}. I_{leak} should, however, be used to set the temporal window of the coincidence detection, since it does this independently of other bias values. A relatively high I_{leak} ensures that the membrane potential returns quickly to the resting potential after a single-input spike. When a single-input spike is not strong enough to charge the membrane capacitance up to the threshold voltage, several spikes have to arrive in quick succession to elicit spikes from the coincidence-detector cell. The temporal window within which the spikes have to arrive is controlled by I_{leak}. An I_{leak} on the order of 10 nA has been used, which results in a temporal window on the order of 1 ms. Next, I_{syni}, V_{CR}, and V_{CG} should be adapted to get the desired number of choppers that influence the coincidence detector. Finally, the threshold voltage V_T of the coincidence detector should then be adapted, so that the coincidence detector spikes when a few of the input spikes from the choppers are simultaneous. In order to obtain a diffusion length L on the order of 3, V_{CR} and V_{CG} have been set to 2.66 and 2.74 V, respectively. I_{syni} is about 80 nA and V_T is 3 V.

A difference in the role of I_{leak} for the chopper neurons stems from the fact that the input to the chopper neurons is a directly injected, continuous analog current and not in the form of current spikes. When the membrane potential is at rest, only an input current larger than I_{leak} will be able to drive the membrane potential towards the threshold voltage. When the input current is larger than I_{leak}, the current that effectively charges the membrane capacitor is given by $I_C = I_{\text{ex}} - I_{\text{leak}}$. For the chopper neurons, I_{leak} thus functions as a stimulation threshold and acts to subtract a constant value from the input current. In the tests in this paper, however, I_{leak} has been minimized to a value well below 1 nA and its effect on the chopper neurons is therefore negligible.

Masker laterality and cueing in forward-masked intensity discrimination[a)]

Robert S. Schlauch,[b)] Bart R. Clement, Dennis T. Ries, and Jeffrey J. DiGiovanni
Department of Communication Disorders, University of Minnesota, Minneapolis, Minnesota 55455

(Received 17 March 1997; revised 2 November 1998; accepted 3 November 1998)

Forward-masked intensity discrimination was measured as a function of level in experiments designed to reveal insights into the mechanism(s) underlying the midlevel elevation of the Weber fraction. The standard and maskers were 1.0-kHz tones that were separated by 100 ms. Performance was measured for listeners with normal hearing using an adaptive procedure. In experiment 1, intensity discrimination was measured in the presence of an ipsilateral masker (80 dB SPL), a contralateral masker (93 dB SPL), and a binaural (dichotic) masker produced by combining the ipsilateral and contralateral maskers. Listeners perceived only the contralateral masker in the binaural-masker condition. The contralateral masker produced a small midlevel elevation of the Weber fraction. The ipsilateral masker and the binaural masker produced a large, midlevel elevation of the Weber fraction. Experiment 2 found that a two-tone masker resulted in a reduction (improvement) in the Weber fraction for some conditions, but the midlevel elevation remained for all subjects in this cue-tone condition. Experiment 3 demonstrated that cross talk could not account for all of the masking observed with contralateral maskers. Taken together, the results suggest that a single complex mechanism or multiple mechanisms may be responsible for the masking seen in these experiments. On the basis of the cueing results, it is concluded that a portion of the masking is due to cognitive factors; however, a sensory mechanism cannot be ruled out for the remaining portion, based on the results of these experiments. Finally, a small but significant amount of masking due to contralateral maskers places the mechanism for this outcome central to the cochlear nucleus. [S0001-4966(99)03402-5]

INTRODUCTION

When pure-tone intensity discrimination is measured in the presence of a high-level forward masker that is turned off 100 ms prior to the onset of the standard, the Weber fraction is elevated relative to the Weber fraction measured in the absence of a masker. Surprisingly, the largest elevation of the Weber fraction is observed for midlevel standards (Zeng *et al.*, 1991). Several studies have attempted to identify the site of the mechanism or mechanisms causing this midlevel elevation of the Weber fraction.

Zeng and Shannon (1995) examined forward-masked intensity discrimination in several conditions in electrical and acoustical hearing. In electrical hearing, they observed elevated Weber fractions for midlevel standards in listeners with cochlear implants, but not in listeners with cochlear-nucleus implants. In acoustical hearing, a large elevation of the Weber fraction occurred for midlevel standards when the masker and standard were presented to the same ear; the masking effect was much smaller when the masker and standard were presented to different ears. The small amount of masking observed for contralateral maskers in acoustical hearing was argued to be consistent with cross hearing. In other words, the high-level masker (typically 90 dB SPL) in these conditions could have exceeded interaural attenuation by an amount sufficient to result in ipsilateral masking in the ear with the standard tone. Taken together, Zeng and Shannon's (1995) results suggest that the site of the mechanism responsible for the midlevel elevation of the Weber fraction in forward-masked intensity discrimination is either the auditory nerve or the cochlear nucleus.

Zeng *et al.* (1991) argue that a possible physiological correlate to the midlevel elevation of the Weber fraction may be the differential recovery from adaptation of auditory-nerve fibers. The spontaneous-firing rates of auditory-nerve fibers are bimodally distributed, as are fiber thresholds (Liberman, 1978). Fibers with low spontaneous rates (SR) tend to have, on average, higher thresholds for a criterion increase in rate than fibers with high SR (Liberman, 1978). Relkin and Doucet (1991) reported that low-SR fibers also have a slower recovery time from prior stimulation than do high-SR fibers. If intensity changes are coded by the firing rate of low-SR and high-SR auditory fibers, the midlevel elevation of the Weber fraction may be related to this slow recovery from prior stimulation of the low-SR fibers. For midlevel standards in the presence of a forward masker, high-SR fibers are saturated by the standard and presumably unable to code intensity changes, whereas low-SR fibers, whose rate-intensity functions normally code midlevel stimuli, would be adapted still by the masker. By contrast, low- and high-level standards would not show an elevation of the Weber fraction. For low-level standards, intensity changes would be coded by high-SR fibers with their rapid recovery from prior stimulation. At high levels, changes

[a)]Portions of this paper were presented at the 129th meeting of the Acoustical Society of America in Washington, DC [Clement and Schlauch, J. Acoust. Soc. Am. **97**, 3276(A) (1995)].

[b)]Electronic mail: Schla001@maroon.tc.umn.edu

would be coded by low-SR fibers because they would be operating in a more optimal region of their response curve.

The findings of Zeng and Shannon (1995) suggest a peripheral origin for the elevation of the Weber fraction seen for forward-masked intensity discrimination, but other studies imply a central influence on the midlevel elevation of the Weber fraction. For instance, the finding that backward-masked intensity discrimination produces a midlevel elevation of the Weber fraction (Plack and Viemeister, 1992) seems inconsistent with the idea that the mechanism responsible for the masking is related to the slow recovery from adaptation of low-SR fibers in the auditory nerve. Although separate mechanisms may cause the elevation observed in forward and backward masking, assuming dual mechanisms is not parsimonious, given the similarity of the data under both conditions. Further, a recent study by Schlauch *et al.* (1997) shows that the elevation of the Weber fraction is greatest when the masker and standard are perceptually similar. In their study, a short-duration masker resulted in more masking than a long-duration masker, a finding inconsistent with studies of adaptation of auditory-nerve fibers (Harris and Dallos, 1979) and a study of the effect of masker duration in forward-masked detection (Kidd and Feth, 1982). It should be noted that Harris and Dallos (1979), in their study of neural adaptation, did not use stimuli identical to those of Schlauch *et al.* (1997), but all of the neural studies of adaptation, to date, report an increase in the amount of adaptation as masker duration is increased (Young and Sachs, 1973; Smith, 1977; Harris and Dallos, 1979).

Given the conflicting hypotheses to account for the midlevel elevation of the Weber fraction (midlevel bump) in forward-masked intensity discrimination, a series of experiments was completed to examine possible mechanisms responsible for this phenomenon.

I. EXPERIMENT 1. DO SUBJECTS SHOW A MIDLEVEL BUMP IF THEY ARE UNAWARE THAT AN IPSILATERAL MASKER IS PRESENT?

As noted earlier, maskers and standards presented to the same ear result in a large elevation of midlevel Weber fractions for forward-masked intensity discrimination, whereas when the masker and standard are presented to different ears, the Weber fraction is elevated, but to a much smaller extent (Zeng and Shannon, 1995). If the amount of masking seen in forward-masked intensity discrimination requires conscious awareness and the listener were somehow made unaware that an ipsilateral masker was present, the midlevel elevation of the Weber fraction should be reduced or eliminated. On the other hand, if the masking effect remained large when the listener was unaware of the presence of the ipsilateral masker, the outcome would be consistent with a sensory or cognitive process that occurs without conscious awareness.

The ''Stenger principle'' provides a means for making a listener unaware that an ipsilateral masker is present. The Stenger principle states that when tones that are identical except for level are presented simultaneously to each ear of a person with normal hearing, the listener perceives the tone only in the ear with the greatest intensity (Martin, 1997). Stenger (1907) developed a test based on this idea to identify persons who are feigning a unilateral hearing loss (described in Rintelmann and Schwan, 1991). The original test was administered with matched tuning forks struck with different amounts of force, but the modern version of this test is administered typically by presenting one tone 10 dB below the person's admitted threshold in the ear with the feigned loss, and the other tone 10 dB above threshold in their other (better) ear. No response is observed to this dichotic stimulus in most persons feigning a substantial unilateral loss, even though the 10-dB sensation-level (SL) tone in the better ear results in an unequivocal response every time it is presented monotically. The Stenger test is very effective (84%) at identifying persons feigning a unilateral loss when the presentation level to the poorer ear exceeds that of the better ear by more than 10 dB (Kinstler *et al.*, 1972). In other words, the more intense tone must be 11 dB or greater in level than the level of the less-intense tone to make the less-intense tone imperceptible.

Our experiment made use of the Stenger principle to render subjects unaware that a masker was present in the same ear as the standard tone in a forward-masked intensity discrimination experiment.

A. Method

Three listeners, aged 42, 24, and 30 years, served as subjects. All had hearing within normal limits (10 dB HL or better) for octave intervals between 0.25 and 8.0 kHz. Further, hearing thresholds were symmetrical, within 10 dB, between ears at each frequency that threshold was assessed. Two subjects (1 and 3) had considerable experience in psychoacoustic experiments. The other subject (2) had never participated in a psychoacoustic experiment previously. All listeners were given several hours of practice at the tasks in this study prior to data collection.

B. Stimuli

Maskers and standards were 1.0-kHz pure tones that were digitally generated at a sampling rate of 20.0 kHz by a custom-designed 16-bit digital-to-analog (D/A) converter. The output of the D/A converter was low-pass filtered with a cutoff frequency of 8.0 kHz. Three channels were employed. The standard and increment were generated using separate channels that were mixed before being presented to the headphones. The increment was added in phase with the standard. A third channel produced the masker tone. Maskers and standards were 100 ms. All stimuli had 5-ms cosine-squared onset and offset ramps.

Before data collection began, potential subjects were screened to determine if the Stenger principle held true for a 13-dB difference in level between ears.[1] Subjects were presented with a 50-trial block. Half of the trials contained a moderate-to-high level, 1.0-kHz tone for 300 ms. The remaining trials contained the same high-level, 300-ms tone, along with a tone that was 13 dB lower, presented simultaneously to the other ear. The level for the higher-level tone was randomly assigned a value for a given trial of between 50 and 90 dB SPL. The level was randomized to eliminate a potential loudness cue. Subjects were asked to judge for each trial whether the tone was presented to one ear or to both ears

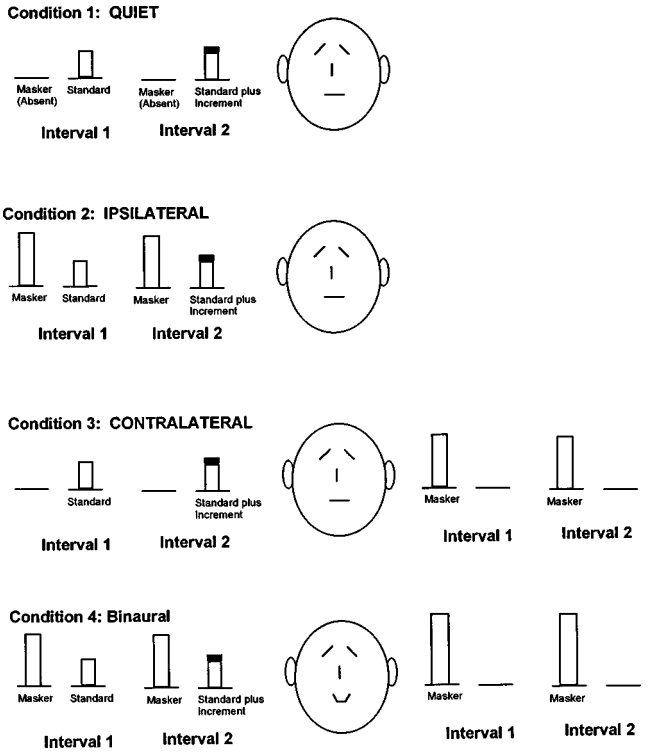

FIG. 1. A schematic drawing representing the four conditions of experiment 1. The increment appears in interval 2 for each of these examples, but it had an equal probability of occurring in either interval in the actual experiment.

simultaneously. No feedback was given regarding performance and trials were separated by 3 s. Lights marked the listening interval. Seven subjects had to be screened before three were found who performed at or near chance for this task (performance$<$0.6; chance$=$0.5). Binaural diplacusis may be responsible for four subjects being able to discriminate the binaural condition from the monaural (Newby, 1979). Burns (1982) reports pitch-intensity functions are significantly different in each ear of some, but not all, listeners. These differences in pitch across ears may have provided a cue to identify the presence of the dichotic stimulus in our four listeners who failed the screening by scoring significantly above chance.

C. Procedure

Intensity discrimination was measured as a function of level for the three subjects for whom the Stenger principle held. For each of four conditions, intensity discrimination was assessed for standard levels ranging from 20 to 80 dB in 10-dB steps. Performance was measured with a two-interval, forced-choice (2IFC) adaptive procedure using a decision rule that targeted 79.4%-correct performance (Levitt, 1971). For every incorrect response, the level of the tone added in phase with the standard was increased by 3 dB, whereas three consecutive correct responses resulted in a reduction in the level of the increment by the same amount. Subjects were given visual feedback regarding the accuracy of their responses following each trial. The Weber fraction for a single block was calculated based on the mean of reversals in stimulus-level direction within a given block. Weber fractions were based on a minimum of three 50-trial blocks that were collected during separate testing sessions (on three different days). If the standard deviation of those three blocks exceeded 3.5 dB, additional blocks, up to as many as eight, were completed. The order of conditions was selected randomly; once a condition was selected, one block for each of the seven standard levels was collected. The four conditions are described below and are also shown schematically in Fig. 1. Subjects listened to stimuli through headphones (Telephonics, TDH-39).

D. Conditions

Condition 1 (quiet): Intensity discrimination was measured in the absence of a masker. The standard was a 1.0-kHz tone. The inter-interval delay was 500 ms. This condition served as a baseline condition, so that the degree of masking in subsequent conditions could be quantified relative to intensity discrimination in the absence of a masker. The right ear was arbitrarily chosen for this condition for each of the subjects.

Condition 2 (ipsilateral masker): Intensity discrimination was measured in the presence of an ipsilateral forward masker that preceded each interval of the 2IFC task. The delay between the masker offset and the onset of the standard (zero voltage) was 100 ms. Both the masker and the standard were 1.0-kHz tones. The masker was fixed in level at 80 dB SPL.

Condition 3 (contralateral masker): In this condition, intensity discrimination was measured in the presence of a contralateral masker that was fixed in level at 93 dB SPL. The task, temporal sequence, and frequency of stimuli were all the same as those of condition 2.

Condition 4 (binaural masker): This condition was employed to induce the Stenger effect. The task, temporal sequence, and frequency of stimuli were the same as those of the previous conditions. Forward maskers were presented simultaneously to each ear of a listener. The masker level was fixed at 80 dB SPL in the ear ipsilateral to the standard tone, and 93 dB SPL in the ear contralateral to the standard tone.

E. Results

Figure 2 illustrates Weber fractions as a function of level for the four conditions in experiment 1. In quiet (condition 1), subjects 1 and 2 show a gradual reduction in the Weber fraction as level increases, a result known as the near miss to Weber's law (McGill and Goldberg, 1968). Subject 3 shows a midlevel elevation of the Weber fraction in quiet. Florentine *et al.* (1987) found individual differences of this sort for Weber fractions in quiet in their study of intensity discrimination.

An ipsilateral masker (condition 2) resulted in a large elevation of the Weber fraction for low and moderate levels of the standard; only a small elevation was found for the highest level of the standard (80 dB SPL). Prior published investigations of forward-masked intensity discrimination with a 100-ms delay between the masker and standard generally find the largest elevation for midlevel standards (Zeng and Turner, 1992). A reason for this difference may be that we used identical durations for the masker and standard (100

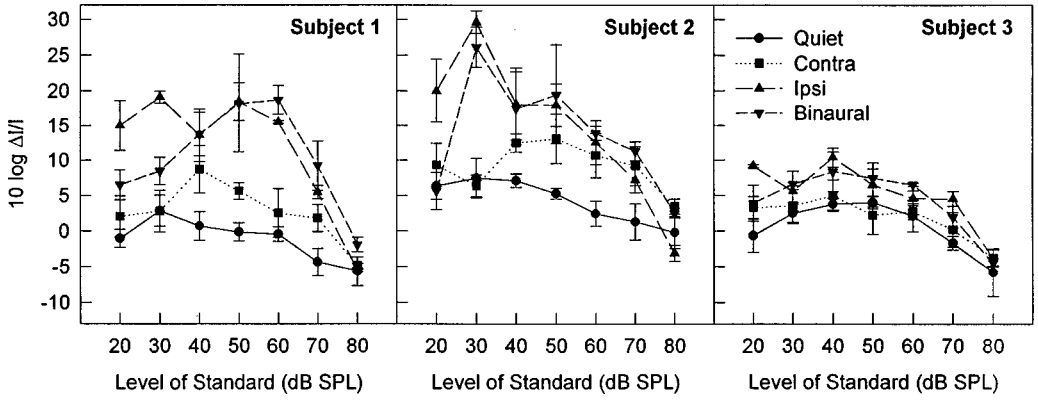

FIG. 2. The Weber fraction (dB) as a function of level for the four conditions of experiment 1 for each subject. Circles represent the quiet condition. Ipsilateral, contralateral, and binaural maskers are represented by triangles, squares, and triangles, respectively. Error bars represent plus- and minus-one standard deviation.

ms), whereas most prior studies employed a masker that was much longer in duration than the standard [e.g., 100 ms for the masker and 25 ms for the standard in Zeng and Turner (1992)]. Schlauch *et al.* (1997) argue that identical duration maskers and standards result in masking due to perceptual similarity, which has its greatest effects for low-level standards.

A contralateral masker (condition 3) resulted in a midlevel elevation of the Weber fraction for subjects 1 and 2. By contrast, subject 3 showed little or no masking for a contralateral masker. This small amount of masking observed for contralateral maskers is consistent with the results of earlier studies (Plack *et al.*, 1995; Zeng and Shannon, 1995).

The binaural masker (condition 4) elevated Weber fractions in a manner very similar to that for the ipsilateral masker, even though the subjects only perceived the higher-level contralateral masker. All of the subjects showed less masking for the binaural masker than for the ipsilateral masker for the lowest-standard levels (20 dB SPL for all subjects and 30 dB SPL for subjects 1 and 2). This improvement in performance seen when the second masker was added may be due to a lateralization cue. That is, in the binaural condition the masker was lateralized to the ear contralateral to the standard, which may have made it easier for the listener to dissociate the masker and standard than when they were both perceived to have originated in the same ear. In any event, a lateralization cue does not appear to be effective for reducing masking for the higher-level standards in this study. A similar outcome is seen in the data of Plack *et al.* (1995), who used equal-level binaural maskers in a forward-masked intensity discrimination experiment.

II. EXPERIMENT 2. DOES A TONAL CUE PRESENTED SIMULTANEOUSLY WITH THE MASKER REDUCE THE MASKING SEEN IN FORWARD-MASKED INTENSITY DISCRIMINATION?

It has been suggested that temporal uncertainty resulting from employing maskers and standards with similar frequencies and bandwidths increases the amount of forward masking in a detection task (Moore and Glasberg, 1982) and an intensity discrimination task (Schlauch *et al.*, 1997). That is, perceptually similar maskers and standards result, for some conditions, in more masking than ones that are perceptually dissimilar. In our experiment 1, where maskers and standards were employed that were identical in every respect except for level, some portion or all of the masking effect may have been due to the perceptual similarity of the masker and standard. In this second experiment, the masker was modified to help subjects distinguish the masker from the standard. To accomplish this, we used a two-tone complex for our masker and a single tone for the standard. The frequencies of the masker complex were 1.0 kHz and 4.133 kHz, whereas the standard frequency was 1.0 kHz. The 4.133-kHz tone is not harmonically related to the frequency of the standard and these two tones are separated sufficiently to avoid masking. Pilot data for subjects 1 and 2 (a few standard levels were sampled) confirmed that the 4.133-kHz tone alone resulted in no elevation of the Weber fraction.

A. Subjects

Subjects 1 and 2, who showed the greatest amount of masking in experiment 1, participated along with two additional subjects (subjects 3 and 4) who were recruited for this experiment. The two new recruits were young adults who met the same criteria for participation as noted in the methods for experiment 1. Subjects 3 and 4 were not administered the Stenger screening test.

B. Stimuli and procedure

Stimulus generation and procedure were identical to those of experiment 1. The only difference was that the masker was a two-tone complex comprised of 1.0-kHz and 4.133-kHz tones, rather than a single, 1.0-kHz tone. The level of each masker was 80 dB SPL.

Pilot data showed that subjects 3 and 4 produced only a small amount of masking with 100-ms maskers and standards. To increase the amount of masking, these subjects were run using 10-ms standards and maskers. Subjects 1 and 2 were run using 100-ms maskers and standards.

C. Results

Adding the remote-frequency cue to the ipsilateral condition resulted in reduced Weber fractions at several standard levels for three of the four subjects. Figure 3 summarizes the results. The greatest reduction occurred for the lowest-level standards for subject 2. Schlauch *et al.* (1997) reported a similar finding for one of their subjects in a condition that employed 10-ms maskers and 10-ms standards in a forward-masked intensity discrimination task. The increase in masking shown by subject 3 in the cue-tone condition is a result of masking by the 4.133-kHz tone. Masking data collected with the 4.133-kHz tone alone showed elevated jnd's even when the masker level was reduced to 60 dB SPL.

III. EXPERIMENT 3. CAN CROSS HEARING ACCOUNT FOR THE BUMP SEEN IN CONDITIONS WITH CONTRALATERAL MASKERS?

This experiment was designed to examine whether the elevation of the Weber fraction for midlevel standards in the contralateral-masker condition is due to the masker tone crossing over to the same ear as the standard tone. If the masker were crossing over to the ear with the standard tone, the skull would attenuate it. The amount of this attenuation, known as interaural attenuation, ranges from 40 to 75 dB for persons wearing TDH earphones mounted in supra-aural cushions (Snyder, 1973). The mean value of interaural attenuation at 1.0 kHz, measured in a group of 228 persons with complete unilateral hearing loss, is 60 dB (Snyder, 1973). Using 40 dB as the most conservative estimate of interaural attenuation, an ipsilateral forward-masking condition was set up in which we presented the maximum amount of ipsilateral masking that could have occurred during the contralateral condition. If contralateral masking is the result of the masker crossing over to the ear with the standard tone, the results for this low-level ipsilateral-masker condition should produce the same amount of masking that was seen with the high-level contralateral masker, or more.

A. Subjects, stimuli, and procedure

The subjects from experiment 2 participated in this experiment. The stimuli and procedures were identical to those of the ipsilateral-masker condition in experiment 2, with the exception that the masker level was set to 53 dB SPL and the masker was a single, 1000-Hz tone. This level represents the greatest amount of crossover that may have occurred in the contralateral condition employing the 93-dB SPL contralateral masker. For subjects 1 and 2, Weber fractions were measured only for the two midlevel standards that yielded the most masking (masked–quiet) in the presence of the contralateral masker (40 and 50 dB SPL for subject 1 and 50 and 60 dB SPL for subject 2). For subjects 3 and 4, Weber fractions were measured for standard levels of 40, 50, and 60 dB SPL.

B. Results

The results of these measurements are shown in Fig. 4. All of the measurements obtained with the 53-dB SPL masker yielded Weber fractions that are smaller than those

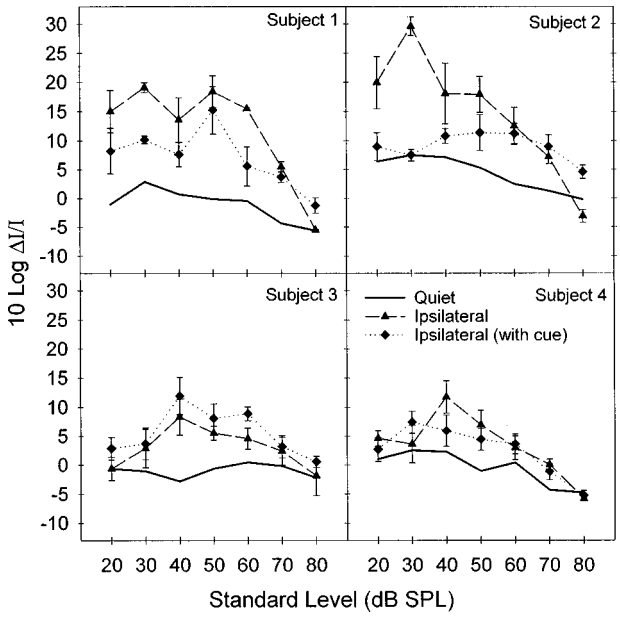

FIG. 3. The Weber fraction (dB) for the condition with an ipsilateral two-tone masker (triangles). For comparison, data are shown for a quiet condition and for an ipsilateral masker condition (data for Subjects 1 and 2 are from experiment 1). Quiet data are shown by a solid line, whereas data for the ipsilateral single-tone masker are shown as diamonds.

obtained with the contralateral masker. Further, this low-level masker yielded Weber fractions that are only slightly elevated and nearly identical in size to those obtained in the quiet condition of experiment 1. Thus, cross hearing cannot account for the full effect of contralateral masking observed in experiment 1. The finding that a 53-dB SPL masker results in only a small increase in the Weber fraction is consistent with the results of Zeng and Turner (1992) and Plack *et al.* (1995).

IV. GENERAL DISCUSSION

The finding that a contralateral masker produced substantially less masking than a binaural masker, even though the two masker conditions were indistinguishable, supports the idea that the midlevel elevation of jnd's in forward-masked intensity discrimination is the result of a mechanism that does not require conscious awareness. Contrary to early descriptions of this phenomenon where the putative mechanism was believed to be associated with adaptation in the auditory nerve (Zeng and Turner, 1992), the present results and those of some other recent studies suggest that it is at least partly due to more central mechanisms. For instance, the result in the current study that the midlevel elevation of jnd's seen with a contralateral masker cannot be accounted for by cross hearing suggests that the mechanism is located within the superior olive, the first station of binaural interaction, or even higher in the auditory system. Other evidence inconsistent with an explanation based on adaptation is the finding that the masker acts to increase rather than to decrease the subjective magnitude of the standard or standard plus signal (Carlyon and Bevridge, 1993; Zeng, 1994), and the finding that short-duration maskers can produce more masking than long-duration maskers (Schlauch *et al.*, 1997).

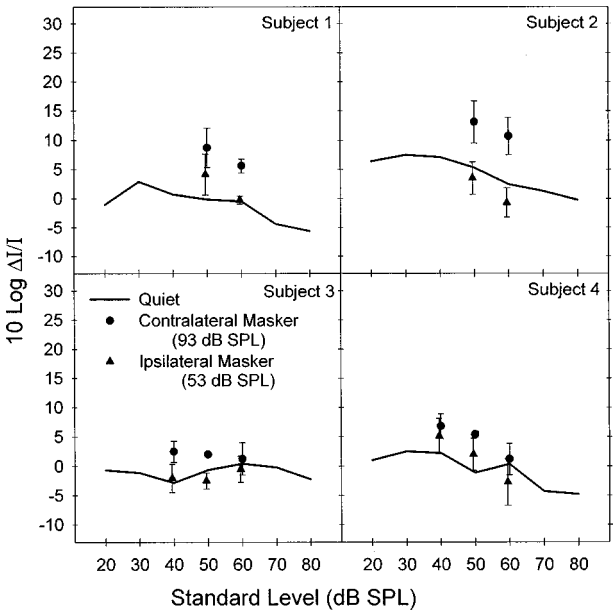

FIG. 4. The Weber fraction (dB) for a low-level masker (53 dB SPL) is shown as an upward-pointing arrow. For comparison, data for a quiet condition and for a contralateral masker are shown for the four participants in experiment 2 as solid lines and circles, respectively. Data for subjects 1 and 2 are from experiment 1. Note that the low-level masker produces less masking than the contralateral masker for all comparisons.

Our results suggest that a portion of the masking observed in our study could be accounted for by cognitive factors. When a two-tone complex was used to help listeners distinguish the masker from the standard, an improvement in performance was observed for some listeners, but the midlevel elevation of the Weber fraction remained. Plack and his colleagues (Plack *et al.*, 1995; Plack, 1996b) have suggested that the memory trace may be corrupted or that the variance of the memory trace may be increased by the presence of the masker in forward-masked intensity discrimination. There is evidence that a forward masker enhances the loudness of midlevel standards and introduces substantial variance in a listener's estimate of that loudness (Zeng, 1994). Plack and his colleagues demonstrated that a stimulus placed in close temporal proximity to the standard, either before or after the standard, results in an improvement in performance compared to a condition where the proximal stimulus was not present. These results demonstrate that listeners are able to make use of the proximal stimulus, but this outcome is not inconsistent with the idea that a sensory mechanism is responsible for the midlevel elevation of jnd's in forward-masked intensity discrimination. Plack (1996b) suggests that the role of the reference signal may be to modulate the sensory trace in a manner that provides the listener with a temporal profile. Changes in the temporal profile would enable listeners to identify the interval with the increment based on a within-interval comparison rather than a comparison of absolute levels across intervals. Plack (1996b) described a temporal model which predicted that the nature of a temporal cue would differ depending on whether the proximal stimulus was presented before or after the standard. Consistent with the model, two groups of subjects trained on tasks with different cues performed poorly when they switched tasks. Although this result is interesting, it does not address the mechanism underlying the midlevel elevation of jnd's.

The midlevel elevation of jnd's in backward masking is another result that is difficult to account for by a peripheral sensory mechanism (Plack and Viemeister, 1992). One possibility, which seems unlikely, is that different mechanisms are responsible for the elevation of jnd's in forward and backward masking; studies have shown that the effects of forward and backward masking on intensity discrimination and loudness are similar under a variety of conditions (Plack and Viemeister, 1992; Plack, 1996a). Another possibility is that masking in forward-masked intensity discrimination reflects a process of central origin known as an ''automatic process.''

An automatic process describes behavior in focused-attention tasks where subjects are unable to ignore an irrelevant stimulus (Schneider *et al.*, 1984). In one example, subjects asked to visually identify a letter in isolation take less time to respond than when they are asked to identify the same target letter in the context of a flanking letter. The longer response time is cited as evidence that subjects automatically processed the flanking letter along with the target letter, even though they knew in advance the location of the flanking letter and that it was irrelevant to the task. Schneider *et al.* (1984, p. 21) state that one defining feature of an automatic process is that it ''demands resources in response to an external stimulus, regardless of the subjects' attempts to ignore the distraction.'' They also state that a possible function of an automatic process is to bias or prime memory for subsequent inputs. In the case of forward- (or backward-) masked intensity discrimination, a high-level stimulus results in an assimilation of subjective magnitudes of moderate-level stimuli that are similar in frequency and presented in close temporal proximity to the high-level stimulus. Plack (1996a) argues that such a process may reflect long-term integration of intensity. Long-term integration of intensity of stimuli with similar spectra may promote perceptual streaming (attending to an auditory source over time). Plack (1996a) notes that such a process would not likely be deleterious to speech perception, given that fine spectral distinctions are not obscured by this type of masking and that intensity processing used for recognizing auditory objects is relative rather than absolute.

V. CONCLUSIONS

The midlevel elevation of the intensity jnd is determined almost entirely by the masker input to the ipsilateral ear rather than by the perceived location of the masker. However, a small elevation of the intensity jnd does occur with a contralateral masker, a finding that is not due to acoustic cross talk. Also, a cue tone reduces the amount of forward masking in some listeners. The reduction in the Weber fraction due to cueing and the finding that contralateral masking is not due to cross talk support the notion that a portion of the masking seen in these conditions is not the result of a peripheral sensory mechanism. On the other hand, conscious awareness of the ipsilateral masker is not necessary for masking to occur. This implies that the mechanism respon-

sible for the midlevel elevation of the Weber fraction is the result of a cognitive process that occurs without conscious awareness, or that a portion of the masking is likely the result of a sensory mechanism.

ACKNOWLEDGMENTS

We are grateful to Dr. Chris Plack for his helpful comments during the review process. Discussions with Dr. Plack about the definitions of concepts such as ''cognitive'' and ''conscious awareness'' were particularly illuminating. This work was supported by NIH-NIDCD R29 DC01542.

[1]Hafter and Kimball (1980) have found that well-trained listeners given feedback are able to identify correctly ($d'=1$) the presence of a low-level tone that is as much as 45 to 50 dB below the level of a tone presented simultaneously to the other ear. The three listeners they tested differed considerably in their ability to do this task, even with training. Subtle differences in the perception of dichotically and monotically presented tones make identification of differences easier when the stimuli are presented in a same/different task such as in Hafter and Kimball's (1980) experiment, rather than our experiment, where short-term memory traces of both examples were not as readily accessible and feedback was not provided.

Amplitude-modulation detection at low- and high-audio frequencies[a)]

David A. Eddins
Psychoacoustics Laboratory, Department of Speech and Hearing Sciences, Indiana University, Bloomington, Indiana 47405

(Received 9 February 1998; accepted for publication 16 October 1998)

Estimates of temporal acuity under comparable conditions at low- and high-audio frequencies are rare. The present study used the amplitude-modulation detection paradigm to estimate temporal acuity over a range of audio frequencies from 800 to 12 800 Hz. Amplitude-modulation detection was measured as a function of modulation frequency for bandlimited noise carriers, and the resulting temporal modulation-transfer functions were used to characterize temporal acuity. The most important result from the two experiments reported is that systematic manipulations of carrier upper-cutoff frequency produced estimates of temporal acuity that did not vary from 800 to 12 800 Hz. When the modulated noise bands were filtered after modulation to control for potential spectral cues, the low-pass cutoff of the modulation-transfer function varied with the carrier bandwidth. However, when the standard stimulus was a quasifrequency-modulated (QFM) noise and the signal was an unfiltered, amplitude-modulated noise, the low-pass cutoff of the modulation-transfer function was independent of carrier bandwidth. These results are consistent with a growing body of evidence demonstrating that auditory temporal acuity is constant throughout most of the audible frequency range. [S0001-4966(99)00402-6]

INTRODUCTION

A number of authors have suggested that the ability of the auditory system to process amplitude fluctuations is limited more by the central auditory system than by the resonant properties of the peripheral auditory system. This position is supported, at one level, by recent data which show that the detection of amplitude modulation depends little on the spectral location of the carrier stimulus (e.g., Eddins, 1993), and on another level by models of amplitude-modulation detection that have required extremely broad predetection filters to account for the behavioral data (e.g., Viemeister, 1979; Forrest and Green, 1987; Strickland and Viemeister, 1997). While such models may be helpful in predicting the type of temporal information that is available to the auditory system, they are often physiologically unrealistic, lacking analogs to important physiological properties such as basilar-membrane filtering. Dau and colleagues (Dau, 1996; Dau *et al.*, 1996; Dau *et al.*, 1997a,b) and Holube and Kollmeier (1996) recently introduced a model of auditory perception that includes a number of physiologically relevant elements, including a filter bank representing basilar-membrane filtering. The model predicts with extraordinary accuracy the perception of amplitude modulation and other auditory phenomena. The portion of the stimulus passing through a given basilar-membrane filter channel undergoes half-wave rectification, low-pass filtering (1000 Hz), and nonlinear adaptation before being delivered to a second bank of filters tuned to a range of envelope frequencies. This modulation-filter bank is the most notable feature of the model, as it provides the basis for the fine temporal resolution required in tasks such as amplitude-modulation detection. It is important, however, to recognize that the decision stage of the model integrates the output from all of the peripheral channels within the spectral range of the input signal.

With the modulation-filter-bank model, Dau *et al.* (1997b) simulated amplitude-modulation detection using the same stimulus conditions as reported by Eddins (1993) and obtained modulation-transfer functions that were very close to the original behavioral results. The stimulus conditions allowed a comparison of modulation thresholds obtained for equivalent absolute-noise bandwidths at different carrier frequencies. In this case, the first stage of the model included very different basilar-membrane filter properties for low- and high-frequency carriers. Because filter bandwidths increased with increasing carrier frequency, the number of filter channels decreased with increasing carrier frequency. Despite variation in the number of active filters and their bandwidths with changes in carrier frequency, the predicted results, like the behavioral results of Eddins, indicated no difference in detection across carrier frequency. Thus, it appears that this spectral integration includes a trade between the number of filter channels and their bandwidths. The empirical results of Eddins and subsequent reports by Strickland and Viemeister (1997) and Dau (1997b) have demonstrated such spectral integration over a carrier frequency range of 500 to 5000 Hz. Other psychophysical paradigms demonstrating similar spectral integration include temporal gap detection (e.g., Eddins *et al.*, 1992) and modified masking-period patterns (e.g., Eddins, 1998). Combining these results with studies of gap detection with sinusoids (e.g., Moore *et al.*, 1993; Shailer and Moore, 1987) and Huffman sequences (Green, 1973), there is strong evidence that temporal acuity does not depend upon

[a)]A portion of this research was presented at the 135th meeting of the Acoustical Society of America [D. A. Eddins, J. Acoust. Soc. Am. **103**, 2842 (A) (1998)].

the stimulus frequency, at least over the range of 500 to 5000 Hz.

The modulation-filter-bank model predicts similar spectral integration at much higher carrier frequencies. Indeed, unless one assumes markedly different auditory processing at high- and low-audio frequencies, estimates of temporal acuity should be comparable throughout most of the audible frequency range. A number of investigators have explored temporal resolution at high-audio frequencies (e.g., >5000 Hz) with disparate results. For example, measurements of amplitude-modulation detection in bandlimited noise by Rodenberg (1977) and Viemeister (1979) resulted in modulation-transfer functions with −3-dB bandwidths that increased with increasing center frequency over the range 200 to 10 000 Hz. In these studies, however, stimulus bandwidth and frequency region covaried, making it difficult to interpret the influence of frequency region on the pattern of results. Measures of temporal gap detection using bandlimited noise with center frequencies as high as 14 000 Hz (Fitzgibbons, 1984; Buus and Florentine, 1985) have revealed shorter gap-detection thresholds with increasing frequency. In these studies, however, the bandwidth and frequency region also covaried. More recently, Snell *et al.* (1994) systematically varied stimulus bandwidth and frequency region and reported gap-detection thresholds that were shorter at midfrequencies than at lower and higher frequencies. These results are not consistent with previous gap-detection results and may have been influenced by audible clicks in the standard interval of the gap-detection task. One goal of the present study was to evaluate auditory temporal acuity over a broad range of audio frequencies (800 to 12 800 Hz) using the amplitude-modulation detection paradigm.

A second motivation for the present experiments was to explore the apparent discrepancies in the literature concerning the influence that stimulus bandwidth may have upon estimates of auditory temporal acuity. Strong bandwidth effects have been reported in experiments on amplitude-modulation detection (e.g., Eddins, 1993) and temporal gap detection (e.g., Eddins *et al.*, 1992), for which explanations have included limits imposed by intensity discrimination and variations in the acoustic properties of the stimuli themselves. In terms of amplitude-modulation detection, Strickland and Viemeister (1997) suggested that changes in the *low-pass cutoff* of the modulation-transfer function with changes in stimulus bandwidth, reported by Eddins (1993) and others, were largely a result of the stimulus generation technique used in those experiments.

Differences in methods of stimulus generation arise from different approaches to minimizing the spectral cues that result from the amplitude modulation of bandlimited noise. Sinusoidal amplitude modulation of a bandlimited noise produces side components above and below the spectral edges of the carrier band. The presence of these components provides a spectral cue in the detection task. In many investigations of modulation detection, the side components have been removed by filtering after amplitude modulation. This equates the spectrum of the modulated signal to that of the unmodulated standard. Such filtering, however, reduces the effective modulation depth. This reduction is greatest for high-modulation frequencies and for narrow-noise bandwidths. An alternative approach is to match the magnitude spectrum of the unmodulated standard to that of the AM signal. This may be accomplished by adding side components to the unmodulated standard at $f_c \pm f_m$, where f_c is the frequency of a given carrier component and f_m is the modulation frequency. The side components have magnitudes identical to the those of the AM signal and phases that are either chosen randomly from a uniform distribution ($0–2\pi$) or phases that are shifted $\pi/2$ radians relative to the respective carrier component. In the latter case, the phase shift of the side components results in a carrier and side components that approximate the central-most components of an FM stimulus. Such a stimulus is termed quasifrequency modulation, or QFM (e.g., Mathes and Miller, 1947). Thus, the magnitude spectra of the standard and signal are statistically identical, but their phase spectra, and therefore their waveforms, are quite different. The distributions of instantaneous amplitude values for noise bands with random or QFM sidebands and random noise without sidebands are nearly identical and are quite different from the distribution of instantaneous amplitudes for a sinusoidally amplitude-modulated noise. Using such a QFM standard, Strickland and Viemeister (1997) reported little effect of stimulus bandwidth on the shape of the modulation-transfer function.

The main goal of the present study was to characterize the temporal acuity of the auditory system over a broad range of audio frequencies using the amplitude-modulation detection paradigm. This was accomplished in two experiments using the two different stimulus generation techniques outlined above. Experiment 1 extended the measurements reported by Eddins (1993), using the filter-after-modulation technique, to frequencies as high as 12 800 Hz. Experiment 2 was essentially a replication of experiment 1, but rather than filtering the amplitude-modulated signal after modulation, a QFM standard stimulus was used to control for spectral cues.[1] Thus, a direct comparison of the results from experiments 1 and 2 can allow determination of whether the bandwidth effect reported by Eddins (1993) was a result of filtering-after-amplitude modulation rather than some property associated with bandlimited noise or auditory perception. Experiment 2 also extends the measurement of modulation detection using a QFM standard to upper-cutoff frequencies as high as 12 800 Hz.

I. METHODS

A. Procedures

An adaptive, two-interval, two-alternative forced-choice method with a three-down, one-up tracking algorithm was used to estimate the modulation depth, 20 log *m*, corresponding to 79.4%-correct detection (Levitt, 1971). The adaptive procedure varied modulation depth using a 5-dB step size for the first three reversals in the adaptive track and a step size of 2 dB thereafter. Modulation-detection thresholds were estimated by averaging the modulation depth at each of the last even number of reversals, excluding the first three reversals. The final threshold for a condition was taken as the average

threshold across three 60-trial blocks. A fourth block was included if the standard deviation across the first three exceeded 2.5 dB. Each trial consisted of two 400-ms observation intervals marked by LEDs and separated by a 400-ms silent interval. Subject responses were followed by visual feedback. Stimuli were presented via ER-2 (Etymotic) insert earphones and testing was conducted in a sound-attenuating chamber.

B. Stimulus generation

All stimuli were generated using a digital-array processor (TDT AP2) and a 16-bit D/A converter with a sampling period of 25.0 μs (40 000-Hz sampling rate). In experiment 1, a broadband noise was generated in the time domain. When required, the broadband noise was amplitude modulated at the desired modulation frequency and depth. A subsequent Fourier transform yielded a complex buffer pair (magnitudes and phases) which was digitally bandpass filtered by setting the Fourier components outside the desired passband to a value of zero. An inverse fast Fourier transform (FFT) on the complex buffer pair then yielded a waveform having the desired spectral and temporal characteristics.

In experiment 2, a different four-step technique was used for stimulus generation. First, a bandlimited-noise carrier with the desired bandwidth and upper-cutoff frequency (UCF) was produced by filling portions of two 16 384-point buffers with the appropriate component magnitudes (Rayleigh distributed) or phases (uniformly distributed from 0 to 2π radians). Upper $(f+fm)$ and lower $(f\text{-}fm)$ side components were then created for each carrier component, such that when added to the carrier, either amplitude-modulated noise (AM) or quasifrequency-modulated (QFM) noise was produced (see Mathes and Miller, 1947). The phase relation of the side components to the corresponding carrier component determined whether AM or QFM was produced. For AM, the side components had the same starting phase as the corresponding carrier component. For QFM, the starting phase of the side components was shifted $\pi/2$ radians relative to the corresponding carrier component. The magnitude of a side component relative to the magnitude of the corresponding carrier component determined the depth of modulation. After adding the ensemble of side components to the carrier components, an inverse FFT yielded a noise waveform having the desired spectral and temporal characteristics.

In both experiments, independent noise stimuli were presented on each observation interval. The stimulus duration was 409.6 ms, including 10-ms $\cos^2$ onset and offset ramps. The magnitude spectra were scaled so that each noise sample had the same overall energy, corresponding to a pressure-spectrum level of 45 dB SPL.

C. Data analysis

One means of data analysis involved obtaining the best-fitting low-pass-filter function to each modulation-transfer function to better characterize the shape and sensitivity of each function. Specifically, for each subject and each bandwidth–UCF combination, the threshold data were fit with the transfer function of a simple low-pass filter of the form: $10\log_{10}[k/(1+(\omega\tau)^2)]$, where $\omega=2\pi f_m$ and $\tau=1/(2\pi f_c)$. Here, f_m is the modulation frequency, f_c is the -3 dB bandwidth, and k is the height or gain of the function at the y intercept $(f_m=0)$. Note that the fitting procedure merely provides a convenient way to summarize the data across the various spectral conditions. Best-fitting low-pass functions should not be interpreted as representing the low-pass-filter stage present in traditional envelope detector models (e.g., Viemeister, 1979).

TABLE I. Stimulus conditions in experiment 1 parsed by bandwidth (rows) and upper-cutoff frequency (columns). The first column shows the four stimulus bandwidths with the modulation frequencies reported at that bandwidth in parentheses. Cell entries in columns two through six indicate the total number of subjects per condition. Individual subject numbers are in parentheses.

	Upper-cutoff frequency (Hz)				
Bandwidth (Hz)	1600	3200	6400	9600	12 800
400 (4–64)	4 (1–4)	5 (1–5)	4 (1–4)	4 (1–4)	5 (1–5)
800 (4–128)	5 (1–5)	5 (1–5)	5 (1–5)	5 (1–5)	5 (1–5)
1600 (4–256)	⋯	5 (1–5)	5 (1–5)	5 (1–5)	5 (1–5)
3200 (4–256)	⋯	⋯	4 (2–5)	4 (2–5)	4 (2–5)

II. EXPERIMENT 1

A. Listeners

Five listeners ranging in age from 22 to 24 years participated in experiment 1. All had normal middle-ear function based on a screening tympanogram (*Y*, 226 Hz) and pure-tone thresholds $\leqslant$15 dB HL at octave frequencies from 250 to 8000 Hz as measured using an ER-3A earphone (ANSI, 1989). Pure-tone thresholds from 9000 to 13 000 Hz were $\leqslant$27 dB SPL as measured using an ER-2 earphone. Sound-pressure levels for the ER-2 earphones correspond to levels measured in a Zwislocki 2-cc coupler with an ER 1-08 adaptor. None of the listeners had previous experience in psychoacoustic listening tasks. Listeners were paid an hourly wage and received a 10% bonus upon completion of the study.

B. Conditions

Amplitude-modulation thresholds were estimated by determining the minimum modulation depth necessary to discriminate noise that was sinusoidally amplitude modulated from unmodulated noise. Specific noise bandwidths and upper-cutoff frequencies are listed in Table I, along with the listeners who participated in each condition.

Upper-cutoff frequencies above 12 800 Hz were not included in these experiments because of the rather dramatic loss of hearing sensitivity above this frequency experienced by typical, young, college-aged listeners (e.g., 20–25 years; see Green *et al.*, 1987). The original set of measurement conditions included modulation frequencies from 4 to 512 Hz in octave intervals with the stipulation that the modulation frequency not exceed one-half of the stimulus bandwidth. During data collection, a threshold run was discarded if the modulation depth requested by the tracking procedure was less than 0 dB $[20\log(1/m)]$, which would have resulted in

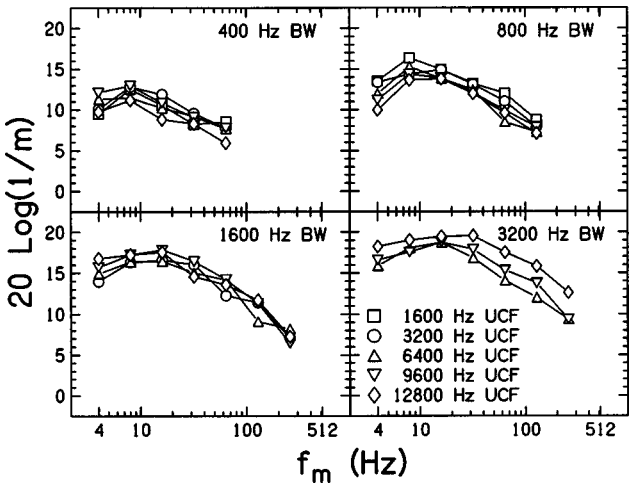

FIG. 1. Mean thresholds for amplitude-modulation detection as a function of modulation frequency with sensitivity to modulation at threshold expressed in terms of $20 \log(1/m)$. Each panel represents a different noise bandwidth and the symbols denote the different noise-band upper-cutoff frequencies.

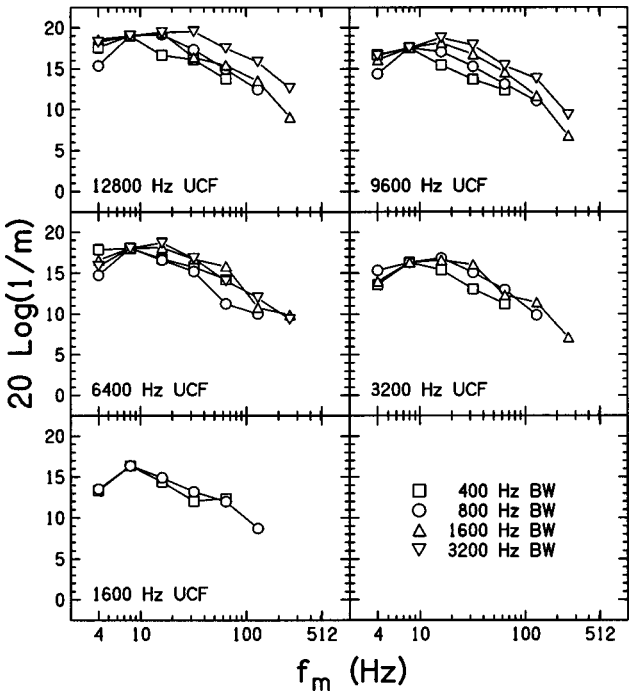

FIG. 2. Threshold data from Fig. 1 replotted with noise bandwidth as the parameter and each panel representing a different noise-band upper-cutoff frequency. Threshold functions in each panel are normalized to the highest threshold at the 8-Hz modulation frequency.

overmodulation. As a result of this protocol, threshold estimates could not be obtained at the highest modulation frequency for a given noise bandwidth in over 80% of the cases. Therefore, thresholds will only be reported for modulation frequencies of 4 to 64 Hz at the 400-Hz bandwidth, 4 to 128 Hz at the 800-Hz bandwidth, and 4 to 256 Hz at the 1600- and 3200-Hz bandwidths. Of the 484 conditions outlined in Table I, the protocol prevented the estimate of threshold ten additional times, spanning nine different conditions. Due to time constraints, listeners 1 and 5 completed only 14 of the 17 bandwidth–upper-cutoff combinations, as shown in Table I.

C. Results and discussion

Modulation thresholds were consistent across the individual listeners and thus only the mean data will be shown. Each panel in Fig. 1 represents a different noise bandwidth and displays the sensitivity to modulation at threshold on the ordinate and modulation frequency on the abscissa. The different symbols indicate upper-cutoff frequency. For each bandwidth–upper-cutoff-frequency combination, the resulting modulation-transfer function shows the characteristic low-pass form. There is considerable overlap among the plotted functions and little systematic difference in the height or the shape of the modulation-transfer functions across the different upper-cutoff frequencies. Comparing the data across the four panels, it is clear that the peak or maximum sensitivity to modulation increases with increasing bandwidth. Using the threshold at a modulation frequency of 8 Hz to compare sensitivity to modulation across frequency, and averaging across upper-cutoff frequencies, sensitivity increases from 12.4 to 18.2 dB as the bandwidth increases from 400 to 3200 Hz. It is rather difficult to compare the shapes across bandwidths, so the data have been replotted in Fig. 2, with all of the bandwidth conditions at a given upper-cutoff frequency shown in the same panel. Bandwidths are distinguished by the different symbols. To further facilitate the comparison of function shape, the transfer function for each UCF has been normalized to the maximum threshold obtained for the 8-Hz modulation frequency. The data for the 9600-Hz upper cutoff (top right) show the largest influence of noise bandwidth on the shape of the transfer function. Here, there is a systematic increase in the low-pass cutoff with increasing noise bandwidth. A similar, though less dramatic, result was obtained at the 12 800-Hz and 3200-Hz upper-cutoff frequencies. This bandwidth effect is less clear at the upper cutoffs of 6400 and 1600 Hz.

Following the fitting procedure outlined above, estimates of the time constant, τ, and the sensitivity parameter, k, were obtained. These values are shown in Fig. 3 as a function of noise bandwidth with τ values in the upper panel and $10 \log_{10}(k)$ values in the lower panel. The symbols indicate the five upper-cutoff frequencies and represent average values across listeners. Beginning with the upper panel, it is clear that τ varies little with upper-cutoff frequency over the range of 1600 to 12 800 Hz, as indicated by the overlapping symbols. In addition, there is a systematic decrease in τ with increasing noise bandwidth. For comparison, the solid line shows the time-constant estimates reported by Eddins (1993). Since his data varied little with upper-cutoff frequency, the solid line represents an average across upper cutoffs of 600, 2200, and 4400 Hz. The results from the two studies show remarkable agreement, and the present measurements extend the previous results to substantially higher upper-cutoff frequencies, demonstrating that the detection of amplitude modulation does not depend on the frequency of the carrier over the range of 1600 to 12 800 Hz. When combined with the results of Eddins (1993), that range extends from 600 to 12 800 Hz.

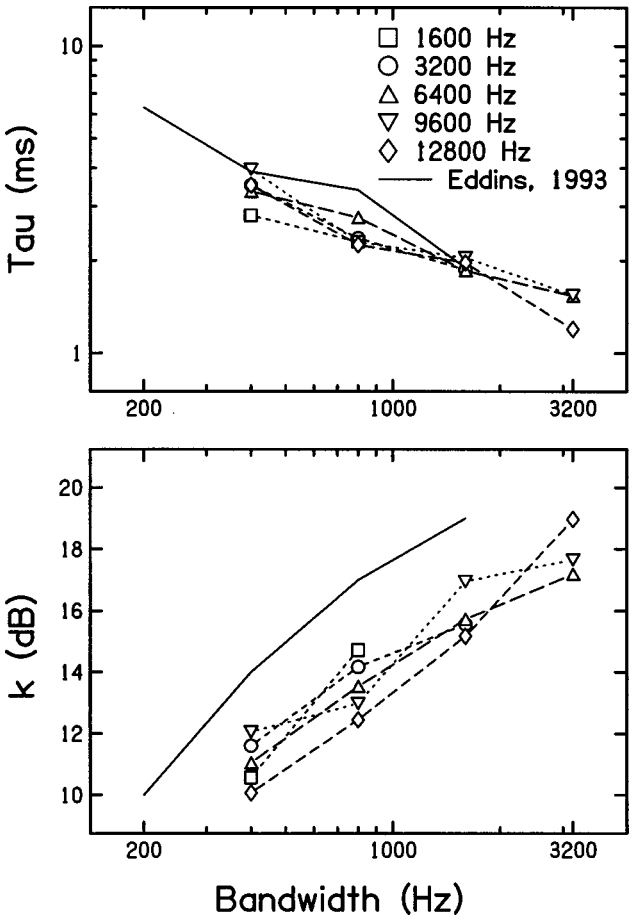

FIG. 3. Constants estimated by the fitting procedure and averaged across listeners (see the description in text). The upper panel shows the time constant, τ, as a function of noise bandwidth. The symbols represent different upper-cutoff frequencies. The lower panel shows the sensitivity to modulation, k, as a function of bandwidth at the same upper-cutoff frequencies. The solid lines in the two panels represents estimates taken from Eddins (1993), averaged across the upper-cutoff frequencies of 600, 2200, and 4400 Hz.

The lower panel of Fig. 3 shows a systematic increase in sensitivity to modulation with increasing noise bandwidth. Again, the pattern of results at low upper-cutoff frequencies is similar to those reported by Eddins (1993), as shown by the solid line. Listeners in the present experiment, however, had consistently lower sensitivity to modulation at each noise bandwidth. This likely reflects individual differences in listeners' ability to detect amplitude modulation. For a given bandwidth, there is considerable overlap among the different upper-cutoff frequencies, demonstrating little change in sensitivity to modulation with upper-cutoff frequency.

In addition to changes in the sensitivity to modulation with increasing bandwidth, the estimated -3-dB bandwidths increased and associated time constants decreased with increasing bandwidth (Fig. 3, upper panel). To determine whether this bandwidth effect resulted from restrictions in the effective modulation depth imposed by filtering after modulation, experiment 2 included the same spectral conditions as in experiment 1 but used a QFM standard to match the magnitude spectrum of the AM signal, rather than filtering after modulation to match the spectrum of the unmodulated standard.

III. EXPERIMENT 2

A. Listeners

Four new listeners ranging in age from 19 to 25 years participated in experiment 2. All had pure-tone thresholds of 15 dB HL or better at octave frequencies from 250 to 8000 Hz and normal middle-ear function based on a screening tympanogram (Y, 226 Hz). Pure-tone thresholds for listeners 1 and 2 were less than 20 dB SPL from 9000 to 13 000 Hz. For listener 4, thresholds gradually increased from 10 dB at 9000 Hz to 32 dB SPL at 13 000 Hz. Thresholds for listener 3 increased from 14 to 52 dB over the same range. None of the listeners had previous experience in psychoacoustic listening tasks. Listeners were paid an hourly wage and received a 10% bonus upon completion of the study.

B. Conditions

Noise bandwidths were 400, 800, and 1600 Hz at upper-cutoff frequencies of 3200, 6400, 9600, or 12 800 Hz. A 3200-Hz bandwidth was included at each of the three-higher upper cutoffs. Modulation frequencies ranged from 4 to 128 Hz for the 400-Hz bandwidth, 4 to 256 Hz at the 800- and 1600-Hz bandwidths, and 4 to 512 Hz at the 3200-Hz bandwidth. Again, threshold runs were discarded if the modulation depth requested by the tracking procedure would have resulted in overmodulation (i.e., 20 log $(1/m)<0$ dB). As a result, 12 out of 448 (112 conditions $\times 4$ subjects) threshold estimates could not be obtained. In cases where a threshold estimate could not be obtained for a particular subject, the mean thresholds reported below represent the mean of the remaining subjects.

A spectral analysis of the analog signals revealed low-level distortion at the frequency of modulation, approximately 55 dB below the spectral level of the bandlimited-noise stimuli. After extensive listening experience, several of the listeners reported hearing a low pitch associated with this distortion when the modulation frequency was 512 Hz, but not for lower modulation frequencies. For those listeners, sensitivity to modulation was better at 512 Hz than at the 256 Hz modulation frequency, suggesting that the distortion was indeed a cue for detection at 512 Hz. Listeners who did not report such a pitch sensation had poorer sensitivity to modulation at 512 than at 256 Hz.[2] To mask distortion components at the frequency of modulation, a low-pass noise (0 to 600 Hz, No=35 dB SPL) was included in all conditions. The low-pass noise was generated in the same manner as the carrier band and both were played simultaneously (409.6 ms) via separate D/A converters. The two noises were mixed using a dual-channel adder (TDT SM1).

C. Results and Discussion

Modulation thresholds were consistent across the four listeners and the mean modulation-detection thresholds are shown in Fig. 4. Each panel represents a different noise bandwidth, with the symbols denoting the various upper-cutoff frequencies. The pattern of thresholds with modulation frequency is similar to those in experiment 1, showing the characteristic low-pass form with considerable overlap in

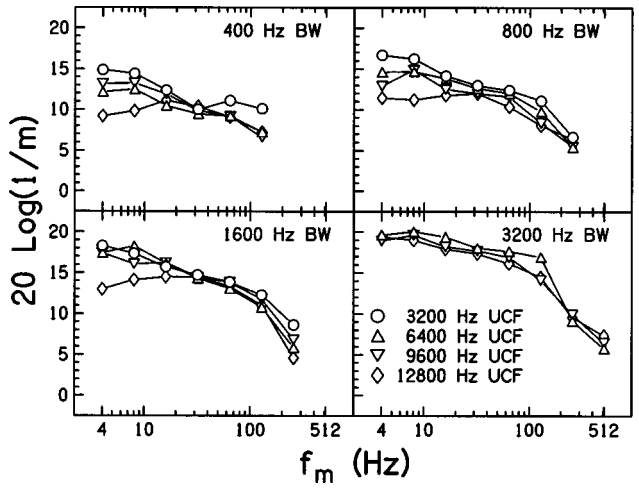

FIG. 4. Amplitude modulation-detection thresholds as a function of modulation frequency from experiment 2. As in Fig. 1, each panel represents a different noise bandwidth and the symbols denote the different noise-band upper-cutoff frequencies.

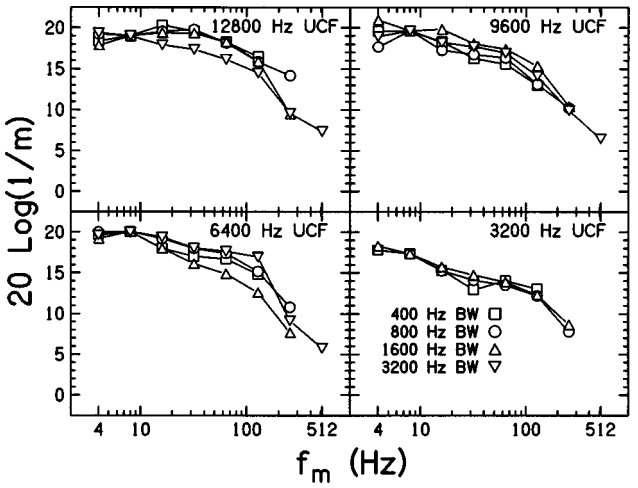

FIG. 5. Data replotted from Fig. 4 with thresholds from the different upper-cutoff frequencies shown in separate panels. The data in each panel are normalized to the highest threshold at the 8-Hz modulation frequency.

thresholds from the different upper-cutoff frequencies. A close comparison of the data in Figs. 1 and 4 reveal two differences in the results from experiments 1 and 2. First, the modulation-transfer functions from experiment 2 are flatter, especially for the narrower bandwidths, reflecting a higher low-pass cutoff frequency. Second, while there was little effect of signal frequency in experiment 1, experiment 2 reveals a reduced sensitivity to modulation at the 12 800-Hz upper-cutoff frequency for modulation frequencies of 4 and 8 Hz, at least for the narrower bandwidths. For modulation frequencies greater than 8 Hz, there was no systematic variation across the four upper-cutoff frequencies. The effect of stimulus bandwidth on the sensitivity to modulation is apparent when comparing across the different panels of Fig. 4. As in experiment 1, the modulation-transfer functions shift upward with increasing noise bandwidth, with sensitivity increasing from about 12 dB at the 400-Hz bandwidth to about 20 dB at the 3200-Hz bandwidth.

To better compare the shape of the transfer functions across noise bandwidth, the thresholds in Fig. 4 have been replotted in Fig. 5 with upper-cutoff frequency represented in the different panels and bandwidth shown by the symbols. As in Fig. 2, each transfer function has been normalized to the maximum threshold obtained at the 8-Hz modulation frequency for a given upper-cutoff frequency. Unlike the data in Fig. 2, there is no systematic influence of stimulus bandwidth on the shape of the function. The results of the curve-fitting procedure described above are shown in Fig. 6, with τ and k values in the same format as in Fig. 3. The solid lines in each panel represent values taken from experiment 1, averaged across upper-cutoff frequency. The τ values in the upper panel show little systematic variation with noise bandwidth, unlike those of experiment 1. Sensitivity to modulation, $10 \log_{10}(k)$, on the other hand, increased with increasing bandwidth, much the same as in experiment 1.

As noted above, sensitivity to modulation was reduced at modulation frequencies of 4 and 8 Hz in the 12 800-Hz upper-cutoff condition relative to the other three upper-cutoff frequencies. It is possible that this result reflects reduced audibility at the highest upper-cutoff frequency. For two listeners, however, pure-tone thresholds were <20 dB SPL from 8000 to 13000 Hz, yet they also demonstrated reduced sensitivity to modulation at 4 and 8 Hz. To further evaluate the possibility that stimulus audibility contributed to this reduced sensitivity, the two listeners who demonstrated the greatest difference in modulation detection at 3200 and

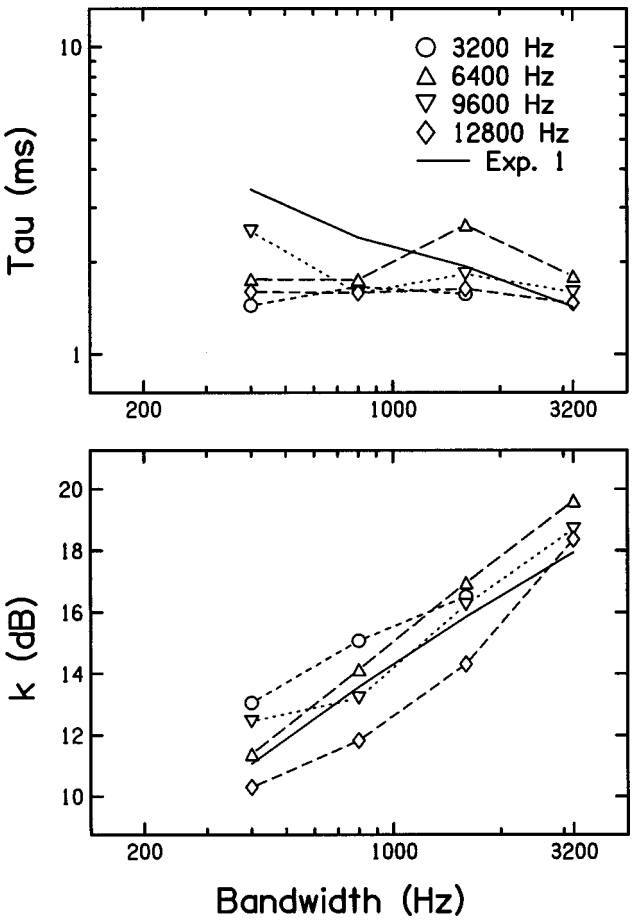

FIG. 6. Constants estimated by the fitting procedure, averaged across the listeners of experiment 2. The solid lines represent estimates taken from experiment 1, averaged across the different upper-cutoff frequencies.

12 800 Hz ($f_m = 8$ Hz) were retested on a subset of conditions in which the spectrum level was increased from 45 to 60 dB SPL. These conditions included a 400-Hz bandwidth, modulation frequencies of 8 and 16 Hz, and upper cutoffs of 3200 and 12 800 Hz. For both listeners, thresholds were nearly identical at the two spectral levels, further indicating that audibility cannot account for the reduced sensitivity to modulation.

A second possibility is that, under typical conditions, modulation detection is enhanced by a spread of excitation to more basal regions of the cochlea, as suggested by Zwicker (1956). Furthermore, the masking-period patterns reported by Zwicker (1976) indicated that this enhancement of modulation depth was greatest for low-modulation frequencies (<64 Hz). Though three of the four subjects of experiment 2 had rather good hearing sensitivity up to 13 000 Hz, it is very likely that this sensitivity declined rapidly at slightly higher frequencies, although thresholds were not measured above 13 000 Hz. If that were the case, then there would be little benefit from an upward spread of excitation for the highest-frequency condition. Others have argued, however, that if inherent fluctuations of the noise carriers limit modulation detection, then the upward spread of excitation would provide little benefit, as both the fluctuations of the noise and the applied modulation would be enhanced (e.g., Maiwald, 1967; Dau *et al.*, 1997a). These authors further argue that, since the nonlinear effects of upward spread of excitation are highly level dependent, modulation detection in narrow-band noise should also be level dependent. There is no empirical evidence to indicate such a level dependence. At this time, there is no clear explanation for the reduced sensitivity to modulation at 4 and 8 Hz, with a UCF of 12 800 Hz.

Although no model simulations are reported here, the present data are entirely consistent with predictions based upon the modulation-filter-bank model of auditory processing mentioned in the introduction (Dau *et al.*, 1997a,b). That model has been used to demonstrate spectral integration of temporal information in various tasks including modulation detection. Using stimuli that were filtered after modulation (cf. experiment 1), the model predicted essentially no effect of stimulus frequency region for audio frequencies from 600 to 4400 Hz, and predicted an inverse relation between carrier bandwidth and the low-pass cutoff of the modulation-transfer function. Of course, the model was subject to the same stimulus limitations imposed by filtering after modulation seen in experiment 1, namely a modulation frequency-dependent reduction in modulation depth. If model simulations were based upon AM vs. QFM stimuli, as in experiment 2, such a reduction in modulation depth would not be present and there would be no basis for a bandwidth effect. To consider model predictions for increases in the carrier frequency to 12 800 Hz, note that the modulation-filter-bank stage is independent of audio frequency, whereas basilar-membrane filtering is simulated by a bank of gammatone filters in the audio-frequency domain with bandwidths proportional to their center frequency. An extension of these basic elements to audio frequencies as high as 13 000 Hz would continue to predict a trading relation between the number of active basilar-membrane filters and the width of those filters when presented with stimuli of fixed absolute bandwidth. Processing in the modulation frequency domain would remain the same, resulting in model predictions in agreement with the present data.

IV. SUMMARY AND CONCLUSIONS

Thresholds for the detection of amplitude modulation were measured as a function of the modulation frequency using bandlimited-noise carriers. The resulting modulation-transfer functions may be used to characterize auditory temporal acuity. Two important issues addressed by these experiments concerned whether estimates of auditory temporal acuity vary across carrier frequency and whether previously reported changes in the shape of the modulation-transfer function with stimulus bandwidth are directly related to the technique of filtering after modulation. The following conclusions can be drawn on the basis of the two experiments reported.

(1) When the stimuli were bandpass filtered after amplitude modulation (experiment 1), the resulting modulation-transfer functions varied systematically with carrier bandwidth, resulting in wider -3-dB bandwidths, shorter time constants, and increased sensitivity to modulation with increasing carrier bandwidth.
(2) When the standard stimulus was a quasifrequency-modulated (QFM) noise and the signal was an unfiltered, amplitude-modulated noise (experiment 2), the shape of the resulting modulation-transfer functions varied little with carrier bandwidth, but the sensitivity to modulation improved with increasing bandwidth.
(3) Combined, one may conclude from the two experiments that the common technique of filtering after modulation reduces the effective modulation depth substantially, having the greatest effect for high-modulation frequencies and narrow-noise bandwidths.
(4) Temporal acuity, as estimated by amplitude-modulation detection, does not vary over a range of audio frequencies from 600 to 12 800 Hz.

APPENDIX: MODULATION DETECTION WITH AND WITHOUT A LOW-PASS NOISE MASKER

During the course of experiment 1 it became apparent that at least one of the listeners was able to use low-level distortion at the frequency of modulation to improve modulation detection when the modulation frequency was 512 Hz. The distortion at the frequency of modulation had a spectral level of -10 dB SPL, or approximately 55 dB below the spectrum level of the nominal signal. This led to the use of a 600-Hz low-pass noise masker in experiment 2. To evaluate how a low-pass masker might influence modulation detection

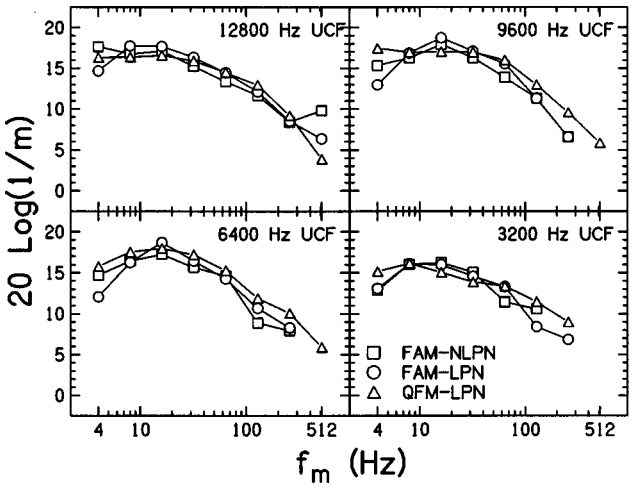

FIG. A1. Amplitude modulation-detection thresholds as a function of modulation frequency for three stimulus manipulations: filtering after modulation with no low-pass noise masker (FAM–NLPN, squares), filtering after modulation with low-pass noise (FAM–LPN, circles), and the QFM technique with low-pass noise (QFM–LPN; triangles). The noise-carrier bandwidth was 1600 Hz, presented at a spectral level of 45 dB SPL. The 600-Hz low-pass noise, when presented, had a spectral level of 35 dB SPL and was gated with the carrier stimulus.

at other modulation frequencies, the following measurements were conducted. Modulation-transfer functions were obtained using the filtering-after-modulation technique with and without a 600-Hz low-pass noise masker. The stimulus conditions included a 1600-Hz bandwidth at upper-cutoff frequencies of 3200, 6400, 9600, and 12 800 Hz and modulation frequencies in octave steps from 4 to 512 Hz. Three of the listeners from experiment 1 participated. These listeners also participated in a pilot experiment using the QFM technique of experiment 2. Since that pilot experiment employed the spectral conditions outlined above, those data are included here for comparison.

Figure A1 shows modulation-detection thresholds for the three stimulus manipulations: filtering after modulation with no low-pass noise (FAM–NLPN), filtering after modulation with low-pass noise (FAM–LPN), and the QFM technique with low-pass noise (QFM–LPN). All data points represent the mean across three listeners with the exception of the 512-Hz modulation frequency at the 12 800-Hz upper cutoff, in which case reliable thresholds could be measured for only two of the three listeners. Several data points are missing at modulation frequencies of 256 and 512 Hz, where at least two listeners failed to achieve reliable threshold estimates. In general, the modulation-transfer functions in each panel are quite similar, indicating no strong effects of the presence of low-pass noise. One notable exception occurs at the 12 800-Hz UCF, $f_m = 512$ Hz, where detection was clearly best in the FAM–NLPN condition, presumably reflecting the use of distortion at the modulation frequency to detect the signal. When masking was added, the threshold dropped markedly. A second exception occurs at the 4-Hz modulation frequency, where the presence of low-pass noise resulted in reduced sensitivity to modulation by about 1.9 dB. The low-pass noise did not reduce sensitivity at other modulation frequencies. Using the low-pass filter-fitting technique described in the Sec. I, mean τ values were 1.6 and 1.7 ms with and without the low-pass noise, and were 1.2 ms for the QFM conditions. These results are consistent with the data from the main experiments. What is clear from these data is that low-pass filtering had a negligible effect on the general form of the modulation-transfer function for these stimulus conditions. One may conclude, therefore, that it is reasonable to compare the data of experiments 1 and 2 despite differences in the presence of a low-pass masker.

[1]Pilot experiments have shown that modulation detection does not depend upon the choice of QFM or random-phase side components for the noise standard. QFM noise bands were chosen as the standard in experiment 2 to be consistent with several experiments in progress in which the discrimination of AM and QFM tones is being measured.

[2]Low-level distortion at the frequency of modulation also was present in the stimuli of experiment 1. Indeed, one of the five listeners (listener 1) in experiment 1 did have reliable threshold estimates at the 512-Hz modulation frequency, and those thresholds were better than her thresholds at the 256-Hz modulation frequency. When specifically asked, that subject reported hearing a low pitch associated with the modulation frequency. The other four listeners may not have benefitted from this potential cue, consistent with the fact that those listeners could not detect modulation at a rate of 512 Hz.

In addition to masking distortion at the modulation frequency, it is also possible that the presence of the low-pass noise in experiment 2 influenced the form of the modulation-transfer function. If so, then it would be difficult to compare the results of experiment 1, which did not include a low-pass masker, to those of experiment 2. As shown in the Appendix, modulation detection with and without the low-pass noise was nearly identical for three of the five listeners in experiment 1. Thus, it is unlikely that differences between experiments 1 and 2 reflect the presence of the low-pass masker in experiment 2.

Strickland and Viemeister (1997) reported a similar phenomenon at a modulation frequency of 512 Hz and attributed the improved detection at high-modulation frequencies to aural-distortion products. An informal series of measurements in our lab, however, failed to reveal detectable changes in the level of otoacoustic emissions in the region of the modulation frequency when comparing unmodulated and amplitude-modulated noise using stimuli identical to those of experiment 1.

Some aspects of the lateralization of echoed sound in man. II. The role of the stimulus spectrum[a)]

(Received 29 December 1997; revised 1 July 1998; accepted 8 October 1998)

The lateralization of clicks and their ''echoes'' was investigated with a view to determining the role of spectral characteristics in lateralization. Lateralization-discrimination performance was measured in a number of two-interval, two-alternative forced-choice experiments using three pairs of binaural clicks designed to elucidate how spectral cues are used in lateralization. The stimulus in one observation interval comprised a diotic click followed, after the interclick interval (ICI), by a dichotic click with either (1) an interaural time delay or (2) an interaural amplitude difference. The dichotic click was in turn followed, after an ICI of the same size, by another diotic click. In the second observation interval, the signals to the two ears were interchanged. The stimulus has the property that the signals delivered to the two ears had either (1) identical energy-density spectra but nonzero interaural-phase differences (IPDs) or (2) zero IPDs but nonidentical energy-density spectra. Under certain circumstances, observers perceived these stimuli as arising from the side of the head opposite that which would be predicted from the direction of the interaural cue in the temporal waveform. Joint consideration of the psychophysical data and the spectral characteristics of the stimuli strongly suggest a spectral ''dominance region'' for lateralization near 750 Hz, observers' lateralization performance was determined predominantly by the IPD cues from this region. In general, the results demonstrate that echoes of transients that arrive within about 2–3 ms of an initial transient are not suppressed, but have a substantial effect on lateralization through their contribution to the resultant spectral characteristics. The results contradict models that represent the precedence effect as the temporary suppression or inhibition of directional information in echoes over 2–3 ms after an initial transient.

INTRODUCTION

Acoustic reflections abound in virtually every environment. Nonetheless, our ability to localize a sound to its source is accurate and appears to depend on directional information in the sound that arrives at the ears first. It has been proposed that the auditory system avoids the problem of reflections by selectively suppressing directional information in reflections that arrive within a few milliseconds of the sound that reaches the ears first via the most direct path (Wallach, Newman, and Rosenzweig, 1949; Zurek, 1980, 1987). The phenomenon is called the *precedence effect* (Wallach *et al.*, 1949).

Two pairs of clicks or brief, broadband noise bursts presented over headphones are often used to simplify the study of the precedence effect and an important parameter is the delay between the first arriving sound and its first ''echo''—the interclick interval (ICI) (Zurek, 1987; Blauert, 1997). Two commonly used stimulus configurations are shown in Fig. 1: The type I configuration (top panel), in which a dichotic click precedes a diotic click by the ICI, and the type II configuration (bottom panel), in which a dichotic click follows a diotic click. These configurations are used in forced-choice lateralization-discrimination paradigms to measure interaural time delay (ITD) thresholds in the dichotic click as a function of ICI (Zurek, 1976, 1980; Gaskell, 1978, 1983; Saberi and Perrott, 1990; Tollin, 1998a; Tollin and Henning, 1998a). The ICI affects the relative precision of lateralization based on information in either the first arriving sound or the echo. For ICIs between about 1 and 10 ms there are two classical features of the precedence effect: (1) ITD thresholds from type I configurations are constant and approximate the thresholds for a dichotic stimulus with no echo, and (2) type II ITD thresholds are 2–8 times larger (Zurek, 1976, 1980; Gaskell, 1978, 1983).

However, a different result appears with ICIs less than about 0.4 ms where the lateralization of both type I and type II stimuli depends on the interaural information in the sum of

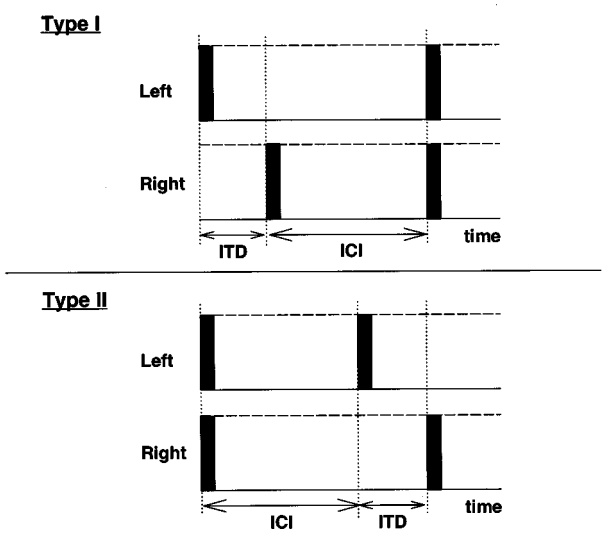

FIG. 1. Two stimulus configurations commonly used in discrimination studies of the precedence effect. The top panel shows the type I stimulus and the bottom panel, the type II.

the direct and echo clicks (Gaskell, 1978, 1983; Tollin and Henning, 1998a). Gaskell (1983) and Tollin (1998a) have suggested that the spectral characteristics of the stimuli determine how the type I and type II stimuli with small ICIs are lateralized. Their analyses concern what Warnke (1941) called *summing localization*—for short ICIs the perceived location of a direct sound and one of its echoes appears at some location determined jointly by the localization cues of both (e.g., Blauert, 1997, p. 204).

The temporal upper bound of summing localization with clicks is often assumed to be around 1.0 ms (Blauert, 1997), so the results and analyses of Gaskell (1983) and Tollin and Henning (1998a) for small ICIs can be assumed to relate solely to the phenomenon of summing localization. Results from other studies, however, indicate ''summing localization'' for ICIs larger than 1.0 ms. For example, both Wallach *et al.* (1949) and Yost and Soderquist (1984), using ICIs of 2 and 1 ms, respectively, found that the function relating the ITD of a first click required to center the intracranial image when the echo click had a fixed ITD was nonmonotonic. A monotonic function might be expected if the sensitivity to directional information in the ''echo'' click was reduced by the mechanism that produces the precedence effect. Moreover, when the first click had zero ITD and the echo click had a $+800$-μs ITD, Wallach *et al.*'s observers consistently reported that the stimulus was on the side of the head *opposite* the side expected from the ITD in the echo. Blauert and Cobben (1978) also observed consistent and regular anomalies in the localization of pairs of narrow-band transients for ICIs up to 3.0 ms (the largest ICI they used), and concluded that the delayed signal (i.e., the echo) obviously codetermined the perceived location of the click pair. Finally, Tollin and Henning (1998a) measured type II ITD thresholds that oscillated between moderate and high values as a function of ICI for ICIs up to 3.2 ms. All these results are difficult to reconcile with the traditional explanation of the precedence effect; that is to say, the results are not indicative of a mechanism which completely inhibits or reduces the effectiveness of the directional information contained in echoes arriving within a few milliseconds of the first click (for reviews, see Zurek, 1987; Blauert, 1997).

Subjective reports from studies of the precedence effect (e.g., Blauert, 1997 p. 216; Yost and Soderquist, 1984; Saberi and Perrott, 1995) share some striking similarities with reports from time-intensity trading experiments (e.g., Hafter and Jeffress, 1968)—diffuse, spacious, and ambiguous images are commonly reported. Observers in time-intensity trading experiments can sometimes discern two separate images, one associated with the interaural delay and one associated with the interaural-level difference (Hafter and Jeffress, 1968). This suggests independent roles for interaural time and level cues in time-intensity trading and may be similar in the lateralization of echoed sounds.

The interaural cues that are important to observers in the lateralization (or localization) of echoed sounds, however, are not readily apparent from their temporal waveforms. To gain further insight, spectral cues must be examined.

A. The problem

A direct sound and one identical (or highly correlated) echo (Fig. 1) produce an energy-density spectrum with periodic ripples (i.e., a comb filter). The periodicity of the cosinusoidal ripple is inversely proportional to the ICI. For each signal configuration shown in Fig. 1, there are two different time lags, one for each ear. Because the time lags differ, the rate of ripple in their resultant energy-density spectra differs; with the type II stimulus in Fig. 1, the rate of ripple in the right-ear signal will be slightly higher than in the left-ear signal. Thus, there will be interaural differences in energy density whose sign and size depends on both frequency and the delays between the clicks in each ear. The ratio of the left- and right-ear energy densities, the relative-energy-density spectrum (RED), displays the differences in energy density at the two ears and the associated interaural-level differences (ILDs) that affect lateralization. The interaural phase-difference (IPD) spectrum is also important, but as Gaskell has pointed out, provided the ITDs as well as the ICIs are identical, the IPD spectrum for the type I and type II stimuli will be identical (Gaskell, 1978, 1983; Tollin, 1998a).

Gaskell concluded that for ICIs greater than about 600 μs, the resultant spectral characteristics alone do not account in any simple way for the differences in lateralization in the two configurations. Although the IPD spectra of the type I and type II configurations are identical when their ICIs and ITDs are the same, the RED spectra for the two conditions are different; it is not immediately clear how these differences can explain the observed discrepancy in performance for ICIs greater than 600 μs (Zurek, 1980; Gaskell, 1983; Yost and Soderquist, 1984). However, this does not establish that the observers were not using the spectral characteristics for greater ICIs.

We investigated the role of spectral cues in the lateralization of clicks particularly to determine the roles of the RED- and IPD-based cues, using stimuli designed specifically to avoid the problems two-click stimuli raise. The re-

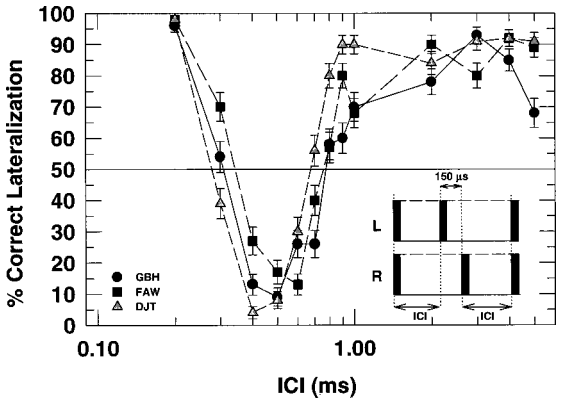

FIG. 2. The percentage of correct lateralization as a function of the ICI in ms (logarithmic axis) for three observers when the stimulus was the three-click stimulus shown in the inset. Each data point is based on 100 observations.

sults indicate the temporal limits over which lateralization cues are influenced by the spectra of the entire stimulus.

I. THREE-CLICK STIMULI: ITD IN THE SECOND PAIR

We can take advantage of the property of the Fourier transform that relates the energy-density spectrum of a given signal to the energy-density spectrum of its time-reversed pair: (1) The energy-density spectrum for a signal with a pure-time delay is identical to the energy-density spectrum of the undelayed signal, and (2) reversing time (i.e., playing the signal backward) does not affect the energy density either (Papoulis, 1962). Time-reversed stimulus pairs, then, have two important properties relevant to our study: (1) since their energy-density spectra are identical, the RED (in dB) will be zero for all frequencies so that (2) the signals differ only in their phase spectra and produce nonzero IPDs.

The three-binaural-click stimulus shown in the inset of Fig. 2 satisfies the conditions above; it is comprised of three equal-amplitude binaural clicks with an ITD of 150 μs in the second pair; the first and last clicks are diotic. Two ICIs are defined as those intervals between the onsets of the elements of the stimulus indicated in the inset of Fig. 2 and were identical in size to ensure that one signal was simply a time-reversed version of the other. In a companion publication, Tollin (1998b) derives the general equations used here to compute the spectral characteristics, including the RED and IPD.[1] When all the clicks are of equal amplitude, the energy-density spectra for the left- and right-ear signals of the three-click stimulus shown in Fig. 2 are identical, so the RED will be zero for all frequencies. However, the IPD will be nonzero at most frequencies and thus provides the *only* spectral cue to noncentral lateralization.

A. Experiment 1

1. Methods

The observers' ability to lateralize the stimuli of Fig. 2 was investigated. The experimental system was based on the Tucker–Davis Technologies (TDT) System II. The signals for the left and right ears were constructed digitally on a TDT AP2, downloaded to the dynamic memory of a TDT DA3-4 analog-to-digital converter (DAC), and converted to full-scale analog voltages (16 bit) by separate DACs at a rate of 200 kHz. The left and right signals were independently attenuated (TDT PA4), low-pass filtered at 10 kHz (Kemo VBF/3, 24 dB/octave), and delivered in parallel via three TDT HB6 high-impedance dual-channel headphone buffers to three matched pairs of TDH-39 earphones driven in phase and mounted in Grason–Stadler 001 muffs.

The stimuli were constructed from sums of scaled and delayed 20-μs clicks. The response to a single 20-μs click over the TDH-39 earphones had a total duration of approximately 500 μs [measured using a 6-cc coupler and a condenser microphone to observe the signal on an oscilloscope (Gaskell, 1978)]. The level of a single click corresponded to approximately 30 dB SL.

A two-interval, two-alternative forced-choice discrimination paradigm was employed in which the observers were required to indicate which of two observation intervals contained the left-most-appearing stimulus. The stimulus in the inset of Fig. 2 represents the stimulus configuration for only one observation interval and, on the basis of the ITD shown, was designated the ''correct'' stimulus. In the second interval, the signals to the ears were reversed. The ITD in the second pair of clicks was fixed at 150 μs because, in the absence of a second echo, observers achieve at least 70% correct over the 0.8–to 6.4-ms range of ICIs which elicit the precedence effect (Tollin and Henning, 1998a; Tollin, 1998a). Three experienced observers with normal hearing (including the two authors, DJT and GBH) from the study of Tollin and Henning (1998a) participated in these experiments. They received no additional practice sessions. Preliminary experiments revealed some ICIs for which performance was consistent but anomalous in that lateralization performance was near 10% correct (Tollin and Henning, 1996); the stimuli were lateralized consistently but in the direction *opposite* that which would have been expected from the ITD. Consequently, in order not to confuse the observers, we gave no feedback.

One of 13 ICIs between 0.1 and 5 ms was psuedorandomly chosen (without replacement) and held constant for 50 presentations. On each trial, the probability that the ITD in the middle click led in the left ear in the first observation interval was 0.5. The beginning of a trial was marked by briefly illuminating an LED on each observers response box. LEDs were also used to indicate the onsets of the two observation intervals, which were separated by a 600-ms pause. After the observation intervals, the observers had a 1-s response interval before the next trial began. Once all the 13 ICIs were used, the process was repeated to yield 100 observations from each observer at each ICI.

2. Results

Figure 2 shows the percent-correct lateralization as a function of ICI. (The error bars in this and all subsequent plots indicate the range of performance corresponding to ± 1.0 standard deviation, assuming that the numbers of correct responses were binomially distributed.) As ICI increases from 0.2 to 0.5 ms, the observers' performance decreases from near 100% correct to 8%–17% ''correct.'' Thus, from

good lateralization at a short ICI in the sense consistent with the ITD in the middle click, the observers go to consistent but *anomalous* lateralization at an ICI of 0.5 ms. As the ICI increases from 0.5 to 1.0 ms, the observers' performance rises from 8%–17% to 68%–90% correct. By an ICI of 2.0 ms, the observers generally achieve performance levels greater than 75% correct.

Anomalous lateralization occurs for ICIs from 0.3 to approximately 0.8 ms. Here, the observers perceived the stimulus configuration in the inset of Fig. 2 as coming from the right, even though the 150-μs ITD in the second pair of clicks favors the left ear. The total stimulus duration is twice the ICI plus the ITD, so that anomalous lateralization occurred for stimuli with total durations from 0.75 to about 1.75 ms.

3. Discussion

It has been suggested that the precedence effect with clicks operates optimally at ICIs between 1 and 2 ms (Wallach *et al.*, 1949; Zurek, 1987; Litovsky *et al.*, 1997). Consistent with this view, Tollin and Henning (1998a) found that for a type II configuration, the same three observers require an ITD of about five times that needed to lateralize a single dichotic click for ICIs in the range of *total* durations for which they show anomalous lateralization here. Gaskell (1983) and Saberi and Perrott (1990) report similar observations with their type II stimuli. In all three of these studies, the largest increases in the ITD threshold occurred with type II stimuli with ICIs between about 1 to 2 ms. It is not surprising, then, that it has been suggested that the precedence effect with clicks operates optimally at these ICIs.

It is tempting to attribute the decreased lateralizability in the two-click experiments to the effects of an echo-suppression mechanism which suppresses directional information in clicks that arrive a few milliseconds after the leading click (e.g., Zurek, 1980, 1987). But our results with three-click stimuli suggest that this is not the case. A mechanism that suppressed directional information in an echo presented 0.6 ms after the direct click would surely suppress the directional information in another echo added only 0.75 ms later (i.e., 1.35 ms after the direct click). But the data of Fig. 2 clearly show that the presence of the third click substantially influenced the perception of these stimuli, even when it was presented up to 2 ms after the direct click. Anomalous lateralization with the three-click stimuli should never occur if the directional information in the first and second echoes were simply suppressed; suppression would lead to performances near 50% correct; no suppression at all would lead to performance near 100% correct. The observers, however, perform consistently near 10%.

B. Supplementary experiment 1

There is considerable similarity between three-click stimuli and the type II configuration: The only lateralization cue in each configuration is an ITD which, after the ICI follows a diotic click that, on its own, provides no useful cue for lateralization in a discrimination task. The three-click stimulus is simply a type II stimulus followed, after an ICI of the same size, by an additional diotic echo. In this experiment, we investigate the effect of adding a second diotic echo 1.45 ms after the onset of the first click on the lateralization of the preceding type II stimulus by manipulating the amplitude of the second echo.

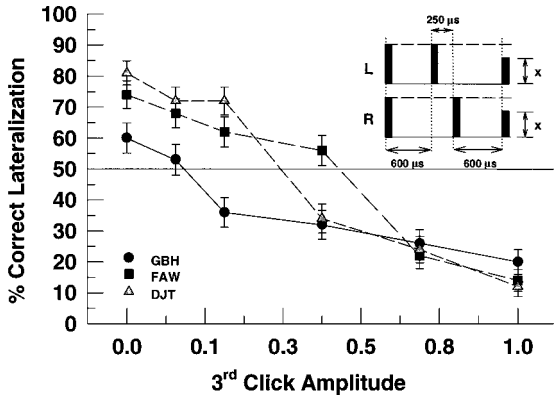

FIG. 3. The percentage of correct lateralization as a function of the amplitude, *x*, of the third binaural pair of clicks relative to the amplitude of the preceeding clicks in the stimulus shown in the inset. The stimulus was a three-click stimulus with an ICI of 600 μs and an ITD of 250 μs. Each data point is based on 100 observations.

1. Methods

The stimulus comprised three binaural clicks with an ICI of 600 μs and an ITD of 250 μs in the first echo; the amplitude of the diotic second echo was manipulated. The inset of Fig. 3 shows the stimulus configuration presented in one observation interval. The experiment was identical to the first experiment except that here, one of six relative amplitudes, *x*, of the third pair of clicks was selected and held constant for 50 trials. Each amplitude was used twice to yield 100 observations per amplitude for each of the same three observers.

2. Results

Figure 3 shows the percentage of correct lateralization judgments as a function of the normalized amplitude of the third pair of clicks (a value of 1.0 corresponds to the 30-dB SL level of our standard click). As the amplitude increased from 0.0 to 1.0, the performance of all observers *decreased* from 60%–80% to 10%–20% correct.

The 250-μs ITD required for consistent and correct performances with zero amplitude (i.e., a type II stimulus) would, on the lines of previous ''explanations'' of the precedence effect, be attributed to suppression of the directional information in the echo click. However, if the directional information in the second pair of clicks were indeed suppressed, one might reasonably expect that the directional information in the third click added a short time later should also be suppressed. Consequently, the third click should have either (1) not affected performance or, (2) because it had zero ITD, simply reinforced a central location. In the former case, performance should not have changed for any amplitude and in the latter case, performance should have approached 50% correct. Neither of these results occurred. The addition of a third pair of clicks, the second echo, contrib-

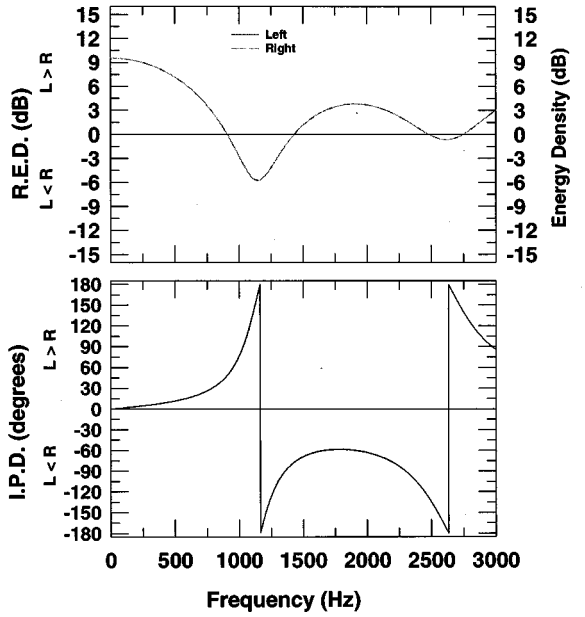

FIG. 4. The right-hand ordinate of the top panel shows the energy-density spectra for the stimuli delivered to the left (solid line) and right (dashed line) ears for the three-click stimulus with an ICI of 200 μs and an ITD of 150 μs in the middle click. The left-hand ordinate of the top panel shows the relative-energy density, RED, over the same frequency range. The bottom panel shows the interaural-phase delay (IPD) in degrees for both stimuli.

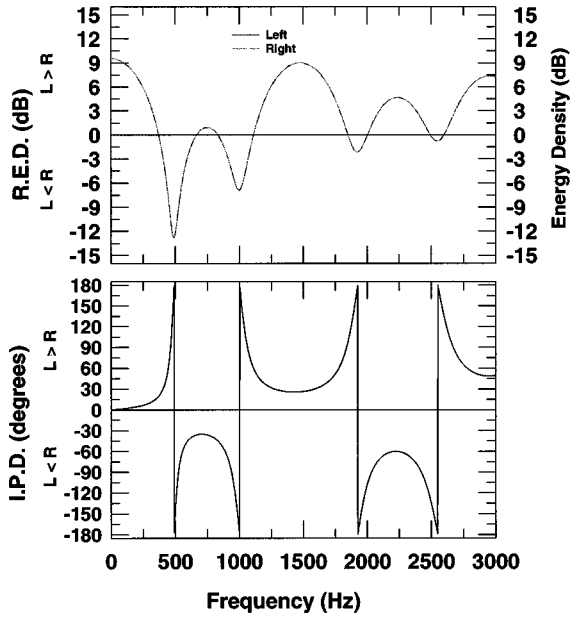

FIG. 5. The spectral characteristics for the three-click stimulus with an ICI of 600 μs and an ITD of 150 μs in the middle click.

uted substantially to the overall perception of the complex, even when its amplitude was 18 dB below the amplitude of the preceding clicks. Thus, neither the information in the second nor the third pair of clicks was suppressed, and echo suppression does not explain the data in Fig. 2 or 3. We require an alternative explanation.

C. Spectral characteristics

Consider the spectral characteristics of the three-click stimuli of experiment 1 for three different ICIs chosen because observers lateralized them differently. The spectral characteristics were computed by specializing the general equations derived in Tollin (1998b) for the three-click stimulus shown in the inset of Fig. 2. The top panel of Fig. 4 shows the energy densities (dB, right-hand ordinate) for the left- and right-ear stimuli which were easily and correctly lateralized—the stimulus had an ICI of 200 μs and an ITD of 150 μs. The energy-density spectra for the left- and right-ear signals are identical so that only one spectrum can be seen and, consequently, the relative-energy density (RED dB, left-hand ordinate) is zero.

The bottom panel of Fig. 4 shows the IPD (in degrees) over the same frequency range. The IPD spectrum provides the *only* cue to noncentral lateralization. The IPD leads in the left ear for frequencies up to nearly 1250 Hz. Further, the energy-density spectra in the top panel reveal that there is energy in this low-frequency region. Since the binaural system is known to be most sensitive to interaural-phase differences for frequencies below 1500 Hz (Rayleigh, 1907; Zwislocki and Feldman, 1956; Henning, 1983), and given that there is energy in the low-frequency region, the highly consistent lateralization achieved by all the observers might reflect their use of the IPD cue around 750 Hz. At 750 Hz, the IPD is on the order of $+30°$ (a left-ear lead of approximately 110 μs).

When the ICI was 600 μs, the observers showed highly consistent but anomalous lateralization near 10% correct. Figure 5 shows the spectral characteristics where, in the frequency ranges 0–500 and 1000–2000 Hz, the IPD shows the left ear leading. If the observers used the IPD cues in either of these frequency regions, they would achieve consistent performances at least better than 50% correct. But given the low energy in the band of frequencies around 500 Hz it is unlikely that the IPD cues from this region could be used. Had the observers used the band of frequencies just below 1500 Hz—where the energy density is high—lateralization above 50% correct would have been expected. But lateralization of this stimulus is consistent and anomalous.

The spectra in Fig. 5 show that in the frequency region between 500–1000 Hz, the IPD favors the right side. At 750 Hz, there is an IPD of $-35°$, which corresponds to an ITD of about 130 μs favoring the right ear. The energy-density spectrum reveals that the intensity of the band of frequencies around 750 Hz was only 8 dB below the levels in the bands centered on 1500 Hz and the lower-frequency regions. If the observers used the IPD information from this region, they would be expected to achieve consistent but anomalous levels of performance and they do; the observers get about 10% correct. The IPDs in the spectral region centered on 2500 Hz are also consistent with the anomalous lateralization. [Note that Henning (1983) has shown that for high-frequency transients, observers are not sensitive to the IPD *per se*, but rather the group delay—the local rate of change of the IPD spectrum. The rapid rates of change of the IPD spectrum of our stimulus occur where the energy density is not zero, so that very large group delays are present and this frequency region remains a possible source of information.]

Finally, when the ICI was 1000 μs, all three observers

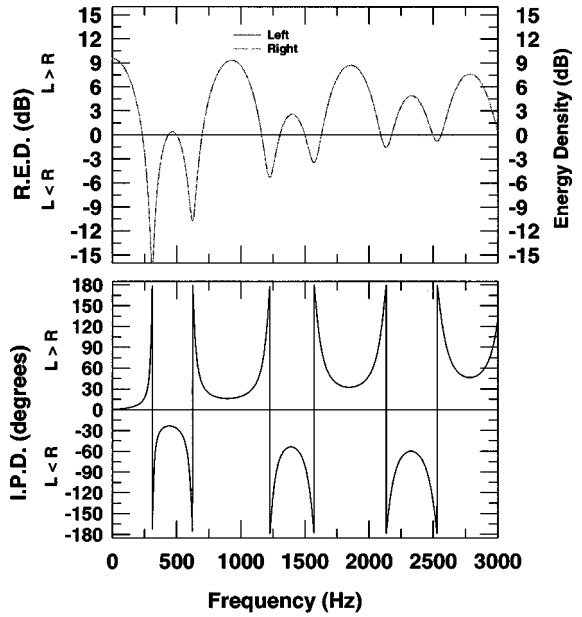

FIG. 6. The spectral characteristics for the three-click stimulus with an ICI of 1000 μs and an ITD of 150 μs in the middle click.

achieved performances of 70% correct or better. Figure 6 shows the relevant spectra. The IPDs favoring the left ear now occupy a region from just above 600 to 1200 Hz and the energy density shows a local maximum near 900 Hz. The observers' performance might be due to their using the interaural-phase information in that frequency region, since the IPD at 900 Hz is $+15°$—a left-ear lead of 45 μs and consistent with performance. The observers did not seem to be distracted by the large negative IPDs near 500 Hz, even though at 500 Hz there is also a local energy maximum. At 500 Hz there is an IPD of $-27°$, 150 μs favoring the right ear. If the observers used the lateralization information in this region, consistent but anomalous lateralization might be expected. This was not the case, showing that the observers did not rely on the IPD information from this region.

D. Discussion

Anomalous lateralization similar to that observed here is not new; it has been observed elsewhere with clicks (Gaskell, 1983; Wallach *et al.*, 1949) and with brief noise bursts (Zurek, 1980). Anomalous localization has also been reported with broad- and narrow-band clicks (David and Hanson, 1962; Blauert and Cobben, 1978). Anomalous performance has usually been observed with two-click stimuli in response to changes in the interaural *amplitude* of a zero-ITD echo which follow a simultaneous equal-amplitude diotic pair. The anomalous lateralization observed here was produced by an interaural *delay* in the second pair of three equal-amplitude clicks.

Further consideration of the spectral characteristics of the three-click stimuli at the remaining ICIs suggested that the observers used the interaural-phase differences from the frequency band around 750 Hz when they could. This seemed to be the case even when the level in the band was 8 dB below neighboring bands. Provided the ICI was 1 ms or less, lateralization performance could be accounted for by

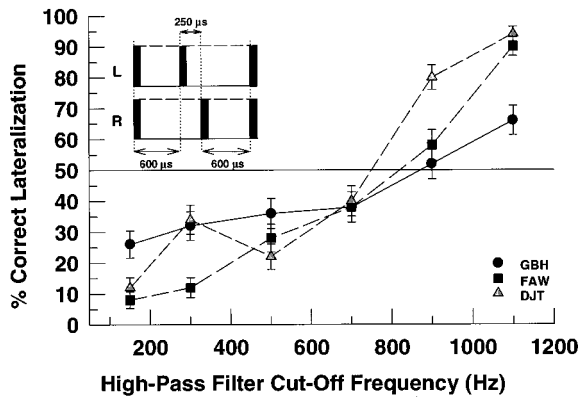

FIG. 7. The percentage of correct lateralization as a function of the high-pass-filter cutoff frequency for three observers for the three-click stimulus with an ITD in the dichotic second pair of clicks of 250 μs and an ICI of 600 μs. Each point represents 100 observations.

assuming that the observers used (or gave more weight to) the IPD cues in the band around 750 Hz. The hypothesis that the spectral characteristics near 750 Hz were responsible for anomalous lateralization was tested in two supplementary experiments. We reasoned that if removing the interaural spectral characteristics consistent with the anomalous lateralization by filtering or making them inaudible by masking removed anomalous lateralization, then those interaural spectral characteristics were likely to be responsible for the anomalous lateralization.

E. Supplementary experiment 2 a: Effects of high-pass filtering

The three-click stimulus, shown in the inset of Fig. 7, had an ICI of 600 μs and an ITD of 250 μs. The solid lines

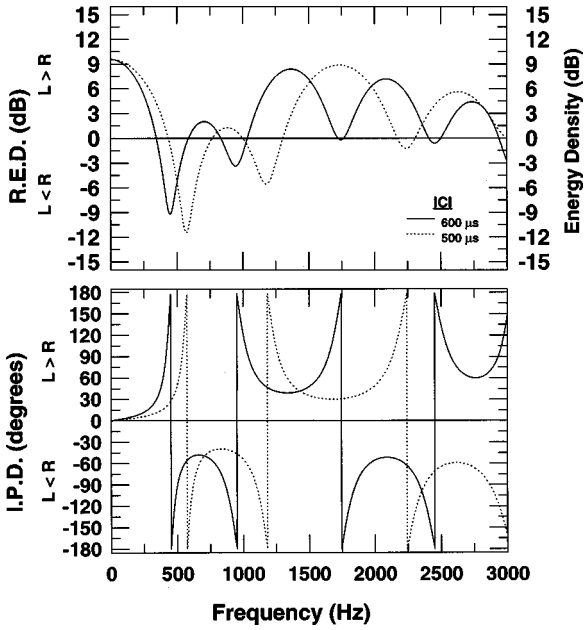

FIG. 8. The spectral characteristics of the two three-click stimuli used in supplementary experiments 2 a and 2 b. The solid lines in each panel show the spectral characteristics for the three-binaural-click stimulus with an ICI of 600 μs and ITD of 250 μs and the dotted lines show the characteristics for the stimulus with an ICI of 500 μs an ITD of 150 μs.

in the top and bottom panels of Fig. 8 show spectra of this stimulus. Our hypothesis predicts anomalous lateralization consistent with the IPD around 750 Hz. By selectively filtering out the components near 750 Hz, it should be possible to see whether the IPDs there were indeed responsible for lateralization.

1. Methods

The same observers participated and the signal generation, experimental apparatus, and the lateralization task were as described in Sec. II A 1, except that the filters were operated in high-pass mode using six high-pass cutoff frequencies between 125 and 1100 Hz. One cutoff frequency was chosen and held constant for 50 trials. Once all six cutoff frequencies had been exhausted, the process was repeated resulting in 100 observations for each cutoff frequency per observer.

2. Results

Figure 7 shows percentage-correct lateralization as a function of the high-pass cutoff frequency. When the cutoff was 200 Hz, observers' lateralization was consistent but anomalous (8%–26% correct). As the cutoff frequency rose to 750 Hz, lateralization approached chance performance (50%). When the cutoff frequency was raised to 1100 Hz, correct performance was achieved for two observers (90%–94%), 66% for the other. Anomalous lateralization disappeared when the 750-Hz band was removed.

One reasonable strategy for observers in these and other precedence-effect experiments (and presumably in actual acoustical environments) where the resultant spectral characteristics of the signals at the two ears may be quite complex, might be to use the interaural cues from only the frequency regions with the most energy. Inspection of the energy density of our stimulus (Fig. 8, solid lines) shows that the unfiltered stimulus has its maximum near 1300 Hz. The sign of the IPD in this region agrees with the ITD in the temporal waveform, so observers using information from this region would achieve performance *at least* greater than chance. But the data show that the observers do not behave in this manner. Rather, they appear to use the IPD cues near the local energy-density peak near 750 Hz.

There are, however, two frequency regions over which the IPD is consistent with anomalous lateralization: one near 750 Hz and the other near 2225 Hz. The data from the current experiment show that when frequencies below about 900 Hz are attenuated, anomalous lateralization disappears. When the high-pass cutoff frequency was 1100 Hz, all observers lateralized the stimuli significantly above chance, with their consistent, correct lateralization in agreement with the positive IPD near 1250 Hz. The results of this experiment, then, support our hypothesis that the anomalous lateralization of this stimulus arises from information the observers take from the region near 750 Hz.

F. Supplementary experiment 2 b: Effects of masking

A continuous pure tone was used to mask the 750-Hz frequency band in a three-click stimulus (not shown) with an ICI of 500 μs and an ITD of 150 μs in the second click; the dotted lines in the panels of Fig. 8 show its spectral characteristics. The IPD in the local energy-density peak near 850 Hz opposes the direction indicated by the ITD in the temporal waveform. Thus, we predict anomalous lateralization for this stimulus.

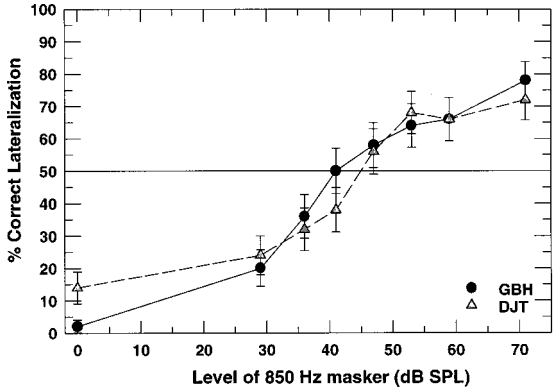

FIG. 9. The percentage of correct lateralization as a function of the level (in dB SPI) of a continuous 850-Hz tone for two observers when the stimulus was a three-click stimulus with an ICI of 500 μs and an ITD of 150 μs. Each point is based on 50 observations.

1. Methods

A continuous pure tone of 850 Hz, generated by a TDT WG2 waveform generator, was added with zero interaural-phase difference to the three-click stimuli through a TDT SM3 weighted-signal mixer. The level of the tone (dB SPL) was controlled via a TDT PA4 digital attenuator. Masker level was held constant for 50 trials and lower masker levels were used before higher. Aside from these additions, the experimental apparatus and psychophysical task were as described in Sec. I A 1. Two observers participated in this experiment.

2. Results

Figure 9 shows percentage-correct lateralization as a function of the level (dB SPL) of the 850-Hz masking tone. When the tone was not present, the observers lateralized anomalously (2% and 14% correct) as predicted. As the masker level increased, performance also increased. At a level of about 45 dB SPL, both observers were at chance performance. With further increases, performance increased above chance, so that at 71 dB SPL, both observers achieved near 75% correct.

Components in the band near 850 Hz were progressively masked by the tone as its level increased. Fletcher (1953) reports that an 800-Hz tone at 40 dB SPL provides 20 dB of masking over a band of frequencies between about 650 and 1000 Hz, corresponding to the bandwidth of the local energy-density peak near 850 Hz. With the tone at 45 dB SPL, both observers were near 50% correct. Thus, one way of interpreting the results is that the masking of the components near 850 Hz reduces the effectiveness of the interaural-phase-difference cues from that band, so for the observers to achieve the correct lateralization they exhibit, they must use cues from a different spectral location. But which? One pos-

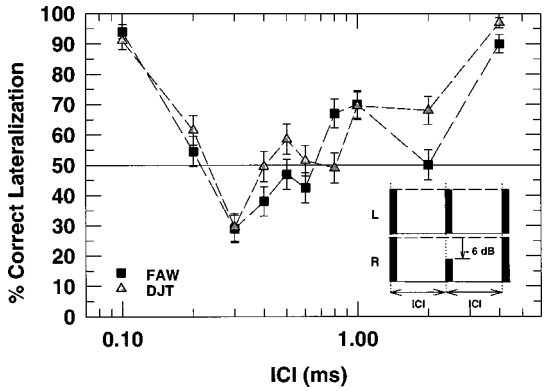

FIG. 10. The percentage of correct lateralization as a function of the ICI in ms (logarithmic axis) for two observers when the stimulus was the three-click stimulus shown in the inset. Each data point is based on 100 observations.

sible insight comes from the observers' reports that the clicks sounded higher pitched when the masker level was 53 dB SPL or greater than when the masker was either not present or at low levels. Examination of the IPD spectrum reveals that in the frequency regions between 1200 and 2250 Hz, the IPD is positive—consistent both with the observers' performance levels near 75% correct and their subjective impressions. Presumably, then, the observers were forced to use the interaural-spectral cues in this region when the masker level exceeded about 45 dB SPL and prevented their using information from their preferred spectral region near 750 Hz.

II. THREE-CLICK STIMULI—AMPLITUDE DIFFERENCE IN SECOND PAIR

We have explored observers' abilities to use interaural phase cues. However, IPDs are only one of the cues to lateralization. Stimuli can also be lateralized with interaural amplitude or energy differences (Tollin, 1998a). In this section, we use a stimulus (shown in the inset of Fig. 10) which has the unique property that the IPD spectrum is zero at all frequencies but the RED is nonzero. The stimulus comprises three clicks with equal ICIs and no interaural-time differences. Rather there is an interaural-*amplitude* ratio of 6 dB in the second click. Observers lateralize a single click with an interaural-amplitude ratio of 6 dB on the side receiving the more-intense click with 100% accuracy (Tollin, 1998a). For this stimulus, the RED represents the *only* interaural cue for noncentral lateralization, as the IPD is zero for all frequencies.

A. Experiment 3

The experiment investigated the ability to lateralize the three-click stimulus as a function of ICI. The stimulus, shown in the inset of Fig. 10, would be expected to be lateralized to the left on the basis of the interaural-amplitude difference favoring the left ear. The experimental apparatus and psychophysical procedure were as described in section Sec. I A 1. Ten values of ICI ranging from 0.1 to 5 ms were used. One of the values of ICI was chosen and held constant

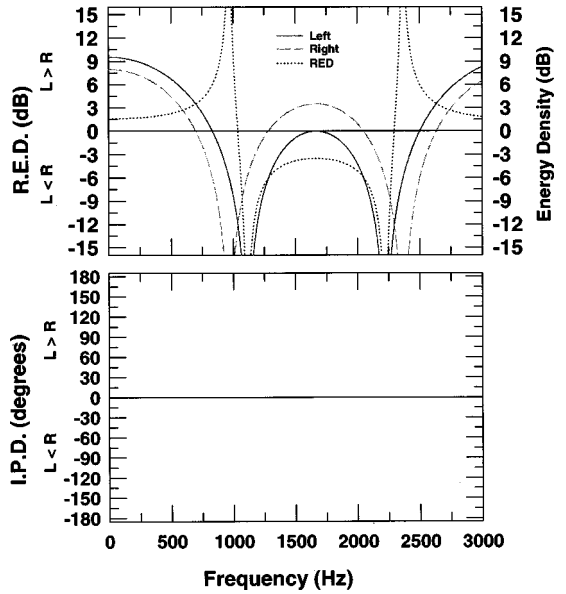

FIG. 11. The spectral characteristics of the three-click stimuli with an ICI of 300 μs and a 6-dB interaural-amplitude difference in the second pair of clicks.

for 50 trials. The process was repeated once all values were used to produce 100 observations for each of the two observers for each ICI. Two observers participated.

B. Results

Figure 10 shows the percentage-correct lateralization as a function of ICI. As the ICI increases from 0.1 to 0.3 ms, performance drops from greater than 90% correct to 30% correct. With an ICI of 0.3 ms, the observers hear the stimulus on the opposite side of the head from that expected from the interaural-amplitude difference in the second click. For ICIs from 0.3 to 0.6 ms, one observer lateralizes the stimuli somewhat anomalously (performance around or below 50% correct), while the other observer performs near chance. For ICIs greater than 1.0 ms, performance by and large improves so that by 4.0 ms, performance is 90% correct or better.

C. Spectral characteristics

The spectral characteristics of this stimulus were considered for each ICI we used but, in the interest of brevity, the spectral characteristics for only the 0.3-ms ICI condition are shown in Fig. 11. The IPD is zero for all frequencies. There are two regions in the frequency range shown where the RED favors the left ear, and one favoring the right. Only the RED in the region centered near 1500 Hz is consistent with the anomalous lateralization exhibited by the observers. But consideration of the RED around 1500 Hz for the stimulus with an ICI of 0.6 ms, where the observers performed at chance or slightly anomalously, reveals a positive RED over a large band; consequently, higher levels of performance would have been expected had the observers used the RED cues from this region.

When the interaural level of the second click pair was manipulated, no fixed spectral region could be found that yielded interaural-spectral characteristics consistently in

agreement with the observers' behavior. One possible explanation for this finding is that there may be no ''dominant region'' for interaural-level cues as there is for interaural time or phase cues (Bilsen and Raatgever, 1973). This is consistent with observers' roughly equal sensitivity to interaural-level cues across frequency (Mills, 1960; Grantham, 1984; Yost and Dye, 1988).

III. DISCUSSION

We have reviewed several instances where neither lateralization nor localization was consistent with the notion of simple postonset suppression of directional information in echoes. Consideration of the spectral characteristics of our various three-click stimuli revealed that spectral cues near 750 Hz were consistent with many of the observed results, particularly where the observers exhibited highly consistent, but anomalous lateralization. Consideration of the time-domain representation of the anomalously lateralized stimuli does not reveal why a particular stimulus configuration should be anomalously lateralized. Examination of the interaural phase-difference (IPD) and relative energy-density (RED) spectra, however, revealed cues which, if used by the observers, would clearly lead to anomalous lateralization.

A. Comparisons with other studies

Gaskell (1983) considered the spectral characteristics of the stimuli for which her observers exhibited anomalous lateralization—20-μs clicks in a type II configuration with no interaural delays, rather an interaural-amplitude ratio of 6 dB in the echo pair and ICIs between 100 and 600 μs. For ICIs less than 600 μs. Gaskell demonstrated a large band of low frequencies over which the IPD spectrum favored the ear *opposite* that in which the higher-amplitude click occurred, consistent with the anomalous lateralization.

Based on our findings with three-click stimuli, we considered the spectral characteristics near 750 Hz for Gaskell's stimuli with ICIs greater than 600 μs. For ICIs between 0.8 and 1.2 ms, the sign of the IPD near 750 Hz is consistent with the sign of the ILD and we would predict nonanomalous performance, as was observed. However, for ICIs between approximately 1.4 and 2.0 ms, the IPD around 750 Hz opposess the ILD. Thus, anomalous lateralization would be expected if IPD were the only cue, but for this stimulus, there are also substantial differences in the left- and right-ear energy densities consistent with the ILD in the echo. Consistent with the use of IPD around 750 Hz, however, one observer's performance decreases substantially and one observer's performance actually drops below 50% correct as the ICI is raised from 1.4 to about 1.6 ms. As the ICI is raised from 2.0 to 2.4 ms, all Gaskell's observers exhibit a dramatic increase in their performance levels. This increase in performance coincides with a transition in the 750-Hz region of the sign of the IPD opposing the ILD to the sign of the IPD consistent with the ILD. Finally, at an ICI of 2.8 ms, the sign of the IPD is again in opposition to the ILD and, if the observers were sensitive to the IPD, would result in decreased performance relative to that at 2.4 ms. Performance for two (of three) observers does, in fact, show the decrease. These are important observations; even though Gaskell manipulated ILDs (and not ITDs), the resultant spectra contained nonzero IPDs whose signs are consistent with or oppose the sign of the ILD, depending on the ICI. (Future experiments on the precedence effect measuring the precision of ILD discrimination in transients should take this into account.)

Zurek (1980) also observed anomalous lateralization in his study of the amplitude-based precedence effect using pairs of 1-ms rectangularly gated Gaussian noise bursts. Zurek (1987) suggested that his results might arise from multiple temporal interactions between the leading and the lagging bursts, provided that the ICI is short enough and that the interaural-amplitude ratio of the second binaural pair of bursts is large, so that there are, in effect, only three clicks; viz., the diotic first click followed, in effect, by a single lagging click presented to one ear only. According to Zurek, the observer may actually perceive *two* interaural delays, one equal to zero due to the coincident initial pair, and another longer ITD due to the interaction between the leading click in one ear and the lagging click in the other. With this stimulus, the direction of the longer ITD is opposite the interaural-amplitude difference and, as Zurek pointed out, anomalous lateralization could result.

At first glance, Zurek's model is wholly consistent with our anomalous results. Consider the putative multiple temporal interactions occurring with a three-click stimulus which can be conveniently summarized by those elements of the broadband cross-correlation function that fall within approximately ± 650 μs of zero—the physiologically meaningful range of interaural delays normally encountered by adult human observers (Kuhn, 1987). The cross-correlation function for a three-click stimulus with an ICI of 600 μs and an ITD of 150 μs contains equal-amplitude peaks at delays of 0 and -600 μs, and a peak of half that amplitude at a delay of 150 μs. [A large peak also occurs at a delay of 750 μs (ICI $+$ITD) that falls outside the range of physiologically reasonable delays.] The large peak at -600 μs is consistent with the anomalous lateralization of this particular stimulus (see Fig. 2), as Zurek might predict.

The cross-correlation model also has some success in conditions that do not lead to anomalous lateralization. Consideration of the cross correlation of a three-click stimulus with an ICI of 1000 μs and ITD of 150 μs yields a peak within the physiological range at 0-μs delay, and a peak of half that amplitude at $+150$ μs, all the other peaks occur at delays well outside the physiologically reasonable range. The observers lateralized this particular stimulus correctly, achieving performance levels of 70% correct or better, consistent with the 150-μs delay. Thus, it seems the cross-correlation model might also be applicable to conditions leading to nonanomalous lateralization.

The cross-correlation model is appealing because it is simple and seems to be compatible with the data for several different stimulus configurations. But a natural question is whether its predictions are compatible with the performance differences between the two-click type I and type II stimuli. Unfortunately, here the theory breaks down because, for identical ICIs and identical ITDs, the cross correlation for the

type I stimulus is identical to that for the type II (Zurek, 1976; Gaskell, 1978, 1983; Tollin, 1998a). Even for small ICIs, where the model seems to be most applicable, it cannot, on its own, explain the robust differences in performance observed with the type I and type II stimuli as Gaskell (1978, 1983) pointed out.

The cross-correlation model also cannot explain why observes' lateralization in supplementary experiment 2 b could be driven from highly anomalous to correct by simply increasing the level of a diotic pure-tone masker. The model might predict that lateralization performance would tend toward 50% with increasing masker level, but performance greater than 50% should not occur. But, the addition of a masking tone to the three-click stimulus produced performance near 90% correct. Clearly, then, the model cannot explain many important aspects of the precedence effect.

One way to preserve the model is to evoke echo suppression—suppression that somehow inhibits the directional information from echoes arriving later than about 1 ms from the onset of the first wavefront is often assumed (Zurek, 1980, 1987; Lindemann, 1986). Such postonset inhibitory theories are attractive because their predictions agree qualitatively with experimental results from a wide range of studies and appear to help account for the failure of the cross-correlation model.

However, our results with three clicks demonstrate that the directional information in clicks presented up to 2–3 ms after the first click is not suppressed. Rather, echoes that arrive as late as 2–3 ms after the initial click affect the spectral characteristics of the sum of the first arriving signal and its echoes in ways that have a substantial effect on lateralization.

B. Temporal integration and sound localization

One interpretation of our results, then, is that the auditory system analyzes sums of delayed transients on the basis of their short-term spectral characteristics with a time constant on the order of at least 2–3 ms, and that these short-term spectral characteristics are important in sound localization. A time constant of about 2–3 ms arises for several reasons. First, the IPD spectrum near 750 Hz for a three-click stimulus with an ICI of 2 ms and an ITD of 150 μs suggests that this stimulus should have been lateralized anomalously, but all observers achieved performances of 80% correct or better (Fig. 2). So, spectral considerations failed to predict observers' performances when the total duration of the three-click stimuli was greater than 4 ms.

Second, monaural temporal-order discrimination of transients with identical energy-density spectra fails for signals shorter than 2–3 ms (Ronken, 1970; Patterson and Green, 1970; Green, 1971; Resnick and Feth, 1974; Henning and Gaskell, 1981). Third, Hall and Lumis (1973) demonstrated that the monaural detection of click pairs in the presence of a notched-noise masker depends on ICI and the spectral location of the notch for ICIs up to just above 2 ms. They showed that detection thresholds oscillated between higher and lower values as a function of ICI in a manner predictable from the energy-density spectrum of the click pairs at the spectral location of the notch.

Further, it has not escaped our notice that the impulse response of the ear canal, pinna, head, shoulders, and torso—whose Fourier transform yields head-related transfer functions—can have total durations near 2 ms (Wightman and Kistler, 1997). Because ''reflections'' from these structures influence localization through their effects on the resultant spectral characteristics of the sounds reaching the ears, a time constant of at least 2 ms again seems appropriate.

C. A ''dominance region'' in the precedence effect

It is well known that observers are most sensitive to interaural time and phase differences for frequencies around 700 Hz (Zwislocki and Feldman, 1956). Bilsen and Raatgever (1973) found a ''dominant-region'' effect whereby the frequency components around 700 Hz were much more effective in the lateralization of broadband noise than were neighboring components. Likewise, Henning (1983), using an 800-Hz-wide transient with an interaural-group delay of 200 μs centered on different frequencies, showed that such stimuli were predominantly lateralized according to the IPDs in the spectral region near 700 Hz. Wightman and Kistler (1992) also established that low-frequency ITD cues are of primary importance in localizing sounds on the horizontal plane in virtual space (and presumably also in ''real'' environments). They found that the low-frequency ITDs completely dominated their observers' judgments of the horizontal positions of virtual-sound sources even when the high-frequency localization cues—interaural-level differences and monaural spectral cues—signaled positions different from that indicated by the low-frequency ITD.

The results of our experiments with the three-click stimuli with an ITD in the second pair are also consistent with this interpretation; the observers appear to lateralize primarily on the basis of the IPD in the region around 750 Hz provided the total duration is less than 2–3 ms. In other words, these results demonstrate that the dominant-region effect also holds for stimulus conditions under which the precedence effect is assumed to operate. We found no such region for interaural-level differences (i.e., REDs).

Others have also investigated the role of spectral dominance in the precedence effect (Blauert and Divenyi, 1988; Divenyi, 1992; Shinn-Cunningham *et al.*, 1995; Saberi, 1996; Yang and Grantham, 1997; Tollin and Henning, 1998b). But aside from Tollin and Henning (1998b), the role of spectral dominance was investigated by independently changing the spectral composition of the direct and echo stimuli. These studies showed that a lead stimulus containing primarily low frequencies will make more difficult the use of the directional information in an echo containing primarily high frequencies, but not vice versa. The present experimental paradigm transcends those techniques and shows more directly that, even for stimuli in which both direct and echoed sounds are broadband and identical, the IPD in the spectral region around 750 Hz is of particular importance.

Two important issues remain. First, in light of the findings that the dominant-region effect holds in our three-click

experiments, a re-examination of why the ITD sensitivity for type II stimuli is much worse than the for type I stimuli with the same ICI is in order. For ICIs less than about 3 ms, can performance be predicted from the type I and type II spectral characteristics around 750 Hz? The second issue of importance concerns the situation where the direct and ''echo'' sounds are uncorrelated. As the direct and echoed sound become uncorrelated, their resultant spectral characteristics diverge considerably from those produced for correlated sounds. Zurek (1980) considered this possibility and measured ITD thresholds for type I and type II stimuli under two different conditions; the direct- and echo-noise burst were either (1) identical, or (2) uncorrelated. His data showed that for ICIs between about 1 and 10 ms, ITD jnd's were roughly the same under both conditions; substantially elevated for the type II stimulus but not for the type I. The implication of Zurek's findings is that the resultant spectral characteristics alone are not necessary to produce a precedence effect with broadband transients. But as we showed in this paper, Zurek's data do not preclude the important role for the resultant spectral characteristic of delayed and added transients or highly correlated sounds in lateralization and localization. These important issues warrant discussion and will be considered in detail in a forthcoming paper.

IV. CONCLUSIONS

To simplify the investigation of the role of the spectral characteristics in lateralization, three-click stimuli were designed to have either (1) nonzero interaural-phase differences (IPDs), or (2) nonzero relative-energy densities (REDs). When the IPD was the only spectral cue, observers' performance was consistent with their using IPDs in a band of frequencies around 750 Hz, provided the total stimulus duration was less than about 2–3 ms. Additional masking and filtering experiments confirmed that the observers used IPD information from this region. The results support the notion of a dominant region for the lateralization in the spectral region around 750 Hz. Joint consideration of the behavioral data and the spectral characteristics for the stimulus with zero IPDs and nonzero REDs revealed no equivalent region for interaural-level differences. Our results demonstrate that echoes that arrive within 2–3 ms of an initial click are not suppressed, but play a substantial role in lateralization through their contribution to the spectral characteristics of 2–3 ms epochs that contain the direct sound and its echoes. The findings challenge the hypothesis that the precedence effect is most effective, in the sense that the directional information in echoes is suppressed, with click stimuli for ICIs between approximately 1–2 ms (Wallach *et al.*, 1949; Gaskell, 1983; Yost and Soderquist, 1984; Saberi and Perrott, 1990; Litovsky *et al.*, 1997).

ACKNOWLEDGMENTS

This work was carried out in The Sensory Research Unit, Department of Experimental Psychology, The University of Oxford, U.K. as a part of the first author's doctoral dissertation. Financial support was provided to the first author through an O.R.S. Award, a St. Catherine's College (Oxford) Graduate Fellowship, and a University of Oxford Overseas Bursary. The first author was supported by NIH NIDCD grants No. DC00045 and No. DC00116 during the preparation of the manuscript. Both authors would also like to thank Drs. E.R. Hafter, D. McFadden, and W. Grantham (the Associate Editor) and two anonymous reviewers for their comments on the manuscript.

Effects of stimulation mode on threshold and loudness growth in multielectrode cochlear implants

Monita Chatterjee[a)]
Department of Auditory Implants and Perception, House Ear Institute, 2100 West Third Street, Los Angeles, California 90057

(Received 29 June 1998; accepted for publication 21 October 1998)

The effect of increasing the separation between the two members of a stimulating electrode pair was studied in four users of the Nucleus-22 cochlear implant. Two experiments were performed. In experiment 1, detection threshold for a 200-ms, 500-pulses/s biphasic pulse train was measured as the spatial separation between the active and return electrodes was increased. In experiment 2, loudness-growth functions were measured as the electrode separation was increased. The results of experiment 1 indicate that (a) threshold decreases monotonically toward an asymptote (monopolar threshold) as the electrode separation is increased and (b) the threshold versus electrode separation function is similar across subjects and electrode location. The results of experiment 2 indicate that loudness L is related to the current amplitude I by a simple exponential function: $L = e^{\beta I}$, where β, the exponent of the loudness function, is, to a first approximation, linearly related to the separation between the electrodes of the stimulating pair. Thus, dynamic range and the shape of loudness growth can be directly linked to the spatial separation between active and return electrodes. [S0001-4966(99)00602-5]

INTRODUCTION

Current cochlear-implant technology is sophisticated enough to allow the clinician freedom to select certain important parameters of stimulation. Depending upon the device, some of these parameters may be the frequency limits of the analysis filters (frequency allocation table), the dynamic range, the compression ratio, and the mode of stimulation (spatial distance separating the active and return electrodes along the cochlea). From an applied perspective, this last parameter is of considerable interest because of its impact on thresholds and, consequently, on battery life and the potential to miniaturize external hardware. From a theoretical point of view, the effect of changing the spatial extent of the stimulating field along the cochlea has implications for signal processing in the electrically stimulated auditory system. In this paper, we describe a detailed study of the quantitative relation between stimulation mode, threshold, and loudness growth in four users of the Nucleus-22 device.

For pulsatile electrical stimuli, the spread of excitation with increasing electrode separation depends upon many factors, including the geometry and impedance of the structures within the electric field, the distance of the neurons from the electrodes, as well as the degree of myelination and other structural features of the neurons (for a review, see Rattay, 1990). Generally speaking, it seems reasonable to assume that the number of neurons responding to the stimulus increases with increasing separation between the two electrodes of a stimulating pair. If threshold is determined by some form of integration of neural activity in the cochlea, increasing the electrode separation should result in a reduction in threshold. Indeed, it is a common observation that broad excitation across the tonotopic axis of the cochlea (as in monopolar stimulation, where the return electrode is a distant electrode placed elsewhere in the body) results in lower thresholds than focused excitation (as in bipolar stimulation, where the active and return electrodes are adjacent to each other), in addition to narrower dynamic ranges (Shannon, 1983; Abbas and Brown, 1991; Shephard *et al.*, 1993; Pfingst *et al.*, 1995).

One source of the large variability in cochlear implant patients' performance is often thought to lie in the variability of nerve-survival patterns across patients. Although there does appear to be a relationship between the total spiral ganglion-cell *count* and etiology of deafness (Nadol, 1997), the relationship between patterns of neural degeneration and factors such as etiology, duration of deafness, age, etc, are not well understood. Anatomical studies of spiral ganglion-cell counts in different regions of the human cochlea (Zimmerman *et al.*, 1995) show considerable variation along the length of the cochlea both within and across patients. Overall, survival appears to be better in the apical half than in the basal half of the cochlea.

We speculate that the rate at which threshold declines with increasing electrode separation should be determined at least partially by the pattern of surviving neurons. Thus, in a patient with a uniform pattern of surviving neurons from base to apex, thresholds should decline continuously with increasing electrode separation, whereas in a patient with large irregularities in nerve-survival patterns, the function may have plateaus or discontinuities. In addition, in patients with irregular nerve-survival patterns, the shape of the threshold vs electrode-separation function should depend strongly upon electrode location in the cochlea. In experiment 1 of the present study, we address these questions by directly measuring threshold as a function of stimulation

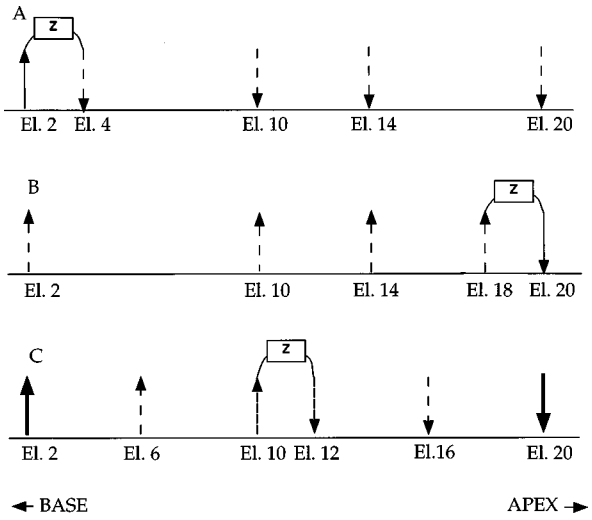

FIG. 1. Schematic illustrations of the different kinds of electrode pair configurations used in the experiments. (A) The active electrode of the pair is fixed at Electrode 2, and electrode separation is changed by changing the return electrode. (B) The return electrode is fixed at Electrode 20, and the electrode separation is changed by changing the active electrode. (C) The electrode separation is changed by changing both active and return electrodes, but their respective distances from Electrode 11 are equal. In (A) and (B), the solid and dashed lines indicate the fixed and variable electrodes, respectively. In (C), the different lines indicate different electrode pairs and current paths. Thus, Electrode 10 is the active electrode, and Electrode 12 is the return electrode in the pair forming the narrowest stimulation mode. The arrows indicate the direction of current flow (upward arrow indicates the active electrode, downward arrow indicates the return electrode). The box labeled ''*Z*'' represents the impedance in the current path.

mode while parametrically varying electrode location.

If the system is nonlinear, the relationship between electrode separation and the resulting neural excitation may be quite different for stimuli presented at threshold compared with stimuli presented above threshold. Such a difference would be reflected in loudness-growth functions obtained at various electrode separations. While it has been observed that dynamic range (in microamperes) is narrower for wider electrode separations, the exact quantitative relationship between the growth of loudness within the dynamic range and electrode separation has not been systematically explored. The aim of experiment 2 of this study was to discover the shape of the function relating the slope of loudness growth to electrode separation, and to relate the findings to the results of experiment 1.

A. Terminology

Figure 1 shows different arrangements of electrode pairs for the same stimulation mode (or electrode separation). In the Nucleus-22 system, electrodes are numbered 1–22 from the base to the apex. Note that in the experiments described here, the apical member of the electrode pair is always the return electrode. In Fig. 1(A), the basal member of the pair is fixed, and the electrode separation is changed by changing the apical member. In Fig. 1(B), the apical member of the pair is fixed, and the separation is changed by changing the basal member of the pair. In Fig. 1(C), the apical and basal members of the pair both change, keeping their respective distances from El. 11 equal. We will refer to these different ways of changing the electrode separation as ''electrode configuration.'' The absolute location of the fixed electrode of the pair will be referred to as ''electrode location.'' The number of electrodes separating the active and return electrodes is referred to as ''stimulation mode'' by some manufacturers. In this paper, we refer to it interchangeably as ''electrode separation'' or ''stimulation mode,'' represented by the variable M, where $M=1$ for the bipolar stimulation mode (active and return electrodes adjacent to each other), and $M=21$ for the widest possible separation, where the active and return electrodes are El. 1 and El. 22, or vice versa. For instance, in one configuration, the basal electrode was fixed, and the apical electrode was varied. Thus, electrode pairs were (2,4), (2,6), (2,8), etc., or (10,12), (10,14), (10,16), etc. We refer to these series as $(2,2+M)$ or $(10,10+M)$. In a second type of configuration, the apical electrode was fixed, while the basal electrode was changed to change the electrode separation [e.g., electrode pairs were (18,20), (16,20), (14,20), etc., referred to as (20-M,20)]. In a third type of manipulation, electrode pairs were chosen to be symmetrically spaced around electrode 11 (for example, electrode pairs were (10,12), (9,13), (8,14), etc., referred to as $(11-M+1,11+M-1)$. Note that the spatial distance separating adjacent electrodes along the array is 0.75 mm. Thus, for the broadest possible separation in the Nucleus-22 system ($M=21$), the spatial distance between electrodes is 15.75 mm.

It is important to recognize that the stimulating pulse is biphasic—thus, the ''active'' electrode receives the positive phase first, while the ''return'' electrode receives the negative phase first. The phases are reversed in the second half-cycle. Depending upon the stimulus configuration, the distance from the electrode, etc., neurons may respond to both phases of the pulse (see Rattay, 1990).

I. METHODS

Subjects were four postlingually deafened adult male users of the Nucleus-22 cochlear-implant system with varying levels of speech recognition in quiet. Table I lists scores they

TABLE I. Subjects, etiology of deafness, and scores obtained on two sound-only tests. The two right-most columns show values of ''*c*'' and ''*k*'' obtained from Fig. 8 for each subject.

Subject	Etiology of deafness	NU6 word list	CUNY sentences, sound only	Value of ''*c*'' from Fig. 8	Value of ''*k*'' from Fig. 8
N3	Unknown	24%	79.4%	0.0038	0.0009
N4	Trauma	70%	99.02%	0.0047	0.0012
N7	Unknown	48%	99.02%	0.0035	0.0010
N14	Unknown	18%	47%	0.0066	0.0014

recently obtained on one run each of the NU6 word list test (percent of words correctly identified out of a recorded list of 50 words uttered by a male speaker presented at 70 dB SPL; Tillman and Carhart, 1966) and on the CUNY sentence test (Boothroyd *et al.*, 1985; percent of words correct out of a recorded list of 12 sentences, female speaker, 70 dB SPL) without the aid of lipreading. Apart from routinely scoring higher on all speech tests administered in the laboratory, subjects N4 and N7 are able to use their implant to communicate over the telephone with little difficulty, while subjects N3 and N14 are unable to do so. All the subjects have acquired considerable experience in psychophysical tasks as a result of having participated in many experiments in our laboratory.

Stimuli were delivered through a custom research interface (Shannon *et al.*, 1990). All stimuli were 200-ms-long trains of 200-μs/phase, biphasic pulses, presented at 500 pulses/s. Accurate estimates of current delivered were obtained from the manufacturer's amplitude-calibration tables for each subject's device.

Thresholds were measured using a 3-down, 1-up, two-interval, forced-choice paradigm, converging at the 79.4%-correct point (Levitt, 1971). The amplitude of the pulse train was adaptively adjusted until a minimum of eight reversals or a maximum of 12 reversals were completed in 60 trials or less. The initial (first three reversals) and final step sizes were 2 and 0.5 dB, respectively. The mean of the last eight reversal points was calculated for each threshold measure, and the mean and standard deviation of at least two measures were calculated for each threshold estimate.

Loudness-growth functions were measured according to the following procedures:

The subject was presented with a soft stimulus (one presentation of the 200-ms, 500-pulses/s pulse train) close to threshold. By pressing the left- and right mouse buttons, the subject could increase or decrease the level of the stimulus in small incremental steps. The subject was asked to increase the level until the loudness reached a maximum acceptable level. Along the way, the subject indicated to the experimenter the relative loudness at each stage. This gave us an idea of the approximate dynamic range for each mode of stimulation. For this procedure, the subject received a single presentation of the stimulus each time he pressed a mouse button.

Subjects tended to be conservative in estimating the maximum acceptable level during the first session. In pilot runs, a subject would sometimes estimate a stimulus to be only moderately loud, even though its amplitude had been set to the maximum level previously obtained. We would then increase the amplitude in very small steps, until the subject estimated it to be at the maximum acceptable loudness. Based upon pilot runs, a minimum of eight amplitude levels was selected to cover the dynamic range. At each amplitude selected, the subject was presented with a sequence of six presentations of the same stimulus (stimulus set). The first presentation was intended as a cue to alert the subject. Next, the remaining five repetitions were presented to the subject (interstimulus interval was 300 ms). An LED flashing in synchrony with each presentation served as a visual cue. The subject was asked to select a number from a scale of 0 (don't hear it) to 100 (too loud) to match the subjective magnitude of the perceived overall loudness of the stimulus set. This procedure was used because during pilot runs, some subjects occasionally reported changes in the loudness of the stimulus between the first and third presentations of the stimulus.

Before beginning the data collection procedure, the subject was presented with an ascending sequence (0.2-dB steps) of the 200-ms pulse train from threshold to the maximum acceptable level, in order to give them some orientation as to the range of stimuli that might be used as well as to ensure that the loudest stimuli were not too loud. A minimum of three to a maximum of eight repetitions were performed for each loudness function. Thus, each loudness function corresponds to at least 24 loudness estimates (a minimum of eight amplitude steps and three repetitions at each step). Whenever possible, the data were obtained on two separate days, three to four repetitions on each day. For a particular electrode pair, all the repetitions for a given day were performed in one session lasting approximately one half h. The mean and standard deviation of all loudness estimates made for a particular electrode pair were computed at each amplitude.

At current levels close to threshold, subjects did not always hear all six presentations, but were asked to judge the loudness of the ones that were audible. As the softest sound was always presented at a higher level than threshold, subjects never used ''0'' to judge the loudness, but fractions were allowed and often used.

The experimenter ensured a rough randomization of the presentation sequence of the stimuli. For each repetition, stimuli were presented in a different order (decided previously by the experimenter). The softest and loudest sounds were most easily recognized by subjects, while sounds in between the two ends of the range were more difficult to judge.

Loudness functions were obtained for the (20-M,20) configuration in all four subjects (results shown in Fig. 6). The remaining electrode locations and configurations were chosen arbitrarily for each subject.

II. RESULTS AND ANALYSIS

A. Amplitude units

It may be useful at this point to address the issue of amplitude units used in electrical vs acoustic stimulation. To accommodate the wide dynamic range of normal sensory systems, the stimulus is often described in logarithmic units. In electrical stimulation of the cochlear-deafened auditory system, the peripheral compressive nonlinearity is absent. As a result, the dynamic range of the system is limited, and the input to the auditory nerve can be directly expressed in microamperes of current or nanocoulombs of charge. In listeners with auditory brainstem implants as well as sizable residual hearing in one ear, Zeng and Shannon (1992) have shown that, in order to achieve loudness balance between the electrical and acoustic stimuli in the two sides, current amplitude (in microamperes) in the implanted side must be pro-

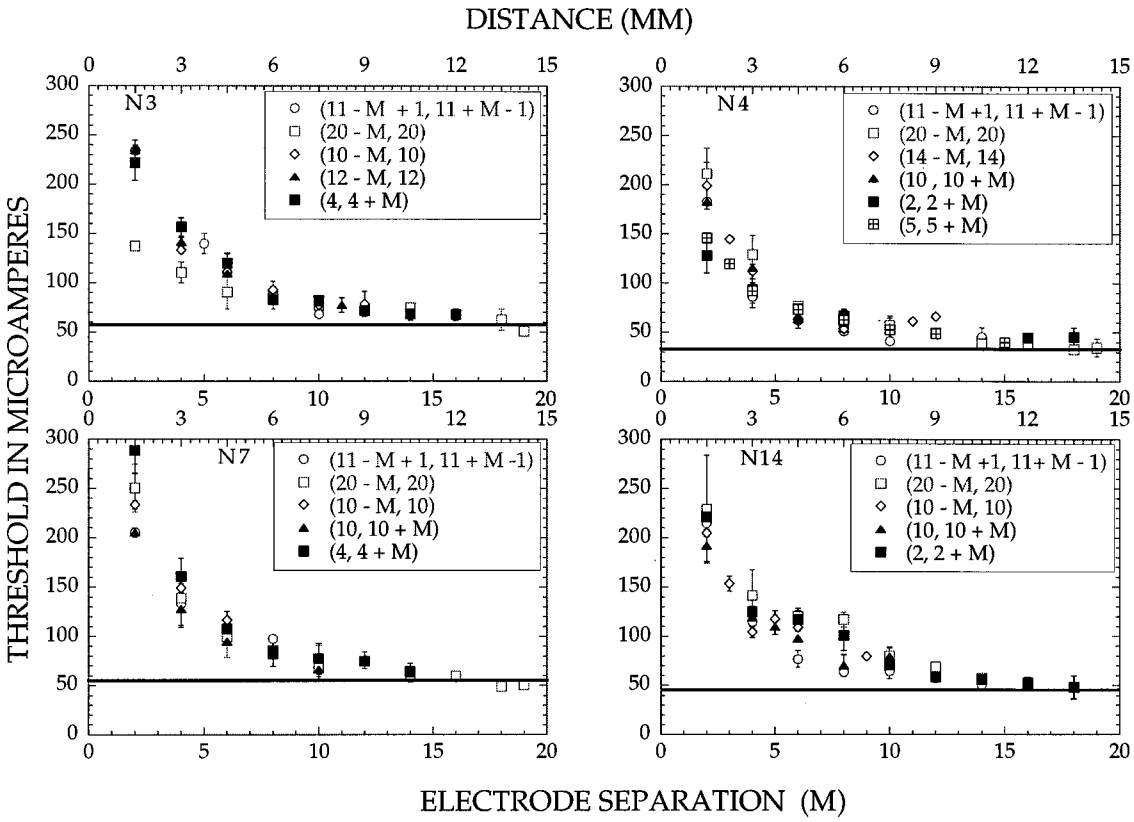

FIG. 2. Thresholds in microamperes as a function of electrode separation *M*, for the four subjects and different electrode configurations (shown in the insets). For each electrode separation *M*, the upper abcissa shows the distance separating the active and return electrodes of the pair in mm. Error bars represent ±1 standard deviation. The horizontal line across each plot represents the mean pseudomonopolar threshold [El. (1,22), $M=21$] for each subject.

portional to dB SPL in the other side. It appears, therefore, that linear units are appropriate in the context of electrical stimulation. The data presented here are plotted using linear microamperes.

B. Experiment 1: The shape of the threshold vs electrode-separation function

Figure 2 plots the threshold in microamperes as a function of electrode separation. Each panel corresponds to data obtained in one subject. Within each panel, each symbol represents data corresponding to a different electrode configuration and/or location. In general, and as expected, thresholds decrease with wider electrode separation. It is apparent that the functions are very similar across subjects, as well as within subjects, across the various configurations and locations. For each subject, for the most focused stimulation, thresholds are most diverse across electrode location (i.e., the data points show greatest scatter for $M=2$), presumably reflecting local variations along the cochlea. Beyond $M=6$ (a separation of 4.5 mm), the functions converge toward a minimum threshold. Presumably, this minimum threshold corresponds to that obtained with monopolar stimulation (Pfingst *et al.*, 1995).

We obtained the threshold for the widest electrode separation [i.e., electrode pair (1,22), corresponding to $M=21$] in each subject. We refer to this as a pseudomonopolar stimulation mode. For each subject, this threshold is shown by the horizontal line across each plot in Fig. 2. To facilitate comparison across subjects and conditions, we normalized the ordinate to the threshold difference between $M=2$ and $M=21$. The result is shown in Fig. 3 for each subject. Symbols show results from different electrode configurations. It is apparent from inspection of Figs. 2 and 3 that the normalized threshold vs electrode-separation function is relatively independent of subjects and electrode configurations. This suggests that the change of threshold with electrode separation can be adequately described by a single function.

If we assume that the threshold decays exponentially from the bipolar threshold T_{BP} (corresponding to $M=1$) until it asymptotes to the monopolar threshold T_{MP}, we can use the following equation to describe the decay:

$$T-T_{MP}=(T_{BP}-T_{MP})e^{-\alpha x}, \tag{1}$$

where T is the measured threshold in microamperes for a particular electrode configuration, x corresponds to the distance separating the electrodes in the array [$x=(M)*0.75$ mm], and α^{-1} represents the space constant. In all cases, T_{BP} can be measured. Although true monopolar stimulation is not possible in the Nucleus-22 system, an approximate value is obtained by measuring the threshold for the pseudomonopolar condition [threshold for electrode pair (1,22), shown by the horizontal lines in Fig. 2]. Thus, α is the only parameter to be adjusted to fit the data. Figure 4 shows examples of the equation applied to the data obtained in two subjects, for the electrode configuration (20-M,20). The values of α and the correlation coefficient R are indicated in the figure. The high values of R (>0.95) suggest that, based on only two measurements—the bipolar threshold

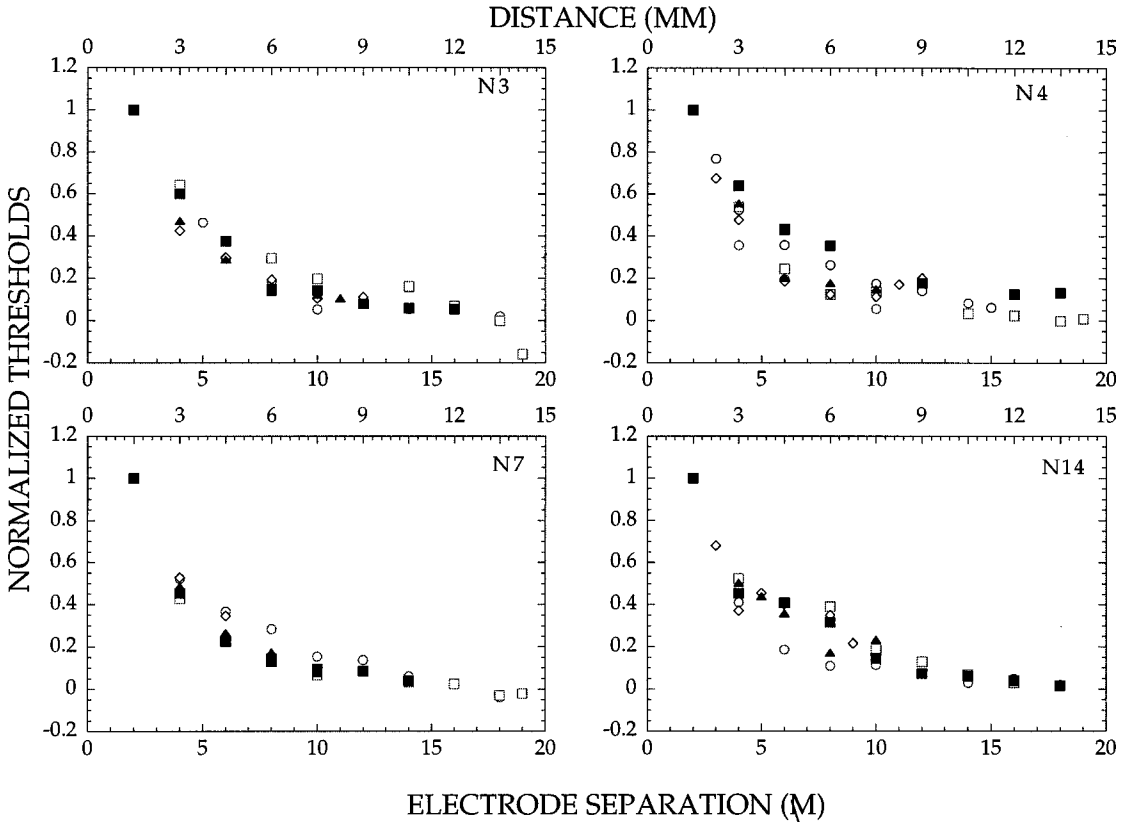

FIG. 3. The data from Fig. 2, normalized by subtracting the pseudomonopolar ($M=21$) threshold from each data point and then dividing by the threshold difference between $M=2$ and $M=21$. The symbols are the same as in Fig. 2.

and the monopolar or pseudomonopolar threshold—we can predict the threshold for all other electrode separations.

The present results are in qualitative agreement with similar data in cochlear-implant subjects reported by Pfingst *et al.* (1995) using a lower pulse rate of stimulation, and with electrically evoked auditory brainstem response (EABR) threshold vs electrode-separation functions measured by Abbas and Brown (1991). Overall, the threshold changes smoothly with electrode separation. The functions are independent of electrode configuration, electrode location, and subject, leading us to conclude that, at least in the present set of subjects, irregularities in nerve-survival patterns do not play a large role in determining the threshold function.

This experiment can also be considered an electrical analog of Fletcher's famous band-widening experiments which led to the concept of critical bandwidth (Fletcher, 1940). From this viewpoint, the threshold vs electrode-separation function is a measure of the spatial width of a channel. The data suggest that beyond a spatial separation of 3–4.5 mm (4–6 electrodes), recruitment of distant neurons does not contribute significantly to the threshold. This estimate is in agreement with many other measures of channel separability (e.g., Shannon, 1983; Tong and Clark, 1986; Lim *et al.*, 1989; McKay *et al.*, 1995; Chatterjee and Shannon, 1998) in multichannel electrical stimulation of the cochlea.

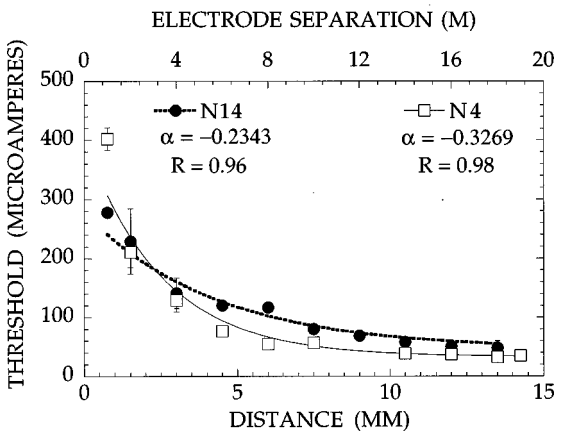

FIG. 4. Threshold versus electrode-separation data (filled circles and open squares) and curve fits (intermittent and solid lines) for two subjects using the electrode configuration (20-M,20). The inverse of the space constant, α, and the correlation coefficient R are indicated for each fit.

C. Experiment 2: Growth of loudness as a function of electrode separation

As loudness estimates made by subjects showed substantial variability, the observations for a particular function were made on two separate days whenever it was possible to do so. Figure 5 shows examples of loudness estimates made by subjects N3 and N7 on two different days. Although the standard deviations on each day were large, the mean functions did not differ greatly from day to day. For purposes of analysis, a grand mean and standard deviation was computed from all recorded estimates corresponding to each amplitude and electrode pair for each subject (across the different days).

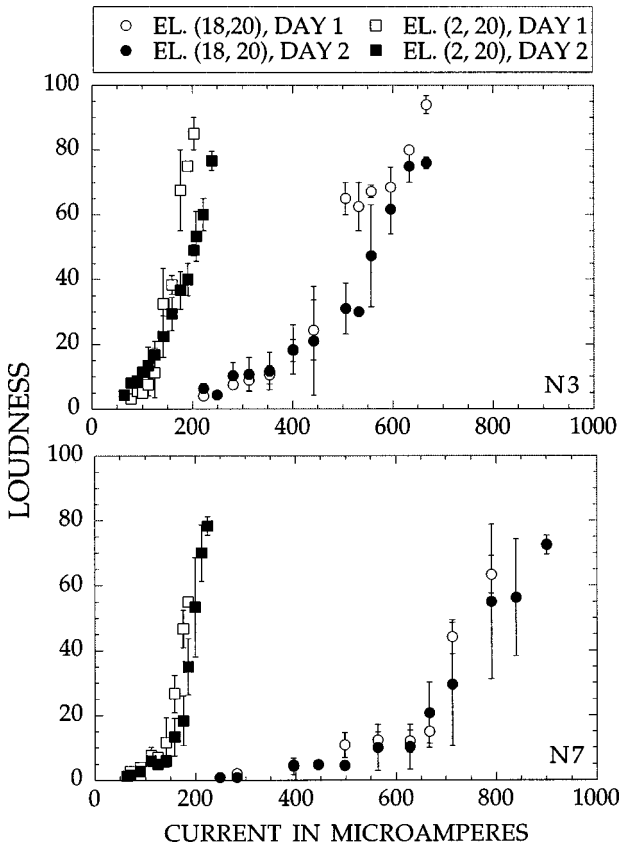

FIG. 5. Two sets of loudness estimates made by subjects N3 and N7 on two different days. The electrode pairs are indicated. Error bars represent ±1 standard deviation.

Figure 6 shows loudness-growth functions in all subjects measured using three different stimulation modes ($M=2$, $M=10$, and $M=18$), with the electrode configuration (20-M,20). In agreement with a large body of previous work (e.g., Shannon, 1981, 1985; Zeng and Shannon, 1992, 1994) the functions suggest that an expansive nonlinearity relates the amplitude of the current pulses to estimated loudness. The intermittent lines in Fig. 6 are curve fits with the equation

$$L = e^{\beta I}, \tag{2}$$

where β is a constant, and I represents the amplitude of the current pulses in microamperes. In all cases, the equation fit the data with a correlation coefficient greater than 0.9. (Power functions also fit the data well, but required an additional parameter.)

Inspection of the data reveals a consistent pattern. In agreement with observations of previous investigators, the dynamic range is widest for the narrowest electrode separation, and narrowest for the widest electrode separation. Consistent with this qualitative observation, the exponent β is smallest for the narrowest electrode separation and largest for the widest electrode separation.

Further examples of loudness estimates made by subjects using different sets of electrode pairs are shown in Fig. 7. Again, the intermittent lines show the curve fits obtained using Eq. (2).

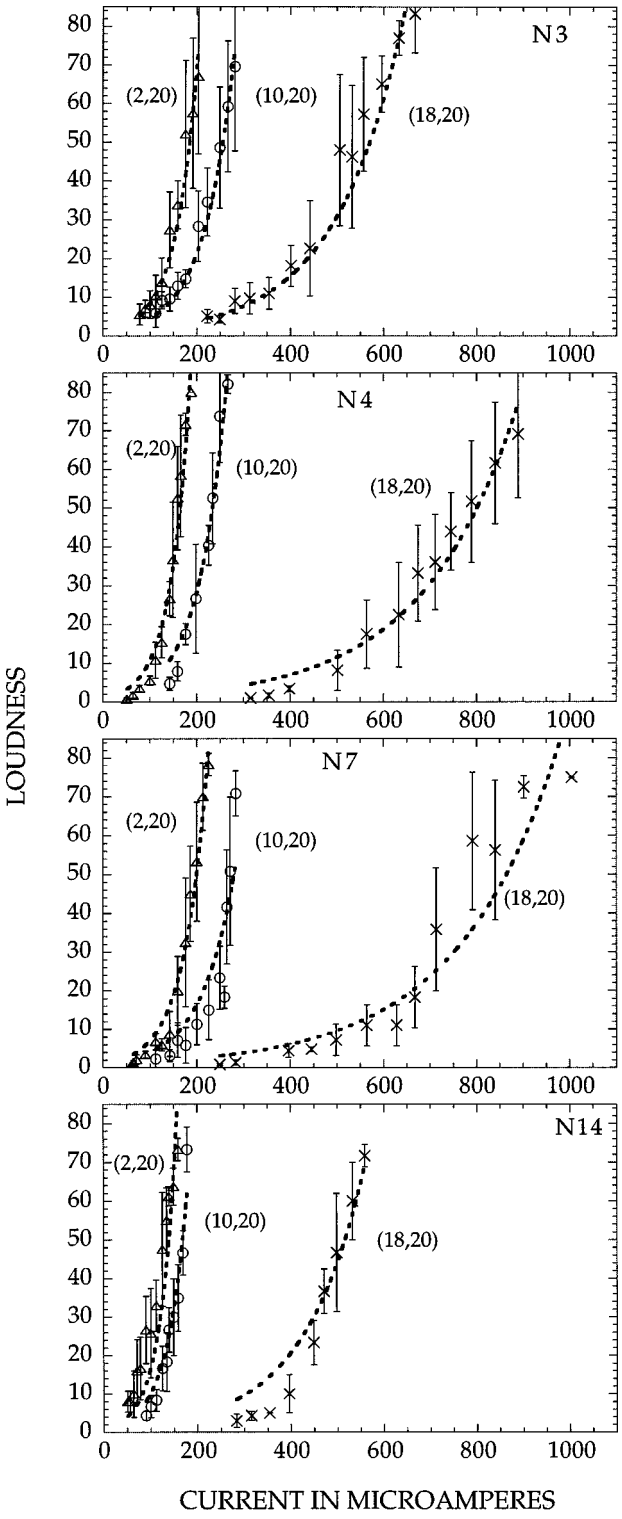

FIG. 6. Loudness functions obtained in four subjects using electrodes (18,20), (10,20), and (2,20). The intermittent lines represent curve fits using Eq. (2) (see the text). Error bars represent ±1 standard deviation.

We measured a number of loudness functions in each subject. Curve fits using Eq. (2) were used to obtain the exponent in each case. To quantify the relationship between the rate of growth of loudness and the spatial separation between electrodes, we plotted the values of β obtained from all the loudness functions obtained in each subject, against the electrode separation M (Fig. 8). Regardless of electrode

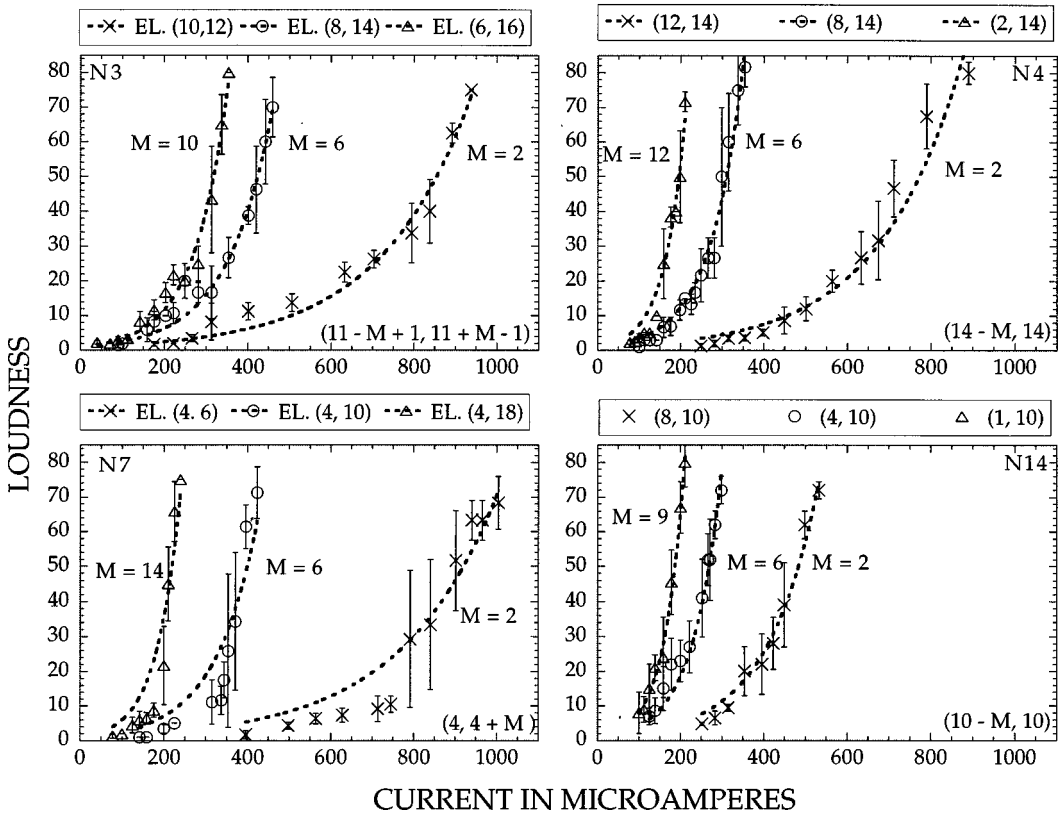

FIG. 7. Further examples of loudness estimates made by the four subjects. The electrode pairs stimulated are indicated above each plot. The intermittent lines represent curve fits using Eq. (2). Error bars represent ±1 standard deviation.

configuration, the derived exponents fall along a single, monotonically increasing function of electrode separation. By inspection, a linear relationship between β and M seems a reasonable first approximation.[1] The lower panel in Fig. 8 shows a scatter plot of the exponents derived from each subject's data, together with linear approximations (the equations are shown adjacent to the plot). We can therefore replace β in Eq. (2) with $(c+kM)$, where c and k are constants. We would thus have

$$L = e^{(c+kM)I}. \tag{3}$$

Or, if x represents the electrode separation in mm, $0.75^*(M) = x$, and

$$L = e^{[c+k(x/0.75)]I}. \tag{4}$$

From Fig. 8, c ranges from 0.0035 to 0.0066 and k ranges from 0.0009 to 0.0014.

We have thus obtained a simple and direct relationship between the spatial separation between electrode pairs in mm and loudness. At least for the stimuli used in this experiment, the exponent of the loudness function depends only on the electrode separation. The relationship between the distance x and the exponent β can be approximated by a simple linear function, the slope k and intercept c of which show some small subject dependence.

For a fixed current amplitude I and different electrode separations $M1$ and $M2$, the corresponding loudnesses $L1$ and $L2$ are related by

$$\frac{L1}{L2} = e^{k(M1-M2)I}, \tag{5}$$

or, in terms of x:

$$\frac{L1}{L2} = e^{k[(x1-x2)/0.75]I}. \tag{6}$$

Thus, for fixed I, increasing the electrode separation by m electrodes increases the loudness by a factor of e^{kmI}. At low-current levels, the change in loudness with m is small, but as I increases, the change is amplified by the expansive nature of the nonlinearity.

Conversely, for a fixed separation M and different levels of stimulation $I1$ and $I2$, the corresponding loudnesses $L1$ and $L2$ are related by

$$\frac{L1}{L2} = e^{(c+kM)(I1-I2)}. \tag{7}$$

Thus, for a particular electrode separation M, the change in loudness for a given change in current is controlled by the value of M. For small M, the change in loudness with I is small, but as M increases, the exponential function amplifies the change.

For a fixed loudness $L = e^n$, the current amplitude I and the separation M are related by $(c+kM)I = n$. Thus, electrode separation and current amplitude have a reciprocal relation at equal loudness.

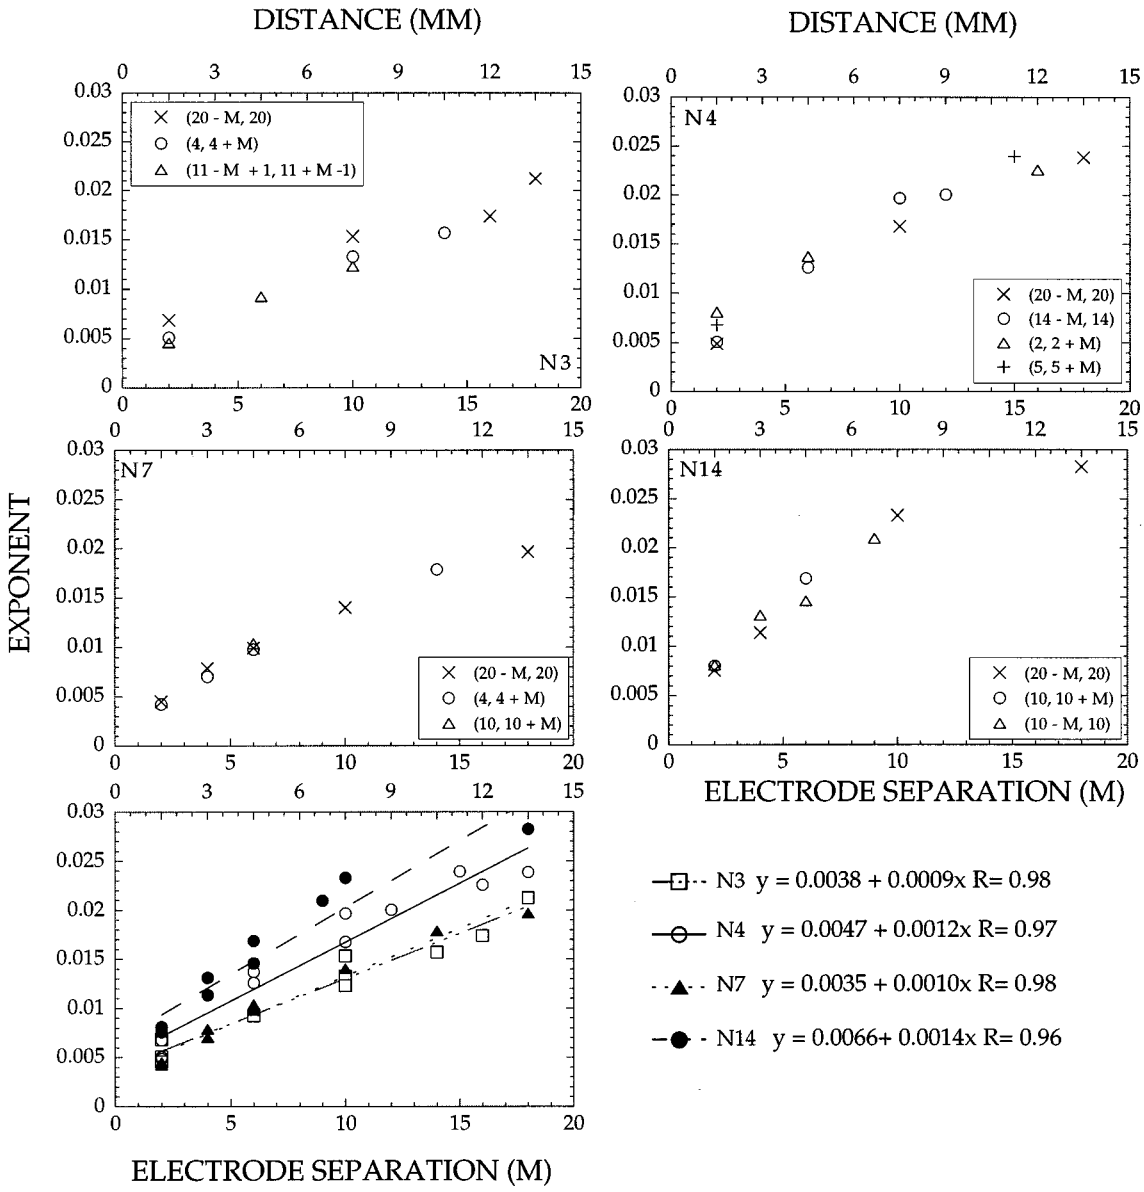

FIG. 8. Upper four panels: Exponents obtained by curve-fitting a large number of loudness functions such as those in Figs. 5 and 6, as a function of the electrode separation. Each symbol represents a different electrode configuration (indicated in the insets). Lower panel: Exponents for each subject pooled and plotted together as a function of electrode separation. Each symbol represents exponents from one subject. The lines represent the linear curve fits (equations shown adjacent to the plot).

It is evident from the above analysis that the two terms, current amplitude I and the electrode separation-related term $(c+kM)$, affect loudness in comparable ways. An increase in one variable changes the subject's sensitivity to the other. Table I shows the values of c and k obtained from Fig. 8, alongside the other potentially relevant information about each subject. Although the values of c and k are largest for subject N14, who is the poorest performer, inspection of the data revealed no orderly relationship between these values for the other subjects and their speech-recognition scores.

III. DISCUSSION

The results of the experiments described here show a clear and consistent dependence of both the exponent of the loudness function and threshold on the separation between active and return electrodes. These relationships hold regardless of the electrode configuration, electrode location, and the differences among subjects in the benefit gained from their implant. Notwithstanding the small number of subjects in this study, this consistency of the results, together with the qualitative agreement with other studies in this area, suggests that these findings may be a fundamental and potentially important aspect of loudness perception in electrical stimulation.

At different electrode locations, thresholds obtained using the more focused stimulation modes showed considerable scatter, suggesting that irregularities do exist in the nerve-survival pattern. However, such local irregularities in nerve survival do not result in large differences in the functions relating threshold and loudness growth to the electrode separation. This may possibly be due to the integration of activity across neurons, resulting in a spatial low-pass filter-

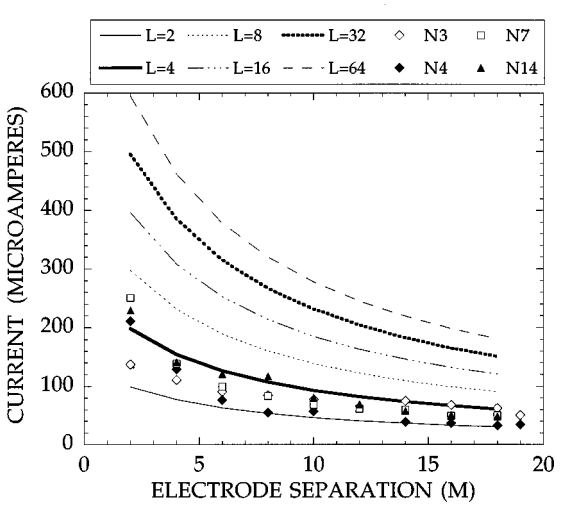

FIG. 9. Equal-loudness functions predicted from Eq. (8), assuming $c=0.0050$ and $k=0.0010$. Each line corresponds to a different fixed loudness ($L=2,4,...,64$). The data points, replotted from Fig. 2, represent the threshold versus electrode-separation data corresponding to the electrode configuration (20-M,20), for the four subjects indicated. Each symbol represents data from one subject.

ing, or smoothing effect, when the spatial extent of the stimulus is increased.

A. Relationship between threshold and suprathreshold measures

Because of the expansive nature of the nonlinearity relating loudness to electrode separation and current amplitude, the effect of the electrode separation on loudness is much larger at high-current levels than at threshold. By setting the loudness L in Eq. (3) to a fixed value $L0$, we can predict the current I required at a given electrode separation M, as follows:

$$I=\frac{\ln(L0)}{c+kM}. \tag{8}$$

From Fig. 8, for the subjects included in the present study, c ranges from 0.0035 to 0.0066, and k ranges from 0.0009 to 0.0014. For the purposes of this discussion, we choose $c=0.0050$ and $k=0.0010$, both intermediate values in their respective ranges. Given these values, we can describe I as a function of M for a particular loudness. Equal loudness plots were constructed from Eq. (8), for different values of L ranging from 2 to 64. Each line in Fig. 9 represents a doubling of loudness. It is evident from the figure that for small M, a large change in I is required to produce a doubling in perceived loudness, whereas for large M, a small change in I will produce a doubling in perceived loudness. The data points shown at the bottom of the figure correspond to the thresholds measured in the four subjects for the electrode configuration (20-M,20).

Most of the threshold data fall in between the lines corresponding to $L=2$ and $L=4$. While the methodological differences between experiments 1 and 2 do not allow for precise quantitative comparisons between the (presumably more objective) threshold data and the predicted equal-loudness functions, the fact that the form of the predicted equal-loudness function at low-current levels is a good approximation to the threshold vs electrode separation data suggests that similar mechanisms may be operating both at and above threshold.

B. Underlying mechanisms and implications for auditory models

The threshold data obtained in this study are in qualitative agreement with results from experiments using the (physiological)-evoked auditory brainstem response in subjects using the Nucleus-22 device (Abbas and Brown, 1991) and with psychophysical data obtained by Pfingst *et al.* (1995). In the Abbas and Brown (1991) study, correlations were also observed between the psychophysical threshold and the physiological EABR thresholds. The same study measured the growth of the EABR peak as a function of stimulus amplitude. Consistent with the results presented here, they found that the EABR exhibits the widest dynamic range for the most focused stimulation. Although they did not measure loudness functions, the authors found that the psychophysical dynamic range was correlated with the slope of the EABR growth function. Shephard *et al.* (1993) also found that the EABR growth function steepened with increasing electrode separation in the cat cochlea. These qualitative similarities are reassuring, and suggest that the psychophysical relationships described here have a basis in peripheral processing. The evoked EABR data are well approximated by the output of Frijns' detailed model of auditory-nerve responses to electrical stimulation (Frijns, 1995), which assumes that the EABR magnitude is determined by a simple sum of activity across the neural population without incorporating any nonlinearities in the input/output function of the auditory neurons.

The precise transformations leading to the psychophysical functions, of course, cannot be determined precisely at our current state of knowledge. For instance, the EABR grows linearly with current amplitude, but the loudness function grows exponentially with current amplitude. If we think of the EABR as broadly representative of the output of a peripheral processing stage, and the loudness function as broadly representative of a central processing stage, the difference between the growth functions may imply the presence of an expansive nonlinearity in between the two stages of processing. An exponential nonlinearity of this nature has been proposed by Zeng and Shannon (1992,1994). Their model of loudness assumes a compressive cochlear nonlinearity, followed by an expansive central nonlinearity. They suggest that for cochlear-implant patients, loudness grows as an exponential function of current amplitude because the cochlear nonlinearity is absent.

For such a model to work, information processing by auditory neurons would have to be similar in electric and acoustic stimulation. Although relatively little is known about the physiological responses of auditory centers to electrical stimuli, the known differences between auditory and electrical stimulation need to be considered before direct comparisons are performed. It is known that auditory neurons in deafened cochleae demonstrate little or no spontaneous firing, and respond with almost perfect synchronization

to electrical stimuli. In contrast, with a normal cochlea, auditory neurons are spontaneously noisy and show poorer synchronization to (acoustically presented) periodic stimuli (Hartmann and Klinke, 1990; Dynes and Delgutte, 1992). Because of their strong synchronization, the firing rates of electrically stimulated auditory neurons show saturation at the rate corresponding to the stimulus period. Thus, regardless of current amplitude, the same neuron will saturate at 200 spikes/s when stimulated at 200 pulses/s, and at 800 spikes/s when stimulated at 800 pulses/s (Javel, 1990). In normal acoustic hearing, the stochastic firing of the neurons results in a dynamic range that is relatively independent of the periodicity of the stimulus. In addition, their dynamic ranges are related to their thresholds and spontaneous activity, which appear to be controlled by the output of the inner hair cell–auditory-nerve synapse. These factors are presumably absent in electrical stimulation of neurons in deafened cochleae. It is apparent from this discussion that, however tempting, comparisons between electric and acoustic stimulation will only be relevant when all the known variables involved in the two modes of stimulation are taken into account.

The present results suggest that current amplitude and the electrode separation along the cochlea play comparable roles in the function determining loudness growth. This fundamental finding is difficult to explain in terms of current models of auditory processing of electric and acoustic stimuli. In normal hearing, it is known that the total loudness of a wideband signal is equal to the sum of the loudness it evokes within each auditory filter (Zwicker *et al.*, 1957; Zwicker and Scharf, 1965). Thus, a wideband signal sounds louder than a narrow-band signal of the same total energy. In electrical stimulation, one may speculate that as the separation between the two electrodes of a stimulating pair is increased, their respective fields interact less and less, and they may function more and more like a pair of true monopoles. If so, the neural populations responding to a widely separated electrode pair may be more independent than neural populations responding to a narrowly separated electrode pair. If similar mechanisms are at play in both acoustic and electric stimulation, the summation of loudness across independent channels may indeed result in lower thresholds and steeper loudness functions for the more widely separated electrode pair.

IV. CONCLUDING REMARKS

The decay of threshold with electrode separation can be quantified using an exponential function, with an asymptote at monopolar threshold. The present work also suggests a simple, robust relation between the stimulation mode and the rate of loudness growth. Although the small size of the subject pool is a disadvantage of this study, the findings are strengthened by the fact that the relationships show consistency regardless of the large intersubject variability in speech recognition with the implant.

The present experiments have been restricted to stimulation with a single electrode pair. The growth of loudness may be quite different when stimulation with multiple pairs of electrodes is considered. Further experimentation is clearly necessary in order to define the parameter space of loudness perception in electrical stimulation.

ACKNOWLEDGMENTS

The author thanks Qian-Jie Fu for the software used to run the experiments. Fan-Gang Zeng, Robert Shannon, Steven Otto, Mark Robert, and the reviewers of the Journal are thanked for helpful comments. Lendra Friesen is thanked for the subjects' scores listed in Table I. We are grateful to our subjects for their enthusiastic participation in the experiments. We thank Dawna Mills and Darlene Fragale of the House Ear Clinic for their help in identifying subjects. Jim Heller, Vena Margo, and Cochlear Corporation are thanked for providing us with the calibration tables for each subject. Work supported by NIDCD RO1 DC01526-05.

[1]Similar relationships were observed when the loudness estimates were plotted against dB microamperes (*re*: 1 microampere), and exponential functions were fit to the data. While the resulting exponents varied linearly with the electrode separation *M*, the slopes and the intercepts were different. These relationships can be derived algebraically.

Investigation of the effects of temporal and spatial interactions on speech-recognition skills in cochlear-implant subjects

Chandra S. Throckmorton[a] and Leslie M. Collins[b]
Department of Electrical Engineering, Duke University, Durham, North Carolina 27708-0291

(Received 30 March 1998; accepted for publication 5 November 1998)

Forward masking was investigated as a measure of spectral and temporal interactions. Such interactions may adversely affect speech recognition in cochlear-implant subjects. Seven subjects, implanted with the Nucleus 22 device, performed a forward-masking task. They also performed an electrode-discrimination task in order to measure spectral interactions without temporal interactions. Correlation analysis indicated a significant relationship between data obtained in the two tasks ($p<0.1$). The two tasks were also correlated with the subjects' scores from five measures of speech recognition. Forward masking and electrode discrimination were strongly correlated with measures requiring consonant and phoneme recognition, respectively. These results indicate that the relationship between forward masking and speech recognition may be due, in part, to a lack of spectral resolution. The data also indicate that consonants may be more readily masked than vowels. Forward-masking data measured for all clinically programmed electrodes in three of the seven subjects were used with a model of the spectral maxima sound processor (SMSP) to estimate the number of electrodes stimulated during a consonant that might be masked by prior presentation of a vowel. These results suggest that temporal interactions across electrodes may be a factor in speech-recognition abilities of some cochlear-implant subjects. [S0001-4966(99)03902-8]

INTRODUCTION

The design of speech processors for cochlear implants relies on several assumptions regarding subjects' perceptual response to electrical stimulation. These assumptions are that each electrode is distinct both spatially and temporally, or equivalently that electrode interactions do not occur. More fundamentally, it is often assumed that each electrode stimulates a unique population of neurons, and that stimulation of one electrode does not affect the perceptual response to stimulation that is applied to other electrodes. When these assumptions are invalid, the information to be transmitted through the electrode array may be distorted, or in the most extreme case, imperceptible. Thus, the evaluation of such assumptions, as well as evaluation of potential remediation strategies that could be implemented when the assumptions are not met, is of significant interest to researchers in implant psychophysics.

Several methods for evaluating such interactions and their effects on speech-processing algorithms have been proposed and evaluated in the literature. These methods can be broadly categorized as methods that are used to evaluate spectral or spatial interactions, and methods that are used to evaluate temporal interactions. In practice, some methods overlap these two categories. Techniques used to evaluate abnormalities in the spectral structure elicited by electrical stimulation include pitch ranking and pitch scaling (Shannon, 1983; Townshend *et al.*, 1987; Busby *et al.*, 1994; Busby and Clark, 1997; Collins *et al.*, 1997), multidimensional scaling (McKay *et al.*, 1996), and electrode discrimination (Busby *et al.*, 1993; Busby and Clark, 1996; Zwolan *et al.*, 1997). Techniques that have been used to investigate temporal interactions include gap detection (Shannon, 1983), as well as forward masking (Shannon, 1983; Tong and Clark, 1986; Lim *et al.*, 1989; Shannon, 1990; Blamey *et al.*, 1993; Chatterjee and Shannon, 1998). However, gap detection and forward masking may also be used to assess spatial interactions since each measure is affected by neural population overlap (Shannon, 1983, 1990; Chatterjee and Shannon, 1998).

The study of electrode interactions allows researchers and clinicians to both quantify the amount of interaction and assess the effectiveness of current methods of speech processing. Factors that can be evaluated regarding the speech-processing algorithms include the set of electrodes that are stimulated, the order in which electrodes are stimulated, and the rate at which they are stimulated. Most of the studies listed above have indicated that electrode interactions do in fact occur, sometimes with deleterious effects. Townshend *et al.* (1987), Zwolan *et al.* (1997), Busby *et al.* (1997), and Collins *et al.* (1997) have discussed possible methods for reducing information distortion and/or loss due to indiscriminable electrodes and unusual ordering of the pitch percept. These methods include removing indiscriminable electrodes from those available for stimulation and reordering the electrodes into tonotopic order. In addition, Merzenich and White (1977), among others, have recommended sequential stimulation rather than simultaneous stimulation of electrodes in order to reduce the summation of electrical fields. This approach also reduces masking effects; however, as Shannon (1983, 1990), Tong and Clark (1986), Lim *et al.*

[a]Electronic mail: cst@ee.duke.edu
[b]Electronic mail: lcollins@ee.duke.edu

(1989), and Chatterjee and Shannon (1998) have shown, forward-masking effects have not been eradicated by sequential stimulation.

Forward-masking studies in both normal-hearing and implanted individuals have suggested that the elevated thresholds observed in forward-masking tasks in which the masker and probe are in close proximity are a result of the refractoriness of the underlying neural population. The amount of the threshold shift observed in masking tasks can thereby be assumed to be proportional to the amount of neural population overlap. Under these assumptions, forward-masking data can potentially be used to estimate the excitation patterns that occur in the cochlea. As such, in a ''textbook'' case, the amount of masking measured for a probe stimulus should decrease monotonically as distance between the probe and masker excitation increases. Deviations from this expected pattern may, in some cases, be indicative of a ''nonideal'' cochlea, and may suggest variability in current paths or nerve survival in implanted subjects.

Since forward masking also occurs in normal-hearing subjects (Jesteadt *et al.*, 1982 and others), the issue becomes not whether forward masking occurs, but whether it negatively affects the implanted individual's speech-recognition skills. One hypothesis is that forward-masking effects correspond to reduced spectral resolution, which can negatively affect speech recognition. This reduced spectral resolution can also be quantified through electrode-discrimination paradigms. A second hypothesis is that forward masking may be considered a measure of temporal interactions, which in turn may adversely affect speech recognition. It is well known that consonant recognition is consistently poorer in cochlear-implant subjects than vowel recognition (Dowell *et al.*, 1982; Blamey *et al.*, 1987; Tye-Murray and Tyler, 1989; Dorman *et al.*, 1991; Tyler and Moore, 1992; Pelizzone *et al.*, 1993; Doyle *et al.*, 1995). One possible explanation for this difference is that, through the phenomenon of forward masking, the energy in a vowel renders the information in a following consonant imperceptible. Both of these hypotheses are explored in this paper.

Because of the large number of masker/probe pairs, data collected in previous forward-masking studies have been limited to a few of the available combinations. Thus, the effects of the delay time between masker and probe, masker level (Chatterjee and Shannon, 1998; Shannon, 1990), masker position (Shannon, 1983), and distance between masker and probe (Lim *et al.*, 1989; Chatterjee and Shannon, 1998) have been studied for only a few combinations of masker and probe electrodes. By varying masker level, masker–probe delay, and probe location for a basal-, apical-, and centrally located masker, Chatterjee and Shannon (1998) noted a possible connection between poorer speech recognition and greater susceptibility to changes in forward-masking parameters. In the present study, data on seven subjects representing a wide range of speech-recognition skills were gathered; thus, it was possible to examine the correlation between speech recognition and forward masking, a topic which has not previously been explored in a rigorous fashion.

In this study, forward-masking patterns were measured for all active electrodes in three subjects implanted with the Nucleus 22 device. In addition, forward-masking patterns were measured for a masker located near the center of the array in four subjects, also implanted with the Nucleus 22 device. Electrode discrimination was measured for all seven subjects. With this data, the relationship between forward-masking effects, electrode discrimination, and speech-recognition ability was investigated. Correlation coefficients between average-masking levels and speech-recognition scores were calculated, and two hypotheses based on these results were investigated. Based on the potential temporal effects of forward masking on speech recognition, the first hypothesis that was investigated was that forward masking causes consonant information to be lost as a result of a previous stimulation occurring in response to a vowel. The possible ramifications of the first hypothesis were estimated through a model of the SMSP speech-processing algorithm (McDermott *et al.*, 1992). The second hypothesis considered forward masking to be a measure of spectral resolution, and its relationship with electrode discrimination, another measure of spectral resolution, was investigated.

I. METHODS

A. Subjects and equipment

One male and two female subjects implanted with the Nucleus 22 device completed the forward-masking task for all of their functioning electrodes, producing masking patterns for each electrode in the form suggested by Lim *et al.* (1989). Additional subjects, one female and three male, completed the forward-masking task for one centrally located electrode. These seven subjects also completed an electrode-discrimination task to determine which electrode pairs in their array were indiscriminable. All subjects had at least 6-months experience with their device. The demographic information for these subjects is presented in Table I. All of the subjects who participated in this study used either bipolar+1 (BP+1) or BP+2 modes of stimulation. In the remainder of this paper, when a specific electrode is referenced, it is the more basal of the bipolar pair (e.g., for the BP+1 mode of stimulation, electrode 1 refers to the bipolar pair [1,3]). The 22 electrodes in the array are ordered sequentially from base (1) to apex (22).

Stimuli were delivered to subjects through an implanted receiver/stimulator driven by a Cochlear Corp. Spectra 22 processor connected to a Cochlear Corp. Dual Processor Interface (DPI). Stimuli were presented in the psychophysical procedures via custom-designed software which interfaced to the device through the DPI and Cochlear Corp. IF4 board. These procedures were run on an IBM personal computer that also controlled the DPI. A color monitor was used to cue the subjects and display feedback information when applicable. Subjects indicated the chosen interval on each trial by depressing the appropriate key on the computer keyboard. The use of human subjects as described in this manuscript was approved by the Duke University Institutional Review Board and the National Institute on Deafness and other Communication Disorders.

TABLE I. Demographic information for the implanted subjects.

Subject	Sex	Age (years)	Age at onset of profound deafness (years)	Age at implantation (years)	Mean/standard deviation of dynamic range across all active electrodes (in μA)	Mode of stimulation
S1	M	71	25	62	122/20.2	BP+1
S2	M	72	16	62	643/176	BP+1
S3	M	65	20	57	517/309	BP+2
S4	F	74	57	66	254/62.5	BP+1
S5	F	48	41	45	535/60.6	BP+1
S6	F	40	23	33	483/104	BP+1
S7	M	60	56	57	184/50.0	BP+2

B. Stimuli

In all of the experimental tasks, the stimuli presented consisted of biphasic rectangular pulses with a constant phase duration of 200 μs/phase, and were presented at a stimulation rate of 500 pps. The loudness of the stimuli was adjusted by changing the amplitude of the stimuli. For the tasks designed to measure threshold level, comfort level, loudness balance level, and electrode discrimination, the stimulus duration was 300 ms and the interstimulus interval was 500 ms.

For the forward-masking task, the duration of the masker was 300 ms, and the duration of the probe was 20 ms. The delay between masker and probe was 2 ms, while the delays between intervals and trials were each 500 ms. Since the elevation of the threshold of the probe is the quantity of interest to evaluate masking effects, unmasked thresholds for all electrodes were also measured using a stimulus duration of 20 ms.

C. Tasks

1. Loudness balancing

In order to perform the loudness-balancing task, it was first necessary to measure the threshold and maximum-comfort level for each of the functioning electrodes. Both were measured using a method of adjustment in which the subject controlled the amplitude of the stimulus using the stimulus-control knob associated with the DPI. For each electrode, the subject adjusted the amplitude until threshold and maximum-comfort level were achieved. The stimulating software controlled the current in ''current level'' units, which vary in size but average approximately 0.16-dB of current. Subsequently, these amplitude values, which range from 1 to 239, are referred to as ''cochlear-device amplitude steps.'' Once the thresholds and maximum-comfort levels of all the functioning electrodes were measured, the task was repeated. The largest values of threshold and maximum-comfort levels for each electrode were assumed to be the correct values.

To loudness balance the stimuli on each electrode, subjects were asked to adjust the loudness of a stimulus presented to one of their electrodes to the loudness of a stimulus presented to a central reference electrode. The amplitude of the stimulus that was presented on the reference electrode was adjusted by the subject to achieve a comfortable loudness level prior to beginning the loudness-balance task. Stimulation alternated continuously between the reference electrode and the test electrode until the subject indicated that a balance had been achieved. At this point, the balanced value was recorded.

This task was performed six times for each electrode comparison. On three of these runs, the initial amplitude of the test electrode was set at its threshold, and the subject increased its amplitude to match the reference electrode's loudness level. In the remaining three runs, the test electrode's initial amplitude was set to a level slightly below the maximum-comfort level, and the subject decreased its amplitude to match its loudness to that of the reference electrode. The six measured values were then averaged for each test electrode, and this average value was considered the loudness-balanced value and was used in the forward-masking task as the masker stimulus level. This procedure was used to avoid subject bias, and to bracket the ''equally loud'' range of stimuli. At the completion of all comparisons, all electrodes were stimulated in sequential order at the loudness-balance level to verify the results of the loudness-balance procedure.

Presenting the maskers at loudness-balance level implies that the actual current levels at which the maskers are presented will differ across subjects and electrodes. Since increasing the current level at which a masker is presented also increases the forward-masking effects produced by that masker, some of the masking effects recorded in this study are probably due to presenting maskers at different current levels. However, one of the goals of this study was to investigate the relationship between speech recognition and forward masking. Speech processors attempt to present speech at a comfortable loudness level for each individual subject; thus, a particular acoustic stimulus may be presented to different subjects at different current levels. Therefore, forward-masking effects for a particular acoustic stimulus will be influenced both by the physiological differences between subjects as well as by the differences in current levels. With this in mind, the maskers were presented at a comfortable loudness level rather than at absolute-current level.

2. Probe threshold baseline measurement

In order to assess forward-masking effects as accurately as possible, each electrode's 20-ms threshold was measured using an adaptive 2 down/1 up two-interval forced choice (2IFC) procedure. After each incorrect response, the signal amplitude was increased by one step, and it was decreased after two correct responses. To estimate the threshold, the

TABLE II. Masker/probe pairs that were measured at least twice to verify the masking level. The asterisk indicates that the second measurement was greater than the first measurement.

Subject	(Masker, probe) pairs	Differences between first and second measurements (dB *re*:1 μA)/dynamic range of probe (dB *re*: 1 μA)

S4	(10,8)	6.99/26.26
	(12,14)	*10.00/30.05
S5	(17,19)	14.77/29.51
	(18,5)	13.80/29.03
	(4,19)	18.06/28.64
S6	(6,19)	22.70/28.64
	(12,10)	11.46/27.21
	(17,18)	15.91/28.31
	(2,4)	18.63/26.11
S7	(2,15)	16.34/25.75
	(19,3)	0.00/27.03

final eight of the 14 reversals obtained were averaged. This converges on the signal amplitude, which produces 70.7%-correct responses (Levitt, 1971). The step size used in the adjustment was one cochlear-device amplitude step. One interval contained the electrode stimulation, while the other interval contained an equal duration of silence. Feedback was provided. The subject's task was to choose the interval in which the electrode was stimulated.

3. Forward-masking procedure

A 2 down/1 up adaptive 2IFC procedure was used to measure the change in the threshold of a particular electrode (probe) due to a preceding stimulation either on the same electrode or a different electrode (masker). The step size used in the adjustment was one cochlear-device amplitude step, and feedback was provided to the subjects. An exhaustive procedure was performed in which each functioning electrode served as a masker. All available odd-numbered electrodes were used as probes. In addition, the two electrodes on either side of the masker as well as the masker electrode also served as probe electrodes. In one interval, only the masker was stimulated while in the other, stimulation of the masker was followed by 2 ms of silence and then stimulation of the probe. The intervals were randomized so that the probe was equally likely to occur in either interval. The total duration of each interval was identical.

The masker amplitude was fixed at the loudness-balanced level, and the initial amplitude of the probe was set so that it was easily detectable. The subject's task was to choose which of the two intervals contained the probe stimulus. The last eight of 14 reversals were averaged to obtain one data point for each masker/probe combination, except when results which were strongly inconsistent with the expected pattern of results were observed during measurement. When this occurred, the combination was tested at least twice to verify that the measurement was not due to laxity on the part of the subject. Table II lists these combinations for each subject, as well as the changes in the measured values. In all cases except one, the second measurement of the masked threshold was lower than the first measurement, and the lower values were considered the masked thresholds.

Although testing each masker/probe pair once is certainly suboptimal, one of the goals of this study was to investigate forward-masking effects across all possible combinations of electrodes for three subjects. Using an adaptive procedure, all three subjects required approximately 1 year of psychophysical testing to complete this protocol (at an average of one test session per week). Future studies will investigate the extent of the variability associated with single versus multiple measurements. The variability by the lack of averaging data affects all of the analyses in this study. However, assuming that the masked thresholds consisted of some overestimation as well as underestimation, the effects of the variation due to single-point measurements in the correlation analysis were probably decreased by using average masking levels rather than the single-point measurements. Furthermore, in the estimation of the number of masked electrodes per consonant, the estimates probably contain some overestimation and underestimation due to single-point measurements, and thus, only the average over all the consonants was considered for comparison between subjects.

4. Electrode discrimination

For the four subjects who completed the forward-masking task for only a central electrode, electrode-discrimination data reported in Collins *et al.* (1997) were utilized. Discriminability between electrodes for the three subjects completing the forward-masking task for all of their functioning electrodes was determined using a 2IFC fixed-level procedure. The amplitudes of stimulation for the electrodes were fixed at loudness-balance levels. Discrimination was measured in 60 trial blocks for each electrode pair, and a d' value was calculated. For each trial, either the same electrode was stimulated in both intervals or each interval corresponded to a stimulus presented on different electrodes. Thus, the subject's task was to decide whether the intervals contained stimulations which were the ''same'' or ''different.'' The presentation of same and different stimuli were equally likely, and feedback was provided after each response.

5. Speech-recognition measurement

The speech-recognition skills of the seven subjects were measured using four speech-recognition tests. The nine-choice closed-set Iowa medial vowel test was administered. In this test, each of the nine stimuli (heed, had, heard, hud, who'd, hawed, hid, head, and hood) were presented five times in random order (Tyler *et al.*, 1986). The Cochlear Corp. version of the 14-choice closed-set Iowa medial consonant-recognition task was administered, in which each of the fourteen stimuli (apa, aba, ama, ana, ata, ada, ava, afa, aga, aka, asa, aza, asha, and aja) were presented five times in random order (Tyler *et al.*, 1986). The NU6 Monosyllabic Words test (Tillman *et al.*, 1966), which was scored for the 50 possible words and 150 possible phonemes, was admin-

istered, along with the CID Everyday Sentences test (Davis *et al.*, 1978), which was comprised of 20 sentences with a total of 100 key words. Taped stimuli were presented to the subjects in a double-walled, acoustically insulated booth (LAC, Bronx, NY). All tests were administered during the last test session of the experiment. The stimuli were presented once, and the subjects recorded their own responses. The subjects used their clinically programmed speech processors during speech-recognition testing. Results are reported as percent correct.

D. Speech processor model

This model was used to investigate possible masking effects on consonants which may occur as a result of the stimulation pattern of a vowel in subjects implanted with the Nucleus 22 device. A model of the spectral maxima sound processor (SMSP) strategy, as described in McDermott *et al.* (1992), was implemented. With this model, it was possible to predict which electrodes would be stimulated in response to various speech tokens along with their corresponding levels of stimulation. The input to this model consisted of the Iowa Medial Consonant test words (Tyler *et al.*, 1986).

McDermott *et al.* (1992) estimate that six pulses can be presented to the electrode array every 4 ms. Based on this estimate, N nonoverlapping 4-ms windows of the test word were processed by the model, where $4N$ was the duration of the stimulus. Each window of speech data produced 16 spectral peaks corresponding to the output of 16 filters (McDermott *et al.*, 1992). Of these 16 peaks, the six largest, along with their corresponding filter numbers, were stored. Thus, each test word produced a filter matrix and a spectral-amplitude matrix which were of dimensions N by 6. The two matrices derived were independent of a particular subject.

The filter numbers were mapped to the set of 16 most apical, available electrodes. The filter with the highest passband was mapped to the most basal electrode of the set, while the filter with the lowest passband was mapped to the most apical of the set. Thus, the filter matrix was mapped to a matrix of electrodes.

The spectral amplitudes were converted to current based on the method described by Skinner *et al.* (1991). It was necessary to assume a maximum-stimulation level in order to carry out this procedure. Normally, the maximum-stimulation level would be set by the subject on their device using the sensitivity control to adjust the automatic gain control. In order to simulate a ''best case'' scenario, the largest amplitude contained within the spectral-amplitude matrix was mapped to the maximum-comfort level, and the other values were mapped accordingly. In this way, the spectral-amplitude matrix was converted into a current-level matrix.

The final stage of this process involved calculating whether the electrodes that are stimulated in response to a vowel would mask the stimuli that occur in response to a consonant following the vowel. For each test word, the electrode matrix and the current-level matrix were separated into phonemes so that these effects could be investigated. Since forward-masking data was gathered under the two conditions that the masker was of 300-ms duration and at loudness-balance level, it was necessary to analyze the data under these conditions. In this analysis, the first condition was matched by looking at the effects of vowels on subsequent consonants, since the vowels typically consist of repeated stimulation of six electrodes for a ''long'' duration.

The second condition was addressed by scaling the current levels of the maskers to loudness-balance level. For each masker, the ratio of the loudness-balance level to the actual-current level was calculated. The largest ratio was used to scale the consonant-current levels, and all the maskers were assumed to be at loudness-balance level so that the measured data could be used. However, all but one of the masker levels calculated using the model were greater than the loudness-balance level as a result of using the largest ratio. Since masking effects increase with masker level (Jesteadt *et al.*, 1982; Lim *et al.*, 1989; Chatterjee and Shannon, 1998), actual masking would be greater than the masking calculated with this model.

To calculate the masking effects vowels have on consonants, a representative window of the vowel phoneme was selected to represent the stimulation pattern that occurs in response to a vowel. Each electrode contained within the vowel window was considered a masker. Calculating the masking effect of the vowel electrodes on the consonant electrodes required use of the forward-masking data gathered across the whole array. If a masker/probe combination was not measured, a value was interpolated from the preceding and subsequent probe measurements. Based on this analysis, the number of electrodes stimulated in response to a consonant that were masked by the vowel stimulus could be calculated.

TABLE III. Speech-recognition scores of all seven subjects using five different measures. Scores are reported as percent correct.

Subject	NU6 (W) (%)	NU6 (P) (%)	CID (%)	Consonants (%)	Vowels (%)
S1	12	27	25	28	62
S2	0	0	0	10	24
S3	8	26	9	27	44
S4	18	49	79	41	84
S5	20	39	56	33	67
S6	12	45	43	46	71
S7	34	55	81	53	59

II. RESULTS

A. Speech recognition

Table III lists the percent correct scores achieved on the NU6 words, NU6 phonemes, Iowa medial vowels, Iowa medial consonants, and the CID sentences tests. Clearly, speech-recognition abilities varied widely across subjects. No ceiling effects were noted on any of the test materials.

B. Masking

The relationship between the masked-probe threshold and its unmasked threshold was examined. Masking patterns, examples of which are shown in Figs. 1–4, were generated for all subjects for each electrode that was used as a masker. These figures plot the measured masking level as a function

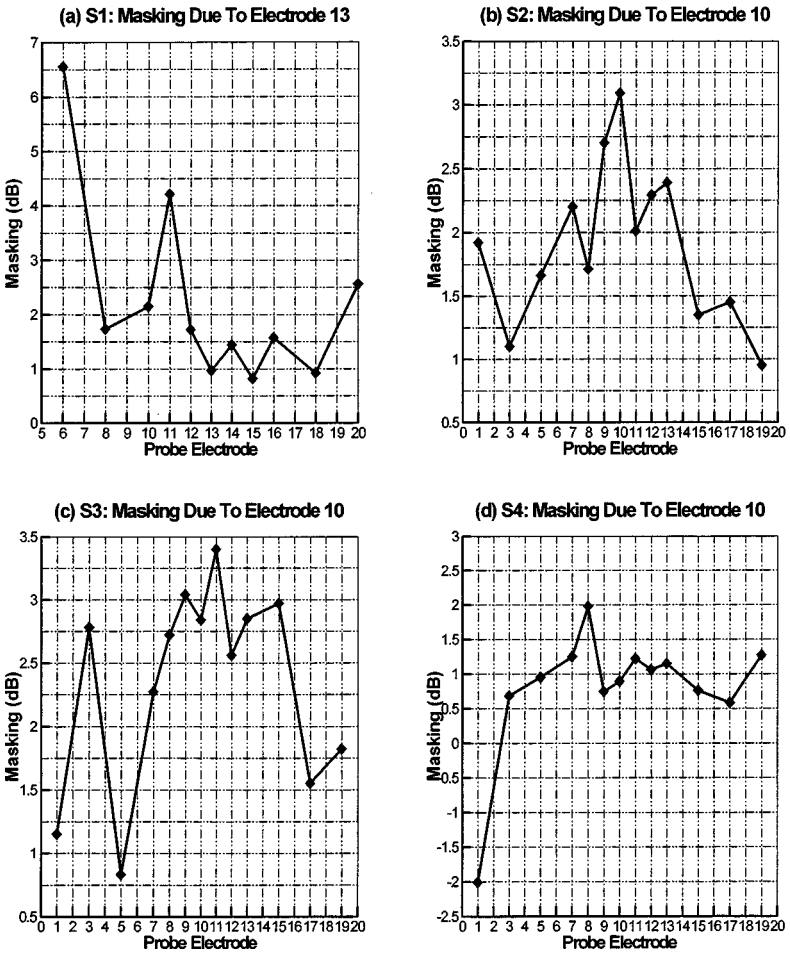

FIG. 1. Masking patterns for those subjects who only completed the forward-masking task for a centrally located electrode. The symbols indicate masker/probe pairs that were measured. The electrodes used as maskers were (a) electrode 13 for S1, (b) electrode 10 for S2, (c) electrode 10 for S3, and (d) electrode 10 for S4.

of the probe electrode number. Each panel in Figs. 1–4 represents the masking pattern measured for a particular masker. Each data point plotted in a panel, shown with a diamond symbol, represents the average of the final eight reversals measured in the adaptive procedure for the probe identified on the abscissa. In order to compare masked levels across probe electrodes, the difference of the masked and unmasked thresholds was normalized, as suggested by Lim *et al.* (1989). The normalization was performed using a ratio of loudness-balanced levels to threshold levels. Thus, the masking level for probe electrode j due to masker i, m_{ij}, was calculated via

$$m_{ij} = (T_j^{\mathrm{msk}} - T_j^{20}) \frac{\mathrm{LB}_i - T_i}{\mathrm{LB}_j - T_j}.$$

T_j and T_i are the 300-ms unmasked thresholds of the probe and masker in dB, LB_j and LB_i are the loudness-balanced levels of the probe and masker in dB, T_j^{msk} is the masked threshold of the probe in dB, and T_j^{20} is the 20-ms unmasked threshold of the probe in dB. A masking level of 0 dB indicates that no masking occurred.

Figure 1 displays the masking patterns resulting from this method of analysis for the four subjects who completed the forward-masking task for one centrally located electrode (S1–S4). Figures 2–4 contain four representative masking patterns for the three subjects who completed the full study (S5–S7). These patterns were selected to illustrate the patterns that were obtained at various locations across the array (apical, mid, and basal), as well as to illustrate the variety of patterns which was obtained.

Theoretically, the most masking should occur when the masker and probe are located at the same electrode, and masking should decrease monotonically as the distance between masker and probe electrodes increases. In addition, the amount of masking should never be less than zero. Although the maximum masking occurred under these conditions for some maskers and subjects, as shown in Fig. 1(b), this was not always the case. An example of a pattern in which the peak in the masking pattern is not located at the masker is shown in Fig. 2(a). In general, however, higher levels of masking did occur for probe electrodes located close to the masker electrode.

In addition, masking patterns did not necessarily decrease monotonically as the distance between the masker and probe electrodes increased. These results are similar to those observed by Chatterjee and Shannon (1998), Lim *et al.* (1989), and Shannon (1983). Chatterjee and Shannon (1998) observed nonmonotonic masking patterns in the majority of their subjects. They also observed that peaks in the masking patterns were not coincident with the masker location for one of the masker/probe combinations obtained from two of their four subjects. Lim *et al.* (1989) and Shannon (1983) both reported nonmonotonic masking functions from their subjects.

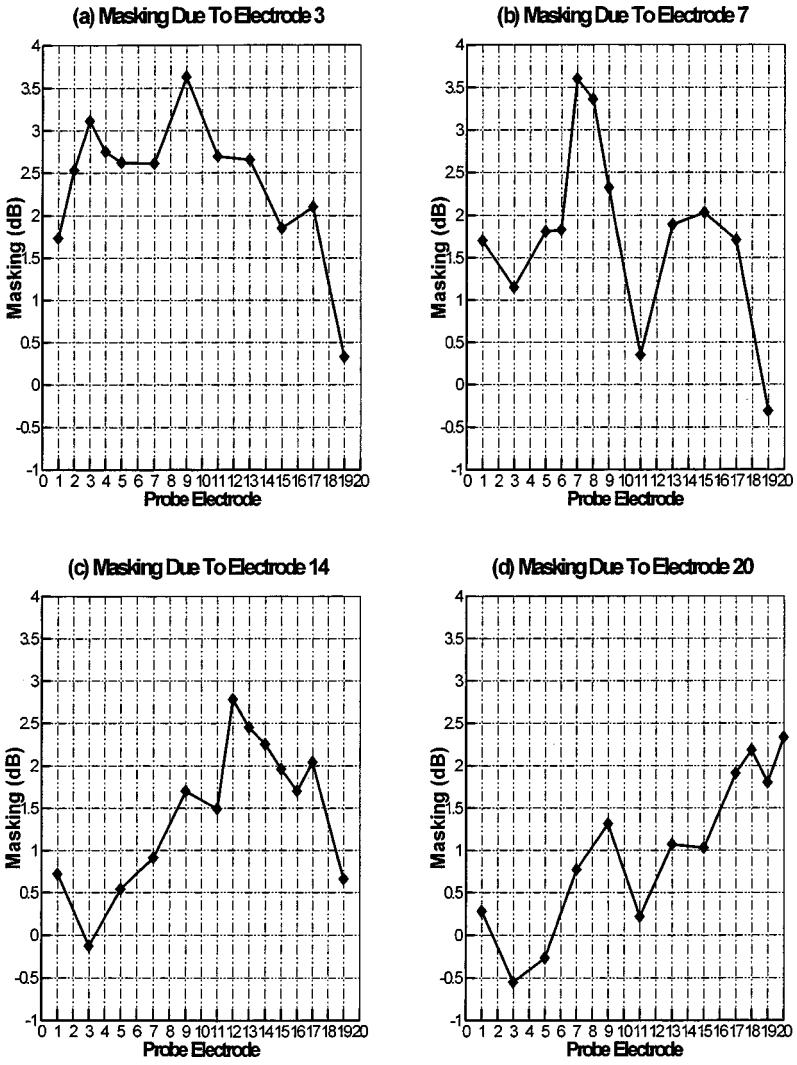

FIG. 2. Four of S5's 20 masking patterns chosen as representative. The symbols mark masker/probe pairs for which forward masking was measured.

To quantify these effects, Table IV lists the number of times the peak in the masking pattern occurred at the masker location for each of the three subjects who completed the complete masking study. In addition, Table IV lists the number of times the masker location was either adjacent to the peak in the pattern, or was the second-highest peak in the masking pattern. The final row of Table IV lists the number of maskers for which masking patterns were measured. Clearly, the degree to which the various subjects' data conforms to the expected pattern in which a peak occurs at or nears the masker is subject dependent. Subject S7, whose data follows the expected pattern more closely than the other subjects, has higher speech-recognition scores than subjects S5 and S6. It is interesting to note that the majority of the subjects who participated in previous masking studies all had relatively high speech-recognition scores. This fact, in addition to the fact that only a few masker–probe combinations were measured, may help explain why there were relatively few instances in which the peak in the masking pattern was not located at the location of the masker in these previous studies.

The data from this study indicates that not only does the maximum masking occur for probes at locations other than the masking electrode in some cases, but some combinations of probe and masker result in masking data less than 0 dB. Negative masking levels occur when the masked threshold is less than the unmasked threshold. Similar results can also be seen in data from other studies (Shannon, 1990; Chatterjee and Shannon, 1998). The adaptive procedure was not restricted to presenting probe stimulus levels that were strictly greater than the 20-ms unmasked thresholds; thus, it is possible that negative masking levels are a result of experimental variability in estimates of both masked and unmasked thresholds.

The data also indicates that maskers affect large portions, if not all, of the electrode array rather than only raising the thresholds of neighboring electrodes. These results are similar to those described in previous studies (Shannon, 1983; Lim *et al.*, 1989; Chatterjee and Shannon, 1998). The extent to which a masker affects the threshold of a probe electrode can be deduced by noting the distance between the probe and the masker at which the masking pattern falls to zero. For example, subjects S1, S2, S3, and S4 showed patterns of results in which the masking patterns either never reached zero (S1, S2, and S3), or reached zero for only one of the most distant electrodes (subject S4, electrode 1) for a masker located in the center of the array. Most subjects showed such electrode interactions, out to a spacing of 10–15 electrodes in some cases. The exception to this pat-

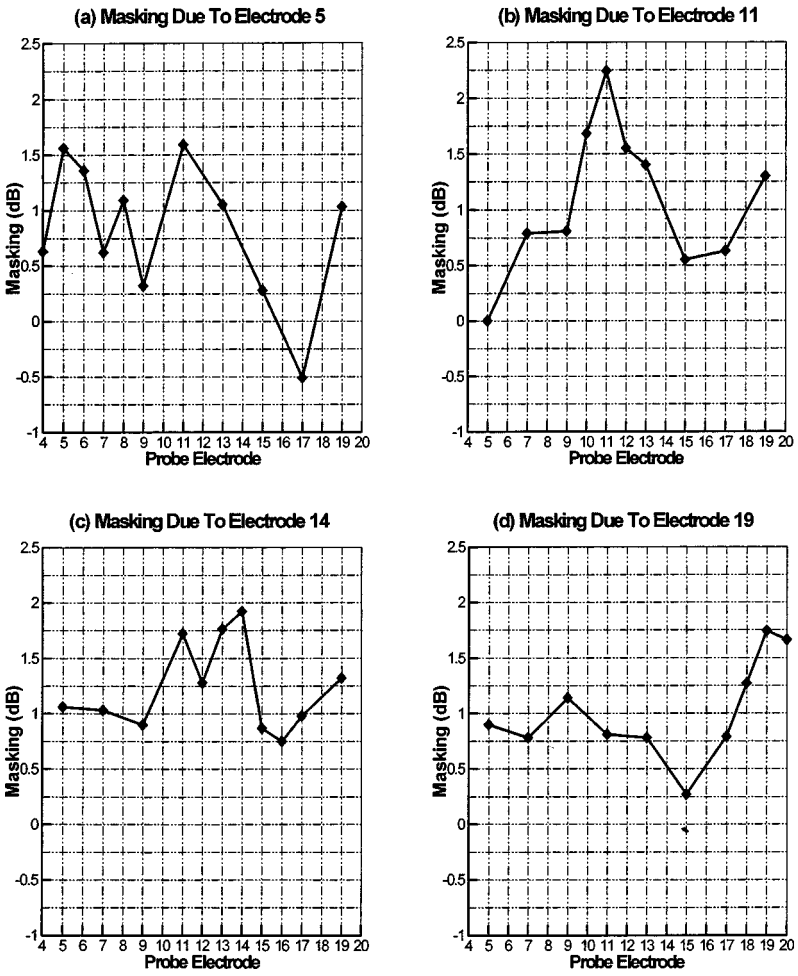

FIG. 3. Four of S6's 17 masking patterns chosen as representative. The symbols mark masker/probe pairs for which forward masking was measured.

tern is subject S7, whose masking patterns tended to fall to zero within approximately four electrodes.

In order to summarize all of the masking patterns collected, Fig. 5 contains the average of all of the masking patterns for subjects S5, S6, and S7. For each subject, the masking patterns obtained for each masker were aligned at the masker and then averaged. The resulting average of the masking patterns is plotted versus probe distance from the masker electrode. The results shown in Fig. 5 indicate that S5 experiences greater masking effects in terms of both amplitude and width of the masking pattern, while S6 differs from S5 mostly in the width of the average masking pattern. In addition, unlike S5 and S7, S6's average pattern increases in masking level, on the apical side, as the distance between masker and probe increases. The amplitude of the masking pattern can be considered to represent the degree of temporal interactions experienced by the subject, while the breadth of the masking pattern can be considered the extent of spatial interactions (i.e., the deficiency in spectral resolution). It should be noted that as the distance between masker and probe increases, the points along the average masking pattern are calculated using fewer measurements. For a subject with 20 functioning electrodes, the point representing a distance of 18 electrodes between masker and probe is the result of only one masking level (that measured for masker electrode 1 and probe electrode 19), while the point representing a distance of 0 electrodes is the average of 20 masking levels (each functioning electrode as masker and probe). Thus, the variance in the estimates of the average masking patterns increases with increasing electrode separation.

To obtain another measure of the variation in spectral resolution across subjects, the average electrode spacing required to reduce the interaction to zero for subjects S5–S7 was calculated. These electrode spacings are listed in Table V. The averages were calculated only for those patterns that decreased to within 0.5 dB of 0 dB. The average spacing required for subject S5 is 8.7 mm, for subject S6 it is 4.6 mm, and for subject S7 it is 2.6 mm. The spatial constant for electrical stimulation reported by Black and Clark (1980) was 2–3 mm which is similar to the average spacing required for subject S7, but substantially lower than that observed for subject S5 and, to some degree, S6. Subject S7, who has the highest speech-recognition scores of these three subjects, exhibits the smallest average spacing required to achieve minimal channel interactions. The differences between the average spacing for each of the three subjects are significantly different ($p<0.005$).

To obtain a relative measure of the amount of electrical interaction generated by a particular masker, an average masking level was calculated across all probe electrodes for each masker as

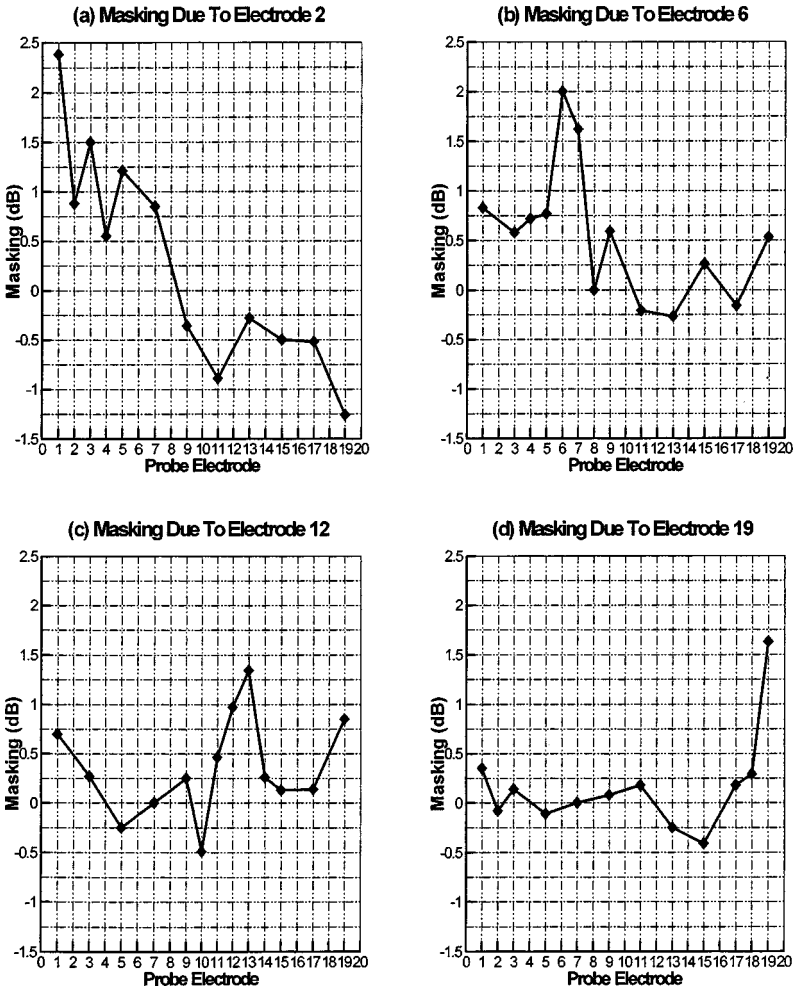

FIG. 4. Four of S7's 19 masking patterns chosen as representative. The symbols mark masker/probe pairs for which forward masking was measured.

$$m_i^{\mathrm{av}} = \frac{1}{P} \sum_{j=1}^{P} m_{ij},$$

where m_i^{av} is the average masking level for masker i, P is the number of probe electrodes measured for masker i, and m_{ij} is the normalized masking level measured at probe j as a result of masker i. Figure 6 shows the average masking levels calculated for each subject. A single point is plotted for those subjects for whom only a central electrode was tested. The average masking level includes effects from both temporal and spatial interactions (i.e., amplitude and breadth of a masking pattern) measured for a particular masker. Noticeable differences in average masking levels exist across subjects. Subjects S1, S2, S3, and S5 experience more masking on the average than subject S6, who in turn experiences more average masking than subject S4 and S7.

For each subject, Table VI lists average speech-

TABLE IV. Analysis of similarity between theoretical masking results and results obtained in this study.

Subject	S5	S6	S7
Number of times peak in masking pattern occurred when the probe was at the masker location	7	3	11
Number of times peak in masking pattern occurred for the probe adjacent to the masker location, or the peak at the probe at the masker location was the second-highest peak	10	7	7
Total number of maskers tested	20	17	19

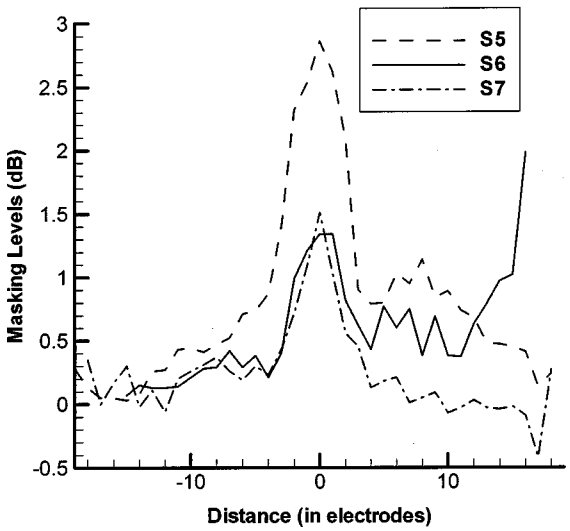

FIG. 5. Average of all masking patterns for S5, S6, and S7. The patterns are plotted with respect to the probe's distance from the masker.

TABLE V. Analysis of the spatial extent of masking for three subjects. Average distance from the masker electrode to the probe electrode at which interactions are minimized are reported in both electrode-to-electrode distance and mm. The differences between the average distance measures for all three subjects are statistically different ($p<0.005$).

Subject	Average distance from masker electrode to probe whose threshold is within 0.5 dB of unmasked threshold
S5	11.6 electrodes/8.7 mm
S6	6.2 electrodes/4.65 mm
S7	3.5 electrodes/2.63 mm

recognition scores along with the average masking level at a centrally located electrode. In general, the order of the subjects in terms of average masking effects (least to greatest) is similar to the order of their speech recognition capabilities (greatest to least).

C. Electrode discrimination

The spectral resolution of the seven subjects was examined by determining the number of electrode pairs which were indiscriminable. The number of indiscriminable electrodes for subjects S1–S4 was determined from data obtained in an earlier study reported by Collins *et al.* (1997). The number of indiscriminable electrodes for subjects S5–S7 was determined using a same/different task (2IFC) from which a d' value was determined. When $d'<1$, the electrode pair was considered to be indiscriminable. The number of indiscriminable electrodes for each subject is listed in Table VI, in the order of least to greatest average masking level. In general, the lower number of indiscriminable pairs corresponds to the higher average speech scores. Since the number of indiscriminable pairs may be used as a measure of spectral resolution, a correlation analysis between the number of indiscriminable pairs and speech-recognition scores was performed. Furthermore, the correlation between the

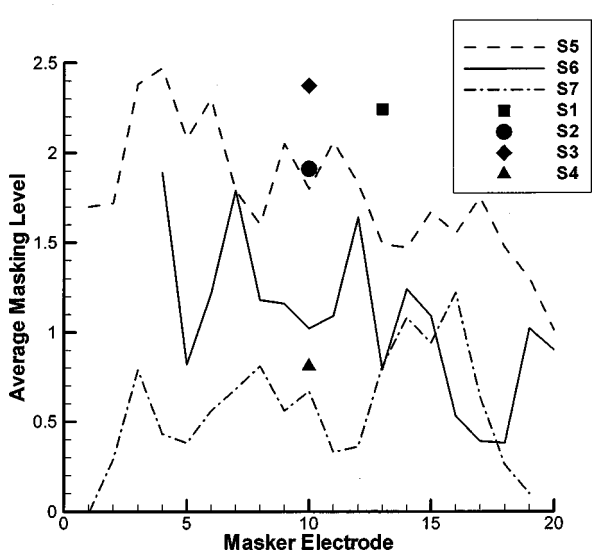

FIG. 6. Plot of the average masking levels due to each masker. Since subjects S1–S4 had only the masking effects of one electrode measured, their average masking amounts are represented by a single point. Subjects S5–S7 have average masking amounts for each functioning electrode in their array.

TABLE VI. Average speech-recognition and masking data for each of the seven subjects. Subjects are ordered in increasing level of average masking. This corresponds closely to an orderly decrease in average speech-recognition score. The number of indiscriminable electrode pairs for each subject is included.

Subject	Average masking at center electrode (dB)	Average speech-recognition score (% correct)	Number of indiscriminable electrodes
S7	0.67	55.2	4
S4	0.81	54.2	1
S6	1.64	43.4	1
S5	1.80	43.0	4
S2	1.91	6.8	11
S1	2.24	30.8	5
S3	2.37	22.8	6

number of indiscriminable pairs and average masking levels was calculated to investigate the possible extent to which forward masking may be related to spatial interactions.

D. Correlation analysis

In order to determine whether a statistical relationship exists between the forward-masking data and speech-recognition scores, the average masking level for each of the seven subjects' central electrodes as well as their speech-recognition scores were used to calculate the nonparametric Spearman rank-order correlation coefficients. These correlation coefficients are listed in Table VII. A strong correlation exists between the average masking levels and three of the five speech-recognition measures. This result suggests two hypotheses for the statistically significant relationship between the types of interactions that can be measured using forward masking and speech-recognition abilities of cochlear-implant subjects. The hypotheses are that a correlation between speech-recognition ability and forward-masking effects exists due to the temporal interactions measured by forward masking, or it exists due to the spectral interactions which both forward masking and speech recognition measure. An interesting observation is that the strongest correlations occur with NU6 phonemes (0.89), Iowa medial consonants (0.86), and CID sentences (0.86), which are significant at $p<0.05$, while the relationship between vowel perception and average masking level is not significant. These results lend some support for the first hypothesis that, due to temporal interactions, consonants which follow vowels may be masked by vowels, thereby reducing speech-recognition scores that include evaluation of consonant perception.

Another possible explanation for the strong correlation between forward masking and speech-recognition skills is that both are affected by spectral resolution. This hypothesis was investigated through electrode discrimination, which provides a measure of spectral resolution which may be affected less by temporal interactions. The number of indiscriminable electrode pairs for each subject was correlated with average masking levels to investigate the extent to which average masking levels may be related to spectral resolution. The number of indiscriminable electrodes was also correlated with each speech-recognition measure to es-

TABLE VII. The Spearman-correlation coefficients calculated using the average masking levels of each subject's centrally located electrode and the subjects' speech-recognition scores, using the number of indiscriminable electrodes and the subjects' speech-recognition scores, and the average masking levels of the centrally located electrodes and the number of indiscriminable electrodes. The bold entries are significant at $p<0.05$, and the entries with the asterisks are significant at $p<0.10$.

	NU-6 (word)	NU-6 (phoneme)	CID sentences	Iowa med. vowels	Iowa med. consonants	Avg. masking level
Avg. masking level	0.74*	**0.89**	**0.86**	0.50	**0.86**	···
Number of indiscriminable electrodes	0.64	**0.84**	0.77*	**0.93**	**0.84**	0.73*

timate the influence of spectral resolution on speech recognition. The results of this analysis are also presented in Table VII. Spectral resolution, measured by electrode discrimination, was strongly correlated with vowel recognition as expected (0.93), as well as consonant recognition (0.84), and phoneme recognition (0.84). It was less strongly correlated with average masking level, which is a measure of both temporal and spatial interaction. The strong correlation of the number of indiscriminable pairs with the measures of phoneme recognition suggest that the relationship between average masking levels and the Iowa medial consonants and NU6 phonemes may be due to lack of spectral resolution rather than temporal interactions alone; however, temporal interactions may have stronger influences on word recognition represented in CID sentences and NU6 words.

E. Model-based analysis of temporal interactions

The ramifications of possible temporal interactions were considered through a model of the SMSP. Each consonant test word entered in the model of the SMSP produced a percentage of consonant electrodes masked by the vowel ''a.'' The percentages from the test words were averaged, and Table VIII lists the averages for the three subjects who completed the full forward-masking study. In general, the model predicted that subjects with more masking effects would experience a reduction in the salience of consonant cues as a result of vowel-like stimulation. Due to the high variance seen for both S5 and S6, the difference in their averages is not statistically significant; however, the difference between S7's average and those of S5 and S6 is statistically significant at $p<0.05$.

TABLE VIII. The estimated average percentage of consonant electrodes masked by the preceding-vowel phoneme window for those subjects who completed the forward-masking study for all of their functioning electrodes. The difference between S7's average percentage and those of S5 and S6 is statistically significant at $p<0.05$.

Subjects	Average percentage
S5	13.02
S6	18.69
S7	5.33

III. DISCUSSION

In this study, masking patterns were obtained with a centrally located electrode serving as masker for seven subjects. In a more exhaustive study, masking patterns for all possible maskers were obtained for three of these subjects. Substantial variability was observed in the individual masking patterns obtained from each subject. This variability is probably due, in part, to the single measurements used to obtain the masking patterns. However, the masking patterns for S5, S6, and S7 based on the average of the single measurements (Fig. 5) showed distinct features predicted by a hypothetical masking pattern. A peak occurred when the masker and probe were the same electrode, and the patterns showed a monotonic decrease from the peak. As the distance between the probe and the masker increases, the number of single measurements in the average decreases, which may explain the decrease in monotonicity in the tails of the average masking patterns. However, if the extreme points in the tails are excluded, S6 still appears to experience a noticeable increase in masking in the right-hand tail. This may be due to physical features within the cochlea of S6. In addition, small negative masking levels as seen for S7 may be explained by experimental variability in measuring thresholds using a single measurement. The adaptive procedure was used to measure the 20-ms thresholds in an attempt to eliminate/minimize such events by providing an accurate measure of unmasked threshold.

Despite the anomalies in the masking patterns, two important insights into the interactions between electrodes stimulated within a narrow time frame are provided by the patterns. First, electrodes in close proximity to one another tend to cause the greatest masking effects. This is a result that has also been observed in other studies of forward masking, including Lim *et al.* (1989), Shannon (1983), and Chatterjee and Shannon (1998). Maskers also tend to elevate probe thresholds across the entire electrode array, rather than merely at neighboring electrodes. This suggests the possibility that subjects may suffer much greater information loss than is commonly assumed. If only neighboring electrodes were affected, then information loss would be bounded by instances in which neighboring electrodes were stimulated sequentially. If, however, the whole array can be affected, any electrode stimulation might be masked by any previous stimulation. Speech-processing strategies that utilize spa-

tially staggered pulses, such as continuous interleaved sampling (CIS), may reduce these effects.

The evidence that some subjects do suffer greater masking effects than others (e.g., the greater amplitude and width of S5's average masking pattern) led to the consideration of how these masking effects might be related to the subject's ability to recognize and understand speech. The statistically significant correlation between the speech-recognition scores and the average masking levels of the central electrodes of the seven subjects suggested a relationship between information loss and forward masking. Two hypotheses for this relationship were considered. The first was that the loss was due to the temporal effect of vowel stimulation masking consonant stimulation. The second was that forward masking also provided a measure of spectral resolution, in addition to temporal resolution, and degradations in spectral resolution led to poorer speech recognition. The strong correlation of the average masking levels with speech-recognition measures that were not strongly correlated with electrode discrimination offers some support for the temporal-interaction hypothesis. However, the statistically significant correlation between average masking levels and electrode discrimination suggests that at least part of the correlation between average masking levels and speech recognition is due to spectral resolution. Thus, the correlation between average masking levels and speech recognition may be the result of both spectral and temporal interactions. If forward masking causes changes in temporal characteristics of speech, the effects on speech recognition may be significant since several studies (Shannon *et al.*, 1995; Boothroyd *et al.*, 1996) which removed spectral information from speech data have shown that temporal cues provide much of the information necessary for phoneme identification.

The 80–100-ms gap between the first vowel and the subsequent consonant in the Iowa medial consonant test words (Tyler *et al.*, 1986) suggests that the masking effects that the preceding vowel might have on the consonant probably affects only those electrodes which are weak in amplitude (e.g., transition periods, antiresonances), since masking effects decrease as the gap between masker and probe increases. The possibility that the vowel has some masking effect on the consonant for a gap of this duration does exist since Shannon (1990) and Chatterjee and Shannon (1998) have shown that masking effects still occur for a gap of this duration for speakers with good speech-recognition skills.

Studies of medial stop consonants in normal-hearing subjects have shown that the consonant–vowel (CV) transition, when the closure duration is short, is the main cue for identifying the consonants for normal-hearing subjects (Dorman and Raphael, 1980; Tartter *et al.*, 1983). Thus, if the vowel stimulation masks, to some extent, the CV transition, it may affect consonant recognition. However, it is more likely that the vowel may mask the vowel–consonant (VC) transition period. The role of the VC transition in consonant and word recognition for normal-hearing subjects is the subject of several studies (Tartter *et al.*, 1983; Streeter and Nigro, 1979; Dorman and Raphael, 1980). For short closure durations, both Dorman *et al.* (1980) and Tartter *et al.* (1983) agreed that the VC transition had some effect on consonant recognition, but that the CV transition was the main cue. Streeter and Nigro (1979) showed that an absent VC transition had no significant effect on distinguishing words from nonwords, but if the VC transition conflicted with the CV transition in place or manner, then word perception decreased. Thus, if forward masking by a vowel on a consonant does not completely eradicate the VC transition, but rather warps the transition in terms of manner or place identification, it is possible that this would affect word recognition. It is interesting to note that average masking level was correlated with NU-6 word ($p<0.10$) and CID sentences ($p<0.05$), while electrode discrimination was not correlated significantly with NU-6 words at all and was less correlated with CID sentences ($p<0.10$). Future studies including more subjects and more repetitions of the measurements will be necessary to further investigate the hypotheses presented in this paper. Furthermore, data collected with more repetitions will allow estimation of which electrodes in individual consonants may be masked. This would provide a method for investigating whether the VC transition periods may be masked by vowel stimulation, thus reducing word comprehension.

ACKNOWLEDGMENTS

We express our thanks and appreciation to the subjects who gave us their time and effort. Also, we thank Dr. Terry Zwolan, Dr. Paul Kileny, and Ms. Pat Roush for their help in contacting and recruiting subjects, and Dr. David W. Smith, Dr. Roger Miller, and Dr. Rich Tyler and one anonymous reviewer for their valuable input. We are indebted to Cochlear Corp. for providing equipment necessary to carry out this study. Blowing pressure, power, and spectrum in trumpet playing

N. H. Fletcher[a] and A. Tarnopolsky
School of Aerospace and Mechanical Engineering, Australian Defence Force Academy, Canberra 2600, Australia

(Received 15 April 1998; revised 6 October 1998; accepted 28 October 1998)

Measurements of sound output as a function of blowing pressure are reported for a group of experienced trumpet players. The study identifies several common features, namely (1) a threshold blowing pressure approximately proportional to the frequency of the note being played, (2) an extended region in which the sound output rises by about 15 dB for each doubling of blowing pressure, and (3) a saturation region in which sound output rises by only about 3 dB for a doubling of blowing pressure. Some players are able to blow with maximum pressures as high as 25 kPa, which is significantly greater than normal systolic blood pressure. A simple theory is presented that provides a physical explanation for the acoustical behavior, but a detailed treatment requires solution of the nonlinear coupled equations both for the lip-valve mechanism and for nonlinear wave propagation in the instrument tube. Frequency analysis of the sound shows a basic spectral envelope determined by the resonance properties of the mouthpiece cup and the radiation behavior of the bell, supplemented by an extension to increasingly high frequencies as the blowing pressure is increased. This high-frequency behavior can be attributed to nonlinear wavefront steepening during sound propagation along the cylindrical bore of the instrument. [S0001-4966(99)02102-5]

INTRODUCTION

Blowing technique is a vital part of the playing of any wind instrument, and it is therefore rather surprising that the study of physical parameters such as blowing pressure has attracted so little attention. The foundations of such a study for many wind instruments were laid as long ago as 1965 by Bouhuys,[1] but the only subsequent detailed measurements of which we are aware are those on the flute by Fletcher[2] and on woodwind reed instruments by Fuks and Sundberg.[3] The only papers on trumpet performance technique of which we are aware are those of Luce and Clark,[4] who examined spectral properties of the sound, and of Bertsch,[5] who studied the sounds produced by different trumpet players but did not correlate these with blowing pressure. There have, of course, been many papers on various more mechanical aspects of sound production in brass instruments that will be referred to later.

Bouhuys' results for the trumpet are summarized as follows. The blowing pressure measured in the mouth ranged from about 30 to 100 mm Hg (4 to 13 kPa) for high notes played *pp* and *ff*, respectively. Corresponding figures for low notes are omitted from the graph. The acoustic power output ranged from about 20 μW to 1 mW for low notes and from 200 μW to 30 mW for high notes. The overall acoustic efficiency was 0.01% to 0.03% for low notes and 0.03% to 1% for high notes, the higher efficiencies applying to fortissimo playing. In each case only one note and two dynamic levels were measured, and the radiated sound power was estimated from on-axis measurements in a normal room.

It is the purpose of the present paper to report more extensive measurements of blowing technique for a group of trumpet players, with detailed studies on one professional player, and to interpret these findings acoustically.

I. MEASUREMENTS

Measurements were made on three players: a professional orchestral trumpeter (GC), and two experienced amateur players (NH and KB). In the measurements to be reported, they all played standard B♭ trumpets, but some measurements were also made of GC playing a B♭ cornet, and a piccolo trumpet in A. A catheter tube, about 2 mm in external diameter, was inserted in one corner of the player's mouth and the blowing pressure was measured on one of two bourdon gauges that had been calibrated against a water manometer. Acoustic measurements were made at a distance of 1–1.5 m from the horn mouth on the axis of the instrument and later corrected to the equivalent level at 1 m distance. The A-weighted sound pressure level was noted and the sound itself recorded for later analysis. In the case of player GC, the measurements were made in an anechoic chamber, while for the other two players a normally furnished living room was used. Because the frequency response of the microphones used fell off above 16 kHz, the reported measurements extend only to this frequency.

The playing tests consisted of a series of steady notes of given pitch played with increasing loudness from pianissimo up to the fortissimo limit for the particular player. The note pitches covered the whole compass of each instrument in an appropriately transposed CFCF . . . sequence, or something close to that.

Figure 1 summarizes the measured results for professional GC playing a standard B♭ trumpet. Several points are

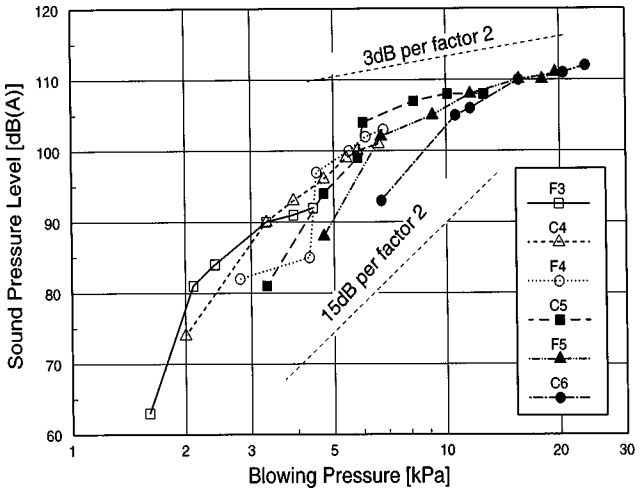

FIG. 1. Equivalent SPL at 1 m produced by player GC on a standard B♭ trumpet in an anechoic chamber, as a function of blowing pressure.

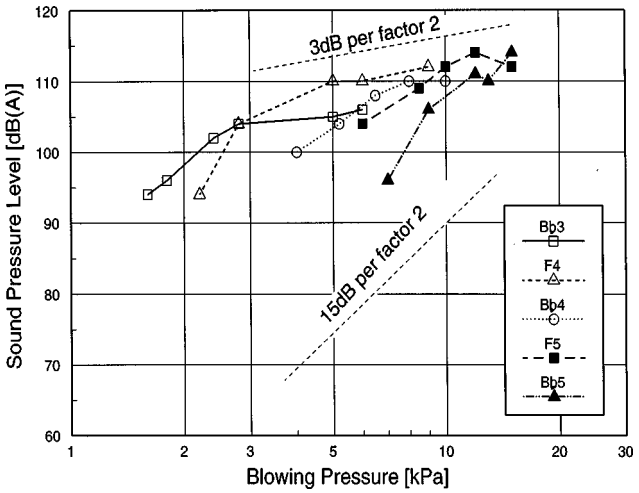

FIG. 2. Equivalent SPL at 1 m produced by player NH on a standard B♭ trumpet, as a function of blowing pressure.

worthy of immediate note. The first is that, in agreement with Bouhuys and the common knowledge of players, there is a threshold pressure required for the sounding of any note, and this threshold increases steadily with the pitch of the note. Second, there is an upper limit to the pressure that can be used for any note, and again this limit increases as we ascend the scale. It is noteworthy that the highest blowing pressure used by this particular player, who is of solid physique, is about 25 kPa. This pressure is much higher than the normal systolic (maximum) blood pressure, which is typically only about 18 kPa, so that it is small wonder that the player reported physiological difficulties when required to play at this level! To appreciate the magnitude of this pressure excess, the graph should be replotted with blowing pressure on a linear scale. Physiological measurements by Fiz *et al.*[6] on the maximum expiratory pressure that can be achieved by trumpet players—not while playing the trumpet, or indeed while actually expelling air—yielded a value of 23 ± 5 Pa, in confirmation of the general level of this result, while they found that similarly fit young men who did not play any brass instrument were able to achieve expiratory pressures of only 19 ± 1 Pa. Presumably muscle training accounts for this difference.

Figures 2 and 3 show similar measurements for players NH and KB. If the two figures are superimposed, then they roughly replicate the measurements in Fig. 1, but player NH, who had a stocky physique similar to that of GC, used only the louder part of the range, while KB, who was much slighter of build and had been criticized by his teacher for not playing vigorously enough, used only the quieter part. The maximum blowing pressure used by KB was only about 7 kPa while NH used pressures up to about 15 kPa.

The professional player GC thus had a much greater range of dynamics and employed a much greater blowing-pressure range than either of the other players, a conclusion that is perhaps not surprising. The measured sound pressure levels should not be compared between players more closely than ±3 dB, because the acoustic environments were somewhat different, but the maximum A-weighted level of about 110 dB for high notes is in good agreement with the maximum measured by Bertsch,[5] as also is the dynamic range.

Figure 4 shows the threshold pressure required by each of the three players to produce notes of various pitches. In all cases, the threshold pressure is very nearly proportional to the frequency of the note being played, but there is a range of about a factor of 2 in the slope of this characteristic, with the professional player GC having threshold pressures within the range spanned by the other two players.

During the course of the study, similar measurements were made of the playing technique of GC on a B♭ cornet and a piccolo trumpet in A. In each case the blowing pressures and sound pressure levels were very similar to those measured for the same notes on the trumpet, with the threshold pressures for the highest notes on the A trumpet appropriately extrapolated upwards.

II. SPECTRAL ANALYSIS

To supplement the measurement of sound pressure level, a recording was made, at a distance of about 1.5 m on the instrument axis, of the sound produced by professional player GC for each note. It is well known that the upper

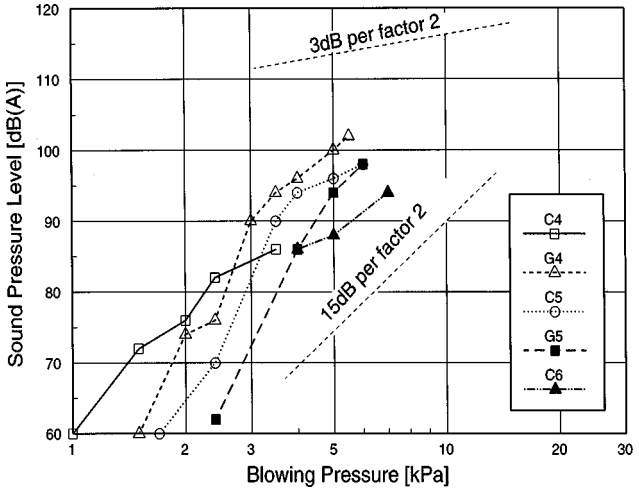

FIG. 3. Equivalent SPL at 1 m produced by player KB on a standard B♭ trumpet, as a function of blowing pressure.

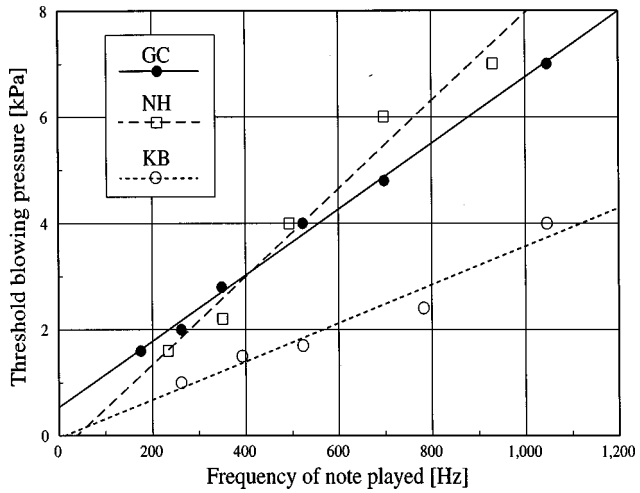

FIG. 4. Threshold blowing pressure used by players GC, NH, and KB to produce notes of various pitches. The sequence of notes played by each player is not exactly the same.

partials of the trumpet sound increase in level relative to the fundamental at high loudness levels, giving incisive brilliance to trumpets in the orchestra. The object here was to investigate this change in timbre over the whole range of playing levels.

Investigations of the envelope of the trumpet spectrum by Luce and Clark[4] characterized it as consisting of two frequency regions. Below the radiation cutoff of the bell, typically about 1000 Hz, the radiated power rose slowly with frequency, typically at 2 to 4 dB/octave, while above cutoff the envelope fell at 15 to 25 dB/octave. They found that the slope below cutoff increased and the slope above cutoff decreased as the intensity level was increased. These measurements apply, not to individual notes, but rather to the average spectrum over the entire instrument.

The present measurements broadly confirm these results, but introduce new detail because they relate to individual notes rather than to the overall spectral envelope. Figure 5

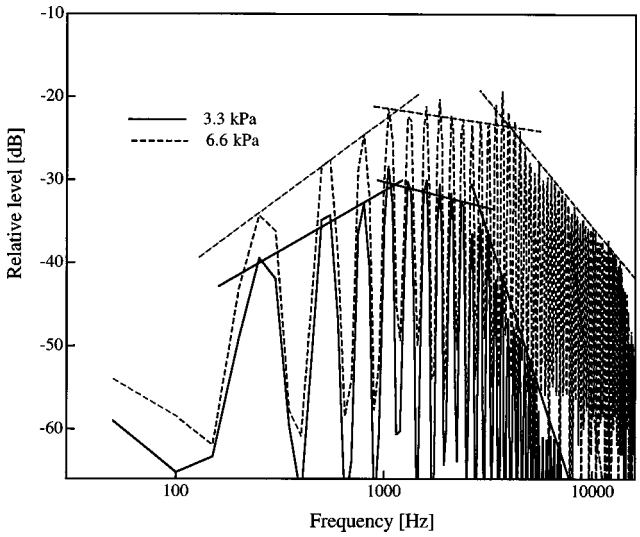

FIG. 5. Spectrum of the note C4 played softly and loudly on a B♭ trumpet. The three slope regions and their transitions are clearly evident, as is the shift with playing level.

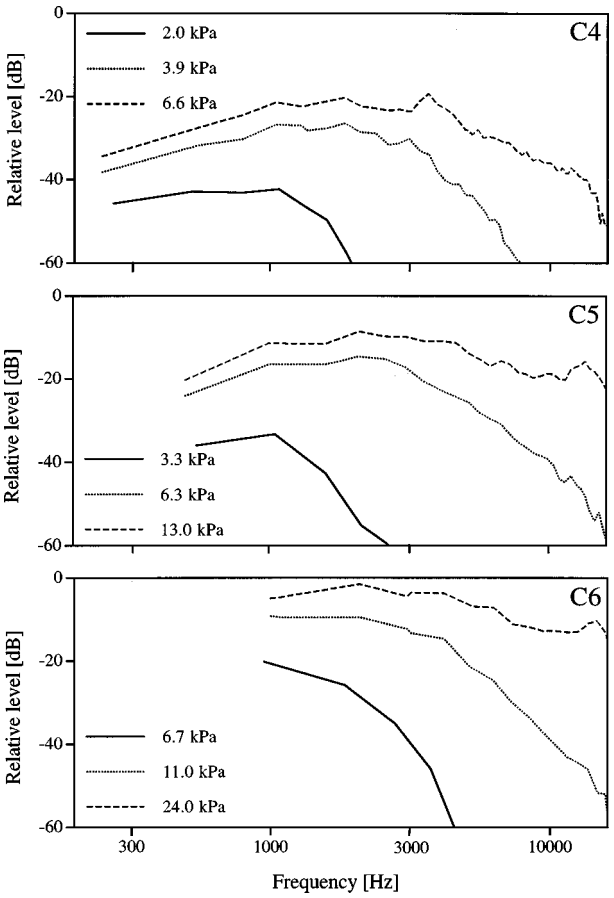

FIG. 6. Spectral development of the noted C_4, C_5, and C_6 as functions of blowing pressure, as played on a B♭ trumpet by GC.

shows typical acoustic spectra for the low note C_4 played softly and loudly on a B♭ trumpet. It is clearly tempting to characterize these spectra in terms of three slopes: a rise of about 6 dB/octave below about 1000 Hz, a nearly constant slope from 1000 Hz to an upper transition at 2–3 kHz which increases with dynamic level, and an upper section with slope about −30 dB/octave at low levels and only about −10 dB/octave at the higher level shown. It is more realistic, however, to examine the spectral envelopes for a wide range of notes and dynamic levels, as shown in Fig. 6. This makes it clear that it is difficult to assign these slopes in an unambiguous manner. What does seem clear, however, is that there is a basic low-level spectral envelope with a characteristic that rises towards a maximum near 1000 Hz and then declines at higher frequencies, as shown by the full curves. On top of this is some other mechanism that extends the envelope to increasingly higher frequencies as the dynamic level is increased. We see below that there is a simple theoretical justification for this interpretation.

III. DESCRIPTIVE THEORY

The sound generation mechanism in brass instruments depends upon the motion of the player's lips, which constitute a pressure-controlled valve. The actual behavior of the lips is certainly complex, for they consist of soft tissue that can support various types of wavelike oscillatory behavior,[7] rather as can the human vocal folds. For our present pur-

poses, however, such detail is not required, and we can use a simple mass-and-spring model. The operation of such simplified valves has been discussed in detail in several publications—for a detailed exposition and list of references the reader is referred to the book by Fletcher and Rossing.[8] The particular case of brass-players' lips has been investigated by Martin,[9] by Elliott and Bowsher,[10] by Yoshikawa,[11] by Adachi and Sato,[12] and by Copley and Strong.[13]

The essence of this mechanism is that the player's lips are driven open and closed by the oscillating sound pressure in the instrument mouthpiece. Details depend upon whether the valve is of the ''outward-swinging door'' $(+,-)$ or ''sliding door'' $(+,+)$ type, or something in between.[11–15] Unlike the ''inward-swinging door'' $(-,+)$ reed valves in woodwind instruments, a brass-player's lips can act as an acoustic generator only within a narrow frequency band quite close to their natural mechanical resonance frequency.[14] This resonance frequency is determined by their vibrating mass and their muscle tension. There is a threshold blowing pressure necessary to initiate the lip vibration that is determined by the lip tension (and is thus related to the lip vibration frequency) and by the acoustic impedance of the instrument and of the player's mouth cavity.[14]

We can put together a simple theory to describe the operation of this lip-valve generator. Suppose that $p_0(f)$ is the threshold gauge pressure in the mouth for excitation of the lip valve when producing a note of frequency f. If it is assumed that the lips are initially held closed, then to a first approximation this pressure will be that which is needed to force the lips open against the lip tension force T, and so will be proportional to T. If the vibrating mass m of the lips were independent of their tension, then their resonant frequency f would be proportional to $(T/m)^{1/2}$, so that we should expect $p_0(f)$ to be proportional to f^2. The structure of the soft tissue in the lips, however, is such that their vibrating mass m decreases markedly with increasing muscular tension. The measurements of Elliott and Bowsher[10] suggest that $m \propto 1/T$, so that it is a better approximation to write

$$p_0(f) = Kf, \tag{1}$$

where K is a constant. This expression agrees well with the experimental data in Fig. 4, which gives a value of about 7 Pa/Hz for K in the case of player GC, 8 Pa/Hz for NH, and 4 Pa/Hz for KB.

Once the lips are forced open by a blowing pressure p greater than p_0, they oscillate in resonance with the instrument horn, because the skilled player has chosen the tension to match the note he wishes to play. The lip vibration is approximately sinusoidal, because the frequency is near resonance, and the vibration amplitude is about equal to the equilibrium lip opening, so that the lips just close once in each cycle.[9] It is thus a reasonable assumption to write the linear opening x of the lips as

$$x = A(p - p_0)(1 + \cos 2\pi f t), \tag{2}$$

where p is the blowing pressure in the mouth and A is another constant, the magnitude of which is inversely proportional to lip tension, and thus to the frequency of the note being played. A is typically about 10^{-7} m Pa^{-1} for a high note, so that the lip opening would reach 1 mm for a blowing pressure 10 kPa above p_0 if it behaved linearly. It should be recognized, however, that the relation (2) cannot hold for very high pressures. Instead, the lip opening x will saturate, because of tissue nonlinearity and also the constraining effect of the mouthpiece, at a value not much more than 1 mm. This can be added as an upper limit to the relation (2).

Equation (2) actually conceals a great deal, for it does not show how the oscillating mouthpiece pressure actually leads to regeneration and thus to vibration of the lips. For this detail, the reader is referred to one of the more complete treatments of brass instruments.[8,10] In brief, however, the oscillating mouthpiece pressure is the main driver of lip motion, and the sounding frequency may be either a little above or below both the lip resonance and the horn resonance, depending upon the geometry of lip motion. For our present purposes, consideration of these details is unnecessary.

The lip opening is typically elliptical, but the axial ratio decreases as the lip opening increases. It is not feasible to model this exactly, but an interpolation is adequate. If the axial ratio of the ellipse remained constant, then the opening area S would vary as x^2, while if the width of the opening remained constant, then S would be simply proportional to x. It is therefore a reasonable approximation to take the area of the opening to be

$$S \approx Cx^{3/2}, \tag{3}$$

where C is a constant, the magnitude of which can be estimated to be about 0.05 $\mathrm{m}^{1/2}$ for typical lip-opening shapes.

At any instant, the quasi-static Bernoulli flow through the lips is then

$$U = (2/\rho)^{1/2}(p - p_1)^{1/2} S = B(p - p_1)^{1/2} x^{3/2}, \tag{4}$$

where p_1 is the back-pressure in the instrument mouthpiece, and B is another constant, of magnitude about 0.06 $\mathrm{m}^2\ \mathrm{kg}^{-1}$, as can be seen from (2) and (3). This back-pressure can be evaluated from the fact that the instrument operates at a resonance, so that its input impedance is nearly purely resistive and has a magnitude R that is typically of order 10^8 Pa m^{-3} s, allowing a bore diameter of about 8 mm and an effective Q-value of around 10 for the resonances. We consider later a refinement in which the magnitude of R varies with frequency. In any case, the back-pressure is $p_1 = RU$. Substituting this in (4), and squaring, leads to the quadratic equation

$$U^2 + B^2 R x^3 U - B^2 p x^3 = 0, \tag{5}$$

which has the solution

$$U = \frac{B^2 R x^3}{2}\left[\left(1 + \frac{4p}{B^2 R^2 x^3}\right)^{1/2} - 1\right]. \tag{6}$$

A. Power and efficiency

Equation (6) can be solved to find the component $\tilde{U}(nf)$ of the flow at the frequency nf of the nth harmonic by substituting (2) for x, performing a Fourier transform numeri-

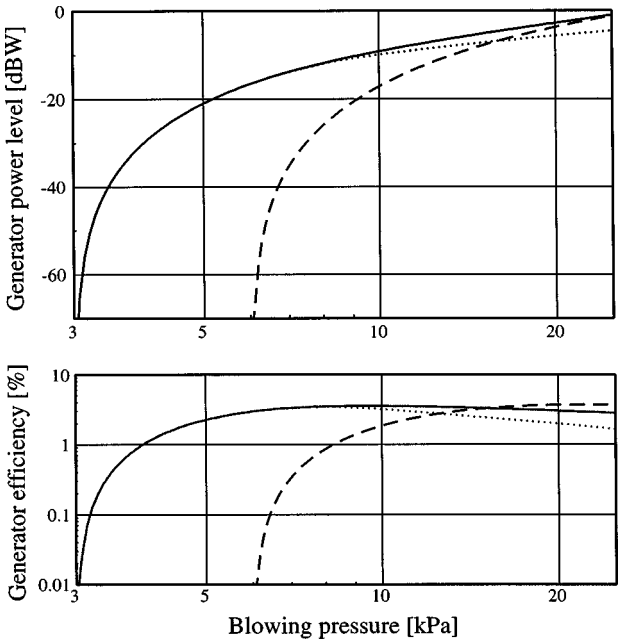

FIG. 7. Calculated acoustic power (in decibels relative to 1 W) produced by the lip generator, and the overall pneumatic efficiency of this generator, both as functions of blowing pressure. Two cases are plotted, corresponding to two notes an octave apart. In the case of the lower note, the dotted curve shows the behavior if the lip opening is limited to 1 mm.

cally, and retaining just the term at this frequency. The acoustic power supplied by the generator to the instrument is then

$$\Pi = \frac{1}{2} R \sum_n \tilde{U}(nf)^2. \tag{7}$$

Figure 7 shows the result of two such calculations for notes an octave apart, 250 and 500 Hz, using the parameter values given in the text and assuming $K = 7$ Pa/Hz in (1), as for player GC. Quantitative details of this calculation should not be given much attention, because the parameters involved were only roughly estimated and only terms up to $n = 3$ were included in the summation, but the overall behavior is significant. The acoustic power supplied by the lip generator rises sharply from zero as the blowing pressure exceeds the threshold value p_0, and settles down to a slope of about 5 to 15 dB per doubling of blowing pressure. If the lip aperture is limited by nonlinearity, however, then the characteristic turns over to a smaller slope at high blowing pressures as shown by the dotted portion of the curve for the lower note. For the higher note, the lip displacement reaches this limit only at about 20 kPa. These curves are individually very similar to the measured curves for individual notes in Fig. 1, though the quantitative agreement is not particularly good. The maximum calculated generator power is about 1 W at a blowing pressure of 25 kPa for no lip motion limitation, and about 0.3 W if the opening is limited to 1 mm. No upper limit to the blowing pressure appears in the case of the lower of the two notes.

Actually the consideration of terms up to only $n = 3$ in (7) is an adequate approximation, because we are dealing with the acoustic power supplied by the lip generator to the mouthpiece, not with the radiated sound. As discussed in the next section, the relative levels of upper harmonics in the mouthpiece flow, and thus in the mouthpiece pressure, are small compared to their relative levels in the radiated sound.

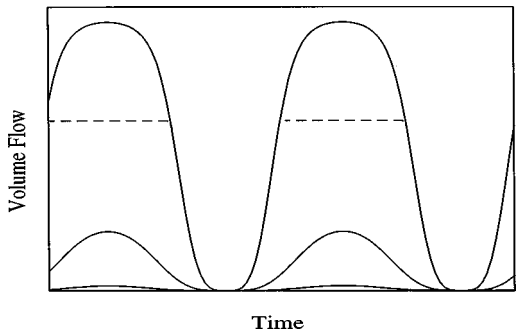

FIG. 8. Calculated lip flow waveforms for a trumpet at low, medium, and high playing levels. The broken curve shows the behavior if the lip opening is limited to 1 mm. The waveforms of the mouthpiece pressure are identical under the assumptions of the calculation.

The quantity plotted in Fig. 7 is not, as we have noted, the radiated acoustic power, but rather the acoustic power produced by the lip generator. Much of this power is dissipated in viscous and thermal losses to the walls of the instrument, and typically less than 10% is radiated as sound. The radiation efficiency itself behaves like the radiation resistance at the open bell of the instrument, and so rises at 6 dB/octave up to the radiation cutoff frequency, which is typically about 1000 Hz for a trumpet, above which it remains constant. We discuss the development of the radiated spectrum in the next section, but for the present we accept that the calculated maximum generator power of 1 W for high notes is therefore expected to result in only about 100 mW of acoustic output power. The measurements in Fig. 1 show a maximum sound pressure level of 110 dB at 1 m, which would correspond to about 1 W of radiated power from an isotropic radiator, since the A-weighting has little effect on total power measured over the frequency range of the trumpet. The trumpet radiation pattern is, however, far from uniform, so that the total radiated power is probably not much more than 100 mW. For lower notes, the transfer efficiency to radiation will be even smaller and, in particular, the lower-frequency full curve of Fig. 8 should be depressed by 6 dB relative to the higher-frequency curve because of the frequency dependence of the radiation resistance. The calculations are thus in better agreement with experiment than might have been expected from their approximate nature.

We might note the implications of this analysis for total acoustic efficiency, as measured by Bouhuys.[1] The total input pneumatic power is approximately $\Pi_0 = pU_0$, where U_0 is the zero-frequency flow component in the Fourier transform calculation above and we have neglected oscillations in mouth pressure. The generator efficiency is then simply Π/Π_0. This efficiency is also plotted in Fig. 7, and ranges from about 0.1% for very soft playing up to about 3% for loud playing, though this efficiency decreases slightly if the lip aperture is limited. Reducing these figures by a factor of about 10 for high notes and as much as 100 for low notes to convert them to radiated acoustic power gives overall efficiencies in remarkably good agreement with those measured by Bouhuys.[1]

B. Spectrum

Solution of Eq. (6) for the flow through the lip valve shows that it has the form in Fig. 8. Since we have assumed a constant value for the input resistance R at the harmonic resonance peaks, the mouthpiece pressure has the same form. For very soft playing the waveform is reasonably sinusoidal, but at higher levels it has a markedly distorted shape, with a plateau for large lip opening, when the flow is limited by the resonant horn resistance and the consequent mouthpiece back-pressure, and a rather sharp decrease to zero as the lips close. This calculation is in good qualitative agreement with the mouthpiece pressure measurements of Elliott and Bowsher.[10]

A flow with this shape has a spectrum that is nearly constant up to a frequency about n times that of the fundamental, where n is the mark/space ratio of the waveform when it is approximated by a rectangular wave. This conclusion, however, derives from the unduly simplified assumption that the resistive part R of the input impedance is the same at all the low resonances of the instrument. For a real trumpet this is not so, for the Helmholtz-type resonance of the volume of the mouthpiece cup, vented through the constricted back-bore and loaded by the characteristic impedance of the instrument bore, produces a resonant envelope to the input impedance, as investigated by Benade.[16] This leads to an envelope for R that rises to a broad peak with a Q value around 5, typically at 500–1000 Hz, and then decreases, and we should expect to find evidence of this in the spectrum. It is not difficult in principle to substitute such a frequency variation for R back into Eqs. (5)–(7), but we shall not bother to do this in detail. It suffices to note that such a procedure would certainly modify the spectrum of the power supplied by the lip-valve generator to reflect a similar mouthpiece resonance. This then explains the common envelope feature seen in all the low-level curves of Fig. 6.

We must now seek to explain the origin of the increased level and apparent actual power gain in the high-frequency components observed in loud playing. That there is indeed a discrepancy between the spectrum measured in the mouthpiece cup and that of the radiated sound is well known, and part of the explanation lies with the radiation behavior of the instrument horn. This is not entirely simple, as discussed by Benade and Jansson,[17] but the general conclusion is that there is a cut-off frequency, around 1 kHz, below which the radiated sound level rises at 6 dB/octave relative to the internal sound pressure, and above which the relation is flat. These considerations, together with the mouthpiece resonance, have been built into a generalized linear model for the transfer function between mouthpiece pressure and radiated sound by Elliott *et al.*[18] They conclude that, above the radiation cutoff, there is little if any power loss, at least for small signal levels where the linear approximation is valid. While this consideration is clearly important in determining the balance between low-frequency and high-frequency components of the radiated sound, it fails to explain the apparent power gain at high frequencies observed in loud playing.

This high-frequency discrepancy in the spectrum has been investigated by Beauchamp.[19] He reported that there is indeed a marked excess in the level of high-frequency components in the radiated sound, particularly above the radiation cutoff frequency, and that this level varies greatly with playing conditions, often appearing as an actual power gain. The explanation of this behavior has been given by Hirschberg *et al.*[20] who showed that it arises from nonlinear acoustic propagation behavior, particularly in the long cylindrical part of the instrument bore. Such nonlinear propagation behavior has been discussed in detail by Beyer,[21] but a brief semiquantitative discussion will be adequate here.

As we have already seen, the mouthpiece pressure p_0 rises each cycle to nearly the blowing pressure in the player's mouth, and thus perhaps as high as 25 kPa or about 180 dB relative to the normal reference level. While the pressure in the main bore is probably lower than this by a factor of at least 3, the level is sufficiently high that the propagation behavior is significantly nonlinear. This can be seen from an examination of a wave of even 2 kPa amplitude, in which the peak acoustic particle velocity is about 5 $\mathrm{m\,s^{-1}}$. Since the cylindrical part of the bore is around 1 m long, this leads to a convective transit-time gain of perhaps 0.05 ms for the high-frequency components in the compressive part of the propagating wave. The result is a steepening of the leading edge of this wave that increases as the pressure amplitude increases. In extreme cases a shock wave may even develop. Adiabatic temperature rise in the wave enhances the effect.

The result of this nonlinear propagation behavior is a transfer of energy from the low-frequency components of the mouthpiece waveform to higher harmonics, the extent of this transfer increasing as the blowing pressure is increased. Because of the initial rise of radiation resistance below cutoff, this transfer increases the radiated sound energy as well as providing an apparent power gain at high frequencies. This leads to an even greater increase in the subjectively perceived loudness, because the wider sound spectrum has less auditory masking, as discussed by Plomp.[22]

While we shall not attempt to investigate these phenomena in any detail in the present paper, it is possible to draw some semiquantitative conclusions from the experimental data. Referring to Fig. 6, we see that, while fitting straight lines as in Fig. 5 is not generally convincing, it is possible to describe the high-frequency extent of each curve by giving the frequency above which the harmonics are more than 20 dB below the spectral peak. This information is plotted in Fig. 9. The highest frequency measurements are limited by the frequency response of the microphone, and points shown as 16 kHz may well be higher. These results show that the high-frequency extension of the spectrum, and by implication wavefront steepening, increases about linearly with blowing pressure, which is what we should expect from the discussion in the previous paragraphs. For a given blowing pressure, the effects of wavefront steepening are less pronounced for higher notes.

It is not difficult to see the general reasons for this behavior, if we make the assumptions that extension of the spectrum above the frequency determined by the mouthpiece resonance and the radiation cutoff, namely about 1000 Hz, is caused almost entirely by nonlinear propagation effects, and that the magnitude of these nonlinear effects is proportional to the pressure amplitude in the propagating wave. Both

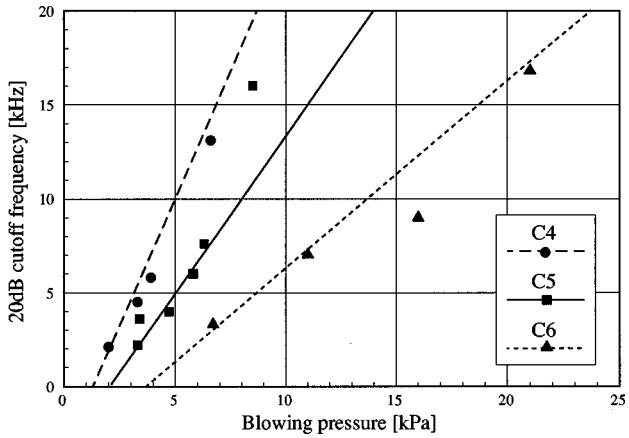

FIG. 9. Frequency at which the spectral envelope falls 20 dB below its peak value, as a function of blowing pressure, for three notes played on a B♭ trumpet. The lines have been drawn according to the prescription discussed in the text.

these assumptions are reasonable in terms of the discussion above, but require detailed justification.

Since the pressure in the instrument bore is proportional to the pressure $p_1 = RU$ in the mouthpiece, it is necessary first to examine the flow U through the lips, as given by (6), with the lip opening x given by (2). It is not possible to derive simply an expression for the extension of the spectrum as a function of blowing pressure for a given note pitch, but we seek rather to see how this extension, whatever it is, scales with pitch and blowing pressure. Suppose therefore that the flow $U(f,p)$ refers to a note of fundamental frequency f played with blowing pressure p. We seek to know the flow $U(\alpha f, \beta p)$ for a note of fundamental frequency αf played with blowing pressure βp. To increase the lip vibration frequency by a factor α requires an increase in lip tension and a decrease in lip moving mass by the same factor α, as discussed in relation to Eq. (1). This increases the threshold pressure p_0 by a factor α and changes the constant A in (2), and thus the value of x at a given pressure, by a factor α^{-1}. Similarly, to a reasonable approximation, increase in the blowing pressure by a factor β increases x by a factor β if the threshold is ignored.

Returning to (6), we find that the expression $4p/B^2R^2x^3$ is typically of order unity for $x \approx 1$ mm, which makes approximation difficult. If x is a good deal larger than this, then $U \approx p/R$, while if x is smaller, then $U \approx Bp^{1/2}x^{3/2}$. Adopting the latter expression and using the argument in the previous paragraph leads to the result

$$U(\alpha f, \beta p) \approx \beta^2 \alpha^{-3/2} U(f,p). \tag{8}$$

This means that, if the note frequency is raised by a factor α and the blowing pressure by a factor $\beta = \alpha^{3/4}$, then the flow, and hence the pressure and the spectral result, are all unchanged. This argument ignores the niceties of threshold pressure, and so holds only well above threshold. The upshot of this simplified argument is to suggest that, whatever the harmonic development curve for a note of sounding frequency f played with pressure p, this can be transformed to the corresponding curve for sounding frequency αf by increasing all the plotted blowing pressures by a factor $\alpha^{3/4}$. The exact value of the exponent in this prescription depends upon the behavior of lip opening shape embodied in Eq. (3). This may vary a little from player to player, but the extreme values are 0.5 and 1.

Referring to Fig. 9, we have a reference curve for the lowest frequency f that is a straight line not passing through the origin. The approximate relation given above then suggests that the curve for frequency $2f$ can be derived by simply multiplying all the pressures in the reference curve by $2^{3/4} \approx 1.7$, and the curve for frequency $4f$ by multiplying all the pressures in the reference curve by $4^{3/4} \approx 2.8$. The lines in the figure have been drawn to this prescription, and fit the experimental data quite well, which gives some measure of confirmation to the assumptions. For much larger blowing pressures and lip openings, we must turn to the result $U \approx p/R$, which suggests that all curves tend to the same asymptote in the limit of high pressures. It does not appear that this asymptote has been reached in the experimental data.

It must be emphasized that this argument is lacking in rigor and serves simply to provide a possible basis for explanation for the observed behavior. A proper analysis clearly requires explicit consideration of the pressure waveform and frequency and quantitative treatment of the nonlinear propagation.

IV. CONCLUSIONS

This experimental study has established, in a general way, the blowing technique used by typical trumpet players. In particular, we recognize the following features:

(1) a threshold blowing pressure for sounding of each note, this pressure rising linearly with the frequency of the note to be played;
(2) a rapid rise of radiated sound output for blowing pressures above threshold, settling down to a regime in which sound output power rises about 15 dB for each doubling of blowing pressure, the sound power for a given blowing pressure being nearly independent of the pitch of the note being played;
(3) a saturation regime, in which the sound output power rises only slowly with increasing blowing pressure, a doubling of blowing pressure increasing the sound level by only about 3 dB.

While this represents the general pattern of performance technique, there is a good deal of variation between individual performers in relation to the pressure range used, and thus the tone quality produced. At a more detailed level, these differences may also depend upon lip shape and musculature and upon learned playing technique. Some variation is also to be expected between trumpets with different mouthpiece sizes and bore diameters, though the range of variation among standard instruments is not large.

A first-order theoretical consideration suggests the underlying physics responsible for these results, in terms of the flow behavior of the vibrating lip-valve generator and nonlinear wave propagation in the main bore of the instrument. These considerations give expressions for the acoustic input power at the instrument mouthpiece, the spectrum of which is then modified by nonlinear propagation behavior in the

instrument bore, which steepens the wavefronts and transfers acoustic energy from low to high harmonics. These high harmonics are more efficiently radiated, produce a narrower radiation pattern, and enhance both the subjective loudness of the tone and its ability to rise above the general orchestral background.

Although manifestly incomplete in many details, the theoretical treatment outlined does appear to capture the essence of the performance technique used by trumpet players and to provide a skeleton upon which a more detailed understanding could be built.

ACKNOWLEDGMENTS

We are grateful to the trumpet players who participated in this study, and to Dr. A. Hirschberg, who provided perceptive comments on the first version of the paper. This work is part of a program supported by a grant from the Australian Research Council.

(Received 17 November 1997; revised 21 September 1998; accepted 23 September 1998)

The perceptual salience of several outstanding features of quasiharmonic, time-variant spectra was investigated in musical instrument sounds. Spectral analyses of sounds from seven musical instruments (clarinet, flute, oboe, trumpet, violin, harpsichord, and marimba) produced time-varying harmonic amplitude and frequency data. Six basic data simplifications and five combinations of them were applied to the reference tones: amplitude-variation smoothing, coherent variation of amplitudes over time, spectral-envelope smoothing, forced harmonic-frequency variation, frequency-variation smoothing, and harmonic-frequency flattening. Listeners were asked to discriminate sounds resynthesized with simplified data from reference sounds resynthesized with the full data. Averaged over the seven instruments, the discrimination was very good for spectral envelope smoothing and amplitude envelope coherence, but was moderate to poor in decreasing order for forced harmonic frequency variation, frequency variation smoothing, frequency flattening, and amplitude variation smoothing. Discrimination of combinations of simplifications was equivalent to that of the most potent constituent simplification. Objective measurements were made on the spectral data for harmonic amplitude, harmonic frequency, and spectral centroid changes resulting from simplifications. These measures were found to correlate well with discrimination results, indicating that listeners have access to a relatively fine-grained sensory representation of musical instrument sounds. INTRODUCTION

It has been traditional to view musical sounds in terms of a spectral model that describes them as a series of sinusoidal components, each having an amplitude and a frequency. Often, as is the case in this article, these sounds have frequencies which are harmonically related to a fundamental frequency, or at least approximately so. While many experiments on timbre have used fixed frequencies and fixed relative amplitudes (Miller and Carterette, 1975; Plomp, 1970; Preis, 1984; von Bismarck, 1974), analyses of musical instrument sounds reveal that these parameters have a great deal of variation, leading to the conjecture that these variations are responsible, in large part, for the uniqueness of the individual sounds.

For example, we can think of the amplitudes (A) and frequencies (f) varying over time (t) and having two parts, a smoothly or slowly moving part (1) and a more rapidly changing microvariation part (2):

$$A_k(t) = A1_k(t) + A2_k(t), \tag{1}$$

$$f_k(t) = f1_k(t) + f2_k(t), \tag{2}$$

where k refers to the harmonic number. Alternatively, since we consider only quasiharmonic sounds here, we can also break the frequency into two other parts:

$$f_k(t) = k\overline{f_0}(t) + \Delta fi_k(t), \tag{3}$$

where $\overline{f_0}$ is the fundamental frequency averaged over several harmonics and Δfi_k is an inharmonic frequency deviation, both varying over time.

Figure 1 gives a block diagram of a spectral representation model using the parameters of Eqs. (1) and (2), which is also an additive, sine-wave-synthesis model. The question to be explored in this article is: to what degree can these parameters be simplified, without making them discriminable, with respect to sounds containing the full amount of information? A given sound can be reconstituted with high quality from the full representation using time-varying additive synthesis. However, such a representation is quite data inten-

[a)]Portions of these results were presented at the 133rd meeting of the Acoustical Society of America (Beauchamp *et al.*, 1997).

sive. Any possibility of reducing the data would alleviate storage problems and accelerate the process of synthesis, which is particularly important for real-time sound synthesis. Also, one might hope that such simplifications would lead to the possibility of streamlined synthesis control using a few well-chosen, perceptually relevant parameters. Most important for us, however, is that knowledge about the sensitivity of human listeners to certain kinds of sound simplifications may provide clues for understanding the sensory representation of musical sounds. Specifically, this study is aimed at determining the relative perceptual importance of various spectrotemporal features which we have suspected are important for making timbral distinctions and for judging sound quality.

A few researchers have already addressed the problem of perceptually relevant data reduction using discrimination paradigms. Grey and Moorer (1977) used a rectangular-window, heterodyne-filter analysis algorithm and time-varying additive synthesis to prepare their stimuli based on 16 sounds from various bowed-string, woodwind, and brass instruments of duration 0.28 to 0.40 s. They asked their subjects (musical listeners) to discriminate between five versions of the sounds: (1) the digitized original analog tape recording, (2) a complete synthesis using all time-varying amplitude and frequency data resulting from the analysis stage, (3) a synthesis using a small number of line-segment approximations to the amplitude and frequency envelopes, (4) the same modification as version (3) with removal of low-amplitude initial portions of attack transients, and (5) the same modification as (3) with frequencies fixed in harmonic relation to the fundamental frequency (frequency-envelope flattening). Listeners heard four tones in two pairs and had to determine which pair contained a different tone. They were allowed to respond ''no difference heard.'' Discrimination scores were computed as the probability that the correct interval was chosen plus half the probability that a no difference response was given (ostensibly to simulate random guessing on those trials).

An important result was the low discrimination scores for comparisons of versions (2) and (3), which ranged from 0.48 to 0.80 (depending on the instrument), with an average of only 0.63. This indicated that microvariations in amplitude and frequency are usually of little importance, implying the possibility for significant data reduction. However, the authors gave no algorithm for fitting the straight lines to the data or criteria for error, but stated only that the number of segments varied between four and eight per parameter over each tone's duration. Also, since the tones were short and some segments were needed to fit attack transients, it is not clear how these results can be extrapolated for longer sounds. Discrimination rates between versions (3) and (4) and between (3) and (5) were similarly low, averaging 0.65 (range: 0.55 to 0.74) and 0.68 (range: 0.56 to 0.92), respectively. The results indicated that there were significant differences among the 16 instruments.

In general, discrimination rates for single simplifications were low, and relatively high rates (above 0.85) only occurred for multiple simplifications. For example, the average discrimination rate between versions (1) and (5), where three simplifications were combined, was 0.86. From our experience, these figures seem low. We can only conjecture that this was due to the short tones used, to noise on the analog tape used for stimulus presentation which may have masked some parameter variation details, and perhaps even to the experimental instructions which specifically oriented listeners toward differences in quality of articulation and playing style rather than toward any audible difference.

Charbonneau (1981) extended Grey and Moorer's study [based on their version (3) representation] by constructing instrumental sounds that maintained their global structure, while simplifying the microstructure of the amplitude and frequency envelopes of each harmonic partial. The first simplification was applied to the components' amplitude envelopes, each component having the same amplitude envelope (calculated as the average harmonic-amplitude envelope) scaled to preserve its original peak value and start- and end times. (This is similar to our amplitude-envelope coherence simplification; see Sec. I below.) The second simplification was similarly applied to the frequency envelopes, each having the same relative frequency variation as the fundamental, meaning that the sound remained perfectly harmonic throughout its duration (similar to our frequency-envelope coherence simplification; see Sec. I below). The third simplification resulted from fitting the start- and end-time data to fourth-order polynomials. Listeners were asked to evaluate the timbral differences between original [version (3)] and simplified sounds on a scale from 0 (no difference) to 5 (large difference). Results indicated that the amplitude-envelope simplification had the greatest effect. However, as for the Grey and Moorer study, the strength of the effect depended on the instrument.

Sandell and Martens (1995) used a different approach to data reduction. The harmonic time-frequency representation derived from a phase-vocoder analysis was treated as a data matrix that could be decomposed into a number of linearly recombinable principal components from either a temporal or a spectral perspective. The recombination of the appropriately weighted principal components can be used to regenerate the signal of a given instrument sound. These authors estimated the number of principal components necessary to

achieve a simplified sound that was not reliably discriminated from a sound reconstructed from the full (though down-sampled) analysis data. From these results, they could then compute the proportion of data reduction possible without compromising perceived sound quality. They achieved considerable data reduction for the three instruments tested, but the amount varied a great deal across instruments. One interpretation problem that often plagues perceptually oriented principal components analyses on acoustic data (see also, Repp, 1987) is that the perceptual nature and relevance of the individual components is most often difficult to conceive. For example, it is not clear that they could represent perceptual dimensions with clearly defined acoustic characteristics along which stimuli could be varied intuitively in sound synthesis.

This reservation notwithstanding, the results of these three studies demonstrate that timbre changes result from simplification of the signal representation. In fact, it is clear from the two earlier studies that the simplifications performed on temporal parameters, and specifically on time-varying functions of amplitude and frequency, influence to a greater or lesser degree the discrimination of musical sounds.

In the present study, we sought to determine precisely the extent to which simplified spectral parameters affect the perception of synthesized instrumental sounds, using tones of 2-s duration and without the use of straight-line approximations. We measured the discrimination of several kinds of simplifications for sounds produced by instruments of various families of resonators (air column, string, bar) and types of excitation (bowed, blown, struck). Two of the simplifications we chose (amplitude-envelope coherence and spectral-envelope smoothness) were derived from previous studies on timbre perception and corresponded to acoustic parameters that are highly correlated with perceptual dimensions revealed by multidimensional scaling techniques (Grey and Gordon, 1978; Iverson and Krumhansl, 1993; Krimphoff *et al.*, 1994; McAdams *et al.*, 1995). The other four simplifications related to the perceptibility of microvariations of amplitude and frequency over time, with much having been written about the latter (Brown, 1996; Dubnov and Rodet, 1997; McAdams, 1984; Sandell and Martens, 1995; Schumacher, 1992).

In addition, various combinations of these simplifications were applied to the sounds in groups of two, three, or four. We hypothesized that accumulated simplification along several perceptual dimensions would increase discrimination. Below, we present the technique used for analyzing and synthesizing the stimuli, followed by a description of the discrimination experiment. The results are then discussed in terms of musical synthesis and the perceptual representation of musical signals.

I. ANALYSIS/SYNTHESIS METHOD

Seven prototype musical instrument sounds were selected for analysis using a computer-based phase-vocoder method (Beauchamp, 1993). This phase vocoder is different than most in that it allows tuning of the fixed analysis frequency (f_a) to coincide with the estimated fundamental frequency of the input signal. The analysis method yields the frequency deviations between harmonics of this analysis frequency and the corresponding frequency components of the input signal, which are assumed to be at least approximately harmonic relative to its fundamental.

A. Signal representation

For each sound, an analysis frequency was chosen that minimized the average of the harmonic frequency deviations. Thus, a time-varying representation was achieved for each sound according to the formula

$$s(t)=\sum_{k=1}^{K} A_k(t)\cos\left(2\pi\int_0^t (kf_a+\Delta f_k(t)dt)+\theta_k(0)\right), \tag{4}$$

where

$s(t)=$ sound signal,
$t=$ time in s,
$k=$ harmonic number,
$K=$ number of harmonics,
$A_k(t)$ is the amplitude of the kth harmonic at time t,
$f_a=$ analysis frequency,
$\Delta f_k(t)$ is the kth harmonic's frequency deviation, such that $kf_a+\Delta f_k(t)$ is the exact frequency of the kth harmonic, and
$\theta_k(0)$ is the initial phase of the kth harmonic.

The parameters used for synthesis that were simplified in this study are $A_k(t)$ and $\Delta f_k(t)$. No attempt was made to simplify $\theta_k(0)$. Although $A_k(t)$ and $\Delta f_k(t)$ were only stored as samples occurring every $1/(2f_a)$ s, the signal was approximated with reasonable accuracy at a much higher resolution (sample frequency 22 050 or 44 100 Hz) by using linear interpolation between these values. Synthesis was accomplished by additive (or Fourier) synthesis of the harmonic sine waves.

B. Prototype sounds

Sounds of the instruments clarinet, flute, harpsichord, marimba, oboe, trumpet, and violin were selected in order to have one representative from each of several families of instruments whose tones are at least approximately harmonic. Five of the sounds were taken from the McGill University Master Samples recordings, one from Prosonus (oboe), and one (trumpet) had been recorded at the UIUC School of Music. An attempt was made to select sounds that were of high quality, that represented the instruments well, and that had fundamental frequencies close to 311.1 Hz (E-flat 4), a note within the normal playing range of these instruments.[1] Since synthesis was accomplished by an additive method based on Eq. (1), it was easy to alter the stimuli's fundamental frequencies (f_a) to be exactly 311.1 Hz. Table I gives some basic characteristics of the prototype sound signals.

C. Analysis method

The phase vocoder method used for analysis consists of the following steps:

TABLE I. Data for the seven instrument sounds used in the study. For McGill source recordings, the numbers indicate volume:track-index. For Prosonus recordings, they indicate woodwinds volume:band-index. Attack (t_1) is the time in the original sound at which the attack was estimated to end. Decay (t_2) is the time in the original sound at which the decay was estimated to begin. The marimba and harpsichord, being impulsively excited instruments, have no sustain portions. The marimba, being shorter than the target 2-s duration, was stretched rather than shortened, and so the attack and decay values were not used.

	Source of original recording	Original fundamental frequency (Hz)	Original duration of sound, t_L (s)	Number of harmonics used in analysis, K	Attack, t_1 (s)	Decay, t_2 (s)
Clarinet (Cl)	McGill (2:10-14)	311.4	3.81	70	0.05	3.50
Flute (Fl)	McGill (9:86-04)	311.0	2.31	70	0.25	2.10
Harpsichord (Hc)	McGill (11:95-06)	311.1	2.97	70	0.04	2.97
Marimba (Mb)	McGill (3:04-23)	312.2	1.83	70	...	...
Oboe (Ob)	Prosonus (W1:04-04)	311.8	2.98	30	0.15	2.20
Trumpet (Tp)	UIUC	350.0	2.43	31	0.32	1.30
Violin (Vn)	McGill (9:63-03)	311.1	4.94	66	0.22	4.10

(1) Band-limited interpolation of the input signal to produce a power-of-two number of samples per analysis period ($1/f_a$), which is the lowest possible to exceed the number of original samples in this time interval.
(2) Segmentation of the input signal into contiguous frames whose lengths are equal to twice the analysis period ($2/f_a$) and which overlap by half an analysis period ($f_a/2$).
(3) Multiplication of each signal frame by a Hamming window function whose length is two analysis periods ($2/f_a$).
(4) Fast Fourier transform (FFT) of the resulting product to produce real and imaginary components at frequencies 0, $f_a/2$, f_a, $3f_a/2$,..., $f_s/2-f_a$, where f_s is the sampling frequency. Components which are not positive integer multiples of f_a are discarded.
(5) Right-triangle solution of each retained real and imaginary part to give the amplitude and phase of each harmonic.
(6) Computation of the frequency deviation for each harmonic by a trigonometric identity which essentially gives the difference in phase between frames for each harmonic.
(7) Storage of the harmonic-and frequency-deviation data in an ''analysis file.'' The number of harmonics stored is less than $f_s/(2f_a)$. The analysis file for each sound is the basis for further sound processing.

Further details of this procedure are discussed by Beauchamp (1993).

The analysis system may be viewed as a set of contiguous bandpass filters which have identical bandwidths (f_a) and are centered at the harmonics of the analysis frequency (f_a). The basic assumption is that the signal consists of harmonic sine waves which line up with the filters such that each filter outputs one of the sine waves. The analysis gives the amplitude and frequency of each sine wave. When the sine waves are summed, the signal is almost perfectly reconstructed. In fact, the sine-wave sum can be viewed as that created by processing the input signal by the sum of the bandpass-filter characteristics. It can be shown that this sum is flat within ± 1 dB over the range $[f_a/2, f_s/2]$. Figure 2 shows a block diagram of the basic analysis/ synthesis system and Fig. 3 shows a typical set of amplitude and frequency data.

D. Types of simplification

Spectral simplifications were performed on the analysis data, after which the sounds were synthesized by the additive method. In order that sound duration would not be a factor in the study, most of the sounds were shortened to a 2-s duration by resampling the analysis data. Rather than resampling at a uniform rate, the sounds were resampled to preserve their attack and decay portions and shorten their interior portions while retaining their microstructural variations in amplitude and frequency. This was done by first observing the sound's rms amplitude given by

$$A_{\mathrm{rms}}(t) = \sqrt{\sum_{k=1}^{K} A_k^2(t)}, \tag{5}$$

and then identifying by eye the time intervals corresponding to the attack and decay as $(0,t_1)$ and (t_2,t_L) (see Table I for chosen values of t_1 and t_2), where t_L is the original sound duration. The marimba was an exception to this procedure, since its original duration was 1.83 s. The data for this instrument were simply stretched to obtain a duration of 2 s,

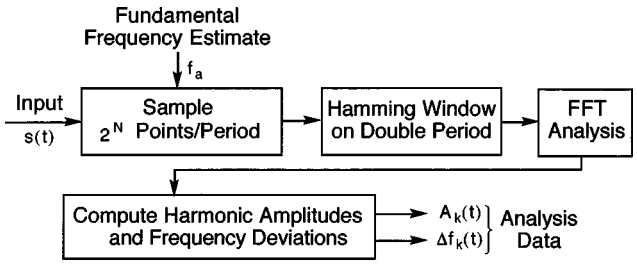

FIG. 2. Method for time-varying spectral analysis that yields the amplitude and frequency deviations for each harmonic k. The exact frequency for harmonic k is given by $f_k = k\, f_a + \Delta f_k(t)$, where f_a is the analysis fundamental frequency.

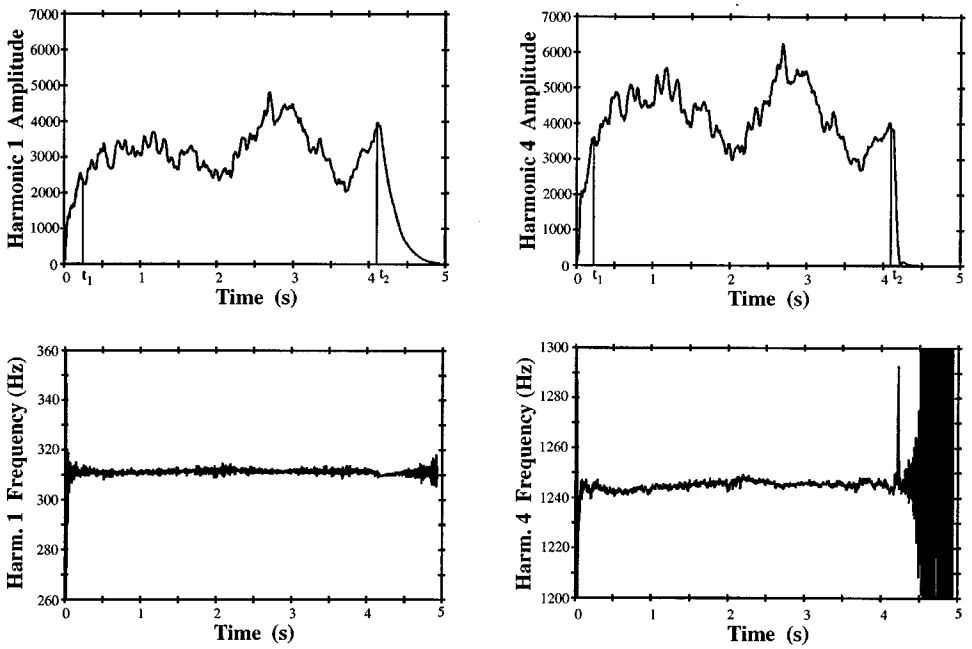

FIG. 3. Example spectral-analysis data for original violin tone (left column: first harmonic; right column: fourth harmonic; upper row: amplitude envelopes; lower row: frequency envelopes). Note the difficulty in reliably estimating the frequency of harmonic 4 when its amplitude approaches zero. Attack (t_1) and decay (t_2) boundaries are indicated.

and no notable degradation of the musical quality of the original was noted by the authors.

Second, for each harmonic amplitude and frequency deviation, the time intervals (t_1, t_1+2) and (t_2-2, t_2) were cross-faded using a cubic function to minimize any discontinuities. Thus, between the times t_1 and t_2, the sound was transformed from what it sounded like in the region of time t_1 to what it sounded like in the region of time t_2 over a period of $2-(t_1+t_L-t_2)$ s. This gave each sound a total duration of 2 s. In order for this method to work properly, we assumed that each sound had a microstructure which was statistically uniform over the interval (t_1, t_2). Since the sounds selected had no vibrato, this assumption seemed to be valid, and the resulting synthesized sounds were judged by the authors to be free of artifacts. Details on the duration-shortening algorithm are given in Appendix A. Figure 4 shows a set of data corresponding to Fig. 3 after application of the duration-shortening algorithm. Note that t_1 and t_2 are indicated in Fig. 3.

Finally, the seven duration-equalized prototype sounds were compared, and amplitude multipliers were determined such that the sounds were judged by the authors to have equal loudness. When the sounds were synthesized with the shortened duration, the amplitude multipliers, and a synthesis fundamental frequency of 311.1 Hz, they were judged to be equal in loudness, pitch, and duration. (It should be mentioned, however, that this equalization was not central for the present study, since each discrimination pair was always derived from a single prototype sound.) The equalized sounds then served as the reference sounds for this study, and their corresponding data sets are henceforth referred to as the analysis data.

Six primary simplifications of the analysis data were performed prior to synthesis. Each of these simplifications constitutes a major reduction in the amount of data used for synthesis.

1. Amplitude-envelope smoothness (AS)

The objective of this operation was to remove microvariations or noise in the harmonic amplitude over time, as these had been shown to be perceptually salient in previous work by Charbonneau (1981). These envelopes $A_k(t)$ were processed by a second-order recursive digital filter having a Butterworth response and a smoothing cutoff frequency of 10 Hz. This essentially removed all microdetail in the amplitude envelopes. However, we did not smooth the attack portions of the envelopes $(0 \leqslant t \leqslant t_1)$ since we only wished to determine the importance of microdetail in the amplitude envelopes thereafter. Smoothing the attack portions would have slowed the attacks, unintentionally affecting discrimination of the simplified sounds from their corresponding reference sounds. In order to avoid discontinuity, the attack portion of each amplitude envelope was cross-faded into the subsequent smoothed portion over a few frame points corresponding to the delay of the filter. In this way, the attack portions were essentially unaltered by the smoothing operation (see Table I for t_1 values).

2. Amplitude-envelope coherence (AC) (spectral envelope fixing)

The objective was to test the effect of eliminating *spectral flux* (defined as the change in shape of a spectral envelope over time) without changing the rms amplitude envelope or the average spectrum. Spectral flux has been found to be an important perceptual dimension of timbre (Grey, 1977; Krumhansl, 1989; Krimphoff *et al.*, 1994). To eliminate spectral flux, the amplitude envelope $A_k(t)$ for each har-

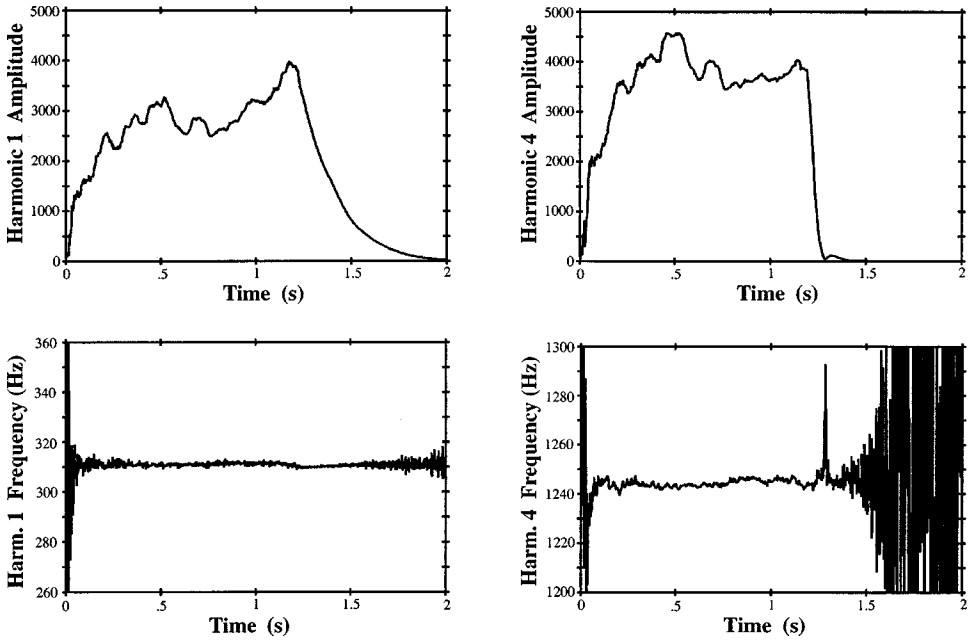

FIG. 4. Example spectral-analysis data for violin tone with duration reduced to 2 s (left column: first harmonic; right column: fourth harmonic; upper row: amplitude envelopes; lower row: frequency envelopes).

monic k was replaced by a function which was proportional to the rms envelope and the average amplitude of the harmonic. Thus, the harmonic-amplitude ratios $[A_2(t)/A_1(t)$, etc.] were fixed during the course of the sound. In addition, the amplitudes were scaled in order to preserve the rms envelope under this transformation. The formula for this transformation is:

$$A_k(t) \leftarrow \frac{\overline{A_k} A_{\mathrm{rms}}(t)}{\sqrt{\Sigma_{k=1}^{K} \overline{A_k}^2}}, \tag{6}$$

where $\overline{A_k}$ signifies the time average of the kth harmonic amplitude over the sound's duration and $\leftarrow$ signifies the replacement operation. Note that with this transformation, all amplitude envelopes of all harmonics have the same shape, albeit with different scale factors.

3. Spectral envelope smoothness (SS)

The question to be answered here is whether jaggedness or irregularity in the shape of a spectrum is perceptually important. For example, the clarinet has a characteristically ''jagged'' up-and-down spectral envelope due to weak energy in the low-order, even harmonics. A smoothing of this spectral envelope would give it more of a low-pass form. Spectral-envelope smoothness was found by Krimphoff *et al.* (1994) to correspond to the third dimension of Krumhansl's (1989) 3D space. To test this, the time-varying spectra were smoothed with respect to frequency. To accomplish this, at each time frame each harmonic amplitude was replaced by the average of itself and its two neighbors (except for endpoint harmonics number 1 and K, where averages of themselves and their neighbors were used)

$$A_1(t) \leftarrow \frac{A_1(t)+A_2(t)}{2}, \tag{7a}$$

$$A_k(t) \leftarrow \frac{A_{k-1}(t)+A_k(t)+A_{k+1}(t)}{3}, \quad k \notin \{1,K\}, \tag{7b}$$

$$A_K(t) \leftarrow \frac{A_{K-1}(t)+A_K(t)}{2}. \tag{7c}$$

This smoothing algorithm is not unique and may not be optimal, but it is perhaps the simplest one can imagine. According to this algorithm, the smoothest possible spectrum is one that follows a straight-line curve (i.e., $A_k = a + b \cdot k$), since such a spectral envelope would not be altered by this transformation.

Figure 5 compares the time-varying amplitude spectrum of a reference sound with those obtained after increasing amplitude-envelope smoothness, amplitude-envelope coherence, and spectral-envelope smoothness algorithms have been applied. The effect of these operations on the reference time-varying spectrum is readily apparent.

4. Frequency envelope smoothness (FS)

We wished to test the auditory importance of frequency microvariations in a parallel fashion to that of amplitude microvariations. Therefore, the envelopes $\Delta f_k(t)$ were processed similarly to the $A_k(t)$ envelopes in amplitude-envelope smoothing described above, except that smoothing was done over the entire sound's duration, including the attack phase. This operation did not grossly affect the frequency variation during the attack, as amplitude-envelope smoothing would have affected amplitude variation during that period had it included the attack.

5. Frequency envelope coherence (FC) (harmonic frequency tracking)

Here, we wanted to test the discriminability of inharmonicity among a sound's partials, even if it sometimes occurs

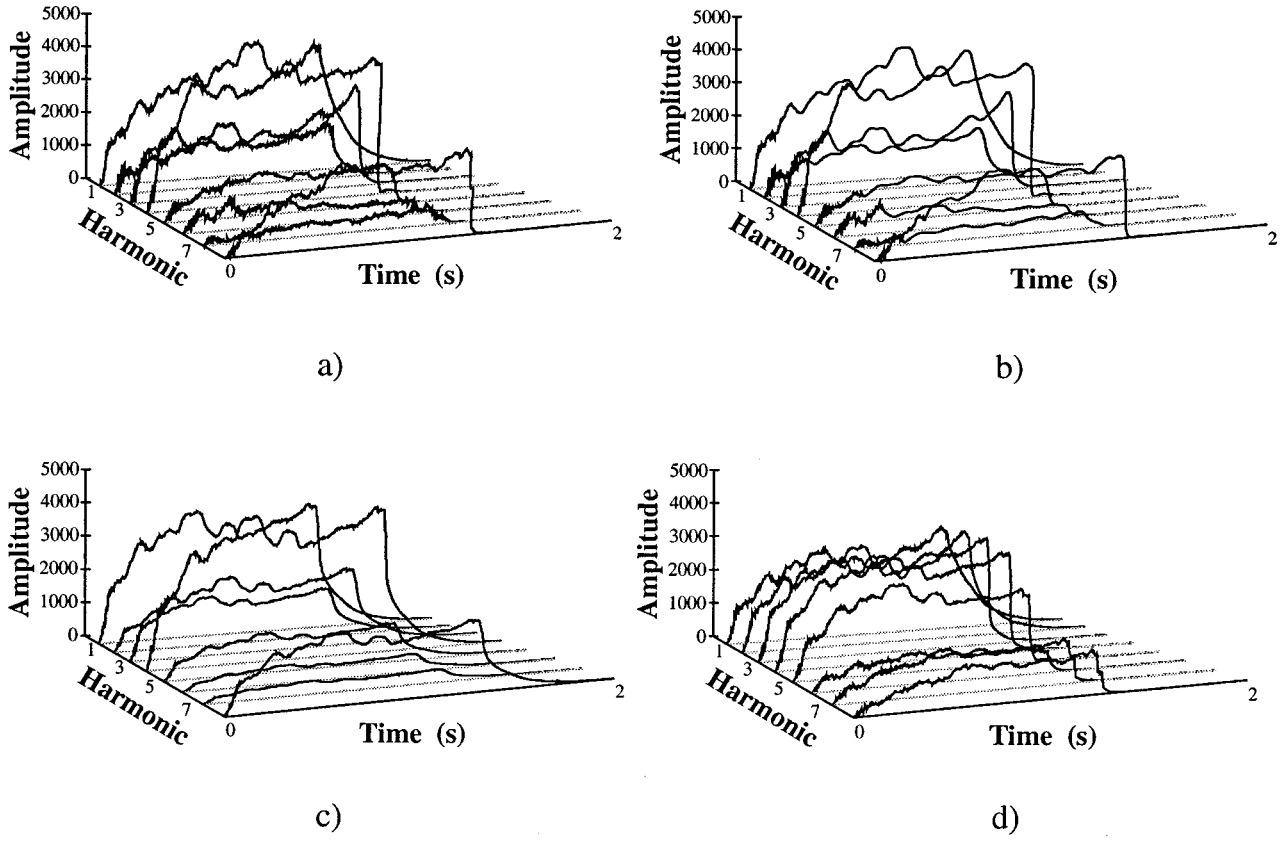

FIG. 5. Simplifications of amplitude envelopes for harmonics 1 to 8: (a) full violin-tone analysis data (reference sound) (b) after amplitude-envelope smoothing, (c) after rms envelope substitution (amplitude-envelope coherence), (d) after spectral-envelope smoothing.

only momentarily. Analogously to the amplitude-envelope coherence case, all frequency envelopes over time are tied together in a perfect harmonic relation. First, an average temporal-frequency contour was computed on the envelope for the first five harmonics, and then the individual harmonic contours were set equal to this contour multiplied by their respective harmonic numbers.

$$f_K(t) \leftarrow k\overline{f_0(t)}, \tag{8}$$

where $\overline{f_0(t)}$ is defined by

$$\overline{f_0(t)} = \frac{\Sigma_{k=1}^{5} A_k(t)\,(1/k)\,f_k(t)}{\Sigma_{k=1}^{5} A_k(t)}. \tag{9}$$

With this method, the strongest harmonics among the first five receive the ''highest votes'' for determining the average fundamental frequency of the sound. The measured frequency of the first harmonic could have been used instead of $\overline{f_0}$. However, it is possible that the first harmonic may be weak in amplitude, which with phase-vocoder analysis would result in a poorly defined frequency envelope (Moorer, 1978). This method obviates that problem.

6. Frequency envelope flatness (FF)

This simplification tested listeners' abilities to discriminate the combination of no frequency variations and no inharmonicity, as after this operation is performed, neither are present in the synthesized sounds. Indeed, there is no frequency envelope, as each harmonic's frequency is set equal to the product of its harmonic number (k) and the fixed analysis frequency (f_a). This operation had previously been found to have an effect on discrimination by Grey and Moorer (1977) and Charbonneau (1981).

Figure 6 shows a reference set of harmonic-frequency envelopes in comparison to those which have been simplified by frequency-envelope smoothing, frequency-envelope coherence, and frequency-envelope flattening.

Each simplification is accompanied by a certain amount of data reduction. Formulas for data reduction are given in Appendix B.

II. EXPERIMENTAL METHOD

A. Subjects

The 20 subjects were aged 19 to 35 years and reported no hearing problems. They included ten musicians (six males, four females) and ten nonmusicians (four males, six females). Musicians were defined as being professionals, semiprofessionals, or having at least 6 years of practice on an instrument and playing it daily. Nonmusicians were defined as having practiced an instrument for not more than 2 to 3 years in their childhood or adolescence, and no longer playing. The subjects were paid for their participation with the exception of three who were members of the auditory-perception team at IRCAM.

B. Stimuli

The seven instruments chosen belong to the air column (air reed, single reed, lip reed, double reed), string (bowed,

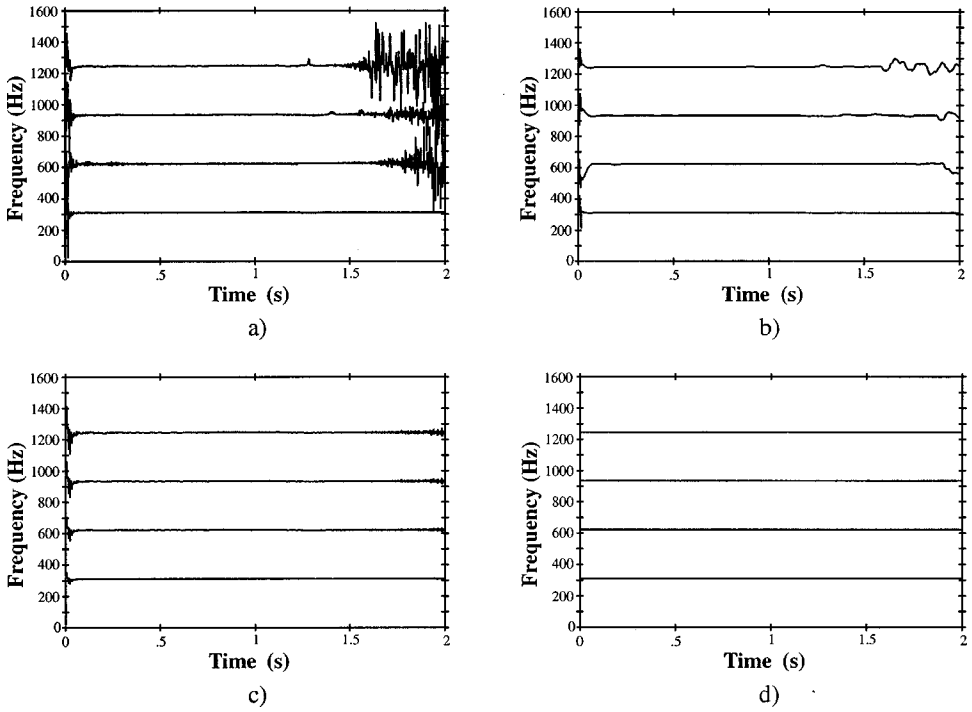

FIG. 6. Simplifications of frequency envelopes for harmonics 1 to 4: (a) full violin-tone analysis data (reference sound), (b) after frequency-envelope smoothing, (c) after average frequency-envelope substitution (frequency-envelope coherence), (d) after replacement by fixed harmonics (frequency-envelope flattening).

plucked), and bar (struck) families: clarinet, flute, harpsichord, marimba, oboe, trumpet, and violin. Each was analyzed and synthesized with the reference sound-analysis data (before modification). In no case could the original recorded sound be discriminated from the full synthesis when presented in an AA–AB discrimination paradigm at better than 64%.[2] The sounds were stored in 16-bit integer format on hard disk. All ''reference'' sounds (full synthesis) were equalized for fundamental frequency (311.1 Hz or E-flat 4) and for duration (2 s) (see Sec. I D for a description of the technique for equalizing duration in synthesis). They were also equalized for loudness in an adjustment procedure by the authors. The different kinds of simplifications and their combinations that were applied to the stimuli are illustrated graphically in Fig. 7. Six simplifications concerned a single parameter, three concerned two parameters, and one each concerned three and four parameters.[3] The 11 simplified sounds for each instrument were synthesized with the method described above on a NeXT computer. They were equalized for loudness within each instrument in an adjustment procedure by the authors.

C. Procedure

A two-alternative forced-choice (2AFC) discrimination paradigm was used. The listener heard two pairs of sounds (AA–AB) and had to decide if the first or second pair contained two different sounds. The dependent variable was the d' measure of sensitivity to the physical difference derived from signal-detection theory using a 2AFC model (Green and Swets, 1974; Macmillan and Creelman, 1991). The trial structure could be one of AA–AB, AB–AA, BB–BA, or BA–BB, where A represents the reference sound and B one of the 11 simplifications. This paradigm has the advantage of presenting to the listener both a ''same'' pair and a ''different'' pair between which the different one must be detected. All four combinations were presented for each simplification and for each instrument. The two 2-s sounds of each pair were separated by a 500-ms silence, and the two pairs were separated by a 1-s silence. On each trial, a button labeled (in French) ''The first pair was different: key 1'' appeared on the left of the computer screen and a button labeled ''The second pair was different: key 2'' appeared on the right. The computer would not accept a response until all four sounds in a trial had been played. This was indicated by a dimming of the labels on the buttons during sound presentation.

For each instrument, a block of 44 trials was presented to the subjects (four trial structures$\times$11 simplifications). Each block was presented twice in succession, and performance for each simplification was computed on eight trials for each subject. Seven pairs of blocks were presented corresponding to the seven instruments. The total duration of the experiment was about two h and 20 min. For 13 subjects, the experiment was divided into two sessions performed on different days, with four instruments on one day and three instruments on the other. For seven other subjects, it was performed in one day with several pauses between instruments.

The experiment was controlled by the PSIEXP interactive program (Smith, 1995) running on a NeXT computer. Subjects were seated in a Soluna S1 double-walled sound-isolation booth facing a window through which the computer screen was visible. Sounds were converted through NeXT digital-to-analog converters, amplified through a Canford power amplifier, and then presented through AKG K1000

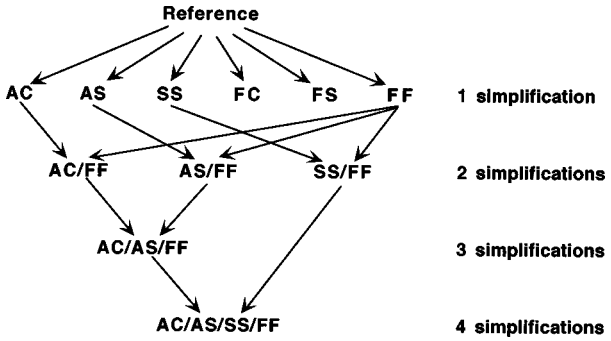

FIG. 7. Schema illustrating the accumulation of stimulus simplifications. For key, see Table II.

open-air headphones at a level of approximately 70 dB SPL as measured with a Bruel & Kajer 2209 sound-level meter fitted with a flat-plate coupler.

At the beginning of the experiment, the subject read instructions and asked any necessary questions of the experimenter. Five or six practice trials (chosen at random from the instrument being tested) were presented in the presence of the experimenter before the first block for each instrument. Then the two experimental blocks for that instrument were presented. The order of presentation of the 44 trials was random within each block, and the order of presentation of the instruments was randomized for each subject.

III. RESULTS

Discrimination rates were computed for each simplification of each instrument's reference sound across the four trial structures and two repetitions for each subject. The means across both groups of subjects for the 11 simplifications on seven instrument sounds are given in Table II and plotted in Fig. 8. Accumulated simplifications involving amplitude-envelope coherence (AC), amplitude-envelope smoothness (AS), and spectral-envelope smoothness (SS) are joined by lines to visualize the effect of accumulation. In general, spectral-envelope smoothness and amplitude-envelope coherence simplifications were the most easily discriminated, followed by coherence (FC) and flatness (FF) of frequency envelopes, and finally amplitude-(AS) and frequency-(FS) envelope smoothness. With one exception, the accumulation of simplifications improved discrimination, attaining nearly perfect discrimination for all instruments. The pattern of discrimination differences across simplification types is very different for each instrument, suggesting that the acoustic structure of each sound is affected differentially by these simplifications.

To evaluate the different factors included in this experiment, several statistical analyses were performed. The dependent variable in these analyses was the d' index of sensitivity (derived from proportion-correct discrimination rates in Table A.5.2 from Macmillan and Creelman, 1991). A global mixed analysis of variance (ANOVA) was performed on between-subjects factor musical training (2) and within-subjects factors instrument (7) and simplification (11). Mixed ANOVAs on musical training and simplification were also performed for the data of each instrument individually.

TABLE II. Results of discriminating six basic simplifications and five combinations of simplifications compared to the reference sounds (complete resynthesis of the originals after frequency, duration, and loudness matching). Key: AC=amplitude-envelope coherence, AS=amplitude-envelope smoothness, SS=spectral-envelope smoothness, FC=frequency-envelope coherence, FS=frequency-envelope smoothness, FF=frequency-envelope flatness, Cl=clarinet, Fl=flute, Hc=harpsichord, Mb=marimba, Ob=oboe, Tp=trumpet, Vn=violin.

	Instrument							
Simplification	Cl	Fl	Hc	Mb	Ob	Tp	Vn	Mean

AC/AS/SS/FF	0.99	0.98	0.98	0.98	0.99	0.97	1.00	0.99

For the data within each instrument, Tukey–Kramer HSDs (''honestly significant differences'') were computed to determine the critical difference between condition means at a significance level of 0.05. This technique allows a robust comparison among all means of a data set by the simultaneous construction of confidence intervals for all pairs (Ott, 1993). Finally, in order to determine which simplifications were reliably different from chance performance, single-sample *t*-tests were performed against a hypothetical mean of 0.50 with probabilities being corrected for multiple tests with the Bonferroni adjustment.

A. Effects of musical training

Musicians discriminated simplifications from reference sounds slightly better overall than nonmusicians (86.8% vs 82.2%) by 3.0% to 7.1% across instruments [$F(1,18) = 8.05$, $p < 0.05$].[4] There was no interaction of this factor with other factors in the global analysis. In the individual ANOVAs, there were significant main effects of musical training for four of the seven instruments [flute: $F(1,18) = 5.01$, $p < 0.05$; marimba: $F(1,18) = 9.76$, $p < 0.01$; oboe: $F(1,18) = 6.99$, $p < 0.05$; violin: $F(1,18) = 5.70$, $p < 0.05$], and there were significant musical training by simplification interactions for two instruments [clarinet: $F(10,180) = 2.93$, $p < 0.05$; violin: $F(10,180) = 2.55$, $p < 0.05$]. So overall, there was a small effect of musical training that was globally reliable and present in the majority of instruments but which varied differently across simplification conditions in only two of the instruments. Given the small size of the effect, we will not consider it any further.

B. Effects of instrument

In the global ANOVA, there were highly significant effects of instrument [$F(6,108) = 28.80$, $p < 0.0001$], simplification [$F(10,180) = 237.97$, $p < 0.0001$], and their interaction [$F(60,1080) = 9.87$, $p < 0.0001$]. This strong interaction revealed very large differences in the effects of a given sim-

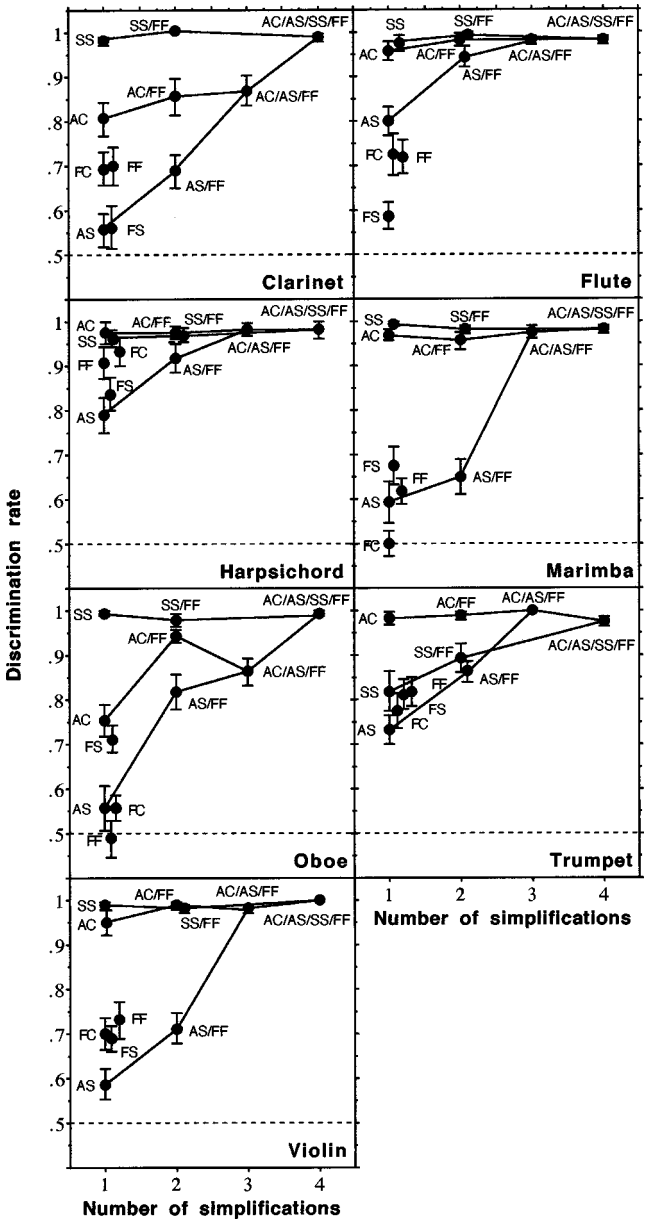

FIG. 8. Discrimination rates as a function of the number of simplifications performed on sounds from seven instruments. The letter codes refer to the simplification types (see Table II caption). Simplifications involving AS, AC, and SS are connected to visualize the effect of their accumulation. The vertical bars represent ±1 standard error of the mean. Chance performance is at 0.5. Some points have been displaced laterally for visibility.

plification across instruments. We will therefore only consider differences among simplifications within the individual ANOVAs for each instrument.

C. Effects of the simplifications and their accumulation

The main effect of simplification was highly significant ($p<0.0001$) for all seven instruments [clarinet: $F(10,180)=40.14$; flute: $F(10,180)=41.14$; harpsichord: $F(10,180)=11.54$; marimba: $F(10,180)=71.82$; oboe: $F(10,180)=43.40$; trumpet: $F(10,180)=22.05$; violin: $F(10,180)=81.65$], indicating a large variation in discriminability of the different types of simplification. Single-sample *t*-tests adjusted for multiple tests indicated that only nine of the 42 single simplifications were *not* discriminated above chance. These include AS and FS for the clarinet, FS for the flute, AS and AC for the marimba, AS, FC, and FF for the oboe, and AS for the violin. Note that no single simplification is ''successful'' (i.e., indistinguishable from the reference sound) for all seven instruments. However, amplitude-envelope smoothness was only reliably discriminated from the reference in flute, harpsichord, and trumpet. In order to evaluate the significance of the differences among simplifications, a clustering organization is projected onto the mean data in Fig. 9 in which means that are smaller than the critical Tukey–Kramer HSD for that instrument are enclosed in a bounded region. The critical differences are listed in Table III. In general, simplifications involving amplitude-envelope coherence (AC) and spectral-envelope smoothness (SS) are found in the highest cluster, showing near-perfect discrimination for most instruments, although AC is less well discriminated in the clarinet and oboe, and SS is less well discriminated in the trumpet.

As a general rule, the discrimination of a multiple simplification was roughly equal to the discrimination of the constituent simplification which had the highest discrimination rate. For example, take the clarinet sound. Discrimination was near chance for AS, around 70% for FF, about 80% for AC, and nearly perfect for SS. Accumulating AS and FF gave a rate no different from that for FF. Similarly, AC/FF and AC/AS/FF had rates no different from that of AC, while SS/FF and AC/AS/SS/FF were not different from SS alone. This rule held for 32 of the 35 multiple-simplification conditions. Thus, there were only three cases where the accumulation of two simplifications was better discriminated than either of the constituent simplifications: AS/FF was better than AS and FF for the flute, and AC/FF and AS/FF were better than their constituents for the oboe. There was only one case where an accumulated simplification resulted in a *decrease* in discrimination performance: AC/AS/FF was discriminated worse than AC/FF for the oboe, suggesting that the addition of the amplitude-envelope smoothness reduced the effect of amplitude-envelope coherence and/or frequency-envelope flatness. Taken together, these results suggest that it is generally sufficient to examine the individual effects of a single, ''most-potent'' simplification for each instrument to explain the behavior of their combinations. In order to compare across instruments, the discrimination rates for the six single simplifications are shown for each instrument in Fig. 10.

IV. MEASUREMENTS OF SPECTRAL DIFFERENCES BETWEEN REFERENCE AND SIMPLIFIED SOUNDS

A. Amplitude and frequency errors

The effect of the simplifications on sounds was directly measured from the analysis file data by computing normalized rms differences between reference and simplified sounds. Accordingly, for the amplitude simplifications, we measured the relative difference between reference (*Ar*) and

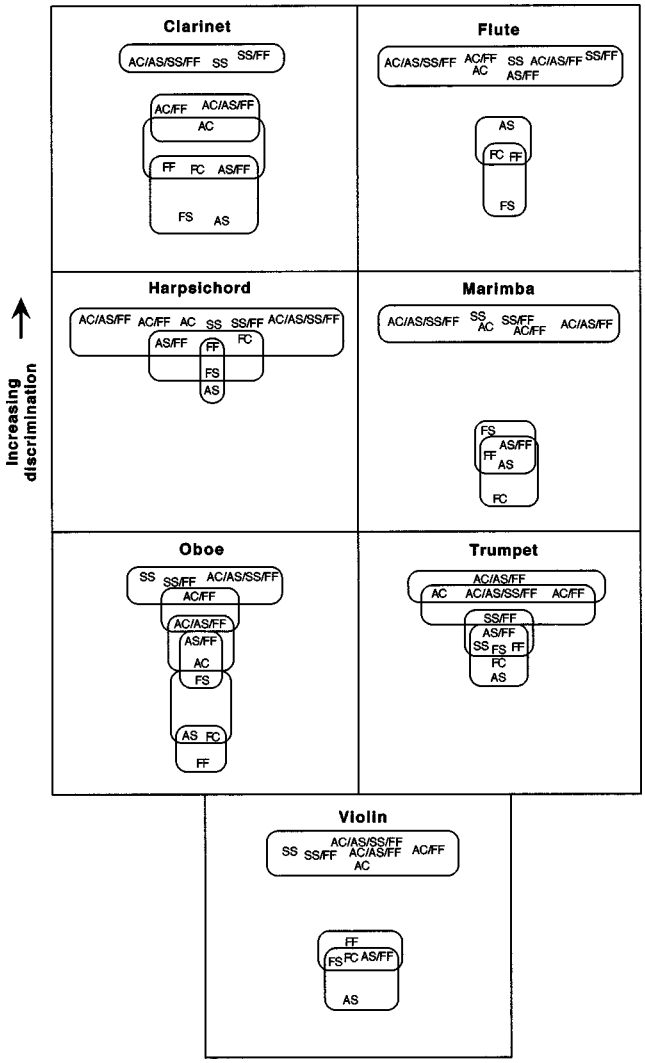

FIG. 9. Schematic representation of significant differences between means as revealed by Tukey–Kramer HSD tests. Discrimination performance is organized along the vertical dimension within each panel, as in Fig. 8. Simplifications with means whose differences are not bigger than the critical difference (see Table III) are enclosed within a bounded region. In the oboe data, for example, FF is not significantly different from AS and FC but is different from FS. However, AS and FC are not significantly different from FS.

simplified (*As*) time-varying amplitude spectra (which are assumed to represent sounds having the same mean frequencies and same duration) using

$$\mathrm{ERR}_{\mathrm{amp}}=\frac{1}{I}\sum_{i=1}^{I}\left(\frac{\Sigma_{k=1}^{K}(As_k(i)-Ar_k(i))^2}{\Sigma_{k=1}^{K}As_k(i)\cdot Ar_k(i)}\right)^{1/2}, \tag{10}$$

TABLE III. Critical Tukey–Kramer differences for the mean discriminations of simplifications computed across both groups of subjects.

Instrument	Critical difference
Clarinet	0.217
Flute	0.196
Harpsichord	0.226
Marimba	0.187
Oboe	0.207
Trumpet	0.215
Violin	0.170

where i is the number of the analysis time frame and I is the total number of frames. $\mathrm{ERR}_{\mathrm{amp}}$ can vary between 0 and 1. In our set of sounds, it varied between about 0.01 and 0.58. With this formula, the error at any instant relative to the amplitude at that instant is computed. Due to the amplitude product in the denominator, Eq. (10) accentuates low-amplitude portions, giving them the same weight as high-amplitude portions. It is assumed here that proportional-amplitude errors are more relevant than absolute-amplitude errors. The normalized squared errors are accumulated over harmonics and are then averaged over time. One could argue that this might be improved by first accumulating amplitudes by critical bands before averaging, but this would complicate the calculation considerably and would not guarantee any improved result.

In a similar manner, for the frequency simplifications, we measured the difference between reference (*fr*) and simplified (*fs*) series of time-varying frequency data using

$$\mathrm{ERR}_{\mathrm{freq}}=\frac{1}{If_a}\sum_{i=1}^{I}\left(\frac{\sum_{k=1}^{K}\left(\frac{(Ar_k(i)(fs_k(i)-fr_k(i))}{k}\right)^2}{\Sigma_{k=1}^{K}Ar_k^2(i)}\right)^{1/2}. \tag{11}$$

Frequency differences are divided by the harmonic number k, because we assume that they are intrinsically amplified linearly with k. The frequency difference for each harmonic k is weighted by its amplitude, giving greater votes to higher-amplitude harmonics. This is beneficial because lower-amplitude harmonics tend to have more oscillation in their frequency data, which is an artifact of the analysis process and not representative of the sound itself (Moorer, 1978). Besides averaging over time, we normalize by the average fundamental frequency (f_a), so that the results are presented as a proportion of the fundamental. The values of $\mathrm{ERR}_{\mathrm{freq}}$ in our set of sounds were very low (between 0.0009 and 0.0134).

The amplitude and frequency-error results for the six basic simplifications for the seven instruments are shown in Tables IV and V, respectively. The mean d' scores are plotted in Fig. 11 as a function of the logarithm of the error values for the amplitude (a) and frequency (b) simplifications. Although there is some dispersion in the plot, the overall relations between listener-obtained discrimination scores and the objective measurements are clear. For most cases, larger errors predict higher sensitivity. If discrimination scores are expressed in terms of d', $\log(\mathrm{ERR}_{\mathrm{amp}})$ explains 77% of the variance in discrimination performance for single-amplitude simplifications. The amount of variance explained increases to 88% if the outlying point due to the AC condition for the marimba is removed. Note that the various amplitude simplifications are quite different overall in their discriminability (AS<AC<SS).

The picture is quite different for the frequency simplifications. First, the data are much more scattered, indicating that $\mathrm{ERR}_{\mathrm{freq}}$ explains much less variance than did $\mathrm{ERR}_{\mathrm{amp}}$ for corresponding conditions; explained variance in d' by $\log(\mathrm{ERR}_{\mathrm{freq}})$ is only 34% but increases dramatically to 57% when the outlying point due to the FF condition for the oboe

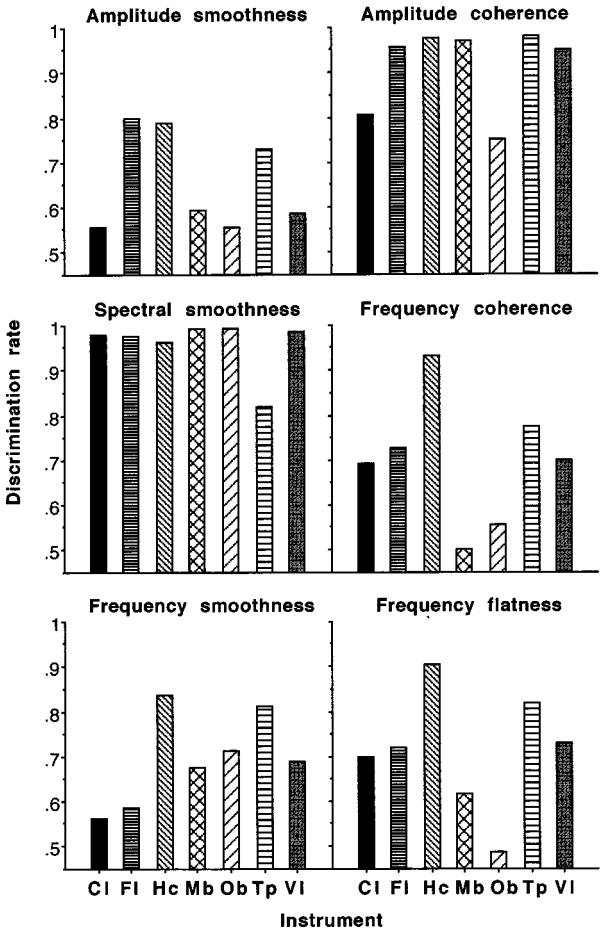

FIG. 10. Discrimination rates for the seven different instrument sounds having been simplified in six ways (see the text for a complete description). For instrument key, see Table II.

is removed. Second, there is a much greater overlap between the conditions indicating that there is a less systematic effect of the simplification condition and that each simplification type affects the various instruments to very different degrees.

B. Effect of spectral-amplitude changes on centroid

Since the centroid of the spectrum has been shown to be strongly correlated with one of the most prominent dimensions of multidimensional-scaling representations of timbral differences (Grey and Gordon, 1978; Iverson and Krumhansl, 1993; Kendall and Carterette, 1996; Krimphoff *et al.*, 1994; Krumhansl, 1989; Wessel, 1979), one might conjecture that a listener's ability to detect spectral-amplitude modifications is due to detection of attendant centroid changes rather than to the modifications themselves. Although in synthesized tones spectral centroid can be controlled independently of other spectral-amplitude modifications, they are not necessarily separable in musical instrument tones. Nonetheless, we have found them to be statistically independent to a substantial degree in a number of our stimuli.

We define time-varying normalized spectral centroid (SC) to be

TABLE IV. Relative spectral differences between reference and simplified spectra for basic and accumulated amplitude simplifications. The values represent ERR_{amp} [Eq. (10)]. Note that the values for basic simplifications and those simplifications accumulated with the FF simplification would be identical, since the FF operation has no effect on the amplitudes. For key, see Table II caption.

	Instrument						
Simplification	Cl	Fl	Hc	Mb	Ob	Tp	Vn
AC	0.100	0.164	0.204	0.033	0.122	0.280	0.350
AS	0.017	0.024	0.035	0.016	0.020	0.024	0.015
SS	0.565	0.324	0.258	0.505	0.377	0.143	0.401
AC/AS/FF	0.101	0.165	0.207	0.035	0.124	0.280	0.350
AC/AS/SS/FF	0.578	0.342	0.282	0.508	0.418	0.299	0.511

$$\mathrm{SC}(i)=\frac{\Sigma_{k=1}^{K} kA_k(i)}{\Sigma_{k=1}^{K} A_k(i)}. \tag{12}$$

To test the degree to which an amplitude simplification affects the centroid, we calculate the rms-amplitude-weighted mean centroid change based on the centroids of the simplified (SCs) and reference (SCr) spectra:

$$\overline{\Delta \mathrm{SC}}=\frac{\sum_{i=1}^{I}\left|\frac{\mathrm{SC}s(i)}{\mathrm{SC}r(i)}-1\right|\cdot A_{\mathrm{rms}}(i)}{\Sigma_{i=1}^{I} A_{\mathrm{rms}}(i)}. \tag{13}$$

This quantity is zero if there is no difference in centroid and it is unbounded, although for our simplifications $\overline{\Delta \mathrm{SC}}$ attained a maximum value of 0.3.

Of course, the amplitude-envelope coherence (AC) simplification may result in a large centroid change for tones with a great deal of spectral flux, since it was designed to eliminate any centroid change during the course of a sound. However, centroid effects, some quite sizable, also occur for AS and SS operations, although the changes induced by AS are generally much less than those due to the other two amplitude simplifications. Table VI gives a list of the average relative centroid changes for the three amplitude simplifications. Mean discrimination data (d') are plotted as a function of $\overline{\Delta \mathrm{SC}}$ in Fig. 11(c). Note that these averages are based on magnitudes of the SC changes. Further inspection of Table VI reveals that for the instruments tested, centroid increases in stimuli with spectral-envelope smoothness are always positive, whereas for the other two simplifications, the change in centroid can go in either direction—even during the sounds. The logarithm of the mean centroid change ex-

TABLE V. Relative spectral differences between reference and simplified spectra for basic frequency simplifications. The values represent ERR_{freq} [Eq. (11)]. Note the values for FF would override all accumulations of this operation with other simplifications. For key, see Table II caption.

FF	0.002	0.005	0.013	0.003	0.010	0.007	0.004

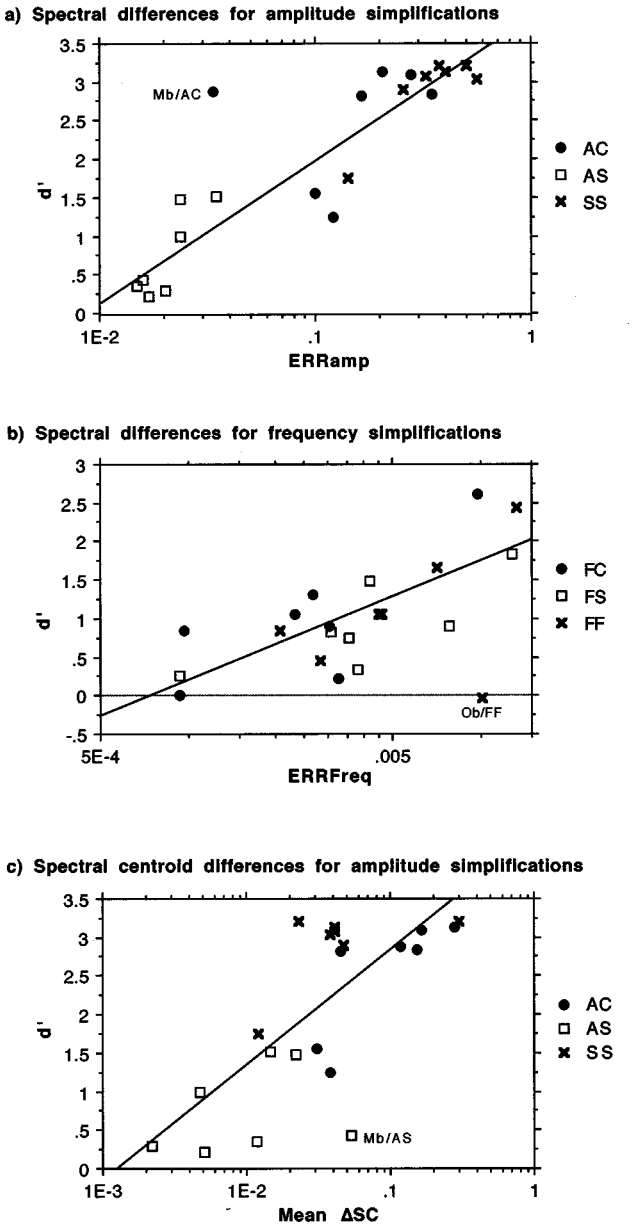

FIG. 11. Discrimination scores (d') plotted as functions of the logarithms of three objective measures [ERR_{amp} (a), ERR_{freq} (b), and $\overline{\Delta SC}$ (c)] for the single amplitude and frequency-envelope simplifications indicated for each panel. The linear regression lines were computed without one outlying point indicated in each panel: Mb/AC in (a), Ob/FF in (b), and Mb/AS in (c), since the removal of these single points resulted in dramatic increases in the correlation coefficients in each case (see the text for complete descriptions of the objective measures).

plains 54% of the variance in d', but this value increases to 65% when the outlying point due to the marimba in the AS condition is removed.

V. DISCUSSION

The discrimination data show that the sensitivity of listeners to simplifications of musical instrument spectra depends on the parameter modified and the instrument sound processed, while being relatively unaffected by the musical training of the listeners. The interaction between type of simplification and instrument is most likely due to a combination of the perceptual salience of the parameter simplified and the strength of that parameter in the particular sound. From Fig. 10 it is quite obvious that spectral-envelope smoothness and amplitude-envelope coherence are the most discriminable simplifications. However, spectral-envelope smoothness causes a smaller perceptual change for the trumpet than the other instruments, which is not unexpected since its spectrum is quite smooth to begin with. For this latter instrument, amplitude-envelope coherence is the most discriminable simplification, due to the strong degree of spectral flux present in brass tones (Grey, 1977). Further, the amplitude-envelope coherence simplification is much less discriminable for the clarinet and oboe because their spectra do not undergo as much spectral flux as most other instruments (Grey, 1977).

The other simplifications result in lesser discrimination scores, either because these involve parameters of lesser perceptual salience or because the parameters have insufficient strength to result in higher scores. Again, scores depend on the instrument tested. Amplitude-envelope smoothness seems to be most important for the flute, trumpet, and harpsichord, the former two because of their relatively large temporal variations and the latter because of its effect on the decay curves.

Objective measures of average spectral ($\overline{\Delta SC}$) and spectrotemporal change (ERR_{amp},ERR_{freq}) were developed in an attempt to quantify the acoustic cues that give rise to the discrimination performance. Figure 11 clearly shows that the three amplitude simplifications (AC, AS, and SS) have different effects on changes in amplitude-envelope structure and consequently that they are discriminated to differing degrees as well. Spectral-envelope smoothness is almost always the most easily detected, followed by amplitude-envelope coherence, and finally by amplitude-envelope

TABLE VI. Average relative-magnitude change of centroid [$\overline{\Delta SC}$, Eq. (13)] for the three basic amplitude simplifications and two accumulations of those simplifications. Note that centroids would not be appreciably affected by the FF simplification since the frequency variations were less than 1% during the significant amplitude portions of the sounds. A minus sign indicates that, on average, the centroid for the simplified sound decreased compared to the reference sound. For key, see Table II caption.

	Instrument						
Simplification	Cl	Fl	Hc	Mb	Ob	Tp	Vn
AC	0.031	0.045	0.279(−)	0.118(−)	0.038	0.166	0.155
AS	0.005(−)	0.023	0.015(−)	0.054(−)	0.002(−)	0.005	0.012(−)
SS	0.039	0.041	0.047	0.299	0.023	0.012	0.042
AC/AS/FF	0.031	0.046	0.282(−)	0.117(−)	0.038	0.166	0.156
AC/AS/SS/FF	0.058	0.061	0.284(−)	0.359	0.038	0.168	0.156

smoothness, which gives performance not far from chance for four of the seven instrument sounds.

Similarly, note that for most sounds the effect of amplitude-envelope smoothness on spectral centroid change (mean=0.016) is much less than that of amplitude-envelope coherence (0.119), with the flute being the only exception (0.023 vs 0.045, respectively). Indeed, the flute has a comparatively high discrimination score for amplitude-envelope smoothness (0.80), whereas the marimba with amplitude smoothness has a moderately high spectral-centroid change (0.054) and a relatively low discrimination rate (0.59). Also, surprisingly, the flute has a high discrimination score for the amplitude-coherence simplification (0.96), even though its change of centroid (0.041) is slightly less than the amplitude-based simplifications (overall mean for the three, 0.045). On the other hand, we see that in comparison to the amplitude-envelope coherence, spectral-envelope smoothness causes moderate to high centroid changes (0.02–0.30), with the trumpet (0.01) being the obvious exception as mentioned above. The marimba exhibits a large relative centroid change (0.30), but this is true because the marimba's sound is dominated by its fundamental. In this case, spectral-envelope smoothness makes a profound change by introducing a second harmonic which was originally nonexistent. Note, however, that spectral-envelope smoothness will have an effect on any jagged spectrum, regardless of whether the spectrum is changing or not, whereas amplitude-envelope coherence only affects sounds with time-varying spectra. Since spectral-envelope smoothness inherently affects the centroid, we cannot tell whether discrimination is due to this effect or directly to the change of spectral-envelope fine structure, but it is probably due to a combination of these effects.

All of the amplitude simplifications produce changes in both $\mathrm{ERR}_{\mathrm{amp}}$ and $\overline{\Delta \mathrm{SC}}$ measures. Further, these two objective measures partially explain the variance in discrimination performance and yet are not strongly correlated between them ($r=0.61$). This suggests that they may both contribute to the discrimination of amplitude-related changes in the spectrotemporal morphology of the simplified instrument sounds. To test this idea, the logarithms of both parameters were selected as independent variables in a stepwise regression across single-amplitude simplifications with d' as the dependent variable. This technique tests the independent contribution of each parameter, which only enters the regression if its contribution is statistically significant (F-to-enter=4, in our case). Both parameters successfully enter into the regression. The final result is given by the following linear regression equation, by which 83% of the variance in the data is explained:

$$d' = 4.34 + 1.35 \cdot \log(\mathrm{ERR}_{\mathrm{amp}}) + 0.64 \cdot \log(\overline{\Delta \mathrm{SC}}). \qquad (14)$$

It becomes clear from this analysis that there are at least two perceptual cues contributing to discrimination performance in these sound simplifications.

The striking thing about the frequency-related simplifications is their relative weakness in creating discriminable differences in the stimuli. This result may be due primarily to the fact that, in normal instrument sounds without vibrato, the amount of frequency variation is relatively small. Indeed, as can be gleaned from Table V, the largest change in frequency variation created by flattening or smoothing the frequency envelopes is for the harpsichord and is on the order of 1.3%; the next largest is on the order of 1% produced by frequency flattening of the oboe. It is perhaps surprising, therefore, that so much has been written in the literature about the importance of frequency microvariations in the creation of naturalness in synthetic sounds (Dubnov and Rodet, 1997; McAdams, 1984; Sandell and Martens, 1995; Schumacher, 1992). Nonetheless, there are certainly classes of musical sounds where pitch contour plays an important role in musical expressiveness, such as vibrato and portamento, particularly in vocal and bowed-string sounds.

The effect of combining amplitude-related and frequency-related cues for the accumulated simplifications is less clear in the data, however. In a stepwise regression of the entire set of d' scores on all three objective measures, only $\mathrm{ERR}_{\mathrm{amp}}$ entered significantly into the regression and then explained only 63% of the total variance. So, while individual cues seem to explain a large portion of the variance for the basic simplifications, their combined use in judging accumulated simplifications remains uncertain. This may be due in part to the judgment strategy discussed above, namely that listeners respond to the most salient parameter in an accumulation of parameters. In the discrimination data, there are only four out of 35 cases where an accumulation gives higher discrimination scores than the best of its component simplifications: AC/FF is better than either component for the oboe, and AS/FF is better than either component for clarinet, flute, and oboe. If our objective measures are truly indicative of the perceptual cues being used by listeners to perform the task, they should have a similar pattern to the discrimination data with accumulations having the same or slightly higher values than their constituent simplifications. Globally this is the case (see Tables IV, V, and VI): AC/AS/FF is approximately equal to AC for all seven instruments in terms of both $\mathrm{ERR}_{\mathrm{amp}}$ and $\overline{\Delta \mathrm{SC}}$, and AC/AS/SS/FF is approximately equal to or slightly higher than SS or AC in all seven instruments in terms of $\mathrm{ERR}_{\mathrm{amp}}$, although it is quite a bit higher for clarinet, flute, and marimba in terms of $\overline{\Delta \mathrm{SC}}$. The combination of the psychophysical data and the objective measurements would thus seem to globally support the most-potent cue judgment strategy.

VI. CONCLUSIONS

The results of this study point very strongly to (1) spectral-envelope shape (jagged vs smooth) and (2) spectral flux (time variation of the normalized spectrum) as being the most salient physical parameters that we have studied related to timbre discrimination, followed in order by (3) the presence of frequency variation, (4) frequency incoherence (inharmonicity), (5) frequency microvariation, and (6) amplitude microvariation. Simplifications (reductions or eliminations) of these parameters give rise to changes in the spectrotemporal morphology of an instrument sound's sensory representation, to which both musician and nonmusician

listeners are very sensitive. This sensitivity is only slightly greater in musicians than in nonmusicians. The level of discrimination resulting from the modifications was globally greater for the amplitude simplifications than for the frequency simplifications, with the exception of amplitude smoothing. Thus, musical-sound synthesis should pay particular attention to spectral-envelope fine-structure and spectral flux if a high degree of audio quality is to be ensured.

Objective measures were defined that predict a great deal of the discrimination performance. These measures are related to changes in the amplitude envelopes and the spectral centroid for amplitude simplifications, and to changes in the frequency envelopes for frequency simplifications. Since discrimination can be predicted by physical measurement of differences in the time-varying spectra, it appears that the importance of these parameters is in direct proportion to the extent to which they actually vary in musical sounds, as we have shown with the strong interaction between simplification type and musical instrument. Further work is needed to examine the relative perceptual sensitivity of listeners to these different physical factors. We have also shown that if several parameters are varied simultaneously, listeners appear to use the most salient one, and their discrimination performance can, for the most part, be predicted on the basis of it alone. While it is likely that this acute sensitivity to the fine-grained spectral and temporal structure of the musical sounds exists across the entire range of pitch, dynamics, and articulation possible on each instrument, further research will be needed to determine the relative importance of the different objective parameters in different regions of an instrument's musical ''space.''

ACKNOWLEDGMENTS

We would like to thank Sophie Savel for running subjects in the control experiment, Bennett Smith for the wonders of PSIEXP, as well as John Hajda and two anonymous reviewers for helpful comments.

APPENDIX A

We can write the reduced-duration harmonic amplitude envelope as

$$A_k(t) \leftarrow \begin{cases} A_k(t), & 0 \leqslant t < t_1, \\ (1-\alpha(x)) \cdot A_k(t) + \alpha(x) \cdot A_k(t+t_2-t_3), & \\ \quad t_1 \leqslant t < t_3, & \\ A_k(t+t_L-2), & t_3 \leqslant t \leqslant 2, \end{cases} \tag{A1}$$

where

$$t_3 = 2-(t_L-t_2), \quad \alpha(x) = 3x^2 - 2x^3, \quad x = \frac{(t-t_1)}{(t_3-t_1)},$$

and t_L is the duration of the original sound.

Note that $\alpha(x)$ is a cubic spline with the following properties:

(1) The derivative of $\alpha(x)$ with respect to x is zero at $x=0$ and $x=1$,
(2) $\alpha(0)=0$,
(3) $\alpha(1)=1$.

The same method obviously applies to the harmonic-frequency envelopes.

APPENDIX B

Since the data rate for each harmonic amplitude or frequency envelope is originally $2f_a$, the overall data rate for K harmonic amplitude and frequency envelopes is $4K \cdot f_a$.

Amplitude-envelope smoothing (AS) and frequency-envelope smoothing (FS) essentially reduce the data rate for each harmonic envelope from $2f_a$ to $2f_c$, where f_c is the filter cutoff frequency. If only amplitude-envelope smoothing were applied, the data rate for K harmonics would be reduced to $2K \cdot f_c + 2K \cdot f_a = 2K \cdot (f_c + f_a)$. In our case, since $f_a = 311$ Hz and $f_c = 10$ Hz, the data reduction factor would be $4.311/[2 \cdot (10+311)] = 1.94$. The same result would apply if only frequency-envelope smoothing were applied. On the other hand, if both were applied the new total data rate would be $4K \cdot f_c$, and the data reduction factor would be f_a/f_c. In our case, this is $311/10 = 31.1$, i.e., there is only a substantial overall data reduction if both amplitude- and frequency-envelope smoothing are applied.

Spectral-envelope smoothing does not reduce the data rate very much, at least not with the current definition of smoothing. Since the order of the smoothing function is 2, the reduction is approximately a factor of 2.

Amplitude- (AC) and frequency coherence (FC) simplifications essentially replace multiple envelopes by single envelopes. If one of these simplifications were applied, the data rate falls from $4K \cdot f_a$ to $2K \cdot f_a + 2f_a = 2(K+1) \cdot f_a$. So, the data reduction factor would be approximately 2. If both were applied, the data reduction factor would be exactly K, the number of harmonics. In our case, this varies from 30 to 70, depending on the instrument.

The data rate for flattened frequency envelopes is zero. So, if frequency flattening (FF) is applied, the data rate goes from $4K \cdot f_a$ to $2K \cdot f_a$, a factor of 2 reduction.

Data rates after combinations of data simplifications can be calculated from the individuals. For example, if AC and FF are combined, the data rate becomes $2f_a$. For AS and FF, it would be $2K \cdot f_c$. For SS and FF, it is $K \cdot f_a$. For AC, AS, and FF, it is $2f_c$. For AC, AS, SS, and FF, it is just f_c. The corresponding data-reduction factors are for AC/FF, $2K$; for AS/FF, $2f_a/f_c$; for SS/FF, 4; for AC/AS/FF, $2K \cdot f_a/f_c$; for AC/AS/SS/FF; $4K \cdot f_a/f_c$.

[1]We were unable to find a trumpet tone of suitable quality recorded at E-flat 4, so we used a tone recorded by author J.B. which was within a whole tone of that pitch, *F*4. When resynthesized at E-flat 4, it sounded perfectly natural to all of the authors.

[2]A control experiment designed to test discrimination of the digitized recordings and the fully analyzed–resynthesized sounds was conducted with six listeners. Each subject performed 40 trials for each instrument using the paradigm described in Sec. II C. The discrimination rates for oboe, clarinet, flute, harpsichord, marimba, trumpet, and violin were 0.62, 0.54, 0.59, 0.64, 0.53, 0.57, and 0.53, respectively. Chance performance would be at 0.50 in this two-alternative forced-choice paradigm. Discrimination rates above

0.55 are significantly different from chance ($p<0.05$) by an exact binomial test for 240 trials (6 listeners×40 trials). Therefore, the full reconstructions were discriminated from the original recordings in four of the seven cases (oboe, harpsichord, marimba, and trumpet), although their discrimination rates are still quite low. That the discrimination scores are as high as 64% is actually quite surprising, given that the authors could not discriminate them informally. The subjects must have been operating from extremely subtle cues which only became obvious upon repeated listening. Two possible cues are phase differences and low-frequency noise differences between the original and synthetic cases. Improvements in the analysis/synthesis algorithms should be able to close this gap in the future. However, for this study we are confident that the vast majority of the spectrotemporal features survived the analysis/synthesis process intact. Moreover, the duration-shortened resynthesized sounds were created to be the reference sounds, so our conclusions, which relate to these sounds, are not affected by this finding.

[3]Audible artifacts were sometimes noticeable with the AC and SS simplifications. Amplitude-envelope coherence created two types of artifacts: a ''shh'' noise at the end of the sound (clarinet) or a kind of general muting of the sound (harpsichord, marimba, and trumpet). In fact, in rendering the amplitude envelopes coherent, one increases the amplitude of weak harmonics that start later and end earlier in parts of the signal that are near the noise floor. The frequency estimation is not very precise for these temporal regions of such harmonics (Moorer, 1978), and by increasing their amplitude, the existing imprecise fluctuations in frequency become clearly audible. The spectral-envelope smoothing creates a kind of gargling sound in the flute, marimba, and trumpet. This simplification also increases the level of weak harmonics whose representations have been corrupted by stronger neighbors due to channel leakage, thus amplifying fluctuations due to imprecise estimation of their frequency. These two kinds of artifacts disappear or are notably reduced when combined with frequency coherence or frequency flatness, since the frequency fluctuations producing the artifacts are then reduced or eliminated.

[4]Probabilities are corrected where necessary by the Geisser–Greenhouse epsilon (Geisser and Greenhouse, 1958), which is a conservative adjustment to account for inherent correlations among repeated measures.

Perception of complex tones and its analogy to echo spectral analysis in the bat, *Megaderma lyra*

Katrin Krumbholz[a] and Sabine Schmidt
Zoologisches Institut der Ludwig-Maximilians-Universität München, Luisenstrasse 14, 80333 München, Germany

(Received 27 March 1998; accepted for publication 2 October 1998)

The gleaning bat *Megaderma lyra* emits broadband echolocation sounds consisting of multiple frequency components. The present study investigates into which perceptual qualities the spectral characteristics of echoes may be translated in the auditory system of *M. lyra*. Three bats were trained in a 2-AFC behavioral experiment to classify nine complex tones, which spectrally resembled *M. lyra*'s sonar calls, into two perceptual categories. Then the bats' spontaneous responses to unknown complex tones were recorded. The results show that the animals based their classifications of the complex tones on a sound quality which was mediated by their broadband frequency spectra. The bats used the training stimuli as *spectral templates* and classified the test stimuli according to their *broadband spectral similarity* with the learned patterns. Assuming that passive hearing and echo processing are governed by similar perceptual qualities and subject to similar limitations, the perceptual mode which was used by the bats to compare the multicomponent spectral patterns in the reported experiments could serve as a powerful tool for the spectral analysis of *M. lyra*'s multicomponent echoes. The analogy between the perception of complex tones and echo spectral analysis in *M. lyra* is theoretically elaborated in the ''formant-mode'' model. [S0001-4966(99)04501-4]

INTRODUCTION

Audition is the most important sense by which echolocating bats acquire information about their environment. They perceive their environment acoustically by emitting calls and analyzing the returning echoes. Moreover, audition plays an important role in the context of intraspecific communication. Finally, passive listening is essential for prey detection in gleaning bats like *Megaderma lyra*.

The echolocation calls with which bats scan their environment are species specific (Neuweiler, 1990). However, they are also situation dependent, i.e., different bat species use echolocation calls of similar time-frequency structure in similar behavioral contexts (Schnitzler and Henson, 1980). When bats are taxing the distance of objects or analyzing their structure, they emit broadband signals which most commonly have a downward frequency-modulated structure. From a theoretical viewpoint, downward frequency-modulated signals with a broad bandwidth allow an optimal performance of an echolocation system that processes the noisy echoes with an adaptive filter that is tuned to the corresponding call (Glaser, 1974; Hänsler, 1996). Further, the dimensions of objects encountered by an echolocating bat are often comparable to the wavelengths of the echolocation signals. Thus, echoes are hardly ever reflected geometrically. Instead, bats perceive the surrounding objects as if they were two- or three-dimensional irregular gratings which reflect a multitude of echoes that form a complex interference pattern. In order to identify the reflecting target, the bat has to analyze the frequency transfer function of the reflection. This can only be accomplished with a broadband echolocation sound (Beuter, 1980).

M. lyra exclusively relies on short and broadband echolocation sounds (Möhres and Neuweiler, 1966; Schmidt, 1992). The average echolocation call of *M. lyra* covers a frequency range from about 20 to 120 kHz. It consists of up to six harmonically related frequency components, each of which is linearly downward frequency-modulated. The frequency of the first harmonic may sweep from about 23 to 18 kHz. The individual frequency components appear as distinct peaks in the composite frequency spectrum of *M. lyra*'s echolocation calls. (Schmidt, 1992; Hanke *et al.*, 1997). Broadband signals of either noiselike or harmonic frequency structure are also important elements of the communication repertoire of *M. lyra* (Leippert, 1994). Finally, the rustling noises that *M. lyra* uses to detect a prey moving on the substrate are broadband and extend into the ultrasonic range (Neuweiler, 1989).

A behavioral study (Schmidt, 1988, 1992) indicates that, in the echolocation context, *M. lyra* evaluates the characteristic changes in the spectral content of the perceived echoes in order to identify certain geometric features of the reflecting target. Schmidt (1988, 1992) presented phantom echoes to the bats which consisted of two delayed replicas of their echolocation calls. The delays of the two echoes differed by a few microseconds. The animals classified the two-wavefront phantom echoes on the basis of their spectral interference profile. It is the aim of the present study to investigate into which perceptual qualities the spectral characteristics of the echoes are translated by the auditory

system of the bats. In the perception of human listeners, the partials in harmonic complex tones within a certain range of fundamental frequencies tend to fuse to elicit a single collective pitch sensation approximately corresponding to the fundamental frequency of the tone complex. This pitch sensation, often referred to as the virtual or residue pitch, is not attributable to a single partial in the tone complex. Actually it is still perceived even if the fundamental component is not physically present in the spectrum (see, e.g., de Boer, 1985). On the other hand, the spectral pitch of a single resolved partial can be heard out in a complex tone. This analytic mode of pitch perception often requires a considerable amount of training in human subjects (Lichte, 1941). Other nonpitch sensory qualities of complex tones depend on the broadband level profile of the component frequencies. The quality of vowels depends on the number and frequency positions of the widely spaced maxima in the harmonic level profile, the formant peaks (Peterson and Barney, 1952; Chistovich and Lublinskaya, 1979). In studies of profile analysis, subjects are distinguishing a complex tone with a flat level profile from a similar complex tone in which the level of one frequency component is incremented (Green, 1988). Thereby, subjects are comparing the level of the incremented component with the levels of the unaltered partials. Preisler and Schmidt (1995, 1998) showed that *M. lyra* can classify quasi-static harmonic complex tones both according to their collective pitch and on the basis of their actual frequency spectrum. They studied the behavioral responses of *M. lyra* to harmonic complex tones that comprised a frequency range similar to the bat's own echolocation calls. The bats were trained to classify complete complex tones as higher or lower pitched than a fixed reference frequency. The spectra of the training signals were confined to the frequency regions either above or below the reference frequency. After training, the bats' spontaneous responses to incomplete harmonic complexes were tested. One or more of the lowest harmonics were missing in their spectra. The test stimuli provided the animals with conflicting information: their fundamental frequencies were lower than the reference frequency whereas their frequency spectra contained only harmonics above the reference. Individual animals classified the ambiguous test stimuli consistently either as lower or higher pitched than the reference—showing that they referred either to the collective pitch of the harmonic tones or to the frequencies of the physically present components.

Schmidt (1995) proposed that *M. lyra* might separate the variable and the invariable information in the perceived echoes into two independent perceptual dimensions. In human speech perception, the different aspects of spectral information are separated into percepts of timbre and pitch (Peterson and Barney, 1952). The harmonic frequency structure would provide the bats with an invariable information and could, analogous to the situation in human speech perception, be translated into a percept of collective pitch. The perception of collective pitch is essentially independent of the relative levels of single partials (Patterson, 1973; Preisler, 1993). The pitch information may be used by the bat to recognize its own calls and to associate a perceived echo correctly with the corresponding emission in a call sequence. On the other hand, the actual level profile of the frequency components in the echo, comparable to the formant structure of speech vowels, depends on the geometry of the reflecting target as well as its spatial position and would thus constitute the variable part of echo information. The bats may use the latter for target identification.

In the present study we examined whether bats that spontaneously classify harmonic complex tones according to their physical frequency spectra could be trained to alter their decision criterion and base their classifications on the collective pitch of the complex tones. Further, we investigated the principles that govern the spectral mode of perception in *M. lyra*. Did the ''spectral listeners'' in the study of Preisler and Schmidt (1995) resolve and compare the spectral pitches of single partials in the complex tones? Or did the bats evaluate the frequencies of the partials in the complex tones on a broad bandscale similar to human subjects that evaluate the frequency positions of the formant peaks in vowel spectra? It is conceivable that the bats analyze not only the relative levels but also the average frequencies of the modulated harmonic components in the spectra of perceived echoes. We present a theoretical scheme for this assumption which is based on the pitch models for modulated sounds (Feth, 1974; Feth and O'Malley, 1977; Feth *et al.*, 1982).

I. MATERIALS AND METHODS

A. Experimental setup

Signals were generated digitally with a DSP board (AP2, TDT) and digital-to-analog converted with a sampling rate of 250 kHz (DA3-2, TDT). They were fed into a low-pass filter (Krohn-Hite 3323) with a cutoff frequency of 100 kHz, attenuated (Elementa), amplified (Harman/Kardon HK6100), and finally presented via a magnetostatic loudspeaker (Technics EAS 10 TH800C). The frequency transfer function of the loudspeaker was linearly decreasing by about 10 dB between 3 and 100 kHz within a $\pm$3-dB range. The experiments were carried out in a sound-attenuated room ($2.5\times3\times2.2$ m^3). The bat's starting position was in the hind upper part of the room. The loudspeaker was mounted at a distance of about 2 m away and 1.5 m below the starting place and was directed to the position of the bat's head. Two feeding dishes were mounted symmetrically on either side of the loudspeaker. The experimenter was seated behind the loudspeaker.

B. Procedure

The experiments were carried out using a two-alternative, forced-choice behavioral (2-AFC) paradigm. In each trial, the experimenter triggered the signal presentation via a computer keyboard. The bat had to respond to the signals by flying to either the right or the left feeding dish. Signal presentation was stopped after the bat had made its choice and the response was stored in the computer memory. During the training periods, the bats had to acquire the correct right–left classifications for a fixed set of training stimuli. Responses to training stimuli were rewarded with a mealworm only if the bat chose the correct side. When the bats correctly classified the training stimuli in more than

90% of the cases, test trials were interspersed among the training trials with a probability of 25%. In the test trials, any choice of a feeding dish was rewarded in order not to influence the spontaneous classifications of the bats. Both training and test stimuli were chosen in a random order. About 30 responses of each bat were collected for each test stimulus to establish the percentage value of choices to the right side for that stimulus. According to a one-dimensional χ^2-test applied to a sample of $N=30$ responses, a fraction of 75% choices to one side differs from the chance value of 50% at a highly significant level of $p<0.01$ (Zöfel, 1988). A four-field χ^2-test was applied to examine whether differences between the responses to two test stimuli were significant (Zöfel, 1988).

C. General properties of signals

Stimuli were pure or complex tones with an overall duration of 400 ms. They had linear on and off ramps with a duration of 2 ms. After a trial had been started, stimuli were presented with an interstimulus interval of 1.2 s until the bat responded. During the initial training, each stimulus was preceded by a reference tone of 23 kHz. The silent gap between reference and experimental stimulus was 400 ms and the interpair interval was 1.2 s. After the bats had memorized the frequency of this reference, the reference tone was omitted in the stimulus presentations, as *M. lyra* is known to have an excellent absolute pitch (Schmidt *et al.*, 1995). All data of the experiments described below were collected without presentation of the 23-kHz reference. The stimuli were presented at an overall level of 47 ± 3 dB.

D. Experimental animals

The experiments were performed with three individuals of the bat species *M. lyra* (one male and two females). All three bats had participated in earlier psychoacoustic experiments. During the experimental sessions the bats were fed on mealworms. In addition, a small house mouse was supplied every two weeks. The bats' weight was monitored daily. The bats were kept in a dimly illuminated flight room at 28 °C where they had free access to water.

The experiments in this study are noninvasive and therefore do not require an animal experimentation approval. Permission to keep and breed *M. lyra* in fulfillment of § 11, Abs. 1, S. 1, No. 1 Tiersch *G* has been given to the Zoologisches Institut der Universität München by the Städtisches Veterinäramt der Landeshauptstadt München, dated 6 November 1992.

II. EXPERIMENT 1: SPONTANEOUS CLASSIFICATION OF HARMONIC SPECTRA

By using the experimental paradigm employed by Preisler and Schmidt (1995, 1998), we first tested whether the bats that were to take part in the subsequent experiments would base their spontaneous pitch judgments of harmonic tones on the collective pitch of the tone complexes or on the content of their physical frequency spectra. Three bats were trained to classify pure tones as higher or lower pitched than

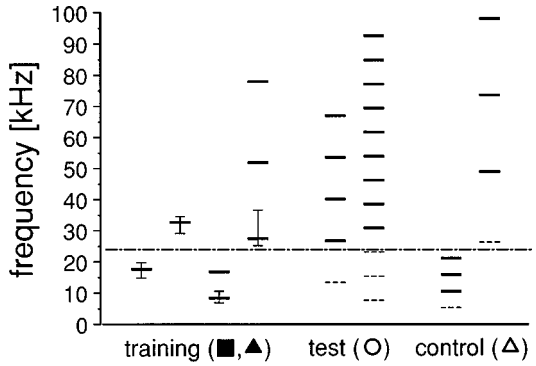

FIG. 1. Spectral composition of training, test, and control stimuli that were used in experiment 1. The long, dash–dotted line indicates the pure tone reference of 23 kHz; the solid lines show the presented harmonics, the dashed lines show the omitted harmonics of the experimental stimuli, respectively. The vertical bars denote the range of pure tone and fundamental frequencies that were used in the training stimuli. Only two examples of a total of six test and four control stimuli are shown. The symbols for the different stimulus types correspond to those used in Fig. 2.

a fixed pure tone reference of 23 kHz (see Fig. 1, training). The six low pitched training tones had frequencies between 14.8 and 19.8 kHz and were rewarded at the left feeding dish. The frequencies of the four high pitched training tones ranged between 29.2 and 34.7 kHz. They were rewarded at the right feeding dish. In a second step, complete harmonic complex tones consisting of two or three harmonics were presented as training stimuli. Six of the harmonic tones had fundamentals between 6.9 and 10.6 kHz and their frequency spectra were confined to the region below 23 kHz. The other four harmonic tones had fundamental frequencies between 25.3 and 36.8 kHz and thus their spectra contained only frequencies higher than 23 kHz (Fig. 1, training). The bats transferred the pitch classification from the pure tones to the complex tones without further training. Test stimuli were six incomplete harmonic tones with fundamental frequencies between 7.0 and 16.9 kHz. All harmonic components with frequencies below the reference of 23 kHz were missing in the test stimuli, i.e., their frequency spectra were confined to the region above 23 kHz, whereas their collective pitches were below the 23 kHz reference (Fig. 1, test). Control trials were interspersed among the test trails. The four control stimuli had fundamental frequencies of 5.3, 7.3, 26.3, and 30.9 kHz (Fig. 1, control). They were missing-fundamental-stimuli consisting of two or three harmonics. The frequency spectra of the control stimuli with fundamental frequencies below or above the reference of 23 kHz were confined to the frequency region below or above the reference, respectively. The individual results of the three animals are shown in Fig. 2. Responses to the test and control stimuli are denoted by open symbols. All three bats classified the test stimuli as ''higher than the reference'' although their fundamental frequencies and, accordingly, their collective pitches were below 23 kHz. The control stimuli were classified as higher or lower than the reference according to their spectral content. The animals thus judged the test stimuli according to their actual frequency spectra.

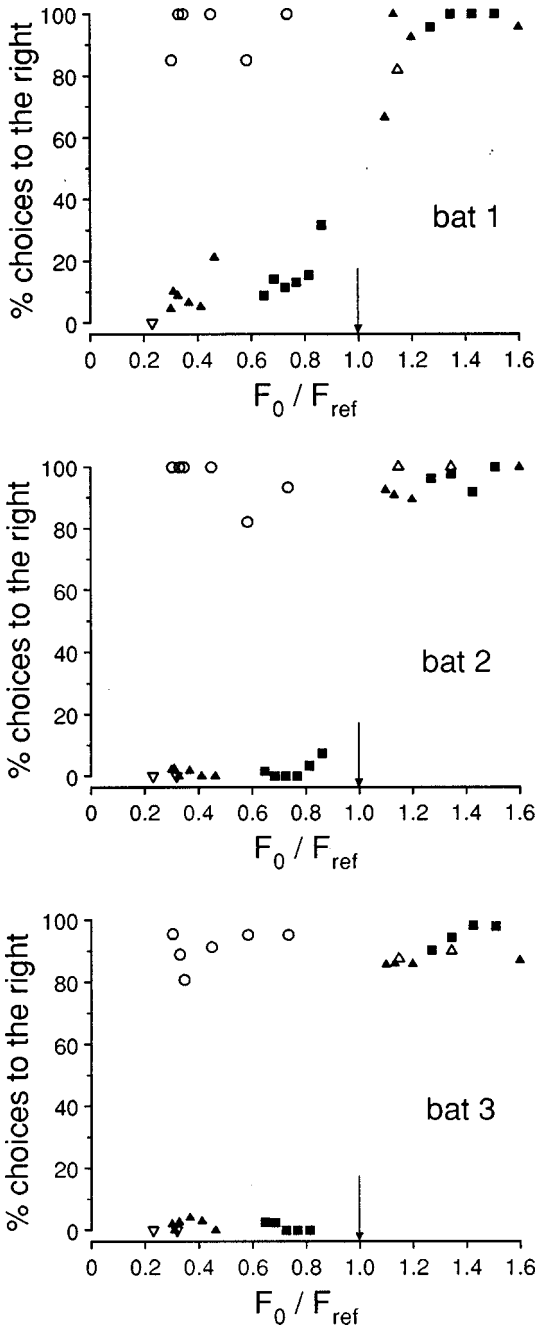

FIG. 2. Individual responses of three bats in experiment 1 expressed as the percentage of choices to the right side. The abscissa shows the pure tone and the fundamental frequencies of the respective training, test, and control stimuli normalized by the reference frequency of 23 kHz (arrow). The different symbols denote the responses to the pure tone (solid squares) and the complex tone (solid triangles) training stimuli as well as to the test (open circles) and control (open triangles) stimuli. Note that all test stimuli are classified to the right side by all three bats, indicating that there is no spontaneous classification of collective pitch in these individuals.

III. EXPERIMENT 2: CAN BATS BE *TRAINED* TO CLASSIFY HARMONIC TONES ACCORDING TO COLLECTIVE PITCH?

The aim of this experiment was to investigate whether the bats could be *trained* to classify harmonic complex tones according to their fundamental frequencies.

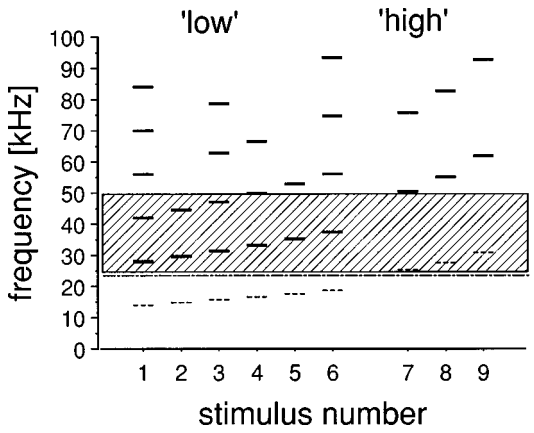

FIG. 3. Frequency content (solid lines) of ''low'' and ''high'' training stimuli of experiment 1 with fundamental frequencies below and above 23 kHz (long, dash–dotted line) respectively. The abscissa shows the stimulus numbers as used in Table I. The fundamentals were omitted in the frequency spectra (dashed lines). Please note that the ''high'' training stimuli contain no spectral energy in the hatched frequency region below 50 kHz.

A. Training stimuli

Training stimuli were a set of nine harmonic complex tones consisting of two to five adjacent harmonics (see Fig. 3). Six of the training stimuli had fundamental frequencies between 14 and 18.7 kHz which were, apart from one exception, identical with the frequencies of the low pitched pure tone training stimuli used in experiment 1. The animals were rewarded for selecting the left feeding dish in response to these stimuli. They will in the following be referred to as the ''low'' training stimuli. The fundamental frequencies of the three ''high'' training stimuli were ranging between 25.3 and 30.9 kHz. They were identical with the frequencies of three of the high pitched pure tone training stimuli of experiment 1. In the presence of these stimuli, the bats were rewarded at the right feeding dish. The fundamental was omitted in the frequency spectra of all training stimuli so that they contained only harmonics above 23 kHz. The spectral content of all training stimuli is listed in Table I. The training stimuli are labeled with numbers 1 to 9.

B. Rationale of test stimuli and decision models

After training, the bats classified the ''low'' and the ''high'' training stimuli correctly on the left and the right

TABLE I. Spectral content of ''low'' and ''high'' training stimuli. The fundamental frequency is indicated by F_0. The physically present harmonics are given in column 3, the rewarded side is given in column 4.

Stimulus No.	F_0 (kHz)	Harmonics	Rewarded side
1	14.0	2–6	left
2	14.8	2–3	left
3	15.7	2–5	left
4	16.6	2–4	left
5	17.6	2–3	left
6	18.7	2–5	left
7	25.3	2–3	right
8	27.5	2–3	right
9	30.9	2–3	right

side, respectively. Still, this does not mean that they actually classified the nine training stimuli according to their collective pitch. Rather, the bats could have acquired three different decision criteria during the training period, each of which would have enabled them to classify the set of training stimuli correctly. Apart from the collective pitch, the frequency of the lowest partial of the training stimuli would have provided a usable cue in the classification task. The second harmonic is the lowest frequency component in all training stimuli (see Fig. 3). Therefore, the frequency of the lowest partial in the ''high'' training stimuli is higher than 50 kHz whereas the ''low'' stimuli contain at least one partial whose frequency is substantially lower than 50 kHz (see the hatched frequency region below 50 kHz in Fig. 3). In humans, the spectral pitches of the lowest and the highest partials tend to be heard out most easily from a tone complex (Moore *et al.*, 1984; Moore and Ohgushi, 1993). Finally, the bats could have memorized the sound of each training stimulus together with the required right–left classification. In this case, the bats possibly attended to a sound quality that was mediated by the broadband spectral composition of the training stimuli. The three optional decision criteria will in the following be referred to as collective pitch A, spectral pitch of lowest partial B, and broadband spectral composition C, respectively.

After the training period, unknown harmonic and inharmonic complex tones, whose spectral composition differed from that of the training stimuli, were presented to the bats (they will be described in the next paragraph). To establish a quantitative relation between the bats' actual decision behavior and the three possible decision criteria A, B, and C, the decision criteria were expressed by scalar numerical measures. The collective pitch criterion A is expressed by the fundamental frequency F_0 of the tone complexes normalized by the reference frequency F_{ref} of 23 kHz. The criterion of lowest partial B is expressed by the frequency of the lowest harmonic in the presented tone complexes (F_{low}) divided by 50 kHz. If the bats attended to a sound quality mediated by the broadband spectral composition of the training stimuli (criterion C), they must have judged the unknown test stimuli according to their perceptual similarity to the learned training stimuli. In order to obtain a measure for decision criterion C, we assumed that the perceptual similarity of the complex tones is determined by the similarity of their broadband frequency spectra. Therefore, we first determined the spectral similarity of each test stimulus with each of the ''low'' and ''high'' training stimuli. The spectral similarity of two tone complexes was expressed in terms of a spectral correlation coefficient. As the frequency spectrum of a quasistatic complex tone is composed of the arbitrarily narrow peaks of the partial tones, the correlation between two complex tones which have no partials in common would equal zero. The complex tones were therefore converted into a spectrally smeared 'internal representation.' Thereby each delta peaked partial tone at frequency f was convoluted with a normal density function to yield the smeared representation $E_f(u)$. Here E_f is a function of frequency u given by

$$E_f(u)=\frac{1}{\sigma(f)\sqrt{2\pi}}\exp\left\{\frac{-(u-f)^2}{2\sigma(f)^2}\right\}. \tag{1}$$

The standard deviation $\sigma(f)$ of the density function was set equal to *M. lyra*'s critical bandwidth at the frequency f of the respective partial tone. It is given by $\sigma(f)=4.9(f/50)^{1.71}$ (Schmidt *et al.*, 1995). The functions $E_f(u)$ may be regarded as approximations of the distribution of excitation for one partial with frequency f (Moore and Glasberg, 1983) or as the probability density of the random variable describing the measurement of f by the auditory system (Goldstein, 1973). The correlation coefficients between the internal representations of two tone complexes with N and M components were calculated according to

$$\mathrm{crr}(C_1^N,C_2^M)=\frac{\int E_{C_1^N}(u)E_{C_2^M}(u)\,du}{\sqrt{\int E_{C_1^N}(u)^2\,du\int E_{C_2^M}(u)^2\,du}}, \tag{2}$$

where C_1^N and C_2^M are the N- and M-dimensional vectors containing the partial frequencies of the two tone complexes. $E_{C_1^N}$ and $E_{C_2^M}$ are the respective internal representations. The integral in the numerator of Eq. (2) was calculated with the boundary condition that each partial in either tone complex was matched with only one partial in the other tone complex. In the next step, the maxima of the spectral similarities of a test stimulus S with the sets of ''low'' and ''high'' training stimuli were calculated. The maximum spectral similarity of S to the ''low'' stimuli was subtracted from the maximum similarity to the set of ''high'' stimuli

$$\begin{aligned}C(S)&=\max\{\mathrm{crr}(S,H);H\in H\}-\max\{\mathrm{crr}(S,L);L\in L\}\\&=\max_{\text{'high'}}-\max_{\text{'low'}},\end{aligned} \tag{3}$$

and this value was taken as a measure for the broadband spectral criterion C. In Eq. (3), L and H denote the sets of ''low'' and ''high'' training stimuli, respectively.

Schmidt (1988, 1992) used a comparable model of spectral correlation to explain the discrimination performance of *M. lyra* for phantom target echoes of the bats' own echolocation sounds. The correlation between two complex spectra in Eq. (2) defines an angular measure of spectral similarity. Other possible measures could be defined by the Euclidean distance or equivalent metrics between the smeared internal representations of two wideband spectra (cf. Schmidt, 1992).

C. Composition of test stimuli

A set of test stimuli was designed to investigate which of the three decision criteria A, B, or C was used by the bats to classify the training stimuli. The test stimuli can be grouped into three classes. Two examples of each class are shown in Fig. 4. The spectral content of all test stimuli are listed in Table II.

Class 1 contained seven test stimuli that differed from the training stimuli only in fundamental frequency and the total number of higher harmonics (Fig. 4, class 1). The class 1 stimuli are labeled with numbers 10 to 16 in Table II. They consisted of two to five adjacent harmonics and like in the training stimuli the fundamental component was omitted in their spectra. The fundamental frequencies of the class 1

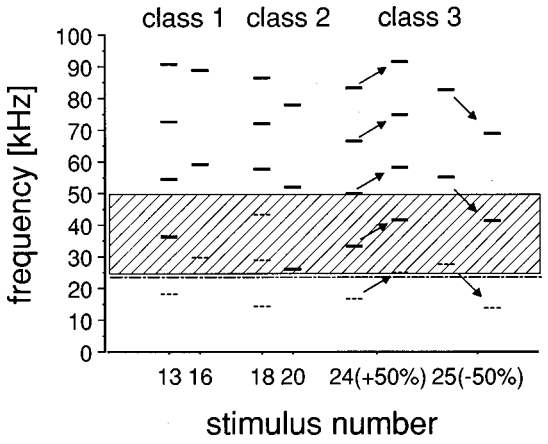

FIG. 4. Spectral composition (solid lines) of the test stimuli used in experiment 2. Two examples of each of the three classes of test stimuli are shown together with their respective stimulus numbers. The inharmonic tone complexes (class 3) are shown with the respective unshifted harmonic complexes (for further explanations see Fig. 3).

stimuli were either higher or lower than 23 kHz and differed from those of the ''low'' and ''high'' training stimuli.

Class 2 of the test stimuli contained five harmonic complex tones (Fig. 4, class 2). Three of the class 2 stimuli (numbers 17 to 19) had fundamental frequencies below 23 kHz, similar to the ''low'' training stimuli. However, unlike in the ''low'' training stimuli, not only the fundamental component but up to three of the lower harmonics were missing in their frequency spectra. Stimuli 18 and 19 consisted only of harmonics above 50 kHz (see Fig. 4, class 2). In this respect, they resembled the ''high'' training stimuli. The two other class 2 stimuli (numbers 20 and 21) had fundamental frequencies of 26 and 31.8 kHz and consisted of the first three harmonics. In contrast to the ''high'' training stimuli, these two test stimuli therefore contained spectral energy well below 50 kHz (see Fig. 4, class 2).

The four tone complexes of class 3 test stimuli (numbers 22 to 25) were shifted out of the harmonic frequency relation by 50% of the fundamental frequency (Fig. 4, class 3; two examples are shown together with the respective unshifted, harmonic tone complexes). In human listeners, such highly inharmonic tones do not elicit any unambiguous percept of the collective pitch (de Boer, 1985). For the inharmonic tones of class 3, the collective pitch criterion A was set to one, as chance performance must be expected for these stimuli without a well-defined collective pitch. Spectrally, class 3 stimuli resembled the ''low'' training examples: they all contained spectral energy below 50 kHz and in all but one case the frequency spacing between the partials was smaller than 23 kHz.

TABLE II. Spectral content of test stimuli of experiment 2. The fourth column highlights the most important attributes of the stimuli (e.g., class, region of F_0 and F_{low} and inharmonic shift in percentage of the F_0 of the respective unshifted complex tone). For further explanations see Table I.

Stimulus No.	F_0 (kHz)	Harmonics	Attributes
10	13.0	2–5	class 1, $F_0<23$ kHz
11	15.3	2–6	class 1, $F_0<23$ kHz
12	16.3	2–3	class 1, $F_0<23$ kHz
13	18.2	2–5	class 1, $F_0<23$ kHz
14	26.8	2–3	class 1, $F_0>23$ kHz
15	28.4	2–3	class 1, $F_0>23$ kHz
16	29.6	2–3	class 1, $F_0>23$ kHz
17	12.1	3–7	class 2, $F_{low}<50$ kHz
18	14.4	4–6	class 2, $F_{low}>50$ kHz
19	17.1	3–4	class 2, $F_{low}>50$ kHz
20	26.0	1–3	class 2, $F_{low}<50$ kHz
21	31.8	1–3	class 2, $F_{low}<50$ kHz
22	12.8	2–6	class 3, +50% shift
23	18.7	2–5	class 3, −50% shift
24	16.6	2–5	class 3, +50% shift
25	27.5	2–3	class 3, −50% shift

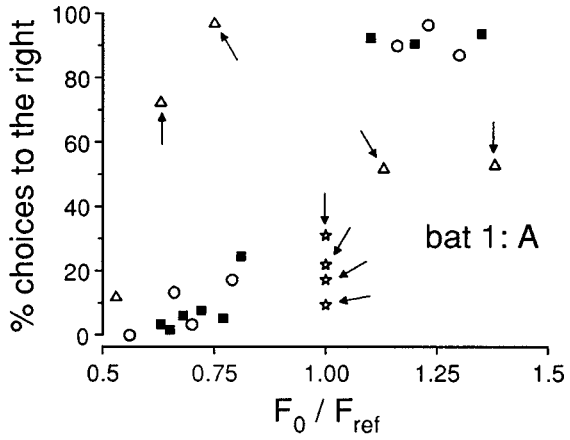
D. Results of experiment 2

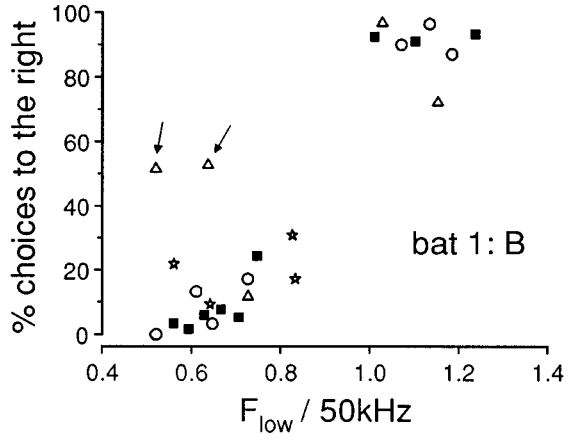
The bats responded to the seven test stimuli of class 1 with a highly significant preference for either one or the other side. Seemingly, the animals judged these test stimuli according to their fundamental frequency: harmonic complexes with a fundamental frequency lower or higher than 23 kHz were classified similar to the ''low'' or ''high'' training stimuli, respectively. However, the test stimuli of class 1 are also spectrally most similar to the corresponding ''low'' and ''high'' training stimuli. It will be shown below that the criteria of lowest partial B and broadband spectral composition C are also both compatible with the bats' behavior for class 1 stimuli.

Assuming that the bats used the collective pitch criterion A, their responses to class 2 test stimuli are not in accordance with the fundamental frequencies of these test stimuli. Stimuli 18 and 19 which had fundamentals below 23 kHz but spectrally more resembled the ''high'' training examples were classified as the ''high'' training stimuli with a clear preference for the right side. The two complete harmonic tones 20 and 21 whose fundamentals were higher than 23 kHz but which comprised partials well below 50 kHz were classified as the ''low'' training stimuli with a clear preference to the left side by two of the bats whereas one bat chose both sides about equally often in response to these two stimuli.

Finally, test stimuli of class 3, which are expected to elicit no unambiguous percept of collective pitch and spectrally resembled the ''low'' training stimuli in that they contained partials with frequencies lower than 50 kHz, were readily categorized as similar to the ''low'' training stimuli by all three bats.

The individual results of the three animals are plotted in Figs. 5, 6, and 7 as a function of the numerical measures of the three decision criteria A, B, and C. As expected, all three decision criteria divide the training and class 1 stimuli (filled squares and open circles) into two well-separated categories, yielding a monotonic relation between the respective decision variables and the animals' responses to these stimuli. However, the relation between the decision behavior and the fundamental frequency criterion A becomes nonmonotonic for the critical test stimuli of classes 2 and 3 (see arrows in Figs. 5, 6, and 7, A). Therefore, it can clearly be excluded that the bats used the collective pitch as their decision criterion in this experiment. In the case of bat 1 (Fig. 5), the lowest partial criterion B can also be excluded as the deci-





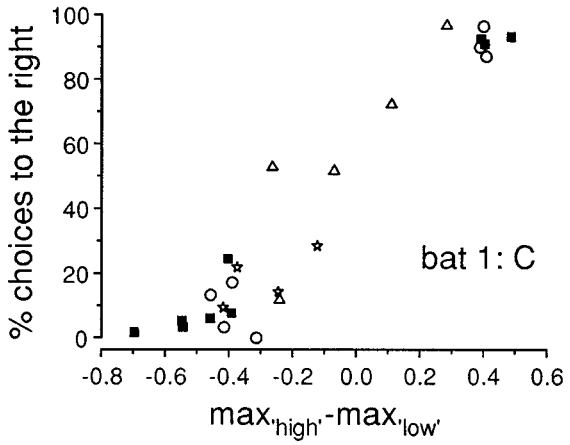


FIG. 5. Individual responses of bat 1 expressed as the percentage of choices to the right side plotted as a function of the decision criteria collective pitch *A*, pitch of resolved partial *B* and broadband spectral composition *C* (see text for explanation). Responses to training stimuli (filled squares), class 1 (open circles), class 2 (open triangles) and class 3 (open stars) test stimuli are characterized by different symbols. Systematic deviations from a monotonic decision function are indicated by arrows.

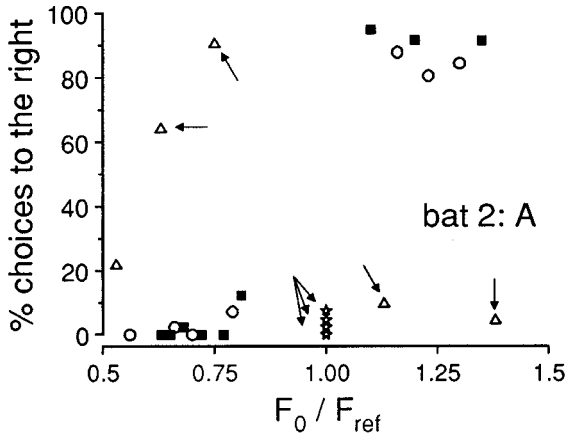

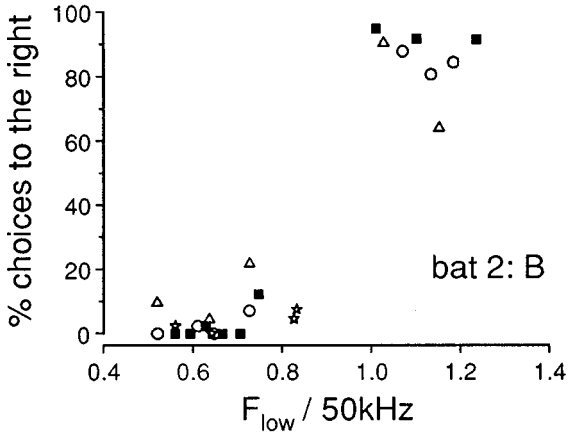

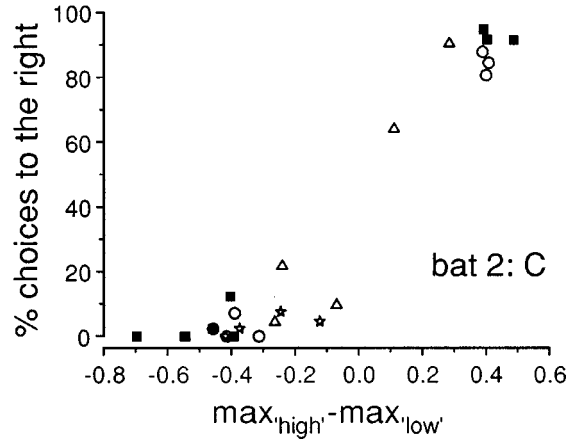

FIG. 6. Individual responses of bat 2 (for further explanations see Fig. 5).

sion variable. Bat 1 showed chance performance in response to the two complete harmonic tones 20 and 21. Had bat 1 based its decisions on the spectral pitch of the lowest partial, it should have classified these stimuli as the ''low'' training stimuli with a clear preference to the left side (see arrows in Fig. 5, B). As the ''low'' training stimuli, both test stimuli 20 and 21 contain a partial well below 50 kHz. For bats 2 and 3, however, the numerical representations of both decision criteria B and C are monotonically related to the actual decision behavior (Figs. 6 and 7, B, C). Further testing was needed in the case of these two bats to distinguish between decision criteria B and C.

IV. EXPERIMENT 3: BROADBAND SPECTRAL ANALYSIS VERSUS RESOLUTION OF A SINGLE PARTIAL

A. Stimuli and conditions

Only bats 2 and 3 participated in this experiment. In experiment 2, these two bats had classified the complete harmonic tones 20 and 21 which consisted of the first three

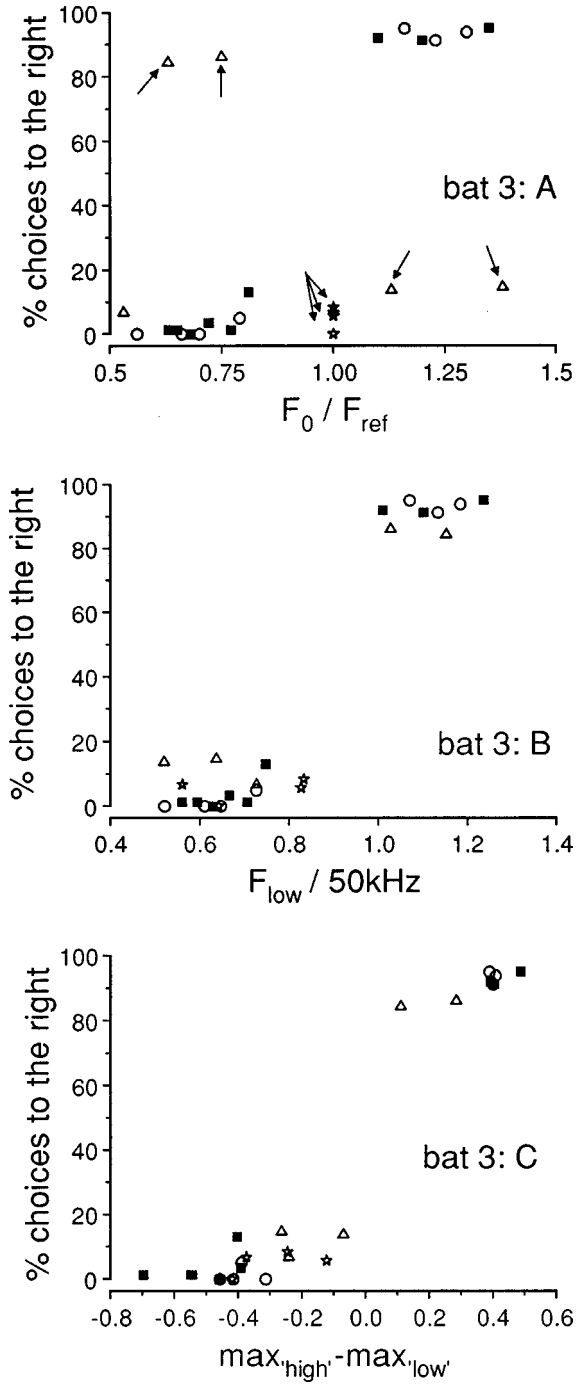

FIG. 7. Individual responses of bat 3 (for further explanations see Fig. 5).

harmonics of a fundamental frequency of 26 and 31.8 kHz, respectively, as the ''low'' training stimuli with a significant preference to the left side. The two stimuli 20 and 21 were now added to the set of 'high' training stimuli (numbers 7 to 9, see Table I). Contrary to the bats' spontaneous classifications, responses to the two complete harmonic tones were then only rewarded at the right feeding dish. Assuming that bats 2 and 3 based their decisions on the spectral pitch of the lowest frequency component in the complex tones (criterion B), this new training should have forced them to change their decision criterion from the lowest partial criterion B to the broadband spectral composition criterion C. The lowest frequency component of the two new ''high'' training stimuli

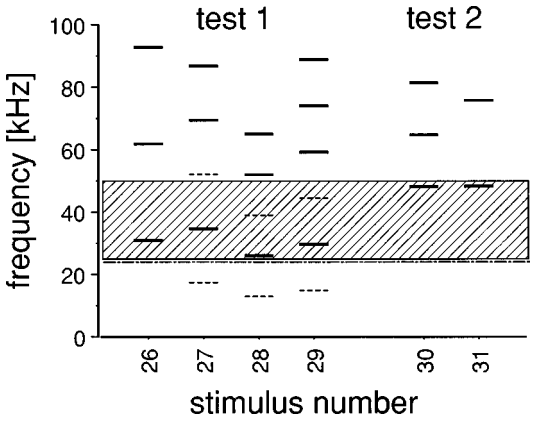

FIG. 8. Spectral content of the two sets of test stimuli used in experiment 3 together with their stimulus numbers. The hatched bar denotes the frequency region below 50 kHz.

was lower than 50 kHz. If the bats decided according to the spectral pitch of the lowest component they would have chosen the right side only in response to stimuli with a lowest frequency component higher than 50 kHz (like the old ''high'' training stimuli 7 to 9). Therefore the new training would have made criterion B useless and it would have forced the bats to attend to spectral similarities in the frequency region above 50 kHz.

If a bat managed to reverse its classifications of stimuli 20 and 21 in no more than one week, its spontaneous responses to a set of four new test stimuli were recorded. The spectra of the four test stimuli are shown in Fig. 8, test 1. Their spectral content is given in Table III (numbers 26 to 29). One test stimulus (number 26) was another complete harmonic tone with a fundamental frequency of 30.9 kHz. The other three (numbers 27 to 29) were harmonic tones with fundamental frequencies between 13 and 17.4 kHz which consisted of adjacent harmonics in the frequency region above 50 kHz and contained only even number harmonics in the region below 50 kHz. Test stimuli 27 to 29 thus spectrally resembled the ''low'' training stimuli in the frequency region above 50 kHz and they were similar to the newly learned ''high'' training stimuli 20 and 21 in the region below 50 kHz. If a bat kept choosing the left side in response to the complete harmonic tones 20 and 21 in more than 75% of the trials after the given time of one week, training was stopped and two other test stimuli, labeled with numbers 30 and 31, were presented (see Fig. 8, test 2 and Table III). Both of them were inharmonic complex tones with a lowest frequency component of 48 kHz. Stimulus 30

TABLE III. Spectral content of test stimuli of experiment 3. For further explanations see Table II.

Stimulus No.	F_0 (kHz)	Harmonics	Attributes
26	30.9	1–3	test 1
27	17.4	2, 4, and 5	test 1
28	13.0	2, 4, and 5	test 1
29	14.8	2, 4–6	test 1
30	16.6	2–3	test 2, +89% shift
31	27.5	2–3	test 2, −25% shift

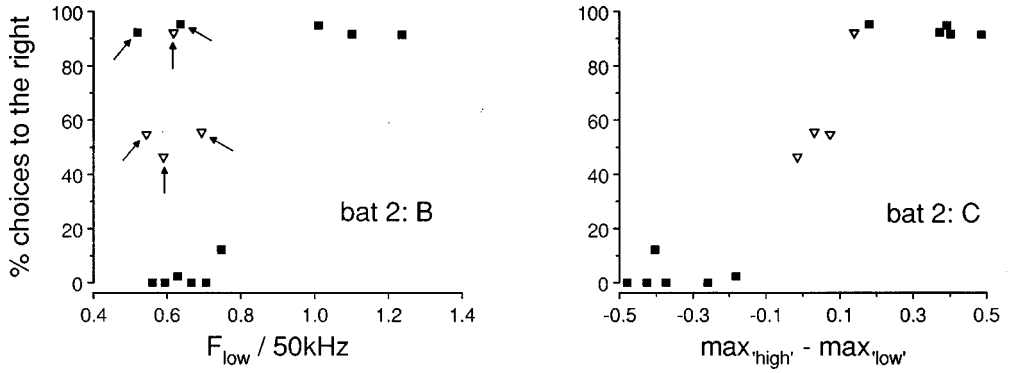

FIG. 9. Individual responses of bat 2 to the new training stimuli illustrated in Fig. 8, test 1, plotted as a function of the two spectral variables B and C. The responses to training stimuli are characterized by solid squares, responses to test stimuli are given as open triangles. Systematic deviations from a monotonic decision function are indicated by arrows.

consisted of three partials with a frequency spacing of 16.6 kHz whereas the two component frequencies of stimulus 31 were separated by 27.5 kHz.

B. Results of experiment 3

1. Bat 2

When responses to the complete harmonic tones 20 and 21 were rewarded on the right side only, bat 2 learned to fully reverse its classifications of these two stimuli in only about five days. Note that the training for experiment 2 had required a much longer time of about two months. This shows that, like bat 1, bat 2 also must have had a concept of the broadband spectral patterns of the ''low'' and ''high'' training stimuli. A complete revision of the decision criterion would certainly have required a longer training time. Bat 2 spontaneously transferred the new classification of the complete harmonic tones to a different fundamental frequency of 30.9 kHz (test stimulus 26). The animal responded to the three new test stimuli 27 to 29 about equally often on both sides (mean % choices to the right=52.5% for all three stimuli for a total of $N=139$ decisions). Obviously, the animal noticed the spectral congruence of these test stimuli with the ''low'' training stimuli in the frequency region above 50 kHz and was at the same time puzzled by their similarity with the newly learned ''high'' training stimuli 20 and 21 in the region below 50 kHz. Bat 2's results for the four new test stimuli are plotted in Fig. 9 as a function of the two spectral decision criteria B and C. The spectral correlations of criterion C were in this case calculated using the enlarged set of ''high'' training stimuli (numbers 7 to 9, 20, and 21). The relation between decision data and the resolved partials criterion B is nonmonotonic not only for the test stimuli (open triangles) but also for the new training stimuli (filled squares; see arrows in Fig. 9, B) whereas the broadband spectral criterion C yields a good match to the observed behavior (Fig. 9, C).

Bat 2 had classified the complete harmonic tones 20 and 21 differently from bat 1 in experiment 2. The present results indicate that this was not because bat 2 used a different decision criterion. Rather, it seems that during the training of experiment 2, bat 2 had learned to focus its spectral comparison on the frequency region below 50 kHz. The ''low'' and ''high'' training stimuli of experiment 2 differ most obviously in this frequency region (see the hatched bar in Fig. 3). The second training forced bat 2 to more strongly consider the high-frequency spectral properties of the experimental stimuli.

2. Bat 3

Bat 3 had also spontaneously classified the complete harmonic tones 20 and 21 as the ''low'' training stimuli in experiment 2. However, unlike bat 2, this animal did not learn to reverse its classifications of these two stimuli. After one week of training it kept choosing the left side in response to stimuli 20 and 21 in more than 75% of the cases even though it was not rewarded for these responses. We therefore stopped the new training and tested bat 3's spontaneous responses to the inharmonic complex tones 30 and 31 (see Fig. 8, test 2). The two parts of Fig. 10 show this bat's responses to the new test stimuli 30 and 31 (open triangles) as a function of the two spectral criteria B and C. Criterion B cannot separate these test stimuli, because their lowest partials have the same frequency. The observed difference between the responses to the test stimuli 30 and 31 is correctly mapped by criterion C. Bat 3 classified test stimulus 31 with a significantly greater preference to the right side (% choices to the right=69.7, $N=33$) than stimulus 30 (% choices to the right=43.3, $N=30$; $\chi^2=4.47$, $p=0.035$). Stimulus 31 spectrally more resembles the ''high'' training stimuli due to the wider spacing of its frequency components (see Fig. 8, test 2). This shows that the animal based its decisions on spectral similarity in the frequency region above 50 kHz if the region below 50 kHz did not provide any usable information. Bat 3 probably most strongly considered spectral similarities in the frequency region below 50 kHz and can thus be said to have made use of both criteria B and C, depending on the spectrum of a given test stimulus.

V. DISCUSSION

The three bats that participated in the present experiments were ''spectral listeners'' as they based their spontaneous pitch judgments of harmonic complex tones on the spectral pitches of the component partial tones. The bats' responses to the test stimuli of experiment 2 proved that the animals did not adopt the collective pitch of harmonic tones as their decision criterion during the training of experiment

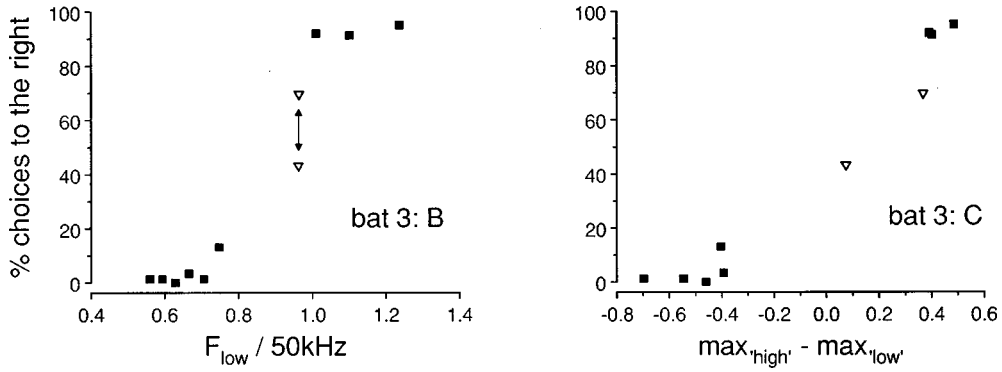

FIG. 10. Individual responses of bat 3 to the two new test stimuli shown in Fig. 8, test 2, as a function of the spectral decision criteria B and C (for further explanations see Fig. 9).

2. In earlier studies (Preisler and Schmidt, 1995, 1998; Schmidt *et al.*, 1995), on the other hand, some bats managed to spontaneously classify harmonic tones according to collective pitch. These individual differences in behavior may be attributable to differences in the distinctiveness of collective pitch perception. Differences in the individual predisposition to the perception of collective pitch have been reported for human subjects (Preisler, 1993). Alternatively, the use of collective pitch by *M. lyra* may be context dependent and may have been impeded by the specific experimental situation. After all, the experimental situation differed from the echolocation context as the animals were passively listening to the stimuli. Therefore, there was no need to attribute the stimuli to any preceding sonar call.

The ''high'' training stimuli do not contain spectral energy in the frequency region below 50 kHz (see hatched frequency region in Fig. 3). The ''low'' training stimuli all contain at least one partial whose frequency is substantially lower than 50 kHz. Experiment 3 revealed that some animals were using this general distinguishing property to a limited extent. However, the animals did not base their decisions exclusively on the pitch of a single partial, although the lowest partial in the training stimuli would have provided a usable criterion. Rather, it seems that all animals had acquired a concept of the broadband spectral compositions of the ''low'' and ''high'' training stimuli. They used the training stimuli as spectral templates for the classification task and classified the unknown test stimuli according to their broadband spectral similarity to individual training stimuli. For their decisions, two animals put a strong weight on spectral similarities in the frequency region below 50 kHz. However, they too had the information in the high-frequency region at their disposal and could switch to it if the low-frequency region did not provide any unambiguous cues. This shows that *M. lyra* can differentially judge the spectral similarity of complex tones in different frequency regions. The bats are able to recognize that certain frequency regions contain more relevant information than others.

Thus, none of the animals had performed a genuine pitch comparison in the present experiments. The bats rather classified the experimental stimuli on the basis of a sensory quality that is mediated by their broadband frequency spectra. The bats' decisions show that the spectral correlation between two complex tones can be taken as a scalar numerical measure for the perceptual similarity between them (see Figs. 5–7, C). As all test and training stimuli have flat amplitude spectra, the correlations between their spectra are determined by the number and frequencies of their partial tones. Correspondingly, the sensory quality that we consider also depends on the number and frequencies of the partials in the complex tones in analogy to the timbre of vowels that is determined by the number and the frequency positions of their widely spaced formant peaks (Chistovich and Lublinskaya, 1979). The sound quality of vowels seems to depend on the relative levels L_1 and L_2 of two formant peaks only if the frequency separation between the two formants is not larger than some critical value. In that case, the two formants can be replaced by a single formant with a frequency that depends on L_2-L_1 in a ''center of gravity'' like manner. The relative levels of widely spaced formants have a minor effect on the vowel quality as long as they are detected. In profile analysis, on the other hand, discriminations are made on the basis of a sound quality that is exclusively determined by the relative levels of the partial tones at least if broadband spectra with widely spaced partials are concerned (Richards *et al.*, 1989). In this respect, the present experimental paradigm has to be distinguished from the profile analysis approach as only complex tones with flat amplitude spectra were used. It can rather be compared to studies of vowel perception if the partial tones in the ultrasonic multicomponent spectra used in the present study are regarded as analogues to the widely spaced formant peaks in a vowel spectrum. Remez *et al.* (1981) investigated a similar analogy between speech sounds and stimuli consisting of discrete partials with frequencies corresponding to the formant peaks.

A. Potential relevance for echolocation: The ''formant-mode'' model of echo perception

The results of the present experiments show that the broadband spectral analysis is a dominant and flexible sensory tool in the bat *M. lyra*. It provides the bat with a measure by which it can estimate the similarity between complex spectral patterns on a broad bandscale and which enables the bat to distinguish between information bearing and irrelevant frequency regions. The bats' remarkable performance in the classification tasks of the present experiments suggest that *M. lyra*'s auditory system is specialized on the analysis of broadband sounds consisting of multiple distinct frequency

components. Under the assumption that passive listening and echolocation in *M. lyra* at least partly involve similar modes of auditory processing, it can be conjectured that the broadband spectral analysis observed for complex tones also plays an important role for the echolocation of *M. lyra*, as this bat's sonar calls exhibit a harmonic multicomponent frequency structure similar to that of harmonic complex tones. In the following we will develop a theoretical framework which relates the perception of quasi-static complex tones investigated in the present experiments to the analysis of the spectral characteristics of echoes in *M. lyra*.

The downward frequency-modulated echolocation calls of *M. lyra* have very short durations. In the laboratory, echolocation calls are shorter than 2 ms (Hanke *et al.*, 1997). If the bat tracks a prey, calls become as brief as 0.4 ms. The modulation rates are correspondingly high. For a typical 1-ms call the modulation rate of the first harmonic component ranges between 4000 and 5000 Hz/ms. For human subjects, there is experimental evidence that the limit of temporal resolution that is commonly measured for spectrally static sounds is also approximately valid for frequency-modulated signals (Madden, 1994). This means that the instantaneous frequency of a dynamic signal is not perceived with an arbitrarily sharp resolution on the temporal scale. The auditory system averages frequency over a certain span of time. Experimental results indicate that for humans this averaging time is in the range of a few milliseconds which is comparable to what is observed in measurements of gap or increment detection (Plomp, 1964; Shailer and Moore, 1983; Moore *et al.*, 1996). Feth and co-workers have proposed the IWAIF (intensity-weighted average of instantaneous frequency) model for the short-time frequency averaging process (see, e.g., Feth *et al.*, 1982, 1995). The model assumes that the auditory system computes a weighted average of the instantaneous frequency, the IWAIF value, with a temporal weighting function equal to the instantaneous intensity of the signal. In the frequency domain, the IWAIF value of a signal corresponds to the ''center of gravity'' of the signal's power spectrum (Anantharaman and Krishnamurthy, 1993).

Gap detection experiments with the echolocating bat *Tadarida brasiliensis* indicate that this species' temporal acuity in passive listening does not vastly excel the human performance (Nitsche, 1993). Nitsche (1992) showed that *T. brasiliensis* is unable to distinguish between an upward and a downward frequency-modulated signal if the duration of the sweeps is shorter than about 4 ms. The synthetic sweeps had a similar frequency content as the echolocation calls of *T. brasiliensis*. The observed temporal threshold exceeds the average duration of *Tadarida*'s approach phase echolocation calls. Thus, in view of the brevity of *M. lyra*'s echolocation calls, it is hardly conceivable that the bat perceptually resolves the time structure of its echolocation calls. More likely, *M. lyra* evaluates the average qualities of the frequency components in the calls, like their overall levels and their average frequencies or IWAIF values.

Assume that the nth frequency component in an echolocation call of *M. lyra* sweeps down from the starting frequency $f_s(n)$ to the end frequency $f_e(n)$. The overall level

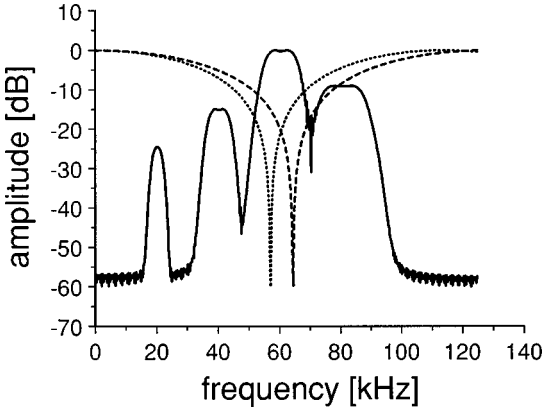

FIG. 11. Two just discriminable reflector transfer functions corresponding to ideal two surface targets with surface distances of 1.3 (dashed line) and 1.5 mm (dotted line). The solid line shows an idealized magnitude spectrum of a typical approach phase echolocation call of *M. lyra*. The two reflectors would yield IWAIF values of the third frequency component differing by 6.9 kHz.

of the nth frequency component is determined by the integral

$$A_n = \int_{f_e(n)}^{f_s(n)} |S(f)|^2 \, df. \tag{4}$$

Here, $|S(f)|$ denotes the magnitude spectrum of the echolocation call. Similarly, the IWAIF value of the nth component is defined by its ''center of gravity''

$$f_n = \frac{\int_{f_e(n)}^{f_s(n)} f|S(f)|^2 \, df}{\int_{f_e(n)}^{f_s(n)} |S(f)|^2 \, df} \tag{5}$$

(compare Anantharaman and Krishnamurthy, 1993). If an echolocation call is reflected by a structured target, the frequency transfer function $|R(f)|$ of the reflection will be imprinted onto the magnitude spectrum of the call. This will change the relative overall level of the nth frequency component according to

$$B_n = \int_{f_e(n)}^{f_s(n)} |R(f)|^2 |S(f)|^2 \, df. \tag{6}$$

As was pointed out in the Introduction, *M. lyra* might evaluate these changes in the relative overall levels of the frequency components to identify the transfer function of the reflection. The bat would thus derive the target structure from a profile analysis of the emission and its echo. However, the average frequencies of the components are also changed by the reflection. The IWAIF value of the nth frequency component in the echo can be written as

$$v_n = \frac{\int_{f_e(n)}^{f_s(n)} f|R(f)|^2 |S(f)|^2 \, df}{\int_{f_e(n)}^{f_s(n)} |R(f)|^2 |S(f)|^2 \, df}. \tag{7}$$

A reflection can shift the IWAIF values of the frequency components by considerable amounts. The dashed lines in Fig. 11 show two reflection transfer functions that are just discriminable by *M. lyra* (from Schmidt, 1992). They correspond to reflections at ideal two-front targets with a distance of 1.3 and 1.5 mm between the two surfaces, respectively. The solid line in Fig. 11 shows an idealized magnitude spec-

trum of a typical approach phase echolocation call of *M. lyra* (Hanke *et al.*, 1997; Schmidt, 1992). The IWAIF value of the third partial calculated with Eq. (4) differs for the two transfer functions by as much as 6.9 kHz. Hence, the average pitches of the partials are, in fact, highly variable characteristics of the echo spectrum that might carry a great deal of information about the reflecting target. Therefore, *M. lyra* probably not only evaluates the relative overall levels of the components in the echoes but also their average frequency positions. This notion is supported by the results of the present experiments: they show that *M. lyra* can simultaneously memorize a multitude of spectral patterns each consisting of several frequency components. The bat is able to classify unknown patterns by comparing the frequency positions of their spectral components with those in the learned patterns. This remarkable performance matches with the predictions of the IWAIF model showing that the frequencies of the spectral components in the echoes mediate information about the reflecting object. Hence, *M. lyra* possibly derives target structure from a broadband spectral analysis which may be seen as a combination of a profile analysislike mode of perception and a vowellike mode of perception. In the auditory system of *M. lyra*, object structures are probably represented as spectral patterns determined by the relative levels and the average frequencies of the up to six components in the bat's sonar echoes. Unknown objects may thus indeed be classified on the basis of a spectral comparison of the perceived echoes with these learned patterns as has been proposed in Schmidt (1992).

Although the relations between the average frequencies v_n of the components in echoes depend on the reflection transfer function and can significantly deviate from the harmonic relation, collective pitch perception may still play an important role for the association of a perceived echo with the corresponding emission in the call sequence as was conjectured by Schmidt (1995). Moore and Glasberg (1986) have shown that a mistuned component in an otherwise harmonic complex tone still significantly contributes to the collective pitch of the complex even if the mistuning is sufficiently large so that the component is heard out as a separate tone.

B. The role of the perception of roughness for the analysis of echo spectra

In the ''formant-mode'' model it is assumed that the time structure of the echolocation calls is not perceptually resolved due to the high frequency-modulation rates. An interesting alternative hypothesis concerning the perceptual dimensions involved in spectral echo processing by *E. fuscus* has been proposed by Miller (1997) (see also Nitsche and Miller, 1996). He suggested that the spectral changes in the echoes might be translated into a perception of roughness. A ripple on the wideband spectrum of a downward-modulated frequency component appears as an envelope modulation of its temporal waveform. The perception of these temporal envelope fluctuations may become important if the ripple on the echo spectrum is too fine to be spectrally resolved by the bandpass filters of the inner ear. However, due to the high-frequency modulation rates of *E. fuscus*' echolocation calls, the behaviorally relevant envelope fluctuations are rather fast in the range of several kilohertz. In a behavioral experiment, Miller (1997) presented bats of the species *E. fuscus* with envelope-modulated phantom echoes of their own echolocation calls and measured the just-detectable modulation depth as a function of the modulation frequency. Moderate and very high modulation frequencies between 1 and 9 kHz were tested. Miller's (1997) results indicate that *E. fuscus* detects an envelope modulation with a depth between 20% and 50% even at the high modulation frequencies. It cannot be excluded, however, that the bats used the spectral sidebands that are an inevitable consequence of envelope modulation (see, e.g., Ambardar, 1995). The envelope fluctuations that are brought about by the interference of multiple echo wavefronts, on the other hand, are not associated with spectral sidebands. More experimentation is therefore needed to further investigate whether roughness perception plays a role in the context of target fine structure analysis.

C. Constraints of the frequency structure of echolocation calls

In the ''formant-mode'' model it is assumed that *M. lyra* perceives the spectral changes between calls and echoes as changes in the average frequency positions and the relative overall levels of the modulated frequency components in its multicomponent echolocation calls. The model therefore suggests that target fine structure is represented in the form of *discrete* spectral patterns in the auditory system of *M. lyra*. The echolocation calls of other bat species do not exhibit such a pronounced multicomponent structure as *M. lyra*'s calls. The broadband portions of *E. fuscus*' echolocation calls, for example, have relatively flat power spectra in the perceptually relevant frequency region (e.g., Modgans *et al.*, 1993; Moss and Schnitzler, 1989; Surlykke, 1992). Assuming that *E. fuscus* infers target fine structure from the spectral characteristics of the echoes (Modgans and Schnitzler, 1990; Simmons *et al.*, 1990), the bat has to analyze the differences between the *continuous* power spectra of call and echo. The concept of a discrete representation of echo spectra would thus not be applicable in a spectral model of echolocation in *E. fuscus*. Concepts for the representation of continuous spectral profiles, like the ripple analysis model (e.g., Shamma *et al.*, 1995), have to be employed.

If a sonar call with a more or less flat power spectrum is reflected from an extended target, the frequency positions of the peaks and notches in the echo spectrum stand in a direct reciprocal relationship to the fine delay differences of the interfering partial echoes. Saillant *et al.* (1993) have exploited this fact in a computational model for echolocation in *E. fuscus* which is referred to as the SCAT model. In the SCAT model, the frequency spectrum of the echo is directly translated into the temporal domain of fine range differences.

D. Spectral versus temporal perspective in modeling approaches

The spectral models of echolocation, like the ''formant-mode'' model presented above, are based on the assumption that bats identify target fine structure by analyzing the power

spectra of calls and echoes. They do not, however, necessarily imply that the geometric structure of the target is reconstructed in the identification process. The spectral models are thus compatible with the assumption that the high-frequency phase information which is present in the multi-wavefront reflection of an echolocation call is lost in the auditory system of the bats. Hence, a spectral model predicts that targets with identical frequency transfer profiles but different phase functions cannot be distinguished by bats. Range-reversed targets, for example, would lead to ambiguities (compare Menne, 1988).

The SCAT model represents a compromise between a purely spectral model and a fully phase-sensitive cross-correlator (compare also Simmons *et al.*, 1979, 1996). The model is a spectral model in the sense that in its initial stages, the perceived echo is translated into a succession of dechirped short-time power spectra. The short-time spectra are represented by the smoothed output of a set of bandpass filters. They correspond to the distribution of excitation along the frequency-place dimension of the auditory system and are therefore comparable to the smeared internal representation of sounds that was used in the present study to compute the spectral correlation coefficients. In the spectral transformation block of the SCAT model, the short-time power spectra of the echoes are converted into a distribution along the temporal domain, referred to as the range distribution. The transformation from the frequency to the time domain can be coarsely regarded as an inverse Fourier cosine transform of the short-time power spectra with a set of modified cosine functions. Not all phase information in the echo is lost by the formation of the short-time power spectra. Therefore, the range distribution contains more information than a mere autocorrelation of the echo with itself. The autocorrelation function of a signal corresponds via the Fourier cosine transform in a one-to-one manner to its power spectrum (Wiener, 1930) and would thus lead to the same ambiguities for range reversed targets. However, the range distribution of the SCAT model contains less information than a cross-correlation between the echo and the corresponding call because part of the high frequency fine structure is smoothed by a low-pass filter. Although the SCAT model still requires a considerable temporal resolution, it is physiologically more plausible than a cross correlator.

Both the purely spectral models, like the ''formant-mode'' model, as well as the SCAT model (Saillant *et al.*, 1993) are concerned with the question of which perceptual dimensions the frequency transfer function of a spatially extended target are translated into. The SCAT model translates the frequency content of the echo into a distribution along a one-dimensional range axis. The geometrical fine structure of a target can be described by a one-dimensional range axis only if it is assumed that the propagation vectors of the interfering wavefronts in a multi-wavefront echo are approximately parallel. This assumption is justified if the distance between the bat and the target is very large and when small targets, e.g., single insects in the open air, are tracked from a distance that is large in comparison to the dimension of the target. However, it certainly does not apply when echoes from slightly different incident angles, which cannot be spatially resolved, interfere, as is the case in the presence of a structured object and densely cluttered background. Here, the representation of target geometry on a small scale, as any representation of space, requires three range dimensions. Further on, the reflection transfer function of each target itself depends on the actual angle of incidence of the echolocation call. The recognition of a certain target must therefore be a complex cognitive process which probably involves the analysis of multiple call-echo pairs and the comparison of the actual estimates with a set of learned patterns. The results of the present study suggest that *M. lyra* performs this comparison along the spectral dimension. Thereby, *M. lyra* probably simultaneously processes different features of the echo spectrum. The relative levels and absolute frequency positions of the echo components may be compared to learned spectral patterns corresponding to certain target structures in a similar way as the test stimuli of experiments 2 and 3 were compared to the training stimuli. Additionally, the frequency relations between the echo components may be perceived as a collective pitch which provides target-independent information. The analysis of the different spectral features of the echoes thus allows the acoustical characterization of targets and object recognition without an explicit translation of the echo spectrum to an ambiguous spatial dimension.

LETTERS TO THE EDITOR

This Letters section is for publishing (a) brief acoustical research or applied acoustical reports, (b) comments on articles or letters previously published in this Journal, and (c) a reply by the article author to criticism by the Letter author in (b). Extensive reports should be submitted as articles, not in a letter series. Letters are peer-reviewed on the same basis as articles, but usually require less review time before acceptance. Letters cannot exceed four printed pages (approximately 3000–4000 words) including figures, tables, references, and a required abstract of about 100 words.

Experimental determination of the effective structure-function parameter for atmospheric turbulence

D. K. Wilson[a)]

(Received 13 November 1997; revised 7 November 1998; accepted 9 November 1998)

The effective structure-function parameter for scattering by atmospheric turbulent velocity fluctuations has normally been assumed to be $C_{\text{eff}}^2=4C_V^2/c_0^2$, where C_V^2 is the velocity structure-function parameter and c_0 the sound speed. However, a new derivation by Ostashev [Waves Random Media **4**, 403–428 (1994)], which takes into account the vectorial nature of the wind velocity field, suggests that $C_{\text{eff}}^2=22C_V^2/3c_0^2$. An experiment was designed to determine the correct value of the coefficient. Sound-pressure amplitude variances were monitored for several discrete frequencies between 380 and 3800 Hz, at distances up to 250 m. Cup and hot-wire anemometers were used to determine C_V^2. A theory for scattering by inertial-subrange turbulence was then used to calculate the C_{eff}^2 coefficient from the amplitude variance and C_V^2. Datasets recorded under different atmospheric conditions yielded different relationships between the coefficients and failed to verify either the 4 or 22/3 value. Some possible explanations for this behavior are discussed, including the need for more realistic meteorological modeling. [S0001-4966(99)04302-7]

PACS numbers: 43.28.Fp [LCS]

An acoustic wave propagating through the atmosphere is affected by turbulent fluctuations in wind velocity and temperature. Following the ideas of Kolmogorov,[1] the statistics of the turbulent fluctuations for each of these fields can be characterized by a structure-function parameter (SFP), C_v^2 and C_T^2, respectively. It is useful to define an ''effective'' SFP for the acoustic wave that combines the effects of the velocity and temperature fluctuations into a single parameter C_{eff}^2. Normally this effective SFP has been assumed to have the form

$$C_{\text{eff}}^2=\frac{C_T^2}{T_0^2}+a_v\frac{C_v^2}{c_0^2}, \tag{1}$$

where T_0 is the average temperature, c_0 the average sound speed, and a_v a constant coefficient. Tatarskii[2] suggested that $a_v=4$, and this value has been used in much subsequent work. However, a more recent derivation by Ostashev,[3] which rigorously accounted for the vectorial nature of the wind velocity field, resulted in $a_v=22/3$. The objective of the experiment described in this Letter was to determine the correct value for the coefficient a_v.

The experiment was performed at a small airport located east of the city of Ottawa, Ontario. Acoustic measurements of a series of pre-recorded tones were conducted with an array of electret microphones, located on the ground surface at intervals of 25 m, out to a distance of 650 m. The signals from this array were amplified and then transmitted to an equipment trailer, where they were filtered, digitized, and recorded. The test tones, at frequencies ranging from 380 to 3800 Hz, were produced with a standard horn-type loudspeaker, which was located on the top of a 1-m tower. Wind velocity and temperature were simultaneously recorded with a cup-type anemometer at 2-m height, a hot-wire anemometer at 2 m, and several temperature sensors on a 10-m tower. The cup anemometer and thermometers had a sampling rate of 0.5 Hz, whereas the hot-wire anemometer signals were filtered with a 250-Hz lowpass filter and sampled

at 1000 Hz. The layout of the experiment is shown in Fig. 1. Further details on the test site, microphone array, and signal processing can be found in Havelock *et al.*[4]

Our method for determining the velocity coefficient in the C_{eff}^2 equation was to compare the variance in the log-amplitude fluctuations of the sound pressure to the SFPs that were estimated from the meteorological measurements. The equation for the log-amplitude pressure variance of a spherically propagating wave is[2]

$$\langle \chi^2 \rangle = 0.031 C_{\text{eff}}^2 k^{7/6} X^{11/6}, \tag{2}$$

where $k = 2\pi f/c_0$, f is the frequency, and X is the source–receiver separation (range). In our trials, the contribution of temperature fluctuations to C_{eff}^2 was small, so that $C_{\text{eff}}^2 \simeq a_v C_v^2/c_0^2$. Hence, by determining $\langle \chi^2 \rangle$ as a function of frequency and range from the microphone signals, and determining C_v^2 from the cup and/or hot-wire anemometer measurements, we should be able to evaluate a_v.

Our method for determining C_v^2 is based on the definition

$$\langle [v(\boldsymbol{r}+\Delta\boldsymbol{r}) - v(\boldsymbol{r})]^2 \rangle = C_v^2 (\Delta \boldsymbol{r})^{2/3}, \tag{3}$$

where $\boldsymbol{r}+\Delta\boldsymbol{r}$ and $\boldsymbol{r}$ are the locations of two sensors, and v is the component of the velocity field aligned with $\Delta\boldsymbol{r}$. For this equation to be valid, Δr must be within the inertial subrange.[1] Assuming the validity of Taylor's hypothesis, which states that the turbulence is ''frozen'' as the wind moves it past a stationary sensor, we have for the velocity SFP,

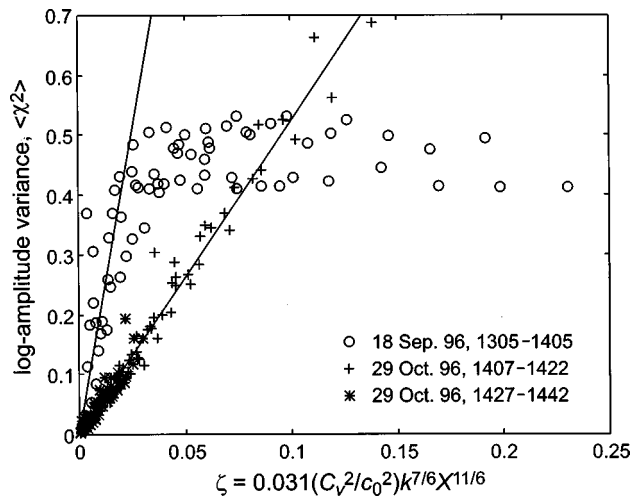

FIG. 2. Log-amplitude variance for the two datasets, as a function of the parameter $\zeta = 0.031(C_v^2/c_0^2)k^{7/6}X^{11/6}$. The lines are least-squares fits to the initial, linear sections of the data.

TABLE I. Summary of the results of the experiment. The coefficient for the effective structure-function parameter is a_v.

Date	C_v^2 ($m^{4/3}/s^2$)	a_v
18 September 1996	0.14	20
29 October 1996	0.088	5.2

$$C_v^2 = \frac{\langle [u(t+\Delta t) - u(t)]^2 \rangle}{(U\Delta t)^{2/3}}, \tag{4}$$

in which t is time, U is the mean wind speed, and u is the wind fluctuation in the direction of the mean. Our calculations for C_v^2 were made using the hot-wire anomemometer data, and are for separations $\Delta r = U\,\Delta t = 1$ m. The reason for selecting 1 m is that this value is less than the height of the anemometer (2 m), yet large enough to avoid the high-frequency roll-off in the sensor response.

The first dataset we consider, lasting 15 min, was recorded between 1350 and 1405 on 18 September 1996. The skies were mostly clear, winds were rather light ($U = 2.5$ m/s) but highly variable, and propagation was roughly cross-wind. A temperature lapse condition resulted in upward refraction. There were six test tones, at 1225, 1550, 2125, 2575, 3250, and 3800 Hz. The value for C_v^2 determined from the hot-wire anemometer was 0.14 $m^{4/3}/s^2$. The circles in Fig. 2 are $\langle \chi^2 \rangle$ for this dataset, plotted vs $\zeta = 0.031(C_v^2/c_0^2)k^{7/6}X^{11/6}$. Only ranges $X < 250$ m are included on the plot, since a shadow zone was evident at longer ranges. Based on Eqs. (1) and (2), the slope of the data points should be a_v. Although the data do collapse fairly well onto a line for small ζ, saturation is evident for $\zeta \gtrsim 0.03$. [Saturation effects were observed some time ago for optical propagation in the atmosphere (e.g., Ref. 5), and more recently for acoustic propagation by Daigle *et al.*[6] For this particular dataset the onset of saturation is complicated by the upward refraction.] The line shown in Fig. 2 is a least-squares fit to those data for which $\zeta < 0.03$. The slope of the line is 20. This is substantially greater than the values 4 or 22/3 suggested by theory.

The second dataset we consider is actually a combination of two 15 min sessions, one from 1407 to 1422 on 29 October 1996, and the other from 1427 to 1442 on the same day. Skies were clear on this afternoon, winds were moderate ($U = 3.4$ m/s), and propagation was downwind. The first session used tones at 1000, 1350, 1700, 2300, 2900, and 3500 Hz, whereas the second used tones at 380, 500, 600, 700, 820, and 940 Hz. The reason why we have combined the two sessions for this analysis is that they collapse nearly onto a single line, suggesting that C_v^2 was stationary through the time period covering the two sessions. The value of C_v^2 determined for the period 1407 to 1442 was 0.088 $m^{4/3}/s^2$. The corresponding plot of $\langle \chi^2 \rangle$ vs ζ is shown in Fig. 2. The line fitted to the combined dataset has a slope of 5.2, which falls between the theoretical values of 4 and 22/3.

Clearly, our experiment has been inconclusive in verifying either $a_v = 4$ or $a_v = 22/3$. The two datasets (summarized in Table I) yielded inconsistent results. It is unclear whether the difference in the slopes between the two datasets is due

to the orientation between the wind and propagation direction or some other factor. In future work, it would be desirable to collect a greater number of datasets.

Although the exact reason why the measured values of a_v differed from the theoretical ones is unclear, there are several possibilities. First, the data could be moderately affected by a large-scale (energy-subrange) turbulence structure, which is anisotropic and dependent on atmospheric conditions. Second, the covariance between temperature and velocity has been assumed negligible in both the theory and data analysis. Although this assumption has a well established precedence in the literature, the covariance term may actually be more significant than the temperature term,[7] and therefore may not be negligible. Finally, C_v^2 was assumed to be independent of height, which is probably a poor assumption. For example, in a surface layer where shear generation of turbulence dominates, $C_v^2 \propto z^{-2/3}$ (e.g., Ref. 8). If the sound in our experiment travels a straight path, simple calculations show that the average value of C_v^2 over the propagation path is 1.03 times the value measured by the hot-wire anemometer at 2 m—a small correction. If there is refraction, however, the correction can be significantly different.

Although the results of this experiment are inconclusive in verifying either $a_v = 4$ or $a_v = 22/3$, they do indicate the need for more realistic meteorological modeling in order to obtain accurate predictions of sound field statistics.

Incorporation of thermal overlap effects into multiple scattering theory

D. Julian McClements,[a] Yacine Hemar,[b] and Norbert Herrmann
Biopolymers and Colloids Research Laboratory, Department of Food Science, University of Massachusetts, Amherst, Massachusetts 01003

(Received 17 October 1997; revised 6 August 1998; accepted 2 November 1998)

Existing multiple scattering theories do not give accurate predictions of the ultrasonic properties of concentrated emulsions because overlap of thermal waves generated by the droplets in the presence of an ultrasonic field is not taken into account [McClements, J. Acoust. Soc. Am. **91**, 849–853 (1992)]. Recently, a core-shell model was developed which accounts for the effects of thermal overlap, but ignores multiple scattering, intrinsic absorption and visco-inertial effects [Hemar *et al.*, J. Phys. II **7**, 637–647 (1997)]. A multiple scattering theory is combined with the core-shell model to obtain a new theory that overcomes the limitations of each of the individual theories. The new theory gives excellent agreement with experimental measurements of the attenuation spectra of concentrated monodisperse emulsions. © *1999 Acoustical Society of America.* [S0001-4966(99)02902-1]

INTRODUCTION

Ultrasonic spectrometry is finding increasing use as an analytical tool for characterizing the properties of concentrated emulsions.[1,2] Commercial instruments have recently become available which can rapidly and nondestructively measure both the disperse phase volume fraction and droplet size distribution of emulsions.[3–5] These instruments measure the attenuation coefficient of an emulsion over a wide range of frequencies (typically from 1 to 150 MHz), and then use ultrasonic scattering theory to find the droplet size distribution and concentration that gives the best fit between the theoretical predictions and the measured attenuation spectra.[1,6,7] The theory used to interpret the attenuation spectra is normally based on a single scattering theory, developed orginally by Epstein and Carhart[8] and then extended by Allegra and Hawley,[9] although corrections for multiple scattering are often included.[1,10] This approach gives excellent agreement with experimental measurements in fairly dilute emulsions ($\phi<0.15$), but may lead to significant deviations between the theory and experiment at higher droplet concentrations.[10]

In the long wavelength regime, the principal form of attenuation in emulsions with low density contrast is the heat flow which occurs between a droplet and its surroundings when the droplet is in the presence of an ultrasonic wave.[11,12] The extent of these thermal losses depends on the magnitude of the temperature gradient between the droplet and its surroundings. The Epstein–Carhart–Allegra–Hawley (ECAH) theory assumes there are no interactions between neighboring droplets, so that the heat generated by one droplet flows directly into the continuous phase.[8,9] In practice, the heat generated by a droplet may propagate into a neighboring droplet, and therefore the temperature gradient between a droplet and its surroundings is reduced, which leads to a decrease in the attenuation. This phenomenon was used to account for the fact that measurements of the attenuation coefficient of emulsions were lower than those predicted by multiple scattering theories at high droplets concentrations.[10,13] Recently, Hemar *et al.*[14] developed a core-shell model to account for the influence of the overlap of the thermal waves generated by the droplets on the ultrasonic properties of concentrated emulsions. Nevertheless, this model is limited because it does not take into account multiple scattering, intrinsic absorption or visco-inertial effects. In this article, we combine a multiple scattering theory with the core-shell model to develop a new theory that overcomes the limitations of each individual theory.

I. MULTIPLE SCATTERING THEORY

A variety of multiple scattering theories are available to relate the ultrasonic properties of emulsions to their microstructure, composition, and thermophysical properties.[15–17] These theories are based on a mathematical analysis of the propagation of ultrasonic waves through an ensemble of particles. One of the most widely used is the Waterman and Truell theory, which is given by the following expression in the long wavelength limit:[15]

$$\left(\frac{K}{k_1}\right)^2=\left(1-\frac{3i\phi A_0}{(k_1r)^3}\right)\left(1-\frac{9i\phi A_1}{(k_1r)^3}\right). \tag{1}$$

Here K is the complex propagation constant of the emulsion ($=\omega/c+i\alpha$), k_1 is the complex propagation constant of the continuous phase ($=\omega/c_1+i\alpha_1$), c is the ultrasonic velocity, α is the attenuation coefficient, ω is the angular frequency, i is $\sqrt{-1}$, ϕ is the dispersed phase volume fraction, r is the droplet radius, and A_0 and A_1 are the monopole and dipole scattering coefficients of the individual droplets.

Epstein and Carhart[8] developed a theory that could be used to calculate the scattering coefficients of individual

[a]Corresponding author. Electronic mail: mcclements@foodsci.umass.edu
[b]Current address: Hannah Research Institute, Ayr KA6 5HL, Scotland.

droplets surrounded by an infinite liquid, which was later extended by Allegra and Hawley.[9] In the long wavelength regime, the following explicit expressions for the monopole and dipole scattering coefficients were derived:[9]

$$A_0 = -\frac{ik_1 r}{3}\left((k_1 r)^2 - (k_2 r)^2 \frac{\rho_1}{\rho_2}\right) - \frac{i(k_1 r)^3(\gamma_1 - 1)}{b_1^2}\left(1 - \frac{\beta_2 C_{P1}\rho_1}{\beta_1 C_{P2}\rho_2}\right) H, \tag{2}$$

$$A_1 = \frac{i(k_1 r)^3(\rho_2 - \rho_1)(1 + T + is)}{\rho_2 + \rho_1 T + i\rho_1 s}, \tag{3}$$

where

$$H = \left[\frac{1}{(1 - ib_1)} - \frac{\tau_1}{\tau_2}\frac{\tan(b_2)}{\tan(b_2) - b_2}\right]^{-1},$$

$$b_1 = \frac{(1+i)r}{\delta_{T,1}}, \quad b_2 = \frac{(1+i)r}{\delta_{T,2}},$$

$$\delta_{T,i} = \sqrt{\frac{2\tau_i}{\rho_i C_{Pi}\omega}}, \quad \delta_S = \sqrt{\frac{2\eta_1}{\rho_1 \omega}}, \tag{4}$$

$$T = \frac{1}{2} + \frac{9\delta_S}{4r}, \quad s = \frac{9\delta_S}{4r}\left(1 + \frac{\delta_S}{r}\right).$$

Here, the density is ρ, the specific heat capacity is C_P, the coefficient of volume expansion is β, the thermal conductivity is τ, the viscosity is η, and the ratio of specific heats is γ. The subscripts 1 and 2 refer to the continuous and dispersed phases, respectively. The parameters δ_T and δ_S are referred to as the thermal and viscous skin depths, respectively, and are related to the distance that the thermal and shear waves generated by a droplet penetrate into the surrounding liquid.[13] The above equations give excellent agreement with experimental measurements for most dilute emulsions ($\phi < 0.15$), and for more concentrated emulsions under certain experimental conditions, i.e., relatively large droplet sizes and high frequencies.[10,11]

Recently, it has been shown that significant deviations occur between the above theory and experimental measurements when the thermal waves generated by neighboring droplets overlap with one another, i.e., at low frequencies and/or in highly concentrated emulsions.[10,14,18] This effect has been accounted for theoretically using a ''core-shell'' model.[14] In this theory, it is assumed that each emulsion droplet is surrounded by a shell of the continuous phase, which is itself surrounded by an effective medium, whose properties are determined by the composition of the whole emulsion (Fig. 1). The thickness of the shell is approximately equal to the average distance between the droplets in an emulsion.

The core-shell model does not take into account multiple scattering, intrinsic absorption or visco-inertial losses.[14] In this article, we show that a more comprehensive theory of ultrasonic propagation in emulsions can be developed by combining multiple scattering theory with the core-shell model to overcome each of their individual limitations.

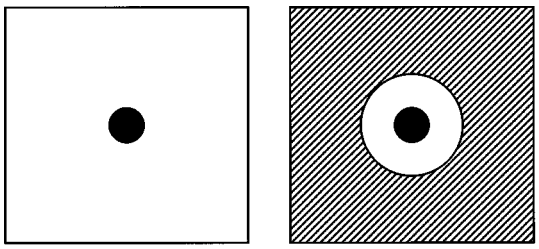

FIG. 1. Schematic diagram of the core-shell model used to take into account thermal overlap effects in the multiple scattering theory.

The approach we adopt in this paper is to compare the analytical expression for the complex propagation constant of an emulsion derived using the core-shell model with that derived using ultrasonic scattering theory under the same approximations, i.e., no intrinsic absorption, no multiple scattering and no visco-inertial losses. By comparing these expressions we show that they are identical except for a single ''thermal term,'' which includes the thermal overlap effects in the core-shell model. The multiple scattering theory is therefore extended by replacing the original thermal term with the one from the core-shell model.

To compare the two approaches under the same assumptions we have to derive an expression for the traditional ultrasonic scattering theory [Eq. (1)] which ignores intrinsic absorption, multiple scattering and visco-inertial effects. Allegra and Hawley[9] showed that the intrinsic losses are contained in the first term on the right-hand side of Eq. (2), so that these losses can be ignored by dropping this term. The visco-inertial effects originate because of the density difference between the droplets and surrounding liquid, and so these losses can be ignored by setting $\rho_1 = \rho_2$, so that A_1 equals zero. The multiple scattering effects are due to ϕ^2 terms in Eq. (1), and therefore these losses can be ignored by dropping these terms. Finally, the following expression for the complex propagation constant of an emulsion is obtained from Eqs. (1)–(3):

$$\left(\frac{K}{k_1}\right)^2 = \left(1 - \frac{3\phi(\gamma_1 - 1)}{b_1^2}\left(1 - \frac{\beta_2 C_{P1}\rho_1}{\beta_1 C_{P2}\rho_2}\right) H\right), \tag{5}$$

where $\gamma_1 (= 1 + T_a \beta_1^2 c_1^2 / C_{P1})$ is the ratio of specific heats in the continuous phase and T_a is the absolute temperature. This equation can be rearranged to give:

$$\left(\frac{K}{k_1}\right)^2 = \left(1 + i\frac{3\phi}{\omega r^2}\frac{T_a}{\kappa_1}\left(\frac{\beta_1}{C_{P1}\rho_1} - \frac{\beta_2}{C_{P2}\rho_2}\right) H \tau_1\right), \tag{6}$$

where the adiabatic compressibility is κ. This equation is analogous to Equation 15 in Ref. 14, but with $H = A\kappa_1 / \kappa_0 \tau_1$, where A is the term in the core-shell model which takes into account the thermal overlap effects (see Equation 24 in Ref. 14) and κ_0 is the volume averaged compressibility of the emulsion [$\kappa_0 = \phi\kappa_2 + (1 - \phi)\kappa_1$].

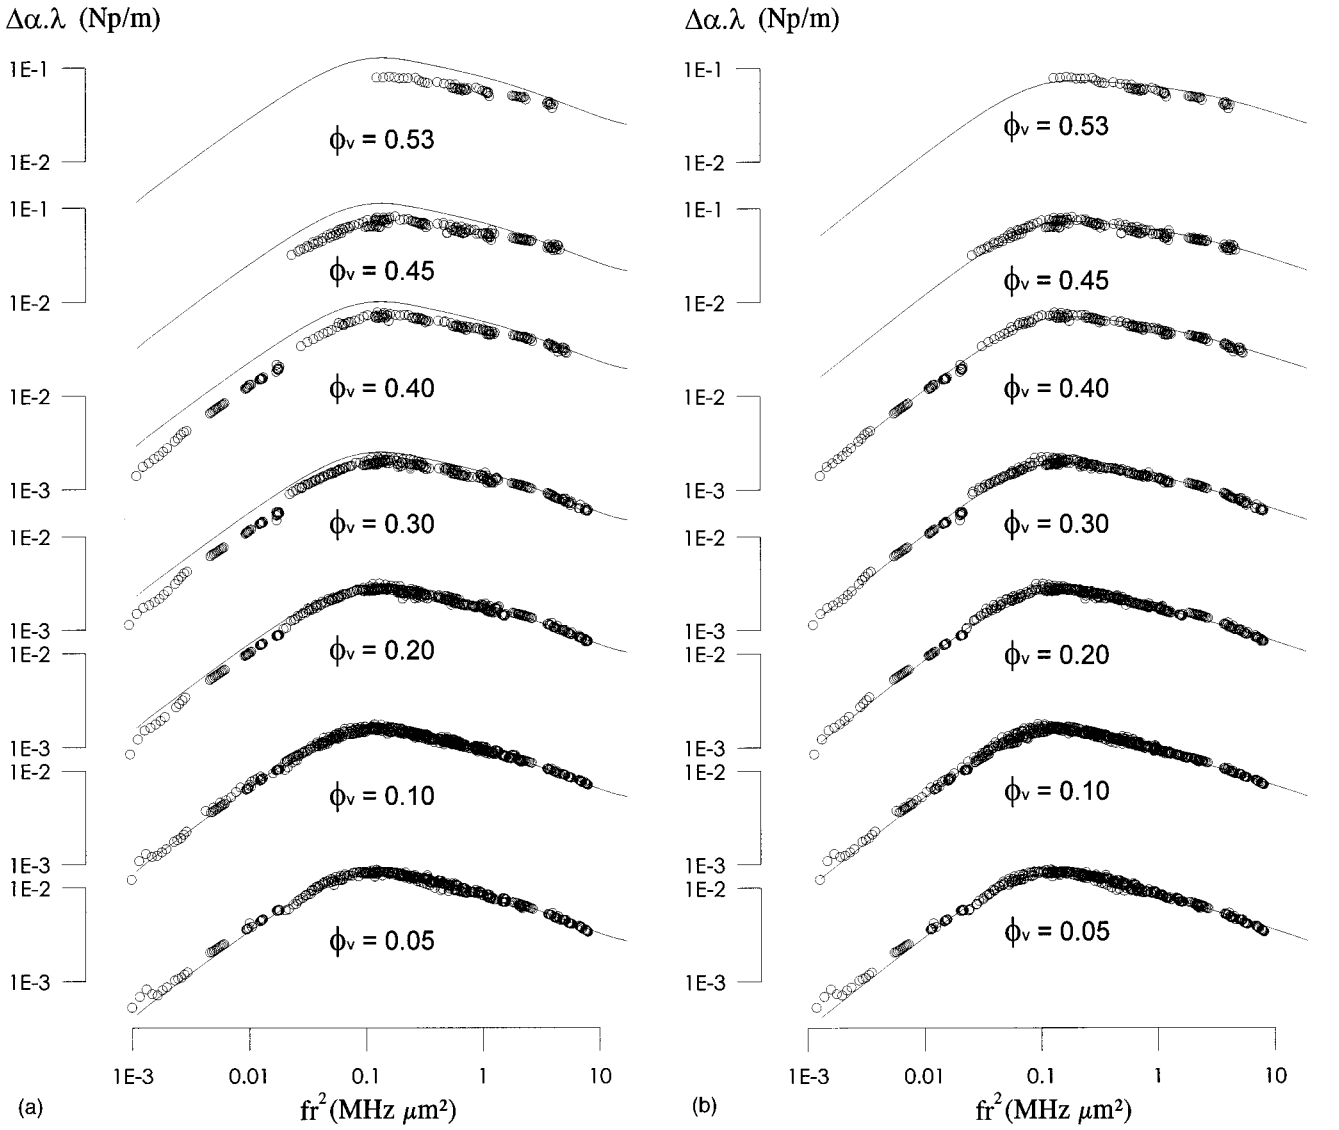

FIG. 2. Comparision of predicted and measured ultrasonic attenuation spectra of *n*-hexadecane oil-in-water emulsions. The open circles are experimental measurements, the full lines are computed using the theory. (a) The data for the traditional ultrasonic scattering theory and (b) the data for the new theory.

We can therefore extend the multiple scattering theory to include thermal overlap effects by replacing the H term given above [Eq. (4)] with the expression derived by Hemar *et al.*:[14]

$$H=\frac{\tau_2\kappa_1}{\kappa_0}\frac{n_2r-\tanh(n_2r)}{EC+FD}\times\left[2\kappa_3\left(\frac{g_1-g_3}{g_2-g_1}\right)n_1x(n_3x+1)+C(1+n_1r)+D(1-n_1r)\right], \tag{7}$$

where

$$g_i=\frac{\beta_i}{\rho_iC_{Pi}},$$

$$C=e^{n_1(x-r)}[\tau_1(n_1x-1)+\tau_3(n_3x+1)],$$

$$D=e^{-n_1(x-r)}[\tau_1(n_1x+1)-\tau_3(n_3x+1)],$$

$$E=\tau_2n_2r+[\tau_1(n_1r+1)-\tau_2]\tanh(n_2r),$$

$$F=\tau_2n_2r-[\tau_1(n_1r-1)+\tau_2]\tanh(n_2r),$$

where $n_i=(1-i)/\delta_{Ti}$ and x is the radius of the shell of continuous phase which surrounds the droplets:[14]

$$x=\frac{r}{\sqrt{3\phi}}. \tag{8}$$

The thermophysical properties of the effective medium which surrounds the shell are given by the following expressions:[14]

$$\rho_3=(1-\phi)\rho_1+\phi\rho_2, \tag{9}$$

$$\kappa_3=(1-\phi)\kappa_1+\phi\kappa_2, \tag{10}$$

$$\rho_3C_{P3}=(1-\phi)\rho_1C_{P1}+\phi\rho_2C_{P2}, \tag{11}$$

$$\tau_3=\tau_1\frac{1+2\phi\chi-2(1-\phi)\zeta\chi^2}{1-\phi\chi-2(1-\phi)\zeta\chi^2}, \tag{12}$$

where

$$\chi = \frac{\tau_2 - \tau_1}{\tau_2 + 2\tau_1}, \quad \zeta = 0.21068\phi - 0.04693\phi^2.$$

It should be noted that the H term given by Eq. (7) tends to that given by Eq. (4) when the spacing between the droplets is much greater than the length of the thermal skin depth, i.e., $x \gg \delta_{T,1}$. This condition is met when emulsions are sufficiently dilute, the frequency is sufficiently high or the particles are sufficiently large:

$$f \gg \left(\frac{\tau_1}{\rho_1 C_{P,1} \pi}\right)\left(\frac{\sqrt[3]{\phi}}{r}\right)^2. \tag{13}$$

It should also be noted that the value of A_0 [Eq. (2)], corrected for thermal overlap effects, can be used in the Lloyd and Berry[16] or Ma *et al.*[17] multiple scattering theories, as well as in the Waterman and Truell[15] theory.

In this study we have been principally concerned with the properties of emulsions in which the density contrast between the droplets and the surrounding liquids is low, so that the dominant form of attenuation is the thermal losses. In systems where there is a relatively high density contrast it would also be necessary to take into account the effect of the overlap of the shear waves generated by the droplets.[19]

II. COMPARISION WITH EXPERIMENTAL MEASUREMENTS

The original and extended multiple scattering theories are compared with experimental measurements of the ultrasonic attenuation spectra of concentrated monodisperse hexadecane oil-in-water emulsions in Fig. 2. These measurements were made using an interferometric technique that has been described in detail elsewhere.[18] The particle size of the emulsions was determined by finding the value which gave the best fit between the measured attenuation spectra and that predicted by either the original theory [Fig. 2(a)] or the extended theory [Fig. 2(b)] for the 10% oil-in-water emulsions. These particle sizes were then used in all of the subsequent calculations. The extended multiple scattering theory gives excellent agreement with the experimental measurements across the whole range of frequencies and droplet concentrations [Fig. 2(b)], whereas the original multiple scattering theory overpredicts the attenuation coefficient at the lower frequencies, particularly in concentrated emulsions ($\phi > 0.15$) [Fig. 2(a)]. These results clearly show that our theory is more useful than the existing theory for interpreting ultrasonic spectra in concentrated emulsions.

III. CONCLUSIONS

The multiple scattering theory has been extended to take into account the overlap of the thermal waves generated by the droplets on the ultrasonic attenuation spectra of emulsions. This theory has been shown to give better predictions of the ultrasonic properties of concentrated emulsions than the traditional multiple scattering theory in concentrated emulsions. The development of this theory should enable manufacturers of instruments that utilize ultrasonic spectrometry to characterize emulsions to extend them to higher droplet concentrations.

(Received 23 September 1998; accepted for publication 11 November 1998)

Recently, Withnell and Yates [J. Acoust. Soc. Am. **104**, 344–349 (1998)] reported a pure tone acoustic enhancement of the transient-evoked otoacoustic emission (TEOAE). They state that their data conflict with the existing theory that the TEOAE represents a one-to-one frequency response to stimulus component frequencies. Therefore, they interpreted the observed enhancement as a result of a complex interaction on the basilar membrane of hypothetical intermodulation distortion products. This Letter reviews recent data and proposes an alternative interpretation that the enhancement results from an impedance discontinuity at the pure tone characteristic frequency (CF) location. TEOAEs at frequencies below this tone are reflected from its CF location rather than from their own CF locations. © *1999 Acoustical Society of America.* [S0001-4966(99)04002-3]

To explore the origin of the transient-evoked otoacoustic emission (TEOAE), Withnell and Yates (1998) extended the work of Sutton (1985) to study the effect of a pure-tone suppressor on the TEOAE with a variety of stimulus spectra and pure-tone suppressors in guinea pig. They hypothesized that a pure tone suppressed a region on the basilar membrane (BM) that roughly matches the suppressor excitation pattern on the BM, with maximum suppression occurring in the region of the pure-tone frequency. If TEOAE generators act independently, then, with the addition of a 70 dB SPL tone, a reduction in the amplitude of the TEOAE power spectrum over a range of frequencies is expected, with the predominant effect being a maximal reduction of the emission near the tone frequency. Enhancement of the emissions is not expected at any frequency. However, they found enhancement in the amplitude of the response spectrum at frequencies corresponding to BM regions apical to the tone. The authors state their finding indicates that the TEOAE does not result solely from independent generators along the BM and interpreted the pure-tone-induced enhancement as a contribution of intermodulation distortion to the TEOAE.

In order to study the interaction between mechanical–electrical and electrical–mechanical transductions of outer hair cells *in vivo*, Ren and Nuttall (1998a) observed the acoustically induced changes in the electrically evoked otoacoustic emission (EEOAE). It was found that a pure tone enhanced the EEOAE fine structure at frequencies below the acoustic frequency and suppressed the overall level of the EEOAE at frequencies above the acoustic frequency. In addition, the EEOAE at frequencies approximately one-half octave lower than the acoustic frequencies were relatively more enhanced or showed relatively less suppression than at other frequencies. As a possible mechanism of acoustic enhancement, Ren and Nuttall suggested that the acoustic stimulus creates an impedance discontinuity at its characteristic frequency (CF) location, leading to a change in the reflected electrically evoked traveling wave, which may enhance or suppress the EEOAE by the vector summation of two waves.

In our laboratory, a novel signal processing method has subsequently been developed to detect the multiple components of the EEOAE. We found that the EEOAE generated by extracochlear electrical stimulation consists of a short delay component (SDC), with a short time delay, and a long delay component (LDC), having a long time delay (Ren and Nuttall, 1998b). The SDC is proposed as the reverse propagated wave from the electrode location; the LDC is proposed as the reflected forward-propagated wave, which originates at the electrode location, travels apically, and is reflected near the CF location. Intravenous furosemide (50 mg/kg) completely suppressed the LDC but not the SDC. A simultaneously presented pure tone altered the power distribution of the LDC: the power level of the LDC below the frequency of the acoustic pure tone increased and that above the tone frequency decreased (Ren and Nuttall, 1998b). These data demonstrate that the intracochlear reflection pattern of the electrically evoked energy was altered by the pure tone, strongly supporting the interpretation that the acoustic modulation of the EEOAE results from change in intracochlear reflection patterns.

Although the above two studies (Withnell and Yates,

a)Electronic mail: rent@ohsu.edu

1998; Ren and Nuttall, 1998a) may appear different, there exist relevant similarities. First, in the study by Withnell and Yates, clicks are wide bandwidth stimuli, as shown by stimulus spectra in their Figs. 1–4. In the study by Ren and Nuttall, a constant current with swept frequency across a wide frequency range was used to evoke the mechanical energy from the electromotility of outer hair cells (Ashmore, 1987; Brownell *et al.*, 1985; Dallos *et al.*, 1991; Santos-Sacchi, 1989). This electrically evoked vibration retropropagates to the external ear canal to form the EEOAE. But conventional forward waves propagate along the BM (Nuttall and Ren, 1995). Note that the wide frequency response of the EEOAE (Ren and Nuttall, 1995) indicates the wide bandpass feature of the forward-propagated wave because of the isotropic property of the BM (Allen and Fahey, 1992). Thus, in both studies, the effective stimulus is wideband. The only difference is that the click evokes simultaneous traveling waves while the swept frequency current causes traveling waves at different times. Thus, the TEOAE is similar to what we described as the LDC of the EEOAE (Ren and Nuttall, 1998b).

It has been suggested that the origin of the TEOAE involves reflections from impedance discontinuities (Kemp, 1986; Kemp and Chum, 1980; Prieve *et al.*, 1996; Probst *et al.*, 1986). Similarly, the LDC of the EEOAE is proposed to be reflected energy from the CF sites when acoustical energy is originally generated by the electrically stimulated cochlear partition near the electrode.

Although the ear canal-measured EEOAE is the vector summation of the reverse wave from the cochlear partition near the electrode and the reflected wave from the CF place, the EEOAE transfer functions (Fig. 2 B, Ren and Nuttall, 1998a) show a similar complex pattern of acoustic enhancement as that revealed by the TEOAE (Figs. 1–4, Withnell and Yates). A simultaneous pure tone increased the amplitude of the emissions at frequencies below the tone frequency and decreased the amplitude in frequencies at and above the tone frequency for both EEOAE and TEOAE. The fine structure, i.e., the amplitude variation, of the emissions was enhanced in the frequency range below tone frequency and suppressed in the frequency range at and above the pure-tone frequency. In addition, we demonstrated that the nonlinear phase/frequency function of the EEOAE became linear when a pure tone (10 kHz, 80 dB SPL) was simultaneously presented (Fig. 4 B, Ren and Nuttall, 1998a).

Withnell and Yates state that if the TEOAE represents a one-to-one frequency response to component frequencies of the stimulus, then simultaneous presentation of a pure tone should suppress those TEOAE components, which are close to the pure-tone frequency. It is true that the simultaneous presentation of a pure tone suppresses the BM vibration induced by a click near the pure-tone frequency in the same way as does two-tone suppression (Geisler and Nuttall, 1997). However, it is not necessary that the amplitude of the TEOAE follow the changes in BM vibration, because the TEOAE is presumably composed of the reflected acoustic energy from the CF location on the BM, and the amplitude of the TEOAE is determined by the amplitude of the incident wave, the BM reflection coefficient, and transmission efficiency of the reflected wave. The simultaneously presented pure tone causes a traveling wave with maximum vibration at its CF place, resulting in an impedance discontinuity. Traveling waves at frequencies below the pure-tone frequency encounter the impedance discontinuity and are reflected from the CF location of the pure tone rather than from their own CF locations. The reflection coefficient for traveling waves from the pure tone CF site may be higher than that from the CF places of frequencies below the tone frequency because of the high magnitude of the vibration and the nonlinear mechanical properties of the BM. Although this may be a passive reflected wave without magnification by hypothetical cochlear amplifier, the transmission efficiency of the reflected energy from the pure tone CF location could be higher than that from the CF locations below the pure-tone frequency due to the change in reflection location from the apical region to base. This proposed model can account for the data presented in Withnell and Yates' Figs. 1–4, where the amplitude of the TEOAE at frequencies below the tone frequency was enhanced.

Important experimental evidence against the interpretation that TEOAE enhancement induced by simultaneous presentation of a pure tone results from intermodulation distortion product (DP) is that acoustic enhancement of the EEOAE does not require intermodulation products. In the experiment by Ren and Nuttall (1998a), a constant current with swept frequency and a pure tone were delivered to the cochlea, and the EEOAE was measured at the frequencies of the electrical current. Neither a DP produced by different EEOAE frequency components nor a DP caused by interaction between electrically evoked traveling waves and pure-tone-induced waves contributed to the data since the EEOAE was measured at the stimulus frequency rather than at any DP frequency.

Whereas a TEOAE present outside the stimulus passband (above 10 kHz) (Fig. 4; Withnell and Yates) is consistent with intermodulation distortion energy contributing to the TEOAE, such energy of the TEOAE evoked by 0–5 kHz is not evident in the bandwidth stimulus (Figs. 2 and 3, Withnell and Yates). Since the single-tone burst evoked TEOAE also shows bandpass features rather than a single frequency peak on the spectrum (Yoshikawa *et al.*, 1998), TEOAE energy outside the single-tone bandwidth is not evidence that TEOAE is generated by the mechanism of the DP production. It can be concluded that TEOAE energy outside the stimulus passband may not be an indicator of DP production in the cochlea.

It is essential to have two normal traveling waves at $f1$ and $f2$ frequency locations to generate DPs. It is also well documented that the presentation of a pure tone near $f1$ or $f2$ frequency can suppress the DPs (Brown and Kemp, 1984; Martin *et al.*, 1987). Even if DPs could be generated by some frequency components of an acoustical click, these DPs likely are suppressed by other frequency components of the same click stimulus. In addition, the simultaneously presented pure tone can also suppress the click-evoked DPs in the same way as the suppression of the two acoustical primaries-evoked DPs.

Withnell and Yates (1998) stated ''The net result would depend on the precise way in which the remaining inter-

modulation products sum, but any outcome presumably is possible from suppression to enhancement.'' However, neither experimental result nor a theoretical model supporting this interpretation was presented in their paper. In our paper (Ren and Nuttall, 1998a) and in this letter, the proposed model for the acoustically evoked changes in the intracochlear reflection pattern predicts frequency dependent enhancement.

In summary, based on recent findings in acoustic enhancement of the EEOAE, it is proposed in this letter that acoustically induced change in intracochlear reflection can interpret the enhancement of the TEOAE. This alternative theory not only satisfactorily interprets the TEOAE enhancement data presented by Withnell and Yates but also is consistent with other studies that the TEOAE represents a one-to-one frequency response to component frequencies of the stimulus (Kemp and Chum, 1980; Kemp, 1986; Probst *et al.*, 1986; Prieve *et al.*, 1996).

(Received 5 November 1998; accepted for publication 11 November 1998)

In a recent paper Withnell and Yates [J. Acoust. Soc. Am. **104**, 344–399 (1998)] suggested that the TEOAE might be comprised of significant quantities of intermodulation distortion energy, based on a series of suppression experiments involving the measurement of the TEOAE with the addition of a pure tone. Ren and Nuttall [J. Acoust. Soc. Am. **105**, 919–921 (1999)] have suggested an alternative explanation for our experiments, wherein a pure tone produces a local impedance change in the nonlinear mechanical properties of the basilar membrane: emission energy at frequencies below the frequency of the pure tone is suggested to arise from reflections at this impedance discontinuity. In this Letter, a response to their hypothesis is given, arguing that it is not consistent with experimental findings, and that, in fact, the TEOAE is comprised predominantly of intermodulation distortion energy [Yates and Withnell, Assoc. Res. Otolaryngol. Abstr. **21**, 5 (1998)]. [S0001-4966(99)04102-8]

We thank Dr. Ren and Dr. Nuttall for their letter offering an alternative interpretation for the findings of Withnell and Yates (1998), although we do observe at the outset that we had already considered and rejected a similar explanation in that paper.

The most important finding of Withnell and Yates (1998) was the absence of strong, frequency-specific suppression of the transient-evoked otoacoustic emission (TEOAE) by a simultaneously presented pure tone, as Sutton (1985) had found previously but Kemp and Chum (1980) had not. The mixture of enhancement and suppression of the TEOAE at frequencies quite unrelated to the tone was an unexpected and entirely secondary finding. To explain our results, we proposed that the TEOAE might be composed of significant quantities of intermodulation distortion energy, generated by interactions between the spectral components of the stimulus click at a continuum of places along the cochlea. In such a proposal, the addition of a pure tone would reduce the click-evoked basilar membrane vibration at, and basal of, the characteristic place of the tone, thereby reducing the amount of intermodulation energy produced at that place. Significant quantities of intermodulation distortion energy would still be generated by activity at other, more apical sites on the basilar membrane, and the result at any given response frequency would depend upon the precise phase relationship between the suppressed and unsuppressed energy. Such a proposal, it was noted, provided a satisfactory explanation for the results of Avan *et al.* (1993, 1995, 1997), findings which were discordant with an independent generator hypothesis (Kemp, 1986; Probst *et al.*, 1986; Prieve *et al.*, 1996). Indeed, it was Prieve *et al.* (1996) who recognized that an independent generator hypothesis for the TEOAE was inconsistent with the level-dependent nonlinear nature of the cochlea.

Ren and Nuttall (1999) have offered an alternative explanation for our findings: namely that the addition of a pure tone produces a local impedance change in the nonlinear mechanical properties of the basilar membrane. Traveling waves at frequencies below the pure-tone frequency encounter the impedance discontinuity and are reflected from the CF location of the pure tone rather than their own CF locations (Ren and Nuttall, 1999). This purportedly provides a mechanism for the observed enhancement of the TEOAE at frequencies below the tone frequency. There is no evidence in the literature, however, of reflections of traveling waves of low frequency caused by simultaneous presentation of higher frequency tones, and such an alternative explanation does not explain the fact that no suppression of the TEOAE was routinely observed at the frequency of the pure tone. Ren and Nuttall argue that suppression of the TEOAE might not be a necessary concomitant of basilar membrane suppression because under their model the component of the wave reflected from the tone CF place may be greater than that from the emission CF place, leading to either enhancement or suppression. However, in the case of suppression of the TEOAE that we were looking for, the characteristic place of the suppressor and of the response frequencies we expected to suppress were one and the same place. It is therefore immaterial which reflection dominates: if the amplitude of the click-induced basilar membrane vibration were reduced, then the TEOAE must necessarily also be reduced.

A readily examinable consequence of the Ren and Nuttall model is that if energy at frequencies below that of the pure tone is reflected from the impedance discontinuity created by the tone (so dominating the total reflected energy at those frequencies), then the group delay of such energy will

[a]Electronic mail: gyates@cyllene.uwa.edu.au

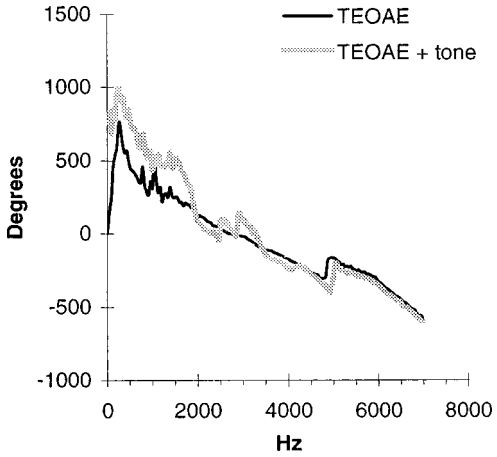

FIG. 1. Phase response data for a TEOAE recorded in response to a 0- to 7-kHz click stimulus with and without the addition of a 5 kHz tone. Phase data below ~1500 Hz is noise.

be less than for the same energy without the pure tone present (which must propagate to its own characteristic place and then back again to the stapes). The difference in group delay will be most manifest at frequencies lower than the pure-tone frequency. Thus, while we hesitate to introduce new data in a communication of this kind, we feel obliged to provide an example of previously unpublished phase data from the suppression experiments of Withnell and Yates (1998). Phase data typically showed the group delay to remain unchanged at frequencies lower than that of the frequency of the added pure tone: Fig. 1 provides an example for the TEOAE in response to a 0- to 7-kHz click, with and without the addition of a 5-kHz pure tone [corresponds to Fig. 1 of Withnell and Yates (1998)]. In fact, Fig. 1 shows no change in the group delay of the TEOAE across the frequency range of the stimulus following the addition of the 5-kHz pure tone.

Ren and Nuttall concede that TEOAE energy outside of the stimulus passband (above 10 kHz) in Fig. 4 of Withnell and Yates (1998) is consistent with intermodulation distortion energy contributing to the TEOAE (Ren and Nuttall, 1999), but also observe that no energy is evident outside of the stimulus passband for Figs. 2 and 3. Closer inspection of Fig. 3 in fact reveals that, with the addition of a 6-, 9-, or 12-kHz tone, there is energy in the TEOAE outside the stimulus passband (0–5 kHz). However, Ren and Nuttall (1999) argue that since the single-tone burst evoked TEOAE also shows bandpass features rather than a single frequency peak on the spectrum (Yoshikawa *et al.*, 1998), TEOAE energy outside the single-tone bandwidth is not evidence that the TEOAE is generated by the mechanism of the DP production, and so they suggest it can be concluded that TEOAE energy outside the stimulus passband may not be an indicator of DP production in the cochlea. However, the experiments of Yoshikawa *et al.* (1998), which they cite, were not carried out with pure tones but rather with cosine-modulated tones of 5-ms duration. Such stimuli have a −20-dB bandwidth of about 600 Hz, very close to, but slightly narrower than, the bandwidth of the responses reported. At center frequencies in the range 1–3 kHz, as used by Yoshikawa *et al.*, there is ample opportunity for intermodulation to occur in a ~300-Hz band. Thus, the experiments of Yoshikawa *et al.* cannot be taken as evidence for production of other frequencies by a single frequency stimulus.

Ren and Nuttall's alternative explanation for the findings of our paper (Withnell and Yates, 1998) is based on their recently reported experiments (Ren and Nuttall, 1998). In this paper, they describe their findings for the electrically evoked otoacoustic emission (EEOAE), stimulated from an extra-cochlear electrode, with the addition of an acoustical pure tone. The present letter (Ren and Nuttall, 1999) claims that the EEOAE in Ren and Nuttall (1998) was enhanced below the pure-tone frequency and suppressed above, but inspection of their figures (Ren and Nuttall, 1998) shows that the response was predominantly one of suppression at all frequencies, apart from a band of enhancement about one-half octave wide and just below the tone frequency. As we commented in our original paper, our TEOAEs were enhanced and suppressed in a far less predictable manner by a pure tone. Ren and Nuttall (1999) draw their parallel between these EEOAE findings and our TEOAE findings based on a claimed similarity between clicks being wideband stimuli and the EEOAE being obtained in response to a constant current with swept frequency across a wide frequency range. However, in a nonlinear system, the sweeping of frequency, which is essentially the presentation of a single frequency at any one time, is not equivalent to a click which presents all frequencies simultaneously.

Ren and Nuttall's (1998) basic observations are in conflict with many reports of interactions between EEOAEs and tonal acoustical stimuli (e.g., Mountain and Hubbard, 1989; Xue *et al.*, 1993; Nakajima *et al.*, 1996, 1998; Kirk and Yates, 1996), all of which report only enhancement of EEOAE responses, except for the case of electrical frequencies close to or just above the local CF of the electrode site, regardless of the frequency of the tone. Ren and Nuttall's (1998) technique would appear to approximate an injection of electrical current into the basal region of the cochlea (the delay times of the EEOAEs would support this). They show some evidence of propagation of a traveling wave from the effective site of electrical stimulation, but not such direct evidence as has been described previously (Kirk and Yates, 1994), where it was demonstrated that acoustical tonebursts could forward-mask compound action potentials generated by the electrically evoked traveling waves, and that electrically evoked traveling waves could forward-mask acoustically generated compound action potentials.

There is no doubt that acoustical tones may modulate the amplitude of EEOAEs, but little direct evidence to indicate that they change intracochlear reflection patterns of traveling waves. Recently, Kirk and Yates (1998) showed that acoustically induced vibration of the basilar membrane directly modulates the EEOAE in direct proportion to the mean open probability of mechanical-to-electrical transduction channels of outer hair cells, and have also suggested that a small shift in outer hair cell operating point could explain acoustic enhancement. Alternatively, Mountain and Hubbard have, for some time, claimed that enhancement of the EEOAE is due to release of the basilar membrane vibrations from a negative feedback loop at low frequencies. No reso-

lution of these competing explanations is yet available, but there is considerably more direct evidence for both of these suggestions than for the reflection hypothesis of Ren and Nuttall (1999).

Finally, we reported in February of this year at the Midwinter Meeting of the Association for Research in Otolaryngology (Yates and Withnell, 1998) that intermodulation distortion energy does indeed contribute to the TEOAE. Our experiments using high-pass filtered clicks demonstrated the presence of physiological vulnerable energy, not present in the original stimulus, both above and below the stimulus passband. This provides unequivocal evidence that the TEOAE is comprised of intermodulation distortion energy; indeed, we were able to demonstrate in this report that the TEOAE is predominantly comprised of intermodulation distortion energy.

PROGRAM OF

Joint Meeting

The 137th regular Meeting of the Acoustical Society of America

2nd Convention of the European Acoustics Association: Forum Acusticum

integrating the 25th German Acoustics DAGA meeting

Berlin, Germany • 15–19 March 1999

NOTE: All Journal articles and Letters to the Editor are peer reviewed before publication. Program abstracts, however, are not reviewed before publication, since we are prohibited by time and schedule.

MONDAY AFTERNOON, 15 MARCH 1999 POSTER GALLERY, 12:00 TO 6:20 P.M.

Posters from various technical sessions remain on display in the Poster Gallery

Also, the following poster sessions are scheduled:
Poster Session 1pPAe
Poster Session 1pPPb
Poster Session 1pSCb

MONDAY AFTERNOON, 15 MARCH 1999 ROOM H3010, 1:55 TO 6:20 P.M.

Session 1pAA

Architectural Acoustics: Concert and Opera Halls: Case Studies of New Halls; Opera Houses

Leo L. Beranek, Cochair
975 Memorial Drive, Suite 804, Cambridge, Massachusetts 02138-5755, USA

Jürgen Meyer, Cochair
Physikalisch-Technische Bundesanstalt, Bundesalle 100, 38116 Braunschweig, Germany

Chair's Introduction—1:55

Invited Papers

2:00

1pAA1. Acoustic design of the Tsuyama Music Cultural Hall based on the preference theory. Y. Ando, Y. Suzumura (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657-8501 Japan, andoy@kobe-u.ac.jp), and I. Yamamoto (Arch. & Env. Res. Ltd., Kobe, Japan)

The city of Tsuyama is located about 100 kilometers west of Kobe. The fundamental shape of the plan and cross sections of the hall were designed by applying the theory of subjective preference [Ando, *Architectural Acoustics* (AIP Press/Springer-Verlag, New York, 1998)]. Special attempts made in the acoustic design of this hall are: (1) a number of columns distributed in front of the walls at the audience level and on the stage: This may keep a small value of the IACC and a certain initial time delay gap between the direct sound and the first reflection, making an increase of the subjective preference for both listeners and musicians; (2) a stage enclosure with the canopy of several triangular reflectors at adjustable height for musicians, to control the preferred delay time of the reflections in performing a certain type of music; and (3) the shape of the rear wall of the stage, to control the IACC for listeners.

2:20

1pAA2. The new Konzertsaal of the KKL Center, Lucerne, Switzerland. I. Acoustics design. Russell Johnson and Eckhard Kahle (Artec Consultants, Inc., 114 W. 26th St., 9th Fl., New York, NY 10001-6812, ek@artec-usa.com)

The 1840 seat concert hall is the first of three halls that will eventually make up the Culture and Convention Center in Lucerne. It was inaugurated on 19 August 1998 to widespread critical acclaim. The hall is the home of the Lucerne International Music Festival, one of the most prestigious international festivals dedicated to symphonic music. The room will first be presented and illustrated, and an outline will be given of the basic acoustics design features such as room shape, seat count, and balcony design. Then, focus will shift to more specific acoustic design features, such as the reverberance chamber surrounding the main audience chamber, the two-part moving canopy with both horizontal and vertical reflecting surfaces, and the acoustically diffusing surface finish on most of the side wall area of the hall.

2:40

1pAA3. The new Konzertsaal of the KKL Center, Lucerne, Switzerland. II. Preliminary acoustical measurements. Eckhard Kahle, Russell Johnson, and Brian Katz (Artec Consultants, Inc., 114 W. 26th St., 9th Fl., New York, NY 10001-6812, ek@artec-usa.com)

The newly opened Concert Hall in Lucerne is the home of the International Music Festival with its extremely varied programs. Furthermore, the remainder of the year requires this hall to provide an appropriate acoustic environment for an even wider range of performances, ranging from conferences and other speech events to symphony orchestra, amplified popular music, ethnic music, and organ recitals. In a town with a population of 60 000, it will also be necessary to accommodate a varying number of audience members. For all these reasons, several elements of acoustic variability have been included in the design of the hall. During the first months of the inaugural season, the settings of the variable acoustics features of the hall were documented for each individual performance in the form of a logbook. This paper will discuss the use of the acoustical elements for selected performances taken from the ongoing log. The results of preliminary acoustical measurements and subjective listening impressions for the selected performances will be given. Furthermore, objective measurements were recorded in the hall at various stages of construction.

3:00

1pAA4. The acoustics evolution of Chicago's Orchestra Hall: A case study. R. Lawrence Kirkegaard (Kirkegaard and Assoc., Inc., 4910 Main St., Downers Grove, IL 60515)

Originally opened in 1904, Chicago's Orchestra Hall was immediately recognized as acoustically flawed due to low reverberation times, poor bass response, a crowded stage, and poor on-stage hearing conditions. In 1991, the Orchestral Association of Chicago decided to renovate and expand Orchestra Hall into a comprehensive Symphony Center for music in Chicago. The core of the project was a commitment to improve the acoustics to the extent feasible within the constraints of the site and the historic beauty of the hall. The Association contracted directly with Kirkegaard and Associates as acoustical consultants to work in parallel with the architects, Skidmore Owings and Merrill. The renovated hall reopened in the fall of 1997, with completion of acoustics work delayed until summer of 1998. The renovated hall is beautiful architecturally, and its acoustics has been gratifyingly improved. This paper describes the history and results of the remodeling. Test data as well as subjective assessments will be discussed and important acoustics lessons shared.

3:20

1pAA5. Yokohama Minato Mirai Hall. Hideki Tachibana (Inst. of Industrial Sci., Tokyo Univ., Roppongi 7-22-1, Minato-ku, Tokyo, 106-8558 Japan, tachibana@iis.u-tokyo.ac.jp) and Hiroyuki Kimura (Nikken Sekkei Ltd., Kouraku 2-1-2, Bunkyou-ku, Tokyo, 112-0004 Japan)

The Yokohama Minato Mirai Hall was planned as a complex cultural facility on the waterfront of Yokohama City and was opened in June 1998. In this building, a large concert hall with 2020 seats (mainly for symphony concerts) and a small concert hall with 400 seats mainly for chamber music are included. For the design and construction of this building, an acoustic design and research group consisting of architects, acousticians, and building engineers was set up and such various acoustic problems as room acoustics, sound insulation between rooms and facades, prevention of structure-borne sound from subway by floating floor construction, and noise reduction of the air-conditioning system were investigated by cooperative work in the group. For the acoustic design of the two halls, computer simulation based on geometrical acoustics and a 1/10 scale model experiment were performed for checking room shape and auralization studies. During and after the construction, acoustic measurements were carried out under various conditions. Before the opening, test concerts were performed with an audience, and acoustic data under occupied conditions were obtained. In this paper, the outline of the design process and the acoustic characteristics of the two halls are introduced.

3:40–4:00 Break

4:00

1pAA6. Acoustical design of the Marienkirche concert hall, Neubrandenburg. Henrik E. Möller and Tapio Lahti (Akukon Oy Consulting Engineers, Kornetintie 4 A, FIN-00380 Helsinki, Finland, henrik.moller@akukon.fi)

St. Mary's medieval gothic cathedral in Neubrandenburg, Germany, was ruined at the end of World War II. Two decades ago a decision was made to turn it into a concert hall. The design started in 1996 with the architectural competition, won by Architects Pekka Salminen. The hall will be a combination of old brick walls and mullioned windows, joined with modern glass and concrete. The back wall and the ceiling are made of glass. An audience of 1200 maximum is divided into three blocks: stalls, a balcony, and a tier behind the stage. The initial properties were promising: rectangular, 21 m wide, 18 m high, and with inherent diffusion. The

acoustical design was challenged by the restriction of not to touch the old restored side walls. A full-audience reverberation time of 2.0 s was set as a goal. Other objectives were moderate reverberation rise in bass, strong spaciousness and lateral energy. The acoustics were designed with a computer using the Odeon hall design program. Main new elements of acoustical control are a cloud array above the stage, triangular sails near the side wall cornices, and glass reflectors beside the stage. The hall is expected to be inaugurated in autumn 1999.

4:20

1pAA7. Festspielhaus Bayreuth—The unique acoustic situation. Karlheinz Müller (Müller-BBM, Robert-Koch-Str. 11, 82152 Planegg b. Munich, Germany)

The Festspielhaus in Bayreuth is the only opera house of the world which was founded and mostly designed by a composer. Richard Wagner himself founded the festival society and was one of the main designers of the opera house, the stage situation, and the pit. It is a very modern opera house, far away from the typical aristocratic or common theater of the times of 1876. The open house has a special acoustic situation. What are the reasons for this acoustic situation? Especially the sunken-pit design is subject to endless controversial discussions. All the maintenance work of the last years had the priority not to destroy the typical mysterious sound of the original Festspielhaus. Although all part of the whole house are now redecorated, the typical Wagnerian sound has been perfectly conserved.

4:40

1pAA8. Acoustics of opera houses: A cultural heritage. Patrizio Fausti, Roberto Pompoli, and Nicola Prodi (Dip. di Ingegneria, Univ. di Ferrara, via Saragat 1, 44100 Ferrara, Italy, pompoli@ing.unife.it)

An important part of contemporary Italian musical culture has developed inside historical opera houses. An outstanding opera repertory was especially conceived to match these places, both from the architectural and the acoustical points of view. But, while extensive attention is devoted to architectural and historical aspects, the acoustical characteristics of an opera house, that is, the set of listening attributes which make such a place unique among all spaces for music, are still nowadays hardly recognized as being paramount. In fact they can be rightly considered a relevant cultural heritage in Italy and can thus be called acoustical heritage. This new kind of heritage calls for accurate study and attention, both from the scientific and social points of view. To preserve the heritage for future generations, it is necessary to know it precisely and to elaborate means of accurate description. A project with the participation of international specialists has been established to agree on a standardized procedure for acoustic measurements specific to Italian historical opera houses in order to investigate the pecularity of these places. The aim of the project is to give a state-of-the-art acoustic documentation fo some theaters with the possibility of later applying up-to-date acoustical analysis.

5:00

1pAA9. New subjective and objective data on 20 opera houses of the world. Leo L. Beranek (975 Memorial Dr., Ste. 804, Cambridge, MA 02138-5755) and Takayuki Hidaka (Takenaka Res. and Development Inst., Chiba, 270-1395, Japan)

Acoustical measurements have been made in opera houses of Europe, Japan, the United States, and Argentina using the same equipment: dodecahedron loudspeaker, stretched impulses, and monaural and binaural sensing devices. The measuring positions were 3 on-stage and 2 in-pit for sources, and 8 to 17 in audience areas for sensors. Quantities measured as a function of frequency were reverberation time RT, early decay time EDT, clarity C80, deutlichkeit D, time gravity Tg, early to reverberant energy ratio as a function of cutoff time $C(t)$, strength G, interaural cross correlation IACC, IACCE, and IACCL, stage support ST1 and ST2, initial-time-delay gap ITDG, and reflectograms. International opera conductors were contacted by mail to rate 20 opera houses, with satisfactory responses. An attempt is made to correlate the objective data with the subjective ratings. Early results indicate that IACCE3 and ITDG are definite indicators. Others seem important in a certain type of opera house.

5:20

1pAA10. Acoustic considerations in the redevelopment of the Royal Opera House, London. Rob Harris (Arup Acoustics, Parkin House, 8 St. Thomas St., Winchester, Hampshire SO23 9HE, UK)

The Royal Opera House, Covent Garden is currently closed for a major redevelopment. It is scheduled to re-open in December 1999 with a refurbished and extended main auditorium, a studio theater seating 400, major new ballet studios and facilities for the Royal Ballet, new and refurbished opera and chorus rehearsal rooms, and a completely new backstage, with full wagon facilities and a double height flytower. This paper discusses the acoustic philosophy behind the design and reports the design solutions and the progress on site to date. Matters of particular interest include the approach to the preservation/enhancement of the acoustic of the main house, the dynamics of the ballet studios, the exceptionally large and complex acoustic scenery doors and the acoustic variability incorporated into the studio theater, which is a box-in-box construction.

5:40

1pAA11. Acoustic quality in the Theatre ''Palafenice,'' Venice. Lamberto Tronchin (DIENCA-CIARM, Viale Risorgimento 2, 40136 Bologna, Italy)

The burning of the Teatro La Fenice, in Venice, has also been a tragedy for the acoustical community. The Municipality of Venice decided to build a tense-structure (called PalaFenice) on the isle of Tronchetto, as a temporary auditorium for operas and concerts. The use of such a structure provokes many different acoustic problems, quite different from those already known to musicians at La Fenice. In this paper the acoustic quality of the theatre has been analyzed, and compared to the acoustic measurement already

performed in the former La Fenice theatre. Binaural measurements have been performed in the hall using the impulse response technique (including absorption of the ceiling), and a dummy head located at different listening positions. According to ISO 3382, many acoustic parameters have been evaluated, like listening level, ITDG, reverberation time, IACC, and others, and their values have been mapped. Also, Ando's quality maps of preferences, with reference to two different kinds of musical signals, was accomplished from experimental measurements. The measurements pointed out an unsuitable behavior of the structure at low frequency and low reverberation time and intelligibility in the hall. Finally, an hypothesis of the acoustic chamber has been formulated.

6:00

1pAA12. Orchestra shells: Acoustical and practical design considerations. Daniel E. Commins (commins acoustics workshop, 15, rue Laurence Savart, F-75020 Paris, France and 350 Fifth Ave., New York, NY 10118, comminsacoustics@compuserve.com)

A hall or an outdoor facility is rarely used for a single type of artistic program. Often, it is necessary to design an orchestra shell that transforms theoretically a theatre or an opera house into a concert hall. The acoustical criteria for opera or concerts are quite different; the design of an orchestra shell that would create proper acoustical conditions on stage for the musicians and in the hall for the audience can be quite complex. The larger the hall and the proscenium opening, the harder it is to come up with an adequate solution. The major problems are the following: architecture and aesthetics, acoustical efficiency, ensemble conditions, acoustic response, diffusion, size, weight, transformation time, and storage. Some progress has been made over the last few years, but the problem remains complex. This paper will attempt to explain the design and construction process and will provide recent examples of small and large shells: Ravinia, Lille concert hall, Gradignan, Porto Teatro S. João, Opera Garnier in Paris, Staatsoper in Munich, and Serralves auditorium in Porto.

Contributed Posters

The following posters will be on display in the Poster Gallery from Monday to Wednesday, 15–17 March. Contributors will be at their posters from 10:00 a.m. to 12:00 noon on Wednesday, 17 March.

1pAA13. Acoustical modifications of the interior design of a 50-ft chapel. Catherine Sémidor and Emmanuel Merida (ERIAC Ecole d'architecture et de paysage de Bordeaux Domaine de Raba, 33405 Talence Cedex, France, catherine.semidor@bordeaux.archi.fr)

In order to organize congresses, the University of Sciences in Bordeaux has bought a building with a chapel which will be modified to become both a lecture room and a place for music entertainment with a small orchestra. This paper deals with an interdisciplinary study from the acoustical inventory to the proposition of the new interior design, realized simultaneously by the acoustician team, the architect, and the university. The place, a church, is notable for its high reverberation time. Given this characteristic, a modified MLS software permitting measurements in such halls was tested. The numerical simulation was ajusted from the room-acoustics measured criteria. This reliable model became the base of the study to validate the architectural choices leading to the ''right acoustics'' for the ''right place.'' Among several acoustical solutions, the one presenting the more practical application was chosen. The design concept developed for this hall actually permits a variable acoustics to achieve the right level of reverberance for music and good speech clarity for lectures. The results of measurements carried out in the newly opened chapel will be compared with the computed criteria of the last model.

1pAA14. The acoustical properties of large studios. Bojan Ivancevic, Hrvoje Domitrovic, and Sinisa Fajt (Faculty of E. E. and Computing, Dept. of Electroacoustics, Unska 3, HR-10000 Zagreb, Croatia, bojan.ivancevic@fer.hr)

New studios for Croatian Radio-Television were planned with the starting user conditions. The background noise level must fulfill $N15$ or $N20$ criteria. Demanded reverberation time for a 400 m^2 radio studio is $Tr=0.6$ s, for TV studios of the same area, $Tr=0.7$ s, and for the 1000 m^2 TV studio, reverberation time is 1 s. Since all three studios with built-in control rooms were built in an urban area with excessive noise, it was necessary to obtain very good protection against noise, and at the same time, using the same elements, achieve the desired reverberation time. Special attention was given to flutter echoes and achievement of diffuse sound fields. The inner shell construction was built up using special acoustical building blocks. Besides using double walls, the broad analysis was done in order to avoid any possible problem in sound insulation. The achieved coincident frequency for walls and floors is 7.6 Hz, and this is quite satisfactory. The computer simulation was used during the design of internal sound-absorbing and reflecting surfaces. Described solutions take care of all user demands, as well as the usage particularities of such spaces. The measurements of relevant acoustical parameters were done after the building was finished.

1pAA15. The sound quality of the Teatro Comunale in Treviso, Italy. Lamberto Tronchin (DIENCA-CIARM, Viale Risorgimento, 2 40136 Bologna, Italy)

The Teatro Comunale of Treviso was designed at the same time as the Teatro La Fenice of Venice, in the middle of the 19th century. Treviso being so close to Venice, the reputation of the Venetian Theatre, just rebuilt after the burning of 1836, influenced the municipality of this little town, which decided to design the Theatre with the same shape as la Fenice. After the burning of 1996, and following the disappointment of losing such unique architecture and sound quality, acoustical measurements were performed in many Italian theatres, especially in historic theatres where acoustical measurements were never before undertaken. In this paper, the results of the acoustic measurements are presented. According to ISO 3382, binaural measurements, with a dummy head, have been performed in 25 positions in the hall, with different positions of the sound source in the proscenium. Acoustical parameters, such as EDT, G, LE were calculated from the impulse responses and mapped. Also, Ando's quality maps of preferences, with reference to two different kinds of musical signals, were accomplished from experimental measurements. From the measurements, a good behavior of the theatre has been pointed out, even if some limitations in some positions have been discovered.

1pAB1. ''Internal spectra'' in the dolphin's auditory system obtained by a minimal-masking technique. Alexander Ya. Supin and Vladimir V. Popov (Inst. of Ecology and Evolution, Russian Acad. of Sci., 33 Leninsky Prosp., 117071 Moscow, Russia)

To understand signal processing in the auditory system, it is of importance to know the ''internal spectrum'' representations of test stimuli, i.e., profiles of excitation along the frequency-representation axis. Such profiles may be obtained using a ''minimal-masking'' technique: An excitation profile is reflected by a masking curve (masker level dependence on frequency) when a masking criterion is not the threshold response to the probe stimulus but the threshold masking effect—a very small standard decrease of the probe response. The dolphin's auditory system provides good opportunities for such measurements because of the large amplitude and high consistency of the auditory brain-stem-evoked potentials (ABR). Minimal-masking curves were obtained in bottlenosed dolphins for various probe stimuli: narrow-band, rectangular, and rippled spectrum stimuli. At low stimulus levels, the profiles reproduced the stimulus spectrum well, except for a little wider bandwidth; this widening corresponded to the bandwidth of peripheral auditory filters. Stimuli with rectangular spectra evoked excitation profiles with enhanced edges, thus indicating enhancement of spectral contrast by lateral effects. Stimuli with rippled spectra evoked profiles reproducing ripples; however, edge ripples were also markedly enhanced. At high stimulus levels, all stimulus types evoked excitation profiles markedly expanded to high frequencies, far beyond the stimulus bandwidth.

1pAB2. Effect of removing physiologically relevant sound-localization parameters on tuning properties of barn owl tectal neurons. Hermann Wagner, Iris Poganiatz (Inst. Biologie II, RWTH Aachen, Kopernikusstrasse 16, D-52074 Aachen, Germany), Israel Nelken, and Gilad Jacobson (Hebrew Univ., Ein Karem, Jerusalem 91120, Israel)

Barn owls use the interaural time difference (ITD) for locating sounds in azimuth and the interaural level difference (ILD) for locating sounds in elevation. Neurons in the optic tectum have spatially restricted receptive fields. Recently, Keller *et al.* [Hearing Res. **118**, 13–34 (1998)] have demonstrated that the spatial patterns of responses were almost indistinguishable in response to virtual [stimuli filtered with head-related transfer functions (HRTFs)] and to free-field stimulation in neurons of the inferior colliculus. The inferior colliculus provides input to the optic tectum. The spatial restriction of tectal neurons is mainly due to their sensitivity to ITD and ILD. This paper deals with the effect of removing ITD and/or ILD from the virtual stimuli on the tuning of tectal neurons. HRTFs of two barn owls were recorded, and noise stimuli with ITDs, ILDs, filtered with HRTFs, filtered with HRTFs but containing no ITDs, and filtered with HRTFs but without ILDs were used in the experiments. Preliminary results suggest that removal of ITDs or ILDs caused a substantial loss of spatial tuning in tectal neurons. These results support earlier findings that suggested an essential role of the tectal neurons in sound-localization behavior. [Work supported by GIF.]

2:40

1pAB3. Temperature effects on the auditory system: An amphibian case history. Peter M. Narins (Dept. of Physiological Sci., Univ. of California, Los Angeles, 405 Hilgard Ave., Los Angeles, CA 90095)

The inner ear of anurans is unique in that it contains three organs specialized for sound reception. The amphibian papilla (AP), the basilar papilla (BP), and the saccule (S) are anatomically distinct, spatially separate organs each with its own complement of sensory hair cells and overlying tectorial structure. The BP and portions of the AP respond exclusively to airborne sounds, whereas other portions of the AP and the S exhibit sensitivity both to airborne sounds and to substrate-borne vibrations. Measurements from the auditory periphery of *Rana pipiens pipiens* suggest that in contrast to BP fibers, AP fiber tuning is highly temperature-dependent. Moreover, hair cells from the rostral AP and S exhibit a clear temperature dependence in their intracellular current step response, unlike caudally located AP and BP cells. Finally, spontaneous otoacoustic emissions, which presumably reflect hair cell motility, are highly temperature-dependent despite the fact that the upper portion of the emission frequency range (600–1600 Hz) corresponds to the domain of the BP. A model is presented that attempts to reconcile these disparate results. [Work supported by NIDCD Grant No. DC-00222.]

3:00

1pAB4. Lateral inhibition in frequency tuning of central auditory neurons. Philip H.-S. Jen (Div. of Biological Sci., Univ. of Missouri, Columbia, MO 65211, pjen@biosci.mbp.missouri.edu)

Previous studies have shown that frequency tuning curves (FTCs) of auditory neurons in the inferior colliculus (IC) are composed of an excitatory area that is either neighbored by an inhibitory area on one flank or is sandwiched by two inhibitory areas. Neurons that are responsible for excitatory and inhibitory areas are likely neighboring neurons. Whereas this neural lateral inhibition sharpens frequency tuning and provides a means to reduce ambiguity in encoding frequency at high stimulus intensities, neurons with two-flank lateral inhibitory areas have larger Q_n values and smaller excitatory areas than neurons with one-flank inhibitory areas. The closer the inhibitory area is to the excitatory area, the sharper the frequency tuning becomes. The Q_n values of IC neurons tend to increase with the ratio of inhibitory area to excitatory area. Application of bicuculline and/or strychnine broadens FTCs of many IC neurons and completely or partially abolishes the inhibitory areas. Corticofugal pathways sharpen the FTC by narrowing the excitotory area and broadening the lateral inhibitory areas. [Work supported by NSF.]

1pAB5. Paradoxical lateral suppression in the dolphin's auditory system. Vladimir V. Popov and Alexander Ya. Supin (Inst. of Ecology and Evolution, Russian Acad. of Sci., 33 Leninsky Prosp., 117071 Moscow, Russia)

A paradoxical phenomenon was found in the auditory system of dolphins: weak sounds suppressed the brain-evoked potential responses to much stronger sounds. This occurred when the brain-evoked potentials were elicited by rhythmically amplitude-modulated sounds at modulation rates from a few hundred to more than a thousand Hz. The rhythmic-evoked response (the so-called envelope-following response) was markedly suppressed by addition of another sound of higher frequency and down to 40 dB lower intensity than the amplitude-modulated stimulus. This phenomenon was called the paradoxical lateral suppression. Only the sustained rhythmic response was a subject of this suppression, while the transient on-response to the stimulus onset was not suppressed, thus indicating that the suppression influenced the ability of evoked potentials to follow rapid amplitude modulations. At certain conditions the paradoxical lateral suppression prevents weak sounds from being masked by stronger ones. When a complex sound consists of two carriers—a higher-level, lower-frequency and a lower-level, higher-frequency, the paradoxical lateral suppression results in that evoked responses follow modulation of the weaker carrier, not the stronger one. It may help a dolphin to perceive weaker echo signals in the background of stronger emitted pulses.

3:40

1pAB6. Analysis of the role of inhibition in shaping responses to sinusoidally amplitude-modulated signals in the auditory system. George D. Pollak (Dept. of Zoology, Univ. of Texas, Austin, TX 78712)

Neurons in the inferior colliculus (IC) typically respond with phase-locked discharges to low rates of sinusoidal amplitude modulated (SAM) signals and fail to phase-lock to higher SAM rates. The hypothesis that these properties are shaped by the integration of phase-locked excitation and inhibition, as they are in lower nuclei, was tested. Responses were recorded from IC neurons evoked by SAM signals before and during the iontophoretic application of bicuculline, a competitive antagonist for $GABA_A$ receptors, strychnine, a competitive antagonist for glycine receptors, and the $GABA_B$ receptor blocker, phaclofen. The hypothesis that inhibition shapes responses to SAM signals in the IC was not confirmed. In more than 90% of the IC*c* neurons tested, the range of SAM rates to which they phase-locked was unchanged after blocking inhibition with bicuculline, strychnine, or phaclofen, applied either individually or in combination. These results illustrate that the same response property, phase-locking restricted to low SAM rates, is formed in more than one way in the auditory brainstem. In lower nuclei, the mechanism is coincidence of phase-locked excitation and inhibition, whereas in IC the same response feature is formed by a different but unknown mechanism. [Work supported by NICD.]

4:00

1pAB7. Measurement of impulse noise-induced temporary threshold shift in endangered and protected animals—Two case studies. Ann E. Bowles, Larry Wolski, Erik Berg, and Pamela K. Yochem (Hubbs-Sea World Res. Inst., 2595 Ingraham St., San Diego, CA 92109, annb1@san.rr.com)

Sonic booms at levels typical for supersonic airlines (<3 psf) are considered harmless to hearing based on laboratory studies. However, data on laboratory animals are difficult to generalize to other species. Wildlife present a particular problem because experimental efforts to induce permanent threshold shift (PTS) cannot be conducted for ethical or management reasons. Instead, ''significant'' temporary threshold shift (TTS) has been proposed as a conservative damage risk criterion (DRC). With this in mind, two series of experiments were conducted using simulated *N* waves at levels up to 6 psf, rise time down to 0.4 ms, and 100- or 300-ms duration—one on seals and sea lions and a second on the desert tortoise. Level of the least-detectable auditory brainstem response (ABR) was used to estimate best sensitivity before and after exposure. Small immediate threshold shifts ($\sim$5 dB) were detected in pinnipeds and larger ($\sim$20 dB) shifts in desert tortoises. The greater impact on desert tortoises may be explained by their greater best sensitivity at low frequencies. No PTS was detected. Thresholds for TTS were therefore detected in both species and may be useful in establishing DRCs for animals. [Work supported by NASA, Contract No. NAS1-20101 and USAF, Contract No. F33615-89-D-4003.]

1pEA1. Factors in the performance of systems for the production of virtual acoustic environments. P. A. Nelson, O. Kirkeby, Y. Kahana (Univ. of Southampton, Southampton SO17 1BJ, England), and H. Hamada (Tokyo Denki Univ., Tokyo, Japan)

This paper will describe recent progress in the development of systems designed to present, at the ears of a listener, the signals necessary to produce the illusion in the listener of the existence of a ''virtual'' source of sound. Attention will be restricted to systems which use a relatively small number of loudspeakers whose input signals are determined by optimal processing of the signal to be associated with the virtual source. It will be demonstrated that the form of the sound field produced is crucial to the success of such systems. Emphasis will be given to a system that uses two very closely spaced loudspeakers to transmit a particular form of sound field which most easily produces the iteraural time delay associated with a given virtual source position. Results will be presented of subjective experiments and of numerical simulations of the sound field. Factors determining the system performance will be discussed, particularly with regard to front–back confusions and individual differences in head related transfer functions. It will also be shown that systems using four louspeakers can significantly reduce the degree of front–back confusion even when assuming a relatively simple model of the listener's HRTF.

2:20

1pEA2. Creating virtual surround using dipole and monopole pressure fields. John W. Norris (Harman Multimedia, Harman Intl., 8500 Balboa Blvd., Northridge, CA 91329)

The objective of virtual 3-D sound technology is to convey to the listener an accurate impression of an acoustic environment. This is accomplished by conveying a realistic directional impression of sounds. Most of the successful techniques for doing this are based on the head-related transfer function (HRTF). In this paper a new method that creates the desired pressure field using dipole and monopole pressure fields will be presented. The object is to recreate locally the pressure field an actual sound source would produce, in a neighborhood of the listener's ears. One of the drawbacks of using HRTF's is that they have the pinna characteristics of the ears used to make the measurement, and so introduce the associated notches and peaks into the transfer function. The listener then has to ''in effect'' listen through these ears. And as pinna characteristics vary widely between individuals, the introduced notches and peaks associated with the measured pinnas may not correlate with the listener's. Thus by approximating the pressure field in the neighborhood of the ears, it is no longer necessary to create artifical peaks and notches in the transfer functions.

2:40

1pEA3. Spatial sound reproduction with wave field synthesis. Marinus M. Boone and Diemer de Vries (TU Delft, Lab. of Acoust. Imaging and Sound Control, P.O. Box 5046, 2600 GA Delft, The Netherlands, rinus@akst.tn.tudelft.nl)

Wave field synthesis is a reproduction technique developed at TU Delft, that enables the generation of high-quality three-dimensional spatial sound fields. The benefit of the method is that spatial impressions are highly independent of the position of the listeners within a large listening area. In short, the method uses a limited number of audio channels that are reproduced by generating plane and spherical wave fields with arrays of loudspeakers that surround the listening place. Applications include spatial sound reproduction in the home and in cinemas, sound reinforcement in theaters, teleconferencing with large video screens, and variable acoustics.

3:00

1pEA4. Comparison of virtual sound source positioning with amplitude panning and Ambisonic reproduction. Holger Strauss and Jörg Buchholz (Inst. of Commun. Acoust., Ruhr-Univ. Bochum, D-44780 Bochum, Germany, strauss@ika.ruhr-uni-bochum.de)

Different kinds of panning algorithms can be applied to render virtual sound sources in pantophonic or periphonic loudspeaker setups. One popular method is constant energy amplitude panning, where only the loudspeakers nearest to the virtual sound source are used for sound reproduction. Another well established reproduction method is Ambisonics, which uses the spherical harmonics theory in combination with knowledge from psychoacoustics to render virtual sound sources by simultaneously using all loudspeakers in a setup. Technical details and background information on both algorithms are given, and technical implementation issues (e.g., required computational effort) are discussed. A series of psychoacoustic listening tests was performed to evaluate virtual sound source localization with both reproduction methods for a six-loudspeaker pantophonic and an eight-loudspeaker periphonic setup. Localization accuracy and the subjects' reaction time were measured. The results show that the localization blur does not depend on the virtual sound source position for Ambisonics, while amplitude panning causes a high localization blue for virtual sources between the loudspeakers and a low localization blur for images close to the loudspeakers. Similar results were found in tests carried out to ascertain how dependent the reaction time is on the virtual sound source position.

3:20

1pEA5. Modification of electrodynamic loudspeakers for 3-D spatialization. E. Grigori Evreinov and V. Alexander Agranovski (Lab. for DIIS, Specvuzavtomatika Design Bureau, 44/5-13 Lenin St., 344038 Rostov-on-Don, Russia, asni@ns.rnd.runnet.ru)

The modification of electrodynamic loudspeakers was developed on a separation base of management cues by spatial and acoustic sound attributes. A loudspeaker has a single diaphragm and segmented surround, because a diaphragm embodiment in a kind of several adjacent parts evokes the losses and distortions at a sound reproduction of low frequencies. Surround's segments have an electrical control by their mechanical properties (a density). It allows the regulation of a velocity of the diaphragm fluctuations in appropriate zones. Thus a redistribution of a sound pressure (or of an acoustic energy) in the near-field or in the immediate neighborhood of pinna occurs according to the changes of spatial coordinates of sound objects. Offered construction provides a spatial localization of sound objects in the near field, even with using a single loudspeaker.

3:40

1pEA6. Sound focusing in reverberating rooms: The time-reversal approach. Sylvain Yon, Christian Dorme, and Mathias Fink (Lab. Ondes et Acoust., Univ. Paris VII/E.S.P.C.I., U.M.R. C.N.R.S. 7587, 10 rue Vauquelin, 75231 Paris Cedex 05, France)

Time reversal is already known as an efficient ultrasonic method to focus through inhomogeneous or multidiffusive media. The presence of pointlike reflectors in these media allows applications of this technique in fields like nondestructive testing, medical imaging, or underwater acoustics. An extension of this technique in audible range acoustics is presented. An array of 70 microphone/loudspeaker couples is used to refocus sound inside of a reverberating room. At a desired focal point, directivity patterns are measured and compared with those obtained by focusing with a cylindrical beamforming technique through the same antenna. Time reversal is shown to strongly improve the focal spot pattern (beamwidth and sidelobes level). These results are related to the ability of time reversal to compensate for reverberation and scattering induced in the studied room. The process acts as a spatio-temporally matched filter to the propagation transfer function of the desired focal point through the room. It makes this technique an auto-adaptive focusing system to a random 3-D cavity. Theory, experimental results, and future applications will be described.

4:00–4:20 Break

4:20

1pEA7. Algorithm for the design of broadband, constant-beamwidth, point-element linear arrays with constant sidelobe level. Joseph B. Gaalaas and Elmer L. Hixson (Dept. of Elec. and Comput. Eng., Univ. of Texas, Austin, TX 78712)

An algorithm has been designed that allows one to calculate the individual element weights, as a function of frequency, required to achieve specified values of sidelobe level and half-power beamwidth. The arrays considered had linear geometry and an odd number of evenly spaced, point elements. The input parameters are the sidelobe level, half-power beamwidth, and the number of elements. For different values of the input parameters, the bandwidth that produced realizable solutions was determined numerically. Upon choosing values for the input parameters that yield realizable solutions, the weighting functions for each element are determined by an explicit calculation. An array may be combined with a scaled version of itself to increase the bandwidth. The element weights for an octave bandwidth broadside array were calculated using this algorithm and this array was combined with a scaled version of itself to extend the bandwidth to two octaves. Microphone and loudspeaker arrays based on these calculated weights were implemented with a digital signal processor. Measurements of the directivity patterns in an anechoic room were compared to the desired directivity patterns to assess the design procedure. [Work supported by NSF Graduate Research Fellowship and Uniden Endowed Thrust 2000 Fellowship.]

4:40

1pEA8. A sound transducer with a flat, flexible diaphragm working with bending waves. Daniela L. Manger (Manger Products, Industriestr. 17, D-97638 Mellrichstadt, Germany)

From the time of the idea to the finally working sound transducer, a period of over 20 years was necessary. The time has been needed for development and research in manufacturing and materials. It took a long time until new synthetic and magnetic materials were available with their best fitting mechanical behaviors. Nowadays it is possible to present a wideband sound transducer working from 100 Hz up to 35 kHz. It follows time precise without any mechanical energy storage the incoming signal. The special structure of the flat and flexible diaphragm works concentrically only with bending waves. A simple mechanical model, theoretical equations and measurements will be presented in comparison to the omnipresent Rice–Kellogg piston loudspeaker. The advantages in perception and hearing will be shown with regard to physiological behaviors of the hearing sense.

5:00

1pEA9. FEM simulations of horn loudspeakers and their experimental verification. Armin Jost and Reiner Kressmann (Inst. for Electroacoustics, Merckstr. 25, D-64293 Darmstadt, Germany, kre@uet.tu-darmstadt.de)

Horn loudspeakers are in common use for sound reinforcement of large rooms because of their high efficiency. In the design of horn loudspeakers, special care has to be taken on the horn's geometry and its interaction with the properties of the driver. In the present work, the finite-element analysis of these coupled acoustical–mechanical systems is compared with classical analytical and finite-difference methods. All simula-

tions are compared with experimental data, obtained from two different horn loudspeakers: First, a folded bass cabinet transducer and, second, a midrange horn loudspeaker. The bass cabinet is 50×54×104 cm in size; the midrange horn measures 40×44×44 cm. Both cabinets are made from wood; therefore, the horn's geometry can only be approximated to the ideal exponential characteristics. In general, the effect of finite horn length, resulting in reflections at the mouth due to mismatch in acoustical impedance, has to be considered. The bass horn, especially, has to be simulated very precisely, since this loudspeaker shows higher impedance mismatch. The finite-element simulations carried out with ANSYS show excellent agreement with the measurements. The sound-pressure level generated was investigated as a function of frequency and angle of radiation.

5:20

1pEA10. New numerical simulation tool for the design of electromagnetic transducers. Michael Schinnerl, Hermann Landes, Manfred Kaltenbacher, Reinhard Lerch (Dept. of Elec. Measurement Technol., Univ. of Linz, Altenbergerstr. 69, A-4040 Linz, Austria, michael.schinnerl@jk.uni-linz.ac.at), and Joachim Schöberl (Univ. of Linz, A-4040 Linz, Austria)

Due to the high geometric complexity and the interaction of different physical field types, like mechanical displacement, acoustic pressure, and magnetic induction, the design of electromagnetic transducers is a challenge for the developers. Since the fabrication of prototypes and experimental-based design is a lengthy and costly process, needs for appropriate numerical simulation tools arise. In this paper, a simulation program is presented which is especially adapted to multifield problems like the one described above. First, the description of the underlying physical fields (acoustic, mechanical, and magnetic) with partial differential equations (PDE) and their coupling is reported. The solution of these PDEs is based on either finite-element methods (FEM), boundary-element methods (BEM), or coupled FE-BE methods, depending on the considered problem type. However, these numerical techniques yield to long computer time, especially in the 3-D case. Therefore, a multigrid solver has been developed which enables considerably faster solutions of the presented numerical tasks. Finally, two application examples, the calculation of an EMAT (electromechanical acoustic transducer) in transmitting and receiving mode and the prediction of the sound field of a vibrating machine part, show the reliability of the simulations.

5:40

1pEA11. Determination of structure of the NARMAX model for dynamic loudspeaker using the orthogonal algorithm. Piotr Pruchnicki and Andrzej Dobrucki (Wroclaw Univ. of Technol., Inst. of Telecommunications and Acoust., Wyb. S. Wyspianskiego 27, 50-370 Wroclaw, Poland)

NARMAX is a general method for modeling of nonlinear systems. In the paper, an application of this method for modeling of nonlinearities in dynamic loudspeakers is presented. In most cases, a polynomial representation of the NARMAX model causes an ill-conditioned equation system which indicates that the use of orthogonalization is necessary to solve the system. The high number of coefficients is the main disadvantage of the NARMAX method, and it results in an erroneous model, and an algorithm for identification of coefficients that is noneffective. A modification of the orthogonal algorithm (classical Gram–Schmidt) is presented. It is based on the premise that the coefficient providing the highest error reduction ratio is chosen in every step of the algorithm. The creation of the model stops when the given accuracy is achieved. This way leads to the choice of only the most significant coefficients. The work and effectiveness of this modified algorithm for systems with given nonlinearities at different levels of accuracy of the model are presented in the paper.

6:00

1pEA12. A proposal to adopt Maxwell distribution as a measure of acoustic field diffuseness in a reverberation room. Matias Han, W. Budhiantho (Dept. of Elec. and Computer Eng., Satya Wacana Christian Univ., Jl. Diponegoro 52-60, Salatiga 50711, Indonesia), and Elmer L. Hixson (Univ. of Texas, Austin, TX 78712)

The existence of an acoustic velocity vector resultant field which follows Maxwell distribution in a reverberation room indicates 3-D diffuseness of the field. Therefore, Maxwell distribution is a better measure for the sound-field diffuseness than Gaussian distribution given by the acoustic pressure in the same room that does not have a directional information. A Gaussian distributed pressure field does not always give a satisfactory diffuseness. The acoustic velocity vector resultant was measured using total energy density sensor. Theoretical and experimental investigations are given to support this proposal.

1pED1. Acoustics education in France: Past, present and future. B. Hamonic (bernard.hamonic@eurobretagne.fr)

Acoustics is the science of sound. The interdisciplinary nature of acoustics implies the broad scope of acoustics education and the necessity to teach it at various levels of the student education, from high school to Ph.D. In the 1960s acoustics was not an important part of the French education system. Progressively teaching acoustics at a higher education level became natural and, in the 1990s, France was the only country to give a diploma between six and eight years after the secondary studies leaving certificate (Bac in french). The quality of this diploma was directly related to the emergence in France of research teams specialized in acoustics. Teaching acoustics at a secondary level came into effect only in 1994 for senior high school students. This presentation will first summarize the current acoustics education system in France with its characteristic in secondary education (senior high school) and higher education, univerities (first, second, and third cycle), engineering schools (French typcial system), etc. The future of acoustic education seems directly related to computer-based courses, the emergence of videotapes and videodiscs demonstration experiments, internet communication, etc. Reflection toward teaching acoustics in France in the future will then be addressed.

2:20

1pED2. Survey of the university institutions teaching acoustics in Poland. Edward Hojan (Inst. of Acoust., Adam Mickiewicz Univ., PL-60-769 Poznań, Matejki 48/49, Poland)

Higher education in Poland is either state owned or private. The total number of students in the institutions of higher education at the university level amounts to 630 000, which makes 15 students per 1000 citizens. As a rule, the education provided by state-owned schools is free. Among the state-owned educational institutions, presently in Poland, there are 13 universities, 18 technical universities, 8 musical academies, and 12 medical academies in which acoustics (or only psychoacoustics) is learned at selected branches of the studies The subject of acoustics is not provided in private schools. In this survey a directory of schools will be given with the details of studies where acoustics is available, including the numbers of students, hours, and the topics taught in the lectures and tutorials.

2:40

1pED3. Acoustics education in the Low Countries. Adrianus J. M. Houtsma (IPO, P.O. Box 513, 5600 MB Eindhoven, The Netherlands)

This presentation is an overview of acoustics education programs found at universities and professional colleges in the Netherlands and Flanders. As has happened in many other academic areas, the traditional organization of educational programs along disciplinary lines has to a large extent made a place for an organization based on application areas. In university programs on acoustics, one finds clusters of specialized subjects that seem to be typical for schools or departments, such as audiology, audiometry, and speech therapy in medical schools, phonetics, music, and speech in humanities departments, and architectural acoustics, noise control, imaging, and fundamentals in applied sciences or engineering departments. Several professional colleges offer courses that are focused on measurement techniques, insulation properties of materials, and noise control in buildings and structures. A fundamental and broad treatment of acoustics, followed by a treatment of specialized applications in the areas of noise control engineering, architectural acoustics, or electroacoustics as elective options, is found in the Advanced Acoustics Course, organized by the Dutch and the Belgian acoustical societies and taught annually in Antwerp.

3:00

1pED4. State and trends of acoustics education in Germany. Peter Költzsch (TU Dresden, Dept. of Elec. Eng., Inst. of Tech. Acoust., Mommsenstraße 13, D-01062 Dresden, Germany, peter.koeltzsch@iname.com)

An overall view of the state of the education in the field of acoustics in Germany, Austria, and Switzerland is given in ''Guide to Acoustics Studies'' (2nd ed., July 1998, edited by DEGA). In Germany, acoustics is taught at 63 institutes (23 universities, 16 universities of technology, and 3 universities for music, art film, or television). In connection with education, the following problem

is of great interest: How is the discipline of acoustics integrated into the traditional faculties of German universities? The present state is: integration of acoustics in mechanical, electrical, environmental engineering *et al*. On the other hand, a characteristic problem also is the existence of a ''strong'' acoustics institute at a university with a considerable research and education potential and, on the other hand, smaller special acoustics research and education capacities in all those scientific disciplines in which acoustics plays an important role. Here the question emerges whether it is more expedient for the development of acoustics to ''keep'' so-called ''acoustics pets'' in several faculties or to found a central acoustics institute to satisfy all requirements at the institutes and at the university in all. However, into which faculty should this ''acoustics institute'' be integrated then?

3:20

1pED5. Acoustics education in Ukraine. Stanislav M. Mayevskyy and Leonid M. Gelman (Dept. of Nondestructive Testing, Natl. Tech. Univ. of Ukraine, 37, Peremogy pr., Kiev, 252056, Ukraine)

Acoustics education in Ukraine is considered. In more than 40 universities, students learn acoustics: in the acoustics department of the National Technical University in Ukraine (only one department in Ukraine) and many related departments such as Nondestructive Testing, Physics, Electrical Engineering, etc. Acoustical specializations of departments are presented. The most promising and developing acoustical specialization is biomedical acoustics.

3:40–4:00 Break

4:00

1pED6. Education in acoustics: The Italian experience. Roberto Pompoli (Eng. Dept., Univ. of Ferrara, via G. Saragat 1, 44100 Ferrara, Italy, rpompoli@ing.unife.it)

Education in acoustics is a topic which has been discussed for many years in different international conferences: ICA, Inter-Noise, Forum Acusticum, etc. Tor Kihlman, analyzing in two papers [Proc. ICA'95, 311–314; Proc. Inter-Noise'96, 87–90] the education programs for students in technical faculties, arrives at the conclusion that two kinds of curricula are needed: one for students who are not specializing in acoustics and another one for students who are specializing in this field. He proposes some strategies to be followed in order to obtain better results when teaching acoustics in the technical faculties. Starting from these considerations, and taking into account on one hand the experience of education in acoustics in Italy, and on the other the analysis of the data collected by the author (in charge of education for the EAA), some possible solutions are proposed for a better coordination of the programs betweens the institutions and for the establishment of a European network of experts and teachers who are willing to move to different universities for short periods. The project could be coordinated by the EAA and funded by the European Commission.

4:20

1pED7. Education on acoustics in Spain and Latin America. Manuel Recuero (Departamento de Ingeniería Mecánica y Fabricación, Universidad Politécnica de Madrid, Ctra. Valencia Km. 7, 28031 Madrid, Spain, mrecuero@diac.upm.es), Constantino Gil, and Antonio Minguez (Universidad Politécnica de Madrid, 28031 Madrid, Spain)

Education in acoustics was incorporated as a part in engineering education in 1969, and from then to today it has had several transformations. In this paper, the results obtained from this education during the last years and how it is today are presented. Also presented are the conclusions reached from the theoretical and experimental knowledge points of view in the last three decades. The present situation of this type of education in the Spanish countries in South America are also expounded: development, implementation, years of teaching, etc. The paper is a summary of the education in acoustics in the Spanish universities with their curricula, laboratories, facilities, and so on, and the premises for the future.

4:40

1pED8. UK education in acoustics. C. G. Rice (Inst. of Sound and Vib. Res., The University, Southampton SO17 1BJ, UK, cgr@soton.ac.uk)

To definitively report on the status of acoustics education in the UK must be regarded as a challenging task. The areas of interest are even wider than the normally accepted classification of acoustic subjects (e.g., PACS), and the variety of situations to which such knowledge can be applied in practice is daunting. However, whatever the level of expertise required of practitioners in acoustics, everyone ought to be educated within a framework of life-long learning and continuing professional development. In the UK such formal educational and training requirements needed to practice the profession of acoustics have been specified, and it is in this context that UK education in acoustics will be reviewed. Formal educational requirements leading to chartered engineer status for individuals (e.g., CEng and FEANI EurIng) have been laid down by the UK Engineering Council in their ''Standards and Routes to Registration (SARTOR)'' document. These procedures were compiled by members from the professional engineering institutions and include guidelines for the accreditation of university degree courses. The Institute of Acoustics plays an important role in the implementation of such procedures. Information relating to the wider role of the importance of acoustics education in nonengineering disciplines will also be presented.

5:00

1pED9. Education in acoustics: Fundamentals and peculiarities. Nikolai A. Dubrovsky (Andreyev Acoust. Inst., #4 Shvernika Ul., Moscow 117036, Russia), Albert A. Dogadov, and Alexandr S. Sigov (Moscow State Inst. of Radiotechnology, Electron. and Automation, Moscow 117454, Russia)

An historical background of university and technical high school education in acoustics in Russia is considered. Basic features of Soviet concepts of training in acoustics are discussed. Main advantages are deep and broad training in basic and applied disciplines, a system of the ''base'' research centers for early research activity of students under leadership of active scientists, and reporting by students of their results in science and technology at conferences and seminars. These advantages had been very positive for the Soviet planned economy. The main drawbacks are redundancy and rigidity of this education system. Transition to free market society forced the modification of basic concepts of education in acoustics: to introduce flexible education similar to European and American ones, to train students in new areas of acoustics intended to enhance the quality of life (ecology, medicine), to provide optional training in acoustics (common or individual), to meet requirements of private enterprises to education of selected students. A new approach to training of foreign students is developed: transition from special high schools for foreigners to joint education of foreigners with Russian citizens in many state educational centers. The role of the Russian Acoustical Society in exchange of education methodology between training centers in Russia is presented.

5:20

1pED10. Acoustics: A route to science literacy in the 21st Century. Thomas D. Rossing (Phys. Dept., Northern Illinois Univ., DeKalb, IL 60115)

Two trends have been apparent during the second half of the 20th Century: the disappearance of acoustics from physics curricula and the decline in the percentage of students who take physics, both in schools and universities. The relationship, if any, between these trends is well worth discussing. More intriguing, however, is the likelihood that acoustics, with its rather wide appeal to students and to the public, can serve as a vehicle to promote science literacy.

2:00

1pMU1. A comparison of wind instrument time-variant spectra. James W. Beauchamp (School of Music and Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana–Champaign, 2136 Music Bldg., 1114 W. Nevada, Urbana, IL 61801, j-beauch@uiuc.edu)

Musical instruments can be compared in terms of the sound spectra that they produce. First, they may be compared in terms of spectral envelope, which allows an observation of change of amplitude with respect to frequency. Moreover, the spectra change with respect to time, usually with a burst of low-amplitude, broadband spectrum initiating the attack phase, followed by a gradual increase of spectral centroid. The so-called ''steady state'' may actually include some interesting changes, depending on performance expressivity. The final decay phase is perhaps the least manipulable by the performer, and is generally characterized by a gradual lowering of the centroid as the amplitude decreases. A centroid-indexed family of spectral envelopes based on data for several tones with different fundamental frequencies gives a good average picture of the spectra for a particular instrument. However, this representation fails to take into account special details such as pitch-dependent and harmonic-dependent spectral features. While such special details are least important for the brass, they are very important for the woodwinds, and several features of the clarinet, oboe, saxophone, and flute will be illustrated and compared.

2:20

1pMU2. Sound production of flue organ pipes. Andras Miklos and Judit Angster (Fraunhofer-Institut Bauphysik, Nobelstr. 12, D-70569 Stuttgart, Germany, angster@ibp.fhg.de)

For understanding the sound production of flue organ pipes, the acoustic properties of the two main components, the acoustic resonator and the air jet generator at the labium (flue + upper lip), have been investigated separately. It was found that the formant structure of the stationary sound spectrum is mostly determined by the geometry of the pipe, including the location, size, and shape of the openings (mouth and open end), while the attack is strongly influenced by the air jet generator. An influence of the wall

vibrations on the stationary sound has been also found, but this effect could be neglected until the wall is not too thin. The spectra of the stationary sound radiated by the openings are markedly different. The analysis of their formant structures implies that the source of the radiation is the acoustic flow at the openings. Experiments performed on labium models and pipes with damped acoustic resonators show that an edge tone with characteristic spectrum appears first during the attack. Its sound field may excite the acoustic resonator purely acoustically, preceding the development of the coupling between jet and acoustic oscillations. This assumption has been supported by the experiments discussed in the paper.

2:40

1pMU3. Sound production in flue instruments: A review. Benoit Fabre, Marc-Pierre Verge (Laboratoire d'Acoustique Musicale, Univ. Paris VI, 11 rue de Lourmel, 75015 Paris, France, fabreb@ccr.jussieu.fr), and Avraham Hirschberg (TUE, 5600 MB Eindhoven, The Netherlands, A.Hirschberg@phys.tue.nl)

The introduction of computer implementation of numerical methods, 40 years ago, has opened the way towards quantitative modeling of the sound production in flue instruments. This has induced a first wave of new research initiated in the late 1960s by the precursor work of Bechert, Cremer, Ising and Coltman. The breakthrough of real-time sound synthesis in the last decade has allowed the judgment of models on the basis of the sound which they produce. With this breakthrough ''verbal'' modeling such as the controversy between Helmholtz and Rayleigh about the nature of the sound source at the labium (volume source or dipole) is now a historical curiosity. However, it has became clear that lumped models as used in sound synthesis will remain semi-empirical caricatures. It has appeared that direct numerical simulation of the details of the flow including the effect of turbulence is still impossible. One observes, therefore, a shift back towards experimental studies such as that of jet response to acoustical excitation, the effect of nicks, the effect of chamfers, the influence of materials, Coanda effect induced by turbulence, etc. A review of these recent studies will be presented.

3:00

1pMU4. A Rayleigh wave model for the lip reed: Qualitative aspects. R. Dean Ayers (Dept. of Phys. and Astron., California State Univ., Long Beach, 1250 Bellflower Blvd., Long Beach, CA 90840, rdayers@csulb.edu), Richard P. Birkemeier, and Lowell J. Eliason (California State Univ., Long Beach, CA 90840)

The stroboscopic technique of Daniel W. Martin [J. Acoust. Soc. Am. **13**, 305–308 (1942)] has been updated by using a video camera. Improved magnification and resolution show that the upper lip's motion is complicated: a Rayleigh wave propagates downstream in a thin, passive layer of flesh. Muscles of the embouchure are used to adjust the tension and dimensions of that layer. The lips of accomplished performers show a wide range of detailed behaviors, due in some cases to asymmetry in the lip structure. The fact that players must find their own particular techniques for efficient control of the Rayleigh wave is significant for brass pedagogy. Seeing their lips in motion may help beginning players to advance more rapidly. Results of a preliminary survey among accomplished performers and beginners will be presented. [Work supported in part by the Scholarly and Creative Activities Committee and the College of Natural Sciences and Mathematics at CSULB.]

3:20

1pMU5. Self-excitation in woodwinds: From a particular model to a generic model. Ana Barjau, Vincent Gibiat (Dept. of Mech. Eng., Polytech. Univ. of Catalunya, Diagonal 647, 08028 Barcelona, Spain), and Vincent Gibiat (ESPCI, 75231 Paris Cedex 05, France)

The process of sound production in a double-reed woodwind is based upon two mechanisms: the Bernoulli mechanism, which is associated only with the reed and air dynamics, and the coupling mechanism, which represents the interaction between the bore and the reed. A realistic model, close to the physical reality of the system, leads to satisfactory simulated results compared to experimental measures. However, the great number of parameters and variables appearing in the mathematical formulation makes it difficult to predict the final behavior of the system. In this paper, the realistic model is presented, and progressive simplifications are done to reduce the formulation to a single equation containing a few control parameters and a single variable. The progressive models are discussed and applied to simulate the internal pressure at the input section of the instrument. Different behaviors are then evident: from more traditional ones (periodic states) to quasiperiodic and chaotic signals.

3:40

1pMU6. Some comments on the artificial blowing of the reed woodwind instrument. Tohru Idogawa (1-14-39 Gakuen-cho, Higashi-kurume, Tokyo 2030021, Japan, RXE07320@nifty.ne.jp)

Important results were obtained by artificial blowings of the reed woodwind instruments: Many states of air column vibrations can be excited under a fixed fingering and a fixed embouchure; these states have their respective regions of blowing pressure in which frequency and waveform of the air column vibration change slightly and continuously as the blowing pressure is varied; a sudden transition from one state to another takes place irreversibly at a blowing pressure, the upper (or lower) boundary of the state, when

blowing pressure is increased (or decreased) gradually. It will be presented that the above-described results are not necessarily valid for a conical brass pipe (0.63 m long), which has the same apex angle as that of the bassoon, blown by the mouthpiece of the soprano saxophone. One of the vibratory states excited has changed to another state without transition. When a cylindrical brass pipe, which has about the same length as that of the clarinet, has been artificially blown with the clarinet mouthpiece, the reed has been easily broken, which has rarely been observed for the clarinet.

4:00–4:20 Break

4:20

1pMU7. Differences between cylindrical and conical reed instruments. Jean-Pierre Dalmont (Lab. d'Acoust. de l'Univ. du Maine, UMR CNRS 6613, 72085 Le Mans, France)

Most investigations on reed instruments have been carried out on clarinet probably because this is the most common reed instrument. However, the extrapolation of the results to conical instruments is risky. The fact that internal clarinet spectrum does not contain even harmonics is not the only difference. For example the transfer function between input and output pressure is very different: this makes a saxophone, for lower notes, much louder than a clarinet. On the other hand, application of linear analysis near the threshold of oscillation to conical reed instruments is limited: because of the inverse bifurcation, small oscillations do not exist for conical reed instruments. This is confirmed by the observation that it is clearly much easier to play pianissimo with a clarinet than with a saxophone or an oboe. The saturation mechanism seems also to be different for conical and cylindrical instruments. On a saxophone the saturation occurs at a lower mouth pressure because of the existence of more than one regime at the fundamental frequency. All these aspects will be discussed with reference to simplified physical models and illustrated by experiments using artificial blowing. [This work has been done in collaboration with C. J. Nederveen, J. Gilbert, and J. Kergomard.]

1pMU8. A complete period-doubling cascade on a cromorn. Vincent Gibiat (LOA/ESPCI CNRS UMR 7587, 10 rue Vauquelin, 75231 Paris Cedex 05, France, Vincent.Gibiat@espci.fr) and Michele Castellengo (Univ. Paris, Paris, Cedex 05, France)

The cromorn is a very simple double reed instrument of the Renaissance which shares with the recorder the valuable property that there is no contact between the musician's lips and the double reed, allowing one to study it without any human intervention and so to control the parameters of the sound production. This has been studied by varying the blowing pressure from small values to the pressure needed to obtain the normal sound of the instrument and then by decreasing it. The sound has been recorded and analyzed in time frequency domain. A complete cascade of period-doubling bifurcations has been obtained following the increase of the pressure. Two chaotic regions have been found, one just after the third period doubling and another after a period tripling. For the lowest pressure in the decreasing process the coupling of the reed and the bore becomes too weak and the reed squeaks. The instrument is simple enough to follow the schematic given by Maganza *et al.* for cylindrical instruments and it will be shown that the decrease of the pressure is equivalent to the sharpening of the nonlinear function which relates pressure and flow that gives the possibility of period doublings.

1pMU9. The motion of air-driven free reeds. James P. Cottingham, C. Joseph Lilly, and Christopher H. Reed (Phys. Dept., Coe College, Cedar Rapids, IA 52402, jcotting@coe.edu)

An earlier study on free reeds from reed organs [P. D. Koopman and J. P. Cottingham, Reed Organ Soc. Bull. **15**, No. 3–4, 17–23 (1997)] yielded information about the variation in amplitude of reed vibration with pressure, but few further details on the reed motion. A more thorough set of measurements of the motion of these reeds has been done, including the use of a variable impedance transducer to measure reed displacement and a laser vibrometer system to measure reed velocity. For reeds from reed organs, at low to moderate blowing pressures, the reed motion at each point is nearly sinusoidal and the reed profile at maximum amplitude closely approximates that calculated for a cantilevered beam vibrating in the first mode. At blowing pressures considerably higher than normal playing pressure, strong indications of the presence of the second beam mode are observed. The nearly sinusoidal reed motion at normal pressure contrasts with the sound pressure waveform near the reed which, as a result of the valve action of the reed, roughly resembles a pulse wave. Similar measurements on accordion reeds yield somewhat contrasting results.

1pMU10. A new algorithm to simulate nonlinear propagation in a tube of any shape. Application to a real-time physical model of trumpetlike instruments. Christophe Vergez and Xavier Rodet (IRCAM, Paris, 1 pl. Igor Stravinsky, 75014 Paris, France)

When air pressure is low enough, wave propagation in a pipe can be considered linear to a reasonable degree. When the pressure level increases, this simplification becomes more and more inaccurate since high pressure values travel faster than low pressure values. The speed of propagation is thus a function of the pressure level. A new time-domain approach is proposed to simulate nonlinear propagation of a sound wave in a tube of any shape. This constraint-based algorithm does not prevent the derivative of the signal from breaking, as it happens when a shock wave occurs. Moreover, the algorithm allows the carrying out of nonlinear propagation even once a shock has occured. Thus, as expected the distorsion of a sinusoidal wave into a N-wave of progressively decreasing amplitude was observed. Moreover, without any additional computational cost, this technique provides fractional delay variation as needed for continuous tube's variations in length. The nonlinear propagation algorithm is included in the real-time high-quality physical model of trumpetlike instruments. Simulation shows a great improvement in the sound quality since this algorithm allows subtle nuances in the timbre as well as hard brassy effects.

1pMU11. Blowing and breathing in the woodwinds: Generation and control of input parameters. Leonardo Fuks (UFRJ–Rio de Janeiro Federal Univ., School of Music, Rua do Passeio 98, Rio de Janeiro, 20021-290, Brazil, leonardo@speech.kth.se)

Wind instruments, being more than an extension to the performer's body, are strongly connected to the respiratory system. Such a relationship permits a multiple and fine control of input parameters, enabling wide ranges of tone variation and expressiveness, but also imposes constraints concerning muscular demands for aerodynamic energy supply, breathhold times, and lung capacity, among others. The present investigation combined physiological and acoustical approaches, focusing on reed woodwinds under naturalistic playing conditions. Airflow and blowing pressure used by professional players were shown to be systematic in rehearsed tasks and to depend on pitch and dynamic level, instrument type, and reed characteristics, suggesting that musical training involves the incorporation and adjustment of the mechanical properties of the system to the musician's technique. Blowing pressure sensation was assessed by a psychophysical method, showing a quasi-linear behavior. Respiratory movements, decomposed into rib cage and abdominal contributions, have been recorded and analyzed during performance by an inductive plethysmographic method, providing insights to the musicians' use of the respiratory system. The ever-changing pulmonary air composition was shown to affect fundamental frequency to some extent. [The research work presented in this paper was carried out at KTH, Stockholm, and was sponsored by a Brazilian CAPES scholarship.]

1pMU12. Swiss horns and their harmonicity. Rolphe F. Fehlmann (Swiss Software Eng. College, Dept. of CAD/CAM Eng., Morgartenstr. 2, CH-3012 Berne, Switzerland)

Earlier it has been shown that there exists an optimal curved waveguide for musical purposes exhibiting a sequence of harmonic resonance modes [R. F. Fehlmann, in Intl. Congress on Acoustics, III (1995), pp. 417–421]. The radiation of some ekmelic overtones even consists of elliptical waves [R. F. Fehlmann, J. Acoust. Soc. Am. **103**, 2774 (A) (1998)]. According to the hypothesis of Risset/Mathews [J.-C. Risset and M. V. Mathews, Phys. Today **22**(2), 23–30 (1969)], the ''warmth'' of a sound source is due to the inharmonicity of the musical tones. However, in this paper, it is shown that this is not the case for the well-known ''warm and melancholic'' sound of the Swiss horns and thus questions the reasoning of Risset/Mathews.

1pNSa1. Trading level for number of aircraft immissions: A full-factorial laboratory design. Joachim Vogt (Univ. of Dortmund, Dept. 14, Organisational Psych., D-44221 Dortmund, Germany, VOGT@WAP-MAIL.FB14.UNI-DORTMUND.DE) and Karl Theodor Kalveram (Univ. of Duesseldorf, D-40221 Duesseldorf, Germany)

To what extent can the number of overflights be increased without enhancing annoyance, if airplanes become softer? An original B737 take-off sound (A-weighted sound-pressure level: $L_{max}=76$ dB) was either reduced or amplified by 4.8 dB. In a 3×3 factorial design, nine groups of ten subjects were exposed for 27 min to 3, 9, or 27 copies of one of these three sounds. Regarding energy equivalence defined by $L_{eqA}=$const, a 4.8-dB sound-pressure reduction compensated for three times the number of the higher level, achieving constant Leq levels in the diagonals of the design. After noise exposure, cardiovascular responses and the subject ratings of loudness, annoyance, and quality of an imagined living area with comparable noise load were analyzed statistically. Comparison of the equal-energy conditions revealed no difference regarding heart rate and blood pressure, but subjective loudness increased with both level and number, and 27 soft aircraft were rated extremely loud. However, annoyance decreased, when 3 loud overflights were converted to 9 medium events, but increased again under 27 soft events. Imagined living quality always decreased with increasing numbers of events, and could not be compensated for by energy-preserving reduction of single-event levels. Conclusion: Beyond 10 events per 30 min the number probably has an increasing over-energetic impact on subjective noise effects.

1pNSa2. Calculation of noise contours for Belgian airports. Elisabeth M. J. Peeters, Jan Thoen (Laboratorium voor Akoestiek en Thermische Fysica, K. U. Leuven, Celestijnenlaan 200D, 3001 Leuven, Belgium), and Ghislain Geusens (Regie der Luchtwegen, 1030 Brussels, Belgium)

Noise contours are an objective way to represent the long-term noise load from departing and arriving aircraft. Many major European airports have a long history of noise contour calculations and related land use planning. For Belgian airports, several noise contour calculations have been made since the 1970s, but have always been based on limited information. Recently, noise contours for the airports of Brussels, Antwerp, and Ostend have been calculated based on detailed flight information. Long-term noise measurements around Brussels airport validated the accuracy of the Brussels airport noise contours. Up to today, neither for the development of noise contours, nor for the land use planning based on airport noise contours, official guidelines or practices exist, and new houses can still be built around the airports. On the other hand, with international harmonization efforts in mind, Belgian airports are not, as some other European airports restrained by legislation, based on dated technology noise contours, but have taken the opportunity to choose noise descriptors and calculation methods based on current evolutions in the international ways of calculating noise contours, as well as on international guidelines.

1pNSa3. Normalized noise spectra of aircraft take-off and landing operations. J. Salvador Santiago and Jose Pons (Instituto de Acustica, C.S.I.C.-c/Serrano 144, 28006 Madrid, Spain, ssantiago@fresno.csic.es)

At Madrid-Barajas Airport, a new runway will enter into service in the year 1999, located to the NW of the two existing ones. This fact implies a new configuration of flight paths, both for take-off and landing operations, and a new definition of the areas adjacent to the airport as regards the noise impact on the population. An ad-hoc regulation states that the dwellings within the area covered by the isophones of $L_{\text{eq day}}=65$ dB and $L_{\text{eq night}}=55$ dB, for the future situation in the year 2010, have to be supplemented by the airport operator with an acoustic insulation to achieve an internal noise level of $L_{\text{eq day}}=35$ dB and $L_{\text{eq night}}=30$ dB. The noise spectra that will be used for measuring the actual insulation of the buildings have been determined along the isophones $L_{\text{eq}}=80$ dB to $L_{\text{eq}}=55$ dB, in steps of 5 dB, for take-off and landing operations, by means of *in situ* tape recordings of 938 aircraft operations, recorded simultaneously in six measuring stations. Out of 5245 valid recordings, 2749 with enough signal-to-noise ratio were analyzed in 1/3 octave bands, and the results presented as spectra normalized to 0 dB.

1pNSa4. Noise problems, savage approaches. From ''just forget it,'' to physical violence. Fernando J. Elizondo-Garza (Laboratorio de Acustica, UANL-FIME, P.O. Box 20 ''F,'' Cd. Universitaria, San Nicolas, 66450, N. L., Mexico, fjelizon@ccr.dsi.uanl.mx)

Different approaches and/or philosophies that can be used to face a noise problem are described and commented on. Both the classical noise control procedures and the savage approaches that go from simply ''forget it,'' to physical violence, are considered.

3:20

1pNSa5. Can population density be used to determine ambient noise levels? Catherine M. Stewart (Oak Ridge Inst. of Sci. and Education (ORISE), Postgrad. Internship Prog., U.S. Army Ctr. for Health Promotion and Preventive Medicine, Environ. Noise Prog., 5158 Blackhawk Rd., Aberdeen Proving Ground, MD 21010-5422), William A. Russell, Jr., and George A. Luz (U.S. Army Ctr. for Health Promotion and Preventive Medicine, Environ. Noise Prog., Aberdeen Proving Ground, MD 21010-5422)

In 1974, the U.S. Environmental Protection Agency (USEPA) published a report endorsing the day–night average sound level (DNL) for nationwide use. Included in this report was an equation predicting DNL from the number of people per square mile. The equation was based on monitoring from 100 sites throughout the U.S. To determine whether the 1974 equation still provided a realistic estimate 25 years later, monitoring was conducted at 50 sites in Baltimore County, Maryland. Population density ranged from 600 to 13 000 people per square mile. To explore seasonal differences and test–retest reliability, the monitoring was conducted for 24 h in the summer and 24 h in the winter. The results are compared to those of the USEPA.

1pNSa6. Development of a curve to predict community annoyance due to transportation noise exposure. Lawrence S. Finegold (U.S. Air Force Res. Lab., Wright–Patterson AFB, OH 45433, LFinegold@falcon.al.wpafb.af.mil)

This paper presents a brief review of the history of the development of a curve to predict community annoyance in response to transportation noise sources beginning with the original ''Schultz curve'' [J. Acoust. Soc. Am. **64**, 377 (1978)]. This seminal article provided the results of a large-scale database meta-analysis (i.e., a secondary analysis of previously published data) using data from the 11 published transportation-elated community annoyance social surveys. The Schultz curve, which relates general transportation noise exposure (in terms of day–night average sound level, DNL) and the percent of a community ''highly annoyed'' (%HA) has been used for decades in environmental impact analyses in much of the world. The community annoyance database used by Schultz has been updated with additional social survey data, nearly tripling its original size in the initial Fidell *et al.* [J. Acoust. Soc. Am. **89**, 221–233 (1991)] analysis. A more recent version of this meta-analysis by Finegold *et al.* [Noise Control Eng. **42**(1), 25–30 (1994)] differs from the Fidell *et al.* analysis on several technical issues and includes 400 data points from 22 international social surveys. The results of the Finegold *et al.* analysis have recently been adopted as part of a U.S. standard on environmental noise (ANSI S12.9-1996/Part 4). This paper reviews the details of this meta-analysis.

1pNSa7. A field study about the effects of low-frequency noise on man. Ana M. Verzini, Carlos A. Frassoni, and Aldo H. Ortiz (Centro de Investigaciones Acusticas y Luminotecnicas UNC, Cordoba, Argentina)

During the last few years, several shopping centers have been placed in residential neighborhoods of Cordoba City, and inhabitants' complaints about noise have been reported. The present paper is a field study about the effects produced by very low-frequency noise on people's health and quality of life. It was carried out in different zones of Cordoba City, where considerable levels of noise in the frequencies below 163 Hz and also in infrasounds had been detected. The generating sources were air conditioning systems, industrial plants, and traffic noise. One hundred people between 21 and 65 years old were surveyed, and the measurements of noise were done in front of each interviewed person's home, with a B&K analyzer, type 2144 and microphone B&K type 4193. Noise levels in dBLin, dBA, dBLin below 163 Hz and dBLin below 20 Hz were found, and due to the multivaried characteristics of the research and the categorical variables used, data from the questionnaire and noise levels were analyzed by means of the multiple correspondence factorial analysis. Several relationships were found among type of noise, sociodemographics, and moderator variables, and effects of noises. [This study was supported by a grant of CONICET.]

1pNSa8. How information about the source influences noise annoyance. Karl T. Kalveram, Juergen Dassow (Univ. of Duesseldorf, Inst. of General Psych., Universitaetsstr. 1, 40225 Duesseldorf, Germany), and Joachim Vogt (Univ. of Dortmund, Dortmund, Germany)

Annoyance following noise exposure can be considered to convey a ''possible loss of fitness signal'' (PLOF-signal), indicating that the individual's Darwinian fitness decreases if she or he continues to stay in that situation. Especially, nonfamiliar conspecifics appearing in the habitat diminish fitness of the inhabitants because they are going to use the same but restricted resources. Therefore, sounds carrying the information that they are manmade are likely to evoke more annoyance than other sounds of equal level and spectral density. In an experiment, subjects were exposed to recorded sounds of ocean surf and party murmur. Both sounds were carefully equalized regarding spectral energy and overall level [$L_{\text{eq(A)}}=52$ dB]. In the ''manmade'' sound condition, subjects felt significantly more annoyed and were significantly more impaired in a free recall memory test. However, physiological stress indices (potassium/sodium measured in saliva) did not discriminate significantly between the conditions. The results support the hypothesis that considered biologically, the main function of noise annoyance is to warn a person that fitness may diminish, but not to induce actual stress. This explains the frequently reported finding that noise, although annoying, causes only little or even no physiological stress reactions.

5:00

1pNSa9. Use of immersive sound in a museum exhibition. Peter Coulter (Powerhouse Museum, P.O. Box K346, Haymarket, Sydney, Australia 2000, peterc@phm.gov.au)

Studies have shown [Schaffer, World Sound Project (1997)] that in our environment, which includes our community, traffic and motorized sounds are growing at a faster rate than nonmotorized human sounds, suggesting that because motorized sound is low-information, high-intensity, it tends to desensitize the populace and results in less social interaction. One role of museums is to preserve a balance of sounds, as a sanctuary from our environment, and explore the consequence of our motorized culture. At the Powerhouse Museum, an exhibition has opened, December 1998, entitled ''Cars and Culture'' which examines the consequence of cars. In the exhibition there is an immersive sound space that has been created using an ambisonic sound system. This soundscape is discussed. An experiment was devised where the degree of sound immersiveness was varied for a number of visitors and their reactions were measured.

5:20

1pNSa10. Loudness evaluation of urban soundscapes by a cross-modal matching method. Patrick Susini (Inst. de Recherche et de Coordination Acoust./Musique (IRCAM), 1 place Igor-Stravinsky, F-75004 Paris, France, susini@ircam.fr) and Valerie Maffiolo (Lab. d'Acoust. Musicale, Paris Cedex 05, France)

In a previous study, loudness of a time-varying pure tone was evaluated using a cross-modal matching method. In this procedure, the loudness was matched to an equivalent muscular force. Subjects had to judge the instantaneous and global loudness using a proprioceptive input device with force feedback. Using this technique, subjects could respond easily, rapidly, continuously, and with feedback concerning their evaluation. The present study examines the relation between instantaneous and global loudness of 16 urban soundscapes lasting about 20 s using the same method. First, the procedure is individually calibrated with 1-s soundscapes presented at different sound-pressure levels. The data obtained for each subject fit well with a linear relation on a log–log scale between the sound-pressure level in dB and the associated force in log Newtons. Then, the global judgments are performed under two experimental conditions: one with instantaneous loudness evaluation during stimulus presentation and one without. Good correlation was found between these two judgments. The global judgment and the average over the instantaneous matching contour are nearly identical. In addition, a fluction factor (FI) calculated on the loudness judgment contour reflects the degree of movement produced by the subject as well as the presence of discriminable sources.

5:40

1pNSa11. Is pleasantness for soundscapes dimensional or categorical? Valerie Maffiolo, Michele Castellengo (Lab. d'Acoust. Musicale, Univ. Paris 6, case 161, 4 place Jussieu, F-75252 Paris Cedex 05, France, maffiolo@ccr.jussieu.fr), and Daniele Dubois (CNRS, UPR 9017, INALF, ENS, Montrouge, France)

This paper focuses on methodological issues regarding the dimensional or categorical properties of pleasantness for soundscapes. Sixteen sequences of urban soundscapes were recorded and reproduced with their real sound intensity, using techniques previously validated to produce the illusion of a real environment. The sequences were processed using two methods: free categorization and pair comparisons. The categorization method consisted of asking subjects to sort out the sequences according to pleasantness and to verbally qualify their categories. In the pair comparison task, subjects had first to choose, for each pair, which sequence was the most pleasant, and then to rate the pleasantness dissimilarity between the two sequences on a nine-point scale. Categories and ratings were processed through a cluster analysis and interpreted in connection with a psycholinguistic analysis of the verbal comments. Binary choices were transformed onto a dimensional representation of pleasantness. The main results lead to the discussion of the influence of procedures and data representations of the interpretation of pleasantness for soundscapes, and suggest that the dimensional aspect of pleasantness is more an artifact of representation than an intrinsic property of soundscapes. Unpleasant soundscapes seem to be more adequately represented as a specific category of sounds rather than values ranging on a scale.

1pNSa12. Assessment of low-frequency noise in dwellings. New Polish recommendations. Marianna Mirowska (Bldg. Res. Inst., Acoust. Dept., Ksawerow 21 02-656 Warsaw, Poland)

The paper presents the new Polish recommendations for evaluation of low-frequency noise penetrating into dwellings from appliances installed inside or outside of building. Based on measurement data of annoyance noise, epidemiological investigations of the influence of noise on the health of exposed inhabitants, laboratory tests of thresholds of narrow- and broadband noise perception, review of the present literature, the new assessment criteria was proposed. In order to assess the noise spectra measured in dwellings, the A10 characteristics as the rating curve have been accepted. Its L levels for one-third-octave bands are determined by relation: $L_{A10} = 10$ kA. The low-frequency noise occurs as annoying when the sound pressure levels of noise exceeds the levels of A10 curve and exceeds the background noise by more than: 10 dB for tone noise and 6 dB for broadband noise.

1pNSb1. Fan noise—In-duct sound power—What are we measuring and why? W. T. W. Cory (Woods of Colchester Ltd., Tufnell Way, CO4 AR Colchester, Essex, UK, Bill.Cory@woods-fans.com)

The paper will review the history of the measurement of fan noise. Early standards will be described and related to the state of knowledge existing at the time. The need for reliable methods of measuring the noise in-duct was foreseen at an early stage. This required the development of microphone shields able to ensure accurate readings of noise in a moving airstream. The relationship of in-duct levels to those measured around the fan in reverberent or free-field conditions will be discussed. Finally, the forthcoming ISO standards will be introduced and the recognized need for a number of different levels to be recorded.

2:20

1pNSb2. In-duct fan sound power measurement. Part I. Review of general problem. Wolfgang Neise and Frank Arnold (DLR-Institut fuer Antriebstechnik, Abteilung Turbulenzforschung Berlin, Mueller-Breslau-Strasse 8, 10623 Berlin, Germany, Wolfgang.Neise@dlr.de)

Many technical fan installations involve a duct on the inlet side and/or outlet side of a fan. Therefore the need arises for a measurement method for determination of the sound power radiated by fans or other fluid handling sources into a duct. In the paper the problems associated with such a method are discussed: Axial standing waves due to sound reflection from the duct end, acoustic loading of the source, turbulent flow pressures superimposed on the sound field, flow noise generated by flow/microphone probe interaction (self noise), discrimination between sound pressures and turbulent flow pressures, measurement position in the duct in view of higher-order mode sound propagation and directional characteristic of the microphone probe used, and modal distribution of sound power. Early and recent work on the above topics is reviewed. A brief description of the standarized in-duct method ISO 5136 (1990) is given.

2:40

1pNSb3. In-duct fan sound power measurement. Part II. Revision of ISO 5136. Wolfgang Neise and Frank Arnold (DLR-Institut fuer Antriebstechnik, Abteilung Turbulenzforschung Berlin, Mueller-Breslau-Strasse 8, 10623 Berlin, Germany, Wolfgang.Neise@dlr.de)

In recent investigations problems with the present version of the in-duct method ISO 5136 (1990) became apparent which indicate that a revision of the standard is necessary. The two major problem areas are: (1) Swirl flow existing in the test duct may interfere with the microphone probe to give too high sound power levels. Farzami and Guedel [1992 Proc. Fan Noise, CETIM Senlis, France, pp. 375–380] showed that this problem can be solved by placing a flow straightener between the fan outlet and measurement plane. (2) By comparison with other methods of sound power determination [Holste and Neise, JSV **152**, 1–26 (1992)], the sound power levels obtained by using the in-duct method are too low by several decibels in the frequency region of higher-order mode sound propagation. It is shown that the discrepancy between the results of the in-duct method and other methods is caused by the so-called modal correction C4 which is to account for the directivity characteristic of the microphone fitted with a turbulence screen in view of the propagation angle of the higher-order duct modes. Experimental and theoretical results are presented for a new combined frequency correction C34 which includes the effects of the superimposed mean flow on the sensitivity and directivity of the microphone probe as well as on the modal sound propagation and characteristics in the duct.

3:00

1pNSb4. Numerical method and software package for prediction of pressure pulsation in centrifugal ventilators. S. Timouchev (InteRe Ltd., DG, 19 Apt. 11, Engels St. 141400 Khimki, Moscow Reg., Russia, irico@glas.apc.org)

A numerical method and software package was developed for designers and researchers in the field of vibration and noise problems in centrifugal ventilators. The numerical procedure is based on a representation of unsteady compressible liquid flow as a form of vortex (pseudo-sound) and acoustic mode superposition. It gives a possibility to determine absolute amplitudes of pressure pulsation in the ventilator casing induced by unsteady interaction between nonuniform flow outgoing from a centrifugal impeller volute tongue or diffuser vanes, so-called blade passing tones. Inupt data includes 2-D ventilator geometry and operation mode. Acoustic impedance boundary conditions can be defined with a circuit specification or by direct inlet and outlet specific complex

impedance definition. It is possible to take into account local wall-specific complex impedance to study a coating effect on reduction of pressure pulsation. Output data represents: unsteady pressure map in the ventilator casing; amplitude distribution map for any selected harmonic; pressure versus time curves with accompanied spectrum information at any point selected by user; total vibration load vectors acting on the ventilator volute casing; and static pressure, velocity, and vorticity distribution in the centrifugal impeller. Validation of the software was completed on the centrifugal pump air model with more than 400 measuring points for two different radial gaps. The mismatch with experimental data is mostly 1.5–2.0 dB of unsteady pressure amplitude. Effects of radial clearance, number and form of impeller blades, exit and wall impedance are considered as well. The successful validation of the numerical method shows a good prospect in optimizing centrifugal ventilator geometry with improving vibration and noise characteristics at the draft stage and reducing refinement costs.

3:20

1pNSb5. Modeling centrifugal fan blade trailing edge noise. Robert H. Schlinker, Bruce L. Morin, C. D. Coffen, and Roger L. Davis (United Technologies Res. Ctr., 411 Silver Ln., East Hartford, CT 06108, schlinrh@utrc.utc.com)

Centrifugal fan noise contains numerous aeroacoustic mechanisms, one of them being trailing edge noise due to turbulent boundary layer flows convecting over the blade trailing edge. A fundamental research program was conducted to develop a trailing edge noise database and assess the ability of existing aeroacoustic models to predict this mechanism. The database included unsteady surface pressure spectra, trailing edge wake characteristics, and acoustic sound power. To focus on trailing edge noise, a mixed flow radial fan was simulated with a circumferential array of nonrotating vanes located in a radial diffuser. Both loaded and unloaded vane geometries were tested to simulate varying pressure gradients in an actual fan blade passage. It was demonstrated that the trailing edge noise mechanism can be accurately predicted if the trailing edge wall pressure spectrum is known *a priori*. However, for radial fans the strong adverse pressure gradients appear to rule out the existence of a ''universal'' wall spectrum shape typically observed in flat plate zero pressure gradient boundary layer flows. Hence, futher trailing edge noise modeling needs to focus on predicting surface pressure spectrum shape, in addition to, amplitude and frequency content.

1pNSb6. Aeroacoustic response of a six-bladed axial fan to installation effects. Jean-Guillaume Lalanne, Hans Boden, and Mats Abom (Dept. of Vehicle Eng./MWL S-10044 Stockholm, Sweden, jgl@fkt.kth.se)

First, the effects of the duct on the aeroacoustic response of an axial fan have been studied experimentally and theoretically. The loading effect was modeled by a 1D model in the plane-wave frequency domain. This model was validated experimentally by changing duct lengths and fan positions. Second, an experimental characterization of the inflow turbulence has been done. Single degree-of-freedom statistical parameters have been measured as autocorrelation and temporal autospectrum for the axial turbulence components in order to estimate the integral scale and turbulence intensity. In parallel (the fan being located between an anechoic room and a reverberant room), sound pressure and sound-power measurements have been carried out. Different grids and supercritical screens have been designed to change the inflow conditions. The next task is to determine the spectral pattern in both the temporal frequency and tangential wave number domains and correlate it to acoustic response. Only the tonal part of the spectrum is considered. [Work supported by EEC.]

1pNSb7. Experimental determination of the fluctuating pressure on a rotating fan blade as a source of acoustic noise. Michael Stremel and Thomas Carolus (Institut fuer Fluid und Thermodynamik, Fachgebiet: Stroemungsmaschinen, Universitaet-Gesamthochschule Siegen, 57068 Siegen, Germany)

The fluctuating pressure on the rotating blades is a significant quantity responsible for the noise emitted from axial fans. In order to compute the noise from flow field data, a model is required which describes the fluctuations as a function of flow parameters. The paper presents the fluctuating pressure, measured on the rotating blade of a fan under different operating conditions. The turbulence intensity and the spectral density of the turbulent inflow velocity fluctuations are varied and measured. From CFD calculations quantities, such as boundary layer thickness, shape parameter, etc., of the flow around the blades are deduced and used as parameters. Simultaneously, the noise emitted from the fan is measured and compared to the fluctuating blade pressure.

1pNSb8. Aeroacoustics of axial propeller: Applying to an acoustic wind tunnel and optimization of an axial propeller for cooling system. Y. Dupont (Sciences Industries Conseils, 14, avenue de Sceaux, 78000 Versailles, France)

A simplified model is more convenient to predict design parameter effects on operating characteristics and radiated noise of a propeller. Thus, the aeroacoustic design software, DECIVENT, is used for subsonic axial flow fan, mounted as well in reduced systems like cooling systems as in greater structures like test wind tunnel. For a given flow rate and with the blades specified in cylindrical sections, the total pressure and torque are provided by the following computations: (i) outlet velocity triangle by solving radial balance, (ii) lift coefficient by a conformal transformation, and (iii) lift and drag forces, evaluated with considerations of laminar or turbulent boundary layer stall. The outlet relative velocity and force fields allow one to compute the radiated noise whose components are (i) loading noise, computed by Lighthill's model, and (ii) broadband noise computed by Fukano's model. Correlations with tests show the validity of this methodology. This software, weak customer in computational duration, may be

connected with an optimization software which, after some hundred iterations, allows one to exhibit the best compromise. Two propellers design by these means will be presented: one for a preliminary plan of an acoustic wind tunnel, and one for a cooling system.

5:00

1pNSb9. Experimental investigation of noise sources in cross-flow fans. Michael Herrmann,[a] Wolfgang Neise (DLR-Institut für Antriebstechnik, Abteilung Turbulenzforschung Berlin, Mueller-Breslau-Strasse-8, 10623 Berlin, Germany, Wolfgang.Neise@dlr.de), and Robert H. Schlinker (United Technologies Research Ctr., East Hartford, CT 06108)

Cross-flow fans are unusual types of blowers which operate in a fundamentally different way from axial or centrifugal fans. The flow enters and leaves the impeller in a direction vertical to its axis and passes the blade row twice, first radially inward and then radially outward. Hence, cross-flow fans are basically two-stage fans. Aerodynamic and acoustic modeling of cross-flow fans is extremely difficult because of the complexity of the flow field in the rotating impeller channels with a reversal of the flow direction during each revolution and large regions of severe flow separations. To obtain experimental input data for modeling efforts, experiments were performed with a scaled up model fan. The fan was installed in an open-inlet/ducted outlet test rig. Measurements were made of the unsteady pressures on the impeller blades and on the fan casing, in particular the vortex wall. The flow fields inside the impeller and at its outer periphery were studied by using hot wire anemometry and a three-hole probe. The effect of different casing geometries was examined. A simple model for broadband noise radiation involving surface dipole sources as suggested in an early paper by Sharland [JSV **1**, 302–322 (1964)] predicts the spectrum measured in an anechoically terminated outlet duct reasonably well for a medium frequency range. [a] Now with Behr GmbH & Co., Mauserstrasse 3, 70469 Stuttgart, Germany

5:20

1pNSb10. Practical approach to ANC of fan noise with feedback compensation. Petr Koníček and Ondřej Jiříček (CTU in Prague, FEE, Dept. of Phys., Technicka 2, 166 27 Prague, Czech Republic, jiricek@fel.cvut.cz)

Attenuation of low-frequency noise is a difficult task using passive methods. This paper presents the results of a fan noise reduction in a duct with circular cross section and a small diameter using active noise control. The control algorithm is designed for the optimum least square control in the time domain and contains acoustic feedback compensation. This algorithm was used for the attenuation of noise generated by a small axial fan. The discrete components of noise were totally canceled and the broadband component was reduced. The results of our project will be used for betterment of the working environment.

5:40

1pNSb11. Noise from airborne air conditioning system. Oleksander I. Zaporozhets and Vadim I. Tokarev (Acoust. Lab., Kyiv Intl. Univ. of Civil Aviation, 1, Ave. Cosmonaut Komarov, Kyiv, 252058 Ukraine, zap@elan-ua.net)

A prediction model for noise produced by an air conditioning system in an aircraft pressurized compartment is described. It is based on analysis of the sound flow energy in air conditioning system channels, including both the generation attenuation effects of the acoustic oscillations within the system. Differences in calculations from those usually used in stationary air conditioning systems for industrial, public, and residential buildings are discussed. The mechanism of noise generation by compressors, cooling turbine, separated flows in regulator, and jet flows from the pipe nozzle are investigated. The calculation results are obtained and carried out for different operational airplane conditions. Optimum tasks for operation conditions of an air conditioning system for noise impact criterion are formulated and solved.

Contributed Posters

These posters will be on display in the Poster Gallery from Monday to Wednesday, 15–17 March. Authors will be at their posters from 10:00 a.m. to 12:00 noon on Tuesday, 16 March.

1pNSb12. Rotational noise generation in peripheral fans. Volkmar Weise (TU Bergakademie Freiberg Institut f. Fluidmechanik und Fluidenergiemaschinen Lampadiusstr. 2, D-09596 Freiberg, Germany)

Peripheral fans are used in technical applications where radial and axial fans cannot supply the required pressure ratio at a low mass flux rate. Characteristic for peripheral fans is their high noise emission in the range above 1000 Hz. In comparison to the theory of noise generation in axial fans the sound sources in peripheral fans are not only the rotational blade forces. From an aeroacoustic viewpoint the main difference between axial fans and peripheral fans is the stripper which is necessary to separate inlet and outlet. The sound generation at the outlet is related to the circulating flow between rotor and side channel. This circulation is the main reason for the momentum and energy transfer from the rotor to the gas. The stripper divides the flow in the side channel from the flow between the blades. The result is the modulation of the circulating flow with monopole sources of aerodynamic noise. At the inlet the relief of the blade chambers filled with higher pressure proved to be the main aeroacoustic source by time-dependent periodical mass flux. According to the theory of aerodynamic sound generation this expansion flow represents a monopole source of noise. [Work supported by DFG.]

1pNSb13. Experiences with attenuation of low-frequency noise in duct. Ondřej Jiříček and Petr Koníček (CTU in Prague, FEE, Dept. of Phys., 166 27 Prague, Czech Republic, jiricek@fel.cvut.cz)

Fan noise still represents a serious component of noise pollution in the working place. Fan noise contains both random and discrete frequency components. This paper presents results of experiments with the ANC system useful for low noise design of air-conditioning systems. Computer simulation and measurements were used to examine the performance of the tested feedforward system. The control algorithm is designed for the optimum least square control in the time domain. Experimental results of an investigation of active control of sound are presented.

1pNSc1. The effects of rail support stiffness on railway rolling noise. David J. Thompson, Chris J. C. Jones, and Guillaume de France (Inst. of Sound and Vib. Res., Univ. of Southampton, Highfield, Southampton SO17 1BJ, UK, djt@isvr.soton.ac.uk)

Rolling noise from trains is radiated by both wheel and track vibrations, the track being dominant in many cases. The stiffness of the rail fastener system, especially the elastomeric rail pad usually inserted between the rails and the sleepers, has a significant influence on the noise emitted by the track. Railways are increasingly using softer pads to reduce potential damage to sleepers and ballast. Softer pads decouple the rail from the sleeper. This reduces the noise from the sleeper but also reduces the decay of vibration with distance along the rail and hence leads to an increase of the noise radiated by the rail. The paper describes experimental and theoretical work to investigate the influence of pad stiffness on the dynamic and acoustic behavior of track. The vibrational behavior has been measured on a dedicated 36-m section of railway track, with different types of rail pad installed. The results are compared with predictions using theoretical models of the track behavior. This allows the effective pad stiffness and damping to be determined, laboratory measurements also being available for comparison. The attenuation of vertical and lateral vibration along the track is measured in order to estimate the effect on radiated noise.

2:40

1pNSc2. Time domain simulation of railway noise. Anders Nordborg (ABB Corporate Research, Appl. Mech., SE-72178 Vasteras, Sweden)

The most difficult problem concerned with railway noise generation is the process occurring in the contact region during rolling. The following computation efficient time domain model determines the vertical rail deflection by use of Green's function of a periodically supported beam. Nonlinear Hertzian contact mechanics are used, less realistic, however, than a discretized contact region allowing for rough surfaces. The wheel is as yet a rigid mass. More advanced contact and wheel models can readily be included later. Calculation results include the following observations. The contact force peaks sharply precisely above the support points, followed by a short loss of rail–wheel contact, also for smooth rails. Vibrations of the rail pinned–pinned mode are impossible to eliminate by removing surface roughnesses, because the excitation is above all caused by forward wheel velocity together with discrete supports. The response amplitude increases with forward velocity. Optimum pad stiffness depends on corrugation amplitude. These new findings should be considered when trying to noise optimize track constructions.

3:00

1pNSc3. Short pitch corrugation on straight tracks—Theory and numerical simulation. Steffen Müller and Klaus Knothe (ABB Res. Ctr., Speyerer Str. 4, 69115 Heidelberg, Germany and Tech. Univ. of Berlin, Marchstr. 12, 10587 Berlin, Germany, steffen.mueller@decrc.abb.de)

Simulation models (Frederick, Sinclair, Valdivia, Hempelmann) which have been developed during the last 20 years showed the formation of short pitch corrugation to be a frequency constant mechanism, where a track mode about 1000 Hz dominates the corrugation process. Based on this, however, it is difficult to explain the relatively small variation in wavelength with vehicle speed which is observed in practice. In this presentation a sophisticated linear wheel-rail model is introduced which could help in resolving this contradiction. The transient dynamics is described by a feedback loop: Fluctuations in the contact geometry and the creepages cause varying contact forces. This produces fluctuating relative displacements between wheel and rail which in turn change the contact geometry and the creepages again. The simulation of the long-term behavior shows how the rail surface is damaged after a high number of wheel passages. Based on numerical results it is demonstrated that, due to contact mechanical effects, short pitch corrugation is growing within a fixed wavelength band, which could explain why the wavelength varies only a little with vehicle speed. The presented model is therefore a good basis for future research on how short pitch corrugation can be suppressed.

3:20

1pNSc4. On the determination of dynamic properties of elastic rail fastenings. Rolf J. Diehl and Paul Hofmann (Müller–BBM, Robert-Koch-Strasse 11, D-82152 Planegg, Germany)

The dynamic properties of the resilient layers of rail-fastening systems play an important role for sound and vibration emission from railway lines. In order to achieve low sound radiation from the rails, a rather stiff fastening for the rail is advisable, whereas for vibration minimization rather soft fixtures would be preferred. The dynamic properties of fastening systems are determined from measurements. In order to have comparable results, a CEN standard is currently being written which is consistent with the method described in ISO 10846 for laboratory measurements of the dynamic stiffness. The method and examples for results will be discussed. For the optimization of the setup for a given situation [track, vehicles, speed(s), operating conditions, surroundings], theoretical models are useful tools. In addition, such models can be used to predict the future impact. Apart from the prediction model itself, the quality of a prediction depends on the reliability of the input data. Results of calculations with the rail/wheel impedance model RIM will be shown to demonstrate the effect of different vertical stiffnesses of the rail fastening and its frequency dependence on the emitted sound and vibration levels.

3:40

1pNSc5. Reduction of ground-borne noise from rail systems. George P. Wilson (Wilson, Ihrig & Assoc., Inc., 5776 Broadway, Oakland, CA 94618)

Over the last 35–40 years there has been an ever increasing awareness of ground-borne noise from rail system train operations and an increasing need for mitigation. In response there have been extensive and continuing efforts to develop rail fixation and support systems which will reduce or control the ground-borne noise which originates at the wheel/rail interface. The rail fixation systems have varied from simple resilient boots on sleepers or resilient pads under rail fixation plates to elaborate concrete floating slab trackforms. Intermediate mitigation designs have included ballast mats, booted duo-block sleepers, and many configurations of resilient rail fixation baseplate assemblies. A review of the various types of ground-borne noise mitigation trackform designs is presented along with indication of the effectiveness for each type or class of design. Further, characteristics or design parameters of the various classes of design which result in poor performance are discussed, particularly for floating slab trackform.

1pNSc6. STV: Silencing goods traffic. Part 2: Demonstrating practical low noise solutions. J. Lub (NS Technisch Onderzoek, P.O. Box 8125, NL-3503, RC Utrecht, The Netherlands)

The Dutch national project, Quiet Rail Traffic (Stiller Treinverkeer STV), aims at an overall A-weighted noise reduction of at least 10 dB for day-to-day goods traffic, with a maximum achievable reduction of 16 dB. The project has as goals the development of validated design and analysis methods, and the demonstration thereof by means of the construction and testing of two prototype quiet goods wagons and a prototype quiet track construction. Validation tests will be performed in November 1998. Static and pass-by noise and vibration tests are conducted with two prototype container carrying wagons, loaded with containers and a reference vehicle. The goods wagons are equipped with laser-cladded wheels, composite brake blocks, drum brakes, magnetic brakes, and wheel skirts. They are operated on a continuously laid slab track construction with embedded rail. The rail type is of a newly designed type, optimized for noise reduction and application in track designs with continuous rail support. Mini-barriers and sound absorption material are applied to the track. A telemetry system is used for measuring wheel noise. The improvements achieved by the total prototype wagon/track combination and components are compared to the predicted noise reduction and data collected in the reference phase of the project.

4:40

1pNSc7. The real sound emission of ''Rasengleis.'' P. Fuerst (cdf Schallschutz Dresden, Wilhelm-Liebknecht-Straße, 6, D-01257 Dresden, Germany, cdf-Schallschutz-DD@t-online.de)

The ''Rasengleis'' (railway lines which are covered by meadow and bedded on conventional ballasted tracks) has indeed a lower noise emission level. Various investigations focusing on the acoustical behavior of the ''Rasengleis'' were carried out in the last years. The results were rather different. The first sequence of measurements took place **before** changing the construction of the second part of the railway line. That was to counterbalance errors due to locality, time (the last measurement was carried out almost 2 years later than the first one), and other ambient conditions. The levels could be easily compared among each other using the results of the reference point. Additionally, the measurements were repeated after at least a year to take aging processes of the meadow into account. Two different types of trams were used. They differ among other things in the kind of absorption used for the wheels. One wheel type contains rubber parts stressed of shearing (Tatra T4D), the other wheel rubber parts are stressed of pressure (Bochum). ''Rasengleis'' reduces noise emission depending on the kind of wheel up to 3 dB (minimum 2 dB). There will be measured levels of drive past, standardized values, and sonograms.

5:00

1pNSc8. Structure-borne noise reduction in a railway tunnel in Cologne by means of a ballastless mass–spring-system-type Züblin with discrete Sylodyn® bearings and dynamically soft Sylodyn® ballast mats. Rüdiger G. Wettschureck (Getzner Werkstoffe GmbH, P.O. Box 162, D-82025 Grünwald/Munich, Germany, Wet@getzner-werkstoffe.de), Franz Breuer (Peutz Consult GmbH, D-40599 Düsseldorf, Germany), Markus Tecklenburg (Getzner Werkstoffe GmbH, Bürs/Bludenz, Germany), and Horst Widmann (Ed. Züblin AG, D-70567 Stuttgart, Germany)

In the vicinity of Chorweiler (a suburb of Cologne) there is a tunnel in the double track of German Railways between Cologne and Düsseldorf which was built for airborne noise protection reasons. On both sides of this tunnel there are very close housing areas built during the last years. The structure-borne noise of the rail traffic caused a considerable interference with the residents. In 1997 measures to reduce the railway vibrations were installed in both tracks of a 970-m-long tunnel section. In one part of the tunnel, 230 m long, a mass–spring system with a natural frequency of 11 Hz, using discrete bearings, was installed. The rest of the tunnel was equipped with ballast mats tuned to extremely low dynamic stiffening and

to main line axle loads (push–pull trains of commuter traffic Rhein/Ruhr) with a specific static stiffness of 0.03 N/mm^3 [according to DB-TL 918071, Edition June (1988)]. The efficiency of these reduction measures, that means their insertion loss, was estimated by means of lumped-parameter models, and measurements of the structure-borne noise during train passages were carried out on identical measuring points before and after the structural alterations in the tunnel and in adjacent buildings. The measurement results show a good correspondence with the calculations and completely confirm the high expectations set in the measures.

5:20

1pNSc9. Short pitch corrugation on straight tracks—Practical experiences. Thomas Klimpel and Klaus Knothe (Tech. Univ. of Berlin, Inst. of Aviation, Dept. of Design, Marchstr. 12, 10587 Berlin, Germany)

One possibility to reduce rolling noise is to reduce roughness excitation. The basis of the paper is measurements of profile irregularities on a test section of the track between Baarn and Amersfoort in the networks of Nederlandse Spoorwegen (NS). In one of two segments, periodic wear pattern (short pitch corrugation) appears with wavelength from 3.5 to 4 cm, whereas the second one is uncorrugated. The line is used only in one direction and mainly by passenger cars with medium speed. Starting from the measured track data, systematic calculations with the program of Müller, which is presented in a separate paper, have been undertaken. The aim is to estimate the roughness growth and to find hints about how the growth can be stopped or at least reduced. In Müller's paper it is explained in detail that roughness growth is restricted to a wavelength range between 2 and 10 cm. Numerical results will be presented in order to clarify how different track components influence the RGG process. The model only takes into account wear as a long-term mechanism. It shall be discussed how the long-term behavior is influenced by plastic deformation, hardness variations, or different values of micro-roughness.

5:40

1pNSc10. A reciprocal method to evaluate low, close to track noise barriers. P. F. van Tol (NS Technisch Onderzoek, Postbus 8125, 3503 RC, Utrecht, The Netherlands) and H. A. Holties (M+P Raadgevende Ingenieurs, 1430 AH, Aalsmeer, The Netherlands)

In the framework of the Dutch program Quiet Train Traffic (Stiller Trein Verkeer) low, close to track barriers and absorptive layers on a slab track have been investigated. Following numerical calculations on low, close to track barriers and absorptive layers an experimental study has been made in order to evaluate the different solutions. A special test site has been constructed, which acoustically resembles a slab track. It enables a quick mounting and dismounting of different low, close to track barriers and absorptive layers on the slab. Using a reciprocal measurement method the acoustical performance (insertion loss) of different solutions has been determined. One of the advantages of a reciprocal method is that the noise reduction for different noise sources on a freight train, such as wheels, rails, and wagon superstructure, due to absorptive layers and low, close to track barriers is easily identified. Note that this stationary method is very efficient since no train passby is necessary. It is explained that a real train passby may be simulated by combining the measurements over multiple angles. Finally, a comparison will be made between the experimental and the numerical results.

1pNSd1. The ''Owl'' as a challenge in airframe noise research. Geoffrey M. Lilley (ICASE, NASA Langley Res. Ctr., Hampton, VA 23681 and Dept. of Aeronautics and Astronautics, Univ. of Southampton, Southampton SO17 1BJ, UK)

The ''silent'' flight of the ''owl'' has captured the attention of the aeronautical community for over 50 years. The silent flight, resulting from changes in the flight feathers of the ''owl'' from all other birds, notably the leading edge comb, the trailing edge fringe, and the upper wing covering of the velvety down feathers, has been known and carefully documented by biologists, ornithologists, and aeronautical engineers. Many of the noise characteristics of an ''owl'' have similarities with airframe noise. By training owls to fly with the leading edge comb removed Kroeger *et al.* (1971) established that the leading edge comb was essential for stable flight at its high lift and low speed. However Kroeger's measurements showed that the ''owl'' had a broadband radiated noise spectrum indicating that the flow in the adverse pressure gradient on the rear upper surface was turbulent at the wing trailing edge. The present paper describes the effect of the trailing edge fringe and the down feathers on the noise spectrum generated by the owl and why the owl remains silent to its prey in spite of their excellent hearing above 2 kHz.

2:30

1pNSd2. Airbus airframe noise reduction—A European harmonized research effort. Werner Dobrzynski (DLR, Institut für Entwurfsaerodynamik, Abt. Technische Akustik, Lilienthalplatz 7, 38108 Braunschweig, Germany)

Very large aircraft—such as the planned Airbus A3XX—require correspondingly high lift forces and extended landing gear structures, thus causing potentially very high airframe noise levels during the landing approach. This problem was realized by the Airbus Consortium, and the first relevant research initiatives date back to the early 1990s. Soon after, initial research at DLR began under contract to Airbus Industrie, dedicated to landing gear airframe noise. Recognizing the general challenge of research for aircraft noise reduction at that time, a European Noise Reduction Initiative (ENRI) was proposed, dealing with both engine and airframe noise. Subsequent technical discussions, however, led to separate programs for engine and airframe noise research, the latter being initiated under the acronym RAIN (reduction of airframe and installation noise). RAIN encompasses analytical and experimental work to describe, predict, and reduce the noise both from landing gears and high lift devices. In parallel, national research programs began: In France wind tunnel and flyover experiments relate to the whole aircraft airframe noise characteristics, while corresponding research in Germany focuses on high lift devices noise. In Great Britain, noise modeling is performed for landing gear noise prediction. These national efforts are coordinated by the Airbus partner companies (3E-program).

3:00

1pNSd3. Directivity of flap side-edge noise as observed with a phased microphone array on landing aircraft. Ulf Michel and Weiyang Qiao[a] (DLR, Müller-Breslau-Str. 8, 10623 Berlin, Germany)

The sound emissions of a large number of aircraft landing at the airport of Frankfurt/Main, Germany, were studied with an 8- by 8-m phased microphone array consisting of 111 irregularly distributed microphones. The data reduction procedure takes account of the motion of the sound sources. The measurement procedure is described and results for the directivity of flap side-edge noise of various aircraft types are reported. Flap side-edge noise is an important airframe noise source on many aircraft and can be clearly identified with the phased array. The variation of this noise source between different aircraft types is considerable, which indicates a substantial noise reduction potential. [a] Permanent address: NW Polytechnical Univ., Xian, PROC.

3:30

1pNSd4. Simulation of acoustic scattering from a trailing edge. Bart A. Singer, Kenneth S. Brentner, David P. Lockard (NASA Langley Res. Ctr., Hampton, VA 23681-2199, b.a.singer@larc.nasa.gov), and Geoffrey M. Lilley (ICASE, Hampton, VA 23681-2199)

Unsteady two-dimensional flow calculations were performed about a thin NACA airfoil with a bluff-body vortex generator positioned at 98% chord. The bluff body produced unsteady vortex shedding, which simulated large coherent eddies in a boundary layer. The shed vortices interacted and occasionally paired as they convected past the sharp trailing edge of the airfoil. The CFD calculations clearly showed acoustic waves emanating from the airfoil trailing edge. The Ffowcs Williams and Hawkings equation [J. E. Ffowcs Williams and D. L. Hawkings, Philos. Trans. R. Soc. A **264**, 321–342 (1969)] was used to compute the acoustic field generated by the unsteady aerodynamic field. Directivity maps and Mach-number scalings have been obtained and compared with the theoretical predictions for trailing-edge noise. The noise below the airfoil displays characteristics typical of a sound field scattered from a sharp edge. The noise above the airfoil is more complicated; it contains significant contributions from both the scattered acoustic field and the bluff-body vortex generator. The effects of spanwise correlation length and the choice of integration surface will also be discussed.

1pNSe1. The noise spectrum of isotropic turbulence. Geoffrey M. Lilley (ICASE, NASA Langley Res. Ctr., Hampton, VA 23681 and Dept. of Aeronautics and Astronautics, Univ. of Southampton SO17 1BJ, UK)

Proudman's solution for the noise radiated from isotropic turbulence at low Mach numbers and high Reynolds numbers was reviewed by Lilley (1994) following the simulation of Sarkar and Hussaini (1993). It was suggested (Lilley, 1996) that the Lighthill–Proudman theory could be used for the prediction of the radiated acoustic power from turbulent free shear flows in the absence of shock waves. In this approximation the Lighthill ''filter function'' was used with distributions of the turbulent kinetic energy, the temperature fluctuations, and the turbulent length scale. The results were compared with experimental measurements. But the method (Lilley, 1996) was only concerned with the total acoustic power. Modifications to this theory are required for the estimation of the spectrum and directivity of the radiated sound. The frequency resolution in time-dependent RANS calculation (TRANS) is limited by the grid used. In most, the large scale structure of the turbulence is resolved and consequently the energy containing scales captured. But the high-frequency part of the spectrum is poorly defined. Present work discusses two models for the high-frequency spectral decay and some of the properties of the high-frequency spectrum in turbulent shear layers.

5:00

1pNSe2. Jet noise of subsonic aircraft: An aeroengine manufacturer's perspective. A. J. Kempton (Installations Eng., Rolls-Royce plc, Derby, UK)

These papers trace the history of jet noise reduction from early pure jets to modern engines with high bypass ratios. Choice of engine cycle is important in reducing jet noise, but there is also the need to balance the requirements of cost, weight, and specific fuel consumption, in addition to minimizing other engine noise sources. Some techniques for reducing jet noise are illustrated. Forced mixers on long-cowl engines are effective in reducing low-frequency jet noise, but can cause an increase in high frequencies (especially in flight). For larger aircraft with more powerful engines, where the noise problem is most severe, installation issues dictate somewhat against long-cowl configurations. The current challenge is therefore to achieve similar noise reductions to forced mixers but on short-cowl engines. In the future, the requirement for further noise reductions might result in much more novel aeroplane and engine configurations. Jet noise experiments can easily give misleading results unless the facilities and rigs are designed to avoid contamination by excess noise and to provide correct simulation of boundary layers and other aerodynamic parameters (including flight simulation). Fortunately, testing at reduced scale is acceptable for noise. Advanced measurement techniques (like source location) can be very beneficial in aiding understanding.

5:30

1pNSe3. Industry perspective on jet noise—Prediction and reduction requirements. David H. Reed, T. R. S. Bhat, and W. T. Conley (Boeing Commercial Airplane Group, Seattle, WA)

Spectacular growth of airline passenger traffic, nearly tenfold since 1970, has been fueled by a steady trend toward lower cost airfares made possible by technological achievements in airframe and aircraft engine design. Of all the advancements in aircraft design, none has been more important than that of the high bypass ratio (HBPR) turbofan engine, first introduced in 1969 on the Boeing 747. Since then, HBPR turbomachinery noise technology has kept pace with other engine refinements, allowing newer aircraft to meet increasingly stringent community noise requirements. Even more advanced turbomachinery and nacelle noise technology is now at hand as a result of government/industry efforts in both Europe and the United States. Engines with substantially lower fan noise will be introduced. Jet noise will remain the major obstacle to further noise reduction. Since the majority of new commercial aircraft over the next 20 years will be powered by HBPR engines, research in jet noise must be a major priority. This paper examines

the needs for jet noise reduction across the range of commercial aircraft types, and suggests technology development efforts including CFD tools for jet characterization, active flow control, installation effects, and novel suppression devices. This paper also discusses challenges in jet noise technology for supersonic airliners.

6:00

1pNSe4. Intensive narrow-band noise of oscillating circular gas jet. Andrew G. Semenov and V. Andrew Rimsky-Korsakov (N. N. Andreev Acoust. Inst., Russian Acad. of Sci., 4 Shvernik St., 117036 Moscow, Russia, bvp@acoins.msk.ru)

Self-sustained oscillations of a jet issuing from a circular nozzle in an impedance plane into unbounded space or interacting with various obstacles, such as a parallel plane or a coaxial rigid circle, are analyzed. In the problem statement region of the circular jet inner boundary, alternative deflection during self-interaction or interaction with obstacles is considered as an axisymmetric monopole (volume) source of axial sound waves inside the jet cylinder directed to the jet root. By means of the corresponding 1-D boundary value problem solution, Nyquist stability criteria are derived for oscillations inside the cylindrical volume bounded by jet boundaries. Conditions favorable for jet boundary axially symmetric self-sustained oscillations excitation are found and their relations to the problem basic parameters are predicted, both for subsonic and supersonic jet cases. The proposed method could be used in various practical jet-obstacle interaction noise-generation problem analyses.

1pPAa1. Studies of scattering from differently shaped objects using the TLM technique. Ulf Kristiansen (Acoust., Dept. of Telecommunication, Norwegian Univ. of Sci. and Technol., O. S. Bragstads plass 2B N-7034 Norway) and Nicolas Brachet (ESM2, Technopole de Chateau-Gombert, 13451 Marseille, France)

The transfer line method (TLM) can be regarded as a discretized version of Huygen's principle. Wave energy propagates along a system of lines connecting regularly spaced node points. An energy packet reaching a node along a certain line will at the next time step be split up and reradiated into all the lines connected to that node. Wave propagation is therefore regarded as a discretized process in space and time with local updating rules. Special rules are applied for reflecting, absorbing, and partially absorbing surfaces. The method has been used for some time in electromagnetic wave propagation, but not so much in acoustic studies. The present study is a 2-D investigation of the scattering of sound pulses from objects having different shapes: circular, triangular, and rectangular. Performing this in the time domain allows the following of the scattering process in detail.

2:40

1pPAa2. Space-wave number representation of transient waves. Experimental determination of the space location origin of Lamb waves on cylindrical shells. Loic Martinez, Jean Duclos, and Alain Tinel (LAUE UPRESA CNRS 6068, BP 4006, Pl. R. Schuman, 76610 Le Havre, France, loic.martinez@lemel.fr)

A new space-frequency-wave number representation is introduced. This representation is obtained by space-sliding window FFT of the space-frequency representation. This new method is used to experimentally define the space origin of the pulse-generated Lamb wave on an air-filled cylindrical shell immersed in water (relative thickness is equal to 0.03). The space-wave number slices also allow the measurement of the Lamb-wave complex wave numbers and their propagation direction (reduced frequencies range from 20 to 1000). The reflected field is experimentally separated from multiple propagating Lamb waves. This efficient method is complementary to the surface wave analysis method (S.W.A.M.) [Martinez *et al.*, 16th ICA and 135th ASA Congress, II, 1359–1360 (1998)]. In particular, the space-wave number representations are not limited by space windowing. The experimental results confirm the theoretical computations performed on waves propagating on a plane plate.

3:00

1pPAa3. Scattering by cylindrical shells: The Scholte–Stoneley wave nature. Naum Veksler, Jean-Louis Izbicki, and Jean-Marc Conoir (LAUE, CNRS UPRESA 6068, Pl. R. Schuman, 76610 Le Havre, France)

A systematic study of the A wave revolving around circular cylindrical elastic shells immersed in water is performed. The resonance frequencies and halfwidths have been computed for a wide range of the b/a ratio (b is the inner radius and a the outer one). The A-wave evolution is studied from the case of the quasisolid cylinder to the case of the very thin shell (b/a equal to 0.99). The resonances are computed from the complex frequency plane; it is then possible to get the dispersion curves of the A wave. The phase velocities dispersion curves, plotted against the adimensional variable ktd (kt is the shear wave number and d the thickness of the shell), practically coincide in the low-frequency range. The resonance halfwidths are small in this frequency range. The A wave is a bending type wave. At higher frequencies, the A wave becomes analogous to a diffracted Franz wave.

3:20

1pPAa4. Sound scattering by Gauss beam from cylindrical objects. I. L. Oboznenko, E. I. Oboznenko (Dept. of Electron., NTUU Kiev Polytech. Inst., Kiev 252056, Ukraine), and Vladimir I. Genis (Drexel Univ., Philadelphia, PA 19104)

Practically, when diagnosing vessels by focusing array, the vessel is radiated not by the plane wave, but a time-limited beam. Here one can see the results of theoretical and experimental research of Gauss beam sound scattering from cylindrical objects with wave resistance different from the medium. Well-known results of sound scattering on cylinders with limited sizes are wrong in reality, because of limiting the vertical size of the cylinder. In fact, all the objects, including the cylinder, are radiated by a nonconcentrated beam, like a Gauss beam. Theoretical and experimental results of Gauss beam scattering in the band of parameter $\alpha = a/w$ (where a-cylinder radius; w-Gauss beam width on e^{-1} range) from 10^{-6} (quasi-plane wave) to 100 (super-narrow beam) show, that a scattered wave spectrum changes very substantially. This point needs caution, and immediately changes classic results for the plane wave. Also, the sound beam echo-signal spectrum in the reverse direction gives one the ability to classify and to differ objects as ''more soft'' or ''more hard'' with respect to medium (for wave resistance it differs up to 5%–10% from medium). This permits the classification of cylindrical foreign inclusions or defects of little vessels like post-, precapillaries.

4:00

1pPAa5. Scattering from cylindrical structures with various end-cap shapes. Angie Sarkissian and Louis R. Dragonette (Naval Res. Lab., Code 7132, Washington, DC 20375-5350, angie@aqua.nrl.navy.mil)

The scattered field from a cylindrical structure near the forward direction is computed using the Kirchhoff approximation of scattering from a screen. The effects of varying the shape of the end-caps are examined by carrying out target strength computations for various shapes. The cylindrical region is modeled to be impenetrable while the effects of varying the reflectivity of the end-cap regions are examined. [Work supported by ONR.]

4:20

1pPAa6. Complex poles of Lamb waves propagating along anisotropic and absorbing fluid-loaded plates. Marc Deschamps and Olivier Poncelet (Laboratoire Mecanique Physique, Univ. Bordeaux 1, 351 Cours de la Liberation, 33405 Talence Cedex, France)

This work presents theoretical and experimental investigations on Lamb wave generation along anisotropic immersed plates. The structure of these guided waves is strongly dependent on the nature of the source (transient source, bounded beam . . .). An incident plane wave for which the signal is time-limited is considered, and leads to transient Lamb waves mathematically defined by complex frequencies. These frequencies are the poles of the reflection/transmission coefficients of the fluid-loaded plates. This point of view, recently developed for isotropic plates, is completely different from the classic approach in terms of leaky Lamb waves, which are harmonic waves. New interesting results are then obtained for the NDT of thin anisotropic plates: the dispersion curves calculated for complex frequencies are very different from those calculated for real frequencies (harmonic waves). Moreover, some modes have a negative imaginary part of the frequency that implies transient phenomena increasing with time. The waveforms of the reflected signals are obtained and explained by the calculation of a contour integral in the complex frequency plane. The roles of anisotropy and absorbing effects are discussed.

4:40

1pPAa7. Experimental determination of the angular width of plate modes. Guy Durinck, Willy Thys (IRC, Katholieke Univ. Leuven, Campus Kortrijk, B-8500 Kortrijk, Belgium), Pascal Rembert, and Jean-Louis Izbicki (Univ. du Havre, 76610 Le Havre, France)

The reflection and transmission coefficient of a plate can be expressed as a function of frequency at fixed angle of incidence or as a function of angle of incidence at fixed frequency. In the first situation, the transmission coefficient can be considered as a superposition of frequency resonances, while in the latter case it can be considered as a superposition of angular resonances [R. Fiorito, W. Madigosky, and H. Uberall, J. Acoust. Soc. Am. **66**, 1857–1866 (1979)]. Using this approximation the properties of frequency resonances of a plate can be determined experimentally [Derible *et al.*, Ultrasonics International 93 Conf. Proc. 483–486 (1993)]. In this work, this approximation is used to determine the properties of the angular resonances. The transmission coefficient as a function of frequency is determined for a large set of angles of incidence by insonifying the plate with an ultrasonic pulse. Then, at fixed frequency, the data are plotted as a function of angle of incidence. The properties of the angular resonances are extracted using the Argand representation of the transmission coefficient. A comparison with theoretical values is made.

5:00

1pPAa8. Wedge diffraction analyzed by localized response function of the boundary value problem. Mitsuhiro Ueda (Tokyo Inst. of Technol., Dept. of IDE, O-okayama, Meguro-ku, Tokyo, 152-8552 Japan, ueda@ide.titech.ac.jp)

A new diffraction principle called virtual discontinuity principle of diffraction, abbreviated by VDPD, which is formulated by considering the wave propagation in a space seen by an observer virtually, has been proposed by this group. The boundary value problem is formulated using VDPD and the Green's theorem. Then it becomes clear that the response function, which shows mutual dependence of the potential on the surface of the object, is composed of two components. One of them is localized near the edges of the object that can be seen by the observer. The other is not localized, just like the response function used in the BEM formulation of the boundary value problem. The observer in the free space can always see the edge of a wedge. Thus the boundary value problem for the wedge diffraction can be formulated using the localized response function only. As a result of the localization near the edge, sampling points of the potential can be limited near the edge. Thus in spite of the infinite size of the wedge, the numerical procedure to solve the problem is simplified remarkably.

5:20

1pPAa9. Modal scattering from orifices. Jane L. Horner, Björn A. T. Petersson (Dept. of Aeronautical and Automotive Eng., Loughborough Univ., Loughborough LE11 3TU, UK, j.l.horner@lboro.ac.uk.), and Richard Lyons (Loughborough Univ., Loughborough LE11 3TU, UK)

When considering a sound wave traveling through a circular orifice in a rigid baffle, both the reflected and scattered field have to be established on the incident side of the orifice. Previous investigations have used Hankel transforms to establish the amplitudes of these two waves. This study concentrates on the coupling of the modes in the scattered and reflected fields, with the object of the investigation being to determine if a modal approach may be taken to describe the reflected sound fields from such an orifice. Results are shown in the form of the modal contributions to the integrand which must be used to obtain the scattered field.

1pPAb1. Reflection coefficient of a Stonely–Scholte wave: An experimental investigation. Edouard Mouton and Manell E. Zakharia (CPE Lyon, LASSSO (LISA, EP92 CNRS), 43 Bd. du 11 Novembre 1918, BP 2077, Bat. 308, F 69616, Villeurbanne Cedex, France)

The Stoneley–Scholte waves are becoming more and more popular in both sediment characterization and nondestructive testing (computation of material and sediment properties, flaw or obstacle detection). When dealing with a 3-D obstacle, the coupling of these evanescent waves with the elastic waves in the target and the continuity conditions may have several definitions. In theoretical papers, some authors choose to impose the continuity of each component of the wave, some others the continuity of the sum vector. A specific tank experiment has been designed and conducted. Its specific goal is to define the continuity conditions that have to be used in future works. A special-purpose mock-up has been built up that contains two different blocks molded in an epoxy resin. One block is ''mechanically hard'' (duraluminum) and the other one is more ''soft'' (PVC). The geometry of both blocks has been especially optimized in order to enhance the reflection and refraction phenomena. For each material, two interfaces were considered: a perpendicular one and sloping one (wih respect to the direction of propagation of surface waves). Frequency range is centered around 100 kHz with an investigation thickness of a few centimeters.

2:20

1pPAb2. Characterization of bonding quality of composites with the nonlinear modulation method. Dimitri Donskoy, Alexander Ekimov, and Alexander Sutin (Stevens Inst. of Technol., 711 Hudson St., Hoboken, NJ 07030)

The nonlinear ultrasonic nondestructive testing technique is emerging as a valuable tool for material characterization and diagnostics. The most widely used nonlinear method is based on measurements of harmonic distortion of the probing ultrasonic wave. Another approach, developed by the authors, utilizes effect of modulation of ultrasound by low-frequency vibration. This method is more sensitive to various material and structural flaws, such as cracks, debonding, delamination, etc. It is also much easier to implement in practice. The present work focuses on characterization of bonding quality of composite plates used in the aerospace industry. The test was performed on 14 samples with various (known) degrees of bonding. The ultrasonic frequencies in the range of 50 kHz to 1.5 MHz were examined to determine the most sensitive frequencies. The modulating vibrations were in much lower frequency range up to 1 kHz. It was found that the average (across the frequency range) normalized modulation level is proportional to the bonding quality and can be used for its quantitative assessment.

1pPAb3. Sound scattering and transmission through cylindrical layer with concentrated defects. Vladimir I. Genis (School of Biomed., Eng., Sci. and Health Systems, Drexel Univ., Philadelphia, PA 19104) and Elena I. Oboznenko (NTUU Kiev Polytech. Inst., Kiev 252056, Ukraine)

An experimental method of defect detection in a cylindrical shell is proposed. Defects are the cylindrical hollows (the projections) on the outside or the inside of the shell, filled up, and encircled by water. The defect diameter makes up 1–2 mm (0–0,95) h long, where h—is a shell thickness. The inverse sound scattering field and pass wave field on the shell axis were measured in the sound acoustic beam. Experimental investigations were compared with theoretical investigations by changing the shell wave dimension in the 2–20 range (the 3-D resilience theory). The presence of the shell resonance clears surges and its inside liquid pillar as lengthening of the defect gradually results in their being illegible. The long defects reduce discrimination of the resonance system shell water. The through defect and the Helmholtz resonator are similar. The measurement results of the shells with defects and without were compared, when the shell was radiated by narrow sound beam (the beam width 10–15 times as much as the defect diameter). The theoretical calculation and experimental measurements of the nondefective shell are practically identical. The proposed method serves for defect presence (or absence) definition in pipelines, blood vessels, and others.

1pPAb4. Modeling of ultrasonic wave interaction with alumine and silica inclusions in steel. Noelle Mercier (LG2mS Acoustique, Univ. de Compiegne, BP 20529, Compiegne, France, Noelle.Mercier@utc.fr) and Nazir Chebbo (Univ. Libanaise, IUT de Saida, BP 813, Saida, Liban)

To progress in the characterization or discrimination of flaws in ultrasonic nondestructive testing, it is essential to have a good knowledge of the interaction of incident ultrasonic waves with these flaws and to model the echographic signals. The flaws considered here are of volumetric type. They have been simulated, in 2-D geometry, by circular cylinder forms. The developed model calculates the stemming time signal of the longitudinal or transverse wave diffused by a cylinder made of a fluid medium, an empty cavity, an elastic, or a rigid solid. The used method is based on the usual modal theory. The time signal is obtained by the Fourier transform of the multiplied monochromatic components, for each frequency, by the spectral response of the transducer. The presented results concern the case of two elastic media which simulate inclusions in steel. The convergence of the modal series, for a quite small flaw, is relatively rapid even for high frequencies. A comparison is presented between experimental and numerical results obtained in retrodiffusion, using a transducer of 10-MHz nominal frequency, for alumine and silica inclusions of about 300 μm. Whereas the beam aspect is not taken into account, the wave curves are similar.

1pPAb5. Depth profiling of residual stress in steel by laser ultrasonics. Weimin Gao, Silvio Elton, X. Kruger,[a] Christ Glorieux, Kris Van de Rostyne, Walter Lauriks, Jan Thoen, and Jacques Charlier[a] (Laboratorium voor Akoestiek en Thermische Fysica, Katholieke Universiteit Leuven, Belgium)

Depth profiling of residual stress in steel is of great interest in many practical applications. Conventional techniques are either destructive (x-ray diffraction and hole drilling) or with obvious restriction (Barkhausen noise). This paper presents a noncontact and nondestructive laser ultrasonics method for determining the depth profile of the residual stress layer in steel samples. It is known that surface acoustic waves penetrate into solids to a depth proportional to the wavelength. They are expected to be dispersive in the presence of gradients in physical properties such as residual stress. Based on the dispersion theory, the depth dependence of an effective velocity $v(z)$, which is related to the stress profile $S(z)$, can be fitted from the frequency dependence of the phase velocity $v(w)$. Due to the advantage of wide bandwidth, laser-generated and -detected surface acoustic waves (SAW) offer a promising nondestructive stress depth profiling method. The profiles obtained by SAW are compared with the stress data obtained by other techniques. [a] Also at Service de Métallurgie Physique, Université Libre de Bruxelles, Belgique.

1pPAb6. Measurements of pulsed velocity field generated by circular and rectangular piezoelectric transducers directly coupled to a block of aluminum. N. Ouarradi and B. Piwakowski (Ecole Centrale de Lille, P.B. 48, Villeneuve d'Ascq 59650, France)

A new computational tool Discrete Representation Acoustic Modelling/Solid (DREAM/S), has been developed for computing the displacement field generated by a pulse-excited transducer, directly coupled to an elastic half-space. It allows the separate determination of different components (shear, compressional, radial, axial) of displacement. This method is based on the spatial pulse response approach and gives directly the transient time-domain field. DREAM/S has already been validated mathematically in regard to analytic and exact methods. The main objective of this paper is to show the experiments performed in order to validate this software. First, a brief presentation of DREAM/S and elementary examples of computing are given. Afterward, the experimental results obtained in the case of circular and rectangular transducers directly coupled to a block of aluminum are presented and compared with the ones obtained by DREAM/S. This comparison displays a good agreement and confirms the high precision of this approach. In order to facilitate the interpretation of multichannel records, including the direct and edge waves and the reverberations from the borders of the model, both computed and recorded signals are displayed in specific format, usually applied in the geophysical imaging.

4:20

1pPAb7. Quality assessment of adherent and fusion-welded joints in silicon wafers by nonlinear ultrasound. A. Wegner, A. Koka, S. Hirsekorn, and W. Arnold (Fraunhofer-IZFP, Univ., Bldg. 37, D-66123 Saarbruecken, Germany, wegner@izfp.fhg.de)

The interest in fusion-welded silicon wafers has increased recently because of their excellent electrical and mechanical properties. Typical applications are in acceleration and pressure sensors. The interface of room temperature bonded wafers contains a physically adsorbed water layer. Bond temperatures higher than 373 K cause a reduction of the adsorbed water by diffusion and thus an increase in bond strength. If electronical components are protected by surrounding silicon wafers, the joining temperature must not be higher than 673 K. The bond strength of the interface essentially defines the reliability of the components. Therefore, a nondestructive method to evaluate the bond quality is required. Binding forces are nonlinear and cause a nonlinear modulation of transmitted or reflected ultrasonic waves. Inhomogeneities in bond strength of an interface can be imaged by the local ultrasonic amplitudes of the insonified frequency and of its higher harmonics measured interferometrically in transmission. A quantitative evaluation of the image data yields information about the variations in bond strength and the size of delaminations and of weakly bonded areas. This paper presents experimental and theoretical investigations of the interface of bonded silicon wafers exploiting the nonlinear transmission of ultrasound. The data are compared to destructive tests.

4:40

1pPAb8. Ultrasonic weld testing using the laser vibrometer detection of a time-reversed A wave. Bruno Morvan, Alain Tinel, and Jean Duclos (L.A.U.E, Univ. du Havre, Pl. R. Schuman, BP 4006, 76610 Le Havre, France, morvan@iut.univ-lehavre.fr)

This study presents a method of weld inspection by a surface wave called A wave. The A wave propagates without attenuation in an immersed plane plate, so it is suitable for a long-range inspection of large structures. The studied structure consists of a brass plate perpendicularly soldered on to another one. For convenience, the welding is discontinuous and a nonsoldered zone is chosen as reference. The A wave is very dispersive, so a time-reversed method is used to temporally focus it on the weld: this improves the signal-to-noise ratio. An immersed transducer transmits a reversed A-wave signal. A laser vibrometer collects, at several locations along a line parallel to the weld, the incident A-wave signal and its reflection on the weld. At each position, owing to the A-wave time-reversal excitation, the two detected signals have the same duration. The correlation of the two signals allows one to determine the time delay between the incident and the reflected signal. Once the group velocity is known, the topography of the weld can be built and the defects localized.

5:00

1pPAb9. One-bit time reversal through high-order multiple scattering media. Arnaud Derode, Arnaud Tourin, and Mathias Fink (Laboratoire Ondes et Acoustique ESPCI—Universite Denis Diderot Paris VII 10, rue Vauquelin 75231 Paris Cedex 05, France, arnaud.derode@espci.fr)

A time-reversal mirror (TRM) is an adaptative device that can focus an ultrasonic wave through an inhomogeneous medium. In a typical experiment, a pointlike source transmits a pulse that propagates through the medium. The distorted wavefronts are recorded by a 128-tranducer array. The 128 signals are digitized over 8 bits, stored in a memory, time reversed, and retransmitted by the array through the medium: the resulting wave converges onto the source, despite the inhomogeneities. In the presence of high-order multiple scattering, the TRM still works and takes advantage of it to refocus a pulse with a finer spatial resolution than in a homogeneous medium. Moreover, it is shown that the TRM is still able to focus a wave even if the recorded scattered wave is encoded over 1 bit, only its sign being used. Reducing the number from 8 bits to 1 does not appear to change the lateral resolution; the signal-to-noise ratio is a little higher. Thus the 1-bit TRM appears to be a very robust and low-cost focusing device. Experiments were carried out in a water tank through a random collection of 2400 parallel steel rods.

5:20

1pPAb10. Characterization of time-reversed elastic waves in ergodic billiards. Julien de Rosny, Carsten Draeger, and Mathias Fink (Lab. Ondes et Acoust., Univ. Paris 7, URA CNRS 1503, ESPCI, 10 rue Vauquelin, 75231 Paris Cedex 05, France, julien.derosny@espci.fr)

One year ago, this laboratory showed experimentally and numerically that an elastic wave can be time reversed in a highly reflecting cavity with a single pointlike source [Draeger and Fink, J. Acoust. Soc. Am. **101**, 3090(A) (1997)]. This is possible because the cavity is low dissipative and its shape is ergodic. Now the properties of this experiment are better understood. Clearly, two parameters are involved. The first one (T) is the beginning of the time reversal window; the second one is its duration ΔT. The lowest value of T which gives an isotropic focusing is the ''angular mixing time;'' it may be related to the ergodicity time. There is another characteristic time: beyond a certain limit, increasing ΔT does not im-

prove the quality of focusing any longer. This ''saturation time'' is very dependent on the initial pulse length; it is analogous to the Heisenberg time. Also, the difference beteween the perfect theoretical time reversal and the experimental one is explained.

5:40

1pPAb11. Backscattering time-reversal of acoustic waves in random media. Arnaud Tourin, Arnaud Derode, and Mathias Fink (Lab. Ondes et Acoust. Univ. Paris VII-ESPCI 10 rue Vauquelin, 75005 Paris, France)

Three years ago, the first experiments showing the reversibility of acoustic waves propagating through high-order multiple scattering media were reported [A. Derode, P. Roux, and M. Fink, Phys. Rev. Lett. **75**, 4206 (1995)]. These experiments were performed in a transmission mode by means of a time reversal mirror (TRM). Here, new time-dependent experimental results obtained in a backscattering mode are reported. The experiment can be described as follows: the TRM used is a linear array of 128 transducers. One of the elements transmits a pulsed wave into the sample which is a random set of 2400 steel rods. In the 128 recorded backscattered signals, short windows are selected which are time-reversed and retransmitted. Surprisingly, it is found that the synthesized time-reversed waves revive their past and converge onto the initial emitting element, despite disorder. Thus the image of the source is recreated, what is referred to as the mirror effect. The spatial refocusing is found to be improved when selecting windows farther and farther in the backscattered signals. The refocused spot time-evolution is well explained by a simple model including both single and multiple scattering contributions.

This poster will be on display in the Poster Gallery from Monday to Wednesday, 15–17 March. Author will be at the poster from 10:00 a.m. to 12:00 noon on Tuesday, 16 March.

1pPAb12. A correlation-measuring system for ultrasonic NDT using maximum length sequences. Torsten Niederdraenk (SIEMENS Audiologische Technik GmbH, D-91050 Erlangen, Germany) and Rainer Thaden (Institut fuer Technische Akustik, RWTH Aachen, D-52056 Aachen, Germany)

In the field of nondestructive material testing (NDT), the advantages of a correlation-measuring technique can be used. In particular, the better dynamic range and gain in the signal-to-noise ratio provide a good possibility of investigating strongly scattering or absorbing materials. The application of maximum length sequences as excitation signals permits the performing of the correlation procedure by using the Fast Hadamard transform (FHT), a very fast correlation algorithm. In nondestructive material testing, a number of special requirements has to be fulfilled. Apart from the driving conditions of the piezoelectric transducers, measurements in NDT often require high measuring frequencies. Based on former developments, a measuring system has been developed that provides a high testing rate; even when using MLS signals of order $n=16$, a rate of 20 Hz is obtained. A partially parallel calculation structure of the FHT gives a vivid looking presentation of the measuring results.

1pPAc1. Higher order effects in finite-amplitude sound fields. Sigve Tjøtta (Dept. of Math., Univ. of Bergen, Johs. Brunsgt. 12, 5007 Bergen, Norway and Dept. of Phys. Univ. of Oslo, P.O. Box 1048 Blindern, NO316 Oslo, Norway)

Nonlinear effects associated with intense sound fields in fluids are considered theoretically. Special attention is directed to the study of higher-order effects that cannot be described within the standard propagation models of nonlinear acoustics (the KZK and Burgers equations). The analysis is based on the fundamental equations of motion for a homogeneous, thermoviscous fluid, for which thermal equations of state exist. Model equations are derived and used to analyze nonlinear sources for generation of flow and heat, and other changes in the ambient state of the fluid. Fluctuations in the coefficients of viscosity and thermal conductivity caused by the sound field are accounted for. Also considered are nonlinear effects induced in the fluid by surface waves in the transducer. The intensity and absorption of finite-amplitude sound waves are calculated, and related to the sources for generation of higher-order effects.

2:20

1pPAc2. Modeling and simulating finite-amplitude propagation through time-varying inhomogeneous absorbing media. Ibrahim M. Hallaj (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, ibrahim@apl.washington.edu), Robin O. Cleveland (Boston Univ., Boston, MA 02215), and Steven G. Kargl (Univ. of Washington, Seattle, WA 98105)

A model equation is derived for three-dimensional wave propagation through an inhomogeneous, time-varying medium. The model equation accounts for arbitrary inhomogeneities, finite-amplitude distortion, and absorption. The effect of time dependence of the background medium parameters is included in the equation. An ordering scheme based on the characteristic time of the evolution of each parameter allows one to evaluate their relative importance. A two-dimensional version of the wave equation is solved in the time-domain using finite-difference methods. Explicit, implicit, and operator splitting techniques were used in the solution to overcome numerical instabilities. Results from the code are compared to known solutions for some simple geometries in homogeneous and

step indexed media. Various modeling and numerical schemes for treating the absorption on the computational domain interior and at the boundaries of the domain will be presented. [Work supported by ONR and DARPA.]

2:40

1pPAc3. Second-harmonic component in the focused beam transmitted through a weakly dispersive liquid layer. Shigemi Saito (Faculty of Marine Sci. and Technol., Tokai Univ., 3-20-1 Orido, Shimizu, Shizuoka, 424-8610 Japan, ssaito@scc.u-tokai.ac.jp)

The characteristic of the nonlinearly generated second-harmonic component in the focused beam which transmits through a layer consisting of weakly dispersive liquid is theoretically and experimentally investigated. In a focused beam, a destructive interference takes place, within the post focal region, between two portions of second-harmonic components which are generated in the pre- and post-focal regions. This is due to the phase delay of the second-harmonic component passing through the focal region relative to the fundamental component. When a weakly dispersive layer is inserted into the focal region, a phase advance occurs for the second-harmonic component passing through the layer due to slightly higher sound-speed for second-harmonic frequency, together with the phase delay due to diffraction. Then the effect of the destructive interference is degraded to result in amplitude increase of the second-harmonic component within the post-focal region. The experiment for a layer of water–oil mixture employed as a dispersive liquid is compared with the nondispersive case and demonstrates the validity of theoretical prediction.

3:00

1pPAc4. Investigation of nonlinear wave distortion in a focal and post-focal region in water. Grazyna Grelowska, Eugeniusz Kozaczka (Naval Acad., ul. Smidowicza 71, 81-919 Gdynia, Poland), and Grazyna Lypacewicz (Polish Acad. of Sci., 00-049 Warsaw, Poland)

The subject of interest is sources of finite amplitude. Focusing sources belonging to both of the two main differentiated groups of such sources have been examined. The first one consists of sources with additional lens, and the second one of the single-element PZT sources. Previous investigations concerned mainly phenomena occurring close to the source—in a prefocal and a focal region. The phenomena appearing at the longer distances in the post-focal region, where the nonlinear wave distortion is obviously considerably greater than in a pre-focal region, is the main topic of this paper. Experiments are conducted in measurements of spatial pressure distribution in a beam radiated by: (1) a single PZT element focused source with a fundamental frequency of 1.5 MHz, (2) a PZT plane circular source coupled with the plano-concave lens with a frequency of 1.0 MHz. A PVdF hydrophone with diameter of 1 mm was used as a pressure probe. The results of the experiments are compared to the theoretically predicted ones. The sound field was modeled by the KZK equation with the equivalent boundary condition adequate to the actual boundary condition.

3:20

1pPAc5. The decay of pulses with complex structure according to Burgers' equation. Sergey N. Gurbatov, Galina Pasmanik (Dept. of Radiophys., Nizhny Novgorod State Univ., Nizhny Novgorod 603600, Russia), and Bengt O. Enflo (KTH, S-10044 Stockholm, Sweden)

Nonlinear plane acoustic waves propagating through a fluid are studied using Burgers' equation in the two cases: small viscosity and viscosity tending to zero. The evolution of initial pulses with monochromatic and noise carrier is considered. The initial pulses are characterized by two length scales. The length scale for substantial changes of the modulation function is much greater than the corresponding scale of the carrier. Some simple pulses with only one length scale are also studied, since their properties are important for the studies of pulses with two scales. With increasing time, the initial pulses are deformed and shocks appear. The shocks then merge, and finally a finite pulse ends up with an N wave and a periodic signal with a sawtooth wave. The decrease of the energy of the wave with time is investigated for pulses with both monochromatic and noise carrier and for vanishing and finite but small viscosity. How the characteristics of the final waves depend on the characteristics of the initial waves is also investigated. Both numerical and analytical methods are used.

3:40

1pPAc6. Investigation of the process of self-demodulation of acoustic waves in the river sand. Veniamin E. Nazarov, Vladimir Yu. Zaitsev (Inst. of Appl. Phys., Russian Acad. of Sci., 46 Uljanov St., 603600 Nizhny Novgorod, Russia), and Andrey B. Kolpakov (Inst. of Civil Architecture, 603600 Nizhny Novgorod, Russia)

Experimental investigation and theoretical description of nonlinear self-demodulation of a pulsed high-frequency acoustic wave and propagation of the secondary low-frequency acoustic pulses in dry and water-saturated sand are carried out. The dependence of the propagation time of the video pulses upon the initial static pressure and the relation of the duration and the form of the secondary pulses with the form of the envelope of the initial high-frequency wave were studied. In order to describe the observed dependences, nonlinear equations of state for the considered grain media were suggested. Using the equations, analytical expressions for the demodulated pulse forms were derived. On the basis of matching the theoretical predictions and experimental data, linear and nonlinear acoustic parameters of the sand are determined. The obtained results may be applied to analysis of seismic signals and used for development of seismoacoustic sensing methods, primarily for diagnostic applications of nonlinear effects.

1pPAc7. Effects of micro bubbles vibration for increase of acoustic streaming. Shinichi Sakamoto and Yoshiaki Watanabe (Dept. of Electron., Doshisha Univ., Kyotanabe, Kyoto 610-0321, Japan, tr0141@mail4.doshisha.ac.jp)

The effects of the existence of micro bubbles in water for the increasing of acoustic streaming velocity are experimentally discussed. Velocity of acoustic streaming is observed on the sound axis by LDV (laser Doppler velocimeter). Acoustic streaming is generated by continuous ultrasonic sound transmitted by some PZT transducers whose diameter is 15 mm and resonant frequencies are 2.98 or 3.46 MHz. Sound pressures of ultrasonic sound are set to 80, 160, and 240 kPa at the last peak position on the sound axis. Micro bubbles are generated by extracting water with a syringe mechanism, decreasing the pressure of water down to 6.4% below static pressure. Average radius of micro bubbles is approximately 220 μm. The experimental results clearly show the velocity of acoustic streaming increases; the velocity increases from 9 to 13.5 mm/s when the micro bubbles exist. The harmonics are observed when the micro bubbles are generated. The mechanism for the increase of acoustic streaming is discussed from the point of view of the nonlinear effect of the bubble vibration.

1pPAc8. Anomalously high elastic nonlinearity and frequency-independent Q-factor as complementary properties of microinhomogeneous solids. Vladimir Zaitsev[a)] (Katholieke Univ., Leuven, Belgium)

During the last few decades, a wide class of media demonstrating anomalously high elastic nonlinearity was experimentally revealed (e.g., rocks, grainy materials, concretes). Their nonlinear parameters often exceeded those of homogeneous liquids and solids by several orders of magnitude, whereas linear elastic properties remained ''normal.'' Just the same, materials often possess an almost frequency-independent Q-factor, which also is quite different from homogeneous liquids. These acoustical peculiarities may be evidently attributed to the influence of structural microinhomogeneities (e.g., cracks, grains, etc.) typical of the mentioned media. Recently, a few physical models describing nonlinearity of grainy

and crack-containing materials were proposed, while the description of the dissipation (almost frequency-independent Q-factor) still is restricted to phenomenological models. The report presents a rather demonstrative model of microinhomogeneous solids, which allows for explanation of the mentioned facts. It follows naturally that the microinhomogeneities may not cause significant change of linear elasticity, whereas a sharp increase of elastic nonlinearity and occurrence of the frequency-independent Q-factor appear to be complementary manifestations of the same microstructure. The model readily allows one to relate medium structural features with its elastic and dissipative properties. 1pPAc9. Dissipation in solids: Thermal oscillations of atoms. Adnan Akay and Cem Celik (Carnegie Mellon Univ., Pittsburgh, PA 15213)

Dissipation in a solid is related to the increase in the average kinetic energy of its atoms as a result of external excitation. This paper investigates the relationship between vibration field of a nonlinear lattice of atoms and its energy absorption properties. Numerical results show that a nonlinear lattice accepts energy when excited within its resonance bands. The width of the resonance bands increases with increased nonlinearity, eventually leading to their overlap.

5:20

1pPAc10. ''Acoustical modeling'' according to the theory of the common networks—Taking into account nonlinear effects. Joern Huebelt and Ennes Sarradj (TU Dresden, Inst. fuer Technische Akustik, Mommsenstr. 13, 01062 Dresden, Germany)

One method to model the electroacoustical transducer consists of describing its basic system components using lumped elements according to the theory of the common networks. In the past this technique has been widely used. However, the validity of the underlying simplifications has to be proofed in particular cases. The modeling of the acoustic behavior of a signal horn shall demonstrate the efficiency of this method. In a first step, a linear model in the frequency domain was established. It turned out that for a more exact simulation, the consideration of nonlinear effects is necessary. Due to the extension to nonlinear components, the analysis of the system has to be carried out in the time domain. The model provides the possibility to include the results of the FEM analysis or the BEM analysis, for those system parts which cannot be reduced to lumped elements. Moreover, it enables a relatively fast and inexpensive examination of the system characteristics compared to the FEM or the BEM analysis and can be easily adapted to similar horn types.

5:40

1pPAc11. On ambiguity in the description of sources and the choice of the acoustic variable. Ricardo E. Musafir (PEM/COPPE and DHS/EE, Universidade Federal do Rio de Janeiro, C.P. 68503, RJ, 21945-970 Brazil, rem@serv.com.ufrj.br)

In a homogeneous medium at rest, a classical problem of source ambiguity is expressed by the fact that one cannot differentiate between the fields of a volume displacement point monopole and of a volume acceleration isotropic point quadrupole. In more complex situations, a similar identity concerning the fields of more elaborate combination of point sources can be shown to exist. This reflects the fact that, since two types of energy are involved in the propagation, one cannot tell, from the wave field alone, of which type was the action responsible for originating the wave, there existing, ideally, always a way of representing a ''mass'' source by a combination of ''momentum'' sources and vice versa. It is shown, however, that, depending on the choice of the acoustic variable—and thus on the operations needed in order to combine the continuity and momentum equations into a single equation, this elegant picture may not be clearly displayed in the wave equation. The particular case of the use of the stagnation enthalpy as dependent variable is examined as an example, the analysis being used to discuss its adequacy as a variable for aerodynamic noise problems.

1pPAc12. Nonlinear effect of the inertia of the fluid on acoustic streaming in cylindrical guides. Ludovic Menguy and Jöoel Gilbert (Lab. d'Acoust. de l'Univ. du Maine UMR CNRS 6613, Ave. Olivier Messiaen, 72085 Le Mans Cedex 9, France)

Acoustic streaming is the mean flow created by a high sound level wave. Classical treatment [J. W. S. Rayleigh, Philos. Trans. R. Soc. London **175**, 1–21 (1884)] considers that in cylindrical guides a standing acoustic wave creates a symmetrical toroidal vortex (slow streaming) due to the action of Reynolds stress forcing resisted by viscosity. A perturbation method followed by a time averaging applied to the conservation equations leads to the equations describing the behavior of the mean flow velocity in a cylindrical air-filled guide. According to a dimensional analysis, the effect of the fluid inertia cannot be neglected if the streaming becomes perceptible. This effect, previously studied for free or semi-infinite space, is controlled in the case of a waveguide by the dimensionless parameter $\mathrm{Re}_{nl}=\mathrm{M}^2/\mathrm{Sh}^2$ (M and Sh are the acoustic Mach number and the Shear number). Numerical resolution of this nonlinear system of equations (Newton–Raphson method) is performed using nonslip conditions on the tube wall and mass flux conservation accross the section of the tube. Results indicate that inertia distorts perceptibly the streamlines, and renders vortex pattern unsymmetrical. A comparison of slow and nonlinear acoustic streaming is finally achieved.

1pPAd1. Sonoluminescence: Current status and future perspectives. Lawrence A. Crum and Thomas J. Matula (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

Considerable recent attention has been directed at the phenomenon of sonoluminescence, especially since the discovery of single-bubble sonoluminescence (SBSL), in which a single, stable, acoustically levitated gas bubble can be made to pulsate with a sufficiently large amplitude to emit light each acoustic cycle. It appears that exciting physics may be associated with this phenomenon. When a sufficiently strong acoustic field is propagated through a liquid containing microscopic cavitation nuclei, similar optical emissions can be observed, although the spectrum of this multiple bubble sonoluminescence (MBSL) often possesses characteristics of the host liquid and its constituents, unlike the spectra of SBSL, which has no discernible bands or lines. Nevertheless, MBSL spectra should be able to shed considerable light on the discipline of sonochemistry. Relevant aspects of the current status of SBSL and MBSL research will be reviewed, some speculations on future directions will be offered. [Work supported in part by the NSF.]

1pPAd2. The cavitation collapse on a sub-ns time scale. B. Gompf, R. Pecha, and W. Eisenmenger (1. Physikalisches Inst., Univ. Stuttgart, Pfaffenwaldring 57, D-70550 Stuttgart, Germany)

A single sonoluminescing air bubble trapped in the pressure maximum of a resonant sound field in water is an ideal model system to investigate the end phase of the cavitation collapse. The dynamics of these single bubbles can be characterized with Mie-scattering. In earlier experiments, the scattered light was detected with photomultiplier tubes (PMT) where the time resolution is limited by the response of the PMT and no spatial resolution is possible. Using a streak camera, the scattered light can be recorded with high spatial and temporal resolution. The streak images show that at the minimum radius the scattered light intensity is not only a function of $R(t)$ anymore, and the changes in the refractive indices inside the bubble and in the highly compressed water surrounding the bubble have to be considered. Together with the width and intensity of the emitted light pulses, the results represent a complete data set for the end phase of the bubble collapse.

1pPAd3. Measuring cavitation conditions by multibubble sonoluminescence. Kenneth S. Suslick, William B. McNamaraIII, and Yuri T. Didenko (Univ. of Illinois, 600 S. Mathews Ave., Urbana, IL 61801, ksuslick@uiuc.edu)

Multibubble sonoluminescence (MBSL) arising from ultrasonic irradiation of solutions containing volatile transition metal carbonyls have been collected and analyzed. The principal emission is the atomic line spectrum from excited states of the metal atoms. This metal atom MBSL has been used to determine the effective emission temperature of cavitation as a function of the dissolved gas, and the effects of changes in the ratio of the heat capacities and of the thermal conductivity of the dissolved gas have been examined. The results strongly support a simple near-adiabatic compression model of cavitation. The results also indicate that the continua in MBSL spectra are due to emission from small molecules, and not due to plasma emission. [Work supported by the NSF and in part by the DOE.]

1pPAd4. Simulation of bubble motion in acoustic cavitation. Robert Mettin, Stefan Luther, Claus-Dieter Ohl, and Werner Lauterborn (Drittes Physikal. Inst., Univ. Göttingen, Bürgerstrasse 42-44, D-37073 Göttingen, Germany, R.Mettin@physik3.gwdg.de)

The motion of cavitation bubbles in an acoustic field is investigated both experimentally and numerically. To simulate the experimental results, a particle approach is employed which calculates the trajectories of many individual bubbles. For this purpose, added mass, drag, and Bjerknes forces are considered, and nucleation and coalescence of bubbles are modeled. Though the particle model is based on simplifying assumptions, it can reproduce different cavitation structure types observed in experiments. 1pPAd5. Bubble dynamics and SBSL in a variable acceleration environment. R. Glynn Holt, Ronald A. Roy, and Sean C. Wyatt (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, rgholt@bu.edu)

In order to prepare for pending experiments in variable g environments, some of the multiple effects caused by the time-varying acceleration of acoustic resonators used in bubble levitation experiments were considered. The coupled effects of the induced changes in ambient pressure (due to a changing hydrostatic head) and bubble position (due to a change in the buoyant body force) were modeled. Changing the ambient pressure, while holding the acoustic pressure amplitude constant, causes changes in the radial bubble response and diffusive equilibrium requirements. Changing the bubble levitation position causes both the local acoustic pressure amplitude and gradient to change, which will again impact bubble response. If the bubble is required to remain in a stable diffusive equilibrium, both of these effects will force the bubble equilibrium radius to change. Finally, by using an empirical relation for emitted SL intensity versus bubble response, the variation of emitted light intensity as a function of the changing ambient acceleration is obtained. Where possible, these results are compared to experimental data. [Work supported by NASA.]

1pPAd6. Single-bubble large-scale cavitation. Vadim A. Simonenko, Vladimir N. Nogin, Nikolay G. Karlykhanov, Gennadiy V. Kovalenko (Russian Federal Nuclear Ctr., ITP, P.O. Box 245, 456770 Snezhinsk, Chelyabinsk region, Russia, sva@sva.ch70.chel.su), and William C. Moss (Lawrence Livermore Natl. Lab., Livermore, CA 94550)

Recent successes in experimental and theoretical studies of single-bubble sonoluminescence (SBSL) suggest the possibility of achieving high energy densities in the collapsed bubble. Scaling analyses and efficient ways for cavitation enhancement are discussed, with particular attention to the geometrical size of the system components and ambient pressure level. The goal is to increase the energy density in the collapsed bubble and increase the size and mass of the heated region. Theoretical estimations and results of direct hydrodynamic numerical simulations are presented for a prospective system with a 0.01- to 0.1-mm-radius gas-filled cavity that is surrounded by a 0.3-m-radius liquid-filled shell. The liquid-filled shell is surrounded by two concentric gas-filled spherical shells. The inner shell contains pressurized hydrogen, whereas, the outer shell contains oxygen. The initial rarefaction phase, which caused bubble expansion, is caused by a sudden release of the hydrogen gas into the outer oxygen-filled shell. The subsequent compression phase results from the combustion of the hydrogen and oxygen gases. [Work was partly supported by CRDF].

1pPAd7. Single-bubble sonoluminescence: Investigation of the emitted pressure wave with a streak camera and a fiber-optic probe hydrophone. R. Pecha, Z. Q. Wang, B. Gompf, and W. Eisenmenger (1. Physikalisches Inst., Univ. Stuttgart, Pfaffenwaldring 57, D-70550 Stuttgart, Germany)

In the collapse end phase of single-bubble sonoluminescence (SBSL), in addition to a short light pulse, a spherical pressure wave is emitted by the bubble into the surrounding liquid. This pressure wave was investigated with two different methods: (1) If the bubble is illuminated by a laser beam, laser light is Mie-scattered by the bubble itself, but also by the outgoing pressure pulse. The scattered light of both was recorded with a streak camera with a spatial resolution of 8 μm and a temporal resolution of 500 ps. From the time-dependent radial distance of the pressure pulse $r(t)$ from the bubble, the velocity $v(t)$ can be determined. The speed of sound in the vicinity of the bubble is increased in comparison to normal conditions. This change in the sound velocity was used to estimate the amplitude of the pressure pulse. (2) At a distance of 2.5 mm from the bubble, a fiber-optic probe hydrophone with a spatial resolution of 100 μm and a rise time of 5 ns was used to measure the pressure wave. Measurements depending on the amplitude of the driving sound field, the gas concentration, and the temperature of the water will be presented.

4:40

1pPAd8. Experimental observations of the effect of ambient pressure on single-bubble sonoluminescence. M. Dan, J. D. N. Cheeke (Phys. Dept., Concordia Univ., 1455 de Maisonneuve Blvd. W., Montreal, QC H3G 1M8, Canada, manas@alcor.concordia.ca), and L. Kondic (Duke Univ., Durham, NC 27708)

The experimental observations of the influence of ambient pressure on single-bubble sonoluminescence will be presented. In the SBSL regime as the ambient pressure was decreased only about 10%, the SL intensity increased significantly as predicted [L. Kondic, C. Yuan, and C. K. Chan, Phys. Rev. E **57**(1), R32–R35 (1998)]. There was an increase of about five times in SL intensity as the ambient pressure was decreased by about 10%–12%, at constant driving acoustic pressure. This increment continued until a certain value of the ambient pressure, below which the bubble became unstable and vanished. The equilibrium radius and the maximum radius of the SBSL bubble both incerased with decrease of ambient pressure. This observation provides valuable insight into the mass flow mechanism between the bubble and the liquid, and gives the first direct confirmation of ''argon bubble hypothesis.'' [Work supported by NSERC and Concordia Seagram Fund for Innovative Research.]

1pPAd9. Parameter space of single-bubble sonoluminescence for various liquid temperatures. D. Felipe Gaitan (NCPA, Univ. of Mississippi, University, MS 38677) and R. Glynn Holt (Boston Univ., Boston, MA 02215)

In a previous paper by the authors [Phys. Rev. Lett. **77**, 3791 (1996)], the region of parameter space (acoustic pressure, ambient bubble radius) in which stable single-bubble sonoluminescence (SBSL) occurs in an air–water system driven at 20.6 kHz was described as a function of the dissolved gas concentration. In this paper, new data (ambient radius, maximum radius, expansion ratio, as well as the emission and extinction thresholds) will be presented for the SBSL parameter space at various liquid temperatures for different gases and liquids. [Work supported by the Office of Naval Research.]

5:20

1pPAd10. Molecular dynamics approach for a sonoluminescing bubble. Burkhard Metten, Thomas Kurz, and Werner Lauterborn (Drittes Physikalisches Institut, Univ. Goettingen, Burgerstr. 42-44, D-37073 Goettingen, Germany, metten@dpi.physik.uni-goettingen.de)

Up to now the numerical calculations for the converging shock or compression wave model of sonoluminescence have been based primarily on continuum methods. Here an alternative approach by molecular dynamics simulation is shown to be feasible with today's computer memory and speed. Both approaches are compared. Results of the simulations are presented for the scaling behavior with the number of particles, for different boundary conditions (spherical and ellipsoidal bubbles) and for one and

more species in the bubble. The dependence of the light intensity and pulse duration on the sphericity of the bubble is discussed. [Work supported by the Graduiertenkolleg Stroemungsinstabilitäten und Turbulenz.]

5:40

1pPAd11. Single-bubble sonoluminescence in water during transitions from hypergravity to low gravity on NASA's KC-135 aircraft and laser-beam extinction methods for studying bubble dynamics. David B. Thiessen, Jeremy E. Young, Mark J. Marr-Lyon, Ben R. Dzikowicz, and Philip L. Marston (Dept. of Phys., Washington State Univ., Pullman, WA 99164-2814)

The sound field which drives SBSL also provides the radiation force which counteracts the average buoyancy of the bubble. One consequence is that the location of the bubble should be altered by the effective acceleration of gravity g_e. Variations in g_e may alter the physical processes giving rise to luminescence. This group's previous experiments have confirmed that SBSL is not automatically quenched in the reduced and enhanced g_e conditions in an aircraft undergoing parabolic flight trajectories [D. B. Thiessen *et al.,* in *Proc. of the 4th Microgravity Fluid Phys. Conf.* (NASA, 1998), pp. 379–383]. The new experiments were carried out with the SBSL chamber in contact with a constant-pressure gas-filled chamber. During intervals of negligible drift in the SBSL intensity, there can be a rapid intensity rise (with a relaxation time of about 5 s) of about 4% as g_e is decreased from 1.8 to near 0 g, but the increase is not seen in all data sets. In related work, diagnostics based on monitoring laser-beam extinction with a photocell [J. S. Stroud and P. L. Marston, J. Acoust. Soc. Am. **94**, 2788–2792 (1993)] is applied to SBSL bubbles in the laboratory. [Work supported by NASA.]

1pPAe1. Acoustic emission signals from the sol–gel transition of tetraethoxysilan (TEOS) and sodium silicate solutions. Jadwiga Rzeszotarska, Feliks Rejmund (Inst. of Fundamental Technolog. Res., Polish Acad. of Sci., Swietokrzyska 21, 00-049 Warsaw, Poland, freymund@ippt.gov.pl), and Jerzy Ranachowski (Polish Acoust. Society, 00-049 Warsaw, Poland)

Sol–gel processes have been used extensively to prepare oxide materials (glasses and ceramics). The acoustic emission (AE) method with broadband piezoelectric transducer (up to 500 kHz) was used to control the evolution of slow gel formation from organic TEOS and fast formations from sodium silicate as the precursors of silica. The obtained dependencies of the AE count rate and rms values versus time characterize the dynamic of the cross-linking and desolvation processes under ambient conditions. The frequency distribution analysis of individual power spectra provides an activity estimation of integral parts of processes. In sodium silicate solutions the spectra of low frequency (17–70 kHz) were mainly observed. On the other hand, the most representative spectra from the gelation of TEOS display at three basic ranges; 16–20 kHz, 200–230 kHz, and 400–470 kHz. The relative intensities of spectra in these ranges were changed considerably during the gel formation. [Work partly supported by KBN Grant No. T 07B 047 15.]

1pPAe2. Ultrasonic velocity and absorption in the binary mixtures of 1-butanol with isomeric butanediols at 298.15 K. Edward Zorebski and Michal Zorebski (Inst. of Chemistry, Silesian Univ., Szkolna 9, 40-006 Katowice, Poland, emz@tc3.ich.us.edu.pl)

From the early days of ultrasonic technology, ultrasonic velocity and ultrasonic absorption have been a rich source of information on the structure and condition of the materials trough in which the ultrasonic waves are propagated. Here an investigation into binary mixtures (in the whole concentration range) of 1-butanol with 1,2-butanediol and 2,3-butanediol at 298.15 K is reported. For the ultrasonic velocity measurements at 2.15 MHz, the pulse-echo-overlap method was used and the ultrasonic absorption in the frequency range 10–200 MHz was determined by the standard pulse technique, where the amplitude of the first transmitted pulse was registered as a function of distance. The results were compared with the previous data for 1-butanol with 1,3-butanediol and 1,4-butanediol and discussed in terms of molecular interactions in highly associated liquids.

1pPAe3. Ultrasonic study of ionic association in aqueous solutions of lanthanide salts. Birutė Voleišienė, Gintara Miglinienė, and Algirdas Voleišis (Ultrasound Res. Ctr., Kaunas Univ. of Technol., Studentų str. 50, LT-3031 Kaunas, Lithuania, ulab@tef.ktu.lt)

The association reactions between trivalent ions of lanthanum, cerium, neodymium, gadolinium, erbium, ytterbium, and nitrate or sulphate ligands has been investigated from ultrasound velocity dispersion measurement data. It is assumed that ultrasound velocity dispersion in aqueous solutions of lanthanide nitrates and sulphates is caused by an association process. The ultrasound velocity was measured by the ultrasonic laser interferometer within the frequency range of 3–200 MHz. The rates of formation of inner sphere complexes $[LnNO_3]^{2+}_{aq}$ and $[LnSO_4]^{+}_{aq}$ were calculated and the interaction between individual ions Ln(III) and water molecules is discussed across the series. A comparison of relaxation parameters for the nitrate solutions with corresponding sulphates was made. It has been shown that a magnitude of an ultrasound dispersion may be the quantity of complexation. Ultrasound velocity dispersion for nitrate solutions is much smaller than that of more diluted lanthanide sulphate solutions. The lanthanide nitrates form predominantly outer sphere complexes with some inner sphere substitution. In order to produce an appreciable amount of inner complexes in nitrate solutions for a similar dispersion and relaxation, a tenfold higher concentration of the nitrates must be used.

1pPAe4. Effect of wall adsorption on the photoacoustic detection of ammonia with a 1.53-μm DFB diode laser. Andreas Hebach, Andras Miklos, and Peter Hess (Inst. of Physical Chemistry, Univ. of Heidelberg, Im Neuenheimer Feld 253, D-69120 Heidelberg, Germany, andreas.miklos@urz.uni-heidelberg.de)

The adsorption of ammonia molecules (and other polar molecules such as nitrogendioxide, water, etc.), on the walls of the photoacoustic (PA) detector influences the accuracy of the concentration measurement. This effect becomes larger for small concentrations and depends on the direction of the concentration change. This means that a hysteresis of the PA signal is observed between measurements carried out by decreasing and by increasing the concentration. The adsorption problem was reduced considerably by performing the measurements in a continuous flow. For measurements with high flow rate a new photoacoustic detector was developed. The differential design provides good flow and electronic noise suppression. The PA signal has been generated by tuning a 40-mW, 1.53-μm GEC-Marconi DFB laser to the absorption peak of ammonia at 1527 nm. The dependence of the PA signal on the flow rate of ammonia–nitrogen mixtures with different concentrations was investigated. In another experiment the hysteresis of the PA signal was investigated by increasing and decreasing the concentration in several steps, but maintaining the same total flow rate. It was found that a higher flow rate results in a smaller error of the concentration measurement and a shorter response time of the PA detector.

1pPAe5. The effects of ultrasonic waves on dye penetration with cellulose fabrics dyed by vinylsulphonic dyes. Vesna Ignjatovič, Mile Novakovič (Faculty of Technol., Leskovac Bulevar, oslobo/enja 124, 16000 Leskovac, vesnateh@tehfin.tehfak.ni.ac.yu), and Milena Miljkovič (Leskovac Bulevar, 16000 Leskovac)

Research has shown that ultrasound traveling in the form of waves through liquids causes the effect of cavitation. Cavitation is manifested in a continuous creation and disappearance of vacuums within the liquid. Therefore, interruptions are created in the liquid, that is, strong forcing waves are made. The cavitation strikes are used in solid matter destruction, emulsion creation, greasy surface cleansing, and the like. The ultrasonic energy has been applied in textile industry, for the most part in soaking processes, and textile washing and cleaning. There is research indicating that ultrasonic energy can be used in dyeing of cotton with direct and reactive dyes, of polyamid and wool with acid dyes, and of polyester and acetate fibers with disperse dyes. Based on previous research, this paper is an account of an experiment whose aim was to implement the latest achievements in vibration and ultrasonic theory in textile dyeing technologies. Thus cotton knitwear has been dyed with vinylsulphonic reactive dye, with and without the use of ultrasonic energy, and with the introduction of an air bubble in the dye tub with the application of ultrasonic energy. Previous experiments have shown that ultrasound contributes to greater dye absorption from the tub, so that equal distribution dyeing with the use of ultrasound requires less dye, shorter period of dyeing, less power consumption, and at the same time the pollution of waste waters is reduced. All these characteristics make this procedure economically and ecologically affordable. So as to intensify the process, this research has been directed towards the introduction of an air bubble in the dyeing tub which is under the effect of ultrasound. Dye absorption from the tub and dye penetration in the fabric have been monitored by means of spectrophotometry (absorption and reflection spectrophotometry). Previous research projects have not been able to explain completely the fundamental interaction of ultrasound and fibers, that is, reactive dyes in water, and with that, in the process of dyeing itself. Therefore, future work will deal with this problem. [This paper is a part of research done for the requirements of the project titled ''Modern Approaches in New Dyeing Procedure Development for Optimal Pollution of the Environment,'' and financed by Science and Technology Ministry of Serbia.]

1pPAe6. The effects of ultrasonic energy on reactive dye absorption in the presence of reduced quantities of salt. Mile Novakovič, Vesna Ignjatovič (Faculty of Technol., Leskovac Bulevar oslobo/enja 124, 16000 Leskovac, vesnateh@tehfin.tehfak.ni.ac.yu), and Milena Miljkovič (Leskovac Bulevar, 16000 Leskovac)

Ultrasonic energy has shown a wide range of application possibilities in many fields of human craftsmanship, and its application in textile industry has been a matter of research for a number of years. For the time being, the best results have been achieved in other research still being done in laboratories. This paper presents a part of the overall research done within the project ''Modern Approaches in New Dyeing Procedure Development for Optimal Pollution of the Environment,'' financed by Science and Technology Ministry of Serbia. One of the predetermined objectives of the project is to examine the possibility of ultrasonic energy application in technological processes of dyeing cellulose fabrics by vinylsulphonic dyes. Having that in mind, it is necessary to systematically investigate all of the aspects of ultrasonic energy effects on textile substrata, the dye, and the relation of dye solution and fiber. In the experiments, cellulose microfiber knitwear has been dyed with vinylsulphonic dyes according to the on-line procedure, at a stable temperature, with the addition of varying quantities of salt. Concerning the fact that salt has the ability of enhancing dye absorption from the tub, and that ultrasonic energy helps the process of absorption, the quantity of salt required may be reduced, and thus reduce the cost of dyeing and the pollution of waste waters. Dye absorption from the tub has been monitored by means of absorption spectrophotometry. With the method of reflection spectrophotometry, spectral remission curves have been measured, K/S values calculated, and respectively the relative intensity of dyeing on the fabric determined.

1pPAe7. Acoustic emission (AE) generated by thermomechanical stress in ceramics. Przemyslaw Ranachowski (Inst. of Fundamental Technolog. Res., Polish Acad. of Sci., Swietokrzyska 21, 00-049 Warsaw, Poland)

The thermomechanical long-term toughness of electrotechnical porcelain of long-rod insulators was investigated. The objects were stressed in thermostat to 63% of nominal strength. The cyclic temperature changes from −25 deg to 40 deg were applied. This treatment corresponds to real environmental conditions on insulators of high-voltage lines. The AE

method was used for monitoring the gradual destruction process during the test. The initiation and propagation of microcracks correlate with AE count rate. It was stated that the magnitudes of consecutive maxims of count rate during the cooling part of the cycle depend on the advancement of material destruction. The increase of these maxims means reduction of ceramics toughness related with multiplication of microcracks number and larger probability of critical cracks appearance. When the ceramics retains its strength, the maxims have approximately the same value in consecutive test cycles. The AE method was successfully applied in product certification procedure and control of electric power system. The degree and parameters of porosity of ceramics have been defined on the basis of velocity and attenuation of ultrasound. The good agreement of theoretical and experimental data was obtained. 1pPPa1. Modeling within- and across-channel processing of amplitude modulation. Torsten Dau (AG Medizinische Physik, Univ. of Oldenburg, Oldenburg, Germany)

Recently, a model was presented in which a modulation filterbank was introduced to analyze the envelope fluctuations at the output of each excited peripheral auditory filter [Dau *et al.*, J. Acoust. Soc. Am. **102**, 2892–2905 (1997)]. As a decision stage, an optimal detector was applied which combines all modulation-filter outputs linearly, assuming independent observations. The model accounts for temporal modulation transfer functions (TMTF) with narrow band and broadband carriers as well as for modulation masking data. The model does not cover conditions which require across-channel processing, such as modulation detection interference (MDI). In this case, the auditory system seems to combine information across frequency channels whose responses are temporally modulated. A new modeling approach is presented that integrates the modulation-filter outputs across frequency channels prior to the decision stage, while preserving the original model's ability to describe TMTFs and modulation masking. To further ensure the possibility of predicting spectral masking, a low-frequency part of the modulation spectrum, including the dc component, is processed separately within each peripheral channel. The model can account for the main features of MDI, but it does not account for comodulation masking release.

2:20

1pPPa2. Computer models of the auditory periphery. Ray Meddis (Ctr. for the Neural Basis of Hearing at Essex, Essex Univ., Colchester CO4 3SQ, UK, rmeddis@essex.ac.uk)

Enough is now known about the auditory periphery to allow the development of useful computational models. These accept an arbitrary acoustic stimulus and predict the response of auditory nerve fibers. Current models are largely based on linear filters representing the mechanical frequency selectivity of the cochlear. Nonlinear models would be more appropriate if they could be developed in a form that replicated physiological measurements. This paper describes one approach that combines a nonlinear model of frequency selectivity with a revised inner hair cell model. The nonlinear filters are evaluated using published data collected at three sites on the basilar membrane. They behave nonlinearly at frequencies close to best frequency and linearly at remote frequencies. They show appropriate impulse responses and patterns of two-tone suppression. The hair cell model incorporates a simple account of the receptor potential and retains a previously developed reservoir model of synaptic flow. An innovation includes a model of the discrete release of transmitter quanta that explicitly assumes a presynaptic origin for the stochastic nature of the auditory nerve response. The combined model gives a useful account of the differences between low-, medium-, and high-spontaneous rate fibers that is consistent with earlier physiological speculation.

2:40

1pPPa3. Modeling the effects of peripheral compression on temporal processing. Andrew J. Oxenham (Dept. of Speech-Lang. Pathol. & Audiol., Northeastern Univ., Boston, MA 02115)

Most psychoacoustic models to date have assumed that the peripheral auditory system can be treated as a bank of quasilinear bandpass filters. Physiological studies have shown that this approximation holds only for damaged cochleae: the response of the basilar membrane in a healthy cochlea to sounds around the characteristic frequency is highly nonlinear and compressive over a wide range of sound-pressure levels. Many aspects of psychoacoustic performance can be explained by taking these nonlinear characteristics into account. Short-term temporal integration in simultaneous and forward masking (where signal detectability improves with increasing signal duration), the critical masking interval (where the detectability of a brief signal temporally centered in a masker decreases with increasing masker duration), and the nonlinear growth of forward masking can be modeled with relatively simple assumptions if a physiologically reasonable nonlinearity is included. Similarly, some aspects of temporal processing in listeners with cochlear hearing impairment can be well described by making the reasonable assumption that cochlear compression is reduced or absent. Thus the altered temporal processing shown in some tasks by hearing-impaired listeners may in many cases be due to reduced cochlear compression and not to more central processing deficits. 3:00

1pPPa4. Recent advances in models of binaural detection and localization. H. Steven Colburn (Hearing Res. Ctr. and Biomed. Eng., Boston Univ., 44 Cummington St., Boston, MA 02215, colburn@enga.bu.edu)

There has been a significant increase in the mathematical modeling of binaural phenomena in the past couple of years by a number of research groups. Available review chapters [e.g., Colburn, in *Auditory Computation* (Springer-Verlag, New York, 1996); Stern and Trahiotis, in *Handbook of Perception* (Academic, New York, 1996)] do not include this new material. Recent advances were stimulated in part by the availability of more powerful computational tools and in part by recent data that include more complex stimulus situations such as noise waveforms with interaural time differences but no interaural intensity differences and vice versa [van de Par and Kohlrausch, J. Acoust. Soc. Am. (1998)]. This presentation reviews recent developments in binaural modeling with particular attention given to models of binaural detection and sound localization. Both pink-box models, which incorporate available information from auditory physiology, and black-box models are considered. [Work supported by NIDCD Grant No. R01 DC00100.]

3:20

1pPPa5. Temporal models of pitch processing. William A. Yost (Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626)

Most models of pitch perception assume three basic stages of processing: cochlear filtering, haircell/neural transduction, and pitch extraction. In temporal models of pitch processing the pitch extraction stage is often based on autocorrelationlike processes. This talk will review our work using regular interval stimuli to study temporal models of pitch perception. Work with regular interval stimuli suggests that temporal models of pitch processing can account for the pitch and pitch strength of complex sounds with both resolved and unresolved harmonics. The pitch and pitch strength of regular interval stimuli appears to be based on the temporal properties of the waveform fine structure. Human and animal psychophysical results, physiological recordings from the cochlear nucleus, and model results will be presented. [Work supported by NIDCD and AFOSR.]

4:00

1pPPa6. Cochlear wavelength representation of acoustic frequency content. Timothy A. Wilson (Dept. of Elec. Eng., Univ. of Memphis, Memphis, TN 38152-6574)

Peak-to-peak wavelengths of the sinusoidal steady-state response of a simple cochlear model (i.e., incompressible, inviscid, linear fluid in a rigid box-shaped chamber with a linear stiffness-damping-mass cochlear-partition model having exponential parameter variation with place) were examined. For a wide range of mechanical parameter values and for a wide range of cochlear places (at least those basalward of the best place, though sometimes extending through the best place toward the cutoff regime), the wavelengths were found to be (1) a decreasing, approximately linear function of the logarithm of the stimulus frequency, and (2) a decreasing, approximately linear function of cochlear place. A simple algorithm for estimating the instantaneous frequency of sinusoidal signal components of complex signals (both constant frequency and chirps), as well as that of the center frequency of pulse- and noise-excited resonances, was developed. Estimator performance for the cases of signals plus noise and of noisy wavelength measurements will be presented.

4:20

1pPPa7. Evaluation of a physiological ear model for the simulation of nonlinear masking effects. Frank Baumgarte (Inst. fuer Theoret. Nachrichtentechnik und Informationsverarbeitung, Univ. of Hannover, Appelstr. 9A, D-30167 Hannover, Germany)

A physiological model of the human auditory system with the aim at generating masked thresholds for arbitrary sound signals was presented at the previous DEGA meeting. The main parts of the ear model are an active nonlinear cochlear model and a threshold detector which evaluates changes in specific loudness. It was shown that the ear model is able to rebuild the level dependency of spectral and temporal masking patterns,

the asymmetry of masking between noise and tone, and the different detection thresholds for amplitude and frequency modulation. This study presents new simulation results for nonlinear masking effects. These results indicate that the nonlinear ear model allows demonstration of other nonlinear psychoacoustical effects such as the additivity of masking, suppression, and distortion product detection. Since the physiological ear model represents a unified approach covering the most important masking effects of arbitrary sounds, it is suitable for applications such as perceptual audio coding. An improved coding efficiency is expected due to the more accurate masked thresholds generated by the ear model in comparison to results from psychoacoustical models commonly used in audio coding which neglect many of the nonlinear effects of auditory perception. [Work supported by DFG.]

4:40

1pPPa8. Physiological measurements and mathematical models for interaural pathways. Hans-Peter Rangol (Zoologisches Institut, Johann Wolfgang Goethe Univ., Frankfurt am Main, Germany, hprangol@gmx.de)

The middle-ear cavities of birds, reptiles, and anurans are often connected through a tube, which can act as an interaural pathway between both eardrums. Such an arrangement of acoustically effective structures is described as a pressure-difference receiver. It is generally assumed that pressure-difference receivers enhance the skills for directional hearing in animals. Sound pressures and phases were measured with probe-microfones in the interaural pathway from Zebra Finches during azimuthal rotation. The results show pressure differences between right and left middle ear, which are dependent on the azimuth and the frequency of the applied sound. A mathematical model was constructed, which gives the resulting pressure and phase of two overlaying waves that travel different distances. Assuming one wave traveling through the pathway and a second around a sphere, the resulting wave from dependency on azimuth and frequency was calculated. The pattern shows the same characteristic pressure differences as the physiological measurements. The same procedures were performed with a sphere as a hardware model for a head with an interaural pathway. The results show again the expected characteristics. The combination of physiological measurements, mathematical modeling, and testing this model with hardware models gives a meaningful explanation for the acoustical properties of middle ears as a basis for psychological acoustics.

5:00

1pPPa9. A network model for the functional architecture of the mammalian medial superior olivary nucleus. Claus Weiland (Dept. of Zoology, J. W. Goethe Univ., Frankfurt/Main, Germany)

The mammalian MSO is part of the superior olivary complex, the lowest level in the auditory pathway, which receives binaural input. The microarchitecture of the anatomical convergence of both paths is considered as fundamental for the nucleus' function in time-domain processing. This architecture is mostly, according to a proposal of Jefress [L. Jefress, J. Comp. Physiol. Psychol., 35–39 (1948)], interpreted as a network of coincidence detectors. However, the topographic organization of the afferent innervation of the MSO shows much more complexity as is assumed in this model. The connection scheme of the afferent fibers indicates even aspects of terminal divergence, which should result in broadly tuned neurons instead of sharply tuned coincidence detectors. This study proposes a network model for the processing of interaural time delays (ITD) in the MSO based on connection patterns and response properties of the MSO fusiform cells. Instead of local coincidence detection, coding of ITD's is distributed over a cluster of fusiform cells, where each individual cell's degree of stimulus resolution is considered as low. While in the Jefress model each delay line is processed as a single channel, cluster formation based on MSO's multipolar cells could be a mechanism for sampling over these different channels.

5:20

1pPPa10. Modeling the precedence effect: Mechanisms of onset enhancement in binaural lateralization models. Roberto M. Dizon and H. Steven Colburn (Hearing Res. Ctr. and Biomed. Eng. Dept., Boston Univ., 44 Cummington St., Boston, MA 02215, dizon@bu.edu)

The general behaviors of several cross-correlation-based lateralization models in response to dynamic impulsive stimuli, specifically those that elicit the precedence effect, are presented as a means of gaining insight into the contribution of individual stages of the models to precedencelike performance. In general, an enhancement of activity at onset relative to later activity in the model outputs (or equivalently, a temporary post-onset suppression in activity) is associated with the relative perceptual emphasis of early portions of stimuli as described by the precedence effect. Onset enhancement in cross-correlation models has thus far only been exhibited using dynamic mechanisms such as that used in a model by Lindemann [J. Acoust. Soc. Am. (1986)]. This work evaluates the dynamic properties of several cross-correlation models that include mechanisms of onset enhancement. These mechanisms include that of Lindemann's model, peripheral mechanisms such as adaptation, and a physiologically based inhibition mechanism adapted from the IC model of Cai, Carney, and Colburn [J. Acoust. Soc. Am. (1998)]. In this work, binaural models are created from various permutations of the mechanisms described above, and the final and intermediate model outputs in response to a few sample stimuli are shown and compared. [Work supported by ONR and NIH (NIDCD R01 DC00100).]

5:40

1pPPa11. A model of primary sensations, pitch, loudness, and timbre, of sound signals. Y. Ando (Grad. School of Sci. and Technol., Kobe Univ., Rokkodai, Nada, Kobe, 657-8501 Japan, andoy@kobe-u.ac.jp)

Primary sensations, pitch, loudness, and timbre, of a given source signal and sound field are described based on the model of the auditory–brain system [Ando, *Architectural Acoustics* (AIP/Springer-Verlag, New York, 1998)]. The model consists of the autocorrelation and interaural cross-correlation mechanisms. (Note that the power density spectrum is identical with the ACF.) In order to describe timbre, the human cerebral hemisphere specialization for the temporal and spatial factors of sound fields is taken into consideration in a similar manner as the subjective preference. Here, timbre is defined by a remaining primitive sensation that cannot be expressed by only pitch and loudness. [Work was partially supported by the Ministry of Education, Grant-in-Aid for Scientific Research (C), 9838022, 1998.]

6:00

1pPPa12. The mechanisms underlying temporal pitch perception studied with sequences of filtered clicks. Christian Bering and Christian Kaernbach (Inst. für Allgemeine Psych., Univ. Leipzig, Seeburgstr. 14-20, 04 103 Leipzig, Germany)

In order to probe the mechanisms underlying temporal pitch perception it is necessary to eliminate all spectral cues from the stimulus, i.e., to use stimuli that cannot be resolved by the cochlea. High-pass filtered clicks combined with the corresponding low-pass filtered noise prove to be especially suitable for the construction of stimuli with specific temporal properties. These stimuli allow for the testing of specific hypotheses concerning temporal processing in the auditory system. The present study compares psychophysical results, obtained with periodic and aperiodic click sequences with single-cell simulations of chopper cells in the ventral cochlear nucleus. The latter are thought to explain the observed sensitivity to temporal regularity.

Session 1pPPb

Psychological and Physiological Acoustics: Cross-Spectral Processing (Poster Session)

Torben Poulsen, Chair
Department of Acoustic Technology, Technical University of Denmark, Building 352, DK-2800 Lyngby, Denmark

Contributed Papers

All posters will be on display in the Poster Gallery from Monday to Wednesday, 15–17 March. Authors will be at their posters from 2:00 p.m. to 4:00 p.m. on Monday, 15 March.

1pPPb1. Effect of target versus distracter-tone frequency region and variance on sample discrimination of frequency differences. Donna L. Neff, Rebecca L. Wrage, and Walt Jesteadt (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131, neff@boystown.org)

This experiment examined how performance in a complex frequency-discrimination task was influenced by the frequency region and relative frequency variability of target versus distracter tones. In a 2IFC sample-discrimination task, normal-hearing listeners were asked to select the interval containing target tones drawn from the higher of two overlapping Gaussian frequency distributions. The target distributions were placed in one of three frequency regions: ''low'' (500 Hz), ''middle'' (1414 Hz), or ''high'' (4000 Hz). For a particular target region (e.g., low), two distracter tones were then drawn at random and added, one from each of the Gaussian distributions at the two remaining frequency regions (e.g., middle and high). All distributions were equivariant on a logarithmic frequency scale. Based on the CoRE model [R. A. Lutfi and K. A. Doherty, J. Acoust. Soc. Am. **96**, 3443–3450 (1994)], it was predicted that tones with greater variance would have a greater influence on performance independent of frequency region. The results indicate that the influence of variance depends on the frequency region of targets versus distractors, with notable individual differences and training effects. [Work supported by NIDCD.]

1pPPb2. Detection of tones of unexpected frequency in amplitude-modulated noise. Matthew B. Fitzgerald and Beverly A. Wright (Audiol. and Hearing Sci. Prog., 2299 N. Campus Dr., Northwestern Univ., Evanston, IL 60208-3550)

The percentage of correct detections of tonal signals presented in wideband sinusoidally amplitude modulated (SAM) noise, or noise with SAM and unmodulated regions, was measured for an expected signal of 1000 Hz and unexpected signals of 200, 600, 1400, and 1800 Hz. The level of each signal was set so the signal could be detected on 85% of trials when presented by itself. When the noise was 100% SAM at 10 Hz, six of nine listeners detected at least one unexpected signal on over 70% of trials. When a 400-Hz wide region centered at 1000 Hz was unmodulated and the remaining wideband noise was SAM, or vice versa, all three listeners still detected at least one unexpected signal on over 70% of trials. With unmodulated noise, all unexpected signals were detected at chance. These results suggest most listeners monitor multiple auditory filters when detecting tonal signals in noise that is entirely or partially SAM. This listening strategy may be related to, but not responsible for, the better detectability of signals in wideband SAM than unmodulated noise, because here signal levels in SAM noise were similarly low for listeners who did or did not detect unexpected signals. [Work supported by NIH/NIDCD.]

1pPPb3. A behavioral reverse correlation technique to decipher early auditory feature coding. Christian Kaernbach (Inst. für Allgemeine Psych., Univ. Leipzig, Seeburgstr. 14-20, 04 103 Leipzig, Germany)

Certainly people do not perceive auditory stimuli as a bunch of time-varying spectral components, but what else could provide a format for early auditory feature coding? This question has been dealt with extensively in vision, revealing sensitivity to waveletlike stimuli and to simple object feature elements. Up to now there has been no attempt to decipher the alphabet of hearing at a coding level higher than that of sinusoidal phonons on the auditory nerve. The present study demonstrates a behavioral reverse correlation technique revealing which kind of features will be detected in random stimuli (noise). When a noise segment is repeatedly presented, it will elicit simple percepts, equivalent to the detection of lines, circles, or faces in random dot images. When these percepts are masked by another noise segment, in about 60% of the cases there is a clear-cut difference of masking level depending on the sign of the masker. By adding up sign-sensitive maskers in the correct polarity, one gets the ''noison'' that elicits this specific percept. The noisons presented in the talk represent only a random selection of possible auditory features, but they give an indication of the potential scope of feature specifications.

1pPPb4. Internal representation of spectral information in dependence of signal type and auditory filter bandwidth. Bernhard Laback and Werner A. Deutsch (Acoust. Res. Lab., Austrian Acad. of Sci., Liebigg. 5, 1010 Vienna, Austria)

Previous studies have shown that enhancement of the spectral background (lower level spectral components) improves intelligibility as well as listening comfort of music signals in subjects with broader than normal auditory filters. This is in contrast to reported results on speech perception in noise, yielding reduced intelligibility as a result of spectral contrast reduction. A proposed model for the internal object representation by separation of ''spectral layers'' accounts for these opposing effects. ''Spectral layers,'' corresponding to different sound sources [in music: dominant/accompanying musical voices; in speech-in-quiet: formant peaks/modulation sidebands of the peaks (transitions); in speech-in-noise: speech foreground/speech background/noise components] are represented in coherent spectral amplitudes. The audibility of ''spectral layers'' is derived from individual masking properties. Pilot experiments with speech tokens and short music fragments agree relatively well with the model predictions: The effect of either increasing or reducing the spectral contrast on discrimination highly depends on the distribution of the perceptually relevant acoustical information in the ''spectral layers'' relative to their audibility. Performance varies for different signal types (simultaneous musical voices, vowel, consonant). [Work supported by the Austrian Academy of Sciences.]

1pPPb5. Amplitude modulation discrimination interference (MDI) and speech intelligibility for normal-hearing and hearing-impaired subjects. Jan Koopman, Rene van der Horst, and Wouter A. Dreschler (Dept. of Exp. Audiol., Academic Medical Ctr., P.O. Box 22660, NL-1100 DD, Amsterdam, The Netherlands, j.koopman@amc.uva.nl)

Modulation detection interference is the decrease of sensitivity for amplitude modulation when the target is presented in the presence of modulating maskers [W. A. Yost and S. J. Sheft, J. Acoust. Soc. Am. **85**(2), 848–857 (1989)]. A typical MDI experiment was carried out in which the maskers were located at 500 and 4000 Hz and the target at 1400 Hz (covering the range of speech frequencies). The modulation depths of the maskers were held steady at 0, 0.18, or 0.30. The modulation rates were 4, 8, or 16 Hz. Also, speech intelligibility was measured by a sentence test in continuous noise. Both experiments were carried out for six normal-hearing and six hearing-impaired subjects. All signals were presented at MCL level. Both groups of subjects were most sensitive for amplitude modulations when they were presented in the presence of the nonmodulating maskers or without any masker at all; the sensitivity decreased by 8 dB for normal-hearing subjects and 6 dB for hearing-impaired subjects for the modulated masker condition. The modulation threshold also increased for increasing reference modulation depths. The amplitude modulation discrimination sensitivity showed a significant correlation with the critical signal-to-noise ratios for speech intelligibility.

1pPPb6. Comodulation masking release in bit-rate reduction systems. Martin D. Vestergaard,[a] Karsten B. Rasmussen, and Torben Poulsen (Dept. of Acoust. Technol., Bldg. 352, Tech. Univ. of Denmark, DK-2800 Lyngby, Denmark, kbr@dat.dtu.dk)

It has been suggested that the level dependence of the upper masking slope be utilized in perceptual models in bit-rate reduction systems. However, comodulation masking release (CMR) phenomena lead to a reduction of the masking effect when a masker and a probe signal are amplitude modulated with the same frequency. In bit-rate reduction systems the masker would be the audio signal and the probe signal would represent the quantization noise. Masking curves have been determined for sinusoids and 1-Bark-wide noise maskers in order to investigate the risk of CMR, when quantizing depths are fixed in accordance with psycho-acoustical principles. Masker frequencies of 500 Hz, 1 kHz, and 2 kHz have been investigated, and the masking of pure tone probes has been determined in the first four 1/3 octaves above the masker. Modulation frequencies between 6 and 20 Hz were used with a modulation depth of 0.75. A CMR of up to 10 dB was obtained at a distance of 6 Bark above the masker. The amount of CMR was found to depend on the presentation level of the masker; a higher masker level leads to a higher CMR effect. Hence, the risk of CMR affecting the subjective performance of bit-rate reduction systems cannot be ruled out. [a] Currently at Oticon Research Centre Eriksholm, 243 Kongevejen, DK-3070 Snekkersten, Denmark, mve@oticon.dk

1pPPb7. Comodulation masking release (CMR) for multiple temporal envelope maskers. Lee Mendoza (Dept. of Commun. Sci. and Disord., Louisiana State Univ., 163 M&DA, Baton Rouge, LA 70803, lmendoz@lsu.edu)

Thresholds for a pure-tone signal were measured in masking noise composed of multiple noise bands. In some conditions, one group of flanking bands (consisting of half of the flanking bands) was comodulated, and independent of the other group of comodulated flanking bands in terms of temporal envelope. The center frequencies of the flanking bands were arranged such that noise bands from the two groups were spectrally interleaved. In these conditions, the band of noise centered on the signal was a combination of two noise bands, which were each comodulated with one group of flanking bands. CMR was obtained but was not of the magnitude observed when all noise bands shared a common temporal envelope. Potential cues in the multiple envelope maskers included the information in the summed representation of the flanking bands, and the degree of temporal envelope correlation between the on-signal band and the flankers. Additional stimulus conditions examined the viability of these cues. The results of these experiments support an envelope correlation explanation for the CMR observed with the multiple temporal envelope maskers. [Work supported by the Louisiana Board of Regents.]

1pPPb8. An exploration of coherence masking protection in a spectral profile discrimination task. Peter J. Bailey (Dept. of Psych., Univ. of York, York YO10 5DD, UK, pjb1@york.ac.uk)

Gordon [P. C. Gordon, Percept. Psychophys. **59**, 232–242 (1997)] has reported a form of masking protection, in which identification thresholds for noise-masked target signals are lower when a nondistinctive cosignal is present. Gordon suggested that target signals are protected from masking as a result of their perceptual coherence with the cosignal. The experiment reported here sought to show whether cosignals enhance performance in a task involving discrimination of spectral profiles. The target signals were increments in the level of components in a complex tone (harmonics $1-7$, $F0=125$ Hz), with the third harmonic incremented in one trial interval and the fifth harmonic in the other. Discrimination threshold increments were measured for four well-practiced listeners in three conditions. In one condition, the complex tone was presented alone, without a cosignal. In the two cosignal conditions, harmonics 8–40 were added, with either a vowellike or a flat spectral profile. Average threshold increments were similar in the three conditions, and no listener showed reliably smaller threshold increments when a cosignal was present. Cosignals may confer protection from the effects of noise masking, but they do not necessarily enhance performance in other auditory tasks. [Work supported by UK MRC.]

1pPPb9. Auditory profile analysis: Effects of asynchrony and ear of presentation. Nicholas I. Hill and Peter J. Bailey (Dept. of Psych., Univ. of York, York YO10 5DD, UK, nih1@york.ac.uk)

The ability of listeners to detect an increment in the level of a 1-kHz tone relative to four flanking tones (having frequencies of 0.16, 0.40, 2.50, and 6.25 kHz) was examined under four conditions of presentation. In two conditions all five tones were presented monaurally to the listener's right ear, while in the other two conditions the 1-kHz tone was presented to the left ear with the flanking tones presented to the right. For each of the two spatial configurations, the tones were either gated on and off at the same time or else the 1-kHz tone was gated on 100 ms before, and off 100 ms after the flanking tones. The flanking tones were always gated on and off simultaneously and had a duration of 200 ms. The overall level of the stimuli was randomized on each presentation. Average thresholds in the two asynchronous conditions were approximately 10-dB higher (signal re: pedestal amplitude) than those in the synchronous, monotic condition. Ear differences alone resulted in an average elevation in threshold of 3 dB. These results suggest that asynchrony is more effective than spatial cues in preventing intensity information from being combined across frequency. [Work supported by UK MRC.]

1pSAa1. An overview of the inverse problem for sound reconstruction in interior spaces. Earl G. Williams (Naval Res. Lab., Washington, DC 20375)

Calculation of the sound field between noise sources and a closed two-dimensional measurement surface is an inverse propagation problem. A powerful and popular method for the reconstruction of sound fields in this space is based on boundary element methods applied to the Helmholtz integral equation. Unfortunately, due to the numerical nature of these solutions, the physics associated with backtracking (backpropagating) the field from the measurement surface to the source surfaces is hidden. Analytic models are used to view this backpropagation as a deconvolution operation on the measured field. The nature of this deconvolving function (called the inverse propagator) is examined; it is a singular function, it is spatially local, and it *unsoothes* the measured pressure field. An understanding of the nature of the inverse propagator is critical to successful solution of the inverse problem by BEM methods (especially the regularization process), as well as the sucessful development of three-dimensional sound projection methods for sound synthesis. Furthermore, this understanding leads to new insights into the solution of the inverse problem. [Work supported by ONR and NASA.]

1pSAa2. Problem of reconstructing the full vibration field from limited data. Yuri I. Bobrovnitskii (Lab. of Structural Acoust., Mech. Eng. Res. Inst., M. Kharitonievsky 4, Moscow 101830, Russia, bobrovni@orc.ru)

The problem of expanding the vibration field from the measured points to unmeasured (inaccessible) points is posed and solved. This field reconstruction problem is one of the inversion problems of structural dynamics and acoustics. The procedure of handling it is the following: the full vibration field under study is described by a mathematical model containing a certain number of parameters (e.g., a modal model with the mode amplitudes as the model parameters); the values of these parameters are identified from the limited data; the field of the structure is then computed using this model. The main result of the present submission is that there exists the best mathematical model (containing a finite number of parameters) which gives the minimal error of describing the field in unmeasured points. Another result presented is that there also exists the optimal volume of the measurement data. The paper contains a general theory, equations relating the error to the measurement accuracy and the data volume, and some computer simulation results. Discussion of how to choose the best field mode using only the measurement data is also presented.

2:40

1pSAa3. An overview of reconstructing acoustic pressure fields using the HELS method. Sean F. Wu (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202)

The acoustic pressures radiated from complex vibrating structures are reconstructed by using the Helmholtz equation least-squares (HELS) method [Wang and Wu, J. Acoust. Soc. Am. **102**, 2020–2032 (1997); Wu and Yu, *ibid.* **104**, 2054–2060 (1998)]. Specific examples include an engine block and the interior space of a passenger vehicle. These structures are of arbitrary shapes and geometry, containing sharp edges and corners, and abrupt changes in surface contour. To test the robustness of the HELS method, measurements of field acoustic pressures are taken over a planar surface at a certain distance away from the structure. The reconstructed acoustic pressures, however, extend over the entire (nonplanar) surface of the structure. Note that the input data in these cases are not error free due either to measurement uncertainties or to the loss of the near-field effect. On the other hand, reconstructed acoustic pressures consist of predominantly the near-field effect. Hence the problem becomes mathematically ill-posed. To overcome this ill-posedness difficulty, an optimization scheme is developed which enables one to obtain satisfactory reconstruction results with a relatively few number of measurements in the field. The HELS method is shown to be effective in the low- to mid-frequency range, and can become a robust noise diagnostic tool for analyzing structure-borne sounds. [Work supported by NSF.]

1pSAa4. Some inverse problems in structural acoustics. D. N. Ghosh Roy (SFA, Inc., 1401 McCormick Dr., Landover, MD 20785), J. A. Warner, and L. S. Couchman (Naval Res. Lab., Washington, DC 20375-5350)

Fundamental problems of direct and inverse solutions of the multidimensional Helmholtz equation in structural acoustics are discussed. Inversion of an obstacle from the far-field pattern is compared to that of a medium and/or an inhomogeneity. An overview of various methods of solving these problems is presented. The linear techniques for a medium and/or inhomogeneity problem and some intrinsically nonlinear methods of inversion for an obstacle are described. Four nonlinear methods are compared, namely, the ansatz of potential over an internal curve, the dual space method using the Herglotz wave functions, methods based on the Rayleigh hypothesis, and the most recent method of shape differentiation combined with the Padé approximation. The efficacy and advantages of the last technique are illustrated by numerically reconstructing both penetrable and impenetrable obstacles of various shapes and orientations. The robustness of the method in regard to the initial conditions and regularization are demonstrated and its extension to elasticity and an acoustical shell structure are presented. Finally, some open questions and future directions are discussed.

1pSAa5. Identification of forces by the RIFF method. C. Pezerat and J. L. Guyader (Lab. Vibs. Acoust. de l'INSA de Lyon, 20 avenue A. Einstein, 69621 Villeurbanne Cedex, France)

The goal of this presentation is to show the application of a test bed which should permit the identification of forces created by an engine when it is not possible to measure them directly. The interest of this experimentation is to have an idea of the forces in the real situation. The mechanism consists of fixing the engine on a known plate which has characteristics related to those of the real situation. To identify forces exciting the plate, the method used, the RIFF method, is based on the computation of the force distribution, i.e., the second member of the equation of motion of the plate, from the knowledge of the flexural displacements. The main difficulty of this inverse problem comes from uncertainties in data that produce a high noise level in the result. To overcome this instability, two regularization techniques are presented. The first approach is based on singular value decomposition (SVD), consisting of eliminating the singular values of the operator applied on displacements. The second approach is based on high wave number filtering. Formulations of techniques are presented and experimental results are shown in order to validate both approaches.

1pSAa6. Source localization on a ''fuzzy structure'' beam using matched-field processing. David Feit and Matthew Craun (Carderock Div. Naval Surface Warfare Ctr., 9500 MacArthur Blvd., West Bethesda, MD 20817-5700)

Matched-field processing (MFP), a technique originally developed by the underwater acoustic community [Baggeroer, Kuperman, and Mikhalevsky, IEEE J. Ocean Eng. **18**, 401–424 (1993)] for source localization, is used to localize the source of excitation on a flexurally vibrating beam to which is attached a ''fuzzy structure (FS).'' The FS, for this study, consists of a set of flexurally vibrating strips, of randomly varying lengths, attached at uniformly spaced points along the length of the beam. MFP differs from classical inverse methods in that it does not require an inversion of the system model. Instead it correlates or ''matches'' observed signals with solutions of the equations of motion for a range of excitation points using a variety of linear and nonlinear methods. In this paper several different MFP algorithms are used and compared where the observed or simulated data is measured both globally, along the entire length of the beam, or locally over a limited region of the structure. Successful localization is found to be dependent on frequency. For lightly damped structures, the MFP localization results become ambiguous at the resonance frequencies of the structure. 1pSAa7. Inverse scattering of acoustic waves by two elastic shells in water. G. C. Gaunaurd (Naval Surface Warfare Ctr., Carderock Div., Code 684, West Bethesda, MD 20817-5700) and H. Huang (Consultant, Bowie, MD 20715)

The key problem of inverse scattering consists of the identification of an unknown target from its scattering pattern (form-function). For a single, simple-shaped target in an infinite medium, the problem has been solved elsewhere. There is present interest in the case of two elastic shells, with centers a distance d apart, insonified by a (distant) sonar, operating at frequency f, in a boundless sea. The determination of the scattering pattern of such a double-shell target was analyzed by this group earlier [viz., J. Acoust. Soc. Am. **98**, 2149–2156 (1995)]. That direct solution is now built upon to solve the associated inverse problem. From the form-function of the two shells—assumed equal—which is also assumed given in two arbitrary directions, it is determined: (a) that there are actually two interacting shells (i.e., spatial resolution), (b) their separation d, (c) the pair orientation angle α, (d) the shape and size of the shells, (e) their thickness, h, and (f) their material composition. This information is all extracted from features in the form-functions, using the detailed procedure explained here, which accounts for all orders of multiple scattering, since the shells could be close to each other, and thus be strongly interacting. A way to obtain/measure the two needed form-functions is using ultra-wideband (UWB) interrogating waveforms or UWB processing. [Work partially supported by the ILIR Program of NSWC-CD.]

1pSAa8. An inversion approach based on multiple-aspect resonance analysis of finite cylindrical shells in water. Alessandra Tesei, Warren L. J. Fox, and Alain Maguer (SACLANT Undersea Res. Ctr., La Spezia, Italy)

Inverse scattering of fluid-loaded, elastic, thin-walled cylindrical shells is addressed by multiple-aspect resonance analysis. A set of aspect-dependent acoustic phenomena is selected from membrane wave and resonance scattering theories, which are expected to be backscattered by fluid-filled or empty thin-walled shells and to give rise to resonance phenomena in the *ka* range (1,50). The features selected are from spatial axial modes, and Lamb-type, Scholte–Stoneley, and shear helical waves. The last three wave families are significant only over a small range of target aspects near broadside, with the width of this range depending on shell properties. Approximate equations are formulated relating resonance behavior in the aspect-frequency domain, to target parameters such as shell outer radius, thickness, length, and material. The inverse methodology is validated on experimental data from a steel cylindrical shell with flat end-caps, filled with air or water and suspended in the water column. The target was continuously rotated on the plane of its longitudinal axis while insonified by broadband pulses. Good agreement between theory and experiment encourages the extension of the approach to more complex scatterers for classification purposes. [Work partially supported by EC (MAST DEO project).]

1pSAa9. High spatially sampled interior acoustic measurements of a turboprop aircraft for near-field acoustic holography (NAH) algorithm development. Peter C. Herdic,[a] Brian H. Houston (Naval Res. Lab., Code 7136, Washington, DC 20375), and Earl G. Williams (Naval Res. Lab., Washington, DC 20375)

Experimental results are reported of in-flight acoustic responses acquired by scanning a dense array of microphones within an aircraft interior. High data quality was obtained in several measurement sets. This database will ultimately be used for inverse and forward projections of the measured, enclosed acoustic surface to determine the velocity of the fuselage skin and the entire interior acoustic field. A discussion of the experimental design methodology will include approaches to measure the in-flight pressure field coherently during the execution of a scan, spatial sampling requirements based on measured vibration over an arc of the fuselage wall, and the effect of ambient noise on the measurement. The in-flight acoustic response shows spatial variation throughout the interior with dominant blade passage harmonics. Two ground-based (engine off) measurement scans were performed where excitation by an internal acoustic source and a point force applied to a frame assist in identification of interior acoustic modes and structural resonances. 1pSAa10. Force spectra identification by FRF matrix inversion: A sensor placement criterion. Matthias Blau (TU Dresden, Inst. fuer Technische Akustik, D-01062 Dresden, Germany)

Excitation force spectra are a key quantity in structure-borne sound characterization. In this paper, the identification of multiple broadband force spectra by FRF matrix inversion is considered. Because of the notorious sensitivity of inverse methods to small errors in measured data, such measurements must be carried out with extreme care. One major decision that could heavily affect the accuracy of the final results concerns the placement of the vibration response sensors. To date, this is often accomplished by just putting them as close as possible to the force input points, or by subjective judgment, or by considering the condition number of the FRF matrix as a criterion. In this paper, an alternative criterion is proposed which takes into account that, especially in the frequency region up to a few hundred Hz, the resulting errors are often dominated by measurement noise-induced bias on response spectra estimates.

1pSAa11. Experimental reconstruction of the vibration field in a cylindrical shell. Alexander A. Kochkin (Lab. of Structural Acoust., Mech. Eng. Res. Inst., M. Kharitonievsky 4, Moscow 101830, Russia, kochkin@hotmail.com)

The problem of reconstruction of a vibration field in an unmeasured region of a thin cylindrical shell is considered. The forced vibrating shell of finite dimension is divided into two parts: the first part (the measurement region) is accessible for measuring any vibration characteristics while the second part (the reconstruction region) is considered as ''inaccessible.'' The problem is solved using the general approach–see the presentation by Yu. I. Bobrovnitskii at this Special Session. The vibration field of the shell was modeled by a finite sum of normal waves, amplitudes of which were determined by equating the modeling values to the data. The SVD technique was used in the inverse procedure for parameter identification. Most attention was paid to finding an appropriate method for choosing the best model of the shell which minimized the reconstruction error. For the measurement error 0.08 of the experiment conducted, the reconstruction error varied from 0.2 to 0.7 as the measurement region diminished from 0.7 to 0.3.

1pSAb1. Iterative feedback control design for active vibration control. Sandor M. Veres (School of Electron. and Elec. Eng., Univ. of Birmingham, Edgbaston B15 2TT, UK, s.m.veres@bham.ac.uk)

Model-based robust feedback control design is widespread: a parametric model is identified with some measure of the unmodeled dynamics present in the most advanced approaches. In off-line design, often open-loop experiments are used which can fail to provide satisfactory models because the identification criterion does not serve the aims of feedback robustness. Another frequent problem is possible large bias of the parametric part because of wrong model orders. In the best case large bias comes with large bounds of the unmodeled dynamics in the H-infinity or the L-1 norms. The conclusion is that the use of a plant model is the source of considerable problems while it has so far seemed a natural approach to controller design. In this paper a new ''model-free'' approach will be outlined for designing feedback vibration controllers. This will be based on a direct search using a sequence of iterative experiments. The experiments will alternate between two types: with and without the vibration source being active. The iterations of the controller parameters allowed by the sequence of experiments will lead to a sequence of improvements of control performance. This will be verified experimentally with reduction of sound-induced low-frequency vibration of a glass plate.
