Editor's Note: *Readers of this journal are encouraged to submit news items on awards, appointments, and other activities about themselves or their colleagues. Deadline dates for news items and notices are 2 months prior to publication.*

New Fellows of the Acoustical Society of America

Kenneth W. Grant—For contributions to auditory-visual speech processing.

James M. Kates—For contributions to signal processing for hearing aids.

Qing Liu—For contributions in computational elastodynamics and acoustics.

48th *Dallas Morning News*—Toyota Regional Science and Engineering Fair

More that 800 students from 86 North Texas schools competed in the 48th *Dallas Morning News*-Toyota Regional Science and Engineering Fair. This year one Senior and three Junior Division contestants won Outstanding Acoustics Project Awards.

Senior Division Winner Mr. Rick Yang, with the guidance of Ms. Rachel Carlson, Jasper HS, Plano ISD, reported sound waves at specifiable frequencies altered anaerobic respiration rates of yeast cultures. Although Mr. Yang offered no explanation, fermentation scientists expressed interest because the conditions under which rates increased did not arise from medium mixing or heating.

Mr. Martin Coffman, a student of Ms. Joyce Carson, Lowery Freshman Center, Allen ISD, received Senior Division Honorable Mention.

Junior Division Winners Ms. Alexa Hanks and Ms. Alianna Whiteaker-Chudecke with the guidance of Ms. Rachel Robb, St. Elizabeth of Hungary Catholic School, Dallas, used doves to affirm a central tenant of systematic biology: live and recorded dove calls elicited species-specific behavior; environmental sounds and calls of other song birds did not. Recorded hawk calls elicited behaviors common to doves and other song birds. Ms. Whiteaker-Chudecke and Ms. Hanks won Third Place in Junior Division Teams (see Fig.).

Junior Division Winner Ms. Jennifer Goebel, supervised by Ms. Deborah Johnston, Schimelpfenig Middle School, Plano ISD, demonstrated how drinking common beverages changed the surfaces lining mouth and throat, and altered the acoustic properties of a singer's voice.

Ms. Bethany Carson, a student of Ms. Doni Cash, Ford Middle School, Allen ISD, received Junior Division Honorable Mention, and the American Psychological Society "Outstanding Research Study" Award as well.

Dr. Peter Assmann, Dr. Greg Hughes, Dr. Ben Seep, and Dr. Michael Daly represented the Society.

Report of the Auditor

Published herewith is a condensed version of our auditor's report for calendar year ended 31 December 2004.

Independent Auditors' Report

To the Executive Council
Acoustical Society of America

We have audited the accompanying statements of financial position of the Acoustical Society of America as of 31 December 2004 and 2003 and the related statements of activities and cash flows for the years then ended. These financial statements are the responsibility of the Society's management. Our responsibility is to express an opinion on the financial statements based on our audits.

We conducted our audits in accordance with auditing standards generally accepted in the United States of America. Those standards require that we plan and perform the audit to obtain reasonable assurance about whether the financial statements are free of material misstatement. An audit includes examining on a test basis, evidence supporting the amounts and disclosures in the financial statements. An audit also includes assessing the accounting principles used and significant estimates made by management, as well as evaluating the overall financial statement presentation. We believe that our audits provide a reasonable basis for our opinion.

In our opinion, the financial statements referred to above present fairly, in all material respects, the financial position of the Acoustical Society of America as of 31 December 2004 and 2003 and the changes in its net assets and its cash flows for the years then ended in conformity with accounting principles generally accepted in the United States of America.

Annual Reports of the Technical Committees

Acoustical Oceanography

Fall 2004 Meeting (San Diego): Acoustical Oceanography (AO) sponsored a special session entitled "Acoustic Characterization of the Benthic Habitat," which was organized by Kenneth Foote (Woods Hole Oceanographic Institution). In addition AO co-sponsored a session with Underwater Acoustics (UW) entitled "Acoustic sensing of internal waves," which was organized by Jim Lynch (Woods Hole Oceanographic Institution) and featured a special lecture by Boris Katsnelson (Voronezh University, Russia). The Best Student Paper Awards in Acoustical Oceanography went to Eric Giddens (Scripps Institution of Oceanography), who won first place for his paper "Geoacoustic inversions in shallow water using Doppler shifted modes from a moving source," and Erica Summers-Morris (CSU Monterey Bay), who won second place for her paper "Geographical information systems (GIS) analysis of high-resolution multibeam bathymetry and remotely operated vehicle data to model rockfish habitat preference." Peter Worcester (Scripps Institution of Oceanography) and Peter Gerstoft (Marine Physical Laboratory) represented AO at the Technical Program Organizing Meeting.

Spring 2005 Meeting (Vancouver): The 2005 Medwin Prize in Acoustical Oceanography was awarded to Svein Vagle of the Institute of Ocean Sciences in Sidney, BC, "for development of acoustical techniques for probing the upper ocean boundary layer." He presented the Acoustical Oceanography Prize Lecture entitled "Acoustic explorations of the upper ocean boundary layer." AO sponsored two special sessions. Bruce Howe (Applied Physics Laboratory, University of Washington) organized a session jointly with UW and Animal Bioacoustics (AB) entitled "Acoustics and Ocean Observatories." Kenneth Foote (Woods Hole Oceanographic Institution) organized a session jointly with UW entitled "Riverine Acoustics." Srinivasan Jagannathan (Massachusetts Institute of Technology) won first place in the competition for the Best Student Paper Award in Acoustical Oceanography for his paper entitled "Could animals detect the approaching tsunami?" Ben Biffard (University of Victoria) was awarded second place for his paper entitled "Single beam echo sounding: considerations of depth and sea bed slope." Mike Wolfson (Applied Physics Laboratory, University of Washington) represented AO at the Technical Program Organizing Meeting.

Information on these and related matters is available on the Acoustical Oceanography Technical Committee web site, for which we are indebted to Gopu Potty and James Miller (University of Rhode Island). It can be reached through the ASA web page by clicking on "Committees." Please e-mail any material for or comments on the web site directly to potty@oce.uri.edu or miller@oce.uri.edu.

This report is my first as Chair of the AO Technical Committee. I want to close by thanking all of the volunteers who have made the activities of the AO Technical Committee possible during this past year.

N. ROSS CHAPMAN
Chair

Animal Bioacoustics

Members of the Animal Bioacoustics Technical Committee (ABTC) continue to play an active role in the affairs of the Society and were well represented at both the San Diego (Fall 2004) and Vancouver (Spring 2005) meetings.

AB sponsored two named sessions at the San Diego meeting. One, on "Marine Mammal Acoustics," was held in honor of Ron Schusterman. It was chaired by Whit Au, Colleen Reichmuch Kastak, and Patrick Moore. A second session, on "Acoustic Monitoring of Large Whales—The Legacy of Paul Thompson," was held in memory of Paul Thompson. This session was chaired by John Hildebrand and Sue Moore. Andrea Simmons presented a lecture on "Hot topics in animal bioacoustics" at the interdisciplinary Hot Topics session. In addition, many AB members attended the tutorial lecture on "Ocean noise and marine mammals" presented by Gerald D'Spain and Douglas Wartzok. The ABTC meeting attracted over 50 attendees; discussion centered around public policy and standards issues.

We congratulate ABTC member D. Vance Holliday on his receipt of the Silver Medal in Acoustical Oceanography.

The recipients of the Best Student Paper Award were Mandy L. H. Cook, from the University of South Florida College of Marine Science, for her paper "Auditory brainstem response hearing measurements in free-ranging bottlenose dolphins (*Tursiops truncatus*)," and Jennifer Miksis-Olds, from the University of Rhode Island Graduate School of Oceanography, for her paper "Differential response by manatees to playbacks of sounds simulating approaching vessels."

ABTC sponsored three special sessions at the Vancouver meeting. Mardi Hastings organized and chaired a session on "Methodology for Measurements of Auditory Evoked Potentials in Aquatic Animals." Bill Burgess and Susanna Blackwell chaired sessions on "Tools for Animal Bioacoustics: New Designs and Directions." Ann Bowles and Ed Walsh organized a session and panel discussion on "Behavioral Audiometric Methods in Animal Bioacoustics: The Search for Standards," which was co-sponsored with the Committee on Standards. This is the first of a series of special sessions related to standards issues, which AB will continue to sponsor for future meetings. AB co-sponsored two other sessions, one with Psychological and Physiological Acoustics, and the other with Acoustical Oceanography and Underwater Acoustics. All of these sessions were heavily attended. Standards issues continued to dominate discussions at the ABTC meeting, which was attended by over 50 people.

Randy J. Hill, from the University of South Florida College of Marine Science, won the Best Student Paper Award for his paper, "Ground-truthing evoked potential measurements against behavioral conditioning in the goldfish, *Carassius auratus*."

Peter Narins and Andrea Simmons are currently organizing the Second International Workshop on Acoustic Communication, to be held at UCLA in the summer of 2007. This will follow up on the highly successful First Workshop, held at the University of Maryland in 2003.

New members of ABTC, whose terms began at the Vancouver meeting and extend to 2008, are Kelly Benoit-Bird, Tecumseh Fitch, Dorian Houser, Lee Miller, Larry Pater, Hiroshi Riquimaroux, Peter Scheifele, and Edward Walsh. Thanks to outgoing members Bill Burgess, Jim Finneran, Adam Frankel, Darlene Ketten, Tom Norris, and Peter Tyack for their service.

The ABTC could not function without the dedication and energy of our members. Mardi Hastings is a member of the Executive Council. Ann Bowles is the AB representative to the Committee on Standards. Charles Greene serves on the Medals and Awards Committee, and Darlene Ketten serves on the Membership Committee. Dave Mellinger is our webmaster. Marla Holt is the AB representative to the Student Council. Ann Bowles and Kate Stafford served as the TPOM representatives for the San Diego and Vancouver meetings, respectively. AB members, including Ann Bowles, Sheryl Coombs, Richard Fay, Mardi Hastings, Art Popper, Aaron Thode, and Ed Walsh, remain active in public policy and Standards issues. Activities include efforts to draft a policy statement on potential consequences of anthropogenic ocean noise on marine animals, and organizing a series of peer-reviewed papers on standards for acoustic measurements.

AB continues to grow in membership, with 665 ASA members now indicating AB as their primary, secondary, or tertiary interest. We encourage all members of ASA to visit our web site: http://cetus.pmel.noaa.gov/bioacoustics.html.

ANDREA SIMMONS
Chair

Architectural Acoustics

The Technical Committee on Architectural Acoustics has had a busy and exciting year. At the Fall 2004 meeting in San Diego, TCAA sponsored a special Topical Meeting, organized by Ning Xiang and Rendell Torres, on "Spatial and Binaural Evaluation of Acoustics in Performing Art Spaces," which spanned two half-day sessions. Other TCAA special sessions and their organizers included "Integration of Synthesis Techniques and 'Acoustical' Music" (K. Anthony Hoover), "Coupled Volume Systems: Design Processes and Implications" (David T. Bradley, Ralph Muehleisen), "Implementation of Classroom Acoustics" (Michael Stinson, Lily Wang), and "Speech in Architectural Spaces—Both Intelligibility and Privacy" (Ken Roy, Peter Mapp). Robin Glosemeyer served as TCAA representative to the Technical Program Organizing Meeting for this conference.

At the Spring 2005 meeting in Vancouver, TCAA sponsored a special Topical Meeting, organized by Murray Hodgson and Lily Wang, on "Classroom Acoustics: The Research Perspective," which included three half-day sessions and an evening public forum. Other TCAA special sessions and their organizers included "Architectural Acoustics and the Green Building Movement" (Ralph Muehleisen, Murray Hodgson), "Possibilities and Problems with Auralizations of Classroom Acoustics" (Bob Coffeen), "Preserv-

ing Acoustical Integrity in the Course of Renovation" (Dan Raichel), and "Soundscapes from an Architectural Viewpoint" (Brigitte Schulte-Fortkamp). Kerrie Standlee and Lily Wang served as TCAA representatives to the Technical Program Organizing Meeting for this conference. A special thanks to Murray Hodgson who served as General Chair for this excellent joint meeting with the Canadian Acoustical Association.

TCAA has several active subcommittees who made reports this past year. The Newman Student Award Fund continues to be active, providing awards to students who excel in their study of architectural acoustics and supporting educators who develop new educational materials through the Schultz Grant; more information may be found on their website at www.newmanfund.org. Another excellent Student Design Competition was organized for the Vancouver meeting by Bob Coffeen, Byron Harrison, and Norm Philipp, with first honors going to Lauren Ronsse and Andy Miller from the University of Kansas. Bill Dohn is leading the planning of the 3rd Concert Hall Research Group Summer School to be held in Aspen, Colorado in August 2006. The Acoustics Product Safety Working Group, chaired by Nancy Timmerman, is organizing a special session on product safety for the upcoming ASA conference in Minneapolis.

A new joint subcommittee with the Technical Committee on Noise concerning Speech Privacy was initiated at the San Diego meeting, chaired by Greg Tocci, and has been actively meeting throughout the year. Another new initiative approved in San Diego is to offer a TCAA Student Paper Award at each conference, along the same lines as many of the other ASA Technical Committees. The first awards will be given to students who present at the Fall 2005 meeting in Minneapolis. Interest in forming another new subcommittee focused on integrating Acoustics in Green Building Design was expressed at the Vancouver meeting; Ralph Muehleisen is leading those efforts.

Greg Miller and Robin Glosemeyer are finalizing the publication "Another Two Decades of Drama Theaters," based on posters submitted at the Spring 2004 meeting in New York City. Work has begun on the next such project: "Another Two Decades of Worship Spaces," organized by Adam Foxwell and Rosemary Su, with a poster session scheduled for the Spring 2006 meeting in Providence, Rhode Island.

Classroom Acoustics continues to be an important topic that TCAA members are strongly advocating. Special sessions on this topic were held at both San Diego and Vancouver, and a unique brainstorming session at the San Diego meeting focused on how to continue with Classroom Acoustics outreach. The TCAA is very grateful to David Lubman and Lou Sutherland for their ongoing efforts in this regard.

Congratulations to TCAA members who became ASA Fellows or were award recipients this year. New Fellows include Bennett Brooks, Klaus Genuit, Murray Hodgson, K. Anthony Hoover, and Volker Mellert. Lily Wang received the 2005 R. Bruce Lindsay Award at the Vancouver meeting.

Many thanks to the following individuals for their efforts this past year in ASA on behalf of TCAA. Red Wetherill is our representative on the Medals and Awards Committee. Greg Tocci serves on the Membership Committee, and George Winzer is TCAA representative to the ASA Committee on Standards. David T. Bradley from the University of Nebraska is our Student Council representative. The Associate Editors in Architectural Acoustics are Mendel Kleiner and Ning Xiang for *JASA* and J. D. Quirt for *ARLO*. Steven Brown is a member on the Executive Council. And last, a special thanks to Tony Hoover for his outstanding service as TCAA Chair for the previous three years.

LILY M. WANG
Chair

Biomedical Ultrasound/Bioresponse to Vibration

At the San Diego meeting the Biomedical Ultrasound/Bioresponse to Vibration Technical Committee (BU/BV) held its annual topical meeting. The one-day full meeting was organized by Kendall Waters and Brent Hoffmeister and the topic was Ultrasound Characterization of Cancellous and Cortical Bone. The topical meeting brought experts from around the world and the talks covered the gamut from historical perspective through the state-of-the-art and looking forward to the challenges in the future. It was concluded with an enthusiastic discussion on the barriers and potential of ultrasound in characterizing bone. Also at the San Diego meeting there was a special session organized by Ronald Roy and Todd Murray on the

combined use of Light and Sound for Imaging in the Body. We had two further sessions of contributed talks. Our TPOM representative was Franco Curra.

Two BU/BV members were honored at the San Diego meeting. James Miller was awarded the Silver Medal of the ASA and he was introduced by Matthew O'Donnell. David Blackstock was the first ever recipient of the Student Council Mentor Award. At the Technical Committee meeting on Thursday we held an election for a new chair of BU/BV and Michael Bailey from the University of Washington, Seattle was duly elected.

At the spring meeting in Vancouver BU/BV had a very strong showing with sessions all day, every day. Thanks go to the special sessions organizers: Mike Bailey and Reiner Schultheiss—Tissue response to shock waves (unfortunately Reiner could not attend due to a herniated disc); Tom Royston—Audible-frequency medical diagnostic methods, including multi-mode techniques; Pierre Mourad and Carr Everbach—Therapeutic ultrasound for the brain; and Pierre Mourad and Mike Averkiou—Gene therapy and molecular imaging. In addition BU/BV had a major impact on the Celebration session for Wesley Nyborg (Uncle Wes) that had been organized by Lawrence Crum and Junru Wu. Our TPOM representative was Michael Bailey. There were 53 people in attendance at the technical committee meeting on Thursday evening.

At the spring meeting BU/BV holds a student paper competition and in Vancouver there were 16 entries. The first prize went to Adam Maxwell from University of Washington and the second prize to Parag Chitnis from Boston University. I would also like to recognize two other students with honorable mentions: Wayne Kreider from University of Washington and Heather Argadine from the Mayo Clinic. Thanks to all the judges for their sterling service to the TC.

At the Minneapolis meeting BU/BV will be hosting a Topical Meeting on Detecting HIFU Lesions which is being organized by Emad Ebbini. We will have two special sessions: Medical Applications of Time Reversal Acoustics by Armen Sarvazyan and Acoustic Radiation Force Methods for Medical Imaging and Tissue Evaluation by Mostafa Fatemi.

My term as BU/BV chair comes to an end with this report and it is my pleasure to introduce the new chair Michael Bailey. I would like to take this opportunity to thank all the people who have helped me with the activities of BU/BV over the past three years. The continued vibrancy of the technical committee is due to the enthusiasm of members who volunteer their service to BU/BV. It has been my privilege to work with you all.

ROBIN CLEVELAND
Chair 2002–2005

Engineering Acoustics

The Engineering Acoustics Technical Committee (EATC) met at each of the two meetings of the Society, San Diego in the Fall and Vancouver in the Spring.

In San Diego, the EATC sponsored two special sessions and one session of contributed papers. The special sessions and their organizers were MEMS Microphones: Fabrication, Calibration, and Application to High Density Arrays—Allan J. Zuckerwar and Qamar A. Shams and Hearing Aids—Gary W. Elko and James G. Ryan. In addition, EATC co-sponsored several other sessions with the various technical committees. The Committee offers many thanks to Steven R. Baker, who served as the representative to the San Diego TPOM. The EATC met in San Diego on the evening of Tuesday November 16.

In Vancouver, the EATC sponsored one special session and two sessions of contributed papers. The special session topic and organizers were Underwater Acoustic Sensor Technologies—Thomas R. Howarth and Dehua Huang. The Committee offers many thanks to Stephen C. Thompson who served as EATC representative to the Vancouver TPOM. The EATC met in Vancouver on the evening of Thursday May 17.

The recipients of the Best Student Paper awards for Engineering Acoustics were, for San Diego, Stefan A. L. Stijlen, "Ultrasonic nondestructive inspection of interface defects in anisotropic fiber-metal-laminates," (4aEA7), and, for Vancouver, Andrew P. Medley, "Radiated fields of thin and flexible high frequency loudspeakers," (1pEAa5).

The Chair of EATC would like to thank all of the people who have worked to make the activities of EATC successful for this year and to invite all interested parties to attend EATC meetings to be held at future meetings

of the Society.
KIM C. BENJAMIN
Chair

Musical Acoustics

2004–2005 was another eventful year for the Technical Committee on Musical Acoustics. In addition to organizing special sessions, members of our technical committee were also responsible for some special events at the two ASA meetings and organized a workshop for instrument builders in conjunction with the Vancouver meeting.

There were some excellent special technical sessions in musical acoustics at the San Diego meeting in November 2004. These included a session on pipe organ acoustics organized by Tom Rossing, a session of invited talks and poster presentations on Computer Music organized by Julius Smith, "Musical Instruments of the Asia-Pacific Region," organized by Jim Cottingham, and "Synthesis Techniques with Acoustical Music," co-sponsored by Musical Acoustics and organized by Tony Hoover and Dick Campbell of Architectural Acoustics (AA). In addition to these, our technical committee was one of the many co-sponsors of the Robert Young memorial session. Following the session on Asian instruments, Christopher Adler of the University of San Diego presented a concert on the *khaen*, the free-reed mouth organ of Laos and Northeast Thailand. The performance also included demonstrations of two single-pipe free reed instruments and a duet in which Christopher Adler was joined by Supeena Insee Adler playing the three-string Thai zither *jakay*. About 150 people attended the concert. A tour and demonstration of two significant pipe organs were arranged in which a busload of participants visited the 73 rank Spreckels outdoor pipe organ in Balboa Park and the 107 rank pipe organ in the First Methodist Church. Our tour guide was Lyle Blackinton, curator of the Spreckels organ and builder of the organ in the Methodist church.

The Vancouver meeting included four special sessions in musical acoustics, two of which were co-sponsored by other technical committees. Courtney Burroughs and Tom Rossing organized "Vibration of and Radiation from Musical Instruments" (joint with Structural Acoustics). Jonas Braasch and William Martens co-chaired a joint session, "Low Frequency Content in Music" (joint with AA and Psychological and Physiological Acoustics). A session on virtual musical instruments was organized by Julius Smith and Tamara Smyth, and "String Instrument Design and Construction" was organized by Tom Rossing and Chris Waltham. Special technical initiative funding was used to support a workshop on acoustics for instrument builders, which was held following the Friday morning session on string instruments. The workshop, organized by Tom Rossing and Chris Waltham, had Friday afternoon and Saturday morning sessions. Many of the invited speakers from the Friday morning special session served as workshop leaders.

In addition to our ongoing efforts to promote student involvement in musical acoustics through the student paper competition, representatives from Musical Acoustics continued to play an active role in the ASA Student Council. Andrew Morrison of Northern Illinois University completed his term on the Student Council at the Vancouver meeting. Brian Monson of Brigham Young University has been appointed as our new Student Council representative. There were 11 entries in the student paper competition in San Diego and 13 in Vancouver. The winner of the First Prize award at San Diego was Rolf Bader of the Musikwissenschaftliches Institut, Hamburg, Germany, who presented "Multiphonic model of split pressure-phase modes using the finite-element method." Second Prize went to Yumiko Sakamoto of Kyushu University for "On the acoustical design of the ears of flue organ pipes." First Prize at Vancouver was awarded to Patricio de la Cuarda from CCRMA, Stanford University, for "A physical model and experimental test-bed for real-time simulation of flute-like instruments." The Second Prize winner was Niels Werner Larsen of Oersted DTU, Technical University of Denmark, who presented "A variable passive low-frequency absorber."

Jim Cottingham served as the representative to the Technical Program Organizing Meetings for San Diego and Vancouver, assisted by Chris Waltham at Vancouver. Representation from Musical Acoustics on ASA committees during the year included Uwe Hansen on the Membership Committee and Ian Lindevald on the Committee on Standards. Jim Beauchamp generously served an additional year on the Medals and Awards Committee after the expiration of his term in the spring of 2004. We expect his successor to be named soon. Diana Deutsch, who will work mainly with papers in the area of music perception, has been appointed as a second *JASA* Associate Editor for Musical Acoustics. She joins Neville Fletcher who will continue to serve as Associate Editor.

The Vancouver meeting was a time of transition, as Jim Cottingham ended his two terms of service as Technical Committee Chair. Jim Beauchamp has been elected as the new Technical Committee Chair, to serve until 2008. Members appointed or reappointed this year to serve on the Technical Committee for terms expiring in 2008 include James W. Beauchamp (Chair), George A. Bissinger, Annabel J. Cohen, James P. Cottingham, Diana Deutsch, Uwe J. Hansen, Roger J. Hanson, Peter L. Hoekje, James H. Irwin, Ian M. Lindevald, Stephen E. McAdams, Gary P. Scavone, and Chris Waltham.
JAMES P. COTTINGHAM
Chair (1999–2005)

Noise

At the Fall 2004 meeting of the ASA in San Diego, the Technical Committee on Noise organized or co-organized several interesting and diverse special sessions. These were "Special Session to Honor the Contributions of Robert W. Young to Acoustics" (organized by Alan Marsh), "Propulsion/Airframe Aeroacoustics" (Joe Posey), "Implementation of Classroom Acoustics" (John Erdreich, David Lubman and Louis Sutherland), "Active Noise Reduction for Hearing Protection: Technology Opportunities and Assessment of Effectiveness" (William Murphy), and "Soundscapes and Sound Quality" (Brigitte Schulte-Fortkamp and Patricia Davies). Our appreciation goes to Alan Marsh for serving as the Noise representative at the Technical Program Organizing Meeting.

The Spring 2005 Vancouver meeting was also host to an interesting array of special sessions organized or co-organized by Noise. These sessions were "Topical Meeting on Classroom Acoustics—The Research Perspective" (three half-days of technical presentations plus a public forum, organized by Murray Hodgson and Lily Wang), "Urban Noise Propagation" (Jian Kang, Ning Xiang, and Keith Wilson), "Progress in Managing Occupational Noise" (Hugh Davies and Murray Hodgson), "Preserving Acoustical Integrity in the Course of Renovation" (Dan Raichel), "Noise Control Feasibility: Technical, Legal and Economic Issues" (John Seiler and Angelo Campanella), "Characterization of Acoustical Materials" (Brandon Tinianov), and "Workshop on Methods for Community Noise and Annoyance Evaluation" (Brigitte Schulte-Fortkamp and Bennett Brooks). Jerry Lilly was the Noise representative at the Technical Program Organizing Meeting.

Classroom acoustics continues to be a major focus of the Noise Committee. The efforts of Lou Sutherland, David Lubman, Murray Hodgson, and others to promote good acoustics for classrooms are appreciated. A new subcommittee, joint between Noise and Architectural Acoustics and chaired by Greg Tocci, has been formed to address speech privacy in health care buildings.

The contributions of several Noise people were recognized at these two meetings. At the San Diego meeting, we had two winners of the Noise Young Presenter award, Beatriz Pinto for her talk "S-shaped glass also stands for soundless. Sound insulation measurements and implication for building practice" and Cesare Hall for his talk "Engine configurations for the Silent Aircraft." In Vancouver, the Noise Young Presenter award went to Connor Duke for his talk "Multi-channel active noise control on an axial fan using variable loads." New Fellows of the Society include Klaus Genuit, Tony Hoover, Bennett Brooks, and Murray Hodgson. Lily Wang was presented with the 2005 R. Bruce Lindsay Award. The winner of the 2005 Helmholtz-Rayleigh Interdisciplinary Silver Medal, in Noise and Physical Acoustics, is Gilles Daigle "for contributions to understanding the micrometeorology, topography, and ground properties on outdoor sound propagation."

Finally, the efforts of several volunteers should be recognized. Nancy Timmerman is the Noise representative on the Medals and Awards Committee, John Erdreich is our representative on the Membership Committee, and Richard Peppin is our representative on the ASA Committee on Standards. Our Student Council representative was Brian Anderson until the end of the San Diego meeting. Connor Duke is our new representative to Student Council and, following the practice initiated a few meetings ago, the secretary for the TC-Noise meetings. The Noise web page (http://www.nonoise.org/quietnet/tcn/) is maintained by Les Blomberg. Ken Cunefare completed his stint as coordinator for the Noise Young Presenter

Awards at the San Diego meeting. Ralph Muehleisen has taken over this role and he handled the coordination for the Vancouver meeting. Serving as an Associate Editor for *ARLO* is Mike Stinson and as *JASA* Associate Editors are Ken Cunefare, Keith Wilson, and Allan Zuckerwar.

MICHAEL R. STINSON
Chair

Physical Acoustics

It is my distinct pleasure to reflect on the past year's activities in Physical Acoustics. We have been redefining ourselves over the past few years. The "hot" fields of sonoluminescence and thermoacoustics have taken a back seat as funding levels have decreased (new discoveries may yet help stimulate more funding). New areas are also emerging (examples include monitoring the Earth, condensed matter, medical acoustics, and Homeland Security research). This is reflected in recent and upcoming special sessions: e.g., Infrasound, Sounds Speeds in Condensed Matter, Shock Wave Therapy, and Applications of Acoustic Radiation Pressure.

After the huge New York meeting, it would have been reasonable to have a small Physical Acoustics turnout at the Fall San Diego meeting, but that was not the case. We had sessions Monday through Thursday. Both special sessions had standing-room only crowds. The session on Sonoluminescence, Sonochemistry, and Sonofusion was exhilarating. Invited speakers came from all over the world, and from academia and industry, to share their most recent discoveries. It is worth noting that from the beginning, when single-bubble sonoluminescence was discovered (pre-1990), the leaders in this important field have had their roots in Physical Acoustics and the ASA. The special session on Applications of Acoustic Radiation Pressure was also standing room only. This session covered a wide range of topics, from basic physics to applications. We wish to thank the organizers for these sessions, Tom Matula and Greg Kaduchak. In addition to the special sessions, there was sufficient interest in the San Diego meeting (perhaps the weather had some role!) to generate several contributed sessions, including Sound Propagation in Ground, and in the Atmosphere, Materials Characterization, and Time Reversal.

The Spring meeting was held in Vancouver, BC. The meeting was larger than expected, and Physical Acoustics sessions ran all week, with some unavoidable concurrent sessions. A major special session was organized on Infrasound: A New Frontier in Monitoring the Earth, organized by Michael Hedlin. It is this author's impression that significant gaps remain between data gathering/reduction/analysis and predictive capabilities. This rapidly growing field is in dire need of Physical Acousticians (graduate students take note!). During the open TC meeting, Hank Bass even suggested that funding for this area may be increasing. This is good news for a TC that has taken some hits with decreased funding levels from the Office of Naval Research (ONR) over the past several years.

We also had special sessions in Scattering from Noncanonical Objects, organized by Steve Kargl; Stochastic Scattering of Elastic and Seismic Waves, organized by Richard Weaver, and another in the line of Physical Acoustics Living Legends sessions, organized by Larry Crum for Wes Nyborg. This session was co-run with Biomedical Ultrasound/Bioresponse to Vibration (B&B), as Wes's contributions significantly influenced the growth of B&B. There has been a lot of positive feedback on continuing these topical Living Legend sessions. Physical Acoustics also shared the stage during the "Hot Topics" session. Thanks to Albert Migliori for taking on the job of presenting our hot topics.

Physical Acoustics takes special pride in acknowledging our most recent award recipients: David Blackstock received the inaugural Student Council Mentoring Award in San Diego. David is continuously promoting and advancing student participation in science and the ASA. The Helmholtz-Rayleigh Interdisciplinary Silver Medal in Noise and Physical Acoustics went to Gilles Daigle. Gilles received the award at the Vancouver meeting. The Rossing Prize in Acoustics Education went to Allan Pierce at the San Diego meeting. Allan's recognition did not stop there; he was awarded the Gold Medal in Vancouver. Congratulations to all our award recipients. A job well done!

I would like to take this opportunity to advertise for the Physical Acoustics Summer School (PASS), held every two years. The next school will be held in June of 2006. This highly successful school takes students on a week-long intellectual journey through many areas touched by physical acoustics. Although funding for the school from ONR is gone, the National Center for Physical Acoustics and Penn State are trying to bridge the gap until new funding can be obtained.

I want to also take the time to acknowledge members of Physical Acoustics who volunteer their services on various committees: Robert "Bonzo" Keolian serves on the Medals and Awards committee; Steve Garrett serves on the Membership Committee; Phil Marston serves on the Books committee, and Sameer Madanshetty serves on ASACOS. Associate editors also deserve accolades; their hard work helps keep *JASA* the premier journal for physical acoustics publications. It is also a pleasure to acknowledge Physical Acoustics members who are active in leadership roles in the ASA. Mark Hamilton is now past vice president of the ASA, the editor-in-chief is Allan Pierce, and Anthony Atchley was just elected President! Congratulations Anthony!

Finally, I wish to humbly thank the Physical Acoustics community for entrusting me to serve as Chair over the past three years. It has been a privilege and honor to serve you. I especially would like to thank the more experienced members for their advice and encouragement over the years. Now, I pass the crown to our new Chair, Murray Korman. Have a great time, Murray; I did!

THOMAS J. MATULA
Chair 2002–2005

Psychological and Physiological Acoustics

Reflecting Psychological and Physiological Acoustics' (P&P) strategy of emphasizing participation at ASA's spring meetings, the 148th Meeting of the Acoustical Society of America, the fall meeting in San Diego, was sparsely attended by the members of P&P. Nonetheless, P&P co-sponsored two special sessions: "Implementation of Classroom Acoustics I and II." In keeping with P&P policy, we will not be a primary sponsor of special sessions at the Minneapolis meeting in the fall, and P&P has asked that calls for papers provided by ASA include a brief explanation of our policy of deemphasizing the fall meetings.

In stark contrast, the spring meeting in Vancouver was buzzing with activity. There were eight sessions sponsored by P&P, one of which was co-sponsored by Speech Communication and one of which was co-sponsored by Animal Bioacoustics. Of the eight sessions, three were special sessions including one named session. We extend our thanks to the organizers of the special sessions: Bertram Scharf and Rhona P. Hellman (Psychoacoustics: In Memory of Søren Buus), Roy D. Patterson and Toshio Irino (Size Information in Speech and Animal Calls), and Lawrence L. Feth and Robert A. Fox (Current Issues in Auditory Spectral Integration). P&P also contributed as co-sponsor of six additional special sessions. Neal Viemeister accomplished the challenge of organizing the P&P sessions for the Vancouver meeting, a task for which we are most appreciative.

The P&P open meeting included an update of the Student Council report by the outgoing student representative, Joshua Bernstein. The P&P Associate Editors provided overview of their efforts, and urged the members of ASA to provide reviews well before the Peer X Press system generates an "overdue notice." The goal is to provide reviews within four weeks of receiving the submitted manuscript. We thank the P&P Associate Editors, Brenda L. Lonsbury-Martin, William P. Shofner, John H. Grose, Gerald D. Kidd, Armin Kohlrausch, Robert A. Lutfi, and Andrew J. Oxenham, for their efforts on our behalf. Finally, there was discussion concerning the need to continue to provide nominations of Fellows to the Acoustical Society of America. We express our thanks to John Culling for organizing the ballot for election to the Technical Committee, and thanks to members of the P&P community who so willingly added their names to the ballot.

The P&P Technical Initiatives continue unchanged. The initiatives include travel support for invited speakers, student receptions, and homepage maintenance. Suggestions for uses of funds, including innovations such as workshops, satellite meetings, etc., are welcome (estrick@purdue.edu).

VIRGINIA M. RICHARDS
Chair, 2002–2005

Speech Communication

The Speech Technical Committee (STC) supports the activities, meetings, publications, etc. for the largest technical area in the Society. The current members of the Committee are Jean Andruski, Patrice Beddor,

Lynne Bernstein, Catherine T. Best, Ocke-Schwen Bohn, Suzanne E. Boyce, Ann Bradlow, Dani Byrd, Roger Chan, Melissa Epstein, Robert Fox, Alexander Francis, Bruce Gerratt, Kenneth Grant, Helen Hanson, James Hillenbrand, Diane Kewley-Port, Jody E. Kreiman, Anders Lofqvist, Andrew Lotto, Benjamin Munson, Terrence Nearey, Peggy Nelson, Douglas O'Shaughnessy, Dwayne Paschall, Joseph Perkell, Astrid Schmidt-Nielsen, Brad Story, and Gary G. Weismer. Other *ex officio* members include Abeer Alwan, Shrikanth Narayanan, and Fredericka Bell-Berti, our representatives to the Membership Committee, ASACOS, and Medals and Awards, respectively; Jennell Vick is the Student Council representative. The continuing Associate Editors for speech are Alexander Francis, Kenneth Grant, Anders Lofqvist, and Douglas O'Shaughnessy; two newly appointed associate editors are Brad Story and Joan Sussman.

We are grateful for the help of our members this year: (1) Dani Byrd, Rob Fox, and Diane Kewley-Port, who revised the PACS numbers for the speech section. The revisions will take place in September 2005. (2) Our paper sorters, who arrange the technical programs: Jody Kreiman and Dani Byrd in San Diego and Terry Nearey and Richard Wright in Vancouver. Special thanks to Bryan Gick who served on the Vancouver local organizing committee. (3) Coordinators for student judging: Alex Francis, Amee Shah, and Ben Munson. We also are very happy to welcome three new fellows to the ASA from the speech communication TC: Catherine Best, Patricia Keating, and Robert Remez.

Student Activities

The Committee sponsored two student activities at each meeting, a competition with a cash award for best student presentation and an evening reception. The evening reception, which is joint with other technical committees, is intended to allow students to meet more senior ASA members informally. The reception was well attended. The student papers were judged by STC members and the winners were awarded $300 for first prize and $200 for second prize. In San Diego the first and second place winners were Jason Tourville of Boston University and Jerry Liu of the University of Southern California.

Special Sessions, Special Talks, and Workshops

Speech Communication has sponsored many interesting special sessions during the past year. In San Diego Sorin Dusin and Lawrence Rabiner organized a special session "Fifty years of progress in speech communication: Honoring the contributions of James L. Flanagan." In addition a session on "Foreign-accented speech: Production, perception and applications" was organized by Amee Shah. In Vancouver a considerable number of special sessions were held. Ruth Litovsky and Mario Svirsky coordinated the session "Communication abilities of congenitally deaf children" held jointly with Psychological and Physiological Acoustics (P&P), which considered cochlear implants, hair cell regeneration and related subjects. Sonya Bird organized "Indigenous languages of North America," which reduced the deficit of published research in this area. Linda Polka, Ocke-Schwen Bohn, and James Hillenbrand sponsored the session "Vowel systems and language learners." "Spectral integration of complex sounds and speech" was organized by Larry Feth, Eva Jacewicz, and Rob Fox, sponsored by P&P and co-sponsored by Speech. In addition, the "First ASA Workshop on Second Language Speech Learning" was held at Simon Fraser University immediately prior to the ASA meeting in Vancouver. The workshop, organized by Murray Munro and Ocke-Schwen Bohn, was attended by over 100 participants and was very highly praised. Finally, we appreciate the efforts of two members who gave excellent and informative presentations at the Vancouver meeting: the hot topics presentation "Imaging for understanding speech communication: Advances and challenges" by Shri Narayanan and the tutorial presentation "Tutorial lecture on automatic speech recognition" by Carole Espy-Wilson.
MAUREEN STONE
Chair

Structural Acoustics and Vibration

Many of the technical activities by members of the Structural Acoustics and Vibration Technical Committee (SAVTC) has been supported by funding by the US Navy on vibrations of, acoustic radiation from, and

self-noise in marine vessels. With Navy funding in these areas decreasing, SAVTC is facing new challenges, in addition to maintaining activities in past areas of interest, which is reflected in the SAVTC activities during this year. At the San Diego meeting in November 2004, there were three special technical sessions. Karl Grosh organized and chaired a session on "Structural Acoustics in MEMS." A session on "Surface Ship Vibration and Noise" was organized and chaired by Ray Fischer. Finally, Dan Russell organized and chaired a session on "Vibrations in Sports Equipments." In addition, there were two technical sessions on analysis and measurement methods. At the Vancouver meeting in May 2005, there were two special all-day technical sessions. David Feit organized and chaired a session on "Approximate Techniques for Fluid Loading Effects." Courtney Burroughs and Tom Rossing, from the Musical Acoustics Technical Committee, organized and chaired a session on "Vibration and Acoustic Radiation from Musical Instruments." In addition, there were SAVTC technical sessions on vibration and acoustic radiation.

This was the year for SAVTC to present a Hot Topics paper. At the San Diego meeting, Courtney Burroughs, Dean Capone, and Karl Grosh presented "Hot topics in structural acoustics; New directions and challenges." There was one new Fellow from the SAVTC. Two new Associate Editors for JASA were appointed. Andy Norris "retired" as Associate Editor after several years of service. Student paper award winners at the San Diego meeting were Matt Allen for paper 4pSA1 and Elizabeth Magluila for paper 2aSA11. In the Vancouver meeting, the two student paper winners were Jerome Pinsonnault for paper 5aSA2 and Dany Francoeur for paper 5aSA1. The student representative for SAVTC to the very active Student Council was Lance Locey (Penn State). He was replaced by Micah Shepard (Brigham Young) at the Vancouver meeting. The SAVTC representative to the San Diego TPOM was Courtney Burroughs and to the Vancouver TPOM, Claudio Bulfone. A special thanks to Claudio, who is not a member of SAVTC, for filling in when no one from SAVTC could attend the Vancouver TPOM.
COURTNEY B. BURROUGHS
Chair

Underwater Acoustics

The year began with preparation for the Fall 2004 meeting in San Diego, for which we thank Peter Gersoft and Peter Worcester for representing the Underwater Acoustics Technical Committee (UWTC) at the Technical Program Organizing Meeting (TPOM). Also, leading up to the San Diego meeting was the prominent cover-article of the October 2004 edition of *Physics Today*, entitled "Shallow-Water Acoustics" by William A. Kuperman and James F. Lynch.

In San Diego the UWTC sponsored special sessions entitled "Very High Frequency [O(100) kHz] Boundary Interaction" that was organized by Gary Heald and "Long Range Acoustic Propagation" that was organized by Peter Worcester. There were 16 papers submitted to the student paper competition for the San Diego meeting under the auspices of the UWTC. Elizabeth T. Kusel (Rensselaer Polytechnic Institute) was awarded first prize for her paper entitled "A single-scattering solution that handles large contrasts across interfaces," and Alexander O. MacGillivray (University of Victoria) received second prize for his presentation entitled "An airgun array source signature model for environmental impact assessments."

Gerald D'Spain presented a Tutorial Lecture on Ocean Noise and Marine Mammals at the San Diego meeting. Closely related to this topic, discussions at the San Diego venue commenced on an ASA Policy Statement on the "Potential Consequences of Anthropogenic Ocean Noise on Marine Animals," by the ASA Panel on Public Policy (PoPP), Working Group on Ocean Noise (James H. Miller and Darlene Ketten, Co-Chairs).

UWTC members Michael Ainslie, Robert Gragg, Phillippe Roux, and Manell Zakharia were recognized as new Fellows of the ASA, and the UWTC also recognizes the contributions of Walter Munk (ASA Honorary Fellowship), Van Holliday (Silver Medal in Acoustical Oceanography), and John Bouyoucos (Silver Medal in Engineering Acoustics), all of whom were recognized in San Diego. Finally, all the Technical Committee Chairs participated in the "Vision 2010 Conference" held at the Scripps Institution of Oceanography the Sunday before the San Diego meeting, with initial recommendations of this conference reported in the Winter 2005 edition of *Echoes*.

The Spring 2005 meeting in Vancouver, BC, held jointly with the Canadian Acoustical Association, was by all measures a fine success. Peter

Dahl represented the UWTC at the January TPOM, and the UWTC sponsored special sessions entitled "Acoustic Interaction with Ocean Boundaries: Single Bounce Measurements," which was organized by Charles Holland, and "Frequency Dependence of Sound Speed and Attenuation in Marine Sediments," which was organized by Gopu Potty and Peter Dahl. There were 21 papers submitted to the student paper competition for the Vancouver meeting under the auspices of the UWTC. Alexander O. MacGillivray (University of Victoria) received first prize for his presentation entitled "An acoustic modeling study of airgun noise from seismic surveys performed offshore British Columbia," and Jie Yang (Georgia Institute of Technology) received second prize for her work entitled "Influence of internal waves on vertical coherence of sound propagation in the East China Sea."

The ASA student paper awards in Underwater Acoustics receive contributions from other, related Technical Committees that do not offer this award; as a result both the paper count and competition is high. Coordinating the judging of these papers is a significant task (we seek at least two, ideally three independent evaluations for each paper), and the UWTC thanks Kyle Becker, who has carried out this coordination role on an *ad hoc* basis for the last three meetings. In Vancouver, the UWTC Chair proposed formalizing this role (*student judge coordinator* with position to last one year; Kathleen Wage has volunteered for this position that will commence with the Minneapolis meeting. We also note the graduation of UWTC Student Council representative Tom Weber (Applied Research Laboratory, Penn State University), who will be replaced by Andy Ganse (University of Washington). Finally the UWTC recognizes the contributions of Svein Vagle who received the Medwin Prize in Acoustical Oceanography in Vancouver.
PETER H. DAHL
Chair

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future. The month/year notation refers to the issue in which a complete meeting announcement appeared.

2005

17–21 Oct.   150th Meeting of the Acoustical Society of America joint with Noise-Con, Minneapolis, MN [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].

27–29 Oct.   5th International Symposium on Therapeutic Ultrasound, Boston, MA [www.istu2005.org; E-mail: info@istu2005.org].

2006

9–12 Feb.   46th Annual Convention, Illinois Speech-Language-Hearing Association, Rosemont, IL [ISHA, 230 E. Ohio St., Suite 400, Chicago, IL 60611-3265; Tel.: 312-644-0828; Fax: 315-644-8557; Web: www.aishil.org].

16–18 Feb.   31st Annual Conference, National Hearing Conservation Association, Tampa, FL [NHCA, 7995 E. Prentice Ave., Suite 100 East, Greenwood Village, CO 80111-2710; Tel: 303-224-9022; Fax: 303-770-1614; E-mail: nhca@gwami.com; WWW: www.hearingconservation.org].

6–9 June   151st Meeting of the Acoustical Society of America, Providence, RI Island [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].

17–21 Sept.   INTERSPEECH 2006 (ICSLP 2006), Pittsburgh, PA [www.interspeech2006.org ⟨http://www.interspeech2006.org/⟩]

28 Nov.–2 Dec.   152nd Meeting of the Acoustical Society of America joint with the Acoustical Society of Japan, Honolulu, HI [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; WWW: http://asa.aip.org].

2008

28 July–1 Aug.   9th International Congress on Noise as a Public Health Problem (Quintennial Meeting of ICBEN, The International Commission on Biological Effects of Noise), Foxwoods Resort, Mashantucket, CT [Jerry V. Tobias, ICBEN 9, P. O. Box 1609, Groton, CT 06340-1609, Tel.: 860-572-0680; Web: www.icben.org; E-mail: icben2008@att.net].

Cumulative Indexes to the Journal of the Acoustical Society of America

Ordering information: Orders must be paid by check or money order in U.S. funds drawn on a U.S. bank or by Mastercard, Visa, or American Express credit cards. Send orders to Circulation and Fulfillment Division, American Institute of Physics, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2270. Non-U.S. orders add $11 per index.

Some indexes are out of print as noted below.

Volumes 1–10, 1929–1938: JASA and Contemporary Literature, 1937–1939. Classified by subject and indexed by author. Pp. 131. Price: ASA members $5; Nonmembers $10.
Volumes 11–20, 1939–1948: JASA, Contemporary Literature, and Patents. Classified by subject and indexed by author and inventor. Pp. 395. Out of Print.
Volumes 21–30, 1949–1958: JASA, Contemporary Literature, and Patents. Classified by subject and indexed by author and inventor. Pp. 952. Price: ASA members $20; Nonmembers $75.
Volumes 31–35, 1959–1963: JASA, Contemporary Literature, and Patents. Classified by subject and indexed by author and inventor. Pp. 1140. Price: ASA members $20; Nonmembers $90.
Volumes 36–44, 1964–1968: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 485. Out of Print.
Volumes 36–44, 1964–1968: Contemporary Literature. Classified by subject and indexed by author. Pp. 1060. Out of Print.
Volumes 45–54, 1969–1973: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 540. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).
Volumes 55–64, 1974–1978: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 816. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).
Volumes 65–74, 1979–1983: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 624. Price: ASA members $25 (paperbound); Nonmembers $75 (clothbound).
Volumes 75–84, 1984–1988: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 625. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).
Volumes 85–94, 1989–1993: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 736. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).
Volumes 95–104, 1994–1998: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 632, Price: ASA members $40 (paperbound); Nonmembers $90 (clothbound).
Volumes 105–114, 1999–2003: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 616. Price: ASA members $50; Nonmembers $90 (paperbound).

Members of Technical and Administrative Committees of the Acoustical Society of America

The Technical and Administrative Committees listed below have been appointed by the Executive Council. These appointments, with such changes as may be made by the President from time to time, will be in effect until the Spring meeting of the Society in 2006.

Technical Committees 2005–2006

Acoustical Oceanography
N. Ross Chapman, *Chair* to 2007

Term to 2008
Daniela Di Iorio
Gerald L. D'Spain
Gary J. Heald
Jean-Pierre Hermand
David P. Knobles
Timothy G. Leighton
James H. Miller
Daniel Rouseff
Emmanuel K. Skarsoulis
Jerome A. Smith
Dajun Tang

Term to 2007
Kyle M. Becker
Grant B. Deane
Christopher Feuillade
Peter Gerstoft
Oleg A. Godin
John K. Horne
Bruce M. Howe
Anthony P. Lyons
Ralph A. Stephen
Kathleen E. Wage
Peter F. Worcester

Term to 2006
Mohsen Badiey
Paul E. Chandler
Dezhang Chu
Kerry W. Commander
Christian de Moustier
Stan E. Dosso
Andone C. Lavery
Zoi-Heleni Michalopoulou
Jeffrey A. Nystuen
David R. Palmer
Simon D. Richards
Martin Siderius

Ex officio:
James F. Lynch, member of Medals and Awards Committee
Mohsen Badiey, member of Membership Committee
Anthony P. Lyons, member of ASACOS

Animal Bioacoustics
Andrea M. Simmons, *Chair* to 2006

Term to 2008
Whitlow W. L. Au
Kelly J. Benoit-Bird
W. Tecumseh Fitch
Dorian S. Houser
Lee A. Miller

Larry L. Pater
Hiroshi Riquimaroux
Peter M. Scheifele
Edward J. Walsh

Term to 2007
Sheryl L. Coombs
Richard R. Fay
Edmund R. Gerstein
Seth S. Horowitz
Cynthia F. Moss
James A. Simmons
Jeannette A. Thomas

Term to 2006
Ann E. Bowles
John R. Buck
Christopher W. Clark
William C. Cummings
Charles R. Greene
Mardi C. Hastings
D. Vance Holliday
David A. Mann
Sam H. Ridgway

Ex officio:
Charles R. Greene, member of Medals and Awards Committee
Darlene R. Ketten, member of Membership Committee
Ann E. Bowles, member of ASACOS

Architectural Acoustics
Lily M. Wang, *Chair* to 2007

Term to 2008
Wolfgang Ahnert
Christopher N. Blair
John S. Bradley
Christopher N. Brooks
Angelo J. Campanella
Quinsan Ciao
Robert C. Coffeen
Peter D'Antonio
Felicia M. Doggett
William Dohn
Timothy J. Foulkes
Richard D. Godfrey
Tyrone Hunter
Clare M. Hurtgen
J. Christopher Jaffe
Mendel Kleiner
Jeff P. Kwolkoski
Brad W. Lewis
Stephen J. Lind
David Lubman
Ralph T. Muehleisen
Michael T. Nixon
Boaz Rafaely
Daniel R. Raichel
Jack E. Randorff
Jonathan Rathsam
H. Stanley Roller
Steven R. Ryherd
B. Schulte-Fortkamp
Noral D. Stewart
Michael Vorländer
Ning Xiang

Term to 2007

Warren E. Blazier
Joseph F. Bridger
Norm Broner
Bennett M. Brooks
Steven M. Brown
Todd A. Busch
Richard H. Campbell
F. M. del Solar Dorrego
Erin L. Dugan
M. David Egan
Jesse J. Ehnert
Michael Ermann
Adam R. Foxwell
Ronald R. Freiheit
Klaus Genuit
Matthew V. Golden
Kenneth W. Good, Jr.
Brad N. Gover
Mark A. Holden
K. Anthony Hoover
Jerald R. Hyde
David W. Kahn
Martha M. Larson
Gary S. Madaras
Benjamin E. Markham
Charles T. Moritz
David L. Moyer
Edward T. Nykaza
Paul B. Ostergaard
Dennis A. Paoletti
Stephen W. Payne
Benjamin C. Seep
Neil A. Shaw
Ryan G. Sieler
Rose Mary Su
Jeff D. Szymanski
Richard H. Talaske
Michelle Vigeant
Ewart A. Wetherill
George E. Winzer
Michael R. Yantis

Term to 2006

Nils-Ake Andersson
Leo L. Beranek
Sergio Beristain
Leslie D. Blomberg
Erica Bowden
David T. Bradley
David Braslau
Todd L. Brooks
Courtney B. Burroughs
Paul T. Calamia
Alexander U. Case
William J. Cavanaugh
Dan Clayton
Elizabeth A. Cohen
Chris L. Davies
Damian Doria
John Erdreich
Robin S. Glosemeyer
Robert D. Hellweg
Murray R. Hodgson
Ian B. Hoffman

Jin Jeon
James A. Johnson
Bertram Y. Kinzey, Jr.
Iraklis E. Lampropoulos
Jerry G. Lilly
Peter A. Mapp
David E. Marsh
Gregory A. Miller
Hideo Miyazaki
Richard A. Moscoso-Bullon
Matthew A. Nobile
Bruce C. Olson
Richard J. Peppin
Scott D. Pfeiffer
James E. Phillips
Joseph Pope
Roy L. Richards
Carl J. Rosenberg
Kenneth P. Roy
Kevin P. Shepherd
Yasushi Shimizu
Gary W. Siebein
Abigail E. Stefaniw
Christopher A. Storch
Jason E. Summers
Louis C. Sutherland
Jiri Tichy
Nancy S. Timmerman
Brandon D. Tinianov
Gregory C. Tocci
Rendell R. Torres
Alfred C. C. Warnock
George P. Wilson

Ex officio:
Ewart A. Wetherill, member of Medals and Awards
Gregory C. Tocci, member of Membership Committee
George E. Winzer, member of ASACOS

Biomedical Ultrasound/Bioresponse to Vibration
Michael R. Bailey, *Chair* to 2008

Term to 2008

John S. Allen
Charles C. Church
Gregory Clement
Floyd Dunn
E. Carr Everbach
Christy K. Holland
R. Glynn Holt
Elisa E. Konofagou
Subha Maruvada
Wesley L. Nyborg

Term to 2007

Constantin C. Coussios
Diane Dalecki
J. Brian Fowlkes
Kullervo H. Hynynen
T. Douglas Mast
Thomas J. Matula
Robert J. McGough
Douglas L. Miller
Ronald A. Roy
Thomas J. Royston
Kendall R. Waters

Pei Zhong

Term to 2006
Shira L. Broschat
Ibrahim M. Hallaj
Joie P. Jones
Inder R. Makin
Michael V. Scanlon
Thomas L. Szabo
Janet M. Weisenberger
Junru Wu
Suk Wang Yoon
Ex officio:
Lawrence A. Crum, member of the Medals and Awards
Committee
E. Carr Everbach, member of the Membership Committee
and member of ASACOS

Engineering Acoustics
Kim C. Benjamin, *Chair* to 2006

Term to 2008
Steven R. Baker
David A. Brown
Stephen C. Butler
Robert D. Corsaro
Stephen E. Forsythe
Brian H. Houston
W. Jack Hughes
Robert M. Koch
L. Dwight Luker
Arnie L. Van Buren
Kenneth M. Walsh
Daniel M. Warren
Joseph F. Zalesak

Term to 2007
Mahlon D. Burkhard
James Christoff
Fernando Garcia-Osuna
Charles S. Hayden
Dennis F. Jones
Jan F. Lindberg
Yushieh Ma
Elizabeth A. McLaughlin
Alan Powell
Roger T. Richards
Kenneth D. Rolt
Neil A. Shaw
James F. Tressler

Term to 2006
Stanley L. Ehrlich
Gary W. Elko
Robert D. Finch
Guillermo C. Gaunaurd
Thomas R. Howarth
Dehua Huang
Sung Hwan Ko
Theodore J. Mapes
Victor Nedzelnitsky
James M. Powers
P. K. Raju
Yongrae Roh
Ahmet Selamet
Stephen C. Thompson

James E. West
George S. K. Wong

Ex officio:
Mahlon D. Burkhard, member of Medals and Awards
Committee and member of ASACOS
Thomas R. Howarth, member of Membership Committee

Musical Acoustics
James W. Beauchamp, *Chair* to 2008

Term to 2008
George A. Bissinger
Annabel J. Cohen

David K. Holger
Seong-Woo Kang
William W. Lang
Richard H. Lyon
Alan H. Marsh
Ralph T. Muehleisen
William J. Murphy
Kenneth J. Plotkin
Joseph Pope
Daniel R. Raichel
Brigitte Schulte-Fortkamp
Ben H. Sharp
Kevin P. Shepherd
Scott D. Sommerfeldt
Kerrie G. Standlee
George S. K. Wong
James C. Yu
Ex officio:

Nancy S. Timmerman, member of Medals and Awards
Committee
John Erdreich, member of Membership Committee
Richard J. Peppin, member of ASACOS

Physical Acoustics
Murray S. Korman, *Chair* to 2008

Term to 2008
Robert T. Beyer
Robin O. Cleveland
Lawrence A. Crum
Kenneth E. Gilbert
Robert A. Hiller
R. Glynn Holt
Bart Lipkens
Thomas J. Matula
Ralph T. Muehleisen
Harry Simpson
John S. Stroud
Preston S. Wilson

Term to 2007
David T. Blackstock
David A. Brown
John A. Burkhardt
Kerry W. Commander
Bruce C. Denardo
Logan E. Hargrove
D. Kent Lewis
Julian D. Maynard
George Mozurkewich
Lev A. Ostrovsky
Andrea Prosperetti
Neil A. Shaw
Victor W. Sparrow
Richard Stern
Roger M. Waxler

Term to 2006
Henry E. Bass
Yves H. Berthelot
James P. Chambers
David I. Havelock
Philip L. Marston

Philip S. Spoor
Larry A. Wilen
D. Keith Wilson
Evgenia A. Zabolotskaya

Ex officio:
Robert M. Keolian, member of Medals and Awards
Committee
Steven L. Garrett, member of Membership Committee
Sameer I. Madanshetty, member of ASACOS

Psychological and Physiological Acoustics
Elizabeth A. Strickland, *Chair* to 2008

Term to 2008
Michael A. Akeroyd
Alain de Cheveigne
Brent W. Edwards
John H. Grose
Gerald D. Kidd, Jr.
Armin Kohlrausch
Brenda L. Lonsbury-Martin
William P. Shofner
Lynne A. Werner

Term to 2007
David A. Eddins
Lawrence L. Feth
Hedwig E. Gockel
Jennifer Lentz
Mario A. Ruggero

Term to 2006
Michelle L. Hicks
Lynne Marshall
Christopher J. Plack
Donal G. Sinex
Magdalena Wojtczak

Ex officio:
Joseph W. Hall, member of the Medals and Awards
Committee
Leslie R. Bernstein, member of Membership Committee
Peggy B. Nelson, member of ASACOS

Signal Processing in Acoustics
Charles F. Gaumond, *Chair* to 2006

Term to 2008
Frank A. Boyle
David H. Chambers
Joe A. Clark
R. Lee Culver
David J. Evans
David M. Fromm
Howard A. Gaberson
David I. Havelock
Jean-Pierre Hermand
George E. Ioup
Juliette Ioup
Matti A. Karjalainen

ACOUSTICAL STANDARDS NEWS

Susan B. Blaeser, Standards Manager

ASA Standards Secretariat, Acoustical Society of America, 35 Pinelawn Rd., Suite 114E, Melville, NY 11747 [Tel.: (631) 390-0215; fax: (631) 390-0217; e-mail: asastds@aip.org]

George S. K. Wong

Acoustical Standards, Institute for National Measurement Standard, National Research Council, Ottawa, Ontario K1A 0R6, Canada [Tel.: (613) 993-6159; fax: (613) 990-8765; e-mail: george.wong@nrc.ca]

American National Standards (ANSI Standards) developed by Accredited Standards Committees S1, S2, S3, and S12 in the areas of acoustics, mechanical vibration and shock, bioacoustics, and noise, respectively, are published by the Acoustical Society of America (ASA). In addition to these standards, ASA publishes Catalogs of Acoustical Standards, both National and International. To receive copies of the latest Standards Catalogs, please, contact Susan B. Blaeser.

Comments are welcomed on all material in Acoustical Standards News.

This Acoustical Standards News section in JASA, as well as the National and International Catalogs of Acoustical Standards, and other information on the Standards Program of the Acoustical Society of America, are available via the ASA home page: http://asa.aip.org.

Standards Meetings Calendar National

At the 150th ASA Meeting joint with Noise-Con, Minneapolis, MN at the Hilton Hotel and Towers, 17–21 October 2005, the ASA Committee on Standards (ASACOS) and ASACOS STEERING Committees will meet as below:

- *Monday, 17 October 2005*
  ASACOS Steering Committee
- *Thursday, 20 October 2005*
  ASA Committee on Standards (ASACOS). Meeting of the Committee that directs the Standards Program of the Acoustical Society.

International Standard Committee Meetings

12–16 December 2005

ISO/TC 108/SC 5 Condition monitoring and diagnostics of machines

This committee and its working groups will meet at the SeaTech Campus of the Florida Atlantic University Graduate School of Ocean Engineering, in Dania Beach, Florida.

American National Standards Call for Comment on Proposals Listed

This section solicits comments on proposed new American National Standards and on proposals to revise, reaffirm, or withdraw approval of existing standards. The dates listed in parentheses are for information only.

AMCA (Air Movement and Control Association)

Revisions

BSR/AMCA 204-200x, Balance Quality and Vibration Levels for Fans (revision of ANSI/AMCA 204-1996)

This standard defines appropriate fan balance quality and operating vibration levels to individuals who specify, manufacture, use, and maintain fans. (20 June 2005)

Final actions on American National Standards

The standards actions listed below have been approved by the ANSI Board of Standards Review (BSR) or by an ANSI-Audited Designator, as applicable.

ASA (ASC S1) (Acoustical Society of America)

Revisions

ANSI S1.13-2005, Measurement of Sound Pressure Levels in Air [revision of ANSI S1.13-1995 (R1999)]

Specifies requirements and describes procedures for the measurement of sound pressure levels in air at a single point in space. These apply primarily to measurements performed indoors but may be utilized in outdoor measurements under specified conditions. This is a fundamental standard applicable to a wide range of measurements and to sounds that may differ widely in temporal and spectral characteristics; more specific ANS complement its requirements. A classification is given of the types of sound generally encountered, and the preferred descriptor for each type is identified. (25 July 2005)

ASA (ASC S1) (Acoustical Society of America)

Reaffirmations

ANSI S1.16-2000 (R2005), Method for Measuring the Performance of Noise Discriminating and Noise Canceling Microphones (reaffirmation of ANSI S1.16-2000): (27 April 2005)

ASA (ASC S1) (Acoustical Society of America)

Withdrawals

BSR/ASHRAE 87.3P-2001 (R200x), Method of Testing Propeller Fan Vibration (reaffirmation of ANSI/ASHRAE 87.3P-2001)

This standard establishes laboratory and on-site diagnostic test methods for identifying causes of vibration problems involving direct-driven propeller fans for condenser cooling in air-conditioning units, heat pumps, and others.

ASTM (ASTM International)

Reaffirmations

ANSI/ASTM E1662-1995A (R2005), Classification for Serviceability of an Office Facility for Sound and Visual Environment [reaffirmation of ANSI/ASTM E1662-1995A (R99)]: (1 May 2005)

IEEE (ASC C63) (Institute of Electrical and Electronics Engineers)

Revisions

BSR C63.19-200x, Methods of Measurement of Compatibility between Wireless Communications Devices and Hearing Aids (revision of ANSI C63.19-2001)

Sets forth uniform methods of measurement and parametric requirements for the electromagnetic and operational compatibility and accessibility of hearing aids used with wireless communications devices operating in the range of 800 MHz to 3 GHz. However, this version is focused on existing services, which are in common use. (20 June 2005)

Project Initiation Notification System (PINS)

ANSI Procedures require notification of ANSI by ANSI-accredited standards developers of the initiation and the scope of activities expected to result in new or revised American National Standards. This information is a key element in planning and coordinating American National Standards.

The following is a list of proposed new American National Standards or revisions to existing American National Standards that have been received from ANSI-Accredited standards developers that utilize the periodic maintenance option in connection with their standards. Directly and materially affected interests wishing to receive more information should contact the standards developer directly.

ASAE (American Society of Agricultural Engineers)

BSR/ASAE/ISO 5007-200x, Agricultural wheeled tractors—Operator's seat—Laboratory measurement of transmitted vibration (identical national adoption)

Specifies a laboratory method for measuring and evaluating the effectiveness of the suspension of operator seats on agricultural wheeled tractors.

BSR/AISI COFS/HEADER-200x, Cold-Formed Steel Framing—Header BSR/ASAE/ISO 5008—200x, Agricultural wheeled tractors and field machinery—Measurement of whole body vibration of the operator (identical national adoption)

Specifies methods for measuring and reporting the whole body vibration to which the operator of an agricultural wheeled tractor or other field machine is exposed when operating on a standard test track.

TIA (Telecommunications Industry Association)

BSR/TIA 1083-200x, Measurement procedures and performance requirements for handset generated in-band magnetic noise (new standard)

Documents the measurement techniques required for measuring in-band (audio) magnetic noise radiated from a telephone handset. The handset may be corded or cordless. Establish performance requirements for magnetic noise signals radiated from a telephone handset.

Project Need: Provide a method and criteria for evaluating the impact to a hearing aid of unwanted magnetic signals (noise) radiating from a telephone handset.

Newly Published ISO and IEC Standards

Listed here are new and revised standards recently approved and promulgated by ISO—the International Organization for Standardization

ISO Standards

ACOUSTIC (TC 43)

ISO 140-11:2005, Acoustics—Measurement of sound insulation in buildings and of building elements—Part 11: Laboratory measurements of the reduction of transmitted impact sound by floor coverings on lightweight reference floors

MECHANICAL VIBRATION AND SHOCK (TC 108)

OBITUARY

Stanley J. Bolanowski ● 1950–2005

Stanley (Sandy) J. Bolanowski, a Fellow of this Society, died suddenly and unexpectedly on January 13, 2005 while on sabbatical leave at Vanderbilt University in Nashville, Tennessee.

Dr. Bolanowski was a professor in the Department of Biomedical and Chemical Engineering in the L.C. Smith College of Engineering and Computer Science and was associate director of the Institute for Sensory Research (ISR) at Syracuse University.

Dr. Bolanowski was born on February 22, 1950 in Utica, New York, where he attended both elementary and high school. He went on to study electrical technology at the State University of New York at Morrisville, where he earned an associate's degree in electrical technology in 1970. At Syracuse University he earned a bachelor's degree in psychology (1973) and was one of the first students to receive a bachelor's degree in electrical engineering—biosystems (1974). It was during his undergraduate studies at Syracuse that he met and worked with Dr. Ronald Verrillo, founder of the somatosensory laboratories at ISR. He received a Ph.D. in sensory sciences at Syracuse University in 1981. He built the vibrotactile physiology laboratory at ISR and utilized it for his Ph.D. thesis titled "Intensity and Frequency Characteristics of Pacinian Corpuscles." His graduate advisers were Dr. Ronald Verrillo and Dr. Jozef Zwislocki.

After receiving his doctorate, he was awarded a postdoctoral fellowship (1980–1982) and then was appointed assistant professor at the Center for Brain Research (1983–1987) at the University of Rochester School of Medicine and Dentistry, and assistant professor at the Center for Visual Science at the University of Rochester (1983–1987). While at Rochester he studied the cortical activity within the visual systems of monkeys and the psychophysical responses of humans to *ganzfeld* stimulation. In this work he collaborated with the noted neurophysiologist Dr. Robert Doty.

In 1988, Dr. Bolanowski returned to Syracuse University and continued his collaboration with Dr. Verrillo, and with Dr. George Gescheider of the nearby Hamilton College Department of Psychology. His 1988 JASA article with coauthors G.A. Gescheider, R.T. Verrillo, and C.M. Checkosky has been described as the "now-classic paper that provided evidence of four different mechanoreceptors…" with "basic findings" that to this day "remain the best theory of mechanoreceptive function" [J.E. Weisenberger, "History of Bioresponse to Vibration in the Acoustical Society of America" in *ASA at 75*, (2004) p. 81]. He was appointed associate professor of bioengineering and neuroscience in 1988 and was promoted to full professor in 1994, a position that he held until the time of his death. From 1995 to 1999 he was director of the Computational Neuroscience Program and in 2002 he was appointed associate director of the Institute for Sensory Research under its current director Robert L. Smith. After his return to Syracuse he continued his association with the University of Rochester where he held an adjunct professorship in the Department of Surgery (Neurosurgery/Neuroendocrine Unit) from 1988–1992. In 1992–1993 and again in 1994–1995 he was a visiting professor in the Department of Otolaryngology at the Keck Center for Integrative Neurobiology and the Coleman Laboratory, University of California at San Francisco. In this position he did collaborative research with Dr. Michael Merzenich on the structure and functioning of the pain, temperature, and touch sensory systems. His collaboration activity with scientists outside of Syracuse was extensive, including M. Holmes, Department of Mathematical Sciences at Rensselaer Polytechnic Institute and J. Bell, Department of Mathematics, SUNY Buffalo, with whom he modeled the mechanics and transduction mechanisms of the Pacinian corpuscle. With D. Dishman of the New York Chiropractic College, Seneca Falls, NY he studied the double-crush syndrome and other spine/nervous system disorders. In this collaboration he also developed a device for controlled spinal manipulations. With V. Apkarian at the SUNY Health Sciences Center at Syracuse he did research on functional MRI and stochastic resonance. His collaboration with U.S. Navy scientists included the design and execution of psychophysical and clinical tests for deep-sea divers at the Naval Submarine Medical Research Laboratory in Groton, Connecticut. With the Naval Air Medical Research Laboratory, Pensacola, Florida, he participated in the design and execution of experiments to evaluate devices to aid in the situational awareness of pilots.

The recipient of numerous research grants from government, military, and industrial institutions, Dr. Bolanowski's expertise spanned many areas of sensory science, including neurophysiology, anatomy, psychophysics, and the modeling of sensory systems. His contributions to sensory science include: The precise determination of the intensity and frequency characteristics of the Pacinian corpuscle at the level of the receptor and spike potentials; the effects of response criteria and skin temperature on the responses to vibration in humans and in excised Pacinian corpuscles; the effects of monocular and binocular contourless stimuli on the visual responses of humans and on the cortical activity of monkeys; the modeling of physiological and psychophysical responses of the tactile sensory channels in human glabrous and hairy skin; the determination of the columnar compression patterns in the lamellae of Pacinian corpuscles by direct video observation; and the distribution patterns of rapidly and slowly adapting mechanoreceptors in cutaneous tissues. His engineering skills manifested themselves in the numerous laboratory instruments that he developed and perfected for use in the somesthetic laboratories at the Institute for Sensory Research. Some of these systems were built and shipped to other laboratories in other parts of the world.

Dr. Bolanowski became a member of ASA in 1984 and was elected a Fellow of the Society in 1993. He became a member of the Technical Committee on Biomedical Ultrasound/Bioresponse to Vibration (1987) and served on the Standards Committee, American Physics Institute since 1992. He was a member of the Planning Committee for the 117th meeting of the Acoustical Society in Syracuse, NY in May 1989. At this meeting he served as registrar and treasurer and organized a special session on "Structural and Functional Aspects of Mechanotransduction" for that meeting. From 1977 to the present he participated in no fewer than 29 oral presentations at meetings of the Society. A frequent contributor to somatosensory and neuroscience journals, he addressed meetings of the Society for Neuroscience more than 50 times in his career.

A manuscript in preparation at the time of his death describes new and revolutionary views of vibrotactile transduction, and NIH funded him in late 2004 to continue these studies, stating in the summary statement that he was "uniquely skilled in anatomical, psychophysical, and cellular approaches to mechanotransduction and well recognized for his contributions in all these areas." The team of researchers that he gathered together and mentored plan to continue his work in the laboratory he built, and add to our knowledge of how we experience the world through our somatosensory system, an area in which his work will be long remembered.

ROBERT L. SMITH

43.30.Pc HIGH RESOLUTION BATHYMETRIC SONAR SYSTEM AND MEASURING METHOD FOR MEASURING THE PHYSIOGNOMY OF THE SEABED

Weiqing Zhu *et al.*, assignors to Institute of Acoustics Chinese Academy of Sciences
29 March 2005 (Class 367/88); filed in China 13 September 2001

A high-resolution sidescan sonar system for ocean bottom profiling is described. It involves an underwater vehicle, either an autonomous vehicle, a remotely operated vehicle, or a towed body, with two sonar arrays mounted symmetrically on the two sides of the lower part of the vehicle. Each of these two sonar arrays has a transmitting line array and three or more parallel, longitudinal, receiving arrays, equally spaced between one-half and a full wavelength at the operational frequency. The system is said to be a high-resolution system having increased precision of measurement, range, and operational efficiency.—WT

6,873,572

43.30.Yj LOW-FREQUENCY SONAR COUNTERMEASURE

Thomas A. Frank, assignor to The United States of America as represented by the Secretary of the Navy
29 March 2005 (Class 367/174); filed 3 May 2004

The design of a low-frequency, expendable, cylindrical-shaped, ship-deployable, sonar projector for countermeasure usage is described. The figure illustrates one subsection of the device which might consist of a number of these subsections connected in coaxial fashion. The actual transducer unit **11** can be either magnetostrictive or piezoceramic and is excited into longitudinal vibrations. Its annular ends **12** are sealed by thin flexible membranes or discs **16**. The transducer is sealed at its outer cylindrical face by a protective shell **13** while a portion **17** of the inner volume is filled with an inert liquid **18** such as a high-purity isoparaffinic solvent. Module **20**, containing battery plus requisite electronics to drive the transducer, is resiliently
mounted from transducer **11** via supports **21**. Since the battery is likely to be a seawater battery, the remainder of the interior is free-flooded via ducts **23**. Adjacent subsections are connected to one another by an open truss **15** consisting of a number of longitudinally oriented rigid members **15A** that create another free-flooded cavity whose portions are identified as **9A**. As the cylindrical-shaped transducers undergo longitudinal vibrations, the ensemble of these free-flooded cavities **9A** radiate to the surrounding medium **9**. It is alleged that the device will operate at a much lower frequency than a conventional cylindrical transducer of the same size.—WT

6,874,212

43.35.Ns METHOD OF MAKING AN ACOUSTIC WAVE RESONATOR

John Dwight Larson III, assignor to Agilent Technologies, Incorporated
5 April 2005 (Class 29/25.35); filed 8 November 2001

This patent describes a method of temperature compensating piezo-electric resonators using INVAR alloys in a layered-composite design. IN-VAR alloys have a low thermal expansion coefficient, so that the composite structure can be engineered to have zero temperature-dependent frequency shift. The use of INVAR in MEMS structures is unusual, and sputtering is used to deposit the material, which is then chemically etched.—JAH

6,874,211

43.35.Ns METHOD FOR PRODUCING THIN FILM BULK ACOUSTIC RESONATORS (FBARS) WITH DIFFERENT FREQUENCIES ON THE SAME SUBSTRATE BY SUBTRACTING METHOD AND APPARATUS EMBODYING THE METHOD

Paul D. Bradley *et al.*, assignors to Agilent Technologies, Incorporated
5 April 2005 (Class 29/25.35); filed 5 March 2001

This patent discloses a method for stagger tuning mass-produced thin film bulk acoustic resonators (FBARs) on silicon wafers. The method used is to add material to the top or bottom of the resonator area, and then selectively etch those that one wants higher in frequency. The examples given are for cell phones at 1900 MHz frequencies using AlN as the piezo material. There are a few model designs given but very little on the performance (bandwidth, electromagnetic coupling) of the resulting filters. What is described here is not novel and is routinely used by practitioners of the MEMS art.—JAH

6,878,604

43.35.Ns SEMICONDUCTOR ELEMENT COMPRISING A SEQUENCE OF LAYERS FOR CONVERTING ACOUSTIC OR THERMAL SIGNAL AND ELECTRICAL VOLTAGE CHANGES INTO EACH OTHER AND METHOD FOR PRODUCING THE SAME

Robert Aigner *et al.*, assignors to Infineon Technologies AG
12 April 2005 (Class 438/396); filed in Germany 20 July 2000

It is not clear what is being claimed as novel here. The patent is very brief and mentions bulk acoustic wave resonators as the application. The claims for layering a Bragg reflector are not new, and the claims for the use of tungsten, molybdenum, and platinum as electrode materials are not new. What is left is the method of fabrication, which involves nothing novel except the step of chemical/mechanical planarization of the metal electrodes prior to deposition of the piezoelectric material. This is emphasized by the authors as improving the coupling coefficient of the resulting layer. That's all.—JAH

6,876,484

43.35.Ty DEFORMABLE SEGMENTED MEMS MIRROR

Dennis S. Greywall, assignor to Lucent Technologies Incorporated
5 April 2005 (Class 359/291); filed 24 March 2003

This patent describes an interesting approach to deformable mirror design. The mirrors are tiled to cover an array of electrodes and are suspended by ingenious hinges. The hinges have several degrees of freedom to allow the mirrors to move independently. It is proposed that this reduces the complexity of the control logic. It is an interesting patent to read.—JAH

6,879,085

43.35.Ty RESONANCE SHIFTING

Lior Shiv *et al.*, assignors to Nanomotion Limited
12 April 2005 (Class 310/312); filed 12 December 2002

The authors of this patent claim to have discovered the principle of ''resonance shifting'' by means of drilling holes or adding protuberances on a piezoelectric plate. Unfortunately, Chladni discovered this and Rayleigh formulated a mathematical description that quantifies the effects of this procedure well in advance of this patent. What remains are some details on how to suspend a plate so that it doesn't break when put into a cell phone.—JAH

6,866,630

43.35.Wa VIVO BIOCOMPATIBLE ACOUSTIC COUPLING MEDIA

Margaret J. Larson *et al.*, assignors to Sonotech, Incorporated
15 March 2005 (Class 600/437); filed 12 March 2001

The patent describes a medical ultrasound coupling medium and lubricant, in gel or liquid form, consisting of polyethylene oxide (PEO) and aqueous solutions. It is asserted that this coupling medium provides long-term biocompatibility with *vivo* human tissue and body fluids. This medium is formulated and manufactured in such a manner and form that render the acoustic medium sterile, non-cross-linked, pseudoplastic, and containing acceptably low levels of pyrogens.—DRR

6,869,407

43.35.Yb ACOUSTIC WAVE DEVICE

Moshe Ein-Gal, Ramat Hasharon, Israel
22 March 2005 (Class 601/2); filed 12 September 2001

Claim is made for a device for generation and focusing of acoustic waves through the use of electromagnetic energy. The device includes a truncated conical acoustic wave transducer. A parabolic reflector may be arranged with respect to the transducer so as to focus acoustic waves towards a focal point located at the apex of the transducer. An electrical
element on the noncylindrical, nonflat, outer contour of a support of the acoustic wave transducer radiates acoustic waves outwardly from that contour's surface. It is envisioned that this apparatus would be used for medical treatment, such as stone fragmentation or orthopedic procedures.—DRR

6,877,975

43.35.Zc ROLLING PIN HORN

David G. Wuchinich, Yonkers, New York
12 April 2005 (Class 425/174.2); filed 16 October 2001

Resonant vibrations of metal horns are used in industry for ultrasonic welding, sealing, laminating, etc. Cylindrical horns capable of rotation permit the continuous processing of materials, but generally tend not to provide uniform radial vibrations. The horns described in the present patent are intended to eliminate this shortcoming. A cylindrical horn described in this patent is tubular, with an interior space that is shaped somewhat like a rolling pin—that is, thin in the middle and becoming thicker towards the ends. A driver that generates axial vibrations is placed in the interior space and connected to the horn via an arrangement of lugs and ridges, so as to induce radial vibrations in the horn.—EEU

6,865,281

43.38.Dv LIQUID COOLED SPEAKER

Jeff B. Jordan, Baton Rouge, Louisiana
8 March 2005 (Class 381/397); filed 28 September 2000

Heat is a byproduct of electrodynamic transduction. This heat needs to be removed to prevent the transducer from burning up. Various schemes such as vented gaps, thermally conductive voice coil formers, forced air circulation, and the like have been patented, and some even implemented, to help remove heat from the motor structure, especially the voice coil. The present invention describes a system that uses a liquid cooled yoke **25** with internal cavity **33** for loudspeaker **1**. The yoke is part of a cooling system
that includes pump **75**, radiator fins **77**, piping **76**, and inlet and outlet connections **34** and **35**. Heat from the voice coil **10** is transferred to yoke **25**, where the fluid in void **33** conducts it away. For special applications this may be a practical method of getting more power handling and less power compression. When used with some present methods that lower the thermal resistance of the air gap, such as ferrofluids, the liquid cooling could be even more effective.—NAS

6,868,166

43.38.Dv CHORD-LIKE VIBRATION LOUDSPEAKER

Xiafu Zhang, Kunming, Yunnan, China *et al.*
15 March 2005 (Class 381/399); filed in Canada 10 June 1998

A ribbon loudspeaker is described. The patent maintains that the magnetic body can be a hollow square column (although in the figure, it appears to be rectangular), a tube, as well as other shapes. This poorly written, short
patent (a page and a half long) includes seven figures (all on one page), none of which are adequately described in the patent text. The utility of this invention is unclear as the radiating surface may interact with itself and have limited power-handling capabilities.—NAS

6,877,385

43.38.Gy CONTACT TYPE MICRO PIEZORESISTIVE SHEAR-STRESS SENSOR

Yean-Kuen Fang *et al.*, assignors to National Science Council
12 April 2005 (Class 73/777); filed in Taiwan, Province of China
16 November 2000

This patent describes a shear-stress sensor based on two piezoresistive sensors embedded in a thin membrane of silicon. Shear stresses are coupled to the membrane by a stub, similar in principle of operation to a joystick. The diagrams and wording in the patent are not very clear, so do not seek this one out for fabrication information.—JAH

6,862,360

43.38.Ja SPEAKER SYSTEM

Jen-Hui Tsai, Wen Shen Suburb, Taipei, Taiwan, Province
of China
1 March 2005 (Class 381/351); filed 19 April 2001

A novel understanding and interpretation of the laws of physics, how electrodynamic loudspeakers and their constituent parts operate, the why and how of enclosure and port design, among other things, lead to an inter-

esting patent that is an excellent example of wishful thinking. The patent basically describes a plurality of volumes **14** and ports **20**, each tuned to a different frequency band, that solve a multiplicity of problems, none of which are adequately described.—NAS
6,845,165

43.38.Ja ACOUSTIC EFFECT APPARATUS AND METHOD AND PROGRAM RECORDED MEDIUM THEREFOR

Haruhiko Motohashi *et al.*, **assignors to Korg Incorporated**
18 January 2005 (Class 381/98); filed in Japan 24 December 1998

To enhance the bass response of a bass drum or string bass, the inventors describe using a nonlinear mechanism to generate overtones and then filtering the result. As shown, a bandpass filter **31** between 200 and 400 Hz
filters the input. This is distorted, filtered, and summed with the input. This is not the first time that nonlinear blocks have been used in this fashion (see United States Patent 6,792,115 [reviewed in J. Acoust. Soc. Am. **117**(3), 990 (2005)]).—MK

6,873,705

43.38.Lc COMBINE AUDIO AND RINGING MODE

Klaus Graef and Edgar Sexauer, assignors to Dialog Semiconductor GmbH
29 March 2005 (Class 379/418); filed 27 November 2001

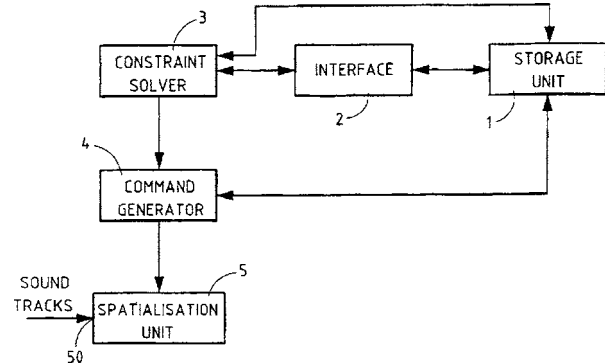
In this mobile phone audio amplifier, two identical analog circuits are bridged to drive loudspeaker **9**. Each circuit includes a ring-signal generator **7** and **8** and pairs of switches **5**, **15** and **6**, **16** to select audio or ringing operation. Level adjustment in either mode is controlled by ladder attenuators **3**, **13** and **4**, **14**. The use of analog circuitry is said to avoid the high power dissipation and slew rate problems of pulse width modulation. It
seems apparent that at least ten components could be eliminated by adding a voltage amplifier and then restricting bridged operation to the output stage alone, but with integrated circuit fabrication the trade-offs may favor the approach taken.—GLA

6,826,282

43.38.Md MUSIC SPATIALISATION SYSTEM AND METHOD

Francois Pachet *et al.*, **assignors to Sony France S.A.**
30 November 2004 (Class 381/61); filed in the European Patent Office 27 May 1998

In conjunction with a spatialization unit, a constraint solver **3** can be used to control the position parameters of the sound sources. Typical con-

straints include minimal distances from sound sources to the listener, angular limits with respect to the listener, and maintaining constant distance to sound sources.—MK


6,868,224

43.38.Md METHOD AND APPARATUS FOR PROVIDING MULTIMEDIA PLAYBACK

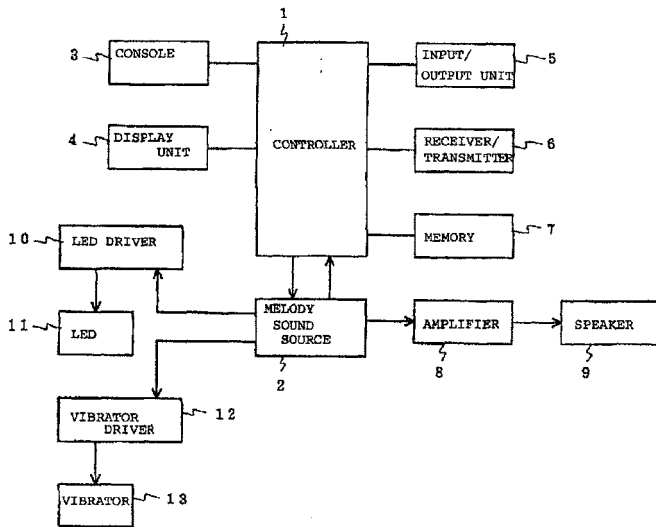
Blair B. A. Birmingham and Cheryl B. Giblon, assignors to ATI International SRL
15 March 2005 (Class 386/68); filed 5 May 1999

To assist searching an audio/video recording, the inventors propose (1) using pitch shifting while in fast forward to bring the spectrum down to an understandable range, (2) removing "blank" portions, thereby shortening the time, and (3) reversing the audio samples during rewind.—MK

6,876,847

43.38.Si CONTROL OF SYNCHRONOUS DISPLAY OF MELODY INFORMATION AND DIFFERENT INFORMATION ON MOBILE COMMUNICATION TERMINAL

Kazuhiro Kudoh, assignor to NEC Corporation
5 April 2005 (Class 455/403); filed in Japan 4 October 2000

A typical fold-up cellular phone houses a number of output devices in addition to a loudspeaker—a graphic display, a vibrator, and a signal light, for example. It may also include a programmable tone generator that can play a melody as an incoming call signal. In some instances, according to this patent, melody generation may also be linked to a computer game in which input and output information must be synchronized with the melody in response to certain actions from the user. In the control method described,


each note of a given melody is coded as a series of attributes, such as frequency, intensity, and duration. This makes it easy to synchronize various outputs with a melody in various modes of operation.—GLA

6,879,698

43.38.Si CELLULAR TELEPHONE, PERSONAL DIGITAL ASSISTANT WITH VOICE COMMUNICATION UNIT

Peter V. Boesen, Des Moines, Iowa
12 April 2005 (Class 381/328); filed 31 May 2001

In his earlier United States Patent 6,094,492, the inventor proposed a method of combining air-conduction and bone-conduction transducers for improved voice pickup. Here, he describes how this method can be advantageously used for mobile, hands-free communications. In the illustration,
earpiece **10** is connected to cellular transceiver **4** via a short-range wireless link.—GLA

6,879,848

43.38.Si METHOD AND APPARATUS FOR ALERTING AN OPERATOR OF AN INCOMING CELLULAR OR PORTABLE PHONE CALL

Edward A. Lygas, assignor to Sony Corporation; Sony Electronics Incorporated
12 April 2005 (Class 455/567); filed 14 December 2001

During the past few years there has been considerable interest in producing audible signals from modulated ultrasonic beams. In a seemingly unrelated field, developments in medical ultrasonic therapy are regularly patented. The invention disclosed in this Sony patent is a kind of hybrid. Instead of a vibrator, a cellular phone employs two concentric, ring-shaped ultrasonic transducers driven at two different frequencies. In this case, the difference frequency lies below the audible band, perhaps only 10 or 12 Hz. The two ultrasonic signals somehow pass through heavy clothing with negligible attenuation and combine in the user's tissue to generate a tactile sensation. There is nothing in the patent to suggest that a working model has yet been tested.—GLA

6,870,942

43.38.Tj LOUDSPEAKER FOR LINE ARRAY SOUND SYSTEM

Curtis H. Graber, Woodburn, Indiana
22 March 2005 (Class 381/349); filed 3 September 2003

A two-way line array system is described. A ported enclosure **24** that can be trapezoidal in section contains a conventional low-frequency unit **18** and a planar transducer **16**. Many, including the manufacturers of line arraysystems that are similar, if not identical, to the described invention, may
be interested in how this invention may not only fail to be novel, but how it may also fail to be a nonobvious, or even obvious, improvement over the prior art.—NAS

6,865,482

43.38.Vk METHOD AND ARRANGEMENT FOR GUIDING A USER ALONG A TARGET PATH

Richard Hull, assignor to Hewlett−Packard Development Company, L.P.
8 March 2005 (Class 701/211); filed in the United Kingdom 6 August 2002

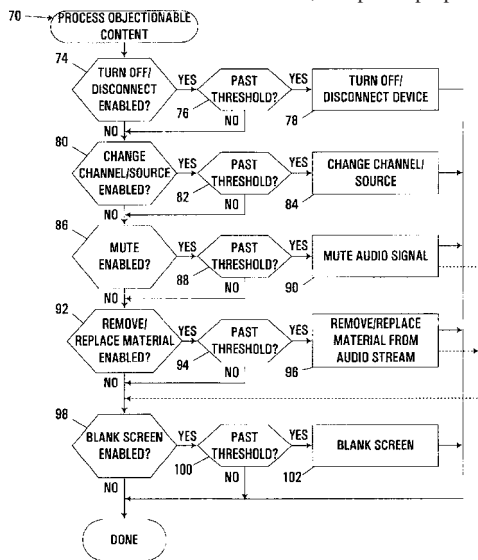
The inventor uses the "Oboe" audio glidescope system of World War II as an auditory display exemplar. Using a positioning system, stereo cues can be given in the headphones to direct the user inside a space such as a museum.—MK

6,829,582

43.38.WI CONTROLLED ACCESS TO AUDIO SIGNALS BASED ON OBJECTIONABLE AUDIO CONTENT DETECTED VIA SOUND RECOGNITION

Eric Lawrence Barsness, assignor to International Business Machines Corporation
7 December 2004 (Class 704/275); filed 10 October 2000

For those who can't bear modern media, this patent proposes machine-

assisted censorship. Using audio and sound recognition, the offensive passages can be blanked. Hear no evil, see no evil, speak no evil.—MK


6,878,237

43.40.Le MACHINE AND PROCESS FOR OPERATING A MACHINE TO MONITOR VIBRATIONS

Eva Scheideler, assignor to Voith Paper Patent GmbH
12 April 2005 (Class 162/198); filed in Germany 27 March 2002

In paper-making machines and the like, material that is passed between rollers may exhibit small periodic thickness variations that are undesirable. In order to detect these variations, an acoustic sensor is placed near the material web or near a roller and the resulting signal is subjected to frequency analysis. Observation of excessive amplitudes informs the machine operators to take remedial action.—EEU

6,879,224

43.40.Sk INTEGRATED FILTER AND IMPEDANCE MATCHING NETWORK

Michael L. Frank, assignor to Agilent Technologies, Incorporated
12 April 2005 (Class 333/189); filed 12 September 2002

This patent concerns the creation of high-pass filters having impedance transforming characteristics along with a built-in notch coming from bulk acoustic wave resonators inserted into the filter network. The novelty stems from the tuning of these notches to coincide with certain cell phone frequency bands, and little else. The patent describes the band rejection performance of some prototype filters built this way.—JAH

6,871,565

43.40.Tm VIBRATION CONTROL BY CONFINEMENT OF VIBRATION ENERGY

Daryoush Allaei, assignor to Quality Research, Development & Consulting, Incorporated
29 March 2005 (Class 74/574); filed 17 October 2003

"Confinement devices" are used to keep vibrations that are injected in a structure at given locations out of locations that are to be protected. These devices, which are intended to block the transmission of vibrational energy, may consist of combinations of translational and torsional springs and masses and/or of active vibration control systems. The embodiments illustrated in the patent apply to one-dimensional structures, such as beams and shafts, but the utility of the approach to two-dimensional structures is also described.—EEU

6,877,711

43.40.Tm VIBRATION ISOLATION TABLE

Masakuni Kainuma *et al.*, assignors to Fujikura Rubber Limited
12 April 2005 (Class 248/638); filed in Japan 28 November 2002

This isolation system, intended to protect sensitive instruments from floor vibrations, is configured to provide very low natural frequencies in the horizontal direction. Vertical isolation is provided primarily via an air spring arrangement consisting of a piston **A** in an air chamber **S1**, with a rolling seal **7** enabling relative motion. Horizontal isolation is obtained via an arrangement in which a rod **19** that rests on a curved surface at the base of a
tube **15a** (which in effect is part of the vertical piston) can deflect relatively freely through a small angle θ from the vertical. A second air space **S2** between a plate **31** that is affixed to the top of the rod and a plate **35** that supports the payload, with the air space sealed by a diaphragm **29**, provides additional horizontal and vertical isolation. The two air spaces are pressurized from a source **C** that is controlled on the basis of floor vibrations detected by a sensor **D**.—EEU

1254   J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Reviews of Acoustical Patents   1254

6,878,873

43.40.Tm DAMPING SLEEVE WITH RESILIENT SUPPORT MEMBERS

Samuel B. Fryberger, Jr. and Brian M. Snyder, assignors to Federal−Mogul World Wide, Incorporated
12 April 2005 (Class 174/48); filed 8 August 2002

The sleeves described in this patent are intended for reducing the rattling noise associated with wiring harnesses and the like in motor vehicles, and also for reducing the vibrations transmitted to these harnesses. A typical sleeve consists of a layer of a material, such as a felt or plastic, that is sewn to a backing material via parallel seams that are spaced apart, creating pockets between the two layers. Elongated flexible elements, which may be visualized as wires, are positioned in these pockets in order to hold the sleeves in place around the items on which they are placed.—EEU

6,876,715

43.40.Yq MEASUREMENT SYSTEM OF TORSION VIBRATION FOR REACTOR INTERNAL PUMP

Naoto Hikida and Seiichi Matsumura, assignors to Hitachi, Limited
5 April 2005 (Class 376/372); filed in Japan 19 July 2002

Reactor internal pumps are sealed and immersed in reactors, so that generally only a limited portion near one of the ends of a pump is available for vibration monitoring. Torsional vibrations are of concern, because matching of a motor frequency to a torsional frequency of the impeller system may lead to structural fatigue. An electrodynamic sensor (which produces a signal proportional to velocity) is affixed to the pump's cylindrical casing at a selected location so as to measure the axial vibrations. An accelerometer is placed at 90° from that location, oriented to measure vibrations in the tangential direction. The accelerometer's signal is integrated and low-pass filtered, then the axial vibration signal (which is unaffected by torsional vibrations) is subtracted from it, resulting in a measure of the torsional vibrations—EEU

6,866,474

43.50.Gf NOISE REDUCTION BY VORTEX SUPPRESSION IN AIR FLOW SYSTEMS

Robert B. Uselton, assignor to Lennox Industries, Incorporated
15 March 2005 (Class 415/121.2); filed 27 January 2003

This device was developed to reduce acoustic vibrations generated by von Kármán vortex streets by shaping members interposed in moving air flowstreams, such as fan guards and grilles, used in forced-flow air conditioning systems. Airflow systems are provided with structural modifications that reduce the formation of, and the shedding of, vortices on the downstream side of such structural elements. Typical configurations are relatively flat rectangular cross-section members with interrupted or nonlinear leading or trailing edges formed by approximately sawtooth or sinusoidal wave forms or connected to spaced-apart structural members, or cylindrical members formed in the shape of a sawtooth or sinusoidal form, or presented with separated rings or grooves interrupting the cylindrical cross section of the member.—DRR

6,877,585

43.55.Ev ACOUSTICAL CEILING TILES

Brandon Dillan Tinianov, assignor to Johns Manville International, Incorporated
12 April 2005 (Class 181/290); filed 30 April 2001

This sound-absorbing ceiling tile uses a first substrate of porous insulation material (like glass fiber, mineral wool, or foam) and a separate facing material (like plastic, semiporous paper, fabric, or perforated film). The two layers have different flow resistances to achieve broadband acoustical absorption.—CJR

6,870,934

43.58.Vb AUDIO LOUDSPEAKER DETECTION USING BACK-EMF SENSING

Andrew C. Krochmal et al., assignors to Visteon Global Technologies, Incorporated
22 March 2005 (Class 381/59); filed 15 July 2002

A method is described to verify that the audio speakers 11 are correctly connected in an automotive audio system during assembly in an environment which can be noisy. The invention uses a scheme that measures the back emf generated by the speakers from a repeatable, computer-controlled
signal to automate the signal and test. This is an improvement over the use of a human test device (the repeatability and attitude is variable) and the door-slam method of generating a back emf signal.—NAS

6,838,994

43.58.Wc ADAPTIVE ALARM SYSTEM

Srinivas Gutta et al., assignors to Koninklijke Philips Electronics N.V.
4 January 2005 (Class 340/575); filed 26 October 2001

Some sleepers truly need disruptive alarm clocks. This invention monitors movement—if the sleeper has not stirred from the bed, then the
power level is increased as shown in the flowchart. Eventually, coupled with a suitable stimulus, it should work.—MK

6,847,587

43.60.Jn SYSTEM AND METHOD FOR IDENTIFYING AND LOCATING AN ACOUSTIC EVENT

Frank K. Patterson, Woodward, Oklahoma *et al.*
25 January 2005 (Class 367/127); filed 24 January 2003

A system is described by which a number of acoustic sensors may be deployed over a large area for the purpose of detecting and identifying gunshots within the monitored area and, more specifically, to determine the location of the shooter. This system differs from prior patented systems in that the individual sensors include a transmission capability, and so do not depend on wired connections. They also include more processing capability to perform some of the analysis before transmission to a central location. The individual sensors may also be equipped with GPS receiving devices, providing each sensor with accurate time and position information.—DLR

6,853,880

43.60.Jn AUTONOMOUS ACTION ROBOT

Yoshiaki Sakagami *et al.*, assignors to Honda Giken Kogyo Kabushiki Kaisha
8 February 2005 (Class 700/259); filed in Japan 22 August 2001

This robotic device would use both audio and visual inputs to determine the direction of an audio source, turn toward the direction of the sound, and identify objects, specifically one or more faces, at the target location,
and then perform various analyses of the detected sources, such as facial expression analysis or speech recognition to extract commands or other information from a speech signal.—DLR

6,879,952

43.60.Jn SOUND SOURCE SEPARATION USING CONVOLUTIONAL MIXING AND A PRIORI SOUND SOURCE KNOWLEDGE

Alejandro Acero *et al.*, assignors to Microsoft Corporation
12 April 2005 (Class 704/222); filed 25 April 2001

One current approach to sound source separation that takes reverberation into account is convolutional independent component analysis. This frequency-domain approach can separate the various frequency components of different sound sources, but has a crucial permutation ambiguity: it is impossible to tell which separated component came from which sound

source. This leads to the possibility of reconstructing a source sound as a meaningless mixture of frequency components from several sources. The patented technique attempts to resolve this ambiguity using prior knowledge about the target source, in particular that it is human speech. A typical cepstral vector speech recognition system can be used by the convolutional scheme (specific methods are presented) to reconstruct a source which is most likely a proper speech signal instead of a garble of permuted components. Since this is computationally expensive, a more practical version is described using a vector quantization codebook of linear prediction vectors.—SAF

6,879,543

43.60.Pt ACOUSTIC PROCESSING FOR ESTIMATING SIZE OF SMALL TARGETS

Anthony A. Ruffa, assignor to The United States of America as represented by the Secretary of the Navy
12 April 2005 (Class 367/131); filed 7 August 2003

This is a signal processing technique for estimating the size of an object that is small compared to the wavelength of the sound it either radiates or reflects. A line array containing a number of receivers of that sound generates that number of independent signals from which a different number of time series are produced via the introduction of sets of time delays. These time series are further processed to produce information indicative of the size of the object in question.—WT

6,879,695

43.66.Ts PERSONAL SOUND LINK MODULE

Albert A. Maltan and Janusz A. Kuzma, assignors to Advanced Bionics Corporation
12 April 2005 (Class 381/315); filed 3 October 2002

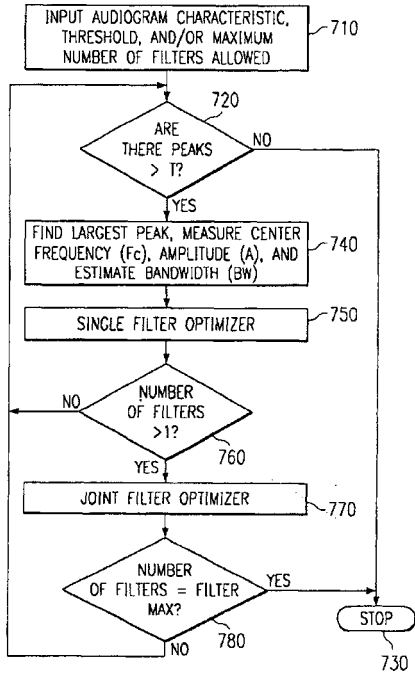
In one embodiment, an easily removable module, containing acoustic input and output transducers, signal processing circuitry, wireless connection capability, and a rechargeable battery, is shaped for insertion into the retro-auricular space connected to the ear canal. An antenna and telemetry
circuitry are included for communicating with a remote source such as a radio, computer, CD player, or television receiver.—DAP

6,876,750

43.66.Ts METHOD AND APPARATUS FOR TUNING DIGITAL HEARING AIDS

Rustin W. Allred et al., assignors to Texas Instruments Incorporated
5 April 2005 (Class 381/314); filed 28 September 2001

Methodology is provided to automatically tune the frequency response of a hearing aid within a specified tolerance of a predetermined target fre-

quency response. The desired target is calculated from an audiogram, which-may be input, or derived in real time, or from a direct input of the desired response.—DAP


6,876,751

43.66.Ts BAND-LIMITED ADAPTIVE FEEDBACK CANCELLER FOR HEARING AIDS

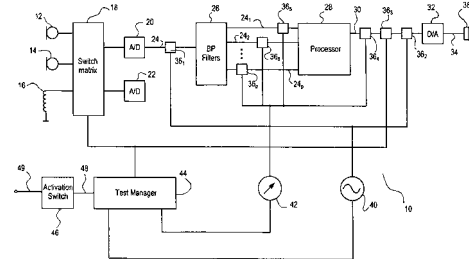
Shawn X. Gao et al., assignors to House Ear Institute
5 April 2005 (Class 381/318); filed 30 September 1999

This patent adds a restricted bandwidth feature to existing feedback canceller configurations. The system is said to adapt more quickly and pro-

duce less audible artifacts by restricting the bandwidth of the feedback cancellation algorithm to frequency regions having unstable feedback.—DAP
6,879,692

43.66.Ts HEARING AID WITH A SELF-TEST CAPABILITY

Kim Hjortgaard Nielsen and Lars Baekgaard Jensen, assignors to Widex A/S
12 April 2005 (Class 381/60); filed 9 July 2001

A test controller disconnects selected portions of a hearing aid and injects test signals at appropriate points in the signal path to diagnose whether the hearing aid is operating properly. For some tests, the hearing aid


is placed in a compartment with hard walls to generate a reflected acoustic signal for use as an input. Level detectors in the test controller determine whether a defect exists.—DAP

6,876,749

43.66.Ts MICROPHONE FOR HEARING AID AND COMMUNICATIONS APPLICATIONS HAVING SWITCHABLE POLAR AND FREQUENCY RESPONSE CHARACTERISTICS

Mead C. Killion et al., assignors to Etymotic Research, Incorporated
5 April 2005 (Class 381/122); filed 11 July 2000

Building on an old idea, this patent proposes that circuitry sense the position of a mechanical shutter that closes and opens the rear tube of a switchable, directional/omnidirectional system. This feature allows the hear-

ing aid to optionally equalize frequency response or do other processing in either the directional or omnidirectional mode, something not included in the 1970s patents.—DAP
6,879,696

43.66.Ts IN-EAR HEARING AID AND METHOD FOR ITS MANUFACTURE

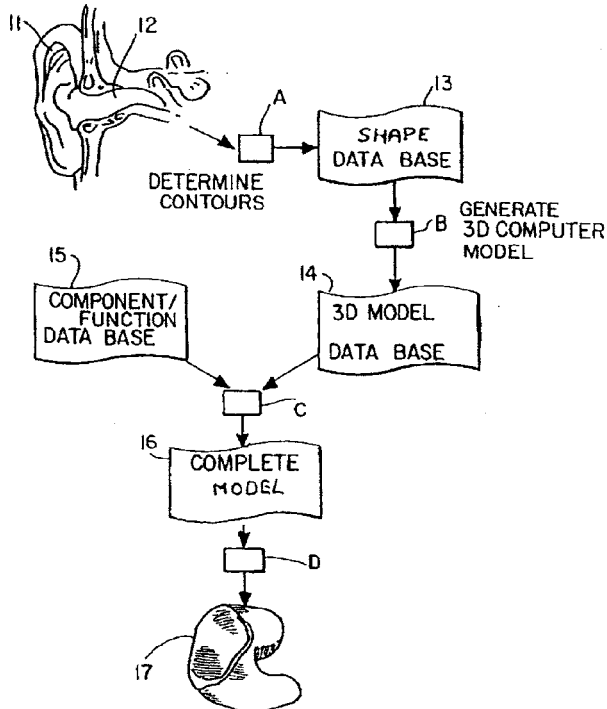
Andi Vonlanthen, assignor to Phonak AG
12 April 2005 (Class 381/322); filed 6 June 2000

A freely vibrating, acoustically transparent membrane protects the out-

put of a hearing aid from debris, such as ear wax, and reduces the need to clean the hearing aid.—DAP
6,879,697

43.66.Ts HEARING AID WITH A FACE PLATE THAT IS AUTOMATICALLY MANUFACTURED TO FIT THE HEARING AID SHELL

Jan Tøpholm, assignor to Widex A/S
12 April 2005 (Class 381/322); filed in the European Patent Office 26 March 2001

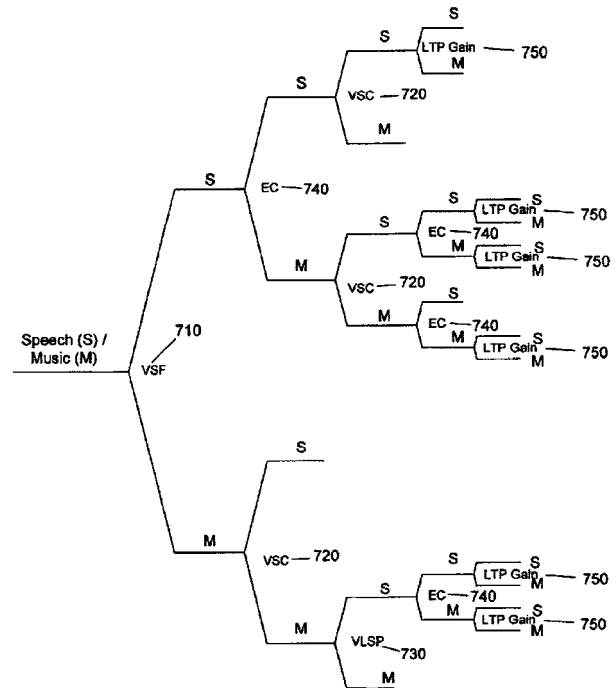
To manufacture a custom hearing aid, digital data regarding the shape of the auditory canal are acquired and converted to a three-dimensional


computer model of a hearing aid shell. Computer-controlled manufacture of a complete custom hearing aid housing is then performed, including a model of the faceplate.—DAP

6,785,645

43.72.Ar REAL-TIME SPEECH AND MUSIC CLASSIFIER

Hosam Adel Khalil *et al.*, assignors to Microsoft Corporation
31 August 2004 (Class 704/216); filed 29 November 2001

Both time domain and frequency domain features are combined to form a classifier. These features include spectral flux **VSF**, energy contrast **EC**, spectral centroid **VSC**, line spectrum pair correlation **VLSP**, and long-term prediction gain **LTP Gain**. As shown, these features can be used in a decision tree to distinguish music from speech. Short-time features (from the


time domain) provide faster localization, whereas long-term features (like the frequency domain methods that use frame-based spectral estimation) offer more accurate classification. The patent text is reasonably clear and explores the tradeoffs between the two types of features.—MK

6,839,672

43.72.Ja INTEGRATION OF TALKING HEADS AND TEXT-TO-SPEECH SYNTHESIZERS FOR VISUAL TTS

Mark Charles Beutnagel *et al.*, assignors to AT&T Corporation
4 January 2005 (Class 704/260); filed 31 December 1998

This patent describes the integration of text-to-speech systems into the MPEG-4 video coding structure and also an apparently minor modification to the standard MPEG implementation consisting of a delineation of which elements of the synthesis process are to be driven by the transmitted data and which may be defined locally at the site of the video/audio re-creation. An additional enhancement consists of a method for smoothing the transitions from one synthesis element to the next. The patent includes detailed descriptions of the animation components, but, not being familiar with the MPEG standard, this reviewer cannot comment upon how much of that material is original in the patent.—DLR

6,876,969

43.72.Ja DOCUMENT READ-OUT APPARATUS AND METHOD AND STORAGE MEDIUM

Makiko Nakao, assignor to Fujitsu Limited
5 April 2005 (Class 704/260); filed in Japan 25 August 2000

A simple idea is proposed, though with limited detail, of using a standard speech synthesizer to fast-forward through a read-out of a document. The idea is to speed up and slow back down to a normal speech rate seamlessly at the user's indication, or perhaps by preset keywords in the document. The notion of rewinding during a document read-out session is also mentioned, though one wonders what rapidly reading backwards would sound like.—SAF

6,832,196

43.72.Ne SPEECH DRIVEN DATA SELECTION IN A VOICE-ENABLED PROGRAM

David E. Reich, assignor to International Business Machines
Corporation
14 December 2004 (Class 704/270.1); filed 30 March 2001

As the patent abstract says more clearly than the title, this is about using a speech recognizer to dynamically format the machine dialog for a voice-enabled database access system. In a network environment, the data-

base will typically reside on a server. A speech processor, also usually on the server, is connected using a voice-enabled markup language, such that the recognizer text output can be incorporated into the interaction dialog.—DLR
6,834,264

43.72.Ne METHOD AND APPARATUS FOR VOICE DICTATION AND DOCUMENT PRODUCTION

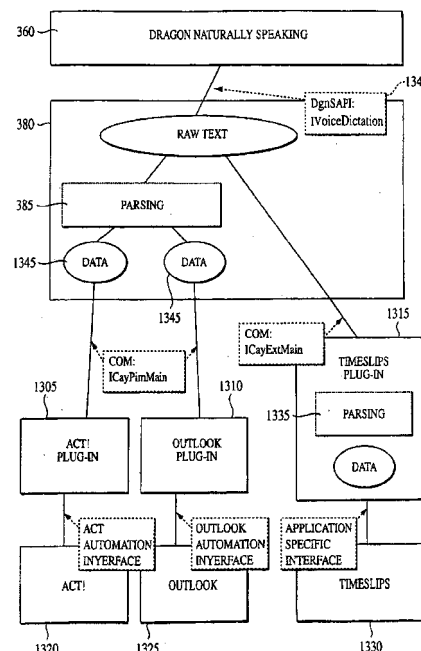
Mark Lucas et al., assignors to Provox Technologies Corporation
21 December 2004 (Class 704/235); filed 11 July 2001

This patent says that if you have a computer and a speech recognizer and you need to generate documents in a database, then you can use the recognizer to locate the database, and the record of interest, and produce text to be saved. An application is described in which a doctor would be able to produce records immediately instead of having to send out his notes to a transcriber. Not only is it obvious, but it's been done. This reviewer worked for a company in the 1990s which sold recognizers for medical transcription.—DLR

6,839,669

43.72.Ne PERFORMING ACTIONS IDENTIFIED IN RECOGNIZED SPEECH

Joel M. Gould et al., assignors to ScanSoft, Incorporated
4 January 2005 (Class 704/246); filed 10 June 1999

This very long patent covers two topics related to the use of speech recognition, each the subject of about half of the text and half of the claims.


The first part deals with the mechanics of getting your voice into the machine. For example, you can use a hand-held recorder while you're away from the computer. These ideas all seem pretty obvious. The second part consists of extensive coverage of a parser to manage the continuous-speech input. The essence seems to be that a large set of finite-state "patterns" are matched against fragments of the input. These patterns are then tied into the semantic structures which govern how a phrase gets interpreted.—DLR

6,839,670

43.72.Ne PROCESS FOR AUTOMATIC CONTROL OF ONE OR MORE DEVICES BY VOICE COMMANDS OR BY REAL-TIME VOICE DIALOG AND APPARATUS FOR CARRYING OUT THIS PROCESS

Walter Stammler et al., assignors to Harman Becker Automotive
Systems GmbH
4 January 2005 (Class 704/251); filed in Germany 11 September 1995

This speech recognition patent describes the simultaneous use of speaker-dependent (SD) and -independent (SI) recognizers, which cooperate by working on the specific and the general aspects, respectively, of the speech input in order to accurately interpret the utterances. The primary application intended for such a system is in the operation of a vehicle. The SI recognizer uses a word template approach to construct a representation of the general form of an input command, while the SD recognizer uses feature analysis to identify specific words or phrases which have been trained by the particular user.—DLR

6,823,308

43.72.Ne SPEECH RECOGNITION ACCURACY IN A MULTIMODAL INPUT SYSTEM

Robert Alexander Keiller and Nicolas David Fortescue, assignors to Canon Kabushiki Kaisha
23 November 2004 (Class 704/256); filed in the United Kingdom 18 February 2000

This patent introduces the concept of multimodal input in a very general way, describing and claiming feature analyzers for various modalities as if they might be parallel to those needed for speech. The reality is a bit more mundane. The only input considered in detail, other than speech, is a mouse. Clicks would be detected and the mouse location used as the referent for demonstratives, such as "this" and "that." A finite-state syntactic structure is assumed to be up to the task of identifying such words and the verb structures which refer to them.—DLR

6,845,356

43.72.Ne PROCESSING DUAL TONE MULTI-FREQUENCY SIGNALS FOR USE WITH A NATURAL LANGUAGE UNDERSTANDING SYSTEM

Mark E. Epstein, assignor to International Business Machines Corporation
18 January 2005 (Class 704/235); filed 31 January 2001

A method is described for integrating a DTMF (Touch Tone®) signal decoder into a speech recognition facility. A step prior to the actual recognition would make a decision on whether or not the input included a DTMF tone. The actual tone decoding is well-known prior art. Once recognized, the tone code could be converted into any of several text forms for direct use by the text analysis portion of the recognition system. For example, a series of digits may be individual digits, a multidigit number, a telephone number, or a date. Each would be presented differently in the text form.—DLR

6,873,686

43.72.Ne NETWORK AND METHOD FOR PROVIDING A CALLING NAME TELECOMMUNICATIONS SERVICE WITH AUTOMATIC SPEECH RECOGNITION CAPABILITY

Zeeman Zhang and Joseph Knoerle, assignors to BellSouth Intellectual Property Corporation
29 March 2005 (Class 379/88.03); filed 9 August 2000

Enhanced features, such as calling name, call forwarding, and automatic recall, are enabled via predetermined voice commands over either landline or wireless telephones rather than requiring users to manually enter dial feature codes on a telephone or computer.—DAP

6,876,970

43.72.Ne VOICE-ACTIVATED TUNING OF BROADCAST CHANNELS

Edward Michael Silver and Linda Ann Roberts, assignors to BellSouth Intellectual Property Corporation
5 April 2005 (Class 704/275); filed 13 June 2001

The patent proposes an automatic method of channel selection via voice commands, either from all persons or only from authorized persons. Specific tuner broadcast channels are associated with appropriate voice commands, such as call letters or program categories, and stored. A DSP chip determines which channel to select, or group of channels to browse, from a voice command.—DAP

6,861,581

43.75.Gh ACOUSTIC GUITAR RESONATOR

John F. Geiger, Atlanta, Georgia
1 March 2005 (Class 84/294); filed 12 June 2003

The use of resonators in acoustic guitars dates back to at least the 1930s (see Schireson's United States Patent 1,887,861). The inventor
proposes that placing an iron-cross-shaped "sound collector" in the sound hole of a guitar will enable the player to obtain "quality sound and high volume."—MK

6,787,689

43.75.St FAST BEAT COUNTER WITH STABILITY ENHANCEMENT

Fang-Chu Chen, assignor to Industrial Technology Research Institute Computer & Communication Research Laboratories
7 September 2004 (Class 84/600); filed 1 April 1999

Beat tracking is an important task in machine listening. Scheirer used a filter bank approach while others, including Brown, used autocorrelation. The inventor wants a computationally simpler and faster algorithm.
Accordingly, the input is downsampled, summed, and then smoothed and differentiated in block **105**. The beat tracking is done by looking at the values of other peaks in a 2-s frame (block **107**). The final stage tries to avoid tracking short-time variations in timing.—MK

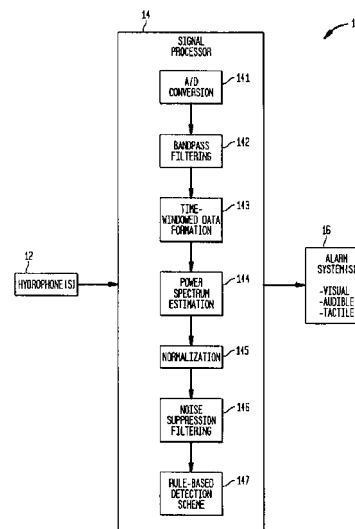
43.80.Ka MANATEE VOCALIZATION DETECTION METHOD AND SYSTEM

Christopher A. Sermarini, assignor to The United States of America as represented by the Secretary of the Navy
12 April 2005 (Class 367/136); filed 31 October 2003

This is a detection system geared to detecting a specific species of sea mammals, namely the manatee. Their vocalizations are discerned by executing a variety of frequency-domain processing operations on sound signals


detected underwater. The overlapping, time-windowed segments of the digitized sound data are converted into the frequency domain. The spectra are then normalized and scored in a series of steps to indicate a manatee vocalization when a threshold score is achieved across a portion of the overlapping time-windowed segments.—DRR

43.80.Qf APPARATUS AND METHOD FOR CHRONICALLY MONITORING HEART SOUNDS FOR DERIVING ESTIMATED BLOOD PRESSURE

Randal C. Schulhauser *et al.*, assignors to Medtronic, Incorporated
22 March 2005 (Class 600/528); filed 26 February 2003

An implantable device, said to be minimally invasive, monitors a patient's blood pressure by recording heart sounds and deriving an estimated blood pressure on the basis of custom heart sound spectral analysis and processing. The device detects pressure waves with an acoustical sensor, preferably piezoelectric. The resulting analog signals are digitized and processed to determine blood pressure based on custom spectral analyses of the first and second heart sounds. The device is also equipped with subcutaneous ECG electrodes and a memory for storing ECG and heart sound data. A detected R-wave on a sensed ECG signal may be used to trigger sampling of the heart sound sensor signal for a specified period of time for detecting the first heart sound. A detected T-wave may be used to trigger sampling of the second heart signal. Heart sound and ECG are continuously sampled and stored in a looping memory based on a first-in, first-out basis. Calibration includes measuring a patient's blood pressure using a standard clinical method and performing regression analysis on multiple variables to identify a set of best fit weighted equations for predicting blood pressure. Concurrent ECG and estimated blood pressure may be displayed for review by a physician.—DRR

43.80.Qf ESOPHAGEAL STETHOSCOPE WITH SEPARATE COVER MEMBER

John L. Atlee III, Hartland, Wisconsin
12 April 2005 (Class 600/528); filed 6 February 2003

This is a really different sort of stethoscope, one that is inserted into the esophagus instead of being placed on a chest in the usual manner as with the conventional stethoscope. It is multifunctional in that it is capable of performing recording, monitoring, or stimulation functions from or within the esophagus, among these being transesophageal monitoring of cardiac activity, transesophageal cardiac stimulation (e.g., cardiac pacing), or
esophageal oximetry. The device consists of a flexible, tubular body incorporating an acoustic input region. A carrier member, separate from the tubular body, engages with the tubular body either proximally or distally of the acoustic input region. On the carrier member may be mounted one or more devices for enabling esophageal recording, monitoring, or stimulation functions. In order to effect cardiac pacing, electrodes may be mounted onto the carrier member.—DRR

43.80.Sh APPARATUS FOR REMOVING PLAQUE FROM BLOOD VESSELS USING ULTRASONIC ENERGY

Robert A. Rabiner and Brad A. Hare, assignors to OmniSonics Medical Technologies, Incorporated
15 March 2005 (Class 606/128); filed 6 August 2003

The patent covers a method and apparatus for removing plaque, fatty deposits, and other occlusions from blood vessels through the use of ultrasonic energy. A special application includes the removal of plaque from the cardoid artery in a nonthermal manner. The device is designed to present a small cross-sectional profile, thus allowing the apparatus to be used in a minimally noninvasive manner. The authors maintain that the device can be
used in both surgical and outpatient treatment with minimal postoperative complications and minimal damage to areas other than the region of treatment. The ultrasonic probe may feature aspiration channels on its outer surface. An aspiration sheath may surround the ultrasonic probe in such a manner that the location of an aspiration port may be varied axially relative to the ultrasonic tip.—DRR

6,869,439

43.80.Sh ULTRASONIC DISSECTOR

Jeffrey S. White et al., assignors to United States Surgical Corporation; Misonix, Incorporated
22 March 2005 (Class 606/169); filed 19 August 2002

The patent disclosure relates to an ultrasonic instrument having an angled blade member and a clamp member that is said to be particularly suited for use in performance dissection and coagulation of tissue. The device includes a vibration coupler supported within a housing and operably connected to an ultrasonic generator. The angled blade member connects to
the distal end of the vibration coupler to conduct high-frequency vibration from the ultrasonic generator to the blade member. A clamp member placed adjacent to the blade member is movable to various positions. The clamp member and angled blade member act together to promote contact between the tissue and the blade member in the course of the operation of the instrument.—DRR

Donald P. Dione *et al.*, assignors to Ultrasound Detection Systems, LLC
12 April 2005 (Class 600/459); filed 28 March 2003

This system uses an imaging chamber in which ultrasound transducer elements are arranged in a number of cylindrical rings. Cone-shaped beams are formed for transmission and reception. An algebraic reconstruction technique is used to produce images of sound speed and slope of attenuation.—RCW

LETTERS TO THE EDITOR

Aircraft noise annoyance in recreational areas after changes in noise exposure: Comments on Krog and Engdahl (2004) (L)

Ronny Klæboe[a)]
Institute of Transport Economics, Grensesvingen 7, Oslo, Norway

When Gardermoen replaced Fornebu as the main airport for Oslo, aircraft noise levels increased in recreational areas near Gardermoen and decreased in areas near Fornebu. Krog and Engdahl [J. Acoust. Soc. Am. **116**, 323–333 (2004)] estimate that recreationists' annoyance from aircraft noise in these areas changed more than would be anticipated from the actual noise changes. However, the sizes of their estimated "situation" effects are not credible. One possible reason for the anomalous results is that standard regression assumptions become violated when motivational factors are inserted into the regression model. Standardized regression coefficients (beta values) should also not be utilized for comparisons across equations. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1984787]

I. INTRODUCTION

There are not many socioacoustic studies published on the effect of aircraft noise on outdoor recreationists, and papers bringing in results in this research area are especially welcome. They provide information on the importance of silent areas having recuperative effects, and establish results that are important input for more precise research hypotheses, improved data collection, and better statistical analyses. However, models of recreationists' annoyance reactions when undertaking voluntary trips in an area exposed to aircraft noise are conceptually more complex than the simpler dose response relationships for residential noise annoyance. The structure of such models should therefore be considered carefully.

In the paper: "Annoyance with aircraft noise in local recreational areas, contingent on changes in exposure and other context variables," Krog and Engdahl (2004) link a set of explanatory variables to aircraft noise annoyance in recreational areas. The data for the analyses come from two sets of before-after surveys; each set consisting of separate samples (not panel data). The first dataset stems from a study area close to Fornebu airport before and after it was closed down. The second set is from a study area near Gardermoen airport before and after it replaced Fornebu as the main airport for Oslo and Southeast Norway. In all surveys the equivalent aircraft noise exposure values $L_{Aeq,air}$ for the duration of each recreationist's trip as well as $L_{Asel,air}$ values

were calculated on the basis of measurements at fixed locations at each interview site deemed representative for the respective walking areas. An additional aircraft noise exposure indicator, the percentage of time aircraft noise was audible during each trip, was also calculated from these measurements.

The socio-acoustic surveys were designed to capture possible changes in the aircraft noise annoyance experienced by recreationists in two "situations:"

(1) After a marked decrease in $L_{Aeq,air}$ values (average reduction *ca.* 22 dB A)
(2) After a slight increase in $L_{Aeq,air}$ values (average increase *ca.* 1 dB A)

II. REGRESSION ANALYSES YIELD VERY HIGH "SITUATION" EFFECTS

Krog and Engdahl (2004) analyzed each of the studies (before and after) separately by means of multiple regression analyses. The degree of aircraft noise annoyance experienced during a recreational trip was the dependent variable, while the independent variables were as follows:

(1) $L_{Aeq,air}$.
(2) Duration of the visit.
(3) Whether the area is the primary recreational area or not.
(4) Reason for participating: The acoustic nature.
(5) Reason for participating: The visual nature experience.
(6) An indicator (a dummy variable) of whether the data stem from the after survey or not and that may capture a "situation" effect.

[a)]Electronic mail: rk@toi.no

The indices for participation in recreational trips in general (not the specific trip) were chosen as "mediator" variables.

Based on the results from the multiple regression analyses, Krog and Engdahl (2004) conclude that there is evidence of "situation" effects. People were less annoyed after the removal of air traffic from Fornebu, and people became more annoyed following the modest increase in average $L_{Aeq,air}$ in Romeriksåsen than predicted from the primary explanatory variables alone (1–5). However, the sizes of these "situation" effects are not credible. Simple calculations based on the published results, Krog and Engdahl (2004: Tables II and III), show that the "situation" accounts for a reduction in aircraft noise annoyance comparable to that of a 134 dB A reduction in $L_{Aeq,air}$ near Fornebu Airport. [The figure of −134 dB is obtained by dividing the estimated effect size of the "situation" (−1.476), with the estimated effect size of the aircraft noise exposure indicator (0.011)]. Vice versa, Gardermoen becoming the main airport for Oslo results in a "situation" effect comparable to a 21 dB A increase in $L_{Aeq,air}$ (0.398/0.019). Both effect sizes are in excess of what one could expect from the relatively well-behaved dose-response relationships for the combined datasets that are illustrated in Krog and Engdahl (2004: Figs. 4 and 5). In the Fornebu before situation the recreationists were exposed to a median $L_{Aeq,air}$ value of 69 dB. According to Krog and Engdahl (2004: Fig. 4), these recreationists, on average, became *rather annoyed*. In the complex multivariate regression model, aircraft noise annoyance in the Fornebu before the situation becomes mainly "explained" by the regression *constant—see* Krog and Engdahl (2004: Table II). The regression model estimated by Krog and Engdahl thus attempts to predict why recreationists become *not annoyed* by aircraft noise annoyance, but fails to explain why they *were* annoyed.

III. THE CONCEPTUAL MODEL IS COMPLEX, AND STANDARD REGRESSION ASSUMPTIONS MAY BE VIOLATED

Taking a trip in a recreational area exposed to aircraft noise is a voluntary decision. For analyzing this decision, it is clearly necessary to have information from recreationists that decide against taking a trip, or choose alternative recreational areas for taking the trip. The effect of aircraft noise on noise annoyance that is estimated is thus contingent on the fact that the recreationists have decided to take a trip in spite of the aircraft noise exposure in the area. The reason for recreational trips may be to experience silence, or the recreationist may have other reasons. It is therefore easy to sympathize with the efforts of Krog and Engdahl (2004) in bringing motivational factors into the conceptual model. No doubt, the reason for taking recreational trips may influence the experience of the trip.

However, incorporating motivational factors among the independent variables for explaining aircraft noise annoyance during the trip yields a highly complex explanatory model. All questionnaire items were filled in "on their way out of the area" and thus in the context of the specific trip. The recreationists' attitudes, noise sensitivity and personality traits may affect both motivation and annoyance. Such non-

modeled factors affecting both independent and dependent variables violate the standard regression assumption of independence between the error term and the dependent variable. The estimated impacts of the motivational factors on aircraft noise annoyance may thus be spurious and the integrity of the regression models compromised. An additional challenge is that when the variation in aircraft noise exposure is small or actual noise exposure has little effect on aircraft noise annoyance, the variation in the aircraft noise annoyance responses mainly reflects individual or other differences between the recreationists. The causal directions of the analytic regression model motivated by the presupposed dose-response relationship then need reexamining. Using the trip duration purely as an independent variable could also be considered problematic.

One possible approach for disentangling the impacts of the different variables is to estimate and report the results from simpler explanatory models before estimating the more complex models. In particular, it would be helpful to know the explanatory power and full report of a model where the exposure variable $L_{Aeq,air}$ is the sole predictor for aircraft noise annoyance. Thereafter models statistically controlling for situation and, possibly, whether the area is the primary recreational area could be established. This would improve transparency and make it easier to follow the implications of the changes in the estimated coefficients and possible quality improvement from introducing additional explanatory variables.

IV. THE FALLACY OF COMPARING STANDARDIZED COEFFICIENTS, BETA VALUES

Krog and Engdahl (2004) are also interested in comparing the effect sizes of the different aircraft noise exposure indicators. For such comparisons, the relative lack of variation in the exposure values in the studies near Gardermoen poses a problem. All recreationists are exposed to fairly low noise levels ($L_{Aeq,air}$) during the trip. To compare aircraft noise exposure indicators, an adequate exposure range for all proposed exposure indicators is required. This is not the case near Gardermoen, and measurement errors and factors other than exposure may play a large role in determining a model fit. As the comparisons of aircraft noise exposure indices are not fully reported, it is difficult to assess the quality of the results.

In an attempt to reduce the problems of comparing different aircraft noise exposure measures with different metrics, Krog and Engdahl (2004) establish separate (complex) regression models, standardize the coefficients (obtain beta values), and proceed to compare the estimated beta values for the different aircraft noise exposure indicators. The exposure indicator having the larger estimated beta value is deemed "better" than an indicator having a lower estimated beta value.

When comparing the explanatory variables that are part of the *same* multiple regression model, beta values may indicate which variable has the largest relative impact on the dependent variable. However, the use of beta values for comparing effect sizes between *different* regression equations is
FIG. 1. (Color online) The proportion of recreationists in two before and after surveys reporting different degrees of aircraft noise annoyance as a function of the percentage of the trip duration that aircraft noise was audible. Mean annoyance response changes indicated by broken lines—annoyance scale to the right.

misguided. The results of such comparisons not only depend on effect size, but also the variation in exposure values. The warning from Greenland *et al.* (1986) against utilizing standardized coefficients to compare results from different analyses is particularly pertinent when the variation in some of the exposure variables is small.

For a dummy variable such as the "situation" effect indicator, the standardized regression coefficient becomes a direct function of the proportion of interviews made in the before and after surveys. This affects both the within-equation and between-equation comparisons, and the beta effect sizes become directly dependent on the relative number of respondents in the before and after survey.

V. TIME AUDIBLE AS A PREDICTOR OF AIRCRAFT NOISE ANNOYANCE

As the methodology for analyzing the impacts of "time audible" on aircraft noise annoyance is the same as for $L_{Aeq,air}$, these results also need to be reexamined. The aggregate results reported by Krog and Engdahl (2004: Figs. 2 and 3) are summarized in Fig. 1. As simple comparisons violate the situational approach advocated by Krog and Engdahl, the relevant changes in mean annoyance responses are indicated using dashed lines. The disparate results from both simple and context sensitive comparisons of the dose-response relationships, suggest one should exercise caution in relying too much on estimation results for partial relationships and that researchers need consider all four datasets when attempting to draw conclusions from the data.

VI. THE DATASETS COULD BE MERGED FOR IMPROVED ANALYSES

The authors analyze the Fornebu and Gardermoen studies separately. The rationale provided is that the situation

effect has different signs in each of the two studies. If we disregard the problems with the conceptual model that have already been discussed in this paper, it would have been possible to incorporate two dummy variables in the multiple regression model instead of one. This would capture all three alternatives: "steady state," "noise increase," or "noise decrease" and data from both before and after studies could have been combined. The whole dataset could then have been utilized to estimate the parameter values for the variables common to both analyses.

VII. CONCLUSION

The sizes of the "situation" effects (removal of air traffic from Fornebu and added traffic at Gardermoen airport) are unbelievably large and the analyses should be reexamined. They authors should provide more detailed information about their conceptual models and provide a rationale for the multiple regression models utilized for the analyses. If possible, a sequential approach reporting fully the results from simpler explanatory models that serve as baselines before proceeding to more complex models could be adopted. This would improve transparency and facilitate the reader's understanding of the contribution of the various explanatory factors in the model. The conclusions reached by comparing standardized regression coefficients should also be reexamined.

A Wigner approximation method for wave propagation (L)

Patrick J. Loughlin

University of Pittsburgh, Department of Electrical and Computer Engineering, 348 Benedum Hall, Pittsburgh, Pennsylvania 15261

Leon Cohen

City University of New York, Department of Physics, 695 Park Avenue, New York, New York 10021

An approximation method for pulse propagation based on the Wigner position-wavenumber representation is presented. The method is very easy to apply and moreover is physically illuminating. One obtains the evolved approximate Wigner distribution from the initial Wigner distribution by a simple linear translation in phase space. Each phase space point propagates at constant velocity given by the group velocity at the phase space point. Dissipative propagation (damping) is also taken into account. From the approximate Wigner distribution, one can obtain the approximate magnitude of the evolved pulse and the approximate local wavenumber, that is, the spatial derivative of the phase of the pulse. Examples are given to illustrate the method. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2001488]

I. INTRODUCTION

The fundamental nature of dispersive wave propagation is that different frequencies travel at different velocities, and hence one would suspect that a transformation of the pulse into a joint position-wavenumber (x,k) representation would be well suited to study such dispersive propagation. We present an approximation method for dispersive propagation based on the position-wavenumber Wigner representation of the pulse. The approximation is remarkably simple to apply and gives considerable insight into the nature of pulse propagation. For simplicity of presentation, we focus on the case of one spatial dimension and single mode propagation, but the approach extends to multiple dimensions and to multiple modes, as we discuss subsequently.

Our method is as follows. Starting with the initial pulse $u(x,0)$, one calculates the Wigner distribution at time zero, $W(x,k,0)$. Then, the approximate evolved Wigner distribution is obtained easily according to

$$W(x,k,t) \approx e^{2\omega_I(k)t}W(x-v_g(k)t,k,0), \qquad (1)$$

where $v_g(k)$ is the group velocity, as usually defined, and $\omega_I(k)$ is the imaginary part of the dispersion relation. Moreover, the approximate magnitude $|u(x,t)|$ and local wavenumber, $\langle k \rangle_{x,t}$, of the pulse $u(x,t)$, are obtained by

$$|u(x,t)|^2 \approx \int W(x,k,t)dk, \qquad (2)$$

$$\langle k \rangle_{x,t} \approx \frac{1}{\int W(x,k,t)dk} \int kW(x,k,t)dk, \qquad (3)$$

where the local wavenumber is defined as $\langle k \rangle_{x,t} = \partial \varphi(x,t)/\partial x$ and $\varphi(x,t)$ is the phase of the pulse, $u(x,t) = R(x,t)e^{i\varphi(x,t)}$.

This approximation, Eq. (1), is remarkably simple: other than to calculate the Wigner distribution of the initial wave, one does not have to do any further calculations—one merely substitutes $x-v_g(k)t$ for x in the initial Wigner distribution and multiplies by $e^{2\omega_I(k)t}$. Moreover, besides being easily obtained, this approximation is interesting and insightful because it is physically interpretable. It shows that the Wigner distribution of the wave evolves (approximately) in the following simple manner. At each point in phase space the point evolves with constant velocity motion where the velocity is the group velocity. It also shows in a simple way the effect of damping and, in particular, it shows the growth or decay of a particular wavenumber: for $\omega_I(k) < 0$ we have damping (energy dissipation), and for $\omega_I(k) > 0$ energy is added to the wave as it propagates (for $t > 0$).

II. WAVE PROPAGATION AND APPROXIMATION

We describe how the above approximations arise. For an initial pulse $u(x,0)$, the pulse at a later time, $u(x,t)$, is given by[1–5]

$$u(x,t) = \frac{1}{\sqrt{2\pi}} \int S(k,0)e^{ikx-i\omega(k)t} dk, \qquad (4)$$

for each mode, where $S(k,0)$ is the initial spatial spectrum,

$$S(k,0) = \frac{1}{\sqrt{2\pi}} \int u(x,0)e^{-ikx}dx \qquad (5)$$

and $\omega(k)$ is the dispersion relation, which we write in terms of its real and imaginary parts,

$$\omega(k) = \omega_R(k) + i\omega_I(k). \qquad (6)$$

As commonly defined, the group velocity, $v_g(k)$, is given by

$$v_g(k) = \frac{d\omega_R(k)}{dk}. \qquad (7)$$

The position-wavenumber Wigner distribution of the pulse is defined by[6–8]

$$W(x,k,t) = \frac{1}{2\pi} \int u^* \left(x - \frac{\lambda}{2}, t \right) u \left(x + \frac{\lambda}{2}, t \right) e^{-i\lambda k} \, d\lambda. \tag{8}$$

By substituting Eq. (4) into Eq. (8), one can show that the Wigner distribution at time t is related to the Wigner distribution of the initial pulse at $t=0$ by[9,10]

$$W(x,k,t) = \frac{1}{2\pi} \int \int W(x',k,0)$$
$$\times e^{i\theta(x'-x)} e^{i[\omega^*(k+\theta/2) - \omega(k-\theta/2)]t} \, d\theta \, dx'. \tag{9}$$

This equation is exact. Equation (1) is obtained by expanding the phase and keeping only low-order terms.[9,10]

To obtain the approximate magnitude and local wavenumber of the pulse $u(x,t)$, first note that from the exact Wigner distribution $W(x,k,t)$, one obtains the squared-magnitude and local wavenumber of the pulse via[6]

$$\int W(x,k,t) dk = |u(x,t)|^2 \tag{10}$$

and

$$\langle k \rangle_{x,t} = \frac{1}{\int W(x,k,t) dk} \int k W(x,k,t) dk = \frac{\partial \varphi(x,t)}{\partial x}, \tag{11}$$

respectively. Therefore, the approximate magnitude and local wavenumber are obtained by using the approximate Wigner distribution in the equations above.

Before illustrating the approximation with examples, we comment on the extension to multiple spatial dimensions and to multiple modes. For a three-dimensional scalar field, the Wigner distribution is defined as

$$W(\mathbf{r},\mathbf{k},t) = \left(\frac{1}{2\pi} \right)^3 \int u^* \left(\mathbf{r} - \frac{\mathbf{r}'}{2}, t \right) u \left(\mathbf{r} - \frac{\mathbf{r}'}{2}, t \right) e^{-i\mathbf{r}'\cdot\mathbf{k}} \, d\mathbf{r}', \tag{12}$$

and the approximation becomes

$$W(\mathbf{r},\mathbf{k},t) \approx e^{2\omega_I(\mathbf{k})t} W(\mathbf{r} - \mathbf{v}_g(\mathbf{k})t, \mathbf{k}, 0), \tag{13}$$

where $\mathbf{v}_g(\mathbf{k})$ is the group velocity vector.

For the multiple mode case, one has an option depending on the use of the approximation. Generally, as with the exact solution or stationary phase method, one studies one mode at a time and that is also the case with the Wigner approximation, as presented. If one considers instead the total solution (i.e., the sum of modes) then, like the autocorrelation function and spectral density, the Wigner distribution and approximation produce cross-products between the modes. One could develop a Wigner approximation that drops the cross-products, and that may or may not be more accurate, depending on whether the modes add coherently or incoherently. Also, we make the following observation regarding modes. Over the past 30 years the concept of multicomponent signals has arisen in signal processing. A multicomponent signal is one that breaks up into distinct parts in phase space/the time-frequency plane.[6,11] One of the very significant advantages of using a phase space approach to study wave propagation is that it can show in a simple way that a wave is multicomponent and allows one to extract information about each component. Since each mode typi-

cally travels with a different group velocity, the modes increasingly separate the further the wave propagates, that is as time increases.

III. EXAMPLES

A. Example 1: Quadratic dispersion

We consider first an exactly solvable case to be able to compare effectively. For the initial pulse and dispersion relation we take, respectively,

$$u(x,0) = e^{i\beta x^2/2 + ik_0 x}, \tag{14}$$

$$\omega(k) = (\gamma_R + i\gamma_I) k^2/2 = \gamma k^2/2. \tag{15}$$

The group velocity is

$$v_g(k) = \gamma_R k. \tag{16}$$

Working out the exact solution, one obtains

$$u(x,t) = \frac{1}{\sqrt{1+\gamma\beta t}} \exp \left(i \frac{\beta}{2} \frac{(x - k_0\gamma t)^2}{1 + \gamma\beta t} + ik_0 x - i\gamma k_0^2 t/2 \right) \tag{17}$$

$$= \frac{1}{\sqrt{1+\gamma\beta t}} \exp \left[\frac{i}{2\beta} \left(\frac{(\beta x + k_0)^2}{1 + \gamma\beta t} - k_0^2 \right) \right]. \tag{18}$$

The exact magnitude and local wavenumber are

$$|u(x,t)|^2 = \frac{1}{\sqrt{(1 + \gamma_R\beta t)^2 + (\gamma_I\beta t)^2}}$$
$$\times \exp \left[\gamma_I t \frac{(\beta x + k_0)^2}{(1 + \gamma_R\beta t)^2 + (\gamma_I\beta t)^2} \right], \tag{19}$$

$$\frac{\partial\varphi(x,t)}{\partial x} = \frac{1 + \gamma_R\beta t}{(1 + \gamma_R\beta t)^2 + (\gamma_I\beta t)^2} (\beta x + k_0). \tag{20}$$

For the Wigner approximation approach, the Wigner distribution of the initial pulse is readily calculated,

$$W(x,k,0) = \delta(k - \beta x - k_0). \tag{21}$$

The approximate Wigner distribution, Eq. (1), follows immediately,

$$W(x,k,t) \approx e^{\gamma_I k^2 t} \delta(k - \beta(x - \gamma_R k t) - k_0) \tag{22}$$

$$= \frac{1}{|1 + \gamma_R\beta t|} e^{\gamma_I k^2 t} \delta \left(k - \frac{\beta x + k_0}{1 + \gamma_R\beta t} \right) = W_a(x,k,t). \tag{23}$$

The approximate magnitude and local wavenumber of the pulse are

$$|u(x,t)|^2 \approx \frac{1}{|1 + \gamma_R\beta t|} \exp \left[\gamma_I t \left(\frac{\beta x + k_0}{1 + \gamma_R\beta t} \right)^2 \right] \tag{24}$$

and

$$\frac{\partial\varphi(x,t)}{\partial x} = \langle k \rangle_{x,t} \approx \frac{\int k W_a(x,k,t) dk}{\int W_a(x,k,t) dk} = \frac{\beta x + k_0}{1 + \gamma_R\beta t}. \tag{25}$$

For comparison, we also give the stationary phase approximation.[1–5] Usually the stationary phase approximation is presented in terms of real dispersion relations. Since,

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

P. J. Loughlin and L. Cohen: Letters to the Editor   1269

in our case, the dispersion relation is complex, we re-write Eq. (4) explicitly in terms of the real and imaginary parts of the dispersion relation as

$$u(x,t) = \frac{1}{\sqrt{2\pi}} \int S(k,0) e^{\omega_I(k)t} e^{ikx - i\omega_R(k)t} dk. \quad (26)$$

Applying the method of stationary phase to approximate this integral yields

$$u(x,t) \sim \frac{S(k_s,0) e^{\omega_I(k_s)t}}{\sqrt{|t\omega_R''(k_s)|}} e^{j(k_s x - \omega_R(k_s)t - (\pi/4)\mathrm{sgn}(t\omega_R''(k_s)))} \quad (27)$$

where k_s are the stationary points, which are obtained by solving $x - \omega_R'(k_s)t = 0$ for k_s. For the specific wave and dispersion relation considered in this example, we obtain

$$u(x,t) \sim \sqrt{\frac{i}{|\gamma_R \beta t|}} \exp\left[\frac{\gamma_I x^2}{2\gamma_R^2 t}\right]$$
$$\times \exp\left[i\left(\frac{x^2}{2\gamma_R t} - \frac{\left(\frac{x}{\gamma_R t} - k_0\right)^2}{2\beta} - \frac{\pi}{4}\mathrm{sgn}(t\gamma_R)\right)\right], \quad (28)$$

by which the approximate magnitude and local wavenumber are

$$|u(x,t)|^2 \approx \frac{1}{|\gamma_R \beta t|} \exp\left[\frac{\gamma_I x^2}{\gamma_R^2 t}\right], \quad (29)$$

$$\frac{\partial \varphi(x,t)}{\partial x} \approx \frac{\beta x + k_0}{\gamma_R \beta t} - \frac{\beta x}{(\gamma_R \beta t)^2}. \quad (30)$$

We now briefly compare some aspects of the approximations to the exact answer. We first note that for both the Wigner approximation and the stationary phase method, knowledge of the dispersion relation is required, as is the case, of course, to obtain the exact solution. For this example, note that if there is no damping ($\gamma_I = 0$), the Wigner approximation is exact, but the stationary phase approximation is not. When there is damping, the Wigner approximation captures the main exponential decay or growth of the pulse magnitude, and it is seen to be an improvement over the stationary phase approximation. Regions of the parameters and time can be studied in detail, but we only note here that by comparing Eq. (19) with Eq. (24), and Eq. (20) with Eq. (25), we see that the Wigner approximation is generally very good when

$$\left(\frac{\gamma_I \beta t}{1 + \gamma_R \beta t}\right)^2 \ll 1. \quad (31)$$

For example, if we consider the long time limit $t \gg 1/\gamma_R\beta$, then we see that the approximation is good when $\gamma_R \gg \gamma_I$, where we have taken all the parameters positive. For small times $t \ll 1/\gamma_R\beta$, the approximation is good when $\gamma_I\beta t \ll 1$. The stationary phase approximation is likewise accurate for $t \gg 1/\gamma_R\beta$ when $\gamma_R \gg \gamma_I$, although the Wigner approximation approaches the exact answer faster. For small times, the stationary phase approximation is not accurate. In a future paper, further discussion and exactly solvable examples will be presented, but we consider next one additional example to illustrate the simplicity of the Wigner approximation coupled with the insights into propagation that it provides.

B. Example 2: Pulse in a waveguide

Consider a pulse propagating in a two-plate waveguide, for which the dispersion relation is[1,5,12]

$$\omega(k) = c\sqrt{k^2 + \kappa_m^2} = ck\sqrt{1 + (\kappa_m/k)^2} \quad (32)$$

where $\kappa_m = m\pi/D$ corresponds to the lowest frequency $\omega_m = \kappa_m c$ per mode m that propagates in the waveguide, D is the separation distance of the plates, and c is the propagation velocity as $D \to \infty$. For the initial pulse we take

$$u(x,0) = \left(\frac{\alpha}{\pi}\right)^{1/4} e^{-\alpha x^2/2 + ik_0 x + i\beta x^2/2}, \quad (33)$$

where x is the range. The initial Wigner distribution is

$$W(x,k,0) = \frac{1}{\pi} \exp[-\alpha x^2 - (k - \beta x - k_0)^2/\alpha]. \quad (34)$$

The group velocity is $v_g = c/\sqrt{1 + (\kappa_m/k)^2}$ and therefore the approximate Wigner distribution per mode is

$$W(x,k,t) \approx \frac{1}{\pi} \exp\left[-\alpha\left(x - \frac{ct}{\sqrt{1 + (\kappa_m/k)^2}}\right)^2\right.$$
$$\left. - \frac{1}{\alpha}\left(k - k_0 - \beta\left(x - \frac{ct}{\sqrt{1 + (\kappa_m/k)^2}}\right)\right)^2\right]. \quad (35)$$

We do not give the stationary phase approximation but invite the reader to try it. In Fig. 1, we plot the initial Wigner distribution, and the approximation for the first mode ($m = 1$) at subsequent times. Note how the pulse contracts for a period before expanding, and changes from a downward chirp to an upward chirp as it propagates.

IV. CONCLUSION

We have presented an approximation for dispersive wave propagation, based on the Wigner distribution representation of the wave. From the Wigner distribution of the initial wave, one obtains an approximate Wigner representation of the wave at some later time in a very simple way. From the approximate Wigner representation, approximations of the magnitude and local wavenumber of the wave $u(x,t)$ can be obtained by integrals of the Wigner approximation. In addition to its simplicity, the Wigner approximation provides insights into the nature of dispersive propagation, and shows the effect of dispersion and damping on a local point in phase space. Also, the case of random media can be developed by considering the expected value of the Wigner distribution.[13,14]

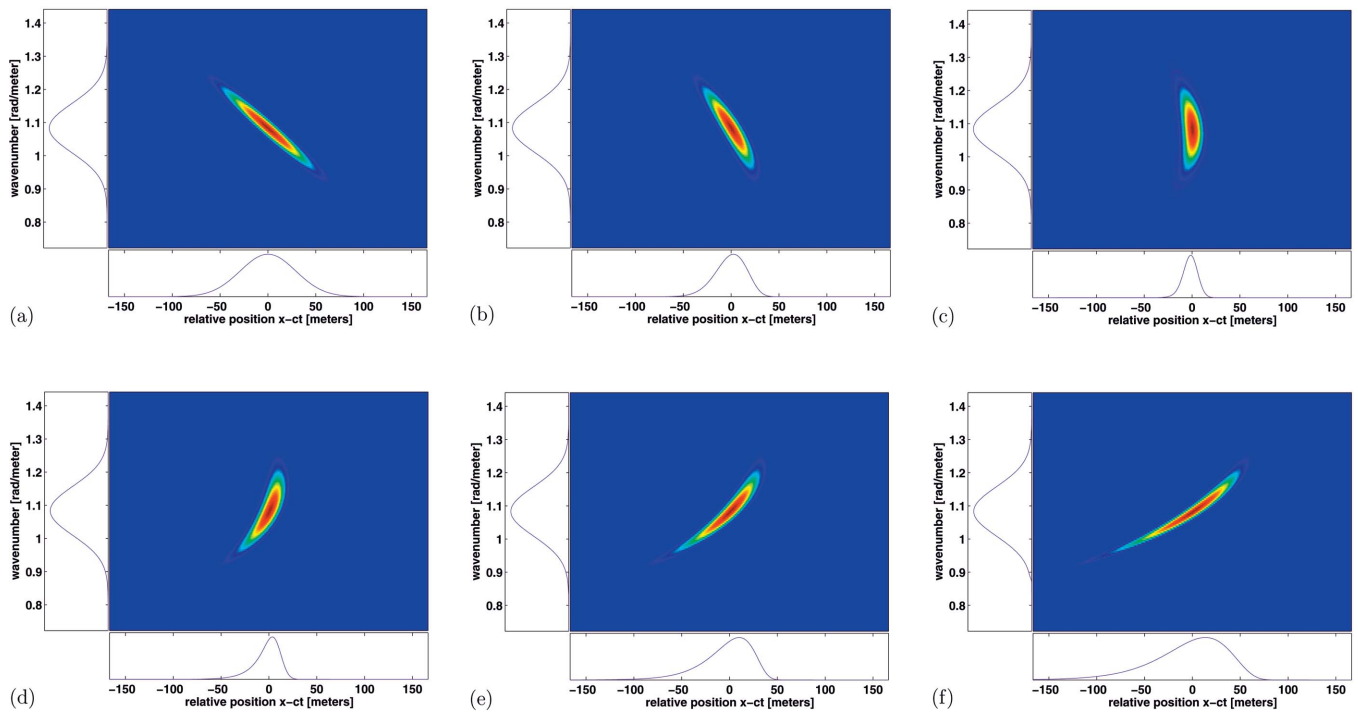
We comment briefly on computational issues. As mentioned previously, the computational requirements of the Wigner approximation involve only the need to compute the Wigner distribution of the initial wave. We emphasize that this calculation does not involve the dispersion relation, unlike, for example, the stationary phase approximation. The approximate time evolved Wigner distribution is then obtained very simply via Eq. (1), which takes into account the


FIG. 1. (a) Exact position-wavenumber Wigner distribution (main panel) of an initial pulse ($t=0$), and then (b)–(f) an approximation for the first mode at five later times ($t=10, 20, 30, 40, 50$ s), simulating propagation of an underwater acoustic wave in a hard-bottom shallow water ocean channel of depth D $=25$ m and an isovelocity sound speed profile of $c=1450$ m/s. The lower panel in each plot shows the squared-magnitude of the pulse, which is exact for $t=0$, and approximate thereafter. The left panel shows the squared magnitude of the spatial spectrum, which is exact in all cases (the approximate Wigner distribution yields the exact magnitude-spatial spectrum). Note that the magnitude-spatial spectrum does not change as the pulse propagates, since there is no damping in this case (the dispersion relation is purely real). The parameters of the initial pulse are $k_0=1.083$ rad/m, $\alpha=1/1450$ m^{-2}, and $\beta= -0.0025$ rad/m^2, which corresponds to a pulse of nominal center frequency $f_0=250$ Hz and duration $\Delta t \approx 20$ ms. Different values for the waveguide and pulse parameters could be used to study other propagation cases.

effects of dispersion (and dissipation) on the wave in phase space. We believe that the primary advantage of the Wigner approximation, besides its simplicity, is in terms of the insights that it provides with regard to dispersive propagation, and, in particular, in showing how the wave evolves locally at each phase space point. We also mention that computational issues for higher dimensions for the standard methods become difficult but are simple for the Wigner distribution approximation.

In a future paper we discuss and compare this approximation in detail but we mention here that one reason the approximation is generally very good is that one does not have to assume that the initial spectrum is slowly varying, as, for example, is done in the stationary phase approximation. In addition, we are investigating higher-order approximations.

Speed of sound in nitrogen as a function of temperature and pressure (L)

Axel Hagermann[a)] and John C. Zarnecki

Planetary and Space Sciences Research Institute, The Open University, Walton Hall, Milton Keynes, MK7 6AA, United Kingdom

Speed of sound measurements in nitrogen by Younglove and McCarty [J. Chem. Thermodynam. **12**, 1121–1128 (1980)] are revisited and an empirical polynomial equation for the speed of sound is derived. The polynomial coefficients differ from those given by Wong and Wu [J. Acoust. Soc. Am. **102**, 650–651 (1997)] with the result that discrepancies between predicted and measured values at low temperatures are reduced. The maximal error over the complete temperature and pressure range from 80 to 350 K and 0.031 to 0.709 MPa is reduced from 5.38% to 0.78%. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000748]

I. INTRODUCTION

Recently, there has been an increase in interest in the physical properties of nitrogen gas at low temperatures in the context of planetary science. Wong and Wu reported a polynomial expression for the speed of sound in nitrogen as a function of temperature and pressure.[1] They used the values from 150 to 330 K as measured by Younglove and McCarty[2] and obtained a remarkable accuracy of 380 ppm in that region. At some low temperatures and high pressures, however, the deviation between measured and calculated values can be as high as 5.38%. In our search for a reasonably accurate function specification applicable to a wider range of temperatures and pressures, we have calculated a new polynomial fit to the complete set of Younglove and McCarty's measurements.

II. TWO-DIMENSIONAL POLYNOMIAL APPROXIMATION

We assume that the speed of sound c in nitrogen gas as a function of temperature T and pressure p can be approximated by a polynomial expression of the form

$$c(p,T) = \sum_{i=0}^{m} \left(\sum_{j=0}^{n} a_{ij} T^j \right) p^i, \qquad (1)$$

where the a_{ij} need to be found by matching the $c(p,T)$ function to experimental data. We assume throughout this paper that p is given in MPa and T in K.

Wong and Wu used a multicolumn coefficient curve matching procedure in the p, T domain, first defining coefficients A_i such that a least-squares fit is applied to the pressure-dependent measurements at temperatures T_k assuming

$$c(T_k) = \sum_{i=0}^{n} A_i p^i, \quad k = 0,1,2,\dots . \qquad (2)$$

Then the a_{ij} can be found using

$$A_i = \sum_{j=0}^{n} a_{ij} T^j. \qquad (3)$$

The function specification uses selected measurements by Younglove and McCarty at temperatures from 150 to 330 K, and is extremely accurate within this range, with a maximum deviation of 380 ppm. This is comparable with the experimental accuracy of 300 ppm. At lower and higher temperatures, however, this function specification is considerably less accurate, particularly with increasing pressure. We found deviations of more than 5% at 110 K and 1.44 MPa. An investigation revealed that the A_i column coefficients in the region from 150 to 330 K take values such that $|A_i| > |A_{i+1}|$, but this is not the case for very low and very high temperatures, explaining the higher error with increasing pressure.

We have used the full set of measurements by Younglove and McCarty. Temperatures were adjusted from the IPTS-68 to the ITS-90 system using an eighth-degree fit.[3] Given the magnitude of errors over the complete p,T range, however, we found this correction to be of minor importance. We then minimized the function of $(m+1) \times (n+1)$ variables

$$L = \sum_{\ell=1}^{237} (c_\ell - c(p_\ell, T_\ell, a_{11}, a_{12}, \dots a_{mn}))^2, \qquad (4)$$

where c_ℓ is the ℓth of the 237 measurements by Younglove and McCarty and $c(p_\ell, T_\ell, \dots)$ is the speed of sound as calculated by Eq. (1). L being a quadratic form, $\partial L / \partial a_{ij}$ can be readily derived, and the solution can be found using conjugate gradients or variants of Newton's method. We used the latter, with Wong and Wu's values as a starting guess.

TABLE I. Polynomial coefficients for our two-dimensional function specification for the speed of sound in nitrogen.

j	a_{1j}	a_{2j}	a_{3j}	a_{4j}
0	$6.721\,128E+01$	$-1.908\,177E+02$	$5.908\,631E+01$	$-6.511\,627E+01$
1	$1.820\,085E+00$	$2.971\,323E+00$	$-1.063\,665E+00$	$1.218\,812E+00$
2	$-5.713\,575E-03$	$-1.699\,747E-02$	$6.173\,142E-03$	$-7.949\,396E-03$
3	$1.320\,687E-05$	$4.219\,848E-05$	$-1.390\,550E-05$	$2.187\,479E-05$
4	$-1.265\,187E-08$	$-3.806\,689E-08$	$9.852\,826E-09$	$-2.165\,669E-08$

III. RESULTS

The polynomial coefficients a_{ij} for Eq. (1) with $n=4$, $m=3$ are given in Table I. The maximal deviation from Younglove and McCarty's measurements has been reduced to 0.78%. As the degree and order of our fit are only 4 and 3, respectively, some trade-offs had to be made in the midtemperature region from 150 to 330 K. Here the maximal deviation is 0.52%. In moderate temperature regimes, Wong and Wu's approximation remains more accurate. However, if we compare our fit to the measurements made by Ewing and Trusler,[4] the maximum deviation is reduced to only 0.22% in the region from 80 to 300 K. This value increases to 0.88% if we include their measurements at 373 K. In extreme conditions like those encountered in planetary science, our function specification maintains its accuracy over the whole range covered by measurements.

In many studies, the influence of intelligibility of the interfering speech is avoided by reversing it in time. Usually, intelligibility with time-reversed interfering speech indeed is higher compared to that with normal interfering speech. However, due to the nature of speech, reversed speech also gives rise to increased forward masking. The latter will result in a decrease in intelligibility. Thus, differences in intelligibility as a consequence of reversing speech in time are due to two opposite effects. This paper describes a speech reception threshold (SRT) test with intelligible and unintelligible interfering speech played normally and time-reversed. With Dutch listeners, Swedish reversed interfering speech gave a rise in SRT of 2.3 dB compared with the Swedish interfering speech (played normally). The difference can be attributed to differences in forward masking. Dutch time-reversed interfering speech gave a decrease in SRT of 4.3 dB compared to (intelligible) Dutch interfering speech. The latter is the result of both a release from informational masking and an increase in forward masking. Therefore, the amount of informational masking is larger than 4.3 dB and, if one assumes similar differences in forward masking for Dutch and Swedish speech, may amount to 6.6 dB. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000751]

I. INTRODUCTION

There are various papers describing speech intelligibility in the presence of one or more interfering talkers (e.g., Festen and Plomp, 1990; Bronkhorst and Plomp, 1992; Bronkhorst, 2000; Drullman and Bronkhorst, 2000; Brungart, 2001; Brungart *et al.*, 2001; Brungart and Simpson, 2002; Summers and Molis, 2004). Remarkably, intelligibility appears to vary greatly between conditions, which in part might be due to the degree of similarity between the target speaker (here: "target" or "signal") and the interfering speakers (here: "masker" or "noise"). The more similar the target and masker are, the more the listener is confused or distracted, which in turn results in poorer performance. Differences between target and masker with respect to gender (male or female speech) or intelligibility of the interfering speech (native or foreign language) have only a small effect with respect to actual energetic masking of the target, but certainly can have a large effect on intelligibility. The phenomenon of excess masking is often labeled as informational masking (Drullman and Bronkhorst, 2000; Bronkhorst, 2000;

Brungart, 2001; Brungart *et al.*, 2001). This paper concentrates on the part of informational masking due to intelligibility of the interfering speech.

In order to study the speech intelligibility in speech-like maskers, and at the same time avoid the informational masking component due to the intelligibility of the interfering speech, many researchers use fluctuating speech-shaped noise (Festen and Plomp, 1990; Bronkhorst and Plomp, 1992; Peters *et al.*, 1998; Versfeld and Dreschler, 2002) or play the interfering speech signal backwards (Festen and Plomp, 1990; Summers and Molis, 2004). Fluctuating speech-shaped noise is made by modulating the long term speech spectrum with the speech envelope of the interfering talker. The envelope can be extracted from broad band speech (one band), two bands (Festen and Plomp, 1990), three bands (ICRA noise; Dreschler *et al.*, 2001), or even more. The fluctuating speech-shaped noise has more or less the same intensity fluctuations in time as real speech, has the same long-term spectrum of speech, but is generally unintelligible because the fine structure is lost.

By using time-reversed speech as a masker, the spectral contents of speech are in essence untouched. The reversed speech is not intelligible and therefore this component of the informational masking by definition is removed. However, the envelope of time-reversed speech is reversed as well. The shape of temporal envelope of speech is typically dominated

[c] Electronic mail: w.a.dreschler@amc.uva.nl

by plosive sounds (Rosen, 1992), and the envelope of these sounds is characterized by quick onsets (steep slope) and slow decays (shallow slope). Reversal of the speech signal thus results in temporal envelopes that have abrupt offsets. Since the auditory system does not follow the offset instantaneously, but rather displays a decay of the envelope across time, abrupt changes cannot be followed accurately, hence soft signals can be easily masked by a preceding strong signal (called forward masking).

Irino and Patterson (1996), Carlyon (1996), Stecker and Hafter (2000), and Schlauch *et al.* (2001) examined the perception of stimuli with ramped envelopes (gradual attack and abrupt decay) and damped envelopes (abrupt attack and gradual decay). The sum of these studies reveal that ramped signals are subjectively judged longer in duration and are perceived louder compared to damped signals. This is explained by the abrupt offset at a high level of a ramped sound which results in a persistence of perception, and more forward masking compared to a damped sound. The same effects could be expected by time reversed speech since its envelope is more ramped compared to the damped normally played speech (Rosen, 1992).

Forward masking has a clear effect on speech intelligibility (Festen, 1987). The recovery time from forward masking is in the range of 100–200 ms (Moore, 2003). For completeness, a second type of masking, present in human auditory perception, should be mentioned, viz., backward masking. In this case, a soft signal is masked by a louder signal that follows it. The phenomenon of backward masking is still poorly understood (Moore, 2003). The amount of backward masking obtained with practiced subjects often is little or none (Moore, 2003). Its effect on speech intelligibility is still unclear and probably not very large.

By reversal of the speech masker in time, one expects on the one hand an improvement in intelligibility of the target speech due to the fact that the masking speech becomes unintelligible (partly release from informational masking), and, on the other hand a decrease in performance due to the fact that the temporal envelope of the reversed speech causes an increase of forward masking. Festen and Plomp (1990) and Summers and Molis (2004) found a slight improvement in performance when using reversed speech instead of normal speech as a masker. This improvement is the result of both effects combined. From these experiments it is not possible to assess the individual contribution of both components.

The goal of the current experiment is to separate informational masking due to intelligibility of the interfering speech from forward masking. Additional masking due to time reversal of the speech is assessed by measuring the speech intelligibility in masking speech of a foreign language. Since the foreign speech is not intelligible (neither forward nor backward), differences in intelligibility due to time reversal must be due to differences in forward masking alone. The same experiment is repeated in native interfering speech. Differences in intelligibility due to time reversal then are the combined effect of an increase in forward masking and a decrease in informational masking. Since the speech materials are similar, and since the single effect of additional masking due to time reversal is known, the effect of informational masking due to intelligibility of the interfering speech can be estimated.

II. METHOD

A. Subjects

Eight normal-hearing subjects (3 male, 5 female) participated. Their mean age was 25 years and ranged from 21 to 39 years. Subjects were native speakers of the Dutch language. Subjects had at least high school education. Each subject had pure-tone thresholds of 15 dB HL or better at octave frequencies from 125 to 8000 Hz (ANSI S3.6, 1996).

B. Stimuli

The target speech material consisted of short every-day sentences, uttered by a male speaker (Versfeld *et al.*, 2000). The speech material comprised 39 lists of 13 sentences and was developed for a reliable measurement of speech intelligibility in noise. The speech was stored with a sampling rate of 44.1 kHz and 16 bits resolution.

Swedish and Dutch speech was used as interfering speech. The Swedish speech was developed by Hagerman (1982) and consisted of short sentences read by a female speaker. For the Dutch language, a corpus similar to that of Hagerman (1982) was developed. The Dutch sentences were uttered by a different female speaker. The Dutch speech was rescaled to obtain the same speaking rate as that of Hagerman's (1982) set, viz., 3.5 s per sentence. Scaling was done by use of the PSOLA method [Pitch-Synchronous Overlap Add, a method for manipulating the pitch and duration of an acoustic speech signal, Moulines and Charpentier, 1990]. Pseudorunning speech was obtained by concatenation of sentences in succession without pauses.

C. Procedure

Subjects were tested individually in a sound-insulated booth. The monaural speech-reception threshold was measured at the better ear for a fixed noise level of 65 dBA. Signals were played out via an Echo soundcard (Gina 24/96) on a PC at a sample frequency of 44.1 kHz and were fed through a TDT Microphone Amplifier (MA2) and a TDT Headphone Buffer (PA4) via THD 39P headphones. After the presentation of a sentence, the subject's task was to repeat the sentence he or she had just been presented. A sentence was scored as correct if all words in that sentence were repeated without any error. A list of 13 sentences, unknown to the subject, was used to estimate the level at which 50% of the sentences was reproduced without any error, the so-called speech reception threshold, or SRT. For a given condition, the first sentence of the list started far below the expected SRT. The sentence was repeated each time at a 4 dB higher level until the subject was able to reproduce it correctly. The 12 remaining sentences in that list were presented only once, following a simple up-down procedure with a step size of 2 dB. The SRT was estimated according to the procedure described by Plomp and Mimpen (1979), i.e., by taking the mean signal to noise ratio (SNR) of sentence 5 to 13 plus the
FIG. 1. Speech reception threshold (dB) as function of interfering speech type. Error bars denote the standard error of the mean.

estimated SNR that would have been used for the 14th sentence. With each sentence presentation, a random sample of the interfering speech was taken. It started 1200 ms before the start of the sentence and stopped at least 800 ms after the sentence.

In total four masking conditions were tested: Dutch masker forward, Dutch masker reversed, Swedish masker forward, and Swedish masker reversed. The experiment was partitioned into two blocks, a test and a retest. To avoid confounding of measurement condition order and sentence lists, the order of conditions and sentence lists was counterbalanced across subjects according to an 8 by 8 Latin Square method. In total, each subject received 8 lists of 13 sentences preceded by 3 practice lists.

III. RESULTS

Figure 1 shows the SRT values averaged across subjects and test-retest for each of the four conditions of the interfering speech. Error bars denote the standard error of the mean. A 4[condition]$\times$2[test/retest]$\times$8[subject] analysis of variance (ANOVA) was performed on the data set. Of the main effects, only differences in "condition" were significant ($F[3,21]=24.6, p<0.001$). The SRT of the retest was on average 1.2 dB better than the test, but this difference was not significant ($F[1,7]=4.6, p>0.05$). Also, differences between subjects were just not significant ($F[7,4]=5.6, p>0.05$). None of the interactions were significant.

The difference in SRT between the two conditions with Swedish speech was significant (Tukey's HSD test, $z=2.4$, $p=0.02$) and was on average 2.3 dB. Thus, by time reversing speech, the SRT increases (i.e., performance worsens) from -13.9 to -11.6 dB. The difference between the two conditions with Dutch interfering speech was also significant (Tukey's HSD test, $z=4.28$, $p<0.001$). Here, time reversal of the masking speech causes the SRT to improve by 4.3 dB. The latter effect was apparent in all subjects, and the result is in agreement with that of Festen and Plomp (1990). Last, the

difference between the two conditions with reversed masking speech was also significant (Tukey's HSD test, $z=3.6$, $p<0.001$).

IV. DISCUSSION

The most important finding of the present experiment is that time reversal of foreign, nonintelligible speech that is used as a masker, affects intelligibility and causes the SRT to increase by more than 2 dB. Most likely, reversal of the envelope of the speech signal results in an increased contribution of forward masking. The main conclusion to be drawn from this experiment is that reversal of a speech masker indeed introduces additional masking on top of energetic masking in the form of forward masking.

Time reversal of intelligible (Dutch) masking speech results in a decrease in the SRT of 4.3 dB. This difference is the result of the elimination of intelligibility of the masker on the one hand (enhancing speech intelligibility), and the introduction of additional forward masking on the other hand (decreasing speech intelligibility). If one assumes that the additional amount of forward masking is similar for the Swedish and Dutch masking speech, then in the present experiment the effect of informational masking due to intelligibility of the speech masker can be estimated to be 4.3 +2.3=6.6 dB.

If intelligibility of the speech masker were the sole factor determining the amount of informational masking, one would expect the SRT with Swedish reversed speech and Dutch reversed speech to be similar. In the present experiment this is not true; the difference is about 3.6 dB. Apparently, the Dutch reversed speech is a poorer masker (SRT $=-15.2$ dB) than the Swedish reversed speech (SRT $=-11.6$ dB). If Dutch interfering speech played in reverse sounds more similar to Dutch speech than Swedisch speech played either forward or in reverse, one would expect the opposite. It is interesting to note that subjects told they could not distinguish between the Swedish reversed speech and the Dutch reversed speech. Also, they misjudged the reversed Dutch speech for Swedish speech and vice versa. Therefore, the effect probably is not very large. As mentioned in Sec. I, other factors than intelligibility contribute to informational masking. From the present results, it is difficult to say which of the many potential factors contributed most; perhaps differences in intonation, rhythm, mean pitch, modulation spectrum, or differences in the long-term speech spectrum. If the interfering native and non-native speech were uttered by the same person, with the same pronounced intonation, rhythm, and pitch, one would expect the SRTs in the reversed condition to be more alike. But even then, differences might still exist due to specific characteristics of the language.

The present experiment is a first attempt to separate energetic masking from informational masking. Future research with different native and non-native interfering speech, uttered by the same person may give more insight into the effects of forward masking and informational masking on speech intelligibility.

V. CONCLUSIONS

By using speech from different languages, played both forward or time-reversed, it is possible to disentangle the effects of informational masking caused by intelligibility of the interfering speech and energetic masking. However, time reversal of speech results in an increase in temporal (forward) masking. In the present experiment, this effect is about 2.3 dB. The release from informational masking by making intelligible speech unintelligible by reversing it in time is obscured by an increase in forward masking. In the present experiment, it is shown that informational masking might be as large as 6.6 dB if one assumes the same amount of additional forward masking with Dutch and Swedish reversed speech.

Symmetry and Snell's law

David R. Bergman[a)]

Department of Physics, Saint Peter's College, Jersey City, New Jersey, 07306

A connection between the acoustic rays in a moving fluid medium (with a sound speed and subsonic flow each depending arbitrarily on position and time) and the null geodesics of a pseudo-Riemannian manifold allows one to derive several well-known results used in underwater and atmospheric acoustic ray theory from one single underlying symmetry principle, isometry. These results being well known in cases with Cartesian symmetry generalize to any system of curvilinear coordinates and three-dimensional fluid flows. Snell's law, range, and travel time integrals for Cartesian and cylindrically symmetry systems are derived and an illustrative example presented. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1979427]

I. INTRODUCTION

A well-known result from the study of geometric acoustics in a stationary medium states that when the sound speed depends on only one Cartesian variable, the equations for the acoustic ray may be integrated to yield a conserved quantity along the ray path. In this case the conservation of $\cos \theta / c$, known as Snell's law, can be used to predict ray paths. Over the years generalizations of this law for special circumstances including a depth-dependent moving fluid medium have appeared in the literature. In most cases the existence of cyclic variables is used to derive the result directly from the second-order ray equations. A complete derivation of a generalized Snell's law for rays in a layered moving fluid can be found in Ref. 1. Treating the acoustic rays as particle trajectories invokes an immediate connection with Noether's theorem, in which the conserved quantities along the particle trajectory are derived from the Lagrangian, or Hamiltonian, rather than from the equations of motion.

Through the purely geometric treatment of acoustic rays as geodesics of a metric space, these conservation laws emerge in a natural way by identifying isometries of an effective acoustic metric. In short an isometry is a rigid motion of a space (a mapping of the space into itself that preserves distances). Once the isometries of a manifold are found, a conserved current for each can be constructed from the infinitesimal generator of the isometry, called a Killing vector. The technique is used extensively in general relativity to describe particle motion in terms of energy conservation in an effective potential rather than by the geodesic equations. The technique is used here to derive Snell's law in a moving fluid for cases with translational and cylindrical symmetry. For a more detailed account of the use of isometries and Killing's theorem the reader is referred to Refs. 2 and 3.

By the same technique the standard ray integrals used in oceanic and atmospheric acoustics emerge. The final results in Cartesian coordinates are well known.[4–7] A salient feature of the approach presented here is that the derivations of several results are encapsulated in one common procedure,

which is applicable in any general curvilinear coordinate system. This brief paper presents the derivation of ray-path integrals in Cartesian and cylindrical coordinates via the procedure of identifying isometries of the acoustic metric along with one example with an exact solution, illustrating the connection between ray theory, differential geometry and Noether's theorem.

II. THE SPACE-TIME ACOUSTIC METRIC AND CANONICAL MOMENTUM

The acoustic rays in a fluid environment with arbitrary sound speed and subsonic current flow are identical to the null geodesics of a pseudo-Riemannian manifold. This result, which follows directly by application of the method of characteristics,[8–10] implies that the ray paths are curves of zero length in space-time:

$$ds^2 = -(c^2 - v^2)dt^2 - 2\vec{v} \cdot d\vec{x}dt + d\vec{x} \cdot d\vec{x} = 0, \qquad (1)$$

in which v and c depend on position and time with $\{x\}$ the standard Cartesian coordinates. Equation (1) defines a metric tensor, referred to in the literature as the acoustic metric, with components $\{g_{00} = v^2 - c^2, g_{0i} = g_{i0} = -v_i, g_{ij} = \delta_{ij}\}$. We define a Lagrangian via $\dot{x}^\mu \dot{x}^\nu g_{\mu\nu} = 2L$ and the Hamiltonian $p_\mu p_\nu g^{\mu\nu} = 2H$, in which the canonical momentum, $p_\mu = \partial L / \partial \dot{x}^\mu = \dot{x}^\nu g_{\mu\nu}$, is defined.[11] From the definition of L and Eq. (1) the translational momentum and energy along the ray are $\vec{p} = c\hat{n}t$ and $p_0 = -c\hat{n} \cdot \dot{\vec{x}}$, respectively,[12] where $\hat{n}$, the unit normal of the wave-front in space, is related to the ray path by $d\vec{x}/dt = c\hat{n} + \vec{v}$. The momentum is proportional to the wave-front gradient and the energy is proportional to the projection of the wave-front gradient onto the ray path velocity. Moving to general curvilinear coordinates Eq. (1) reads

$$ds^2 = -(C^2 - V^2)dt^2 - 2(V_i)dq^idt + G_{ij}dq^idq^j = 0, \qquad (2)$$

in which $C \equiv c(\vec{q}, t)$, $V_i \equiv \vec{v} \cdot \partial \vec{x} / \partial q^i$, and $G_{ij} \equiv (\partial \vec{x}/\partial q^i) \cdot (\partial \vec{x}/\partial q^j)$, all as functions of $\{q\}$.[13] The $\{V_i\}$ are the components of $\vec{v}$ projected onto the $\{q\}$ coordinate curves.

In this paradigm the acoustic rays are null geodesics in a four-dimensional space-time manifold. The geometry of the

FIG. 1. Ray tangent and wavefront normal in three dimensions. Polar and azimuth angles for each are defined.

FIG. 2. Relationship between the wavefront, fluid velocity, and ray tangent in Cartesian space for two-dimensional planar rays.

manifold is determined by the environmental parameters, $c(\vec{x},t)$ and $\vec{v}(\vec{x},t)$, and described by the acoustic metric appearing in Eqs. (1) and (2). An isometry of a manifold is a symmetry indicated by the presence of a cyclic variable in the metric tensor. If $g_{\mu\nu}(x^\alpha)$ does not depend on one of the coordinates x^S, then any curve may be translated along the x^S coordinate curves with no change. From the point of view of dynamical systems theory with L defined above this cyclic coordinate leads to a quantity $p_S = g_{S\nu}\dot{x}^\nu$ which is conserved along the geodesic (ray path).

Specializing to a time-independent environment leads immediately to conservation of energy,[14] $\kappa_0 = c\hat{n}\cdot\dot{\vec{x}}$, where a minus sign has been absorbed into the definition of κ_0. If the parameters of the medium depend on only one general coordinate, say q_1, then there are two other conserved quantities corresponding to the components of translational momentum P_2 and P_3, referred to collectively here as the transverse momentum $\vec{P}_T$, $i C\hat{N}_T = \kappa$ Snell's law in vector form may be stated simply as conservation of the transverse momentum to energy ratio,

$$\frac{\vec{p}_T}{p_0} = \frac{\hat{N}_T}{C + \vec{V}\cdot\hat{N}} = \vec{\alpha}, \tag{3}$$

in which $\vec{\alpha} = \vec{\kappa}/\kappa_0$. For example, in Cartesian coordinates the assumption of a depth-dependent medium, $c(z)$, $v(z)$, leads to the transverse momentum $\vec{p}_T$, $ic\hat{n}_T = \vec{\kappa}$, and $\hat{n}_T/(c+\vec{v}\cdot\hat{n})$ =const.

III. RAY PATH GEOMETRY

Here we work exclusively in Cartesian coordinates. Equation (3) may be solved to give the direction of the wave-front normal at all points along the ray. Figure 1 shows $\hat{n}$ and $d\vec{x}/dt$ in a local Cartesian frame with polar and azimuth angles defined. In spherical coordinates $\hat{n}$ =$(\sin\theta\cos\varphi, \sin\theta\sin\varphi, \cos\theta)$. The ratio of n_y/n_x and the magnitude of $\vec{\kappa}$ give

$$\tan\varphi = \frac{\kappa_y}{\kappa_x}, \tag{4a}$$

$$\frac{\sin\theta}{c + \sigma\sin\theta + v_z\cos\theta} = \kappa, \tag{4b}$$

respectively, in which $\sigma = v_x\cos\varphi + v_y\sin\varphi$ and $\kappa = \sqrt{\kappa_x^2 + \kappa_y^2}$. Equation (4a) states that the wave-front propagates through the medium with a constant azimuth, as expected. Having solved Eq. (4a), Eq. (4b) is then solved for $\cos\theta$,

$$\cos\theta = \frac{-cv_z \pm (\lambda^{-1} - \sigma)\sqrt{(\lambda^{-1} - \sigma)^2 + (v_z^2 - c^2)}}{v_z^2 + (\lambda^{-1} - \sigma)^2}. \tag{5}$$

Equations (4a) and (5) determine $\hat{n}$. From this information the direction of the ray tangent is found from the relation $d\vec{x}/dt = c\hat{n} + \vec{v}$,

$$\tan\bar{\varphi} = \frac{c\sin\theta\sin\varphi + v_y}{c\sin\theta\cos\varphi + v_x}, \tag{6}$$

$$\tan\bar{\theta} = \frac{\|c\hat{n}_T + \vec{v}_T\|}{c\cos\theta + v_z}. \tag{7}$$

In underwater and atmospheric acoustics it is common to assume $v_z = 0$, $v_y = 0$ and treat only rays initially fired in the x-z plane. Making these assumptions, the angle of the wave-front normal and the tangent vector are related by[15] $c\cos\theta$ =$\|d\vec{x}/dt\|\cos\psi - v$; see Fig. 2, which in turn implies $\|d\vec{x}/dt\| = v + \sqrt{c^2 - v^2(\sin\psi)^2}$. Inserting this result into Eq. (3) leads immediately to the result

$$\frac{1}{c}\frac{\varepsilon\mu^2\cos^2\psi - \varepsilon\mu^2 + \mu\cos\psi\sqrt{1 - \varepsilon^2\mu^2\sin^2\psi}}{1 - \varepsilon^2\mu^2 + \varepsilon^2\mu^2\cos^2\psi + \varepsilon\mu\cos\psi\sqrt{1 - \varepsilon^2\mu^2\sin^2\psi}} = \alpha, \tag{8}$$

in which $\varepsilon = v/c$ is defined as the local Mach number and $\mu = c_0/c$ is the index of refraction (Kornhauser's notation is used). This result can be compared to that of Kornhauser, where use of the trigonometric identity $\cos^2\psi + \sin^2\psi = 1$ shows they are identical.

IV. RANGE AND TRAVEL-TIME INTEGRALS

A. Cartesian symmetry

Applying the formalism of Sec. II leads to the following first-order equations for the ray coordinates and travel time:

$$(c^2 - v^2)\dot{t} + \vec{v}\cdot\dot{\vec{x}}_T = \kappa_0, \tag{9}$$

$$\dot{\vec{x}}_T - \vec{v}\dot{t} = \vec{\kappa}, \tag{10}$$

where it has been assumed that $v_z=0$, $\vec{v}=\vec{v}_T$. Equations (9) and (10) combine to give

$$\dot{t} = c^{-2}(\kappa_0 - \vec{v}\cdot\vec{\kappa}), \tag{11}$$

$$\dot{\vec{x}}_T = \vec{\kappa} + c^{-2}\vec{v}(\kappa_0 - \vec{v}\cdot\vec{\kappa}). \tag{12}$$

Inserting Eqs. (11) and (12) into the null constraint leads to an equation for z,

$$\dot{z} = \pm c^{-1}\sqrt{(\kappa_0 - \vec{v}\cdot\vec{\kappa})^2 - c^2\vec{\kappa}\cdot\vec{\kappa}}. \tag{13}$$

The ratio of Eqs. (11) and (13) gives dt/dz while that of Eqs. (12) and (13) gives $d\vec{x}_T/dz$, which determine the travel-time and range coordinates of a ray as a function of depth,

$$t(z) = \int_{z_0}^{z} \frac{1 - \vec{v}\cdot\vec{\alpha}}{c\sqrt{(1-\vec{v}\cdot\vec{\alpha})^2 - c^2\alpha^2}}\, dz, \tag{14}$$

$$x_T(z) = \int_{z_0}^{z} \frac{c^2\vec{\alpha} + (1-\vec{v}\cdot\vec{\alpha})\vec{v}}{c\sqrt{(1-\vec{v}\cdot\vec{\alpha})^2 - c^2\alpha^2}}\, dz, \tag{15}$$

in which $\vec{\alpha}=\vec{\kappa}/\kappa_0$ and a factor of κ_0 has been absorbed into the definition of the ray parameter λ. When $\vec{v}=0$ Eqs. (14) and (15) reduce to the standard integrals found in most texts on oceanography; see, for example, Ref. 16.

B. Environments with cylindrical symmetry

In this section the technique is applied to systems with cylindrical symmetry, which find application in atmospheric acoustics. Let the environment be a rotating fluid with $c(r)$ and $\vec{v}=v_\varphi(r)\hat{\varphi}+v_z(r)\hat{k}$, $v^2=v_\varphi^2+v_z^2$. Expressing the Lagrangian in cylindrical coordinates

$$-(c^2-v^2)\dot{t}^2 + \dot{r}^2 + r^2\dot{\varphi}^2 + \dot{z}^2 - 2v_\varphi r\dot{\varphi}\dot{t} - 2v_z\dot{z}\dot{t} = 0, \tag{16}$$

there are three cyclic coordinates, t, z, and φ which lead to conservation of energy, linear momentum in the z direction, and angular momentum about the z axis[17]:

$$(c^2-v^2)\dot{t} + v_\varphi r\dot{\varphi} + v_z\dot{z} = 1, \tag{17}$$

$$\dot{z} - v_z\dot{t} = k, \tag{18}$$

$$r^2\dot{\varphi} - v_\varphi r\dot{t} = \alpha. \tag{19}$$

Combining these leads to

$$\dot{t} = c^{-2}(1 - r^{-1}v_\varphi\alpha - v_z k), \tag{20}$$

$$\dot{\varphi} = r^{-2}\alpha + r^{-1}c^{-2}v_\varphi(1 - r^{-1}v_\varphi\alpha - v_z k), \tag{21}$$

$$\dot{r} = \pm c^{-1}\sqrt{(1 - r^{-1}v_\varphi\alpha - v_z k)^2 - c^2(r^{-2}\alpha^2 + k^2)}. \tag{22}$$

As before these lead to the ray travel time and range as functions of r:

$$t(r) = \int_{r_0}^{r} \frac{(r - v_\varphi\alpha - rv_z k)}{c\sqrt{(r - v_\varphi\alpha - rv_z k)^2 - c^2(r^2k^2 + \alpha^2)}}\, dr, \tag{23}$$

$$\varphi(r) = \int_{r_0}^{r} \frac{(c^2\alpha + v_\varphi(r - v_\varphi\alpha - rv_z k))}{cr\sqrt{(r - v_\varphi\alpha - rv_z k)^2 - c^2(r^2k^2 + \alpha^2)}}\, dr. \tag{24}$$

The cylindrical version of Snell's law is similar in form to Eq. (3) with the exception that the rotational component is scaled by a factor of r. For two-dimensional problems in the (r,φ) plane the local horizontal is lined up with curves of constant r, θ of Sec. III (see Ref. 4) becomes the angle between $\hat{n}$ and $\hat{\varphi}$, and Snell's law becomes $\alpha=r_0\cos\theta_0/(c_0 + v_0\cos\theta_0)$.

V. EXAMPLE

As a simple example consider rays in a vortex flow described by $c=ar$ and $v_\varphi=br$, $v_z=0$ with the condition $a>b>0$ (i.e., the flow is always subsonic). The ray path is

$$t = \frac{1}{a\sqrt{1-p^2}}\ln\left(\frac{r}{r_0}\frac{\sqrt{1-p^2} + \sqrt{1-p^2-(a+bp)^2k^2r_0^2}}{\sqrt{1-p^2} + \sqrt{1-p^2-(a+bp)^2k^2r^2}}\right), \tag{25}$$

$$\varphi = (b + ap)t, \tag{26}$$

$$\lambda = -\left.\frac{1}{k^2(a+bp)}\sqrt{1-p^2-(a+bp)^2k^2r^2}\right|_{r_0}^{r}, \tag{27}$$

$$z = z_0 + k\lambda, \tag{28}$$

in which $p=\cos\theta_0$ and $\varphi_0=t_0=0$. For $k=0$ Eqs. (26) and (27) become

$$\varphi = \frac{(b+ap)}{a\sqrt{1-p^2}}\ln\left(\frac{r}{r_0}\right), \tag{29}$$

$$\lambda = \frac{1}{2}\frac{(a+bp)}{\sqrt{1-p^2}}(r^2 - r_0^2), \tag{30}$$

respectively. Rays fired in the (r,φ) plane will fly off to infinity while those fired with nonzero value of k have a radial turning point at $r_{tp}=k^{-1}(a+bp)^{-1}\sqrt{1-p^2}$, as indicated by Eq. (22), eventually spiraling in towards the z axis. Rays with $r=0$ define helices about the z axis. A careful analysis of Eq. (21) for this case indicates that φ does not change direction and rays fired against the wind with $\cos\theta_0=-\varepsilon$ travel in the radial direction, $\varphi=0$. Equations (26), (29), and (30) give a time-parametrized ray allowing wave-fronts to be easily traced with little effort. Solving Eq. (28) for $r(t)$ gives

$$r = \frac{2AB}{D^2e^{\omega t} + A^2e^{-\omega t}}, \tag{31}$$

in which $A=r_0^{-1}(B+\sqrt{B^2-D^2r_0^2})$, $B=\sqrt{1-p^2}$, $D=(a+bp)k$, and $\omega=aB$. For rays in the horizontal plane, $k=0$, a glance at Eq. (22) shows that $r=0$ when $\hat{n}=\pm\hat{\varphi}$ or $\theta=0,\pi$, indicating that rays fired in the $\pm\hat{\varphi}$ direction define circles $r=r_0$ about the center of the vortex. Sample ray traces illustrated in Figs. 3–5 show the deformation of the wave-fronts for rays in the horizontal plane, $k=0$, while Fig. 6 shows a sample three-dimensional ray trace for $k=0.1$.
FIG. 3. Rays and wavefronts for a point source placed at (1.0 m, 0.0 m). Fluid flow is clockwise about the origin with $a=1.5$ and $b=0.5$. Wavefronts are traced out to $t=1.0$ s in increments of 0.2 s. A fan of 21 rays is shown for equal increments of $p=\cos\theta_0$. The rays marked $p=1$ and $p=-1$ define a circle about the origin.

FIG. 5. (a) Wavefronts for the same scenario as depicted in Fig. 3 for $t=20.0$ s to $t=3.0$ s. (b) Detail of the deformation near the origin.

Equation (30) describes rays launched away from the z axis, with $r_0>0$. Rays launched towards the z axis are described by Eq. (30) with $\omega\rightarrow-\omega$. Equations (26) and (27) together describe the z coordinate of a ray from its initial position to its radial turning point. The upper portion of the ray is determined by $z\rightarrow 2z_{tp}-z$.
FIG. 6. Sample three-dimensional ray trace for $k=0.1$. Only rays launched away from the origin are presented in the interest of cleanliness. A vertical line is placed at the origin of the x-y plane as a reference to better illustrate the spiraling of the rays toward the z axis.

VI. CONCLUSIONS

The technique used in this letter is an ubiquitous part of mathematical physics, finding its greatest use in general relativity. The deep connection between isometry and Noether's theorem is well known in the study of dynamical systems.[18] The application of this method to acoustics serves a dual purpose in (a) encapsulating a plethora of very common, disconnected results in one easily accessible principle, geometric symmetry, while illustrating the connection between these results, and (b) providing a general technique for dealing with ray systems that do not possess Cartesian symmetry. Although only two examples were given, cylindrical and Cartesian symmetry, the method applies equally well to any system of coordinates.

A time-variant impulse response method is proposed, developed, tested, and shown to provide new insights into different scattering problems involving moving surfaces. The method proposed is general, conceptually straightforward, and can accommodate moving sources and receivers. While the time-variant impulse response method has been developed specifically in this study to extend the capability of the wedge assemblage (WA) model [e.g., R. S. Keiffer and J. C. Novarini, J. Acoust. Soc. Am. **107**, 27–39 (2000)], the framework can be applied to other scattering models including those based in the frequency domain. Calculations involving moving periodic surfaces and moving receivers are presented and compared with good results to a generalized grating equation and small wave-height approximation perturbation theory. The time-variant impulse response model is also applied to time-evolving sea surfaces, and the previously published results of Pourkaviani and Willemsen [J. Acoust. Soc. Am. **90**, 426–432 (1991)] are confirmed. It is also shown that windward-oriented backscatter geometries can lead to a Doppler spectrum that peaks at higher than expected Doppler shifts. [DOI: 10.1121/1.1992687]

I. INTRODUCTION

Previously, the details of a time-domain model for the (finite) acoustic impulse response of *static*, two-dimensional (2D), impenetrable, rough surfaces that is based on wedge diffraction theory[1] were reported. That approach, referred to as the wedge assemblage (WA) method, was shown to compare very well with a "benchmark accurate" frequency-domain solution over a broad range of grazing angles for the problem of backscattering from 2D sea surfaces. Earlier implementations of the WA method have been proven accurate for scattering from pressure-release (soft) sinusoidal surfaces,[2] and soft and hard disks.[3] Over the years since the WA method was first suggested, there have been many published papers testing this modeling approach. The interested reader can refer to the papers cited in Ref. 1, also Chaps. 11 and 12 of Medwin and Clay's book,[4] and the exact impulse response solution[5] on which the WA model is based. The work by Svensson *et al.*[6] deriving analytic expressions for the response of truncated wedges may also be of interest. More recently, a hybrid ray-WA model has been described that allows for acoustic scattering from rough surfaces over-lying refracting, range-independent media.[7] Finally, the important work by Chu,[8] and also Davis and Scharstein,[9] extending the exact Biot–Tolstoy solution to density-contrast

wedges, opens the way for the application of the WA model to certain seafloor scattering problems.

The main purpose of this paper is to describe and validate a method for extending the WA model to scattering problems in which the surface, source, and receiver are in motion. The time-variant interface scattering problem is of significant practical interest in underwater acoustics where, for example, sonar systems involving moving sources and receivers are common, and significant reverberation from time-evolving seas may be unavoidable. The approach developed in this study uses time-variant linear filter theory as a general framework, and addresses the kinematics of the problem in the time domain where the impulse response of a moving interface is the fundamental quantity that needs to be calculated. The process of scattering, in addition to its spatial dependence, is regarded as a time-variant linear filter, the complete specification of which is provided by the time-variant impulse response function. This viewpoint, when coupled to an ordered accounting of single- and multiple scattering contributions, leads to a significant simplification of the kinematics of the problem. And, it results in conceptually straightforward numerical algorithms for computing the received signal even under circumstances where the source, receiver, and scattering surface all move in complicated trajectories.

The utility of the time-variant impulse response method is not restricted to extending the WA model to time-varying scattering problems. For example, the method has been used within the framework of small wave-height perturbation

theory[10] to examine the implications of the so-called frozen surface approximation. In addition, as pointed out by Wetzel,[11] most treatments of rough surface scattering are derived from a boundary value problem in integral form based on Green's theorem in the frequency domain. While the linearity of the governing equations allows the response of a surface to an incident signal to be assembled by Fourier synthesis from single-frequency solutions, there are difficulties in the interpretation of this approach, particularly under dynamic time-varying conditions. One of the advantages of working in the time domain is that it allows for a causal-based analysis of the scattering process. Interactions can be followed in sequence as they occur. In the frequency domain, a direct identification of the sequence of events is not possible because of the intrinsic limitation imposed by the cw condition.

Finally, it should be pointed out that a moving interface causes the surrounding medium to move as well. Censor,[12] acknowledging that "strictly speaking the medium's effects and scatterer's boundary effects should be considered simultaneously," has examined this issue within the limiting circumstances of irrotational flow and slow variations in the ambient medium in space and time relative to distances and times on the order of the acoustic wavelength and period. He found that the (Doppler) effects of the medium motion are comparable to the effects of the moving interface, but become negligible as the distance from the observer to the region of the medium that is in motion is increased. On the other hand, the (Doppler) effects of interface motion on the scattered field are independent of distance.

The basic layout of the paper is as follows. In Sec. II a brief example problem is considered and the Doppler spectrum is derived to introduce the basic equations from time-variant linear filter theory and the impulse response approach. In Sec. III, the kinematics of insonifying a moving interface and the single-scatter approximation are discussed. Section III closes with details of the numerical implementation of the time-variant WA method, a discussion of sampling rates, and the numerical calculation of the bifrequency function.[13] In Sec. IV, the time-variant WA method is exercised in a series of numerical experiments that forms the basis of an initial validation of the model.

II. EXAMPLE PROBLEM: DOPPLER SPECTRUM AT A MOVING POINT RECEIVER

To briefly introduce nomenclature, establish transform conventions, and generally define terms, a simple example problem is considered in this section. Imagine a motionless medium where the sound speed is constant (c) throughout and a motionless point source located at $\bar{R}_S$ that instantaneously (at time $t=\tau$) begins injecting mass at a constant rate s_0. The impulsive pressure wave that radiates outward from the source is a solution to the wave equation

$$\nabla^2 p(\bar{r},t) - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}p(\bar{r},t) = -s_0\delta(t-\tau)\delta(\bar{r}-\bar{R}_S). \quad (1)$$

In the context of linear filter theory, the solution to Eq. (1), with due regard to the boundary conditions, is called the time-varying impulse response function. It is denoted in this paper, without explicit reference to its spatial dependency as $h(t,\tau)$. In free space, this time-variant impulse response function is

$$h(t,\tau) = \frac{s_0}{4\pi|\bar{r}-\bar{R}_S|}\delta\left(t-\tau-\frac{|\bar{r}-\bar{R}_S|}{c}\right). \quad (2)$$

The impulse response function becomes time variant when, for example, the receiver undergoes uniform rectilinear motion, $\bar{r}=\bar{R}_0+\bar{u}t$. Letting $\bar{R}=\bar{R}_0-\bar{R}_S$ and assuming that $|\bar{R}| \gg |\bar{u}T|$, that is, assuming that over the duration of the observation interval (T) the receiver travels a small distance compared to the initial source–receiver separation, then $|\bar{R}+\bar{u}t| \approx R+\hat{R}\cdot\bar{u}t$ and $|\bar{R}+\bar{u}t|^{-1}\approx R^{-1}$ are valid approximations, and the time-variant impulse response function can be accurately approximated by

$$h(t,\tau) \approx \frac{s_0}{4\pi R}\delta\left(qt-\tau-\frac{R}{c}\right), \quad (3)$$

with $R=|\bar{R}|$, $\hat{R}=R/|\bar{R}|$, and $q=1-\hat{R}\cdot\bar{u}/c$. The bifrequency function, $B(f,v)$, results from the sequential Fourier transforming the time-variant impulse response function with respect to t and τ. The following convention is adopted:

$$B(f,v) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t,\tau)e^{i2\pi ft}e^{-i2\pi v\tau}dt\,d\tau. \quad (4)$$

In the case of uniform receiver motion, the "far-field" bifrequency function is

$$B(f,v) = \frac{s_0}{4\pi R}\delta(f-qv)e^{i2\pi vR/c}. \quad (5)$$

The bifrequency function has the attractive property that the frequency response due to a particular input signal can be obtained from the overlap integral[13]

$$P_{\text{out}}(f) = \int_{-\infty}^{\infty} P_{in}(v)B(f,v)dv. \quad (6)$$

Here, $P_{\text{in}}(v)$ is the Fourier transform of the input signal $p_{\text{in}}(t)$. A time-harmonic input signal having frequency $v_0 > 0$, has, in this example, the output signal

$$P_{\text{out}}(f) = \frac{s_0 e^{i2\pi Rf/qc}}{8\pi R}[\delta(f+qv_0)+\delta(f-qv_0)]. \quad (7)$$

From Eq. (7) it can be seen that the received signal is a frequency-shifted copy of the input signal. Looking at the positive received frequencies ($f>0$), the shift in received frequency is, as expected, $\eta=-[(\hat{R}\cdot\bar{u})/c]v_0$, where shift frequency η is defined as $\eta=f-v_0$. Closely related to the frequency spectrum of the output signal is the (one-sided) Doppler spectrum. It is defined for $f>0$ as twice the magnitude squared of the received frequency spectrum when expressed in terms of the shifted frequency η. The Doppler spectrum is the main quantity of interest in upcoming sections of this paper where numerical calculations are presented. There, finite duration input signals are considered. Of course, in the development of the far-field form of the impulse response

function, Eq. (3), it was already assumed that the input signal has a finite duration. Therefore, Eq. (7) represents the limiting form of the far-field output spectrum for very long-duration input signals. When the receiver is not far from the source, or if the receiver motion is not uniform rectilinear motion, a closed-form expression for the received spectrum may not be available. In that case one can always proceed numerically. If the details of the windowing function, $w(\tau)$, are important, then the frequency spectrum of the output signal is calculated from

$$P_{\text{out}}(f) = \frac{1}{2} \int_{-\infty}^{\infty} W(\upsilon)[B(f, \upsilon + \upsilon_0) + B(f, \upsilon - \upsilon_0)]d\upsilon, \qquad (8)$$

where $W(\upsilon)$ is the Fourier transform with respect to τ of the window $w(\tau)$.

The simple example developed in this section illustrates the application of time-variant linear filter theory to a moving receiver problem. It is important to note that the methodology can be easily implemented numerically to handle irregular trajectories and include source motion as well. And, in comparison to other methods suitable for that general problem [e.g., Ref. 14], the quasistatic approach just described is conceptually quite simple.

III. SINGLE-SCATTER IMPULSE RESPONSE OF A MOVING SURFACE

The following definitions are adopted regarding single and multiple scattering: the single-scatter component of the impulse response is due to those points on the interface (secondary sources) that are directly insonified by the source and in turn directly insonify the receiver. Multiple scattering is a generic term that refers to the additional scattering that follows from the reinsonification of the interface by these original and subsequent secondary sources. In most cases, the single-scatter component of the impulse response dominates and the practical limitations imposed by the additional computations needed to include multiple scattering effects are not typically justified by substantial increases in the accuracy of the predictions. Therefore, in what follows, the discussion of the approach used to extend the WA approach to time-variant scattering problems is limited to the single-scatter component of the impulse response. It should be kept in mind, however, that the methodology could be applied in a self-consistent manner to each successive order of scattering.

A. Kinematics and the single-scatter impulse response

Suppose that a moving (subsonic) point source, having instantaneous location $\bar{R}_S(t)$, stops at time $t = \tau$ and immediately begins injecting mass at a constant rate into a homogeneous (static) fluid medium. The pressure impulse that radiates outward from the source travels (with speed c) from the location of the source at the time of emission and insonifies a moving (subsonic), impenetrable, rough surface, $z_s(x, y, t)$. As the impulsive source wavefront sweeps across the time-varying surface, it intercepts or detects each point on the surface at a discrete instant of time. Call this time of detection t_d. By definition, t_d solves the equation

$$t_d - \tau - \frac{|x\hat{x} + y\hat{y} + z_s(x, y, t_d)\hat{z} - \bar{R}_S(\tau)|}{c} = 0. \qquad (9)$$

The locus of surface points detected by the impulsive source signal defines a new, effective surface, $\zeta(x, y, \tau)$, the frozen, quasistatic surface[11]

$$\zeta(x, y, \tau) = z_s(x, y, t = t_d). \qquad (10)$$

It is clear from causality that the time history of the surface prior to the arrival of the incident impulse cannot affect the scattered response. Similar considerations lead to the conclusion that the single-scatter component of the scattered response cannot be affected by the time history of the surface after the initial source insonification. In other words, the single-scatter component of the scattered response depends only on the shape of the detected surface. The effect of source and surface motion on the time variation of the impulse response function can be modeled (in the single-scatter approximation) by examining the impulse responses of a time sequence of the quasistatic surfaces, $\zeta(x, y, \tau)$.

Receiver motion can also be included. Regarding each point on the surface $\zeta(x, y, \tau)$ as a secondary source that emits a scattered impulse at $t = t_d$, let t_R be the time at which that scattered signal reaches the moving receiver at $\bar{R}_R(t_R)$

$$t_R = t_d + \frac{|x\hat{x} + y\hat{y} + \zeta(x, y, \tau)\hat{z} - \bar{R}_R(t_R)|}{c}. \qquad (11)$$

Each secondary source on $\zeta(x, y, \tau)$ emits a scattered impulse that reaches the moving receiver at a discrete, potentially different, future location $\bar{R}_R(t_R)$. The effect of receiver motion can be included in the modeling by using the correct static receiver location in the impulse response calculation of each secondary source and then summing all the impulse responses with due respect to time of arrival.

B. Numerical implementation

The details of a numerical implementation of the WA model for backscattering problems involving static 2D surfaces have been discussed previously.[1,3,4] Although it is appropriate to repeat some of that material here, the focus of this section is on the numerical implementation of the methodology being proposed to extend the WA model to time-variant problems. Begin by assuming that the time-varying surface, $z_s(x, y, t)$, is represented on a fixed uniform spatial grid ($\Delta x = \Delta y$) and that the time evolution of the surface is known at all times. Then, at any discrete horizontal location (x_i, y_j), the value of the surface height function detected by the impulse emitted by the source at time $t = \tau$ defines $\zeta(x_i, y_j, \tau)$. This quasistatic surface can be determined numerically, for example, by applying any of a number of root-finding algorithms to Eq. (9). In some cases, closed-form expressions can be derived that accurately approximate the detected time and surface [for example, see the Appendix of this paper or Ref. 10].

Finally, many surfaces of interest are modeled by filtering random numbers in the wave number domain and then Fourier transforming to the spatial domain. In the case of sea

surfaces, the time evolution of the interface is accomplished by advancing or retarding in time the phase angle of different spectral components by amounts commensurate with the gravity wave dispersion relation. For these surfaces it is not efficient to specify the entire surface at many different times in order to determine t_d and $\zeta(x_i, y_j, \tau)$ at a particular (x_i, y_j) location. To limit the number of forward and inverse two-dimensional FFTs, the strategy used in this paper is to generate, at regular time intervals, a sequence of "snapshots" of the spatially discretized surface $z_s(x_i, y_j, t)$ and then, assuming the temporal sampling rate is adequate, interpolate to obtain surface heights at intermediate times.

The preceding paragraph touches on three different methods that can be used to determine the surface detected by an impulse emitted at time, $t = \tau$. To calculate the (finite) impulse response of this surface using the WA method, the surface $\zeta(x_i, y_j, \tau)$ is "tiled" or tessellated using, for convenience, triangularly shaped facets.[1,4] These triangular facets are determined by first interpolating between any four surface heights of the square sample area to create a center surface height value. This divides the primitive area into triangularly shaped pieces. Adjacent triangular facets are used to define finite-length wedge apices. The diffracted response (P_δ) of every (nonshadowed) finite-length apex in the assemblage of wedges is calculated at discrete times, $t_i = (i-1)\Delta t$, from the Biot–Tolstoy solution and added with due respect to time of arrival

$$h(t_i, \tau) = \sum_{m=1}^{M} \varepsilon_m \frac{1}{\Delta t} \int_{t_i}^{t_i + \Delta t} P_{\delta_m}(\bar{r}_S, \bar{r}_R, t, \tau) dt. \quad (12)$$

With source wedge coordinates r_0 and θ_0, receiver coordinates r and θ, wedge angle θ_w, and offset distance Z (all of which are specific to the mth finite-length apex), the diffracted component is given by

$$P_\delta(t) = \left(\frac{-s_0 c}{8 \pi \theta_w} \right) [r r_0 \sinh(Y)]^{-1} [D_{++} + D_{--} + D_{+-} + D_{-+}], \quad (13)$$

$$Y = \cosh^{-1} \left[\frac{c^2 t^2 - (r^2 + r_0^2 + Z^2)}{2 r r_0} \right], \quad (14)$$

$$D_{\pm\pm} = \frac{\sin \left[\frac{\pi}{\theta_w} (\pi \pm \theta_0 \pm \theta) \right]}{\cosh \left[\frac{\pi Y}{\theta_w} \right] - \cos \left[\frac{\pi}{\theta_w} (\pi \pm \theta_0 \pm \theta) \right]}. \quad (15)$$

In Eq. (13), s_0 is the rate of mass injection by the source and c is the sound speed. It is understood that the mth finite-length wedge apex has a diffracted response that is zero outside of the time interval $[t_{a_m}, t_{b_m}]$. The factor ε_m can take on the value of 1.0 or 0.5 depending on the symmetry of the finite-length (physical) apex about the least time point on the infinite length (virtual) apex that contains it. Figure 1 shows a schematic of the gridded surface tessellation and gives details of the wedge specific coordinate system used in the Biot–Tolstoy solution.
FIG. 1. (a) The decomposition of a 2D surface into triangular facets with line segment **AB** coincident with a finite-length wedge apex. **Q** is the point on the associated infinite apex for the least time of any source-to-apex-to-receiver transmission. (b) Side and (c) plan views of the wedge geometry used in the Biot–Tolstoy solution.

For a fixed source emission time τ, sampling the impulse response function in time t, at interval Δt, determines, after discrete Fourier transform (DFT), a time-variant transfer function, $H(f_i, \tau)$, and (discrete) transform variable, f_i. $H(f_i, \tau)$ is defined on principal interval, $-f_{\text{Nyq}} \leq f_i \leq f_{\text{Nyq}}$, the highest frequency of which is the Nyquist frequency for the received frequency: $f_{\text{Nyq}} = (2\Delta t)^{-1}$. The finite extent of the rough surface ultimately limits the length of impulse response function and determines the received frequency resolution, $\Delta f = 1/N\Delta t$. The discrete received frequencies are given by $f_i = -f_{\text{Nyq}} + (i-1)\Delta f$, where i is a positive integer that is no greater than $N+1$. Based on past experience with static sinusoids and sea surfaces, choosing Δt so that f_{Nyq} is about an order of magnitude larger than the highest received frequency of interest (f_{max}) is usually adequate to make the effects of aliasing acceptably small in the received frequency band of interest.

Similarly, for a fixed reception frequency, f_i, sampling the transfer function $H(f_i, \tau)$ as it varies with source emission time τ (M samples at interval $\Delta\tau$) introduces, after the corresponding DFT, another transform variable that can be identified as the discrete source frequency, $v_j = -v_{\text{Nyq}} + (j-1)\Delta v$. Here, j is a positive integer that is no greater than $M+1$. The

discrete bifrequency function, $B(f_i, v_j)$, that results after this second DFT is specified in a two-dimensional frequency space over a rectangularly shaped principal band that is limited in one dimension by $-f_{Nyq} \leq f_i \leq f_{Nyq}$ and the other by $-v_{Nyq} \leq v_j \leq v_{Nyq}$. Here, the source Nyquist frequency, $v_{Nyq} = (2\Delta\tau)^{-1}$, should be large enough to satisfactorily minimize the "folding" of high-frequency information down into the principal frequency band.

There is usually some numerical efficiency that can be gained by bandshifting or heterodyning the principal interval associated with the source frequency, $-v_{Nyq} \leq v_j \leq v_{Nyq}$, so that for each received frequency f_i the discrete bifrequency function is centered on the energetic part of the spectrum. For the problems considered in this paper where the Doppler shifts are a small fraction of the source frequency, it is expected that nearly all of the scattered energy will be centered about the line $v=f$. Multiplying the sampled transfer function, $H(f_i, \tau_j)$, by a time-harmonic signal, $\cos(2\pi f_i \tau_j)$, prior to the second DFT (involving τ and v) has the effect of specifying the discrete bifrequency function over a stair-stepped principal interval that straddles the line $v=f$. The received spectrum is obtained by holding the source frequency fixed and examining (in increments of Δf) the bifrequency function from one horizontal limit of the stair-stepped principal band to the other. The Doppler spectrum is simply the received power spectrum expressed in terms of the shift frequency variable, $\eta = f - v$.

IV. EXAMPLE CALCULATIONS AND COMPARISONS

In this section, the extension of the WA method to time-variant scattering problems is used to calculate the frequency spectrum of the scattered pressure in a variety of backscattering scenarios involving moving single- and two-component sinusoidal surfaces, time-evolving sea surfaces, moving receivers, and static point sources. Moving periodic surfaces were particularly useful for an initial evaluation of the time-variant WA method because under far-field conditions they provide discrete conditions for constructive interference, and a generalized grating equation is available to provide an independent prediction for the shifted source and received frequencies associated with different diffracted orders.

To check the energy partition among different diffracted orders, a small wave-height approximation (SWHA) perturbation theory for moving standing wave surfaces that has been modified to correctly account for the basic kinematics of the problem[10] is used as a standard (see the Appendix). In Ref. 10, it is shown that by treating the kinematics of the moving surface scattering problem in the time domain, an explicit quasistatic or frozen surface approximation naturally occurs prior to the small wave-height approximation. In the standard approach, the frozen surface approximation occurs as a result of the SWHA itself. It was also shown in Ref. 10 that the standard SWHA approach predicted (for the periodic surfaces) upshifted diffracted orders that lost energy, and downshifted diffracted orders that gained energy. This unphysical behavior is corrected in an SWHA perturbation approach that makes an explicit frozen surface approximation prior to invoking the small wave-height approximation. The

backscattered pressure fields were calculated via this new SWHA perturbation theory, which was carried out to third order in dimensionless expansion parameter [see the Appendix]. These results were used to benchmark the time-variant WA method in the limit of very small roughness, and then to track the initial agreement and eventual departure of the WA method from the SWHA results as the surface roughness was increased from very small to moderate values.

In the final section, the time-variant WA method is applied to the problem of backscattering from fully developed, time-evolving seas due to different wind speeds. Again, SWHA perturbation theory is used as a benchmark but, because in this case the calculation of higher order terms is substantially more involved, these scattered pressures are restricted to the first-order estimates. To augment this stage of the validation, rather, to corroborate discrepancies between the time-variant WA predictions and first-order perturbation theory, the previously published work of Pourkaviani and Willemsen,[15] which looked at the effect of higher-order perturbative corrections on the location of the spectral peak, is introduced. Finally, the work by Fuks[16] is specialized for the particular cases studied and used to generate estimates for the spreading of the Doppler spectrum.

A. Moving sinusoidal surfaces and moving receivers: Comparisons with the grating equation

In this first set of example calculations, the time-variant WA method was used to calculate the Doppler spectrum of the pressure field backscattered from a 512-m-long (and wide) pressure-release, long-crested, sinusoidal surface having a wavelength of 8 m, that moved with x-directed velocity, $u_x = 8$ m/s

$$z_s(x,t) = a \cos\left[\frac{2\pi}{\Lambda}(x - u_x t)\right]. \tag{16}$$

The scattered signal was detected at a distant receiver (restricted to the x–z plane) that receded from the origin with velocity (in m/s) $\bar{v} = -10\hat{x} + 5.775\hat{z}$. The sound speed in the medium containing the source and receiver, and underlying the pressure-release boundary, was constant ($c = 1500$ m/s). The mean grazing angle of incidence was $30°$. At time $t=0$, when the first finite impulse ($\Delta t = 1.953 \times 10^{-4}$ s) was emitted by the source, the receiver was collocated with the source. Subsequent impulses were emitted by the source at 0.05-s intervals for a duration of 3.5 s. Source emissions propagated to and scattered from the sinusoidal surface and were collected at the moving receiver. After padding with zeros, an FFT ($N=32\,768$) of each impulse response was performed to yield the time-varying transfer function. For each discrete received frequency, the time-dependent transfer function was multiplied by the time-harmonic signal, $\cos(2\pi f_i \tau_j)$, as discussed in the previous section, again padded with zeros, and the $\tau \rightarrow v$ FFT was performed using $M=128$. The received power spectrum expressed in terms of the (Doppler)-shifted frequency $\eta = f - v$, is shown in Fig. 2(a). The combination of zero padding and time sampling rates resulted in a source frequency resolution that equaled the

Keiffer *et al.*: Impulse response of moving surfaces   1287
FIG. 2. Doppler spectra calculated by the time-variant WA model for backscattering (30° grazing) from a sinusoidal surface having an 8-m wavelength that is moving away from a fixed source with a horizontally directed speed of 8 m/s and detected at a receiver moving (a) away from the fixed origin of the surface and (b) toward the fixed origin of the surface.

received (and Doppler shift) frequency resolution: $\Delta\nu = \Delta\eta = 0.15\,625$ Hz. With the first diffracted order appearing at source frequency of 108.75 Hz, one can count in Fig. 2(a) five regularly spaced regions of constructive interference (diffracted orders, Bragg beams, Floquet modes, grating lobes, etc.) before the Doppler shift exceeds -10.0 Hz. At this point, diffracted orders appearing at higher source frequencies (above 600 Hz) become aliased due to an insufficient τ sampling rate. It can be seen that the most energetic of these aliased diffracted orders appear at positive Doppler shifts.

For this moving periodic interface problem, a grating equation can be derived that establishes the source and received frequencies required for constructive interference at the moving receiver[10]

$$\nu_n = n\left(\frac{c - u_x\hat{R}_{R_0} \cdot \hat{x}}{\Lambda(\hat{R}_S + \hat{R}_{R_0}) \cdot \hat{x}}\right), \qquad (17)$$

$$f_n = n\left(\frac{c + u_x\hat{R}_S \cdot \hat{x}}{c}\right)\left(\frac{c - \hat{R}_{R_0} \cdot \bar{v}}{\Lambda(\hat{R}_S + \hat{R}_{R_0}) \cdot \hat{x}}\right). \qquad (18)$$

When applied to the current problem, Eqs. (17) and (18) predict constructive interference for source frequencies that are integral multiples of 108.75 Hz, received frequencies that are integral multiples of 106.92 Hz, and received Doppler shifts, $\eta_n = f_n - \nu_n$, that are positive integral multiples of -1.83 Hz.

In Fig. 2(b), this numerical experiment is repeated with the direction of the sinusoid reversed ($u_x = -8$ m/s). In this case, the motion of the receiver is almost compensated by the motion of the surface. The result was that the source frequencies that allowed for constructive interference (107.75 Hz/order) at the receiver were slightly lower than their static values (108.25 Hz/order) and the Doppler shifts were small (0.16 Hz/order). Tables I and II compile for these two numerical experiments a comparison between WA-

TABLE I. The source frequencies (Hz) and Doppler shifts (Hz) at which diffracted orders (constructive interference) occur for the numerical experiments shown in Fig. 2(a). Comparison is between the time-variant WA model and the grating equations [Eqs. (17) and (18)].

predicted source and Doppler shift frequencies and the grating equation values. For all nonaliased orders, the time-variant WA model predictions were in agreement with the grating equation predictions to within the resolution of the numerical computation ±0.15 625 Hz. Before leaving this section, we note that the surface and receiver motion cause the conditions for constructive interference to change, and so both the source and received frequencies are altered as a result. Diffracted orders manifesting negative (positive) Doppler shifts are accompanied by source frequencies that are higher (lower) than the static surface values, which in this case would be 108.25 Hz/order.

B. Standing wave surfaces: Comparisons with SWHA perturbation theory

Employing a scattering geometry identical to the one used in the previous section, the time-variant WA model was used to calculate the Doppler spectrum from a series of five different standing wave surfaces

$$z_s(x,t) = 2a \cos[2\pi x/\Lambda]\cos[2\pi Ft]. \quad (19)$$

In all cases, the opposite traveling sinusoids producing the standing wave pattern had wavelengths of 8.0 m, x-directed speeds of ±10.0 m/s, $F=±1.25$ Hz, and with amplitudes (a) that ranged from 0.0125 to 0.5 m. The Doppler spectra of the pressure fields backscattered from four of these

TABLE II. The source frequencies (Hz) and Doppler shifts (Hz) at which diffracted orders (constructive interference) occur for the numerical experiments shown in Fig. 2(b). Comparison is between the time-variant WA model and the grating equations [Eqs. (17) and (18)].

surfaces are shown in Fig. 3. It should be noted that in each case, the dynamic range of the plot is constant (45 dB), but the maximum values plotted are adjusted to accommodate the most energetic diffracted order.

Beginning with Fig. 3(a), the smallest amplitude surface where $a=0.0125$ m, it can be seen that there are only three diffracted orders that appear to be detectable. One of these orders, the unshifted one, is very weak compared to the other two. Based on perturbation theory (see the Appendix), this is to be expected since, at the received frequencies (f) where these first diffracted orders appear, the dimensionless expansion parameter, ka, is very small compared to 1 ($ka \approx 0.005$). Since ka is small, the Doppler spectrum should resemble the linear superposition of the individual Doppler spectra from each of the two opposite-traveling sinusoidal components considered alone.

Now consider Fig. 3(b), where, after increasing the surface amplitude a to 0.025 m, two additional diffracted orders appear. These additional regions of constructive interference fall along lines that pass through the origin and the first diffracted orders. From the earlier calculations shown in Fig. 2, it is known that these two newly visible diffracted orders depend entirely on one sinusoid or the other. It is interesting to note that of the three diffracted orders with source frequencies near 216 Hz, the zero-shifted diffracted order, which depends on both sinusoidal components, has a scattered intensity that is 6 dB stronger than either of the other two.

In Fig. 3(c), the effect of increasing amplitude a to 0.1 m is shown. Four more diffracted orders are now visibly energized. The conclusion of this series of plots is shown in Fig. 3(d). Here, the backscattered Doppler spectrum is plotted for a standing wave composed of opposite-traveling sinusoids having surface wave-height amplitudes equal to 0.5 m. Almost a dozen diffracted orders are now detectable.

Table III contains a list of (normalized) scattered intensities from the spectral peaks of the time-variant WA data shown in Fig. 3. Also listed in Table III are the locations of the various diffracted orders, that is, the source and shift frequencies (received–source) where these peak spectral intensities occur. Calculations for the peak scattered intensities and their locations were also made using SWHA perturbation theory under the assumption that true plane waves and infinite surfaces were involved. In those calculations, the details of which are discussed in the Appendix, terms up to third order or in the dimensionless expansion parameter ka were retained. To facilitate a comparison between SWHA perturbation theory and the time-variant WA method for the partition of the scattered energy among the various diffracted orders, the following normalization scheme was developed. For both calculation methods, but independent of each other, the intensity of the most energetic diffracted order for the least rough surface ($a=0.0125$ m) was set to 0 dB and all other intensities were scaled relative to this value. Because in this smallest roughness case both the WA model and perturbation theory identified the same diffracted order as the most energetic, this self-normalization procedure allowed for an extended comparison between the two models.

In determining the validity of the time-variant WA

FIG. 3. Fixed source, fixed receiver Doppler spectra calculated by the time-variant WA model for monostatic backscattering (30° grazing) from a standing wave surface composed of oppositely traveling sinusoidal surfaces ($\Lambda=8.0$ m, $F=\pm1.25$ Hz) each having surface amplitudes of (a) 0.0125 m; (b) 0.025 m; (c) 0.1 m; and (d) 0.5 m.

method to predict the partition of scattered energy among the available diffracted orders, it is critical that there be agreement with the SWHA results in the "small roughness" regime where perturbation theory is expected to be accurate. From Table III, it can be seen that the agreement between the two models is excellent (less than 0.3-dB difference) for all detectable orders up to a surface roughness of $a=0.025$ m. Then, as expected when the surface amplitude increases, more diffracted orders become energized and the two models begin to depart from each other. This departure can be seen first in the diffracted orders at higher source frequencies of the $a=0.05$ m surface. When the surface amplitude reaches $a=0.5$ m, the strong agreement has significantly eroded. A notable exception to this trend is the second-order scattered intensities; the SWHA results track well against the time-variant WA model for all of the standing wave surfaces in Table III.

Before leaving this section, the following observation is worth noting and discussing. Table III shows that, in all cases, upshifted diffracted orders are slightly more energetic than their downshifted counterparts. While this result can be anticipated from the kinematics, the standard formulation of SWHA perturbation theory for moving surfaces would have predicted just the opposite relationship between scattered intensity and Doppler shift. As previously stated in this paper, the perturbation calculations were based on an approach in which an explicit frozen surface approximation is made before invoking the small roughness approximation [see the Appendix]. As a result, this error in which the upshifted diffracted orders are less energetic than their downshifted counterparts is corrected.

C. Application to sea surfaces

The results of the numerical experiments discussed in the previous section show that the time-variant WA method yields results that agree with SWHA perturbation theory in the limiting circumstance where that standard is known to be accurate. Those "two-component" results also demonstrate the increasingly important role that higher-order terms play as the magnitude of the dimensionless expansion parameter increases. When the scattering surface is composed of a broad band of spatial scales, the number of significant contributions to the overall Doppler spectrum that come from higher-order terms can proliferate. These higher-order terms contribute to the received spectrum with different Doppler shifts, sometimes contributing to the same locations in the two frequency spaces of the Doppler spectrum, and sometimes not. It is not at all clear how their cumulative effect will alter the regime over which first-order perturbation can be considered accurate. An implementation of higher-order perturbation theory for the moving multiscale interface scattering problem is beyond the scope of the current study. However, it is known from the published literature that the details of the surface motion can affect the validity of SWHA perturbation theory. In a study of backscattering from moderate wind speed, 2D, isotropic seas, Pourkaviani and Willemsen[15] showed that the effect of including the next few higher-order perturbative corrections in calculations for the scattered intensity was to move the peak of the Doppler spectrum away from the expected Doppler shift of the Bragg component and toward *smaller* (lower) Doppler shifts. For the assumed monostatic backscatter geometry, where k is the scattered wave number and ψ is the grazing angle, the Doppler shift associated with the Bragg-scale component is

$$\eta_{\text{Bragg}} = \frac{1}{2\pi}\sqrt{2gk\cos\psi}. \tag{20}$$

The results that follow demonstrate that this change in the location of the spectral peak away from the expected first-order Doppler shift is not, as some have suggested,[17] an artifact of scattering from isotropic seas. This phenomenon can be reproduced by the time-variant WA method for backscattering from anisotropic, 2D seas when the scattering plane is oriented crosswind to the main wind/wave direction. It is also shown, to our knowledge for the first time, that windward-oriented backscattering geometries can yield spectra that peak at Doppler shifts that *exceed* the shift of the Bragg component.
FIG. 4. Comparison of the first four impulse responses for monostatic backscattering from time-evolving seas that are traveling away from the source/receiver location. The plot shows the first 0.05 s of impulse responses that were approximately 0.3 s long. The time separation between pings was 0.1 s. The wind speed for this example was 5 m/s and the grazing angle was 30°.

The time–variant WA model was used to compute the average backscattered Doppler spectrum from ensembles of 2D time-evolving sea surfaces. The surfaces used in this study were modeled as fully developed seas having a $\cos^2(\phi/2)$ azimuthal dependence. Here, the wind direction is assumed to be into the $\phi=0°$ direction, and each spectral component of the surface was time evolved according to the dispersion relation for ocean gravity waves. Each surface realization had a Pierson–Moskowitz roughness spectrum that was due a wind speed (at 10-m height, U_{10}) of 5, 10, or 13 m/s. Surface realizations having the desired roughness spectrum were generated on a uniform 2D grid ($\Delta x=\Delta y =0.245$ m) having 1024 points on a side. The length of the surface generated was 251.3 m, which was long enough and finely sampled enough to include almost all of the expected surface variance as well as the longest waves having a significant contribution to the total variance. As in the previous examples, the sound speed in the medium containing the source and receiver was constant ($c=1500$ m/s), a monostatic geometry was assumed, and the nominal grazing/ scattering angle was 30°. Backscattering geometries oriented windward and crosswind to the main wind/wave direction were considered. A finite impulse ($\Delta t=1.953\times 10^{-4}$ s) was emitted by a distant source at 0.1-s intervals for 8.0 s. The source impulse propagated to, and scattered from, the quasi-static sea surface, and was then collected at the receiver. In Fig. 4, the beginning 0.05 s of the first four impulse re-

sponses ($\tau=0.0$, 0.1, 0.2, and 0.3 s) are shown. Note that, as expected for monostatic backscattering from seas moving away from the source/receiver, in the successive pings certain features of the time series can be seen arriving at later and later times.

After applying a Parzen window[18] to each impulse response and after padding with zeros, an FFT ($N=32\,768$) of each impulse response was performed to yield a time-varying transfer function. For each discrete received frequency, the time-dependent transfer function was then band-shifted as discussed previously, again windowed and padded with zeros, and the second FFT ($M=128$) was performed. This arrangement led to a source frequency resolution that equaled the received frequency resolution (and hence the Doppler shift resolution): $\Delta\upsilon=\Delta\eta=0.156\,25$ Hz. When identical signal processing was applied to the progression of impulse responses from an equivalent *static* surface, the spectral width of the windowed response could be measured. It was found that the scattered intensity was peaked on zero Doppler shift and dropped from this peak value with increasing Doppler shift. The scattered intensity was down by more than 4 dB for Doppler shifts greater than $\pm 0.156\,25$ Hz. Sidelobes from the Parzen window were more than 50 dB down from the mainlobe.

The average Doppler spectrum of the received signal was calculated from 15 realizations of the same sea surface spectrum. For each ensemble-averaged Doppler spectrum
FIG. 5. Ensemble-averaged Doppler spectra calculated by the time-variant WA model for monostatic backscattering (30° grazing) from a fully developed sea due to 5-m/s winds that are oriented (a) windward and (b) crosswind to the scattering plane.

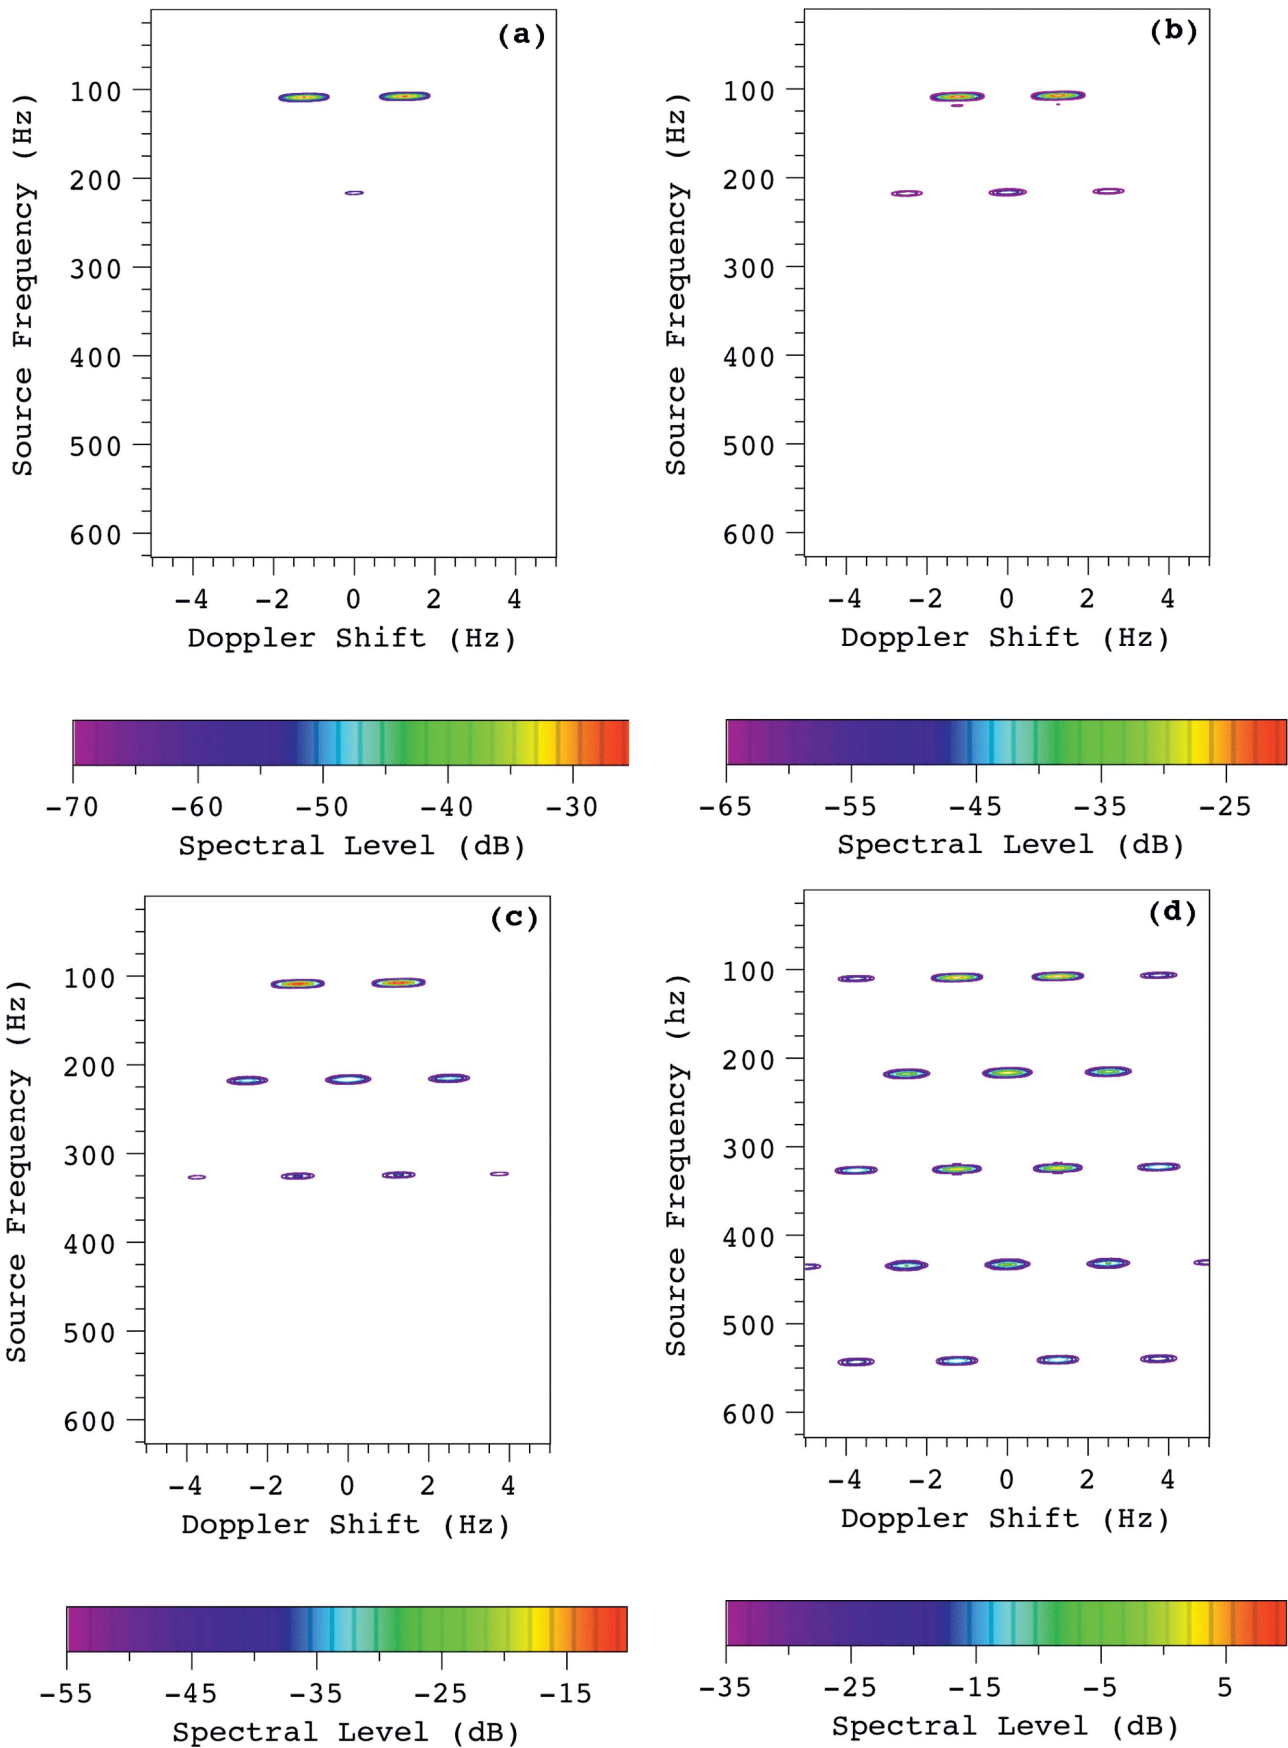
and for each source frequency, the peak level of the Doppler spectrum was set to 0 dB and all other spectral levels, occurring at other frequency shifts but having the same source frequency, were scaled accordingly. The purpose of this normalization procedure was to make more identifiable the spectral peak for each source frequency. In each example shown, the location of the expected Doppler shift from first-order perturbation theory is plotted as a function of source frequency. To augment the analysis, spectral half-width predictions based on the work of Fuks[16] are also plotted. These predictions are based on a two-scale scattering theory and purport to include broadening due to motion of the ripple and large-scale wave components. For the assumed scattering geometry and Pierson–Moskowitz wave spectrum, the spectral half-width (Δ) given by Fuks and defined as the standard deviation of the instantaneous frequency fluctuation, reduces to

$$\Delta = 1.24\left(\frac{f}{2\pi c}\right)(\sin^2 \psi + \cos^2 \psi \cos^2 \phi)U_{10}. \qquad (21)$$

In the first pair of results, the Doppler spectra for windward and crosswind azimuthal orientations are calculated for seas due to winds of 5 m/s and plotted in Figs. 5(a) and 5(b).

Superimposed on each of these plots is a solid line identifying the location of the spectral peak as predicted by first-order perturbation theory. Also drawn on each plot is a pair of dashed lines which indicate the spectral half-width according to the predictions of Fuks. This first example is the case of low wind speed and, consequently, a low to moderate surface variance ($\sigma_5^2 = 0.0248$ m^2). As expected in this situation, first-order perturbation theory predicts the same location for the spectral peak as does the time-variant WA model over the entire range of source frequencies considered (25–1260 Hz). Note that, at the maximum received frequency shown in this plot, the perturbative expansion parameter, $k\sigma_5 < 1$. According to first-order perturbation theory, the azimuthal orientation of the scattering surface should not affect the location of the spectral peak. The time-variant WA results are in agreement with this prediction, and this supports the assertion that in this situation roughness at the Bragg spatial scale is the dominant source of scattering.

There are, however, differences between the two orientations that are worth noting and perhaps indicative of the onset of significant scattering associated with non-Bragg spatial scales. Specifically, both the time-variant WA model and Fuks results predict spectral widths that depend on azimuthal

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005


Keiffer et al.: Impulse response of moving surfaces   1293
FIG. 6. Ensemble-averaged Doppler spectra calculated by the time-variant WA model for monostatic backscattering (30° grazing) from a fully developed sea due to 10-m/s winds that are oriented (a) windward and (b) crosswind to the scattering plane.

orientation. While differing in absolute terms, both of these models predict that the Doppler spectrum in the windward orientation is spread more than in the crosswind orientation. There is also a reasonable agreement between these two models for the rate at which the spectral width grows with increasing source frequency. Note that in the crosswind case the spreading is more symmetric about the expected Bragg shift. In the windward case, the spectrum spreads preferentially toward larger Doppler shifts.

Moving on to the 10-m/s example (see Fig. 6), specifically for the windward orientation, it can be seen that, for source frequencies above about 400 Hz ($k\sigma_{10} > 1.05$), the thin solid line representing the spectral peak predicted by first-order perturbation theory no longer travels down the middle of the −1-dB (red) contours of the WA data. Above about 400 Hz the WA spectral peak is consistently located at slightly greater (more negative) Doppler shifts. This is not the situation for the crosswind orientation. There, the two predictions remain in agreement over the full range of source frequencies. With regard to the spectral widths, similar observations noted for the 5-m/s surfaces apply but are somewhat more demonstrative: at any source frequency the Doppler spectrum in the windward orientation is significantly

wider than in the crosswind orientation. The spectral width predictions of Fuks remain centered on the WA results better in the crosswind case than they do for the windward orientation. Finally, the Fuks prediction for rate at which the spectral width grows as the source frequency increases seems to track the WA results reasonably well.

In the final pair of plots for this section, the backscattered Doppler spectrum from seas due to 13-m/s winds is considered. In this case the surface variance is 1.34 m², so at received frequencies greater than about 200 Hz the perturbative expansion parameter is larger than 1. Trends already present in the lower wind-speed cases are now somewhat more pronounced. In the windward oriented case [Fig. 7(a)] it can be seen that above about 300 Hz the WA prediction for the spectral peak begins to move to higher Doppler shifts than expected from first-order perturbation theory and the Bragg component. Also, the prediction of Fuks for the spectral half-width is, even more noticeably, not centered on the WA prediction. More difficult to detect by eye, but still quite evident, is the trend of the WA prediction toward lower than expected Doppler shifts in the case of the crosswind oriented scattering geometry [Fig. 7(b)]. In this geometry it is clear that the WA prediction for the spreading in the Doppler spec-

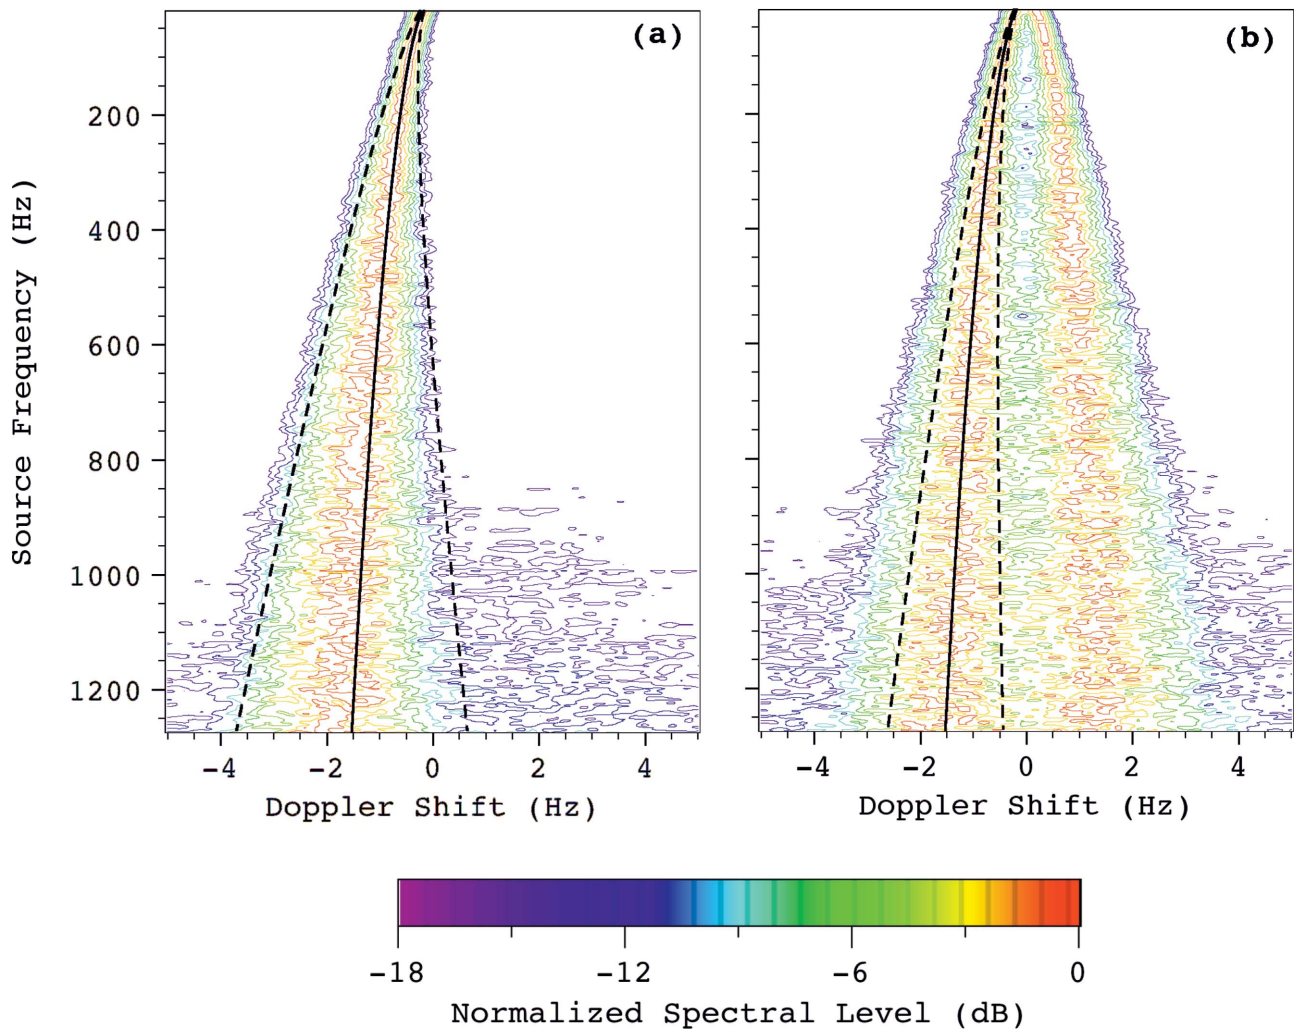
Keiffer *et al.*: Impulse response of moving surfaces


FIG. 7. Ensemble-averaged Doppler spectra calculated by the time-variant WA model for monostatic backscattering (30° grazing) from a fully developed sea due to 13-m/s winds that are oriented (a) windward and (b) crosswind to the scattering plane.

trum is preferentially towards lower Doppler shifts. At very small Doppler shifts there is evidence of significant overlap from the upshifted and downshifted components of the Doppler spectrum.

D. Identifying multiscale scattering contributions

In this last section, numerical experiments are presented that are designed to provide a closer look at the role that non-Bragg roughness scales have on the Doppler spectrum. By generating surface realizations from a sea surface roughness spectrum that is zero at wave numbers higher than $K = 1$ rad/m, one can ensure that the backscattered field that results contains no first-order perturbative contributions above about 138 Hz. That is, the scattered response can be interpreted as being due only to higher-order perturbative terms. Shown in Fig. 8 are the ensembled averaged (ten realizations) Doppler spectra for backscattering geometries oriented windward and crosswind (wind speed 5 m/s, 30° grazing angle). In the windward case [Fig. 8(a)], it can be seen that for source frequencies above 138 Hz there is sudden decay in the mainlobe of the Doppler spectrum. And, at higher frequencies, there appears to be a ghost-like replica of the lower (source) frequency part of the Doppler spectrum.

These higher-order contributions appear with Doppler shifts that are greater than the expected Bragg shift and account for the fact that in the windward orientation the spread in the Doppler spectrum is preferentially toward higher Doppler shifts. When the roughness or source frequency increases, higher-order contribution become more important and these can change the location of peak in the Doppler spectrum away from the expected Bragg shift and toward higher Doppler shifts.

Looking now at the crosswind results [Fig. 8(b)], it can be deduced that the higher-order terms contribute to the Doppler spectrum at Doppler shifts that are both higher and lower than the Bragg shift. In this orientation, there are surface wave components advancing on and receding from the source/receiver location. It can be seen that there is significant overlap near zero Doppler, and it is probably this behavior that causes the peak in the Doppler spectrum to squeeze toward lower than expected Doppler shifts.

V. CONCLUSIONS

A time-variant impulse response method has been proposed, developed, tested, and shown to provide new insights into different scattering problems involving moving surfaces.
FIG. 8. Ensemble-averaged Doppler spectra calculated by the time-variant WA model for monostatic backscattering (30° grazing) from wave number-truncated, fully developed sea due to 5-m/s winds that are oriented (a) windward and (b) crosswind to the scattering plane.

The method proposed is general, conceptually straightforward, and can easily incorporate moving sources and receivers. While the time-variant impulse response method has been developed specifically in this study to extend the capability of the WA model, the framework can be applied to other scattering models including those based in the frequency domain. First, calculations involving moving periodic surfaces and moving receivers were compared with a generalized grating equation to establish that the discrete Doppler shifts expected for these types of scattering problems were being modeled correctly. Then, SWHA perturbation theory, carried out to third order in the dimensionless expansion parameter, was used as a standard to validate that this new model predicted the correct energy partition among backscattered diffracted orders. Comparisons of the SWHA results with the time-variant WA model show very good agreement in the regime where SWHA is valid, and show a reasonable departure from the SWHA results in the regime where the perturbation approach is known to be dubious. The time-variant impulse response model was applied to time-evolving sea surfaces. The earlier results of Pourkaviani and

Willemsen,[15] which indicated that under isotropic conditions the peak in the Doppler spectrum could move from the expected Bragg shift toward smaller Doppler shifts, were confirmed. It was also shown that windward-oriented backscatter geometries can lead to a Doppler spectrum that peaks at higher than expected Doppler shifts.

ACKNOWLEDGMENTS

APPENDIX: SWHA PERTURBATION THEORY FOR STANDING WAVE SURFACES

The scattering surface under consideration consists of two oppositely traveling sinusoidal waves of equal amplitude a, angular frequency $\Omega \geqslant 0$, and spatial wave number $K \geqslant 0$.

The impulse response function $h(\bar{r},t;\bar{r}_0,\tau)$, at location $\bar{r}$ and time t, is the total acoustic field due to the impulsive, point source excitation (at location $\bar{r}_0$ and emission time τ) of the homogeneous, isospeed medium together with the standing wave boundary. Here $h(\bar{r},t;\bar{r}_0,\tau)$ is a solution to the scalar wave equation

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)h(\bar{r},t;\bar{r}_0,\tau) = 0, \tag{A1}$$

subject to the Dirichlet boundary condition on the moving surface

$$h[x,z_s(x,t),t;\bar{r}_0,\tau] = 0. \tag{A2}$$

The small wave-height approximation (SWHA) perturbation solution begins with a power-series expansion of the impulse response function in powers of wave-height parameter a

$$h(t;\tau) = \sum_{p=0}^{\infty} a^p h_p(t;\tau). \tag{A3}$$

Usually, the next step is to expand the boundary conditions (A2) in a Taylor series expansion about $z=0$. This implicitly introduces the arrival time $t_0 = \tau + \sqrt{(x_0-x)^2-(y_0-y)^2-z_0^2}/c$ and the quasistatic surface, $z_s(x,t_0)$. This approach also retains in the series expansion an explicit dependence of the surface height function on t which, owing to the operational properties of derivatives of the delta function, introduces quasistatic time derivatives of the surface height function. These additional terms lead to unphysical effects[10] which can be avoided simply by making an explicit frozen surface approximation prior to the Taylor series expansion of the boundary condition. When $r_0 \gg r$ and the source is constrained to the xz plane, then $t_0 \approx \tau + (r_0/c) - [(x \sin \theta_0 \cos \phi_0)/c]$, and, in the spirit of the SWHA, the time-varying surface $z_s(x,t)$ is replaced by an equivalent quasistatic surface, $\zeta(x,\tau) = z_s(x,t_0)$. In this case of a standing wave surface

$$\zeta(x,\tau) \approx 2a\cos(Kx)\cos(\Omega t_0). \tag{A4}$$

In the frozen surface approximation, the boundary condition becomes

$$h[x,\zeta(x,\tau),t;\bar{r}_0,\tau] = 0, \tag{A5}$$

and is expressed in a Taylor series expansion about $z=0$

$$0 = h\Big|_{z=0} + \zeta(x,\tau)\left[\frac{\partial h}{\partial z}\right]_{z=0} + \frac{\zeta^2(x,\tau)}{2}\left[\frac{\partial^2 h}{\partial z^2}\right]_{z=0}$$
$$+ \frac{\zeta^3(x,\tau)}{6}\left[\frac{\partial^3 h}{\partial z^3}\right]_{z=0} + \cdots . \tag{A6}$$

Substituting Eq. (A4) into Eq. (A6), collecting like powers in surface height parameter a, and requiring that individual coefficients of a^p must vanish generates the usual system of equations that defines terms in the expansion of the impulse response function. Sequential Fourier transforms using the convention

$$B(f;v) = \int_{-\infty}^{\infty}\int_{\infty}^{\infty} h(t;\tau)\exp[i2\pi(v\tau - ft)]dt\,d\tau, \tag{A7}$$

applied to both sides of these equations yield a corresponding set of equations that defines terms in a power-series expansion of the bifrequency function. Including powers up to the third furnishes the following approximation for the bifrequency function:

$$B(f;v) \approx \frac{1}{4\pi r_0}\sum_{m=-3}^{3}\sum_{n=-3}^{3}\delta\left(v - f + m\frac{\Omega}{2\pi}\right)\exp[i(k_{ix}$$
$$+ nK)x + \gamma_{m,n}z]\sum_{p=0}^{3} a^p C_{m,n}^p, \tag{A8}$$

where $\gamma_{m,n}$ is the vertical wave number

$$\gamma_{m,n} = \left[\left(\frac{2\pi v + m\Omega}{c}\right)^2 - (k_{ix} + nK)^2\right]^{1/2}, \tag{A9}$$

and $k_{ix} = -(2\pi v/c)\sin\theta_0\cos\phi_0$. Now, using $k = 2\pi f/c$ as the scattered wave number, the nonzero coefficients in Eq. (A9) are

$$C_{0,0}^0 = -1, \tag{A10}$$

$$C_{1,1}^1 = C_{-1,1}^1 = C_{1,-1}^1 = C_{-1,-1}^1 = ik\cos\theta_0, \tag{A11}$$

$$C_{1,1}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l}\gamma_{0,0}(\gamma_{-1,-1} + \gamma_{1,-1} + \gamma_{-1,1} + \gamma_{1,1}) + \gamma_{-1,1}\gamma_{0,2}\\ + \gamma_{1,1}\gamma_{0,2} + \gamma_{1,-1}\gamma_{2,0} + \gamma_{1,1}\gamma_{2,0} + \gamma_{1,1}\gamma_{2,2}\\ - \frac{1}{2}(2\gamma_{-1,1}^2 + 2\gamma_{1,1}^2 + \gamma_{-1,-1}^2 + \gamma_{1,-1}^2) + \frac{3}{2}[k\cos\theta_0]^2\end{array}\right|, \tag{A12}$$

$$C_{1,-1}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l}\gamma_{0,0}(\gamma_{-1,-1} + \gamma_{1,-1} + \gamma_{-1,1} + \gamma_{1,1}) + \gamma_{-1,-1}\gamma_{0,-2}\\ + \gamma_{1,-1}\gamma_{0,-2} + \gamma_{1,-1}\gamma_{2,-2} + \gamma_{1,-1}\gamma_{2,0} + \gamma_{1,1}\gamma_{2,0}\\ - \frac{1}{2}(2\gamma_{-1,-1}^2 + 2\gamma_{1,-1}^2 + 2\gamma_{-1,1}^2 + \gamma_{1,1}^2) + \frac{3}{2}[k\cos\theta_0]^2\end{array}\right|, \tag{A13}$$

$$C_{1,3}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l} \gamma_{-1,1}\gamma_{0,2} + \gamma_{1,1}\gamma_{0,2} + \gamma_{1,1}\gamma_{2,2} \\ -\frac{1}{2}(\gamma_{1,1}^2 + \gamma_{-1,1}^2) + \frac{1}{2}[k\cos\theta_0]^2 \end{array}\right|, \tag{A14}$$

$$C_{1,-3}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l} \gamma_{-1,-1}\gamma_{0,-2} + \gamma_{1,-1}\gamma_{0,-2} + \gamma_{1,-1}\gamma_{2,-2} \\ -\frac{1}{2}(\gamma_{-1,-1}^2 + \gamma_{1,-1}^2) + \frac{1}{2}[k\cos\theta_0]^2 \end{array}\right|, \tag{A15}$$

$$C_{-1,1}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l} \gamma_{0,0}(\gamma_{-1,-1} + \gamma_{1,-1} + \gamma_{-1,1} + \gamma_{1,1}) + \gamma_{-1,-1}\gamma_{-2,0} \\ + \gamma_{-1,1}\gamma_{-2,0} + \gamma_{-1,1}\gamma_{-2,2} + \gamma_{-1,1}\gamma_{0,2} + \gamma_{1,1}\gamma_{0,2} \\ -\frac{1}{2}(2\gamma_{1,1}^2 + 4\gamma_{-1,1}^2 + \gamma_{1,-1}^2 + 2\gamma_{-1,-1}^2) + \frac{3}{2}[k\cos\theta_0]^2 \end{array}\right|, \tag{A16}$$

$$C_{-1,-1}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l} \gamma_{0,0}(\gamma_{-1,-1} + \gamma_{1,-1} + \gamma_{-1,1} + \gamma_{1,1}) + \gamma_{-1,-1}\gamma_{-2,-2} \\ + \gamma_{-1,-1}\gamma_{-2,0} + \gamma_{-1,1}\gamma_{-2,0} + \gamma_{-1,-1}\gamma_{0,-2} + \gamma_{1,-1}\gamma_{0,-2} \\ -\frac{1}{2}(\gamma_{1,1}^2 + 2\gamma_{-1,1}^2 + 2\gamma_{1,-1}^2 + 4\gamma_{-1,-1}^2) + \frac{3}{2}[k\cos\theta_0]^2 \end{array}\right|, \tag{A17}$$

$$C_{-1,3}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l} \gamma_{-1,1}\gamma_{-2,2} + \gamma_{-1,1}\gamma_{0,2} + \gamma_{1,1}\gamma_{0,2} \\ -\frac{1}{2}(\gamma_{-1,1}^2 + \gamma_{1,1}^2) + \frac{1}{2}[k\cos\theta_0]^2 \end{array}\right|, \tag{A18}$$

$$C_{-1,-3}^3 = \frac{k\cos\theta_0}{4i}\left|\begin{array}{l} \gamma_{-1,-1}\gamma_{0,-2} + \gamma_{1,-1}\gamma_{0,-2} + \gamma_{-1,-1}\gamma_{-2,-2} \\ -\frac{1}{2}(\gamma_{-1,-1}^2 + \gamma_{1,-1}^2) + \frac{1}{2}[k\cos\theta_0]^2 \end{array}\right|, \tag{A19}$$

$$C_{0,0}^2 = \frac{k\cos\theta_0}{2}(\gamma_{-1,-1} + \gamma_{1,-1} + \gamma_{-1,1} + \gamma_{1,1}), \tag{A20}$$

$$C_{2,0}^2 = \frac{k\cos\theta_0}{2}(\gamma_{1,1} + \gamma_{1,-1}), \tag{A21}$$

$$C_{2,2}^2 = \frac{k\cos\theta_0}{2}(\gamma_{1,1}), \tag{A22}$$

$$C_{0,2}^2 = \frac{k\cos\theta_0}{2}(\gamma_{-1,1} + \gamma_{1,1}), \tag{A23}$$

$$C_{-2,-2}^2 = \frac{k\cos\theta_0}{2}(\gamma_{-1,-1}), \tag{A24}$$

$$C_{0,-2}^2 = \frac{k\cos\theta_0}{2}(\gamma_{-1,-1} + \gamma_{1,-1}), \tag{A25}$$

$$C_{2,-2}^2 = \frac{k\cos\theta_0}{2}(\gamma_{1,-1}), \tag{A26}$$

$$C_{-2,0}^2 = \frac{k\cos\theta_0}{2}(\gamma_{-1,-1} + \gamma_{-1,1}), \tag{A27}$$

$$C_{-2,2}^2 = \frac{k\cos\theta_0}{2}(\gamma_{-1,1}). \tag{A28}$$

Existing techniques in correlation spectroscopy, such as coda wave interferometry and diffusing acoustic wave spectroscopy, determine the average motion of scatterers or change in the propagation velocity from the temporal change of multiply scattered sound. However, neither of them gives an indication of the spatial extent of the change in the medium. This study is an extension of the technique coda wave interferometry, where multiply scattered waves are used to determine the change in the wave field due to a localized perturbation in the propagation velocity. Here, the propagation of multiply scattered sound is described using the diffusion approximation, which allows the cross-correlation function of the unperturbed and perturbed wave fields to be related to the localized change in the propagation velocity. The technique is tested numerically for two-dimensional (2D) acoustic waves using synthetic seismograms calculated using finite-differences before and after a small perturbation in the propagation velocity has been introduced. Despite the relatively small size and magnitude of the change, multiple scattering greatly amplifies small perturbations, making changes in the phase or travel time of the wave field visible in the later-arriving waveforms. Potential applications of this technique include nondestructive evaluation of inhomogeneous materials and time-lapse monitoring of volcanoes and highly heterogeneous reservoirs. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000827]

I. INTRODUCTION

Most imaging techniques using scattered waves rely on the single scattering approximation. Seismic imaging[1] mostly uses primary reflected waves to obtain an image of the subsurface. In many physical problems, however, waves are strongly scattered and the single scattering approximation is not a valid model for the propagation of waves through the medium. In such cases we have to use a model that accounts for the multiple scattering of waves and the associated attenuation. The diffusion model has been used with success to characterize a wide range of wave phenomena in strongly scattering media.[2–6] In this model, wave energy transport acquires a diffusive character, e.g., wave energy is transported in a process similar to heat diffusion. In medical imaging, for example, diffusing near-infrared light has been used to image localized heterogeneities of tissue.[7]

In many practical applications the medium changes over time, and therefore the image of the medium changes. We then would like to obtain time-lapse measurements in order to monitor temporal changes in the medium. Examples of applications where detecting temporal changes may be useful include the monitoring of volcanoes, oil reservoirs, radioactive waste disposal sites, and fluidized suspensions. In reflection seismology, dynamic reservoir characterization provides optimal management of a reservoir, which leads to increased production. Time-lapse (4D) reflection seismic aims at inferring changes from the medium from changes in the seismic amplitudes and/or travel times from seismic reflection data that have been acquired at two different times. As an example, a 4D dataset recorded at Weyburn Field, Canada, has been used to infer time-lapse changes in the oil reservoir caused by a massive miscible CO_2 flood to enhance oil recovery.[8,9] The main goal of these 4D studies is to extract information about local changes in the reservoir using mainly the amplitude information.

The fine structure of strongly scattered waves can provide a wealth of new information in seismology, ultrasonics, acoustics, and other fields that study wave propagation in heterogeneous media.[10] Multiple scattering theory has been used to determine the number and the scattering strength of scatterers in motion inside a highly reflecting cavity, and more specifically for fish counting in a tank.[11,12] In biophysics and medical imaging, diffusing photons are now used to view body function and structure after it was found that photon transport within tissues is dominated by scattering rather than absorption.[7] Diffuse transmission spectroscopy[13] has been used to probe the structure of opaque materials such as colloids, foams, and sand, using multiply scattered photons.

Multiply scattered waves have also been used to study the dynamics of complex media and turbulent fluids. Diffuse light spectroscopy[7] has been used to measure the spatial variations in the absorption and scattering of large tissue volumes. Diffusing wave spectroscopy (DWS) is a technique in which multiply scattered light is used to study the dynamics

of colloidal suspensions;[14] this technique was adapted later to acoustic waves.[15] This technique estimates the average motion of the scatterers from the temporal fluctuations of multiply scattered sound. In this technique, the propagation of multiply scattered sound is described using the diffusion equation, which makes it possible to relate the temporal field fluctuations with the dynamics of the multiple scattering medium. Recently, coda waves have been used to study the temperature dependence of the seismic velocity in granite[16] and in a reverberant three-dimensional cavity[17] using a technique called *coda wave interferometry*. In this technique, multiply scattered waves are used to detect temporal changes in a medium by using the scattering medium as an interferometer. For small changes in the medium, estimates of this perturbation can be obtained from multiply scattered waves by a cross correlation in the time domain.[16] For larger changes, the decay of the correlation of the diffuse field is related to distortion and is an interesting system-dependent quantity.[17] Coda wave interferometry has also been used to determine the relative location of earthquakes for scattered waves.[18]

In none of those approaches has an attempt been made to determine the spatial extent of the change or local perturbation in the medium. When the random multiple scattering medium changes over time, changes in the diffuse field are related to changes in the medium. The sensitivity to perturbations in the medium enhances as the scattering order increases and thus becomes an interesting tool to detect the appearance of a very small defect in a multiple scattering sample.[19] In this study we develop a technique that relates the localized changes in the propagation velocity of the medium to the travel time change of the multiply scattered waves. As in diffuse wave spectroscopy, this technique relies on the diffusion approximation of the intensity in strongly scattering media. Therefore, we can model the mean travel time change of waves with propagation time t before and after a small and localized change in the propagation velocity has been introduced in the medium. This work is an extension of coda wave interferometry in the sense that it accounts for localized changes in the propagation velocity of the scattering medium. Thus, we are able to model the fluctuation in the phase of the multiply scattered wave field for a given localized time-lapse velocity perturbation of the multiple scattering medium. We assess the validity of our theory using finite-difference simulations of multiple scattering of acoustic waves in 2D media.

The paper is divided into five parts. Section II explains how the diffusion approximation is used to describe energy transport in strongly scattering media and its relation with a random walk process. Section III introduces coda wave interferometry and how it can be used to obtain an estimator for the mean travel time change of scattered waves. In Sec. IV we derive theoretically an expression for the mean travel time change of multiply scattered waves by using the analogy between a diffusion process and random walks. The main result of this work is the expression that relates the mean travel time change of multiply scattered waves with the localized perturbation in the propagation velocity of the medium. In Sec. V we validate the theory with numerical experiments.

amples using finite-difference synthetic seismograms. We found good agreement between our theory and results from the finite-difference seismograms, despite some fluctuations that are analyzed in Sec. VI. Finally, we discuss applications and limitations of the technique in Sec. VII.

II. DIFFUSION ENERGY TRANSPORT AND RANDOM WALKS

The transport of energy through a strongly scattering medium has attracted considerable attention in numerous fields of physics, such as astrophysics, optics, acoustics, solid-state physics, and heat conduction. In any of these fields, one studies a pulse of energy that propagates through the medium with an intensity $P(r,t)$. The diffusion equation describes the propagation of the average intensity in a multiple scattering medium.[20] In a two-dimensional medium of infinite extent, constant scattering properties, without intrinsic attenuation, and in the long-time limit,[21] the average intensity at **r** can be approximated by the solution of the diffusion equation

$$P(\mathbf{r},t) = \frac{1}{4\pi Dt} \exp\left[\frac{-r^2}{4Dt}\right], \qquad (1)$$

where r is the distance to the source and D is the diffusion constant. Equation (1) describes the temporal evolution of the average intensity after the waves have scattered multiple times from small-scale heterogeneities. Figure 1 shows the average intensity for receivers located 500, 1500, 2500, and 3500 m away from the source. The actual mean intensities were calculated after averaging over 100 different receiver locations after propagating a seismic wave field through a medium with random velocity fluctuations using finite differences as described in Sec. V. Figure 2 shows one of the seismograms calculated for a source–receiver distance of 2500 m. Despite the random appearance of the individual seismogram, an ensemble of such seismograms yields an average intensity that obeys the diffusion equation. The mean intensities from the finite-difference simulations are shown as solid curves, whereas the best diffu-
FIG. 2. Example of a finite-difference seismogram for a source–receiver distance of 2500 m after propagating a finite-bandwidth pulse through a medium with random velocity fluctuations.

FIG. 4. Observed distribution of distances for the 5000 realizations of random walks (open circles) versus the diffusion curve (solid line) for $t=3$ s.

sion fits [Eq. (1)] are shown as dashed lines. Notice the good agreement between the diffusion curves and the average intensities.

Given a seismogram such as the one shown in Fig. 2, it is extremely difficult to determine if a specific trajectory gives rise to an energy impulse at a specific time t. The problem is simplified if, instead of considering one specific trajectory, we consider the average wave field obtained after summing the contributions of all possible trajectories arriving at the receiver at time t. When scattering is strong and waves follow infinitely many trajectories, wave propagation can be considered as a random walk process. This simplifies the problem because a random walk process can on average be described with the solution of the diffusion equation. This provides us with the advantage of a simple physical picture where the diffusively scattered wave field is represented as the sum of partial waves traveling along various diffuse paths.[22]

The multiply scattered waves travel through the medium in a random walk process that is characterized in n-D (where n is the number of dimensions) by the transport mean free path l^*, the energy velocity v_e, and the diffusion coefficient $D=v_e l^*/n$.[15] Figure 3 shows three realizations of random

walk in 2D calculated numerically using $D=3.45 \times 10^5$ m²/s and $v_e=5300$ m/s. The random walks were calculated until a maximum elapsed time $t=3$ s. If we calculate many realizations, the distribution of distances r traveled from the origin at a given time t is given by Eq. (1). This is shown in Fig. 4, were we show the distribution of distances traveled for the random walk particles for 5000 different realizations of random walks starting from the origin with total elapsed time $t=3$ s. In Sec. IV we use the random walk approximation to multiple scattering to derive an expression for the mean travel time of waves in a strongly scattering medium.

III. CODA WAVE INTERFEROMETRY

When a strongly scattering medium changes, the speckle pattern of multiply scattered waves changes, which reflects the changes that occur in the interference of waves traveling with different scattering paths through the sample. Multiply scattered waves are useful in such situations, because they are increasingly sensitive with time to the perturbations in scatterer locations or perturbations in the propagation velocity of the medium. This increased sensitivity is due to the fact that waves bounce more often among scatterers as time increases, and as a result, small changes in the medium are amplified through multiple scattering.

For a small perturbation in the propagation velocity, an estimate of this perturbation can be obtained by a time-windowed cross correlation of the unperturbed and perturbed scattered waves.[23] The unperturbed wave field $u_{\text{unp}}(t)$ can be written as a summation of waves over all possible trajectories T[24]

$$u_{\text{unp}}(t) = \sum_T A_T(t), \qquad (2)$$

where a trajectory T is defined by the sequence of scatterers that a particular multiple scattering wave encounters, and $A_T(t)$ is the corresponding waveform. For diffusive wave propagation the trajectories T can be thought of as a collection of random walks.

FIG. 3. Three realizations of the random walk characterized by $D=3.45 \times 10^5$ m²/s and $v_e=5300$ m/s.

C. Pacheco and R. Snieder: Monitoring with multiply scattered waves

When we introduce a small perturbation of the propagation velocity, the dominant effect on the multiple scattering waveform is a travel time perturbation τ_T of the wave that travels along the trajectory T

$$u_{\text{per}}(t) = \sum_T A_T(t - \tau_T). \tag{3}$$

We can characterize the change in the wave field using the time-windowed cross-correlation function[23]

$$C_{\text{up}}^{(t,t_w)}(t_s) = \int_{t-t_w}^{t+t_w} u_{\text{unp}}(t')u_{\text{per}}(t' + t_s)dt', \tag{4}$$

where t denotes the center of a time window of length $2t_w$, and t_s is the lag time for the correlation. When Eqs. (2) and (3) are inserted into Eq. (4), double sums $\Sigma_{TT'}$ appear. We assume that in these double sums, the cross terms related to different trajectories $(T \neq T')$ are incoherent and average out to zero when the mean of the source signal vanishes. The contribution of the cross terms is estimated in Ref. 25. A dimensionless measure of the change of the wave field is given by the time-windowed correlation coefficient, which is given by

$$R^{(t,t_w)}(t_s) = \frac{\int_{t-t_w}^{t+t_w} u_{\text{unp}}(t')u_{\text{per}}(t' + t_s)dt'}{\left(\int_{t-t_w}^{t+t_w} u_{\text{unp}}^2(t')dt' \int_{t-t_w}^{t+t_w} u_{\text{per}}^2(t')dt'\right)^{1/2}}. \tag{5}$$

For time shifts t_s much smaller than the dominant period of the wave, a second-order Taylor expansion of the $A_T(t' + t_s - \tau_T)$ in τ_T gives[23]

$$R^{(t,t_w)}(t_s) = 1 - \frac{1}{2}\bar{\omega}^2\langle(\tau - t_s)^2\rangle_{(t,t_w)}, \tag{6}$$

where $\bar{\omega}$ is the dominant frequency of the wave. In this expression $\langle \ldots \rangle_{(t,t_w)}$ denotes the average over all waves that arrive in the time window $(t-t_w,t+t_w)$ with a weight factor that is equal to the intensity of the waves.[23] Thus, averages are taken with a weight factor that is given by the intensity of each wave. This means that in this work, the average travel time change $\langle\tau\rangle_{(t,t_w)}$ is given by an average of the travel time change of individual waves with different trajectories T arriving on the time window $(t-t_w,t+t_w)$, i.e.,

$$\langle\tau\rangle_{(t,t_w)} = \frac{\sum_T w_T(t,t_w)\tau_T(t,t_w)}{\sum_T w_T(t,t_w)}, \tag{7}$$

where the weighting factor $w_T(t,t_w)$ is given by the intensity for the diffuse waves arriving on the time window $(t-t_w,t+t_w)$.

IV. MEAN TRAVEL TIME CHANGE IN THE DIFFUSION REGIME

A. Random walk probabilities

Each random walk from the source to the receiver has an associated probability which depends on the diffusion of the intensities in the strongly scattering medium. Recalling Eq. (7), and considering waves arriving on the time window $(t$
FIG. 5. A random walk particle going from source $\mathbf{s}$ at the origin to volume element dV at $\mathbf{r}'$ on time t', and then to receiver at $\mathbf{r}$ on time $t-t'$.

$-t_w,t+t_w)$, the average or mean travel time change $\langle\tau\rangle$ is a weighted average of the travel time changes of the individual trajectories T, i.e.,

$$\langle\tau\rangle = \frac{\sum_T I_T \tau_T}{\sum_T I_T}, \tag{8}$$

where I_T is the intensity or probability associated with the trajectory T, which can be calculated using the solution to the diffusion equation. In the following, we show how to derive an expression for this intensity for a given source and receiver location.

Let us assume that the seismic energy transport can be described as a diffusion process. Thus, the space and time evolution of the diffusive intensity in the medium due to an intensity impulse at the origin at time $t=0$ is given by $P(\mathbf{r},t)$, as defined in Eq. (1). In multiple scattering of waves, this diffusive energy corresponds to the ensemble averaged or mean intensity $\langle I\rangle$.

We can interpret $P(\mathbf{r},t)$ in a different way, regarding diffusion as a random walk process. In random walk theory, the product $P \times dV$ represents the probability of a particle on a random walk of visiting a volume element dV at location $\mathbf{r}$ at a given time t.[26] If, at time $t=0$, a normalized intensity impulse is generated at the source, the total energy within some region V at some later time is given by the integral

$$W(V,t) = \int_V P(r,t)dV(r). \tag{9}$$

Integration over all space gives the total energy of the system, which by the normalization is $W(t)=1$. The quantity $W(V,t)$ is equal to the probability of a particle on a random walk of visiting the volume region V at a time t.

We now consider the probability that a random walk particle leaves a source at $\mathbf{s}$ at time $t=0$, visits a volume element dV at $\mathbf{r}'$ at time t', and arrives at $\mathbf{r}$ at time t as depicted in Fig. 5. Assuming that the two paths, from source to the volume element, and from the volume element to the receiver, are independent, this probability is equal to the product of two probabilities: the probability of the particle of going from $\mathbf{s}$ to $\mathbf{r}'$ in a time t', and the probability of going from $\mathbf{r}'$ to $\mathbf{r}$ in a time $t-t'$, i.e.,

$$P(\mathbf{r}',\mathbf{r},\mathbf{s},t',t) = P(\mathbf{r}',\mathbf{s},t')P(\mathbf{r},\mathbf{r}',t-t'), \qquad (10)$$

where $P(\mathbf{r}',\mathbf{r},\mathbf{s},t',t)$ stands for the probability of all the trajectories visiting the volume element at location $\mathbf{r}'$ at time t' given that the walk started at the source location $\mathbf{s}$ and ended at the receiver location $\mathbf{r}$ at time t.

The probability of a particle to travel from the source to the receiver is given by the solution to the diffusion equation for homogeneous medium given in Eq. (1). This solution also gives the time-dependent intensity $P(\mathbf{r},\mathbf{s},t)$ at the receiver location due to a unit intensity impulse at the source. This intensity is obtained by summing the contributions to the intensity of all waves traveling with all possible diffuse trajectories going from the source to the receiver, i.e., integrating Eq. (10) over all possible volume elements $dV(\mathbf{r}')$

$$P(\mathbf{r},\mathbf{s},t) = \int_V P(\mathbf{r}',\mathbf{r},\mathbf{s},t',t)dV(\mathbf{r}')$$

$$= \int_V P(\mathbf{r},\mathbf{r}',t-t')P(\mathbf{r}',\mathbf{s},t')dV(\mathbf{r}'). \qquad (11)$$

The integrand $P(\mathbf{r}',\mathbf{r},\mathbf{s},t',t)$ contains the contributions to the intensity of all paths which are initiated at the source location $\mathbf{s}$, visit the location $\mathbf{r}'$, and end at the receiver located at $\mathbf{r}$. By integrating over all the volume where scattering occurs, we are summing the contributions over all possible trajectories from the source to the receiver. Note that in Eq. (11) no integration over t' is performed. Equation (11) is a restatement of the Chapman–Kolmogorov equation[26]

$$\int_V P(\mathbf{r},\mathbf{r}',t)P(\mathbf{r}',\mathbf{s},t')dV(\mathbf{r}') = P(\mathbf{r},\mathbf{s},t+t'), \qquad (12)$$

which states that a random walk process starting at $t=0$ at location $\mathbf{s}$ reaches $\mathbf{r}$ at t via one of the possible values $\mathbf{r}'$ at a intermediate time t'.

The quantity $P(\mathbf{r}',\mathbf{s},t')$ in Eq. (11) is the diffuse intensity at a time t' at $\mathbf{r}'$ due to an impulse source at $\mathbf{s}$ activated at time $t=0$, and $P(\mathbf{r},\mathbf{r}',t-t')$ is the intensity at $\mathbf{r}$ at time t due to an impulse source at $\mathbf{r}'$ on a time $t-t'$. Equation (11) holds for all times $0 < t' < t$.[26] If we integrate both sides of Eq. (11) over time t' over the interval $0 < t' < t$, we obtain

$$tP(\mathbf{r},\mathbf{s},t) = \int_V \int_0^t P(\mathbf{r},\mathbf{r}',t-t')P(\mathbf{r}',\mathbf{s},t')dt'\, dV(\mathbf{r}'),$$
$$(13)$$

where we can identify the time integral $\int_0^t P(\mathbf{r},\mathbf{r}',t-t')P(\mathbf{r}',\mathbf{s},t')dt'$ as the time convolution of the two intensities: one at location $\mathbf{r}'$ due to an impulse intensity at $\mathbf{s}$ and the other at location $\mathbf{r}$ due to an impulse intensity at $\mathbf{r}'$. If we divide both sides of Eq. (13) by $P(\mathbf{r},\mathbf{s},t)$, we arrive at the following integral representation for the travel time of the diffuse wave field:

$$t = \frac{1}{P(\mathbf{r},\mathbf{s},t)} \int_V \int_0^t P(\mathbf{r},\mathbf{r}',t-t')P(\mathbf{r}',\mathbf{s},t')dt'\, dV(\mathbf{r}').$$
$$(14)$$
FIG. 6. (Color online) Sensitivity kernel K in 2D for source (asterisk) and receiver (triangle) separated 3000 m and $t=2$ s. The diffusion constant is 5.8×10^5 m^2/s.

We have obtained in Eq. (14) a representation for the time t at $\mathbf{r}$ in terms of the diffuse intensity due to an impulse source at $\mathbf{s}$. The time t corresponds to the time of propagation of the diffuse intensity. If we define the kernel $K(\mathbf{r}',\mathbf{r},\mathbf{s},t)$ as

$$K(\mathbf{r}',\mathbf{r},\mathbf{s},t) = \frac{1}{P(\mathbf{r},\mathbf{s},t)} \int_0^t P(\mathbf{r},\mathbf{r}',t-t')P(\mathbf{r}',\mathbf{s},t')dt',$$
$$(15)$$

we can express the travel time t as the following volume integral:

$$t = \int_V K(\mathbf{r}',\mathbf{r},\mathbf{s},t)dV(\mathbf{r}'), \qquad (16)$$

where $K(\mathbf{r}',\mathbf{r},\mathbf{s},t)$ represents the time of flight distribution of multiply scattered waves started at the source at location $\mathbf{s}$, visiting location $\mathbf{r}'$ and detected on a receiver at location $\mathbf{r}$. Figure 6 shows a plot of the sensitivity kernel calculated for a source and receiver separated 3000 m, $t=1$ s, and $D=5.8 \times 10^5$ m^2/s. Note that the kernel vanishes outside the area of an ellipse with foci at the source and receiver location.

B. Integral representation for the mean travel time change of the diffuse wave field

When the scatterers in a multiple scattering material move, or when the propagation velocity of the medium changes, the diffuse wave field changes. In diffusing acoustic wave spectroscopy,[15] the fluctuations of the multiply scattered wave field are measured and analyzed to provide a sensitive technique for probing the dynamics of the scatterers. Here, we use a similar approach, considering the phase changes in the diffuse wave field which arise due to a spatially localized change in the propagation velocity.

We perturb the slowness in a finite region of the medium as shown in Fig. 7. We work under the assumption that the perturbation is weak so that the scattering coefficient does not change, and the waveform for each scattering path stays approximately the same. Also, the scattering paths remain unchanged so that the only difference between the unperturbed and the perturbed field is a small travel time perturbation, τ_T. If the mean slowness of the medium is denoted by
FIG. 7. Multiple scattering paths and a localized perturbation. After the perturbation the paths remain the same. The source location is represented by an asterisk and the receiver by a triangle.

s, we calculate the mean length $\langle L(t) \rangle$ of the multiple scattering paths at time t by dividing Eq. (16) by s

$$\langle L(t) \rangle = \int_V \frac{1}{s} K(\mathbf{r}', t) dV(\mathbf{r}'), \qquad (17)$$

where we have placed s inside the integral since it is assumed to be independent of location. For notation simplicity we have removed the explicit dependence of K on the source and receiver location. A perturbation in the slowness gives rise to a perturbation in the travel time or phase of the wave field, i.e.,

$$t + \delta_t = \int_V K(\mathbf{r}', t) \frac{(s + \delta_s)}{s} (\mathbf{r}') dV(\mathbf{r}'), \qquad (18)$$

where δ_s is the perturbation in the background slowness. Since in the integral in Eq. (18) we are averaging the contribution to the travel time perturbation of all volume elements, δ_t becomes the average or mean travel time change that we define as $\langle \tau(t) \rangle$. We have assumed that the perturbation in the slowness is small ($\delta s / s \ll 1$) so that the travel time perturbation depends only linearly on the slowness perturbation. The average or mean travel time change for the multiple scattering paths with path length L is then

$$\langle \tau(t) \rangle = \int_V K(\mathbf{r}', t) \frac{\delta s}{s} (\mathbf{r}') dV(\mathbf{r}'), \qquad (19)$$

where $\langle \tau(t) \rangle$ is the mean travel time change of the multiply scattering waves with travel time t and path length $\langle L(t) \rangle$ due to the relative slowness perturbation $\delta s / s$. Note that this average is weighted by the intensity, since the integration kernel $K(\mathbf{r}', t)$ represents the intensity of diffuse trajectories going through location $\mathbf{r}'$ with total travel time t, as needed in the averaging in Eq. (8).

To calculate the mean travel time change for a particular source and receiver configuration, we need to integrate the kernel K weighted by the slowness perturbation $\delta s / s$ over the volume where scattering takes place. The kernel K is given by the time convolution in Eq. (15). For a source and receiver at different locations, this time convolution does in general not have an analytical solution so it must be evaluated numerically. For the special case of coincident source

and receiver, an analytical solution for this convolution can be obtained. In the Appendix we calculate the kernel K for coincident source and receiver for two- and three-dimensional media. In 3D, the kernel K is given by

$$K_{3D}(\mathbf{r}, t) = \frac{1}{2\pi D r} \exp\left[\frac{-r^2}{Dt} \right]. \qquad (20)$$

From Eq. (20) we see that the main contributions to the travel time change come from paths located close to the coincident source and receiver location. Also, we can see that for a fixed distance r the integration kernel K increases with time t. In multiple scattering, the effective distance traveled by diffuse waves is proportional to the square root of distance ($r \sim \sqrt{4Dt}$). For smaller value of the diffusion coefficient, the stronger the scattering is and the smaller the effective distance traveled by diffuse waves (wave paths become more localized around the source and receiver location). Thus, with increased time, diffuse waves sample the same region multiple times and consequently the travel time change increases with time.

For the special case of 2D wave propagation the integration kernel K is for coincident source and receiver (see the Appendix for derivation)

$$K_{2D}(\mathbf{r}, t) = \frac{1}{2\pi D} \exp\left[\frac{-r^2}{2Dt} \right] K_0\left[\frac{r^2}{2Dt} \right], \qquad (21)$$

where K_0 is the modified Bessel function of the second kind. If we insert Eq. (21) into Eq. (19) and integrate over area instead of volume, we obtain

$$\langle \tau(t) \rangle = \frac{1}{2\pi D} \int_A \exp\left[\frac{-r^2}{2Dt} \right] K_0\left[\frac{r^2}{2Dt} \right] \frac{\delta s}{s} (\mathbf{r}) dA(\mathbf{r}), \qquad (22)$$

where r is the distance from the slowness perturbation $\delta s / s (\mathbf{r})$ element to the coincident source and receiver location. In Eq. (22), we have obtained an explicit expression relating the mean travel time change $\langle \tau \rangle$ of the diffuse waves to the localized slowness perturbation $[\delta s / s(\mathbf{r})]$ in a multiple scattering medium for coincident source and receiver. In general, for a given perturbation in slowness, we can predict the mean travel time change $\langle \tau \rangle$ for any source and receiver configuration by numerically calculating the convolution in Eq. (19).

V. TRAVEL TIME CHANGE FROM FINITE-DIFFERENCE SYNTHETICS

To generate synthetic seismograms for our study of multiple scattering, we use a fourth-order 2D acoustic finite-difference code that propagates a finite-duration pulse through a specified velocity field. Following Ref. 27, we model the 2D velocity field as a constant-background model with added random velocity fluctuations that constitute the scatterers (see Fig. 8). The total velocity field can be decomposed as

$$v(\mathbf{r}) = v_0 + v_r(\mathbf{r}), \qquad (23)$$

where v_0 is the background velocity and v_r are the random velocity fluctuations. The velocity fluctuations are characterized by a Gaussian autocorrelation function with correlation
FIG. 8. 2D velocity model with random velocity fluctuations added to it. The correlation length of the velocity fluctuations is 40 m.

distance a, with zero mean and standard deviation σ (see Fig. 8 for a realization of the velocity model). The autocorrelation function of the velocity fluctuations v_r has the form

$$\langle v_r(\mathbf{r}')v_r(\mathbf{r}+\mathbf{r}')\rangle = \sigma^2 \exp\left[\frac{-r^2}{a^2}\right]. \tag{24}$$

The synthetic seismograms were created by transmitting a bandlimited pulse with a dominant wavelength of 240 m. The grid size used was 20 m and the autocorrelation a length was set to 40 m, which is much smaller than the wavelength. The mean velocity v_0 is equal to 6000 m/s. To ensure strong scattering, we created a velocity field with a relative standard deviation of 25% about the mean velocity value. To test the validity of the diffusion approximation for our numerical model, we performed a numerical experiment where we placed a source in the middle of the model and recorded the seismograms on an array of receivers around the source. Figure 9 shows 100 synthetic seismograms computed at a distance of 250 m (left) and 3000 m (right) from the source. Note the strength of the multiple scattered arrivals after the highly attenuated ballistic arrival, especially for a distance of 3000 m from the source. The average intensity (which was

FIG. 10. Slowness perturbation added to the initial velocity model to create the perturbed velocity model. The side length of the square is 3000 m and the magnitude of the perturbation is $\delta s/s=0.005$. The source is shown as a star and the receivers as triangles.

shown in Fig. 1) was obtained by averaging the squared envelope of all calculated waveforms at a given distance to the source.

We test our theory with the finite-difference simulations of acoustic waves in the multiple scattering regime before and after a localized slowness perturbation has been introduced in the model. We perturb the random velocity model which represents the unperturbed medium by adding a localized slowness perturbation as shown in Fig. 10. The value of the relative slowness perturbation is $\delta s/s=0.005$.

We first analyze the unperturbed and perturbed synthetic seismograms for the receiver **R1** located on the perturbed region of our model 2000 m away from the source. Figure 11 shows both the unperturbed and perturbed seismograms for receiver **R1**. The waveforms consist of diffuse or multiply scattered waves that have followed a multitude of paths from the source to the receiver. Notice the strength of the coda waves for late times. At first sight there seems to be no substantial difference between the wave field before and after the perturbation. However, zooming at around 2 s (see Fig.

FIG. 9. Seismograms recorded at 250 m (left) and 3000 m (right) from the source.
FIG. 11. Unperturbed (solid) and perturbed (dashed) synthetic seismograms recorded at the receiver **R1** located 2000 m away from the source.

FIG. 13. (Color online) Theoretical versus measured mean travel time change for receiver **R1** located 2000 m away from the source.

12) we see that the unperturbed seismogram lags in time with respect to the perturbed seismogram. More careful inspection indicates that the behavior of the time lags with travel time is systematic, i.e., the lag is increasing with travel time t.

We calculate the theoretical mean travel time change using Eq. (19) for receiver **R1** at several propagation times t and compare the result with the mean travel time change estimated from the synthetic seismograms using the time-windowed cross-correlation technique. Figure 13 shows good agreement between the theoretical and the measured mean travel time change $\langle \tau \rangle(t)$.

We also calculated the mean travel time changes for the receivers **R2** and **R3** located 5500 m away from the source. Even though the distance to the source is the same for these receivers, their locations with respect to the perturbation is different and therefore the mean travel time change is different for the two receivers. The theoretical travel time change for receiver **R2** is almost twice the travel time change for receiver **R3** (see Fig. 14). Also note that we have obtained a good agreement between the theoretical and estimated mean travel time change. This sensitivity of the mean travel time

change to the relative source and receiver locations with respect to the perturbation can be exploited in an inversion scheme to estimate the propagation velocity change from measurements of the mean travel time change at different receiver locations. Notice also that for all receivers there are fluctuations of the measured travel time change about the theoretical value. We explore the origin of these fluctuations and how to minimize them in the following.

VI. FLUCTUATIONS OF THE MEAN TRAVEL TIME CHANGE

We measured the mean travel time change from the synthetic seismograms using a time-windowed cross-correlation technique. The measured mean travel time change measured in this way is approximately an average of the time lags for the many scattering events on that time window. The fluctuations seen on the estimated mean travel time change are due to a number of factors, of which the most important is the size of the time window. We measure time lags of a continuous signal. Special care must be taken not to choose too small a time window to ensure stability of the estimation in the time-windowed cross correlation. The larger the time

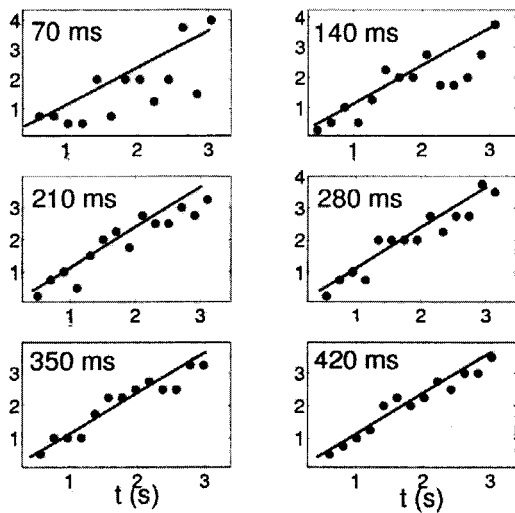
FIG. 12. Zoom of the unperturbed (solid curve) and perturbed (dashed curve) synthetic seismograms recorded at the receiver **R1** located 2000 m away from the source. Note the time lags between the unperturbed and perturbed seismograms at different times.
FIG. 14. Theoretical versus measured mean travel time change for receivers **R2** and **R3** located 5500 m away from the source.


FIG. 15. Mean travel time change $\langle\tau\rangle(t)$ estimated from the synthetic seismograms for receiver **R1** using different window lengths on the cross correlation. The mean travel time change is in milliseconds. Note the reduction in the fluctuations of the measured mean travel time change (circles) around the theoretical value (solid line) for larger window lengths. The dominant period is 40 ms. The window length is shown in the upper-left corner of each plot.

$$\langle\tau(t)\rangle = \int_V K(r,t) \times \frac{\delta s}{s}(r) \times dV$$

FIG. 16. (Color online) Schematic view of the tomographic problem in matrix form. The sensitivity kernel K relates linearly the unknown parameters $\delta s/s$ with the measured traveltime change $\langle\tau\rangle(t)$. Each row in the matrix operator corresponds to a different receiver location.

window the more averaging of travel time perturbations occurs. Thus, choosing a larger window may help minimize the fluctuations of the observed mean travel time change.

We can reduce the fluctuations of the estimated mean travel time change $\langle\tau\rangle(t)$ by choosing a larger time window length $2t_w$ on the time-windowed cross correlation. Reference 25 shows that increasing the time window length decreases the magnitude of the cross terms on the average intensity $\langle I \rangle$, and therefore the fluctuations of the time lags measured in the cross correlation. Larger contributions from the cross terms to the average intensity imply larger departures from the diffusive behavior.

The decrease of the fluctuations with the increase of the time window length $2t_w$ can be appreciated in Fig. 15, where we plot the measured mean travel time change (circles) versus the theoretical mean travel time change (solid line) using different window lengths on the time-windowed cross correlation for the receiver **R1** of example 1 of the previous section. We see that the fluctuations of the measured travel time change decrease with increasing window length $2t_w$. For this synthetic example, the dominant period T_{dom} is 40 ms. The length of the time window in Fig. 15 varies from 70 to 420 ms.

VII. CONCLUSIONS

We have developed a technique that relates the mean travel time changes to the local changes in the propagation velocity of the medium. The theory is formulated by means of the diffusion approximation of the multiple scattering wave field. The sensitivity kernel $K(r,t)$ describes the dependence of the mean travel time change with the source and receiver location, the relative slowness perturbation, and the diffusion constant of the medium.

Equation (19) relates the mean travel time change $\langle\tau\rangle \times (t)$ at time t with a localized slowness perturbation $\delta s/s(\mathbf{r})$.

Note that this equation can be used as the basis of a standard linear inverse problem, as there is a linearized relation between the data (mean travel time change for different times t, and different source/receiver pairs) and the unknown parameters of the medium (localized slowness perturbation) which we want to retrieve. In the previous section we showed that the mean travel time change is a function of time and of the source and receiver locations. This dependence of the mean travel time change on the relative source and receiver location with respect to the localized slowness perturbation can be exploited in the inversion scheme for the spatial location of the slowness change.

We have developed our technique for homogeneous media. In practice, detectors will most likely need to be placed on the surface of the medium, so that boundary conditions will have to be taken into account. Also, the medium may contain layers, so we will have to account for heterogeneity as well. The problem of analyzing the precise effect of a contrast of wave velocities and/or scattering strengths between them will arise. Under the assumption of an almost isotropic scattering field[28] we determined the boundary conditions for the diffusion and radiative transfer equations for layered media. Undoubtedly all this will make our kernels more complicated.

Future work includes developing an inversion scheme to obtain the shape and magnitude of the slowness perturbation from the measured travel time changes at different receiver locations. This is similar to the transmission tomography problem, with the added complication that we are not only taking first or minimum time arrival but all multiple arrivals due to the interference of multiply scattered waves. The problem is simplified due to the fact that we are not using explicitly the paths as in transmission tomography but rather using the average wave field obtained with the diffusion approximation. Instead of calculating the travel time change with infinitely many line integrals, we calculate the mean travel time change using a much simpler volume integral that

C. Pacheco and R. Snieder: Monitoring with multiply scattered waves

contains the contributions of all possible paths. For a given time t and for a fixed source location we can set up the inverse problem in matrix form using different receivers as is shown in Fig. 16. The matrix operator (calculated from the time of flight distribution K) which multiplies the unknown parameter vector [slowness perturbation $\delta s/s(\mathbf{r})$ as a function of position] generates the data (mean travel time change for different receiver locations). Each row in the matrix corresponds to an observation of mean travel time change for a specific source–receiver pair at a discrete number of times t.

This technique can be used to detect temporal changes in highly heterogeneous material or reservoirs given that the diffusion approximation of the intensities is valid.

ACKNOWLEDGMENTS

APPENDIX A: SENSITIVITY KERNEL K FOR COINCIDENT SOURCE AND RECEIVER

We start from the expression

$$K(\mathbf{r}',\mathbf{s},\mathbf{r},t) = \int_0^t \frac{P(\mathbf{r},\mathbf{r}',t-t')P(\mathbf{r}',s,t')}{P(\mathbf{r},t)} dt', \qquad (A1)$$

where $P(\mathbf{r},t)$ is the intensity at the receiver located at $\mathbf{r}$ due to a normalized impulse source at the origin at time $t=0$, and is given by Eq. (1). For homogeneous media it depends only on time and on the distance r between source and receiver. In 2D it is equal to

$$P(\mathbf{r},t) = \frac{1}{4\pi Dt} \exp\left[\frac{-r^2}{4Dt}\right]. \qquad (A2)$$

The time convolution is given by

$$P(|\mathbf{r}'-\mathbf{s}|) * P(|\mathbf{r}-\mathbf{r}'|) = \int_0^t P(|\mathbf{r}'-\mathbf{s}|,t')P(|\mathbf{r}-\mathbf{r}'|,t$$
$$-t')dt'. \qquad (A3)$$

Substituting Eq. (A2) into Eq. (A3) gives for coincident source and receiver $(\mathbf{r}=\mathbf{s}=\mathbf{0})$

$$P(\mathbf{r}',t) = \int_0^t \frac{\exp\left[\dfrac{-r'^2}{4Dt'}\right]}{4\pi Dt'} \frac{\exp\left[\dfrac{-r'^2}{4D(t-t')}\right]}{4\pi D(t-t')} dt'. \qquad (A4)$$

As there is symmetry around $t/2$, we can write after renaming $\mathbf{r}'$ as $\mathbf{r}$

$$P(\mathbf{r},t) = \frac{2}{(4\pi D)^2} \int_0^{t/2} \frac{\exp\left[\dfrac{-r^2}{4D}\dfrac{t}{t'(t-t')}\right] dt'}{t'(t-t')}. \qquad (A5)$$

We apply the following changes of variables: $\epsilon = 1/[t'(t-t')]$ and then $\nu = r^2t[\epsilon-(4/t^2)]$ to obtain

$$P(\mathbf{r},t) = \frac{2}{(4\pi D)^2} e^{[-r^2/t]} \int_0^{\infty} \frac{e^{-\nu}d\nu}{\sqrt{\nu^2 + \dfrac{\nu r^2}{Dt}}}. \qquad (A6)$$

This integral can be calculated identifying it as a integral of the type

$$\int_0^{\infty} \frac{e^{-px}dx}{\sqrt{x(x+a)}} = e^{ap/2}K_0\left(\frac{ap}{2}\right), \qquad (A7)$$

for $a>0$ and $p>0$. The solution to the integral in Eq. (A7) can be found in Ref. 29. Setting $p=1$ and $a=r^2/Dt$, expression (A7) becomes

$$(P*P)(\mathbf{r},t) = \frac{2}{(4\pi D)^2 t} \exp\left[\frac{-r^2}{2Dt}\right] K_0\left[\frac{r^2}{2Dt}\right], \qquad (A8)$$

where K_0 is the modified Bessel function of the second kind. Substituting Eqs. (A4) and (A2) into Eq. (A1), we arrive at the expression for the kernel $K(\mathbf{r},t)$ in two dimensions for coincident source and receiver

$$K_{2D}(\mathbf{r},t) = \frac{1}{2\pi D} \exp\left[\frac{-r^2}{2Dt}\right] K_0\left[\frac{r^2}{2Dt}\right]. \qquad (A9)$$

To obtain the sensitivity kernel K in three-dimensional media, we substitute Eq. (A2) with the Green's function for the diffusion equation in 3D

$$P(\mathbf{r},t) = \frac{1}{(4\pi Dt)^{3/2}} \exp\left[\frac{-r^2}{4Dt}\right]. \qquad (A10)$$

Solving the integral defined in Eq. (A1) using the same changes of variables as in the 2D case, we obtain the expression for the kernel $K(\mathbf{r},t)$ in three dimensions for coincident source and receiver

$$K_{3D}(\mathbf{r},t) = \frac{1}{2\pi Dr} \exp\left[\frac{-r^2}{Dt}\right]. \qquad (A11)$$

On the sound field of an oscillating disk in a finite open and closed circular baffle

Tim Mellow

Leo Kärkkäinen
Nokia Research Center, Helsinki, Finland

Equations describing the radiation characteristics of a rigid disk in a finite open baffle are derived using a method similar to that used by Streng for a circular membrane based upon the dipole part of the Kirchhoff–Helmholtz boundary integral formula. In this case, however, a power series solution to the radiation integral is derived in order to eliminate the need for numerical integration. Hence, a set of simultaneous equations is obtained by simply equating the coefficients of the power series, which leads to two mathematical functions, one real and one imaginary, that can be applied to any radial velocity distribution. This provides an alternative method to obtain the sound scattered by a disk or the complementary hole in an infinite resilient screen according to Babinet's principle. Using the principle of superposition (or Gutin concept), it is shown how the sound radiation characteristics of a disk radiating from just one side can be obtained by combining the radiation field of a disk in a finite baffle with that of a disk in an infinite baffle. This one-sided radiator may be interpreted as a disk in a thin, circular enclosure. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000828]

I. INTRODUCTION

The radiation characteristics of elementary sources are invaluable in providing lumped parameters for acoustics models based upon equivalent electrical circuits. Furthermore, they serve an important educational purpose in illustrating fundamental radiation and diffraction theory. They may also be used to provide benchmarks for boundary or finite element modeling (BEM/FEM). This can provide us with much information about the required element size and what kind of meshing geometry to use.

In addition to describing the radiation characteristics of a disk in an open or closed circular baffle, a more general aim of this paper is to present a simple unified approach to the problem of flat, axially symmetric sound sources based upon the Green's function in cylindrical coordinates and the Kirchhoff–Helmholtz boundary integral formula.[1] The latter is a general equation that describes the spatial distribution of the pressure within and on the surface bounding an acoustic medium. However, in the case of surfaces radiating into free space, the volume integral term can be omitted and the Green's function for an unbounded medium $g(\mathbf{r}|\mathbf{r}_0)$ is used so that the pressure distribution is described by

$$\widetilde{p}(\mathbf{r}) = \int\int g(\mathbf{r}|\mathbf{r}_0)\frac{\partial}{\partial n_0}\widetilde{p}(\mathbf{r}_0) - \widetilde{p}(\mathbf{r}_0)\frac{\partial}{\partial n_0}g(\mathbf{r}|\mathbf{r}_0)dS_0, \quad (1)$$

where the first term (or *monopole* part) is the integral of the inward-pointed normal gradient of the boundary values of $p(\mathbf{r}_0)$ and $g(\mathbf{r}|\mathbf{r}_0)$ over the surface, and the second term (or *dipole* part) is the integral of the boundary values of $p(\mathbf{r}_0)$ and the inward-pointed normal gradient of $g(\mathbf{r}|\mathbf{r}_0)$ over the surface.

Many of the classical analytical results reproduced during the course of this paper are best known through the works of Beranek[2] and Olson.[3] Fifty years ago, it must have been a formidable task calculating these results without the benefits of modern computing power. Even today, the task of reproducing the results of the original papers,[4,5] from which they were derived, is perhaps not so trivial unless the reader is well versed in the mathematical methods used. Hence, it is useful to derive a compact set of equations suitable for modern computer applications. Bouwkamp[6] and Spence[7] independently derived the first rigorous solutions to the problem of the freely suspended disk using iterative methods based upon oblate spheroidal wave functions, while Meixner and Fritze[8] calculated its near-field pressure response. Nimura and Watanabe[9] calculated the radiation impedance and directivity of a rigid disk in a finite circular open baffle for lower values of ka. Pachner[10] described a calculation method using spherical Bessel and Legendre functions and used the superposition of fields, although no results were presented. Crane[11] calculated the radiation impedance of a circular piston in a closed circular baffle directly by applying the boundary conditions of a sound field resulting from the superposition of a disk in a finite open baffle upon a disk in an infinite baffle. In theory, it should be possible to extract the open baffle impedance from these results simply by doubling them and then subtracting the infinite baffle impedance. However, given the approximate nature of this calculation method and the fact that the real open baffle impedance is so small at low frequencies, the result is inevitably wildly inaccurate. In the last few decades, there has been much interest in time-domain techniques.
FIG. 1. Rigid disk in a finite open-back circular baffle.

Previously, one of the present authors[12] has used the least mean square (LMS) algorithm to tackle this problem, but found it to be numerically unsatisfactory for larger baffle sizes. Instead, the velocity of the radiator and its baffle is described, in this paper, by a step function using a Bessel function series, which produces a membrane-like expression. This allows a set of simultaneous equations to be obtained by simply equating the coefficients of the power series.

II. RIGID DISK IN A FINITE OPEN-BACK CIRCULAR BAFFLE

A. Boundary conditions

The disk shown in Fig. 1 lies in the xy plane, with its center at the origin and oscillates in the z direction with velocity $\tilde{u}_0$, thus radiating sound from both sides. The radius of the disk is a and it is assumed to be infinitesimally thin. It is surrounded by an infinitesimally thin circular baffle, the inner and outer radii of which are a and b, respectively. If $b=a$, the problem reduces to that of a *rigid disk in free space*. The area of each surface element is given by

$$\delta S_0 = w_0 \delta w_0 \delta \phi_0. \tag{2}$$

The pressure field on one side of the xy plane is the symmetrical "negative" of that on the other, so that

$$p(w,z) = -p(w,-z). \tag{3}$$

Consequently, there is a Dirichlet boundary condition in the plane of the disk where these equal and opposite fields meet.

$$p(w,0) = 0, \quad b < w \leq \infty \tag{4}$$

On the front and rear surfaces of the baffle, there is a Neumann boundary condition

$$\frac{\partial}{\partial z} \tilde{p}(w,z)|_{z=0\pm} = 0, \quad a < w \leq b. \tag{5}$$

Also, on the front and rear surfaces of the disk, there is the coupling condition

$$\frac{\partial}{\partial z} \tilde{p}(w,z)|_{z=0\pm} = -ik\rho c \tilde{u}_0(w), \quad 0 \leq w \leq a \tag{6}$$

where ρ is the density of air or any other surrounding medium, and c is the speed of sound in that medium. The annotation $\sim$ denotes a harmonically time-varying quantity where we have suppressed the term $e^{i\omega t}$. In order to tackle this problem, we shall use the second term or *dipole* surface integral part of Eq. (1). However, some prior expression for the frontal surface pressure distribution $\tilde{p}_+(w_0)$ is needed. Also, because the disk can radiate from both sides, the rear surface pressure distribution $\tilde{p}_-(w_0)$ must be included too, where $\tilde{p}_+(w_0) = -\tilde{p}_-(w_0)$. Streng[13,14] showed that the surface pressure distribution for any flat, axially symmetric unbaffled source (or sink), based upon Bouwkamp's solution[6] to the free-space wave equation in oblate spheroidal coordinates, could be written as

$$\tilde{p}_+(w_0) = -\tilde{p}_-(w_0) = \sum_{m=0}^{\infty} \tilde{A}_m \left(1 - \frac{w_0^2}{b^2}\right)^{m+(1/2)}. \tag{7}$$

where $\tilde{A}_m$ are the as yet unknown power series coefficients.

B. Solution of the free-space wave equation

The pressure distribution, in accordance with the Huygens–Fresnel principle, is given by the second term or *dipole* part of Eq. (1) written in cylindrical coordinates as follows:

$$\tilde{p}(w,z) = -\int_0^{2\pi} \int_0^b (\tilde{p}_+(w_0) - \tilde{p}_-(w_0))$$
$$\times \frac{\partial}{\partial z_0} g(w,z|w_0,z_0)|_{z_0=0+} w_0 \, dw_0 \, d\phi_0, \tag{8}$$

where the Green's function $g(w|w_0)$ is the solution to the following free-space wave equation in the presence of a monopole point source located at (w_0,z_0) on the surface of the disk:

$$(\nabla^2 + k^2) g(w,z|w_0,z_0) = -\delta(w-w_0, z-z_0), \tag{9}$$

where

$$\nabla^2 = \frac{\partial^2}{\partial w^2} + \frac{1}{w}\frac{\partial}{\partial w} + \frac{\partial^2}{\partial z^2}, \tag{10}$$

$$k = \frac{2\pi}{\lambda} = \frac{\omega}{c}. \tag{11}$$

However, the pressure produced at each point (w,z) in space by each dipole element is defined in the integral of Eq. (8) by the product of the surface pressure, the inward-pointed normal gradient of the Green's function, and the area of each element given by Eq. (2). A solution to Eq. (9) is the free-space Green's function in cylindrical coordinates,[1] also known as the Lamb or Sommerfeld integral, which is given by

$$g(w,z|w_0,z_0) = \frac{i}{4\pi} \int_0^\infty J_0(\mu w) J_0(\mu w_0) \frac{\mu}{\sigma} e^{-i\sigma|z-z_0|} d\mu,$$

$$(12)$$

where

$$\sigma = \sqrt{k^2 - \mu^2}. \tag{13}$$

Due to axial symmetry, only the zeroth term of the original power series is shown in Eq. (12). The normal gradient of the Green's function at the surface is given by

$$\frac{\partial}{\partial z_0} g(w,z|w_0,z_0)\big|_{z_0=0+}$$

$$= \frac{1}{4\pi} \int_0^\infty J_0(\mu w) J_0(\mu w_0) \mu e^{-i\sigma z} d\mu. \tag{14}$$

Inserting this together with Eq. (7) in Eq. (8) and integrating over the surface of the disk and its baffle yields

$$\tilde{p}(w,z) = -b \sum_{m=0}^\infty \tilde{A}_m 2^{m+(1/2)} \Gamma\left(m + \frac{3}{2}\right) \int_0^\infty \left(\frac{1}{\mu b}\right)^{m+(1/2)}$$

$$\times J_{m+(3/2)}(\mu b) J_0(\mu w) e^{-i\sigma z} d\mu, \tag{15}$$

where the following identity[15] has been used:

$$\int_0^a w_0 \left(1 - \frac{w_0^2}{b^2}\right)^{m+(1/2)} J_0(\mu w_0) dw_0$$

$$= b^2 \int_0^1 t(1-t^2)^{m+(1/2)} J_0(\mu b t) dt$$

$$= b^2 2^{m+(1/2)} \Gamma\left(m + \frac{3}{2}\right) \left(\frac{1}{\mu b}\right)^{m+(3/2)} J_{m+(3/2)}(\mu b), \tag{16}$$

where $t = w_0/b$. Applying the boundary conditions of Eq. (5) and Eq. (6) leads to

$$\frac{\partial}{\partial z} \tilde{p}(w,z)\big|_{z=0\pm}$$

$$= ib \sum_{m=0}^\infty \tilde{A}_m 2^{m+(1/2)} \Gamma\left(m + \frac{3}{2}\right) \int_0^\infty \left(\frac{1}{\mu b}\right)^{m+(1/2)}$$

$$\times J_{m+(3/2)}(\mu b) J_0(\mu w) \sigma d\mu = -ik\rho c \tilde{u}_0 \Phi(w), \tag{17}$$

where

$$\Phi(w) = \begin{cases} 1, & 0 \le w \le a, \\ 0, & a < w \le b. \end{cases} \tag{18}$$

C. Series representation of the velocity distribution

Let the Bessel series have the form

$$\Phi(w) = \sum_{n=1}^\infty a_n J_0(j_{0n} w/b), \tag{19}$$

where j_{0n} is the nth zero of J_0 such that $J_0(j_{0n})=0$. Multiplication of Eq. (19) by the normalizing function $J_0(j_{0m}w/b)$ and integration over w gives
FIG. 2. Bessel series representation of the surface velocity distribution.

$$\int_0^b \Phi(w) J_0(j_{0m}w/b) w \, dw$$

$$= \int_0^a J_0(j_{0m}w/b) w \, dw$$

$$= \sum_{n=1}^\infty a_n \int_0^b J_0(j_{0n}w/b) J_0(j_{0m}w/b) w \, dw. \tag{20}$$

Integrating over w yields

$$\frac{ab}{j_{0m}} J_1(j_{0m}a/b) = \frac{b^2}{2} \sum_{n=1}^\infty a_n \delta_{mn} J_1^2(j_{0n}), \tag{21}$$

where the following identities[15] have been employed:

$$\int_0^a J_0(j_{0m}w/b) w \, dw = \int_0^1 J_0(j_{0m}ay/b) y \, dy$$

$$= ab J_1(j_{0m}a/b)/j_{0m}, \tag{22}$$

and

$$\int_0^1 J_0(\alpha x) J_0(\beta x) x \, dx = \begin{cases} 0, & \alpha \ne \beta, \\ J_1^2(\alpha)/2, & \alpha = \beta, \end{cases} \tag{23}$$

where $y = w/a$, $x = w/b$ and α, β are zeros of J_0. Hence

$$a_n = 2 \frac{a J_1(j_{0n}a/b)}{b j_{0n} J_1^2(j_{0n})}. \tag{24}$$

A series expansion[15] of $J_0(j_{0n}w/b)$ is given by

$$J_0(j_{0n}w/b) = \sum_{q=0}^\infty \frac{(-1)^q}{(q!)^2} \left(\frac{j_{0n}}{2}\right)^{2q} \left(\frac{w}{b}\right)^{2q}. \tag{25}$$

Substituting Eq. (24) and Eq. (25) in Eq. (19) yields

$$\Phi(w) = \frac{a}{b} \sum_{n=1}^N \sum_{q=0}^Q \frac{(-1)^q J_1(j_{0n}a/b)}{(q!)^2 J_1^2(j_{0n})} \left(\frac{j_{0n}}{2}\right)^{2q-1} \left(\frac{w}{b}\right)^{2q}, \tag{26}$$

where both infinite power series limits have been truncated. The result is plotted in Fig. 2 for $a = \frac{1}{2}$, $b = 1$, $N = 10$, and $Q = 50$.

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

T. Mellow and L. Kärkkäinen: Disk in a circular baffle   1313

D. Formulation of the coupled problem

Equation (17) can be written more simply as

$$\sum_{m=0}^{\infty} \tau_m I_m(w,k) = -\Phi(w), \tag{27}$$

which needs to be solved for the normalized power series coefficients τ_m, where

$$\tau_m = \frac{\widetilde{A}_m}{(m+3/2)kb\rho c\widetilde{u}_0}, \tag{28}$$

and

$$I_m(w,k) = I_{mR}(w,k) + iI_{mI}(w,k), \tag{29}$$

where the real part of the integral in Eq. (29) is given by

$$I_{mR}(w,k) = b^2\Gamma\left(m+\frac{5}{2}\right)\int_0^k \left(\frac{2}{\mu b}\right)^{m+(1/2)}$$

$$\times \sqrt{k^2-\mu^2}J_{m+(3/2)}(\mu b)J_0(\mu w)d\mu, \tag{30}$$

and the imaginary part is given by

$$I_{mI}(w,k) = b^2\Gamma\left(m+\frac{5}{2}\right)\int_k^{\infty} \left(\frac{2}{\mu b}\right)^{m+(1/2)}$$

$$\times \sqrt{\mu^2-k^2}J_{m+(3/2)}(\mu b)J_0(\mu w)d\mu. \tag{31}$$

E. Solution of the real integral

Substitution of $\mu=k\sin\vartheta$ in Eq. (30) gives

$$I_{mR}(w,k) = 4\Gamma\left(m+\frac{5}{2}\right)\left(\frac{2}{kb}\right)^{m-(3/2)}\int_0^{\pi/2} \frac{\cos^2\vartheta}{(\sin\vartheta)^{m+1/2}}$$

$$\times J_0(kw\sin\vartheta)J_{m+(3/2)}(kb\sin\vartheta)d\vartheta. \tag{32}$$

A series expansion[15] of $J_{m+3/2}(kb\sin\vartheta)$ is given by

$$J_{m+(3/2)}(kb\sin\vartheta)$$

$$= \sum_{q=0}^{Q} \left(\frac{kb}{2}\right)^{2q+m+(3/2)} \frac{(-1)^q(\sin\vartheta)^{2q+m+3/2}}{q!\Gamma(q+m+5/2)}. \tag{33}$$

Replacing j_{0n}/b in Eq. (25) with $k\sin\vartheta$, and substituting this together with Eq. (33) in Eq. (32) gives

$$I_{mR}(w,k) = 4\sum_{q=0}^{Q}\sum_{r=0}^{R} \frac{(-1)^{q+r}\Gamma(m+5/2)}{(q!)^2r!\Gamma(r+m+5/2)}\left(\frac{w}{b}\right)^{2q}$$

$$\times \left(\frac{kb}{2}\right)^{2(q+r)+3}\int_0^{\pi/2} \cos^2\vartheta(\sin\vartheta)^{2(q+r)+1}d\vartheta. \tag{34}$$

Solution of the integral in Eq. (34) is enabled by use of the following identity:[16]

$$\int_0^{\pi/2} \cos^2\vartheta(\sin\vartheta)^{2(q+r)+1}d\vartheta = \frac{\sqrt{\pi}\Gamma(q+r+1)}{4\Gamma(q+r+5/2)}. \tag{35}$$

Evaluating the integral over ϑ yields

$$I_{mR}(w,k) = \sum_{q=0}^{Q}\sum_{r=0}^{R} \frac{\sqrt{\pi}(-1)^{q+r}\Gamma(m+5/2)\Gamma(q+r+1)}{(q!)^2r!\Gamma(r+m+5/2)\Gamma(q+r+5/2)}$$

$$\times \left(\frac{kb}{2}\right)^{2(q+r)+3}\left(\frac{w}{b}\right)^{2q}. \tag{36}$$

F. Solution of the imaginary integral

In order to change the infinite limit of Eq. (31) to a finite one, Streng[13] replaced the Bessel function $J_{q+3/2}$ with Hankel functions $H_{q+3/2}^{(1)}+H_{q+3/2}^{(2)}$. By applying contour integration theory, together with the substitution $\mu=ke^{i\vartheta}$, he showed that the imaginary integral Eq. (31) could be expressed as

$$I_{mI}(w,k) = \Re\left(4i\left(\frac{2}{kb}\right)^{m-(3/2)}\Gamma\left(m+\frac{5}{2}\right)\right.$$

$$\times \int_0^{\pi/2} e^{i[(1/2)-m]\vartheta}\sqrt{e^{2i\vartheta}-1}J_0(kwe^{i\vartheta})$$

$$\left.\times \{J_{m+(3/2)}(kbe^{i\vartheta}) + iY_{m+(3/2)}(kbe^{i\vartheta})\}d\vartheta\right). \tag{37}$$

A series expansion[15] of the Neumann function is given by

$$Y_{m+(3/2)}(kbe^{i\vartheta}) = \sum_{q=0}^{Q} \left(\frac{kb}{2}\right)^{2q-m-(3/2)} \frac{(-1)^{q+m}e^{i\vartheta(2q-m-3/2)}}{q!\Gamma(q-m-1/2)}. \tag{38}$$

Replacing j_{0n}/b in Eq. (25) and $k\sin\vartheta$ in Eq. (33) with $ke^{i\vartheta}$, and substituting these together with Eq. (38) in Eq. (37) gives

$$I_{mI}(w,k) = -4\sum_{q=0}^{Q}\sum_{r=0}^{R}\Re\left(\frac{(-1)^{q+r}\Gamma(m+5/2)}{(q!)^2r!\Gamma(r+m+5/2)}\left(\frac{w}{b}\right)^{2q}\right.$$

$$\times \left(\frac{kb}{2}\right)^{2(q+r)+3}i\int_0^{\pi/2} \sqrt{e^{2i\vartheta}-1}e^{2i\vartheta(q+r+1)}d\vartheta$$

$$- \frac{(-1)^{q+r+m}\Gamma(m+5/2)}{(q!)^2r!\Gamma(r-m-1/2)}\left(\frac{w}{b}\right)^{2q}\left(\frac{kb}{2}\right)^{2(q+r-m)}$$

$$\left.\times \int_0^{\pi/2} \sqrt{e^{2i\vartheta}-1}e^{2i\vartheta[q+r-m-(1/2)]}d\vartheta\right). \tag{39}$$

Solution of the integrals in Eq. (37) is enabled by use of the following identity:[16]

$$\int_0^{\pi/2} \sqrt{e^{2i\vartheta}-1}e^{2i\gamma\vartheta}d\vartheta = \frac{1}{2\gamma}\left({}_2F_1\left(-\frac{1}{2},\gamma;\gamma+1;-1\right)e^{i\pi\gamma}\right.$$

$$\left.- \frac{\sqrt{\pi}\Gamma(\gamma+1)}{2\Gamma(\gamma+3/2)}\right). \tag{40}$$

Evaluating the integrals over ϑ yields

$$I_{ml}(w,k) = 4\Gamma\left(m + \frac{5}{2}\right)\mathfrak{R}\left(\sum_{q=0}^{Q}\sum_{r=0}^{R} F_Y(q,r,m)\left(\frac{kb}{2}\right)^{2(q+r-m)}\right.$$

$$\left.\times\left(\frac{w}{b}\right)^{2q} - iF_J(q,r,m)\left(\frac{kb}{2}\right)^{2(q+r)+3}\left(\frac{w}{b}\right)^{2q}\right),$$

$$(41)$$

where the subfunctions F_Y and F_J are given by

$$F_Y(q,r,m) = (-1)^{q+r+m}\left(\frac{{}_2F_1(-1/2,\alpha;\alpha+1;-1)e^{i\pi\alpha}}{2\alpha(q!)^2 r!\Gamma(r-m-1/2)}\right.$$

$$\left.-\frac{\sqrt{\pi}\Gamma(\alpha)}{4(q!)^2 r!\Gamma(r-m-1/2)\Gamma(\alpha+3/2)}\right), \quad (42)$$

$$F_J(q,r,m) = (-1)^{q+r}\left(\frac{{}_2F_1(-1/2,\beta;\beta+1;-1)e^{i\pi\beta}}{2\beta(q!)^2 r!\Gamma(r+m+5/2)}\right.$$

$$\left.-\frac{\sqrt{\pi}\Gamma(\beta)}{4(q!)^2 r!\Gamma(r+m+5/2)\Gamma(\beta+3/2)}\right), \quad (43)$$

where

$$\alpha = q + r - m - 1/2, \tag{44}$$

$$\beta = q + r + 1. \tag{45}$$

However, for integer values of q and r, $iF_J(q,r,m)$ is purely imaginary and therefore makes no contribution to the real part of $I_{ml}(w,k)$. Similarly, the $e^{i\pi(q+r-m-1/2)}$ term of F_Y (q,r,m) is also purely imaginary and can therefore be excluded. Thus, the final result can be written

$$I_{ml}(w,k)$$

$$= -\sum_{q=0}^{Q}\sum_{r=0}^{R}\frac{\sqrt{\pi}(-1)^{q+r+m}\Gamma(m+5/2)\Gamma(q+r-m-1/2)}{(q!)^2 r!\Gamma(r-m-1/2)\Gamma(q+r-m+1)}$$

$$\times\left(\frac{kb}{2}\right)^{2(q+r-m)}\left(\frac{w}{b}\right)^{2q}. \tag{46}$$

G. Calculation of the power series coefficients (final set of simultaneous equations)

Truncating the infinite power series in Eq. (27) to order M and equating the coefficients of $(w/b)^{2q}$ yields the final set of M simultaneous equations in τ_m as follows:

$$\sum_{m=0}^{M}({}_m\mathbf{B}_q(kb) - i\,{}_m\mathbf{S}_q(kb))\tau_m = -\Phi_q, \tag{47}$$

where $\mathbf{B}$ shall be named the *Bouwkamp* function as defined by

$${}_m\mathbf{B}_q(kb) = \sqrt{\pi}\sum_{r=0}^{M}\frac{(-1)^{q+r}\Gamma(m+5/2)\Gamma(q+r+1)}{r!(q!)^2\Gamma(r+m+5/2)\Gamma(q+r+5/2)}$$

$$\times\left(\frac{kb}{2}\right)^{2(q+r)+3}, \tag{48}$$

and $\mathbf{S}$ shall be named the *Streng* function as defined by

$${}_m\mathbf{S}_q(kb) = \sqrt{\pi}\sum_{r=0}^{M}\frac{(-1)^{q+r+m}\Gamma(m+5/2)\Gamma(q+r-m-1/2)}{r!(q!)^2\Gamma(r-m-1/2)\Gamma(q+r-m+1)}$$

$$\times\left(\frac{kb}{2}\right)^{2(q+r-m)}, \tag{49}$$

and

$$\Phi_q = \frac{a}{b}\sum_{n=1}^{N}\frac{(-1)^q J_1(j_{0n}a/b)}{(q!)^2 J_1^2(j_{0n})}\left(\frac{j_{0n}}{2}\right)^{2q-1}, \tag{50}$$

which is solved for $q = 0, 1, 2, \ldots, M-1, M$. In the case of $b = a$, the problem reduces to that of *a rigid disk in free space*, in which case

$$\Phi_q = \delta_{q0}, \tag{51}$$

where δ_{q0} is the Kronecker delta function. In the case of $b = 8a$, calculations were performed with $M = 200$, $N = 40$, and 140 digits of precision. These values were reduced in proportion to b/a for smaller baffle sizes.

H. Surface pressure

From Eq. (28), it follows that

$$\tilde{A}_m = \tau_m(m + 3/2)kb\rho c\tilde{u}_0. \tag{52}$$

After substituting this in Eq. (7), the surface pressure can be written as

$$\tilde{p}_+(w_0) = kb\rho c\tilde{u}_0\sum_{m=0}^{M}\left(m+\frac{3}{2}\right)\tau_m\left(1-\frac{w_0^2}{b^2}\right)^{m+(1/2)}. \tag{53}$$

I. Radiation impedance

The total force $\tilde{F}$ acting upon the disk can be found by integrating the pressure from Eq. (53) over its surface on *both* sides as follows:

$$\tilde{F} = -\int_0^{2\pi}\int_0^a 2\tilde{p}_+(w_0)w_0\,dw_0\,d\phi_0$$

$$= -2\pi kb^3\rho c\tilde{u}_0\sum_{m=0}^{M}\tau_m\left\{1-\left(1-\frac{a^2}{b^2}\right)^{m+(3/2)}\right\}. \tag{54}$$

The acoustic radiation impedance z_{ar} is then given by

$$z_{ar} = \frac{\tilde{F}}{S\tilde{U}_0} = \frac{\tilde{F}}{S^2\tilde{u}_0} = \frac{2\rho c}{S}(R_R + iX_R), \tag{55}$$

where $\tilde{U}_0$ is the total volume velocity produced by the disk and S is the area of the disk given by $S = \pi a^2$. R_R is the normalized radiation *resistance* given by

$$R_R = -kb\frac{b^2}{a^2}\sum_{m=0}^{M}\mathfrak{R}(\tau_m)\left\{1-\left(1-\frac{a^2}{b^2}\right)^{m+(3/2)}\right\}, \tag{56}$$

and X_R is the normalized radiation *reactance* given by
FIG. 3. Normalized radiation impedance of a disk in a finite open-back baffle.

$$X_R = -kb\frac{b^2}{a^2}\sum_{m=0}^{M} \Im(\tau_m)\left\{1 - \left(1 - \frac{a^2}{b^2}\right)^{m+(3/2)}\right\}. \quad (57)$$

This result is plotted in Fig. 3. By using standard curve-fitting methods, the following asymptotic expressions can be written:

$$R_R \approx 0.068\left(\frac{b^2}{a^2} - 0.56\right)k^4a^4, \quad kb < 0.5, \quad (58)$$

$$X_R \approx \frac{8(3b - 2a)}{3\pi(3b - a)}ka, \quad kb < 0.5. \quad (59)$$

J. Near-field pressure response

Applying expression for $\widetilde{A}_m$ in Eq. (52) to Eq. (15), the normalized near-field pressure can be written

$$\frac{\widetilde{p}(w,z)}{\rho c\widetilde{u}_0} = -kb^2\sum_{m=0}^{\infty} \tau_m\Gamma\left(m + \frac{5}{2}\right)$$
$$\times \int_0^{\infty}\left(\frac{2}{\mu b}\right)^{m+(1/2)} J_{m+(3/2)}(\mu b)J_0(\mu w)e^{-i\sigma z}d\mu. \quad (60)$$

By substituting $\mu = kt$, Eq. (60) can be written

$$\frac{\widetilde{p}(w,z)}{\rho c\widetilde{u}_0} = -4\sum_{m=0}^{M} \tau_m\Gamma\left(m + \frac{5}{2}\right)\left(\frac{2}{kb}\right)^{m-(3/2)}$$
$$\times \left(\int_0^1 \frac{1}{t^{m+(1/2)}}e^{-ikz\sqrt{1-t^2}}J_{m+(3/2)}(kbt)J_0(kwt)dt\right.$$
$$+ \left.\int_1^{\infty} \frac{1}{t^{m+(1/2)}}e^{-kz\sqrt{t^2-1}}J_{m+(3/2)}(kbt)J_0(kwt)dt\right). \quad (61)$$

The infinite integral in Eq. (61) converges so rapidly that the infinite limit can be replaced with a finite value of say, 50, without significant loss of accuracy. The result is shown in Fig. 4 for $b=2a$ with various values of ka.

$ka = 1$

$ka = 3$

$ka = 5$

$ka = 10$
FIG. 4. Near-field pressure response of a disk in a finite open-back baffle with $b=2a$.

K. Far-field pressure response

In the case of the far-field response, it is more convenient to use spherical coordinates so that the far-field polar responses can be obtained directly. Rayleigh's far-field approximation[1] is ideal for this purpose

$$g(r,\theta,\phi|w_0,\phi_0,z_0) = \frac{1}{4\pi r}e^{-ik[r-w_0\sin\theta\cos(\phi-\phi_0)-z_0\cos\theta]}. \quad (62)$$

Again, the second term or *dipole* part of Eq. (1) is used, but this time in spherical coordinates

$$\tilde{p}(r,\theta,\phi) = -\int_0^{2\pi}\int_0^b (\tilde{p}_+(w_0) - \tilde{p}_-(w_0))$$

$$\times \frac{\partial}{\partial z_0} g(r,\theta,\phi|w_0,\phi_0,z_0)|_{z_0=0+} w_0\, dw_0\, d\phi_0. \tag{63}$$

However, it is necessary to find the surface normal gradient of the far-field Green's function given in Eq. (62)

$$\frac{\partial}{\partial z_0} g(r,\theta,\phi|w_0,\phi_0,z_0)|_{z_0=0+} = ik\cos\theta\frac{1}{4\pi r}e^{-ikr}$$

$$\times e^{ikw_0 \sin\theta \cos(\phi-\phi_0)}. \tag{64}$$

As the disk is axially symmetric, any reference angle ϕ may be chosen in Eq. (64). Therefore, the problem can be simplified by letting $\phi=\pi/2$ so that $\cos(\phi-\phi_0)=\sin\phi_0$. Inserting Eq. (64) and Eq. (53) into Eq. (63) and integrating over the surface of the disk yields

$$\tilde{p}(r,\theta) = -ik\rho c S\tilde{u}_0\frac{1}{2\pi r}e^{-ikr}D(\theta), \tag{65}$$

where S is the area of the disk, given by $S=\pi a^2$, and the following identities[15] have been used:

$$\frac{1}{2\pi}\int_0^{2\pi} e^{it\sin\phi_0}d\phi_0 = J_0(t), \tag{66}$$

where $t=kw_0\sin\theta$ together with Eq. (16), where $\mu=k\sin\theta$. The directivity function $D(\theta)$ is given by

$$D(\theta) = -kb\frac{b^2}{a^2}\cos\theta\sum_{m=0}^{M}\tau_m\Gamma\left(m+\frac{5}{2}\right)\left(\frac{2}{kb\sin\theta}\right)^{m+(3/2)}$$

$$\times J_{m+(3/2)}(kb\sin\theta). \tag{67}$$

The on-axis pressure is evaluated using $\theta=0$ in Eq. (64) before inserting it into Eq. (63). This results in an integral that is similar to the one for the radiation impedance in equation Eq. (54). Hence

$$D(0) = -kb\frac{b^2}{a^2}\sum_{m=0}^{M}\tau_m. \tag{68}$$

It is worth noting that in the unbaffled case, where $b=a$, the on-axis response is simply defined by $D(0)=R_R+iX_R$. Again, using standard curve-fitting methods, the following asymptotic expression can be written:

$$D(0) \approx i0.66\left(\frac{b}{a}-0.3\right)ka, \quad kb<0.5. \tag{69}$$

The normalized on-axis response is shown in Fig. 5, where the normalized SPL is given by

$$\text{SPL}_{\text{Norm}} = 20\log_{10}|D(0)|. \tag{70}$$

The normalized directivity function $20\log_{10}(|D(\theta)|/|D(0)|)$ is plotted in Fig. 6 with $b=2a$ for various values of ka and in Fig. 7 with $ka=\pi/2$ for various values of b/a.
FIG. 5. Normalized far-field on-axis response of a disk in a finite open-back baffle with constant acceleration.

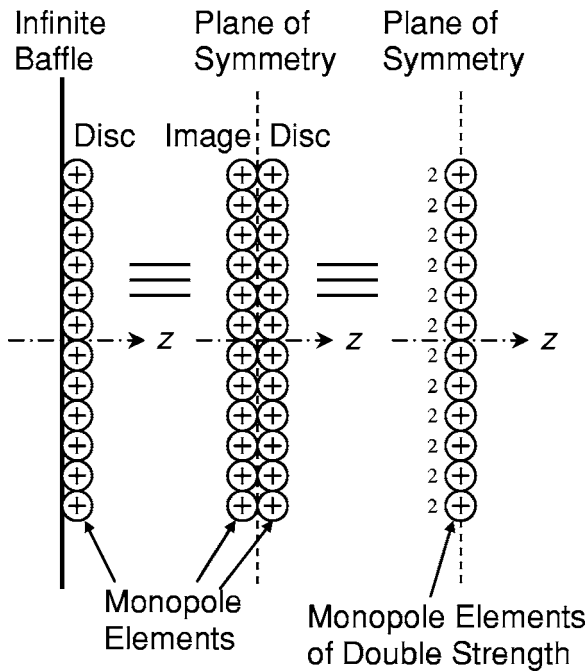

FIG. 8. Rigid disk in an infinite baffle.

III. RIGID DISK IN AN INFINITE BAFFLE

A. Boundary conditions

The original derivation of the radiation impedance by Lord Rayleigh[17] over 100 years ago used an ingenious coordinate system to simplify the problem. Stenzel[18] derived the near-field pressure response using the simple omnidirectional Green's function. Since equations describing the radiation characteristics of a disk in an infinite baffle are needed for Sec. IV, it is perhaps worth providing a brief review of King's method,[19] which is consistent with Sec. II as it uses the Green's function in cylindrical coordinates.

The disk shown in Fig. 1 is now mounted in an infinite baffle in the xy plane and oscillates in the z direction with a harmonically time-dependent velocity $\tilde{u}_0$. The area of each surface element is given by Eq. (2). However, the dipole elements are replaced with *monopole* elements as shown in Fig. 8. The monopole source elements and their images together form the disk source. Since they are coincident in the plane of the baffle, they combine to form elements of double strength. Hence, the disk in an infinite baffle can be modeled as a "breathing" disk in free space. It may also be considered as a pulsating sphere of the same radius compressed into the plane of the disk. Due to the symmetry of the pressure fields on either side of the baffle, there is the following Neumann boundary condition on its surface:

$$\frac{\partial}{\partial z}\tilde{p}(w,z)\big|_{z=0+} = 0, \quad a < w \leq \infty, \tag{71}$$

and on the surface of the disk there is the coupling condition

$$\frac{\partial}{\partial z}\tilde{p}(w,z)\big|_{z=0+} = -ik\rho c\tilde{u}_0, \quad 0 \leq w \leq a, \tag{72}$$

where ρ is the density of air or any other surrounding medium and c is the speed of sound in that medium.

B. Near-field pressure

The pressure distribution, in accordance with the Huygens–Fresnel principle, is given by the first term or *monopole* part of Eq. (1) taking into account the double-layer source

$$\tilde{p}(w,z) = 2\int_0^{2\pi}\int_0^a g(w,z|w_0,z_0)$$

$$\times \frac{\partial}{\partial z_0}\tilde{p}(w_0,z_0)\big|_{z_0=0+}w_0\,dw_0\,d\phi_0. \tag{73}$$

Inserting the Green's function of Eq. (12), together with Eq. (72), into Eq. (73), while integrating over the surface of the disk yields

$$\frac{\tilde{p}(w,z)}{\rho c\tilde{u}_0} = -ka\int_0^\infty J_1(\mu a)J_0(\mu w)\frac{1}{\sigma}e^{-i\sigma z}d\mu, \tag{74}$$

where we have used Eq. (22) with $y=w_0/a$ and $\mu=j_{0m}/b$. By substituting $\mu=kt$, Eq. (74) can be written

$$\frac{\tilde{p}(w,z)}{\rho c\tilde{u}_0} = -ka\left(\int_0^1 \frac{1}{\sqrt{1-t^2}}e^{-ikz\sqrt{1-t^2}}J_1(kat)J_0(kwt)dt\right.$$

$$\left. + i\int_1^\infty \frac{1}{\sqrt{t^2-1}}e^{-kz\sqrt{t^2-1}}J_1(kat)J_0(kwt)dt\right). \tag{75}$$

The infinite integral in Eq. (75) converges so rapidly that the infinite limit can be replaced with a finite value of, say, 50 without significant loss of accuracy. This result is shown in Fig. 9 for various values of ka.

C. Radiation impedance

The total force $\tilde{F}$ acting upon the disk can be found by integrating the pressure from Eq. (74) over its surface as follows:

$$\tilde{F} = -\int_0^{2\pi}\int_0^a \tilde{p}(w,z)\big|_{z=0+}w\,dw\,d\phi = 2\pi ka^2\rho c\tilde{u}_0$$

$$\times \left(\int_0^k \frac{J_1^2(\mu a)}{\mu\sqrt{k^2-\mu^2}}d\mu - i\int_k^\infty \frac{J_1^2(\mu a)}{\mu\sqrt{\mu^2-k^2}}d\mu\right), \tag{76}$$

where Eq. (22) has again been used. Using King's solutions[19] to the integrals over μ in Eq. (76) leads to the following expression for the acoustic radiation impedance:

$$z_{ar} = \frac{\tilde{F}}{S\tilde{U}_0} = \frac{\tilde{F}}{S^2\tilde{u}_0} = (R_R - iX_R)\frac{\rho c}{S}, \tag{77}$$

where $\tilde{U}_0$ is the total volume velocity produced by the disk and S is its surface area given by $S = \pi a^2$. R_R is the normalized radiation *resistance* given by

ka = 1

ka = 3

ka = 5

ka = 10
FIG. 9. Near-field pressure response of a disk in an infinite baffle.

$$R_R = 1 - \frac{J_1(2ka)}{ka}, \tag{78}$$

and X_R is the normalized radiation *reactance* given by

$$X_R = \frac{\mathbf{H}_1(2ka)}{ka}, \tag{79}$$

where J_1 is the first-order Bessel function and $\mathbf{H}_1$ is the first-order Struve function. This result is plotted in Fig. 10. The following well-known asymptotic expressions can also be written:
FIG. 10. Normalized radiation impedance of a disk in an infinite baffle.

$$R_R \approx k^2 a^2/2, \quad ka < 0.5, \tag{80}$$

$$X_R \approx 8ka/(3\pi), \quad ka < 0.5. \tag{81}$$

D. Far-field response

Again, the first term or *monopole* part of the K-H boundary integral formula (1) is used, but this time in spherical coordinates

$$\tilde{p}(r,\theta,\phi) = 2 \int_0^{2\pi} \int_0^a g\,(r,\theta,\phi|w_0,\phi_0,z_0)\big|_{z_0=0+}$$

$$\times \frac{\partial}{\partial z_0} \tilde{p}(w_0,\phi_0,z_0)\big|_{z_0=0+} w_0\,dw_0\,d\phi_0. \tag{82}$$

Equation (62) and Eq. (72) can now be inserted into Eq. (82), again letting $n=0$ and $\phi=\pi/2$ so that $\cos(\phi-\phi_0)=\sin\phi_0$. Integrating over the surface of the disk while using Eq. (66) and Eq. (22) with $j_{0m}/b=k\sin\theta$ yields

$$\tilde{p}(r,\theta) = -ik\rho c S\tilde{u}_0 \frac{1}{2\pi r} e^{-ikr} D(\theta), \tag{83}$$

where S is the area of the disk given by $S=\pi a^2$. The directivity function $D(\theta)$ is given by

$$D(\theta) = \frac{2J_1(ka\sin\theta)}{ka\sin\theta}. \tag{84}$$

The normalized directivity function $20\log_{10}|D(\theta)|$ is plotted in Fig. 11 for various values of ka. The on-axis pressure is evaluated using $\theta=0$ in Eq. (62) before inserting it into Eq. (82), which leads to

$$D(0) = 1. \tag{85}$$

The final result is most commonly written

$$\tilde{p}(r,0) = -i\omega\rho\tilde{U}_0 \frac{1}{2\pi r} e^{-ikr}, \tag{86}$$

where the volume velocity is given by $\tilde{U}_0 = S\tilde{u}_0$.
FIG. 11. Normalized far-field directivity function of a disk in an infinite baffle.

FIG. 12. Rigid disk in a finite closed-back circular baffle.

IV. RIGID DISK IN A FINITE, CLOSED-BACK CIRCULAR BAFFLE

A. Boundary conditions

The disk shown in Fig. 1, together with its circular baffle, lies in the xy plane and oscillates in the z direction with velocity $\tilde{u}_0$. The radius of the disk a and the inner and outer radii of the baffle are a and b, respectively. However, the configuration is now modified so that sound from the rear of the disk is blocked by a small cylindrical enclosure of radius b and depth h. The model is valid providing $h \leqslant a/4$, although the radiation impedance is virtually the same as that of a *rigid disk at the end of a flanged infinite tube* (or an unflanged tube[5] in the case of $b=a$). The area of each surface element is given by Eq. (2).

B. Near-field pressure

It is shown in Fig. 12 that the pressure distribution of the closed-back radiator is the sum of the outputs of the same radiator with an open back and in an infinite baffle. In other words, it uses the full K-H boundary integral of Eq. (1) in-

cluding both the dipole and monopole parts. Hence, the near-field pressure distribution can be obtained by summing Eq. (61) and Eq. (75). However, in order to normalize the response, the resulting pressure is halved. The result is shown in Fig. 13 with $b=2a$ for various values of ka.
C. Radiation impedance

The same argument can be applied to the radiation impedance too, which is simply proportional to the sum of the surface pressures. The real part of the normalized radiation impedance can thus be obtained by combining Eq. (56) and Eq. (78) as follows:

$$R_R = \frac{1}{2}\left(1 - \frac{J_1(2ka)}{ka}\right.$$
$$\left. - kb\frac{b^2}{a^2}\sum_{m=0}^{M}\Re(\tau_m)\left\{1 - \left(1 - \frac{a^2}{b^2}\right)^{m+(3/2)}\right\}\right). \quad (87)$$

Similarly, the imaginary part can be obtained by combining Eq. (57) and Eq. (79)

$$X_R = \frac{1}{2}\left(\frac{\mathbf{H}_1(2ka)}{ka}\right.$$
$$\left. - kb\frac{b^2}{a^2}\sum_{m=0}^{M}\Im(\tau_m)\left\{1 - \left(1 - \frac{a^2}{b^2}\right)^{m+(3/2)}\right\}\right). \quad (88)$$

This result is plotted in Fig. 14. The asymptotic expressions can be written

$$R_R \approx k^2 a^2/4, \quad ka < 0.5, \quad (89)$$

$$X_R \approx \frac{4}{\pi}\left(\frac{2b-a}{3b-a}\right)ka, \quad ka < 0.5. \quad (90)$$

D. Far-field response

The far-field response takes on the same form as that in both a finite open baffle given by Eq. (65) and an infinite baffle given by Eq. (83)

Pressure

ka = 1

Pressure

ka = 3

Pressure

ka = 5

Pressure

ka = 10
FIG. 13. Near-field pressure response of a disk in a finite closed-back baffle with $b=2a$.

$$\tilde{p}(r,\theta) = -ik\rho cS\tilde{u}_0 \frac{1}{2\pi r} e^{-ikr} D(\theta), \qquad (91)$$

where S is the area of the disk given by $S=\pi a^2$. The direc-
tivity function $D(\theta)$ is obtained by combining the directivity
FIG. 14. Normalized radiation impedance of a disk in a finite closed-back baffle.

function in a finite open baffle given by Eq. (67) with that in
an infinite baffle given by Eq. (84)

$$D(\theta) = \frac{J_1(ka\sin\theta)}{ka\sin\theta} - kb\frac{b^2}{a^2}\cos\theta\sum_{m=0}^{M}\tau_m\Gamma\left(m+\frac{5}{2}\right)$$

$$\times \left(\frac{2}{kb\sin\theta}\right)^{m+3/2} J_{m+(3/2)}(kb\sin\theta). \qquad (92)$$

Similarly, the on-axis response may be obtained by combin-
ing the on-axis response in a finite open baffle given by Eq.
(68) with that in an infinite baffle given by Eq. (85), where
the latter is just unity

$$D(0) = \frac{1}{2}\left(1 - kb\frac{b^2}{a^2}\sum_{m=0}^{M}\tau_m\right). \qquad (93)$$

The normalized on-axis response is shown in Fig. 15 again
using Eq. (70). The normalized directivity function
$20\log_{10}(|D(\theta)|/|D(0)|)$ is plotted in Fig. 16 with $b=2a$ for
various values of ka and in Fig. 17 with $ka=\pi/2$ for vari-
ous values of b/a.

V. BABINET'S PRINCIPLE

Babinet's principle,[20] as developed by Bouwkamp[6] and
Wiener,[4] states that the diffraction pattern resulting from the
transmission of a plane wave through a hole in an infinite
resilient screen (i.e., with zero surface impedance) is equiva-
lent to that produced by the scattering of the same incident
FIG. 15. Normalized far-field on-axis response of a disk in a finite closed-
back baffle with constant acceleration.
FIG. 16. Normalized directivity far-field function of a disk in a finite closed-back baffle with $b=2a$.

wave by the complementary rigid disk. Furthermore, the scattered wave is identical to that produced if the disk itself were oscillating in free space, providing the velocity of the disk is equal and opposite to the particle velocity of the incident wave at the surface of the disk or hole in the absence of any obstacle. This is illustrated in Fig. 18. For clarity, the diagram portrays the scattering of a sound wave at some very high frequency where there is minimal diffraction. However, the principle applies at all frequencies. The resulting sound field is given by

$$\widetilde{p}(\mathbf{r}) = \widetilde{p}_{\text{Inc}}(\mathbf{r}) + \widetilde{p}_{\text{Scat}}(\mathbf{r}), \tag{94}$$

where $\widetilde{p}_{\text{Inc}}(\mathbf{r})$ is the incident sound field in the absence of a hole or disk given by
FIG. 17. Normalized directivity far-field function of a disk in a finite closed-back baffle with $ka=\pi/2$.
FIG. 18. Babinet's principle.

$$\widetilde{p}_{\text{Inc}}(z) = \begin{cases} -ik\rho c\widetilde{\Psi}(e^{ikz} - e^{-ikz}), & \text{bright side of screen} \\ 0, & \text{dark side of screen} \\ -ik\rho c\widetilde{\Psi}e^{ikz}, & \text{without disk(or screen)} \end{cases}$$

$$\tag{95}$$

and using Eq. (75) for $\widetilde{p}_{\text{Scat}}(w,z)$ or Eqs. (83) and (84) for $\widetilde{p}_{\text{Scat}}(r,\theta)$. Also, it can be stated that the force $\widetilde{F}_{\text{inc}}$ exerted upon the disk by an incident wave is given by

$$\widetilde{F}_{\text{inc}} = z_{\text{ar}}S\widetilde{u}_{\text{p}}, \tag{96}$$

where $\widetilde{u}_{\text{p}}$ is the undisturbed incident wave particle velocity at the surface of the disk and S is its surface area. The radiation impedance z_{ar} is given by Eqs. (55)–(57).

VI. APPROXIMATION FOR THE RIGID DISK IN FREE SPACE (RADIATION FROM AN UNBAFFLED RESILIENT DISK)

The following section contains a review of a historical approach to the problem of the disk in free space.[1] Prior to the work of Bouwkamp,[6] the Kirchhoff theory of diffraction had been used, which makes an assumption of equally distributed surface pressure in order to simplify the problem. In the case of diffraction, the pressure across the complementary hole in an infinite resilient screen is assumed to be the same as that of the incident wave, as if it were completely unaffected by the hole. In the case of radiation from a disk, if the pressure is constant, the velocity has to be allowed to vary across its radius so that it is no longer rigid. In fact, this produces a hypothetical sound source in which an equal driving force is applied directly to each air particle over the surface represented by the resilient "disk." Unlike a membrane, however, there is no boundary condition of zero displacement at the perimeter. Hence, this model creates some problems since it requires constant pressure to be maintained right up to the outer edge, where there is effectively an acoustic "short circuit" between the front and rear surfaces. Therefore, the reactive particle velocity at the perimeter is infinite, as is also the imaginary admittance.

The disk shown in Fig. 1 lies in the xy plane and a uniform driving force $\widetilde{F}$ is applied in the z direction. The area of a surface element is given by Eq. (2) and the boundary

conditions of Eq. (3), Eq. (4), and Eq. (6) are assumed with $b=a$. Let the surface pressure distribution on the front and rear faces be defined by

$$\tilde{p}_+(w_0) = -\tilde{p}_-(w_0) = -\frac{\tilde{F}}{2S}, \tag{97}$$

where the total surface area S on each face is given by $S = \pi a^2$. Inserting Eq. (97) together with Eq. (14) in Eq. (8) and integrating over the surface area of the disk yields

$$\tilde{p}(w,z) = \frac{a\tilde{F}}{2S_D} \int_0^\infty J_1(\mu a)J_0(\mu w)e^{-i\sigma z}d\mu, \tag{98}$$

where Eq. (22) has been used. The disk velocity $\tilde{u}_0(w)$ can be derived from the boundary condition of Eq. (6) as follows:

$$\tilde{u}_0(w) = \frac{i}{k\rho c} \frac{\partial}{\partial z} \tilde{p}(w,z)\big|_{z=0+}$$

$$= \frac{a\tilde{F}}{2k\rho c S_D} \int_0^\infty J_1(\mu a)J_0(\mu w)\sigma \, d\mu. \tag{99}$$

Integrating the velocity over the area of the disk provides the total volume velocity $\tilde{U}_0$ as follows:

$$\tilde{U}_0 = \int_0^{2\pi}\int_0^a \tilde{u}_0(w)w \, dw \, d\phi = \frac{\pi a^2 \tilde{F}}{k\rho c S_D} \int_0^\infty J_1^2(\mu a)\frac{\sigma}{\mu}d\mu, \tag{100}$$

where Eq. (22) has been used again. The acoustic radiation impedance z_{ar} can now be written as

$$z_{ar} = \frac{\tilde{F}}{S_D\tilde{U}_0} = \frac{2\rho c}{S_D Y_R}, \tag{101}$$

where Y_R is the normalized acoustic radiation *admittance*, which is expressed here as the sum of its real and imaginary parts

$$Y_R = G_R + iB_R, \tag{102}$$

where G_R is the normalized *conductance* given by

$$G_R = \frac{2}{k}\int_0^k \frac{\sqrt{k^2 - \mu^2}}{\mu} J_1^2(\mu a)d\mu, \tag{103}$$

and B_R is the normalized *susceptance* given by

$$B_R = \frac{2}{k}\int_k^\infty \frac{\sqrt{\mu^2 - k^2}}{\mu} J_1^2(\mu a)d\mu. \tag{104}$$

The solution[16] to Eq. (103) is

$$G_R = 1 + \frac{1}{ka}J_1(2ka) - 2J_0(2ka) - \pi[J_1(2ka)\mathbf{H}_0(2ka)$$

$$- J_0(2ka)\mathbf{H}_1(2ka)] \approx \frac{k^2a^2}{6}, \quad ka < 0.5. \tag{105}$$

Unfortunately, the integral in Eq. (104) does not converge and therefore cannot be solved due to the acoustic short circuit at the perimeter mentioned above. However, using the admittance of a disk in an infinite baffle from Sec. III and
FIG. 19. Normalized radiation admittance of a disk in free space according to historical approximation.

doubling it yields a reasonably good approximation to the actual solution for a rigid disk as follows:

$$B_R = \frac{2ka\mathbf{H}_1(2ka)}{[ka - J_1(2ka))^2 + (\mathbf{H}_1(2ka)]^2} \approx \frac{3\pi}{4ka}, \quad ka < 0.5. \tag{106}$$

The real and imaginary admittances G_R and B_R are plotted in Fig. 19 along with the actual admittances derived from Sec. II for comparison. Also, the impedance may be written as

$$R_R = \frac{G_R}{G_R^2 + B_R^2} \approx \frac{8k^4a^4}{27\pi^2}, \quad ka < 0.5, \tag{107}$$

$$X_R = \frac{B_R}{G_R^2 + B_R^2} \approx \frac{4ka}{3\pi}, \quad ka < 0.5. \tag{108}$$

Again, using Eq. (64) together with Eq. (97) and inserting them into Eq. (63) leads to the following directivity function:

$$D(\theta) = \frac{2J_1(ka \sin\theta)}{ka \sin\theta}\cos\theta. \tag{109}$$

VII. CONCLUSIONS

Referring to Fig. 5, it can be seen that in the case of an unbaffled rigid disk radiating from both sides, the on-axis sound output falls at 6 dB/octave for small values of ka due to the decreasing path difference (as a proportion of wavelength λ) between the antiphase rear radiation and the front radiation, which it partially cancels.

At larger values of ka, the rear radiation from the disk moves in and out of phase with that from the front. However, the comb filter effect is fairly "smeared," the largest peak being 3 dB at $ka=\pi/\sqrt{2}$ or $\lambda=2\sqrt{2}a$. The reason for this is that rear radiation comprises many point sources spread all across the radius of the disk, each with a different path length to the front, so that at no particular frequency do they produce a combined source that is either directly in phase or out of phase with the output from the front.

By contrast, when including a circular baffle and then increasing its size, the actual radiating area decreases in proportion to the total so that it behaves more like a coherent point source at the center. Hence, in the case of $b=4a$, a deep null can be seen at $ka=\pi/2$ or $\lambda=4a$, which is the distance

from the center to the edge. Of course, a disk at the center of a circular baffle is the "worst case," and it would be interesting to compare these results with those of an offset disk in a circular, rectangular, or elliptical baffle, for example, in order to "smear" the path difference effect. It could be postulated that, if the size of the baffle were increased still further, the response would converge towards that of an infinite baffle, where the latter is just a ruler flat line.

At larger values of ka, it can be seen that the near-field pressure responses in finite and infinite baffles converge (see Figs. 4 and 9, respectively). It seems that, as the polar response narrows, obstacles that are placed either side of the sound source have less effect upon the sound field. Also, distinct interference patterns start to emerge due to the presence of a rigid (i.e., opaque) sound source, or obstacle in the case of a scattered incident wave.

The on-axis response of the disk in a closed baffle, shown in Fig. 13, holds few surprises. As would be expected from the averaged response of a disk in a finite baffle and an infinite baffle, the same ripples as in Fig. 5 appear, but are reduced in magnitude. It is fairly well known that a source in a small enclosure produces 6 dB less sound output at low to medium frequencies in free space than when placed against a large plane surface. At high frequencies, of course, the size of the baffle has little effect and the source behaves as though the baffle is infinite. From the curves of Fig. 13, some idea may be gained of how the frequency at which the 6-dB shift occurs is related to the size of the baffle. In the impedance plot of Fig. 14, Crane's results for $b=a$ and $b=8a$ are included for comparison. In the case of $b=a$, the two calculation methods differ by less than 10%. However, when b is increased to $8a$, the real impedance differs by up to 24%, although the imaginary impedance matches within 5%.

Applying the unbaffled curve of Fig. 5 to the sound transmitted through a circular aperture (according to Babinet's principle), it can be seen that the hole is a weak radiator for small ka, as would be expected when considering that as the radiation impedance approaches zero, it increasingly matches that of the rest of the reflective screen. Even what little power does pass through the hole tends to flow back towards the screen. The power transmission coefficient is the real unbaffled impedance of Fig. 3. As Bouwkamp[6] and Spence[7] pointed out, a hole in a rigid screen is a much more effective radiator of power at low frequencies, returning an asymptotic transmission coefficient (or real radiation admittance) of $8/\pi^2$. The latter is a pressure source like the unbaffled resilient disk described in Sec. VI, where the pressure is that of the undisturbed incident wave and could therefore be considered as a resilient disk in an infinite baffle.

It can be seen from Fig. 17 that the approximation to the radiation admittance of a rigid disk in free space is surprisingly close to the actual solution and indeed converges towards it at low frequencies, yielding rational asymptotic expressions for the admittance and impedance. The main difference is that the ripples are missing from the real part at higher frequencies. The real part, however, is the rigorous transmission coefficient of the hypothetical resilient disk, and shows that such a transducer would be a much more effective radiator at low frequencies than a rigid disk, for

which the transmission coefficient is the real impedance. However, the directivity function given by Eq. (109) is perhaps not such a useful approximation except at low frequencies ($ka \leqslant 3$). At high frequencies, it does not converge towards that of a disk in an infinite baffle, as does the actual directivity function of an unbaffled rigid disk.

Finally, when the surface velocity is expressed as a power series function of the radius, it is theoretically possible to accommodate any velocity distribution. This enables Eq. (17) for the velocity distribution to be applied to fluid-structure coupled problems, such as a circular membrane or plate, providing a suitable Green's function is used for the structure. In order to verify the method described in Sec. II, it has been found that Streng's results[14] can be reproduced, but only if the $m=0$ term of Eq. (7) is included. The reason originally stated for omitting this term[10] was that there is neither outward-radial nor axial particle displacement at the perimeter and therefore the radial pressure gradient there is expected to be zero. However, the radial particle displacement at the perimeter is due to the sum of the front and rear radial pressure gradients, which are equal and opposite and therefore cancel. The method has also been verified using FEM. It is hoped that the solutions provided in this paper serve as an illustration of how the symbolic handling capability of modern mathematical software tools may be used to simplify fundamental problems. For example, the conventional equations describing the radiation impedance of a rigid disk in free space or a finite open baffle were considered too complicated to reproduce in most textbooks, whereas Eqs. (47)–(51) and Eqs. (55)–(57) appear to be relatively compact.

This paper aims to apply the radiative transfer method to acoustical diffraction by obstacles. Some fictitious sources are introduced at diffracting wedges and a transfer equation based on energy balance determines the diffracted powers. It leads to a set of linear equations on diffracted powers which can be solved in a finite number of steps. It is then possible to calculate the diffracted field anywhere. Some applications to diffraction by obstacles of various shapes are presented. Results of this method are compared with Geometrical Theory of Diffraction and BEM reference calculations. It is shown that this method is particularly efficient in case of multiple diffraction where the ray-tracing technique involves an infinite number of rays between a source and a receiver point. © 2005 Acoustical Society of America. LIST OF SYMBOLS

γ_0 = solid angle of space;
Ω = acoustical domain;
Γ = surface of Ω;
Δ = set of diffracting points of Γ;
c = speed of sound;
m = attenuation factor;
W = energy density;
$\mathbf{I}$ = intensity vector;
G = energy density of direct field;
$\mathbf{H}, H$ = intensity of direct field, magnitude;
D_ω = energetic coefficient of diffraction;
ρ = magnitude of actual sources;
σ = magnitude of diffraction sources;
$\mathbf{u}, \theta, \alpha$ = emission direction, emission angles;
$\mathbf{v}, \varphi, \beta$ = incidence direction, incidence angles;
$\mathbf{s}$ = source point;
$\mathbf{r}$ = receiver point;
$\mathbf{p}, \mathbf{q}$ = diffraction point.

I. INTRODUCTION

The Geometrical Theory of Diffraction (GTD), stated by Keller[1] in the 1960s, leads to an elegant description of diffraction in terms of rays. Starting from a generalized Fermat's principle, GTD states the existence of diffracted rays by wedges and peaks, creeping rays, and many others in addition to the classical direct and reflected rays of geometrical optics. It is then possible to predict the field in the shadow zone of obstacles in a simple way, provided that all paths from the source to the receiver point are listed. The field at the receiver point is simply the sum of all the fields attached to individual rays.

GTD has been successfully applied in acoustics for the problem of single-edge diffraction[2,3] and all problems of diffraction around corners such as buildings or the top of the noise barriers. When the diffracting structure has more than one point of diffraction, waves can be diffracted at each point more than once. This is referred to as multiple diffraction, and can lead to an unlimited number of possible paths for diffracted rays. Pierce[4] gives an approximate expression for double-edge diffraction by a thick, three-sided barrier based on concepts inherent to the GTD. His formulation is particularly well suited for convex-shaped edges, small angles of diffraction, and when the width of the barrier exceeds one wavelength. It was used by Kurze[5] to assess the efficiency of wide barriers. The work of Medwin *et al.*[6] is dedicated to double diffraction in the time domain and is applicable to any multiple diffraction. The technique consists in introducing an infinite number of infinitesimal sources at the first edge, each of which spawns an infinite number of diffractions at the second edge. This method is applied by Ouis[7] to improve the evaluation of the insertion loss of a hard wedged barrier. The multiple diffraction, up to second order, between the top of the wedge barrier and its base is considered. In the same context, Jin *et al.*[8] predict the insertion loss of partially inclined noise barriers considering multiple diffraction occurring at convex as well as concave edges. Formulations for single to triple diffracted waves are constructed based on Kouyoumjian and Pathak's diffraction theory.[9] They show that including additional diffraction at edges improves GTD by removing many small oscillations in the frequency domain. In any case, all these methods take into account a finite number of diffraction order. GTD is particularly well suited in cases where the number of paths is limited or, at least, where all paths can be clearly identified. But, in all other cases, the determination of all source-receiver paths may lead to unsuspected difficulties.

There exists another way to present geometrical acoustics: the so-called "standard procedure" or factor view method in radiative transfer.[10] It is based on a transfer equation which states the equilibrium of energy exchange between two facing surfaces. All rays traveling between these two surfaces, including infinitely reflected ones, are taken into account in the form of an integral equation.

[a] Electronic mail: alain.le-bot@ec-lyon.fr

In acoustics, an application of this method leads to the so-called "radiosity method,"[11–14] which aims at the prediction of reverberation time beyond the validity of Sabine's formula. Applied to the determination of SPL in rooms,[15] vibrational levels in built-up structures[16] or radiation of sound,[17] the radiative transfer approach provides an alternative to both the ray-tracing technique in room acoustics and the statistical energy analysis in vibroacoustics. Related works based on an energy approach include for room acoustics[18] and for noise radiated by structures.[19]

This paper aims to generalize the radiosity method to account for diffraction, that is, to establish the transfer equation for diffraction sources. However, this study is limited to diffraction by wedges and peaks. Diffraction by smooth objects such as cylinders involves creeping waves that are not included in this work. For wedges and peaks, some fictitious diffraction sources are introduced at diffracting vertices. The total diffracted power of these sources is the sum of the diffracted powers of the individual rays. The transfer equation for diffraction sources is established. In some cases of multiple diffraction, i.e., where several diffraction sources interact, it reduces to a linear set of equations on power of diffraction sources. It is then possible to determine the diffracted powers and so, the energy field in the whole acoustical domain. This method allows the solving of multiple diffraction problems in a finite number of steps, to be compared with the infinite number of rays needed in the classical ray-tracing approach. Some results have been published[20] in a short note but limited to the particular two-dimensional case. In this paper, the development of the method is completely detailed including the three-dimensional case.

The outline of the present paper is as follows. In Sec. II all the theoretical material is presented, fictitious diffraction sources are introduced, and the transfer equation which determines their magnitude is derived from power balance. In Sec. III, the transfer equation is solved in the case of a plane wave incident on a three-dimensional wedge, and it is shown that it is consistent with the classical solution of GTD. The diffraction by double wedges is dealt with in Sec. IV. This example highlights the method for solving the transfer equation and the difference with classical ray-tracing algorithms of GTD. A more elaborate example is developed in Sec. V to assess the power of the method.

II. RADIATIVE TRANSFER EQUATION

Let us denote by G the energy density attached to the direct field and by $\mathbf{H}$ the intensity field. Expressions for direct fields depend only on the dimension of the wave but not on the kind of system. For instance, the decrease of energy of a circular wave is the same in vibrating plates and on liquid surfaces. The following expressions are valid for any isotropic and homogeneous medium:

$$G(\mathbf{s},\mathbf{r}) = \frac{1}{\gamma_0 c}\frac{e^{-ms}}{s^{n-1}}, \tag{1}$$

$$\mathbf{H}(\mathbf{s},\mathbf{r}) = \frac{1}{\gamma_0}\frac{e^{-ms}}{s^{n-1}}\mathbf{u}, \tag{2}$$

where $\gamma_0 = 2$ and $n=1$ for plane waves, $\gamma_0 = 2\pi$ and $n=2$ for cylindrical waves, and $\gamma_0 = 4\pi$ and $n=3$ for spherical waves. c is the group speed, $s = |\mathbf{s}-\mathbf{r}|$ the source-receiver distance, and m is the attenuation factor to account for the decrease of wave magnitude when traveling. $H=cG$ denotes the magnitude of intensity vector $\mathbf{H}$, and sometimes, for the sake of brievety, $G(\mathbf{s},\mathbf{r})$ and $H(\mathbf{s},\mathbf{r})$ will be denoted $G(s)$ and $H(s)$ with $s = |\mathbf{s}-\mathbf{r}|$.

In some cases, an obstacle located between the source and the receiver can stop the direct field. The receiver is not affected by the direct field, but can be affected by some reflected or diffracted fields. It is then convenient to introduce a visibility function $V(\mathbf{s},\mathbf{r})$ equal to 1 when $\mathbf{r}$ is visible from $\mathbf{s}$ and 0 otherwise. Final expressions for direct field are

$$G(\mathbf{s},\mathbf{r}) = V(\mathbf{s},\mathbf{r})\frac{1}{\gamma_0 c}\frac{e^{-ms}}{s^{n-1}}, \tag{3}$$

$$\mathbf{H}(\mathbf{s},\mathbf{r}) = V(\mathbf{s},\mathbf{r})\frac{1}{\gamma_0}\frac{e^{-ms}}{s^{n-1}}\mathbf{u}. \tag{4}$$

Thus, direct field is equal to zero in shadow zones of obtacles.

Now, consider the field in a domain Ω induced by some distributed actual sources $\mathbf{s}$ of power density ρ. The direct field is simply the superposition of all individual direct fields, that is, $\int \rho G d\Omega$ where $d\Omega$ is the Lebesgue measure in Ω. Furthermore, waves when traveling are reflected by the surface Γ of the domain and also diffracted by all wedges, peaks, and more generally all singularities of the surface Γ. The set of all diffracting lines is denoted Δ_1 while the set of all diffracting vertices is denoted Δ_0. Some fictitious sources are introduced at all these points where something occurs to incident waves. The power of these fictitious sources is denoted by σ, which may depend on the position of the source but also on the emission direction and time for time-varying problems. In any case, the field radiated by these sources is $\int \sigma G d\Gamma$ for reflection, $d\Gamma$ being the surface measure on Γ, $\int \sigma G d\Delta$ for diffraction by wedges, $d\Delta$ being the length measure on Δ_1 and $\Sigma \sigma G$ for diffraction by peaks, the sum running over the set Δ_0 of all diffracting peaks. Finally, the complete field at any point is obtained by adding the contributions of all types of sources. Therefore, the energy density is at any $\mathbf{r} \in \Omega$ and at time t,

$$W(\mathbf{r},t) = \int_\Omega \rho(\mathbf{s}, t - s/c) G(\mathbf{s},\mathbf{r}) d\Omega_\mathbf{s} + \int_\Gamma \sigma(\mathbf{p},\mathbf{u},t$$
$$- r/c) G(\mathbf{p},\mathbf{r}) d\Gamma_\mathbf{p} + \int_{\Delta_1} \sigma(\mathbf{p},\mathbf{u},t$$
$$- r/c) G(\mathbf{p},\mathbf{r}) d\Delta_\mathbf{p} + \sum_{\mathbf{p} \in \Delta_0} \sigma(\mathbf{p},\mathbf{u},t - r/c) G(\mathbf{p},\mathbf{r}),$$
$$\tag{5}$$

and the intensity is

$$\mathbf{I}(\mathbf{r},t) = \int_{\Omega} \rho(\mathbf{s},t-s/c)\mathbf{H}(\mathbf{s},\mathbf{r})d\Omega_{\mathbf{s}} + \int_{\Gamma} \sigma(\mathbf{p},\mathbf{u},t$$

$$-r/c)\mathbf{H}(\mathbf{p},\mathbf{r})d\Gamma_{\mathbf{p}} + \int_{\Delta_1} \sigma(\mathbf{p},\mathbf{u},t$$

$$-r/c)\mathbf{H}(\mathbf{p},\mathbf{r})d\Delta_{\mathbf{p}} + \sum_{\mathbf{p}\in\Delta_0} \sigma(\mathbf{p},\mathbf{u},t-r/c)\mathbf{H}(\mathbf{p},\mathbf{r}),$$

$$(6)$$

where $s=|\mathbf{r}-\mathbf{s}|$ and $r=|\mathbf{r}-\mathbf{p}|$. $\mathbf{u}$ is the unit vector from the source point $\mathbf{s}$ or $\mathbf{p}$ to the receiver point $\mathbf{r}$ and r/c (or s/c) is the time delay for the propagation of energy from the source point to the receiver point.

Let us turn to the determination of the unknown σ. On the surface Γ where reflection occurs, several reflection laws can be adopted. The case of diffuse reflection has been developed in Ref. 15 and leads to an integral equation on the potential σ which has been solved using a collocation method. Otherwise, a specular law of reflection leads to a functional equation on σ.[21] In all cases where it works, the method of image sources provides a solution of this functional equation.

Consider now the case of diffraction. $D_{\omega}(\mathbf{v},\mathbf{u})$ is an energetic diffraction coefficient depending on two variables, the incident direction $\mathbf{v}$ and the emission direction $\mathbf{u}$. The subscript ω is used to specify that this coefficient also depends on frequency. First, if σ belongs to Δ_0, the energetic coefficient of diffraction $D_{\omega}(\mathbf{v},\mathbf{u})$ is defined as the ratio of the emitted power $d\mathcal{P}_{\text{emit}}$ per unit solid angle du about $\mathbf{u}$ and the incident intensity I_{inc} stemming from $\mathbf{v}$,

$$D_{\omega}(\mathbf{v},\mathbf{u}) = \frac{1}{I_{\text{inc}}} \times \frac{d\mathcal{P}_{\text{emit}}}{du}. \qquad (7)$$

Second, when σ belongs to Δ_1, $D_{\omega}(\mathbf{v},\mathbf{u})$ is defined as the ratio of the emitted power $d\mathcal{P}_{\text{emit}}$ per unit solid angle du about $\mathbf{u}$ and per unit length $d\nu$ of the edge, and the incident intensity I_{inc} stemming from $\mathbf{v}$,

$$D_{\omega}(\mathbf{v},\mathbf{u}) = \frac{1}{I_{\text{inc}}} \times \frac{d\mathcal{P}_{\text{emit}}}{d\nu du}. \qquad (8)$$

When incident energy is distributed among all directions, the emitted power about $\mathbf{u}$ is the sum of contributions of incident intensities leading to the detailed energy balance,[22]

$$\frac{d\mathcal{P}_{\text{emit}}}{du} \text{ or } \frac{d\mathcal{P}_{\text{emit}}}{d\nu du} = \int D_{\omega}(\mathbf{v},\mathbf{u})I_{\text{inc}}(\mathbf{v},t)dv, \qquad (9)$$

where I_{inc} is the incident intensity impinging on the diffracting point $\mathbf{p}$ at time t and stemming from direct, reflected fields and the field diffracted by all other diffracting wedges.

On the other hand, at a distance ϵ of any diffraction point, the emitted intensity is σH, and therefore the flux crossing an infinitesimal solid angle is $d\mathcal{P}_{\text{emit}}=du\sigma H\epsilon^{n-1}$ $=du\sigma e^{-m\epsilon}/\gamma_0$ with the limit $du\sigma/\gamma_0$ for small ϵ. Substitution in Eq. (9) then leads to
FIG. 1. Plane wave incident on a wedge with direction $\mathbf{v}$. The emission direction is denoted $\mathbf{u}$.

$$\frac{\sigma(\mathbf{p},\mathbf{u},t)}{\gamma_0} = \int_{\Omega} D_{\omega}(\mathbf{v},\mathbf{u})\rho(\mathbf{s},t-s/c)H(\mathbf{s},\mathbf{p})d\Omega_{\mathbf{s}}$$

$$+ \int_{\Gamma} D_{\omega}(\mathbf{v},\mathbf{u})\sigma(\mathbf{q},\mathbf{v},t-r/c)H(\mathbf{q},\mathbf{p})d\Gamma_{\mathbf{q}}$$

$$+ \int_{\Delta_1} D_{\omega}(\mathbf{v},\mathbf{u})\sigma(\mathbf{q},\mathbf{v},t-r/c)H(\mathbf{q},\mathbf{p})d\Delta_{\mathbf{q}}$$

$$+ \sum_{\mathbf{q}\in\Delta_0} D_{\omega}(\mathbf{v},\mathbf{u})\sigma(\mathbf{q},\mathbf{v},t-r/c)H(\mathbf{q},\mathbf{p}). \qquad (10)$$

This is a functional equation on the unknown σ for both Δ_0 and Δ_1. Once the potential σ is known, the field at any receiver point $\mathbf{r}$ is determined by applying Eqs. (5) and (6).

III. DIFFRACTION BY WEDGE

In this section, the problem of a steady-state plane wave diffracted by a wedge is solved using the method exposed in Sec. II. The aim is to check whether the energy solution agrees well with the classical GTD analysis in terms of rays. So, consider a plane wave of intensity I_{inc} impinging on a wedge with incidence $\mathbf{v}=\varphi,\beta$ as shown in Fig. 1. The edge of the wedge is along the ν axis. The outer angle of the wedge is denoted ϕ. For any emission direction $\mathbf{u}=\theta,\alpha$, the diffracted potential σ is given by Eq. (10) where the right-hand side reduces to the direct field term, i.e., the first integral,

$$\frac{\sigma(\nu,\theta,\alpha)}{4\pi} = D_{\omega}(\varphi,\beta;\theta,\alpha)I_{\text{inc}}. \qquad (11)$$

It is well known that all energy with incidence β is diffracted into a cone of axis the edge of the wedge and of half-angle β. This is the so-called Keller's cone. The bidirectional energetic coefficient of diffraction $D_{\omega}(\varphi,\beta;\theta,\alpha)$ then reduces to the particular form,

$$D_{\omega}(\varphi,\beta;\theta,\alpha) = D_{\omega}(\varphi,\theta)\delta(\alpha-\beta). \qquad (12)$$

It is found in the Appendix that $D_{\omega}(\varphi,\theta)=|d(\varphi,\theta)|^2$ is the energetic coefficient of diffraction at normal incidence,
FIG. 2. The emission angle α_ν depends on the receiver point **r**. There is a single point $\mathbf{p}(\nu_0)$ where the emission angle equals the incidence angle β.

$d(\varphi, \theta)$ being the classical diffraction coefficient used in GTD. The energetic diffraction coefficient remains unchanged when incidence and emission directions are interchanged following the reciprocity principle,

$$D_\omega(\varphi, \theta) = D_\omega(\theta, \varphi). \tag{13}$$

Furthermore, the symmetry with respect to the medium plan of the wedge implies that the coefficient is invariant under the change of angle $\zeta \to \phi - \zeta$,

$$D_\omega(\varphi, \theta) = D_\omega(\phi - \varphi, \phi - \theta). \tag{14}$$

Now, introducing Eqs. (11) and (12) into the third integral of Eq. (5) leads to the diffracted energy at any point **r** $= r, \theta, z$ in cylindrical coordinates centered on the ν axis,

$$W_{\text{dif}} = \int_{-\infty}^{\infty} \sigma(\nu, \theta, \alpha_\nu) G(\mathbf{p}, \mathbf{r}) d\nu$$

$$= \frac{I_{\text{inc}}}{c} \int_{-\infty}^{\infty} D_\omega(\varphi, \theta) \delta(\alpha_\nu - \beta) \frac{d\nu}{R_\nu^2}, \tag{15}$$

where θ, α_ν are the emission angles at point **p** of coordinate ν on the edge toward **r** and R_ν is the distance between **p** and **r**. To evaluate this last integral, the following result of the theory of distributions is used;

$$\int g(x) \delta[f(x)] dx = \sum_i \frac{g(x_i)}{|f'(x_i)|}, \tag{16}$$

where the sum runs over all zeros of f included in the range of integration. It is found that the function $f(\nu) = \alpha_\nu - \beta = \arctan[r/(z-\nu)] - \beta$ has a single zero $\nu_0 = z - r/\tan\beta$ which corresponds to the unique point for which emission angle α_0 toward **r** equals the incidence angle β (Fig. 2). Then,

$$f'(\nu_0) = \frac{d\alpha_\nu}{d\nu} = \frac{1}{1 + \frac{r^2}{(z-\nu)^2}} \times \frac{d}{d\nu}\left(\frac{r}{z-\nu}\right) = \frac{r}{R_\nu^2}. \tag{17}$$

Finally, the diffracted energy is

$$W_{\text{dif}} = \frac{I_{\text{inc}}}{c} D_\omega(\varphi, \theta) \times \frac{1}{r}, \tag{18}$$

that is, the energy is inversely proportional to the wedge-receiver distance r. The decrease of the energy of the field like $1/r$ well agrees with the decrease of the magnitude of the field like $1/\sqrt{r}$ predicted by GTD.[2]

A numerical simulation is proposed to compare the results given by the radiative transfer method to those given by the GTD. The edge outer angle is $\phi = 7\pi/4$ rad. An incident plane wave hits the wedge and gives rise to a reflected wave, a diffracted wave, and a surface ray propagating along the
FIG. 3. Diffraction by a wedge of a plane wave with incidence $\varphi = 217.5°$. (a) Comparison of the SPL vs θ at $r = 1.5$ m obtained from the radiative equation (—) and GTD (---). The frequency is 1.5 kHz. The boundaries of direct field and diffracted field are, respectively, $\theta = \varphi - \pi$ and $\theta = 2\phi - \varphi - \pi$. (b) Comparison of the SPL vs frequency at $r = 1.5$ m and $\theta = 27.5°$ obtained from the radiative equation (—) and GTD (---). The receiver point is in the shadow area.

wedge. The receiver point is assumed to be far enough from the edge so that surface rays can be neglected. Two results are shown in Fig. 3. On the one hand, the behavior of the acoustical field around the wedge, at a constant distance $r = 1.5$ m from the edge, is represented in a plane perpendicular to the edge of the wedge. The frequency is 1.5 kHz. The incident direction is $\varphi = 217.5°$ from the right side of the wedge, $\beta = 40°$ (Fig. 1). In this problem, there are two boundary lines that, respectively, mark the transition from illumination to shadow for the incident field ($\theta = \varphi - \pi$) and for the reflected field ($\theta = 2\phi - \pi - \varphi$). GTD is known to fail near these geometrical boundaries, and so the radiative transfer method which uses the diffraction coefficient of the GTD also gives inaccurate results in these areas. Thus, both methods lead to similar results all around the wedge including these transition areas where they both lead to unphysical results. On the other hand, the same calculation is performed for a fixed position of the receiver point $r = 1.5$ m, $\theta = 27.5°$ in the shadow area of the wedge, but versus frequency. Both
FIG. 4. Plane wave incident on a double wedge of width l with incidence angle φ. Two fictitious sources are located at $\mathbf{p}_1$ and $\mathbf{p}_2$.

methods are again in good agreement and show that the amplitude of the diffracted field decreases as the frequency increases.

IV. DIFFRACTION BY DOUBLE WEDGE

Let us now arrive to multiple diffraction. The simple case of double diffraction of a steady plane wave is solved by using GTD and Eq. (10). This example is chosen in order to illustrate similarities and differences of GTD and Eq. (10).

Consider a two-dimensional rigid three-sided barrier. An incident plane wave with intensity I_{inc} is impinging on the left-hand side, and one takes an interest in the evaluation of the energy density on the other side of the barrier. Let us introduce two fictitious diffraction sources at corners $\mathbf{p}_1$ and $\mathbf{p}_2$ of powers σ_1 and σ_2. The incidence angle φ and the emission θ are defined in Fig. 4. For the sake of simplicity, $\sigma_1(0)$ and $\sigma_2(\phi_2)$ are denoted σ_1^- and σ_2^+. Equations on σ_1^- and σ_2^+ are obtained by applying Eq. (10):

$$\frac{\sigma_1^-}{2\pi} = I_{inc}D_\omega(\varphi,0) + \sigma_2^+ H(l)D_\omega(0,0), \quad (19)$$

$$\frac{\sigma_2^+}{2\pi} = \sigma_1^- H(l)D_\omega(\phi_2,\phi_2), \quad (20)$$

where l is the width of the barrier, ϕ_i is the outer angle of corner $\mathbf{p}_i$. It has been assumed that the incident wave propagates upwards, i.e., $\varphi > \pi$. Otherwise a term for direct intensity must be added in the second equation. Applying again Eq. (10) leads to σ_2 at any emission angle θ,

$$\frac{\sigma_2(\theta)}{2\pi} = \sigma_1^- H(l)D_\omega(\phi_2,\theta). \quad (21)$$

By using the relationship $D_\omega(\phi_2,\phi_2)=D_\omega(0,0)$ from Eq. (14), the solution of Eqs. (19) and (20) is

$$\sigma_1^- = I_{inc}\frac{2\pi D_\omega(\varphi,0)}{1 - 4\pi^2 H^2(l)D_\omega^2(0,0)}. \quad (22)$$

And then,

$$\sigma_2(\theta) = I_{inc}\frac{4\pi^2 D_\omega(\varphi,0)H(l)D_\omega(\phi_2,\theta)}{1 - 4\pi^2 H^2(l)D_\omega^2(0,0)}. \quad (23)$$

The field at any point $\mathbf{r}$ on the right side of the barrier below the top, i.e., $\theta < \phi_2 - \pi$ is given by Eq. (5) with the only contribution of the diffracted field from $\mathbf{p}_2$:

$$W(\mathbf{r}) = \sigma_2(\theta)G(r), \quad (24)$$

where $r = |\mathbf{p}_2 - \mathbf{r}|$. Thus,

$$W(\mathbf{r}) = \frac{I_{inc}}{c}\frac{D_\omega(\varphi,0)D_\omega(\phi_2,\theta)}{1 - \dfrac{D_\omega^2(0,0)}{l^2}} \times \frac{1}{lr}, \quad (25)$$

by assuming that the attenuation factor is zero, that is $H(l) = 1/2\pi l$ and $G(r)=1/2\pi cr$. This expression for energy is valid under the condition that $D_\omega(0,0)/l < 1$.

Let us turn to the same problem by means of the GTD. The pressure p_2 at point $\mathbf{p}_2$ is determined by summing all contributions of rays arriving at this point and can be written as

$$p_2 = p_0 D_\omega(\varphi,0)\frac{e^{-ikl}}{\sqrt{l}}\sum_{n=0}^{\infty}\left[d(0,0)\frac{e^{-ikl}}{\sqrt{l}}\right]^{2n}, \quad (26)$$

where p_0 is the pressure of the incident plane wave at $\mathbf{p}_1$. The first term of the infinite sum ($n=0$) is a single diffracted wave, that is, the incident plane wave diffracted once at point $\mathbf{p}_1$ before reaching $\mathbf{p}_2$. The second term ($n=1$) is a triple diffracted wave, that is, the incident plane wave first diffracted at point $\mathbf{p}_1$ and then diffracted at point $\mathbf{p}_2$, being again diffracted at point $\mathbf{p}_1$ before reaching $\mathbf{p}_2$. Other terms are for a greater number of round trips between $\mathbf{p}_1$ and $\mathbf{p}_2$. The diffracted pressure at point $\mathbf{r}$ is

$$p(\mathbf{r}) = p_2 d(\phi_2,\theta)\frac{e^{-ikr}}{\sqrt{r}} \quad (27)$$

$$= p_0 d(\varphi,0)d(\phi_2,\theta)\frac{e^{-ikl}}{\sqrt{l}}\frac{e^{-ikr}}{\sqrt{r}}\sum_{n=0}^{\infty}\left[\left(d(0,0)\frac{e^{-ikl}}{\sqrt{l}}\right)^2\right]^n, \quad (28)$$

where $d(\phi_2,\theta)e^{-ikr}/\sqrt{r}$ is the cylindrical acoustical wave from the corner $\mathbf{p}_2$ to the observation point $\mathbf{r}$. It is instructive to determine the energy $W(\mathbf{r})=|p(\mathbf{r})|^2/2\rho c$ of this field. By squaring Eq. (28) and neglecting all cross-product terms, it yields

$$W(\mathbf{r}) = \frac{|p_0|^2}{2\rho c^2}|d(\varphi,0)|^2|d(\phi_2,\theta)|^2\frac{1}{lr}\sum_{n=0}^{\infty}\left[|d(0,0)|^2\frac{1}{l}\right]^{2n} \quad (29)$$

$$= \frac{I_{inc}}{c}\frac{D_\omega(\varphi,0)D_\omega(\phi_2,\theta)}{1 - \dfrac{D_\omega^2(0,0)}{l^2}} \times \frac{1}{lr}, \quad (30)$$

where $I_{inc}=|p_0|^2/2\rho c$ and $D_\omega=|d|^2$. The series converges when $D_\omega(0,0)/l < 1$. It is then apparent that GTD leads to the same energy field as predicted by Eq. (10) provided that all interferences between rays have been neglected. The set of Eqs. (5), (6), and (10) can thus be considered as an extension of geometrical acoustics in its strict sense, that is, with no phase attached to rays, which includes diffraction effects as done in GTD.

V. DIFFRACTION BY RECTANGLE

Consider a steady-state cylindrical wave of power ρ_0 diffracted by a rectangular obstacle of dimensions $a \times b$ as shown in Fig. 5. The incident wave is reflected on the front wall and diffracted by the four corners denoted by $\mathbf{p}_i$ with $i=1,\ldots,4$. Thus, the direct field is $\rho_0 G(\mathbf{s},\mathbf{r})$ at any point $\mathbf{r}$

Reboul, Le Bot, and Perret-Liaudet: Transfer equation for diffraction
FIG. 5. Diffraction of a cylindrical wave emanating from **s** by a rectangle $a \times b$. Four fictitious sources of diffraction $\mathbf{p}_i$ are localized at the corners with powers $\sigma_i^{\pm}$ in grazing directions. The image source for reflected rays on the left side is **s'**.

and the reflected field is $\rho_0 G(\mathbf{s}', \mathbf{r})$ where **s'** is the image source given by reflection of **s** on the front wall.

At each diffracting corner is put a fictitious source $\sigma_i(\theta)$ whose particular values at angles $\theta=0$ and $\theta=3\pi/2$ are denoted σ_i^- and σ_i^+. Equations on $\sigma_i^{\pm}$ are obtained by applying Eq. (10). No reflected ray can be diffracted and therefore the second integral of Eq. (10) vanishes. Finally, $\sigma_i^{\pm}$ is only related to direct intensity $\rho_0 H(s)$ for points 1 and 2 and other values of $\sigma_j^{\mp}$,

$$\frac{\sigma_1^+}{2\pi} = \sigma_2^+ D_\omega\left(0, \frac{3\pi}{2}\right) H(a) + \sigma_3^- D_\omega\left(\frac{3\pi}{2}, \frac{3\pi}{2}\right) H(b)$$
$$+ \rho_0 D_\omega\left(\varphi_1, \frac{3\pi}{2}\right) H(s_1), \tag{31}$$

$$\frac{\sigma_1^-}{2\pi} = \sigma_2^+ D_\omega(0,0) H(a) + \sigma_3^- D_\omega\left(\frac{3\pi}{2}, 0\right) H(b)$$
$$+ \rho_0 D_\omega(\varphi_1, 0) H(s_1), \tag{32}$$

$$\frac{\sigma_2^+}{2\pi} = \sigma_1^- D_\omega\left(\frac{3\pi}{2}, \frac{3\pi}{2}\right) H(a) + \sigma_4^+ D_\omega\left(0, \frac{3\pi}{2}\right) H(b)$$
$$+ \rho_0 D_\omega\left(\varphi_2, \frac{3\pi}{2}\right) H(s_2), \tag{33}$$

$$\frac{\sigma_2^-}{2\pi} = \sigma_1^- D_\omega\left(\frac{3\pi}{2}, 0\right) H(a) + \sigma_4^+ D_\omega(0,0) H(b)$$
$$+ \rho_0 D_\omega(\varphi_2, 0) H(s_2), \tag{34}$$

$$\frac{\sigma_3^+}{2\pi} = \sigma_1^+ D_\omega\left(0, \frac{3\pi}{2}\right) H(b) + \sigma_4^- D_\omega\left(\frac{3\pi}{2}, \frac{3\pi}{2}\right) H(a), \tag{35}$$

$$\frac{\sigma_3^-}{2\pi} = \sigma_1^+ D_\omega(0,0) H(b) + \sigma_4^- D_\omega\left(\frac{3\pi}{2}, 0\right) H(a), \tag{36}$$

$$\frac{\sigma_4^+}{2\pi} = \sigma_2^- D_\omega\left(\frac{3\pi}{2}, \frac{3\pi}{2}\right) H(b) + \sigma_3^+ D_\omega\left(0, \frac{3\pi}{2}\right) H(a), \tag{37}$$

$$\frac{\sigma_4^-}{2\pi} = \sigma_3^+ D_\omega(0,0) H(a) + \sigma_2^- D_\omega\left(\frac{3\pi}{2}, 0\right) H(b), \tag{38}$$

where s_1, s_2, φ_1, and φ_2 are defined in Fig. 5. This is a set of linear equations on the eight unknowns $\sigma_i^{\pm}$. Furthermore, the potential σ_i in all other directions θ is also given by Eq. (10),

$$\frac{\sigma_1(\theta)}{2\pi} = \sigma_2^+ D_\omega(0, \theta) H(a) + \sigma_3^- D_\omega\left(\frac{3\pi}{2}, \theta\right) H(b)$$
$$+ \rho_0 D_\omega(\varphi_1, \theta) H(s_1), \tag{39}$$

$$\frac{\sigma_2(\theta)}{2\pi} = \sigma_1^- D_\omega\left(\frac{3\pi}{2}, \theta\right) H(a) + \sigma_4^+ D_\omega(0, \theta) H(b)$$
$$+ \rho_0 D_\omega(\varphi_2, \theta) H(s_2), \tag{40}$$

$$\frac{\sigma_3(\theta)}{2\pi} = \sigma_1^+ D_\omega(0, \theta) H(b) + \sigma_4^- D_\omega\left(\frac{3\pi}{2}, \theta\right) H(a), \tag{41}$$

$$\frac{\sigma_4(\theta)}{2\pi} = \sigma_2^- D_\omega\left(\frac{3\pi}{2}, \theta\right) H(b) + \sigma_3^+ D_\omega(0, \omega) H(a). \tag{42}$$

Thus, the functions $\sigma_i(\theta)$ are well defined by the particular values $\sigma_i^{\pm}$.

Finally, the field at any point **r** is given by adding the contributions of the direct field, the reflected field and the four diffracted fields. It yields

$$W(\mathbf{r}) = \rho_0 G(\mathbf{s}, \mathbf{r}) + \rho_0 G(\mathbf{s}', \mathbf{r}) + \sum_{i=1}^{4} \sigma_i(\theta_i) G(\mathbf{p}_i, \mathbf{r}), \tag{43}$$

$$\mathbf{I}(\mathbf{r}) = \rho_0 \mathbf{H}(\mathbf{s}, \mathbf{r}) + \rho_0 \mathbf{H}(\mathbf{s}', \mathbf{r}) + \sum_{i=1}^{4} \sigma_i(\theta_i) \mathbf{H}(\mathbf{p}_i, \mathbf{r}), \tag{44}$$

where θ_i is the emission angle at point $\mathbf{p}_i$ toward **r**. Remember that only some of the six fields can reach the point **r** depending on its position, the others being stopped by the obstacle.

Two numerical simulations are proposed in Figs. 6 and 7. The size of the rectangle is 10 m × 2 m and the source point is located at a distance of 4 m on the left of the rectangle and on the middle axis. In Fig. 6, the frequency range of the sound source is the third octave band centered on 250 Hz, and the wavelength of sound is about 1.4 m, which is not very different from the smaller dimension of the diffracting object. In Fig. 7, the frequency range of the sound source is the third octave band centered on 5000 Hz, and the wavelength of sound is about 0.07 m, which is very small with regards to the size of the diffracting object. For both cases, two results are provided, on the one hand the SPL from Eq. (43) is plotted at the centered frequency and on the other hand, the BEM is employed. For BEM studies, calculations are performed every 25 Hz for the third-octave band centered on 5000 Hz and every 5 Hz for the third-octave band centered on 250 Hz, and the final result is the quadratic average of these, or, in other words, is the rms value.

For both cases, the transfer equation leads to infinite results in the vicinity of the boundaries between illuminated and shadow zones. These boundaries are visible on the SPL
FIG. 6. Diffraction of a cylindrical wave by a rectangular obstacle (10 m × 2 m). SPL in dB around the obstacle predicted by (a) the boundary element method and (b) the transfer equation. (c) Energy density along the contour line beginning at the left bottom corner, with the boundary element method (—) and with the transfer equation (---). The frequency is 250 Hz.

FIG. 7. Diffraction of a cylindrical wave by a rectangular obstacle (10 m × 2 m). SPL in dB around the obstacle predicted by (a) the boundary element method and (b) the transfer equation. map in Fig. 6(b) and in Fig. 7(b) and where they appear as white areas. Oblique boundaries correspond to the limit of influence of direct and reflected fields while others correspond to the limit of influence of fields diffracted by the opposite corner. It is well known that in the vicinity of these

boundaries the acoustical field cannot be developed in terms of rays. This is the same limitation as encountered in GTD since the diffraction coefficient implemented in this calculation is the one of GTD.

The main difference between the result given by the BEM and the result from the transfer equation is that the

fluctuations due to the existence of some remaining interferences are noticeable on the BEM result, while they do not appear on the result from the transfer equation which is based on the assumption that direct, reflected, and diffracted waves are uncorrelated. These interferences have a major effect when the wavelength of sound is close to the size of the diffracting object as shown in Fig. 6(a), and in this case, the result given by the transfer equation only represents the average behavior of the acoustical field around the rectangle [Fig. 6(c)]. However, when the frequency increases, or more generally, when the ratio between the wavelength and the size of the diffracting object decreases, the effect of interferences vanishes and, thus, both methods well agree as shown in Figs. 7(a)–7(c).

VI. DISCUSSION

One of the main advantages of the radiative transfer method for the prediction of sound fields is that computation times are significantly reduced compared to some other methods such as the BEM. The calculations absolutely do not depend on the wavelength of sound if parameters such as atmospheric or material absorption coefficients do not depend on frequency. Otherwise, the variations of these parameters define the frequency step to use in order to apply the method. Thus, in the case of diffraction, the energetic diffraction coefficient depends on frequency: the magnitude of the diffraction coefficient introduced in GTD decreases like $1/\sqrt{k}$ so the energetic diffraction coefficient decreases like $1/k$, where k is the wave number. The allowed frequency bandwidth for the study depends on the frequency variations of the energetic diffraction coefficient: the frequency step is chosen so that the diffraction coefficient does not vary much on the bandwith. Thus, the change in the nature of the acoustical field will be well described by the radiative transfer method, except for interference effects. However, as any ray approach, this method cannot give accurate results for low frequencies where the wavelength is of the same order as the typical length of the problem. In such cases, wave-based approaches should be employed. For instance, the typical lengths for the example of Sec. III (Figs. 1 and 3) are the source-edge and edge-receiver distances. Ray theory then applies provided that these distances are larger than one wavelength beyond the near-field influence. In the example of Sec. IV (Fig. 4), the distance between the two diffracting lines must also be larger than one wavelength whereas in the example of Sec. V (Figs. 5 and 7) length and width of the rectangle must respect the same criteria. The method would fail for arbitrarily small diffracting objects (Fig. 6).

VII. CONCLUSION

In this paper, it has been proposed to apply the radiative transfer approach to diffraction. The functional equation (10) gives the power of fictitious sources of diffraction. The interest of such an equation is to determine the total diffracted power in any direction. All well-known results on diffraction by wedges in the frame of GTD are recovered. Equation (10) leads to a set of linear equations. By solving this system, it is possible to determine the total diffracted power by corners, without following the rays as is usually done with the ray-tracing technique.

The method has two main limitations. First, some unphysical results are obtained in the vicinity of boundaries between illuminated and shadow zones. This is the same limitation as in GTD for same reason. Second, interference effects cannot be described by the present method because energies are added. This is an additional limitation which does not occur in GTD.

Compared with BEM this method is CPU-time saving. BEM is limited in practice to low frequencies. In the high frequency range, the number of fictitious sources introduced on the mesh is rapidly prohibitive in regard to current computers. On the other hand, the number of fictitious sources required in the transfer equation (10) does not depend on the frequency, which leads to a constant CPU time at any frequency. This provides an alternative method in the field of high frequency diffraction.

Furthermore, this approach is better suited than GTD to the case of multiple diffraction. All orders of diffraction are simultaneously taken into account and thus, in practice, results are more accurate than using GTD where a limited number of rays are used. Besides, it does not require the knowledge of all ray paths between the source and the receiver point which can be tedious to determine in practice.

APPENDIX

This Appendix concerns the evaluation of the energetic diffraction coefficient D_ω. Consider an incident ray in the direction $\mathbf{v} = \varphi, \beta$ impinging on a wedge at point $\mathbf{q}$. The diffracted field at any point $\mathbf{r}$ in the direction $\mathbf{u} = \theta, \alpha$ is given by

$$p_{\text{dif}}(\mathbf{r}) = p_{\text{inc}}(\mathbf{q}) d_\alpha(\varphi, \theta) \frac{e^{-ikR}}{\sqrt{R}}, \tag{A1}$$

where k is the wave number, $p_{\text{inc}}(\mathbf{q})$ is the incident field at the diffraction point $\mathbf{q}$, and $R = |\mathbf{q} - \mathbf{r}|$ is the distance measured along the diffracted ray. The diffraction coefficient d_α depends on φ and θ the incidence and emission directions defined to the right side of the wedge (Fig. 1) and also on the outer angle of the wedge ϕ by means of the wedge index $\nu = \pi / \phi$. According to Keller's law of diffraction[1] the angle of diffraction α equals the angle of incidence β so that the diffracted rays emanating from $\mathbf{q}$ belong to a cone whose axis is the diffracting edge. An expression for d_α is derived using the method of steepest descent,[2,4]

$$d_\alpha(\varphi,\theta) = \frac{e^{-i\pi/4}\nu\sin(\nu\pi)}{\sqrt{2\pi k\sin\alpha}}\left[\frac{1}{\cos(\nu\pi) - \cos[\nu(\theta+\varphi)]}\right.$$

$$\left. + \frac{1}{\cos(\nu\pi) - \cos[\nu(\theta-\varphi)]}\right]. \quad (A2)$$

d_α becomes singular on incidence or reflection boundaries. This coefficient depends on the frequency through the wave number k.

The diffracted intensity $I_{\text{dif}}(\mathbf{r}) = |p_{\text{dif}}|^2/2\rho c$ where c is the sound speed, ρ is the fluid density, is from Eq. (A1)

$$I_{\text{diff}}(\mathbf{r}) = \frac{I_{\text{inc}}(\mathbf{q})}{R}|d_\alpha(\varphi,\theta)|^2, \quad (A3)$$

with $I_{\text{inc}}(\mathbf{q}) = |p_{\text{inc}}(\mathbf{q})|^2/2\rho c$ the incident intensity. By denoting $r = R\sin\alpha$ the edge-receiver distance, Eq. (A3) is written by means of the diffraction coefficient $d(\varphi,\theta)$ at normal incidence $\alpha = \pi/2$,

$$I_{\text{dif}}(\mathbf{r}) = \frac{I_{\text{inc}}(\mathbf{q})}{r}|d(\varphi,\theta)|^2. \quad (A4)$$

By comparing with Eq. (18) and noting that $I_{\text{dif}} = cW_{\text{dif}}$, it is readily found that $D_\omega(\varphi,\theta) = |d(\varphi,\theta)|^2$. This is the energetic diffraction coefficient at normal incidence.

Compact nonporous windscreen for infrasonic measurements

Qamar A. Shams,[a] Allan J. Zuckerwar, and Bradley S. Sealey

NASA Langley Research Center, Mail Stop 238, Hampton, Virginia 23681

Infrasonic windscreens, designed for service at frequencies below 20 Hz, were fabricated from a variety of materials having a low acoustic impedance, and tested against four specifications (the first three in a small wind tunnel): (1) wind-generated noise reduction ("insertion loss") at a free-stream wind speed of 9.3 m/s, (2) transmission of low-frequency sound from a known source (subwoofer), (3) spectrum of sound generated from trailing vortices (aeolian tones), and (4) water absorption (to determine suitability for all-weather service). The operating principle is based on the high penetrating capability of infrasound through solid barriers. Windscreen materials included three woods (pine, cedar, and balsa), closed-cell polyurethane foam, and Space Shuttle tile material. The windscreen inside diameter ranged from 0.0254 to 0.1016 m (1 to 4 in.), and wall thickness from 0.003175 to 0.01905 m $\left(\frac{1}{8} \text{ to } \frac{3}{4} \text{ in.}\right)$. A windscreen made of closed-cell polyurethane foam revealed a wind noise reduction of 10–20 dB from 0.7 to 25 Hz, transmission coefficient near unity from 10 to 20 Hz, and spectral peaks beyond 20 Hz due to vortex-generated sound. Following a description of past methods, the principle of operation, and the experimental method, experimental data are presented for a variety of windscreens. [DOI: 10.1121/1.1992707]

I. INTRODUCTION

A fundamental difficulty in the detection of outdoor infrasound is the so-called "wind noise" problem. Because of ever-present wind-generated turbulence, the atmosphere is inherently noisy at frequencies of interest (typically between 0.1 and 20 Hz). Accordingly, effective wind screening is vital to the success of outdoor infrasonic measurements. Past methods of screening a microphone from the wind include a piped array, a barrier, or an open-mesh (e.g., cloth or foam) enclosure.

The piped array, as introduced by Daniels,[1] consists of long (603.5 m) lengths of pipe with flow resistors to provide areal sampling of pressure signals using a single acoustic sensor. The pipe is tapered to eliminate acoustic internal reflections. A filter with 100 inlets is found to reduce atmospheric noise approximately 20 dB at wind speeds up to 13 m/s. This method improves the reception of signals but is inherently directional. Burridge[2] devised a simpler device having an untapered pipe and concluded that one can obtain equally good results with a pipe of uniform bore. Consequently an array of several perforated pipes, called a "spider," fanning out radially from a microphone situated in an enclosed housing is needed to achieve omnidirectionality. Alcoverro[3] proposed a filter consisting of several clusters, or rosettes, of low-impedance inlets. Each inlet is connected to a summing manifold by a solid pipe which connects each secondary summing manifold to one primary summing manifold or directly to the sensor.

Hedlin and Raspet[4] used the concept of Lizska and Bernoulli scaling between wind speed and pressure. They used a 50% porous barrier with a 2-m height and a 5.5-m base. A fine mesh wire of 1 mm square was used on a side to reduce the wind flow further. They observed infrasonic noise reduction of 20–25 dB above the reduced corner frequency and 4 dB below the corner frequency (−3 dB). One main advantage of the wind barrier over the rosette spatial filter is that the signal is not integrated after propagation through a system of narrow pipes.

The piped array has the shortcomings of being expensive and requiring typically an area equivalent to an athletic field. It is not of practical use in a three-dimensional array (in which one or more microphones are elevated, for example on a tower). The wind barrier, likewise of a sizeable and noncompact configuration, displays "large reductions only when the scale size of the turbulence is smaller than the height of the barrier."

Several compact windscreens have been proposed, among which a few candidates have been considered for infrasonic service.

The windscreen of Bruel[5] consists of a wire framework covered with a cloth-type material of low air resistance, the microphone being located at the center of the structure. His observation was that if the selected cloth is of an open mesh, the sound waves will penetrate without any appreciable loss in energy, but the wind resistance of the material will be sufficient to dissipate any direct air-flow around the microphone. These windscreens were designed for the audio frequency range and are not effective for infrasound.

Anderson[6] offered a different design. His windscreen comprises an inner cylindrical screen, providing an enclosure for a microphone, and an outer cylindrical screen assembly substantially concentric with, and spaced from, the first screen, whereby a shunt airflow path is provided around the inner screen. Anderson claimed this windscreen to be highly effective and to generate no appreciable wind noises of itself within the frequency band of sound to be detected. The diameter of his windscreen depends upon the desired fre-

[a] Electronic mail: qamar.a.shams@nasa.gov

quency range. For a frequency range between 130 and 330 Hz, he used an inner windscreen of 0.1524 m (6 in.) and an outer windscreen of 0.381 m (15 in.) in diameter. No other spectral information is included.

Ballard[7] developed a windscreen for reducing or eliminating the effect of wind flow on signals received by a transducer in the low sonic and infrasonic range. He used a concentric arrangement of the multiple windscreens, which constitutes a wind noise reduction system. His smallest concentric screen diameters are in the range of 0.381–0.6096 m (15–24 in.) while the largest are about 2.4389–3.6576 m (96–144 in.). Ballard's patent shows unscaled time histories but no spectra.

Morgan and Raspet[8] compared the noise reduction characteristics of various spherical open-cell foam windscreens of different size and porosity. During their first test, they compared spherical screens with streamlined screens designed to reduce wake shedding. They determined that the performance of streamlined screens tested worse than the spherical screens. In their second test, they compared the wind noise reduction characteristics of different size and porosity windscreens, and concluded noise reduction to be relatively insensitive to diameter and pore size. Although data were taken in third-octave bands, only a wideband spectrum in the range 1.6 Hz to 25 kHz is reported.

The lack of adequate spectral information precludes the possibility of evaluating prior compact windscreens, made of cloth or open-cell foam, for infrasonic service.

An effective infrasonic windscreen must fulfill four basic requirements: (1) reduction of noise generated by ambient wind near the microphone, (2) transmission of infrasound propagating to the microphone position, (3) all-weather operation, and (4) avoidance of sounds within the infrasonic passband (<20 Hz) due to vortex shedding (aeolian tones).

The windscreen described here is based on an entirely different principle, namely that infrasound at a sufficiently long wavelength will penetrate any barrier of practical thickness. Thus a windscreen having solid, nonporous walls will block convected pressure fluctuations from the wind, while transmitting acoustic waves within the infrasonic passband. The transmission coefficient depends strongly upon the ratio of the acoustic impedance of the windscreen material to that of air. Several materials having a low impedance ratio (in parentheses), namely closed-cell polyurethane foam[9] (222), Space Shuttle tile material[10] (332), and balsa (323) have proved suitable in that they permit high transmission of infrasound with walls of practical thickness.

The purpose of this study is to test the windscreens experimentally against the requirements listed above; comparison with theory is beyond the scope of this paper.

II. PRINCIPLE OF OPERATION

The principle of the windscreen is based on the great penetrating capability of infrasound through matter. Consider the classical problem of sound transmission through a solid wall with air on either side, as illustrated in Fig. 1. The sound power transmission coefficient from medium 1 to medium 3 is
FIG. 1. The three-media problem: transmission of sound in air 1 through a solid wall 2 of thickness W into air 3 on the other side.

$$|T| = \frac{1}{\cos^2 x + \frac{1}{4}(Z_2/Z_1 + Z_1/Z_2)^2 \sin^2 x}, \quad (1)$$

where

$$x = \frac{2\pi f W}{c_2} \quad (2)$$

and f is the frequency, W is the wall thickness, Z_1 is the acoustic impedance of air, Z_2 is the acoustic impedance of the wall material, and c_2 is the speed of sound in the wall.[11] Equations (1) and (2) reveal that a high transmission coefficient is favored by a low frequency, low impedance ratio, and small wall thickness. The transmission pass band is taken here, for design purposes, to span the infrasonic region, namely at frequencies below 20 Hz. The impedance ratio depends upon the selection of suitable materials. The wall thickness is limited by considerations of structural stability. For illustration, the transmission coefficient for a material with a low impedance ratio (balsa, 323) and with a high impedance ratio (steel, 1.13×10^5) is shown in Fig. 2. A cutoff frequency f_c is defined as the location of the half-power point. For a balsa windscreen having a wall thickness of 0.0127 m $\left(\frac{1}{2}\text{ in.}\right)$ the cutoff frequency is 20 Hz, well suited for infrasonic service and structurally stable. For a steel windscreen having the same wall thickness, the cutoff frequency is 0.075 Hz, confining the transmission to the far infrasound.

Table I lists several candidate materials for infrasonic service. Windscreens made of white pine and cedar, requiring a wall thickness no greater than 0.003175 m $\left(\frac{1}{8}\text{ in.}\right)$ to
FIG. 2. Transmission coefficient of sound through a solid wall (balsa or steel) of thickness $W=0.0127$ m $\left(\frac{1}{2}\text{ in.}\right)$ versus frequency. The figures in parentheses are the specific acoustic impedance relative to air. The cutoff frequency f_c is the frequency at the half-power point. Balsa reveals excellent transmission at infrasonic frequencies.

FIG. 3. Top: The family of tested windscreens. Bottom: View from the bottom of windscreens having an internal diameter of 0.0762 m (3 in.), internal depth of 0.23 m (9 in.), and wall thicknesses of 0.01905, 0.0127, and 0.00635 m ($\frac{3}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$ in.), respectively. In service a windscreen is fitted with a bottom cap to accommodate the microphone.

achieve a cutoff frequency of 20 Hz, were found to develop cracks in the sidewalls and proved impractical for field deployment. The remaining candidate materials—balsa, closed-cell polyurethane foam, and Space Shuttle tile material—were found to achieve the desired cutoff frequency of 20 Hz, with a structurally sound 0.0127-m ($\frac{1}{2}$-in.) wall, and thus proved favorable for field application.

Windscreens were fabricated in the shape of a hollow cylinder, capped permanently at one end and open at the other end for installation on the test fixture described below (see Fig. 3). The internal diameter ranged from 0.0254 to 0.1016 m (1 to 4 in.), the wall thickness from 0.003175 to 0.01905 m ($\frac{1}{8}$ to $\frac{3}{4}$ in.), and the interior height was fixed at 0.23 m (9 in.). For subsequent field service, the open end was fitted with a cap containing a hole for installation of a microphone.

III. INFRASONIC WINDSCREEN TEST SETUP

An existing standard on windscreen testing is explicitly intended for the audio range of frequencies (0.125–10 kHz).[12] Consequently, to test the infrasonic windscreen performance, a small wind tunnel was constructed consisting of a fan, test section, test fixture, anemometer, microphone, subwoofer, and data acquisition system, as illustrated in Fig. 4.

The fan (Orion model OA254AP-11-1TB) delivered 0.27 m^3/s (574 ft^3/min) airflow with a fan speed of 3500 rpm and rated noise level of 55 dB. The fan forced the air to flow down a converging duct, 1.28 m (48 in.) long $\times 0.0323$ m^2 (6×6 in.^{2}) at the exit. The air velocity was 11.6 m/s at the exit and fell to 9.3 m/s near the windscreen, as the air expanded into the microphone test section. The test section dimensions were 0.9144 m long $\times 0.533$ m $\times 0.533$ m (36 in. long $\times 21$ in. $\times 21$ in.). The microphone (and preamplifier) protruded through a pinewood fixture, which contained a boss to fit the open end of the windscreen. The windscreens that were tested were fitted snugly to the fixture assembly and were firmly held in place with two retaining cables, thus insuring that the interior microphone was tightly sealed. The fixture was mounted on a metal plate that was bolted to the test section. The windscreen test microphone was an infrasonic pressure-field microphone (B&K type 4193) with a frequency response of 0.07–20 Hz (-2 dB), and a rain cover (B&K type UA 0393) was installed

on the microphone to simulate field test conditions. The data acquisition system consisted of a PC-based multi-analyzer system (B&K Pulse type 3560 with a type 3110 input module). Its frequency response was determined by a filter setting, in this case 0.7–100 Hz (wind noise) or 0.7–200 Hz (transmission).

To measure the wind noise generated by the windscreen, the fan was turned on to generate airflows known to cause wind-induced windscreen noise, which was detected by the microphone inside the windscreen. The airflow rate was held constant at 9.3 m/s (21 mph), as measured with a hot wire
FIG. 4. Wind tunnel used for wind noise reduction (insertion loss) and sound transmission tests. Not to scale.
FIG. 5. Sound pressure level of wind noise measured by the microphone as a function of windscreen material. The windscreens had an internal diameter of 0.0762 m (3 in.) and wall thickness of 0.0127 m ($\frac{1}{2}$ in.). The wind speed was 9.3 m/s. Legend: (1) no windscreen, (2) Space Shuttle tile material, (3) balsa (dashed), and (4) polyurethane foam.

FIG. 6. Sound pressure level of wind noise measured by the microphone as a function of internal diameter (ID). The windscreen material was polyurethane foam and the wall thickness was 0.0127 m (0.5 in.). Legend: (1) no windscreen, (2) ID=0.0254 m (1 in., dashed), (3) 0.0508 m (2 in.), (4) 0.0762 m (3 in., dashed), and (5) 0.1016 m (4 in.).

anemometer probe near the windscreen test fixture. The anemometer was connected to a PC-based Labview program, which measured, calculated, and displayed the airflow value. The multi-analyzer system recorded the average of 20 sets of data from 0.7 to 100 Hz taken with a frequency resolution of 0.125 Hz. The noise reduction was determined by comparing the microphone signals with and without the windscreen.

The subwoofer (Janis model M1) used to perform the infrasound transmission test operated in the range of 10–200 Hz. To determine the windscreen transmission (still air) of low frequency sound, a function generator (HP Model 3314A) was used to generate a logarithmic frequency sweep. The signal was amplified with a power amplifier (B&K Type 2713) and then applied to the subwoofer. The frequencies tested were 10 to 200 Hz over two sweep intervals of 120 s each, while the microphone response was recorded by the multi-analyzer system. Here the frequency resolution was 0.5 Hz. The transmission coefficient was determined by comparing the microphone signals with and without the windscreen, as was the case with the wind noise reduction test.

IV. TEST RESULTS

A. Wind-generated noise reduction

Tests were conducted to evaluate the reduction of wind-generated noise in the infrasonic region and to compare windscreen materials, internal diameters, and wall thicknesses.

Figure 5 shows the sound pressure level for windscreens made of polyurethane foam, balsa, and Space Shuttle tile material, all having an internal diameter of 0.0762 m (3 in.) and wall thickness of 0.0127 m ($\frac{1}{2}$ in.). The upper plot (1) is the sound pressure level without the windscreen. The foam and balsa windscreens (3, 4) reveal a comparable noise reduction of about 20 dB at 10 Hz and 10 dB at 0.7 Hz. The Space Shuttle tile material (2) reveals a somewhat lesser wind-noise reduction. Several peaks due to aeolian tones can be seen, but all lie outside the infrasonic region. These tones are expected to appear at a Strouhal frequency of approximately 0.2×wind speed/outer diameter.
Figure 6 shows the dependence of sound pressure level upon the internal diameter of foam windscreens with internal diameters of 0.0254, 0.0508, 0.0762, and 0.1016 m (1, 2, 3, and 4 in.), respectively, and wall thickness of 0.0127 m ($\frac{1}{2}$ in.). The data reveal a general trend of increasing wind-noise reduction with internal diameter, but in the interval 10–20 Hz, the 0.0762-m windscreen shows the greatest wind-noise reduction.

Figure 7 shows the dependence upon wall thickness. The polyurethane windscreen internal diameter remained at 0.0762 m (3 in.), while the wall thickness had values of 0.00635, 0.0127, and 0.01905 m ($\frac{1}{4}$, $\frac{1}{2}$, and $\frac{3}{4}$ in.), respectively. The result is anomalous in that the wind-noise reduction appears to reach a maximum at a wall thickness of 0.0127 m.

The large tones are attributed to aeolian tones resulting from vortices shed from the cylinders. These are seen to lie beyond the infrasonic region.

B. Transmission of infrasound through the windscreen walls

The tests were conducted with the subwoofer to compare the same windscreens as used in the wind noise reduction tests. The transmission coefficient is defined as the
FIG. 7. Sound pressure level of wind noise measured by the microphone as a function of wall thickness W. The windscreen material was polyurethane foam and the internal diameter was 0.0762 m (3 in.). Legend: (1) no windscreen, (2) W=0.01905 m ($\frac{3}{4}$ in., dashed), (3) 0.0127 m ($\frac{1}{2}$ in.), and (4) 0.00635 m ($\frac{1}{4}$ in.).
FIG. 8. Transmission coefficient as a function of windscreen material. The windscreen had an internal diameter of 0.0762 m (3 in.) and wall thickness of 0.0127 m ($\frac{1}{2}$ in.). Legend: (1) polyurethane foam, (2) balsa (dashed), and (3) Space Shuttle tile material.

FIG. 10. Transmission coefficient as a function of wall thickness W. The windscreen material was polyurethane foam and the internal diameter was 0.0762 m (3 in.). Legend: (1) $W=0.01905$ m ($\frac{3}{4}$ in.), (2) 0.0127 m ($\frac{1}{2}$ in.), and (3) 0.00635 m ($\frac{1}{4}$ in., dashed).

sound power ratio at the microphone with and without the windscreen. Data are shown for the frequency range 10–100 Hz.

Figure 8 shows the transmission coefficient for the windscreens made of polyurethane foam, balsa, and Space Shuttle tile material, all having an internal diameter of 0.0762 m (3 in.) and wall thickness of 0.0127 m ($\frac{1}{2}$ in.). The foam and balsa windscreens reveal a comparable transmission coefficient in the infrasonic region, below 20 Hz, but the foam has a higher attenuation in the audio region. Below 20 Hz both windscreens show an unexplained gain around 6 dB. The transmission coefficient of the Space Shuttle tile material remains at unity (0 dB) over the entire range of test frequencies.[13]

Figure 9 shows the dependence of the transmission coefficient upon internal diameter. Except for the windscreen with the 0.0254-m ID (1 in.), the windscreens all show the unexplained gain at frequencies below 20 Hz. The foam and balsa windscreens show comparable infrasonic transmission coefficients, the foam being slightly better.

Figure 10 shows the dependence upon wall thickness. A thickness of 0.0127 m ($\frac{1}{2}$ in.) appears to be optimal.

C. Water retention

Water retention is a prime specification for the suitability of a material for outdoor service. Herewith, the polyurethane

FIG. 9. Transmission coefficient as a function of internal diameter (ID). The windscreen material was polyurethane foam and the wall thickness was 0.0127 m (0.5 in.). Legend: (1) ID=0.0254 m (1 in.), (2) 0.0508 m (2 in.), (3) 0.0762 m (3 in., dashed), and (4) 0.1016 m (4 in.).

windscreen, having the 0.0762-m diameter×0.0127-m wall thickness, was held in water for 10 min, removed, had its excess water shaken off, and its weight monitored as the water evaporated. The weight measurements revealed an exponentially decaying water content with time. From an extrapolation back to zero time, it was determined that the windscreen retained 2.54% water by weight—a specification indicating excellent suitability for outdoor service.

V. CONCLUSIONS

A compact and structurally sound windscreen has been developed for microphones deployed in the field for the detection of outdoor infrasound. The windscreen principle is based on the high penetrating capability of infrasound through barriers, which is dependent upon the acoustic impedance ratio (wall-to-air) and wall thickness. Windscreen designs were found to satisfy four requirements for infrasonic service (20 Hz and below): high reduction of wind-generated noise (insertion loss), high transmission of infrasound below the cutoff frequency, absence of aeolian tones within the infrasonic passband, and low water retention as needed for all-weather service.

Most woods, like pine and cedar studied here, have an impedance ratio near 3000 or higher, in which case transmissions below 20 Hz require walls so thin as to cause structural stability problems. Three materials, namely balsa, Space Shuttle tile material, and closed-cell polyurethane foam, all revealing an impedance ratio in the 200–300 range, were found experimentally to meet the above acoustic requirements with windscreen walls of practical, structurally sound thicknesses. A windscreen made of closed-cell polyurethane foam, having an internal diameter, internal height, and wall thickness of $0.0762 \times 0.2286 \times 0.0127$ m $\left(3 \times 9 \times \frac{1}{2} \text{ in.}\right)$ respectively, was found experimentally to achieve the best specifications, namely,

wind-noise reduction:	10 dB at 0.7 Hz and >20 dB at 20 Hz,
infrasonic transmissions:	≥0 dB below 20 Hz,
aeolian tone frequencies:	>20 Hz,
water absorption:	2.54%.

Balsa and Space Shuttle tile material revealed comparable acoustical performance for the same geometry, but the

use of balsa would require a protective film for outdoor service and that of Space Shuttle tile material would be constrained by its high cost.

The selection of specific instruments for testing does not imply endorsement by the National Aeronautics and Space Administration.

Focal depth shifting of a time reversal mirror in a range-independent waveguide

S. C. Walker,[a] Philippe Roux, and W. A. Kuperman

Marine Physical Laboratory of the Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92093-0238

A time-reversal mirror refocuses back at the original probe source position. A goal has been to refocus at different positions without model based calculations. A method to refocus at different ranges has already been developed using frequency shifting. Here we present a technique to refocus at different depths than the original probe source in a shallow ocean range-independent waveguide. The requirement is to collect data from various ranges at a single depth, as from a moving broadband radiator, over a distance sufficient to construct the relevant frequency-wave-number (f-k) structure of the waveguide. With this information, it is then possible to focus at arbitrary depth at any of the ranges that the probe source data were taken. Experimental results confirm the theory. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1940447]

I. INTRODUCTION

Acoustic time-reversal (TR) focusing has been demonstrated to produce temporally and spatially focused acoustic signals in a static ocean environment. TR focusing consists of recording the pressure field from a distant probe source over a portion of the water column, reversing the signal in time and propagating the time-reversed signal back through the medium resulting in a pressure field that is temporally and spatially focused at the probe source location. The spatiotemporal focusing is a consequence of the time-reversal invariance of the linear lossless wave equation describing acoustic propagation in the ocean environment.[1] In waveguide acoustic environments that are range independent, the acoustic field propagates as dispersive normal modes.[2] In shallow ocean waveguide applications, TR is often implemented using a vertical line array (VLA) of acoustic transducers covering some or all of the water column. The VLA is often referred to as a time-reversal mirror (TRM).[1]

A TRM is limited by the requirement that a probe source initially broadcast from the desired focal spot. A method for shifting the TR focus in range by altering the frequency characteristics of the pressure field has been experimentally demonstrated.[3] As well, a method for shifting the TR focus in both depth and range in an iso-velocity waveguide in the high bandwidth limit has been proposed.[4] The ability to depth shift a TR focus might find applications to MIMO communications.[5,6] For example, the data rate can be increased by sending different information to different depths simultaneously. This paper introduces a method for shifting the TR focus in depth from the initial probe source depth in the finite bandwidth modal propagation regime. The method is an extension of the frequency-wave-number (f-k) mode extraction method introduced in Ref. 7. Although other methods for extracting the depth dependence of the propa-

gating modes exist (such as the control feedback method introduced in Ref. 8, the amient noise eigen-value decomposition methods discussed in Refs. 9 and 10, and the moving source singular-value decomposition method proposed in Ref. 11), we find the f-k analysis of Ref. 7 particularly useful for depth shifting.

Similar to the method of Ref. 12 generalized to broadband signals in the far-field regime, the f-k structure of the waveguide is constructed by Fourier transforming, in both range and time, the acoustic pressure fields measured over a TRM from sources at many ranges all at the same depth, z'. Due to the dispersion of the waveguide, it is possible to isolate the modes according to their discrete wave numbers in the f-k domain and extract them individually. In addition, their wave-number components may be modulated independently. Noting that the relative intensities of the modal components of the f-k structure are a function of the source depth and the depth dependence of the modes, the extracted modes can be used to remodulate the isolated modal components individually resulting in a depth shifting of the f-k structure. Transforming the depth shifted f-k structure back to the time-range domain yields the desired depth shifted time-domain TRM pressure fields for each initial source range. The depth shifted pressure fields can be time-reversed to produce TR foci at any of the initial ranges. The process is presented schematically in Fig. 1. The dimensions of Fig. 1 describe our experiment at ultrasonic frequencies ($\sim$600 kHz, $D/\lambda \approx 10$, $\Delta r/\lambda \approx 250$), where λ is the carrier wavelength of the acoustic field, D is the water depth, and Δr is the range over which data is recorded. The process is equally applicable to spatial scales characteristic of the shallow ocean in the regime $\Delta r/\lambda \approx (D/\lambda)^2$.[13] Choosing a practical limit on the range aperture, $\Delta r \lesssim 5$ km, limits the applicability of this technique to regimes involving 5–40 propagating modes, $5 \lesssim D/\lambda \lesssim 40$, where the lower limit results from the minimal TR focus resolution for which depth shifting is useful.

---

[a]Electronic mail: shane@physics.ucsd.edu
FIG. 1. Experimental setup. A time-reversal mirror (TRM) composed of Q transducers at depths z_q (black open circles) located at range $r=0$ individually recorded pressure fields from acoustic point sources (black closed circles) at ranges $r=r_h$ and depth z'. The resulting depth shifted TR foci at depth z'' at selected ranges (gray closed circles) were measured with a vertical receive array (VRA–gray open circles) with elements at depths $z_{q'}$.

Though this technique may be adapted to weakly range-dependent (adiabatic) bathymetries, we have chosen to limit our analysis to range-independent environments in order to facilitate the description of the underlying physics. Broadening the scope of the discussion to range-dependent environments would overly complicate the analysis.

The theory of depth shifting by mode remodulation is presented in Sec. II. It is developed and presented in conjunction with experimental results in Sec. III. The experimental results serve to illustrate the theory. Complications associated with the depth shifting procedure are dealt with in Sec. IV. A discussion and summary is given in Sec. V.

II. THEORY OF MODE REMODULATION DEPTH SHIFTING

According to normal mode theory, the pressure field at angular frequency component, ω, measured over a vertically oriented TRM (with elements at discrete depths z_q $\{q=1,2,\ldots,Q\}$) located at $r=0$ due to a point source at (r,z') in a range-independent waveguide can be expanded into a superposition of depth-dependent normal modes,

$$\boldsymbol{P}(z',r,\omega) = \sum_{m=1}^{M} \boldsymbol{\phi}_m(\omega)\phi_m(z',\omega)\psi_m(r,\omega), \qquad (1)$$

where

$$\psi_m(r,\omega) \equiv \frac{i\widetilde{S}(\omega)}{4\rho_0}H_0^{(1)}(k_m(\omega)r). \qquad (2)$$

$\widetilde{S}(\omega)$ is the complex frequency component of the source signal, $k_m(\omega)$ is the mode m propagating wave number, and ρ_0 is the medium density. Throughout the paper boldface symbols represent vectors over the depths of the TRA elements. Thus $\boldsymbol{\phi}_m(\omega) \equiv \{\phi_m(z_q,\omega)\}$ and $\boldsymbol{P}(z',r,\omega) \equiv \{P_q(z',r,\omega)\}$ are Q component vectors representing the projections over the TRM of the mode m depth dependence and the pressure field, respectively. M is the total number of propagating modes supported by the waveguide.

Each normal mode arrives at the TRM with an associated amplitude and phase given by $\phi_m(z',\omega)\psi_m(r,\omega)$. The depth dependence of the mode amplitudes, $\phi_m(z',\omega)$, has been isolated in Eq. (1) in order to emphasize the dependence of the mode amplitudes on the source depth. The pres-

sure fields from point sources at different depths at the same range differ only by the relative amplitudes of the modes and are related through

$$\boldsymbol{P}(z'',r,\omega) = \sum_{m=1}^{M} \boldsymbol{\phi}_m(\omega)\phi_m(z'',\omega)\psi_m(r,\omega)$$

$$= \sum_{m=1}^{M} \boldsymbol{\phi}_m(\omega)\left(\frac{\phi_m(z'',\omega)}{\phi_m(z'',\omega)}\right)\phi_m(z',\omega)\psi_m(r,\omega).$$

$$(3)$$

Noting that a TRM produces an acoustic focus back at the source depth, depth shifting can be achieved by remodulating the relative weighting of the modes according to the term in parentheses. This remodulation strategy requires that the mode amplitudes at depths z' and z'' be known and that the modes be isolated, or uncoupled, so that they may be individually remodulated.

There are two basic strategies for isolating the modes so that they may be independently modulated. The first strategy capitalizes on the orthonormality of the modes over a full spanning array, $(1/\rho_0)\boldsymbol{\phi}_n \cdot \boldsymbol{\phi}_m = \delta_{nm}$. Here, the dot notation (·) indicates an inner product. The modal amplitudes can be isolated by projecting the individual modal depth dependencies over the measured array data,

$$\frac{1}{\rho_0}\boldsymbol{\phi}_n \cdot \boldsymbol{P}(z',r,\omega) = \phi_n(z',\omega)\psi_n(r,\omega). \qquad (4)$$

In this sense, the projection operation acts as a filter. The isolated modal amplitudes can be remodulated and the modal depth-dependence reintroduced. The depth shifted pressure field is synthesized from the depth shifted modal components. It is important to emphasize that projection requires an accurate knowledge of the modes over the entire water column and is only effective in full-spanning applications. Projection will be revisited in Sec. IV A. In the second strategy, mode isolation is achieved by directly localizing the wave-number characteristics of the modes.[7] By performing a wave-number analysis, it is possible to isolate the modes according to their discrete propagating wave numbers. Though this requires the accumulation of pressure fields from many ranges, it has the advantages that it can be applied over a limited aperture TRM and that it results in depth shifting over many ranges (see Fig. 1). As a result, the depth shifting procedure developed throughout the remainder of the paper is based on the latter strategy.

III. LABORATORY DEMONSTRATION OF DEPTH SHIFTING

Depth shifting is now developed in the context of wave-number isolation based on the mode extraction method of Ref. 7. Experimental results are presented and used to illustrate the development of the wave-number isolation depth shifting technique. The development is carried out in three phases: mode extraction, depth shifting, and time-reversal. For the sake of clarity, a discussion of complicating factors that arise during the development is delayed until Sec. IV.

A. Mode extraction from experimental data

The first step of the depth shifting method requires the extraction of the acoustic modes from measured data alone. Applying the mode extraction method of Ref. 7, the modes are extracted from the *f-k* structure of the waveguide according to their discrete propagating wave numbers. The *f-k* structure results from applying Fourier transforms over both time and range to accumulated pressure field data from many ranges,

$$P(z',k,\omega) = \mathcal{F}_r\{\mathcal{F}_t\{P(z',r,t)\}\}$$

$$= \sum_{m=1}^{M} \boldsymbol{\phi}_m(\omega)\phi_m(z',\omega)\psi_m(k,\omega). \qquad (5)$$

Here $\mathcal{F}_t\{\}$ and $\mathcal{F}_r\{\}$ indicate the Fourier transforms over time and range, respectively. The ranges need not be evenly spaced.[14] The modal wave-number components of the *f-k* structure, $\psi_m(k,\omega)$, are peaked about $k(\omega)=k_m(\omega)$. For example, for the case of uniform range sampling at interval dr over a range aperture Δr centered at range r_c in the far-field limit $(\lim_{k_m r\rightarrow\infty} H_0^{(1)}(k_m r)\sim e^{-ik_m r})$ of a range-independent waveguide [see Eq. (2)], the modal components of the *f-k* structure can be approximated by the classical array diffraction result,

$$\psi_m(k,\omega) \approx \frac{i\widetilde{S}(\omega)e^{-ik_m(\omega)r_c}}{4\rho_0\sqrt{k_m(\omega)r_c}}\left(\frac{\sin\left((k_m(\omega)-k(\omega))\dfrac{\Delta r}{2}\right)}{\sin\left((k_m(\omega)-k(\omega))\dfrac{dr}{2}\right)}\right).$$

$$(6)$$

In deriving Eq. (6) we neglected the effects of cylindrical spreading in applying the range-wave-number transform. The fast Fourier transform in range results in a signal-to-noise ratio (SNR) gain that is proportional to the number of range samples, $\Delta r/dr$ (dr is the nominal sampling interval).

The first phase of the experiment involved the accumulation of pressure field data over range. The experiment was performed in a laboratory waveguide using an ultrasonic transducer (400 kHz bandwidth at a carrier frequency of 600 kHz). The waveguide consisted of approximately 27 mm ($\approx 10.5\ \lambda$) of water over a homogeneous sand bottom. Together, the far-field requirement and the finite length of the waveguide constrained the operational range limits to between 400 and 1000 mm ($\approx 160-400\ \lambda$).

The experimental configuration is illustrated in Fig. 1. A TRM (open black circles) located at $r=0$ individually recorded pressure fields from the acoustic source at many ranges (closed black circles) all at the same depth, z'. The TRM consisted of $Q=31$ evenly spaced hydrophone elements spanning most of the water column. Denoting the TRM elements by the index q, the time-domain pressure field measured at element q due to a source at depth z' and range r' is represented by the notation $P_q(z',r',t)$. Panels (a) and (c) of Fig. 2 show typical measured time-domain pressure fields (the remaining panels of Fig. 2 are discussed later).
FIG. 2. Experimental depth shifting (DS) result at a single range. (a) Time domain pressure field, $P_q(z',r',t)$, recorded on the TRM due to an acoustic source at (r',z') produced (d) TR focus at (r',z'). (b) Depth shifted time domain TRM pressure field, $P_q(z'\rightarrow z'',r',t)$, and (e) resulting TR focus at (r',z''). (c) TRM pressure field, $P_q(z'',r',t)$, due to acoustic source at (r',z'') and (f) its TR focus at (r',z''). The source depth, z', and desired focal depth, z'', are indicated by the symbols (∗) and (♯) respectively. $z'\approx 25$ mm, $z''\approx 7$ mm.

Figure 3(a) shows the depth averaged modulus of the *f-k* structure, $1/Q\Sigma_{q=1}^{Q}|\hat{P}_q(z',k,\omega)|$, which results from Fourier transforming the measured data over range. The hat notation, $\hat{\boldsymbol{P}}\equiv\{\hat{P}_q\}$, indicates that a frequency-wave-number rotation transformation has been applied to the time-range domain pressure field prior to applying the Fourier transformations. This initial rotation transformation, introduced in Ref. 15, facilitates mode extraction. As discussed in Ref. 7, the rotation transforms the location of the modal wave numbers in the *f-k* domain, $k_m(\omega)\rightarrow k_1(\omega)-k_m(\omega)$. In addition to exaggerating the intermodal intervals, this choice of rotation mitigates aliasing of the high order modes. As a result, the range sampling interval can be increased, $dr=2\pi/|k_w-k_b|$, where k_w and k_b are the wave numbers at the carrier frequency in the water and bottom, respectively. The inverse transformation is well defined and easily applied to the depth shifted pressure field discussed in Sec. III B.

Most of the modes (appearing as dark curved regions)
FIG. 3. (a) Depth averaged modulus of the rotated *f-k* structure of the experimental waveguide. Propagating modal wave numbers appear as dark gray curved regions. The modal wave numbers, which are enumerated for clarity, appear at their rotated values, $k_m(\omega)\rightarrow k_1(\omega)-k_m(\omega)$. Solid black lines indicate the mode 7 mask region. (b) Mode 7 depth dependence extracted from masked region.

Walker, Roux, and Kuperman: Depth shifting   1343

are localized and distinct from one another in wave number. Following the mode extraction method detailed in Ref. 7, the well-localized modes were masked and extracted individually. A mask defines a region in the *f-k* domain containing only one mode that is projected over all TRM elements. The only requirement on the masking procedure is that each mask contain a significant contribution from only one mode. Otherwise the mask shape is arbitrary. The mode 7 mask is plotted in Fig. 3(a) as an example. Figure 3(b) shows the resulting extracted mode 7. Modes 3–10 were successfully extracted in this manner. Because the extraction process involves frequency averaging, the extracted modes are the modes averaged over their respective masks. To denote this averaging, the set of extracted modes are written with an overline notation, $\bar{\phi}_m(z)$. Due to the frequency averaging associated with the mode extraction process, it is necessary to limit the frequencies spanned by each mask to bandwidths where the modes are weakly frequency dependent. The major advantage of this method is that the modes can be extracted over a partial spanning array (in this case the TRM) using data alone.

Modes 1 and 2 were not well extracted. Due to the limited range aperture of the experiment, the low order modes were not well localized and could not be separated and individually masked. In addition to limiting mode extraction, poor localization resulting from insufficient range aperture also complicates depth shifting. Poorly localized modes cannot be modulated independently. Due to SNR considerations, the range aperture limitation is likely to be encountered in at sea applications of the depth shifting (DS) method. The issues of determining poorly extracted modes and remodulating poorly localized modes are dealt with in Secs. IV A and IV B.

B. Depth shifting experimental data

In addition to facilitating mode extraction, the mode masking technique makes it possible to independently remodulate the modes with only a knowledge of the source depth. The source depth need not be known *a priori*. It can be determined by applying mode matching techniques to the set of extracted modes.[16–18] Once the source depth, z', is determined, the set of extracted modes are used to calculate the modal remodulation coefficients, $\bar{\phi}_m(z'')/\bar{\phi}_m(z')$[the parentheses term of Eq. (3)]. Remodulation is accomplished simply by multiplying each mask by its corresponding remodulation coefficient. This is valid since the method has been restricted to weakly frequency dependent regimes. Intermodal *f-k* structure not included in any masks is irrelevant to far-field modal propagation and is discarded (set to zero). As well, it is possible to discard high order modes for which the TRM depth sampling is inadequate. Figure 4 shows the experimental masked *f-k* structure [compare to Fig. 3(a)]. Modes 3–10 were remodulated by directly multiplying each mask by its corresponding remodulation coefficient. The independent remodulation of modes 1 and 2 was achieved by the method described in Sec. IV A.

Since the array data now represent an ensemble of acoustic fields excited at depth z'' rather than z', applying the
FIG. 4. Depth averaged modulus of the masked rotated *f-k* structure of the experimental waveguide. Dark regions indicate the relevant masked modal regions. White regions indicate intermodal modal structure exterior to masks that has been set to zero.

inverse *f-k* rotation transformation and inverse Fourier transforming the depth shifted *f-k* structure back to the time and range domains yields depth shifted time domain pressure fields for all original data ranges,

$$\boldsymbol{P}(z' \rightarrow z'', r, t) = \widetilde{\mathcal{F}}_r\{\widetilde{\mathcal{F}}_t\{\boldsymbol{P}(z' \rightarrow z'', k, \omega)\}\}. \quad (7)$$

$\widetilde{\mathcal{F}}_t\{\}$ and $\widetilde{\mathcal{F}}_r\{\}$ indicate the respective inverse Fourier transformations. Panel (b) of Fig. 2 shows an experimental depth shifted time domain pressure field from a selected range. The depth shifted pressure field resembles the pressure field measured from a source at the desired depth, z'', at the selected range shown in panel (c), particularly with respect to the early arrivals (low order modes). Close examination of panels (b) and (c) reveals that there is more energy in the high order modes relative to the low order modes in the depth shifted pressure field than in the measured pressure field. This is likely due to errors associated with the remodulation procedure. As a result, the depth shifted TR pressure more intense sidelobes in depth than the expected TR result [panel (c)].

C. TR focusing experimental data

Time-reversing the depth shifted pressure fields produces TR foci at any of the initial source ranges. This result was experimentally verified. Depth shifted TR foci were experimentally observed at all initial source ranges (represented schematically in Fig. 1 by the closed gray circles). The foci were measured at selected ranges with a limited aperture vertical receive array (VRA). Figure 2(e) shows the experimental TR focus produced by the depth shifted pressure field shown in panel (b). The limited aperture of the VRA resulted in observed clipping at the shallowest and deepest depths. The data source depth and desired focal depth are indicated by (∗) and (♯), respectively. As a control, this result is compared to the optimal TR foci [panels (d) and (f)] produced by the measured pressure fields from the source and desired depths shown in panels (a) and (c), respectively. Figure 5 shows experimental depth shifted TR foci at various depths at a given selected range. Figure 6 shows experimental depth shifted TR foci at various ranges at a given desired focal depth.
FIG. 5. Experimental depth shifting results at multiple depths. TR foci produced at several depths at the same range. The source depth, z', and desired focal depth, z'', are indicated by the symbols ($*$) and ($\sharp$) respectively.

IV. OVERCOMING SOME COMPLICATIONS

Thus far the DS procedure has been developed in the context of ideal conditions; namely, that all modes are well localized and maskable in the f-k domain. In practice, this is often not the case. In the following we discuss methods for dealing with poorly localized modes.

A. Remodulating coupled modes

As mentioned in Sec. III A, wave-number resolution may limit the localization of the low order modes which complicates the masking procedure. The range aperture, Δr, sampled by the data determines the wave-number resolution,

$$dk = \frac{2\pi}{\Delta r}. \tag{8}$$

Adjacent modes (in the f-k domain) for which the intermodal spacing is of the order of the wave-number sampling interval, dk, cannot be masked, extracted, or independently remodulated. Because intermodal spacing decreases with mode order, the lowest order modes are the most prone to the effects of wave-number resolution limitations.

The simplest strategy for dealing with modes that cannot be separated is to eliminate them from the depth shifted f-k structure entirely. Neglecting the low order modal contributions leads to sidelobes in the time-reversed field. The experimental TR field resulting from a depth shifted pressure field from which modes 1 and 2 were eliminated is shown in Fig. 7. Comparing this to a case where the depth shifted pressure field included properly remodulated contributions from modes 1 and 2 [Fig. 2(e)], we see that neglecting the low order modes leads to poor depth shifting results.

In the special case where the depth dependence of the poorly localized modes is known over most of the water

column (by most here we mean the portion of the space over which the modes can be considered orthogonal to one another), modal wave-number isolation and remodulation can be achieved by the projection procedure mentioned in Sec. II. However, recalling that the mode extraction procedure of Ref. 7 is also limited by the wave-number resolution, the depth dependence of poorly localized modes cannot be determined by this technique. Later on we outline an optimization procedure for determining the depth dependence of poorly localized modes from a knowledge of the depth dependence of the known, well-localized modes. Here we continue with the projection remodulation procedure under the assumption that the depth dependence of the poorly localized modes is known over most of the water column.

Applying the projection of a given mode to f-k domain rotated pressure field, $\boldsymbol{P}(z',k,\omega)$, yields

$$\Psi_\alpha(k,\omega) \equiv \frac{1}{\rho_0}\boldsymbol{\Phi}_\alpha \cdot \boldsymbol{P}(z',k,\omega) \approx \phi_\alpha(z',\omega)\psi_\alpha(k,\omega), \tag{9}$$

where $\boldsymbol{\Phi}_\alpha$ represents an optimized poorly localized mode projected over the TRM. The wave-number components are then remodulated independently, $(\Phi_\alpha(z'')/\Phi_\alpha(z'))\Psi_\alpha(k,\omega)$. The depth dependence of the corresponding modes, $\boldsymbol{\Phi}_\alpha$, is reintroduced and the components summed with the masked regions of the depth shifted f-k structure. Figure 8 shows a schematic of the process applied to experimental data. Panel (a) shows a magnification of the unlocalized low order modes (see Fig. 3). Panels (c) and (e) show the modulus of the isolated mode 1 and 2 wave-number components, $|\Psi_1(k,\omega)|$ and $|\Psi_2(k,\omega)|$, respectively, resulting from the projection procedure. The mode 1 and 2 depth dependencies used to make the projections appear in panels (b) and (d). The array diffraction behavior predicted by Eq. (6) is apparent for each mode. The projection would not have succeeded in separating modes 1 and 2 had the TRM spanned only a small portion of the water column.

Remembering that mode extraction only works in the case of well-localized, maskable modes, we point out that modes 1 and 2 shown in panels (b) and (d) did not result from the original extraction technique. Rather they resulted from an optimization algorithm.
FIG. 8. Rotated frequency-wave-number (f-k) structure resulting from projection of optimized modes. (a) Magnification of Fig. 3 showing low order modes. (b) Optimized mode 1. (c) Projected mode 1 f-k structure. (d) Optimized mode 2. (e) Projected mode 2 f-k structure.

We developed a genetic algorithm,[19] based on the orthogonality conditions relating the modes, to construct a small subset of the lowest order modes from a larger subset of known higher order modes. Based on the appearance of the f-k structure (Fig. 3) we assumed that modes 4–10 were well extracted, modes 1 and 2 were poorly extracted, and mode 3 was questionable. The optimization cost functions for modes 1–3 were defined as

$$F_\alpha \equiv |\mathbf{\Phi}_\alpha \cdot \mathbf{\Phi}_\alpha - c_{\alpha\alpha}| + \sum_{m=4}^{10} |\mathbf{\Phi}_\alpha \cdot \bar{\phi}_m - c_{\alpha m}|. \qquad (10)$$

The $\mathbf{\Phi}_\alpha$ ($\alpha = 1, 2, 3$) represent the optimized modes. $c_{\alpha m}$ and $c_{\alpha\alpha}$ are scalars introduced to account for the fact that the optimization was not performed over the entire space. Because the TRM spanned most of the water column and did not sample the bottom, the set of known modes are not expected to be strictly orthogonal to one another, nor are they expected to be strictly orthogonal to the optimized modes. These scalars were calculated using a crude environmental model based on minimal knowledge of the environment, namely an estimate of the bottom sound speed, bottom density, and the sound speed profile. The resulting optimized modes (solid black curves) are plotted along with the modes derived from the masking extraction process (gray dashed curves) in Fig. 9. That the optimized mode 3 so closely resembles the extracted result tells us that the mode 3 mask was valid. Therefore, only modes 1 and 2 were remodulated by projection.

B. Complications due to weakly excited modes

Depth shifting achieves optimal results when the source excites all propagating modes. Modes whose excitations are too low to appear distinctively in the f-k structure cannot be masked nor extracted. Hence, these modes cannot be included in the depth shifted pressure fields which in turn ad-
FIG. 9. Experimental mode extraction results. Modes resulting from mode masking extraction technique (gray dashed lines) are plotted along with optimized modes (dark solid lines). Modes 4–10 were used to optimize for modes 1–3.

versely effects the resulting TR focus. Therefore, the efficacy of the DS algorithm depends on the source depth. Optimal TR focusing results when the source is not near any of the modal nodes. In a Pekeris waveguide, for example, the bottom is an ideal depth for the source.

As well, care must be taken in the case of maskable modes whose excitations are small but measurable. Because the source depth excitation appears in the denominator of the mode remodulation coefficient, $\bar{\phi}_m(z'')/\bar{\phi}_m(z')$, small errors in either the denominator or numerator may result in large errors in remodulation. Remodulation errors resulting in overexcitation are avoided by defining a threshold, β_{max}, for the remodulation coefficients. All coefficients above the threshold are set to zero removing the given mode from the depth shifted f-k structure. Underexcitation is preferable to overexcitation.

V. SUMMARY AND DISCUSSION

Depth shifting of a TR focus over a large portion of a range independent waveguide using broadband sources from many ranges has been experimentally demonstrated at ultrasonic frequencies in a laboratory setting that scales to typical shallow water scenarios. Data from many ranges were used to perform a frequency-wave-number (f-k) analysis of the waveguide so that the modes could be isolated according to their characteristic wave numbers. The isolated modes were extracted and remodulated independently resulting in a depth shifting of the waveguide f-k structure. The depth shifted f-k structure was used to produce depth shifted TR foci over the extent of the original range aperture. In cases where the range aperture is large enough to resolve the characteristic wave numbers of all the modes, it is possible to achieve optimal depth shifted TR focusing with a partial spanning TRM. In cases, such as our experiment, where the range aperture is not adequate to resolve all the modes, optimal depth shifted TR focusing can only be achieved with a TRM that spans most of the water column. We achieved good experimental results using a 90%-spanning TRM.

A scattering-chamber approach for solving finite rough surface scattering problems

John A. Fawcett

DRDC-Atlantic, P.O. Box 1012, Dartmouth, Nova Scotia, B2Y 3Z7, Canada

In this paper a new method is derived for the computation of scattering from a finite, rough free surface. The free surface is infinite in extent but only a portion of it is rough. In order to reduce the amount of numerical computation for such a problem, it is desirable to restrict the computations to the interval of roughness, even for remote sources and receivers. This can be easily done in the case that the rough portion of the surface is only directed into the surrounding fluid medium. In this case, the use of the appropriate half-space Green's function will restrict the integral equation to the interval of roughness only. However, for general deformations this Green's function cannot be used. The use of truncated integral equations utilizing the free space Green's function is discussed. An alternate approach is then described. A system of boundary conditions is derived for a finite curve containing the interval of roughness and a surrounding contour in the fluid half-space. The resulting equations are solved using the method of wave-field superposition. The derived method is also easily generalized to the case that the rough surface under consideration is the upper boundary of a waveguide. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1993130]

I. INTRODUCTION

The study of scattering from a rough surface is a problem of much interest in underwater acoustics, electromagnetics, and geophysics. The case of a rough upper pressure release (or free) surface (i.e., the ocean/air interface) is often studied to understand its effects on signal propagation, reverberation, scattering, etc., or, in general, its effect on sonar system performance, both passive and active (for example, Refs. 1–4). The rough upper surface may be spatially extended or, as is considered in this paper, the extent of the roughness of interest can be finite and small relative to, for example, the source and receiver distances. For computational efficiency, it is desirable to have a computational method which requires the solution for the unknown pressure field quantities in only a small region containing the interval of roughness. In addition, the depth of the acoustic transmitter may be small relative to its horizontal range to the area of surface roughness. In this case the acoustic energy incident upon the region of roughness will have a very small angle of incidence (as measured from the horizontal). This small-angle scenario is emphasized in this paper.

The scattering of sound from such rough surfaces has been examined by many authors, often using approximation techniques such as perturbation theory,[5] the Kirchhoff approximation,[6] the small-slope approximation,[7] or more numerical techniques such as parabolic equation methods,[8] finite difference methods,[9] or wedge-based methods.[10] The technique we consider in this paper is the boundary integral equation method (BIEM). This method has the advantage that it includes all wave propagation effects, including backscatter, but the unknown field quantities which must be determined are restricted to the upper pressure release surface. Various authors[11–18] in the areas of acoustics, electromagnet-ics, and geophysics have utilized boundary integral equation methods for rough free surface or range-dependent waveguide problems.

In order to consider a solution on a surface which has an infinite horizontal extent, some approaches invoke periodicity of the medium and the solution, and other authors use a truncated domain utilizing the free-space Green's function or its normal derivative. The solution to these periodically extended or truncated integral equation problems provide an approximate solution to the infinite surface scattering problem. For a fixed incident field and a fixed set of receivers, the length of the truncation interval (or the length of the interval which is periodically extended) is increased until a suitably converged solution is obtained. There are certainly many problems for which an accurate solution can be obtained in such a manner with a reasonable number of computation points. However, there are clearly scenarios where the required length of these computational intervals will be large. For example, the incident field on the roughness area from a distant, shallow point source will consist of the direct energy and a specular reflection from the flat upper surface (and the case of an incident plane wave at a shallow grazing angle is similar). The specular reflection point of a shallow-angle ray on the flat surface may still be distant from the roughness area. Similarly, for distant shallow receivers, some of the energy scattered from the roughness area (as well as the incident field) will reflect off the flat upper surface before reaching the receiver and for shallow-angle rays this reflection point will be distant from the roughness interval. For these cases, by sufficiently increasing the computational domain, the truncated solutions will yield an accurate approximation to the infinite surface solution. However, the required number of computational points may become very large. The advantage of the method described in this paper is that it will use only a moderate computational grid independent of the

source and receiver locations. The incident fields need not be tapered and, in fact, the method is also applicable to the case where the scattering surface is the upper surface of a bounded waveguide. In this case, a distant point source will produce energy incident upon the roughness interval at a wide variety of angles.

In the case that the roughness profile (deformation to the flat surface) points only into the fluid half-space, then by using the half-space Green's function which satisfies the pressure release boundary condition along $z=0$ (the flat portion of the infinite scattering surface is denoted as $z=0$) the resulting boundary integral equation can be restricted to just the interval of roughness.[17] The integral for the extrapolation of the surface solution to yield the pressure at a receiver is also limited to just the interval of surface roughness. For this type of roughness, this form of boundary integral equation accomplishes what is desired: a finite computational domain which allows for the exact numerical computation (assuming a sufficiently fine discretization) of the scattering from a finite interval of roughness surrounded by an infinite, flat scattering surface. The sources and receivers may be arbitrarily far from this finite region. Unfortunately, in the case that the roughness has both outward and inward deformations, then, as will be discussed, this particular boundary integral approach is no longer valid. The aim of this paper is to obtain an analogous approach for this more general case. We wish to find a method which utilizes a fixed, compact computational domain for the solution of the scattering problem and does not depend upon the location of the sources and receivers relative to the interval of roughness.

To derive the method of this paper, a set of boundary conditions for the pressure field and its normal derivative along a section of the scattering surface (including the interval of roughness) and a curve extending into the bounding fluid is considered. The curve along the surface and the curve in the fluid constitute a single curve. The interior of this curve is what we consider to be the "scattering chamber." The portion of the curve in the fluid relates the incident and scattered fields in the surrounding half-space to the field quantities within this chamber. The concept of using a bounding curve or surface to bring incident energy into and scattered energy out of a small region is not new and has been used previously in finite difference[19] methods (in this reference, the term "scattering chamber" is used). In Ref. 20, a finite element solution is coupled to the elastic field in the outside surrounding medium using a multipole expansion expression. In the present paper, all field quantities within the chamber and exterior to the chamber are expressed in terms of the pressure fields from point sources exterior (for the interior fields) and interior to the chamber (for the external fields). The coupling of the solutions across the curve in the water column and the satisfaction of the pressure release boundary condition along the top of the chamber allow for the amplitudes of the point sources to be determined. It is also straightforward to model the incident field and the scattered field from the chamber into the surrounding medium if, in fact, the surrounding medium is a bounded waveguide. Wave superposition methods or multi-center multiple expan-
FIG. 1. A schematic of the geometry for the rough surface scattering problem.

sion methods have been used by many authors[21–26] to solve surface, volume, and target scattering problems.

In Sec. II (Theory), the boundary integral equations which can be used for the modeling of scattering from a rough surface are described and some of the approaches and issues when using truncated integral equations are discussed. The problem with using the half-space Green's function for general rough surfaces is described and the scattering chamber approach of this paper is derived. In Sec. III (Numerical Examples) the case of a roughness profile with only an inward deformation is considered. For this case, we can use the exact half-space Green's function approach of Ref. 17 as a benchmark solution. We compare the results of the benchmark solution with those from the scattering chamber approach for a variety of different types of incident fields: incident plane waves, tapered plane waves, and point sources and many different receiver ranges. We also show the computed results using truncated integral approaches (for a fixed computational interval). For the case of a roughness profile with both inward and outward deformations, we can no longer use the exact boundary integral approach to benchmark the scattering chamber approach and, in this case, rely on a truncated integral equation approach (making sure that this solution has converged for the receivers considered) to validate the method. Finally, we present a rough surface/ bounded, penetrable waveguide example using the approach of this paper.

Finally, it should be noted that the boundary integral equation and wave-field superposition methods described in this paper are only computationally feasible for regions of surface roughness of fairly limited size. For many realistic situations, methods such as the parabolic equation[8,19] method would need to be used. The methods described in this paper could be used to provide benchmark solutions for other computational approaches.

II. THEORY

In Fig. 1 a schematic of a rough pressure-release surface is shown. The flat surface is $z=0$. Four contours are shown: (1) C_I is the infinite contour along the upper surface (deformation and flat surface), (2) C_1 is a truncated version of C_I including any flat segments, (3) C is the line $z=0$ corresponding to the horizontal extent of C_1, and (4) C_2 is a con-

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

John A. Fawcett: Rough surface scattering   1349

tour such that $C_1 \cup C_2$ is a closed contour enclosing the roughness patch. The method of this paper will also apply for the case of a rigid surface with the appropriate change of boundary conditions and Green's function. The truncated integral equation approaches described in this paper will not utilize the curve C_2, but such an enclosing curve will be used by the wave-field superposition method. For the truncated integral equation approaches the curve C_1 will include a significant portion along the flat surface. For other approaches, the curve C_1 will consist only of the section of roughness (and, perhaps, a few neighboring points along the flat surface).

A. Boundary integral approaches

Considering the infinite surface described parametrically by $(x(s), z(s))$ (the contour C_I in Fig. 1), the Helmholtz equation relating the pressure field away from the surface, at a field point $\vec{x} = (x, z)$, to the values of the normal derivative of the pressure field, p_n, on the surface can be written

$$p(\vec{x}) = \int_{-\infty}^{\infty} G(\vec{x}; \vec{x}(s')) p_{n'}(\vec{x}(s')) ds' + p^{inc}(\vec{x}), \qquad (1)$$

where

$$G(\vec{x}; \vec{x}(s')) \equiv \frac{i}{4} H_0^1 (k\sqrt{(x - x(s'))^2 + (z - z(s'))^2}), \qquad (2)$$

with H_0^1 denoting the zeroth-order Hankel function of the first kind and $p^{inc}(\vec{x})$ denotes the incident field. The normal derivative points upwards in the positive z direction. The choice of the Hankel function used for the Green's function is dictated by the time convention used—in this paper, the form $\exp(-i\omega t)$ is assumed.

Following, for example, Thorsos,[6] we apply the normal derivative operator to Eq. (1) to obtain

$$p_n(\vec{x}) = \int_{-\infty}^{\infty} G_n(\vec{x}; \vec{x}(s')) p_{n'}(\vec{x}(s')) ds' + p_n^{inc}(\vec{x}). \qquad (3)$$

Taking the limit of Eq. (1) as the field point $\vec{x}$ approaches the surface $(x(s), z(s))$ yields

$$\frac{p_n(\vec{x}(s))}{2} = \int_{-\infty}^{\infty} G_n(\vec{x}(s); \vec{x}(s')) p_{n'}(\vec{x}(s')) ds' + p_n^{inc}(\vec{x}(s)), \qquad (4)$$

where special care must be taken with the limit of the integral as $\vec{x}$ approaches the surface, resulting in the factor of $\frac{1}{2}$ with the left-hand side of Eq. (4). In practice, Eqs. (1) and (4), which we will implement numerically, must be truncated at finite integral limits. These limits can be numerically determined by increasing them until the computed pressure fields at the desired set of receivers have converged (using some appropriate definition of convergence).

In Ref. 17 another approach was taken for computing the scattered fields in a waveguide with a rough free surface (with only inward deformations with respect to the flat upper surface); the waveguide Green's function was used in the integral equations. Because this function satisfies the appropriate boundary conditions on the undeformed portions of the boundaries it is easy to show that the boundary integral equation can be restricted to the area of deformations, with all other integral contributions being zero. For an upper pressure release surface, we write for the half-space Green's function,

$$\widetilde{G}(x, z; x', z') = \frac{i}{4} (H_0^1(kR) - H_0^1(k\widetilde{R})), \qquad (5)$$

where

$$R \equiv \sqrt{(x - x')^2 + (z - z')^2}, \quad \widetilde{R} \equiv \sqrt{(x - x')^2 + (z + z')^2}. \qquad (6)$$

The incident field, $\widetilde{p}_n^{inc}(\vec{x}(s))$, in this case is the wave field which would exist if the upper surface were flat. For the case that the horizontal range of the surface roughness is $[x_1, x_2]$ we can write Eq. (4) in the form

$$\frac{p_n(\vec{x}(s))}{2} = \int_{x_1}^{x_2} \widetilde{G}_n(\vec{x}(s), \vec{x}(s')) p_{n'}(\vec{x}(s')) ds' + \widetilde{p}_n^{inc}(\vec{x}(s)) \qquad (7)$$

and Eq. (1) as

$$p(\vec{x}) = \int_{x_1}^{x_2} \widetilde{G}(\vec{x}, \vec{x}(s')) p_{n'}(\vec{x}(s')) ds' + \widetilde{p}^{inc}(\vec{x}). \qquad (8)$$

An important consideration[17] in the numerical treatment of Eq. (7) is the behavior of $\widetilde{G}(\vec{x}, \vec{x}(s'))$ as $x' \to x$ and $z' \to z$ with the rough surface smoothly approaching the mean plane $z = 0$. In this case, the term $\widetilde{G}_n(\vec{x}, \vec{x}(s'))$ becomes increasingly singular due to the image source at $(x', -z')$. As is shown in Ref. 17, the integrand can be regularized by subtracting an analytic expression from $\widetilde{G}_n(\vec{x}, \vec{x}(s'))$ and extracting a corresponding integral contribution. This contribution when moved to the left-hand side of Eq. (7) causes this side of the equation to become approximately equal to $p_n(\vec{x}(s))$ for $z' \to z$ and $z \approx 0$ [recall that with the definition of the incident field in this BIEM that $\widetilde{p}_n^{inc}(\vec{x}(s))$ on the flat surface is equal to twice the value of the corresponding incident field for the BIEM using the free space Green's function].

The problem with this method of using the half-space Green's function is that it is only valid for deformations of the boundary extending into the acoustic half-space. For outward deformations, the function $\widetilde{G}(x, z; x', z')$ of Eq. (5) now has two singularities within portions of the half-space and, in fact, because of this it cannot be referred to as a Green's function (Ref. 27, p. 353). In particular, if one considers a simple outward deformation and the reflection of this deformation into the waveguide, the function $\widetilde{G}(x, z, ; x', z')$ has two singularities in this resulting region. This means that in the derivation of the Helmholtz integral equation, Eq. (1), from Green's identity[28] (for the two-dimensional half-space volume V and the upper bounding surface S),

$$\int_V (p(\vec{x}')\nabla'^2 G(\vec{x};\vec{x}') - G(\vec{x};\vec{x}')\nabla'^2 p(\vec{x}'))dV'$$

$$= \int_S (p(\vec{x}')G_{n'}(\vec{x},\vec{x}') - G(\vec{x};\vec{x}')p_{n'}(\vec{x}'))dS', \qquad (9)$$

there will be certain values of $\vec{x}$ for which the first term in the volume integral of Eq. (9) yields $p(\vec{x}) - p(\tilde{\vec{x}})$. This will occur when the image point of $\vec{x}$ with respect to $z=0$, $\tilde{\vec{x}}$, is also in the volume V. Thus for outward deformations, the Helmholtz integral equation resulting from Eq. (9) no longer has the form of Eq. (1). However, the method of Ref. 17 provides an useful method for benchmarking more general methods in the case of an inward deformation.

There are two basic steps in the computation of the pressure field at a field point $\vec{x}$ using a BIEM for general deformations of the upper surface. [For inward deformations, we can use Eqs. (7) and (8).] First there is the integral equation [e.g., Eq. (4)] to solve for the surface field $p_n(\vec{x}(s))$ and then the extrapolation of this field to $\vec{x}$ [e.g., using Eq. (1)]. However, even when the surface field has been computed from the solution of Eq. (4) for a general deformation, it is possible to use the half-space Green's function, using Eq. (8) to extrapolate the computed surface field [and it is only the values of $p_n(\vec{x})$ for $z \neq 0$ which are required]. This integral relation is not valid for receiver points whose negative image about $z=0$ lies within the rough half-space. However, this is often a small restriction on the receivers which can be considered. The advantage of using Eq. (8) is that it explicitly models the specular reflection of the incident field (i.e., the incident field as defined in this BIEM consists of the direct and upper flat surface reflection) and also any interactions of the field scattered by the roughness with the infinite flat surface. The integral relation of Eq. (1) can also be accurately used as long as the truncated interval is sufficiently large to accurately model the interactions of the incident and scattered fields with the infinite upper surface. When considering the computed solutions using a truncated BIEM, we will consider both methods of extrapolation.

In this paper, different types of incident fields will be considered. First, an untapered incident plane wave is considered. This is an incident field which is infinite in extent. Second, an incident tapered plane wave is considered. This type of incident field may be an appropriate model for some types of incident beams. Numerically, it has the advantage that the amount of incident energy outside of a finite domain can be considered negligible. In this case, the approximation differences which arise from the truncation of the incident field should be small for a numerical domain which is approximately the same size (or slightly bigger) as the effective extent of the tapered incident field. An example of an incident tapered plane wave constructed from a superposition or integral of plane waves[6] is described mathematically by

$$p^{inc}(x,z) = \frac{1}{\sqrt{\pi}\Delta\theta} \int_{-\pi/2}^{\pi/2} \exp\left(-\frac{(\theta' - \theta_{inc})^2}{(\Delta\theta)^2}\right)$$

$$\times \exp(ik(x\sin\theta' + z\cos\theta'))d\theta', \qquad (10)$$

where $\Delta\theta \equiv 2/(kg\cos\theta_{inc})$, g is a specified tapering dis-

tance and θ_{inc} is the specified angle of incidence. In Ref. 6 it is shown how an accurate analytical approximation to this integral can be derived. In this paper we will simply numerically evaluate the normal derivative of the expression of Eq. (10), thus avoiding any questions about the accuracy to which the approximate analytic expression for Eq. (10) satisfies the wave equation.[6,16] In the case that the half-space BIEM is used, the corresponding incident field $\tilde{p}^{inc}$ is given by

$$\tilde{p}^{inc}(x,z) = \frac{1}{\sqrt{\pi}\Delta\theta} \int_{-\pi/2}^{\pi/2} \exp\left(-\frac{(\theta' - \theta_{inc})^2}{(\Delta\theta)^2}\right)$$

$$\times \{\exp(ik(x\sin\theta' + z\cos\theta'))$$

$$- \exp(ik(x\sin\theta' - z\cos\theta'))\}d\theta'. \qquad (11)$$

Although tapering of the incident field can be very useful in the numerical modeling of scattering from a rough surface, there are some issues which need to be considered. First, in some theoretical investigations, it is the scattering response as a function of the plane-wave incident angle which is desired. The tapered incident field is effectively a spectral average over plane waves at different incident angles. In order to obtain a very small interval of angular (spectral) averaging, then the spatial extent of the incident field must be large. Conversely, if one wishes to have an incident field of very small spatial extent, then a large amount of angular spectral averaging results. For many situations, a good compromise between the spectral and spatial extent can be found. However, if the grazing angle of interest is very small, then there is the additional problem when one wishes the Gaussian weighting to be negligible for $\theta' = \pm\pi/2$ [i.e., the spectral values at the endpoints of the integral of Eq. (10) should be small]. In this case, it is necessary to make g suitably large.[16]

Another type of incident field which is untapered is that from a point source (although the amplitude of the field from the source does decrease with the square root of the range from the source). For a source distant from the scattering region and at a shallow depth, the field incident on the roughness interval is similar to that from an untapered plane wave at a shallow grazing angle. Finally, we will consider a case of a point source where there is also a bounding bottom seabed.

B. The scattering chamber approach

In Ref. 17 it was outlined in the Appendix how a system of integral equations could be set up for the case of an outward deformation. However, for the general case of both inward and outward deformations, this method becomes complicated. In this paper, we propose a simpler approach. In Fig. 1, a deformed surface is shown and an arc of a circle which contains the deformation area within it. Within the area defined by C_1 and C_2 we have the set of integral relations for points $\vec{x}(s)$ along the curves:

$$\int_{C_1} G(\vec{x}(s);\vec{x}(s_1'))p_{n'}(\vec{x}(s_1'))ds_1'$$

$$+\int_{C_2} G(\vec{x}(s);\vec{x}(s_2'))p_{n'}(\vec{x}(s_2'))ds_2'$$

$$-\int_{C_2} G_{n'}(\vec{x}(s);\vec{x}(s_2'))p(\vec{x}(s_2'))ds_2' = p(\vec{x}(s)) \qquad (12)$$

with $p(\vec{x}(s)) \equiv 0$ along C_1. We now consider an integral relation on the exterior of C_2 (i.e., consider the observation point just below the circular arc) and we use the half-space Green's function $\tilde{G}$ so that contributions from the flat portion of the upper surface are zero,

$$-\int_{C_2} \tilde{G}(\vec{x}(s);\vec{x}(s_2'))p_{n'}(\vec{x}(s_2'))ds_2'$$

$$+\int_{C_2} \tilde{G}_{n'}(\vec{x}(s);\vec{x}(s_2'))p(\vec{x}(s_2'))ds_2' + p^{inc}(\vec{x}(s)) = p(\vec{x}(s)).$$
$$(13)$$

The combined set of integral equations gives enough conditions to solve for p_n along C_1 and for p and p_n along C_2. In Eqs. (12) and (13) the normal is pointing out of the area enclosed by C_1 and C_2 and s_1' and s_2' are taken to increase in a clockwise direction (e.g., s_1' increases with increasing x along C_1). This system of equations is a Fredholm system of the first kind and hence it is not clear how numerically stable the system will be. In fact, we found numerically that for small incident angles, the numerical convergence as a function of the discretization size was poor. One can differentiate the equations with respect to the normal to derive a new set of equations. However, this leads to integral kernels with various singularities. Instead of using this integral approach, we now describe a wave-field superposition technique which can be used with the domain of Fig. 1.

The total pressure field within $\Omega \equiv C_1 \cup C_2$ (including the flat portions of C_1) is taken to be represented by a set of point sources located a fraction of a wavelength outside of Ω. This type of approach is used in a variety of other wave-field superposition applications.[21–26] We take a discretization of C_1 and C_2 and consider the point sources offset along the normal direction from the corresponding discretization points along C_1 and C_2 (some of these sources are shown as squares in Fig. 2). Let us denote the number of point sources offset from C_1 as N_1 and the number of point sources offset from C_2 as N_2, with $N_3 \equiv N_1 + N_2$. At a point $\vec{x}$ in Ω we can write for the total pressure field

$$p(\vec{x}) = \frac{i}{4}\sum_{q=1}^{N_3} a_q H_0^1(kR_q(\vec{x})), \qquad (14)$$

and for its normal derivative along a curve

$$p_n(\vec{x}) = \frac{-i}{4}\sum_{q=1}^{N_3} ka_q H_1^1(kR_q(\vec{x}))\frac{\partial}{\partial n}R_q(\vec{x}). \qquad (15)$$

Here, the normal derivative is computationally taken to have a positive z component (since we will be simply satisfying a
FIG. 2. A schematic of the geometry for the rough surface scattering problem showing some of the locations of the computational point sources for the wave-field superposition method. The outer ones (squares) are used to represent the total field within $C_1 \cup C_2 \equiv \Omega$ and are free space point sources. The sources just within C_2 represent the scattered field in the half-space outside of Ω. They also include the negative image about $z=0$ in their representation so that the scattered field automatically satisfies the pressure release condition along $z=0$.

continuity equation at a set of points, the polarity of the normal vector is not important as long as it is consistently defined for all field quantities). In Eqs. (14) and (15) we use free space point sources to represent the total field within Ω. The pressure release condition along the top surface of Ω will used as one of the boundary conditions to determine the coefficients of the point sources. Similarly for a point in the half-space outside of Ω we consider a set of N_2 point sources just inside C_2 to represent the scattered field (some of these sources are shown as triangles in Fig. 2), but in this case they will take the form that satisfies the pressure release condition along the surface $z=0$,

$$\tilde{p}(\vec{x}) = \frac{i}{4}\sum_{q=1}^{N_2} b_q[H_0^1(kR_q(\vec{x})) - H_0^1(k\tilde{R}_q(\vec{x}))] \qquad (16)$$

and

$$\tilde{p}_n(\vec{x}) = \frac{-i}{4}\sum_{q=1}^{N_2} kb_q\left[H_1^1(kR_q(\vec{x}))\frac{\partial}{\partial n}R_q(\vec{x})\right.$$

$$\left. - H_1^1(k\tilde{R}_q(\vec{x}))\frac{\partial}{\partial n}\tilde{R}_q(\vec{x})\right]. \qquad (17)$$

Here R_q is the range from the source point $\vec{x}_q$ and $\tilde{R}_q$ is the range from the image point above the upper flat surface. We can now set up systems of equations for a_q and b_q by imposing the various constraints at discrete values $\vec{x}_m$: the pressure release condition along C_1 and the continuity of the expressions [Eqs. (14)–(17)] for the pressure field and its normal derivative along C_2,

$$p(\vec{x}_m) = 0, \quad \vec{x}_m \in C_1, \qquad (18)$$

$$p(\vec{x}_m) = \tilde{p}(\vec{x}_m) + p^{inc}(\vec{x}_m), \quad \vec{x}_m \in C_2, \qquad (19)$$

$$p_n(\vec{x}_m) = \tilde{p}_n(\vec{x}_m) + p_n^{inc}(\vec{x}_m), \quad \vec{x}_m \in C_2. \qquad (20)$$

The first boundary condition yields N_1 equations, the second boundary condition, N_2 equations, and the third boundary condition, N_2 equations, for a total of $2N_2+N_1=N_3+N_2$

John A. Fawcett: Rough surface scattering

equations with $N_3 + N_2$ unknowns. One could attempt to satisfy the boundary conditions at more discrete points than unknowns, resulting in an overdetermined system of equations. For the case of a rigid boundary condition, Eq. (18) is replaced with the constraint $p_n(\vec{x}_m) = 0$ and the representations of Eqs. (16) and (17) are modified to satisfy the rigid boundary condition along $z = 0$.

In the case that there is a lower seabed boundary, then the expressions of Eqs. (16) and (17) are replaced by

$$\widetilde{p}(\vec{x}) = \sum_{q=1}^{N_2} b_q G^w(\vec{x}; \vec{x}_q) \tag{21}$$

and

$$\widetilde{p}_n(\vec{x}) = \sum_{q=1}^{N_2} b_q G_n^w(\vec{x}; \vec{x}_q), \tag{22}$$

where G^w denotes the waveguide Green's function (this is similar to the approach taken in Ref. 24 for a target in a perfect waveguide). Also the incident fields in Eqs. (19) and (20) are now those corresponding to the waveguide. With the representations of Eqs. (21) and (22), the solution exterior to C_2 satisfies the waveguide boundary conditions at both the top and seabed interfaces. We will consider a Pekeris waveguide, that is, a constant sound speed water column bounded above by a pressure release surface and below by a homogeneous seabed. The Green's function for such a waveguide can be expressed as a wave-number integral.[29] However, in this paper we will use the complex image representation for propagation in a waveguide[30] to express the Green's function as a set of point sources with complex amplitudes and positions. This has the advantage that the expression is computationally efficient and also allows one to simply replace the half-space Green's function in the computational code with a sum over the complex images. We can use this same expression to evaluate the field anywhere in the waveguide for ranges up to several waveguide depths; otherwise, one could use the wave-number integral or the discrete modal representation for ranges sufficiently far from the scattering region.

III. NUMERICAL EXAMPLES

In the numerical examples we will consider a variety of boundary integral approaches as well as the wave-field superposition method. First, we will implement truncated versions of Eq. (4) and Eq. (1) to solve and to extrapolate the solution; we will call this method "I." Second, we will use Eq. (4) to solve for the normal derivative along the truncated surface and then use Eq. (8) (i.e., using the half-space Green's function) to extrapolate the solution to the field points. This will be denoted as method "II." In this case, the incident field corresponds to the incident field of method I with the addition of the field reflected from a flat surface along $z = 0$. The wave superposition/scattering chamber (WSSC) method, using Eqs. (18)–(20), is also numerically implemented. Once the point source coefficients a_q and b_q in Eqs. (14)–(17) have been determined, then for a specified receiver position, the appropriate sum, Eq. (14) or (16) is used, depending on whether the receiver is interior or exte-
FIG. 3. The top panel shows the scattered pressure field (the difference between the total field and the field which would exist in the half-space for a perfectly flat top surface) as computed by method I (solid line) and the half-space method (dashed line) for an inward deformation for receivers along the line $z = -2.5$ m. The second panel shows the same results for the same deformation but outwards pointing. The third panel shows the results of using method I (solid line) and method II (dashed line) for a line of receivers at $z = -1.0$ m and the outward deformation. The incident field is a tapered ($g = 9$ m) plane wave incident at $60°$.

rior to the domain Ω. Finally, there is the method of using the half-space Green's function in both the integral equation and in the extrapolation [i.e., Eqs. (7) and (8)]. This will serve as the benchmark method in the case of inward deformations.

For the first set of computations we consider a deformation of the form,

$$z(x) = -0.5a\left(1 + \cos\left(\pi \frac{x}{2w}\right)\right), \quad -\frac{w}{2} < x < \frac{w}{2}. \tag{23}$$

For $a > 0$ the deformation is pointing into the fluid half-space and for $a < 0$ it is pointing outwards. The frequency for the computations is 1.5 kHz, the width of the deformation is $w = 10$ m, and the maximum height (negative direction) is 1.2 m. For the truncated BIEM the deformation area is discretized with 101 points and an additional 160 points are used on either side of the deformation (i.e., an extra 320 points) so that the total horizontal extent is 42 m with an equal Δx spacing of 0.1 m. The total system of equations has dimension 421×421. For the BIEM using the half-space Green's function [Eqs. (7) and (8)] there is no need to extend the computational domain outside of the deformation region and hence only 101 points are used. As a first numerical example we illustrate the problems which arise when using the half-space Green's function as the kernel of the BIEM. First, in Fig. 3 we show a comparison of the computed scattered pressure field for a line of receivers located along the line $z = -2.5$ m and a tapered plane wave incident at an angle of $60°$ using the standard truncated integral equation approach (method I—solid line) and using the half-space Green's function approach (dashed line). We use the definition that the scattered field is the difference between the total field and the field which would exist for the flat surface half-

space. The results show very good agreement as is expected since the deformation is completely inward pointing. We now repeat the numerical computations with the sign of the deformation reversed so that it is pointing strictly outward. As can be seen the agreement is very poor. This is because the use of the half-space Green's function is not valid in this case. Finally, for the outward deformation, we extrapolate the solution computed along the upper surface, using the truncated integral equation, to the receivers located along the line $z=-1.0$ m using the truncated integral, Eq. (1) (method I—solid line in Fig. 3) and using the half-space Green's function (method II—dashed line in Fig. 3). The solutions are in very good agreement except for the interval where the line of receivers is within the reflected image of the deformation. This region, where method II is inaccurate, is the interval predicted by theory. This example confirms that the half-space Green's function approach yields the correct solution for inward deformations and can serve as an accurate benchmark solution in this case. However, the approach breaks down for deformations which contain outward components. It also shows that the extrapolation using the half-space Green's function is accurate as along as the receivers are not within the region of the negative image of the deformation.

In the next series of computations we consider $a>0$ in Eq. (23) (i.e., inward pointing) and thus the half-space Green's function approach can serve as a benchmark in these cases. The computational parameters for the integral equations are the same as for the previous example. We stress that, as discussed previously, the computational results from method I would approximate the benchmark solution accurately if the computational domain was suitably extended. Here, we are instead fixing the size of the domain to what we consider a reasonable size and examining the resulting agreement with the benchmark solution provided by the half-space Green's function approach. For the WSSC method, we use 100 points along the rough surface and 20 points along the flat portion (10 on each side of the roughness area). The same number of points is used along the curve in the water. Thus, the resulting system of equations has a dimension of 360×360. By numerical experimentation it was determined that displacing the point sources a distance of 0.12 m from the computational curves yielded excellent results and this value is used for all the computations.

The scattered pressure field is computed for a line of receivers located at $z=-2.5$ m and for -20 m $<x<40$ m and 80 m $<x<100$ m (Fig. 4, top and bottom panels, respectively). An untapered plane wave is incident at an angle of 70°. In the top panel of Fig. 4 we show the resulting scattered pressure field (real part) computed using the benchmark method (solid line) and method I (dashed line). In the second panel we show the corresponding results for method II (dashed line) and in the third panel the results obtained using the WSSC approach (dashed line). As can be seen all three methods give good agreement with the benchmark solution in the region of the roughness (-5 m $<x<5$ m). The results of method I begin to diverge from the benchmark solution for values of x away from the center of the computation grid. In Fig. 4 we see that the results of method II and the scatter-
FIG. 4. The top three plots show the scattered pressure field computed at a line of receivers $z=-2.5$ m and -20 m $<x<40$ m for plane wave incident at 70°. The deformation is 1.2 m inwards, the frequency is 1500 Hz. The solution is computed (top) using the exact integral formulation (solid line) and the truncated formulation, method I (dashed line); (middle) using the exact integral formulation (solid) and method II extrapolation of the solution; and (bottom) the exact integral formulation (solid) and the WSSC solution. The same computations are then repeated for 80 m $<x<100$ m.

ing chamber approach (WSSC) both show excellent agreement with the benchmark solution for 80 m $<x<100$ m. The method II extrapolation uses only the computed values of $p_n(\vec{x})$ along the section of roughness and it explicitly accounts for the interactions of the incident and scattered fields with the flat portions of the upper surface. Method I shows poor agreement with the benchmark method for these longer ranges. As we will see with the next example, the main source of the disagreement is due to the abrupt truncation of the incident untapered plane wave.

In Fig. 5 the previous computations are repeated for a tapered ($g=9$ m) plane wave incident at an angle of incidence of 70°. In this case we find that once again the results of method II and the WSSC are in excellent agreement with the benchmark solution (scattered field). The results of method I are now in much better agreement with the benchmark solution, but one can see that for 80 m $\lesssim x \lesssim 100$ m the results are still not in good agreement. This is because, even with the tapered incident field, there is still an error in mod-
FIG. 5. The top three plots show the scattered pressure field computed at a line of receivers $z=-2.5$ m and $-20 < x < 40$ m for a tapered ($g=9$ m) plane wave incident at 70°. The deformation is 1.2 m inwards, the frequency is 1500 Hz. The solution is computed (top) using the exact integral formulation (solid line) and the truncated formulation, method I (dashed line); (middle) using the exact integral formulation (solid) and method II extrapolation of the solution; and (bottom) using the exact integral formulation (solid) and the WSSC solution. The same computations are then repeated for 80 m $< x <$ 100 m.

eling the interaction of the scattered field with the upper surface when the computational domain is not sufficiently large.

As the angle of incidence becomes closer to the horizontal, then the truncated solution begins to diverge from the exact solution even in the case that the extrapolation method of method II is used. In Fig. 6 we show the results (scattered field) of method II (dashed) and WSSC (dashed) compared with the benchmark solution (solid) for an untapered plane wave at an angle of incidence of 85°. For this example, the agreement of method II with the benchmark solution is poorest for -20 m $\leq x \leq 40$ m and is noticeable, but not as bad, for 80 m $\leq x \leq 100$ m. The WSSC solution is in excellent agreement with the benchmark solution everywhere. It is possible to consider a tapered incident field at this angle of incidence but, as discussed, in order to obtain an incident tapered wave which has a negligible spectral amplitude at $\theta' = \pi/2$ the spatial extent of this incident tapered plane wave needs to be large.
FIG. 6. The top two plots show the scattered pressure field computed at a line of receivers $z=-2.5$ m and -20 m $< x <$ 40 m for a plane wave incident at 85°. The deformation is 1.2 m inwards, the frequency is 1500 Hz. The solution is computed (top) using the exact integral formulation (solid line) and method II (dashed line) and (bottom) the exact integral formulation (solid) and the WSSC solution (dashed line). The same computations are then repeated for 80 m $< x <$ 100 m.

Finally, a distant point source at $x_s=-1000$ m and $z_s=-5$ m is considered. In this case the agreement of method II with the benchmark solution (scattered fields) is very poor (the levels are incorrect by about a factor of 3). However, as is seen in Fig. 7 the agreement of the benchmark solution with the WSSC is still excellent.

Thus far, with the exception of the first example, we have considered a rough surface which consists of only an inward deformation. In this case, we could use an exact BIEM approach as the benchmark solution. For the more general case of a rough surface with both inward and outward deformations we will need to rely upon a truncated solution, using either method I or II to extrapolate the integral equation solution, as the "benchmark." For the results shown in Fig. 8 we consider a plane wave incident at 70° with tapering ($g=9$ m) and use the truncated integral equation approach. We will use the half-space Green's function (method II) to extrapolate the solution to a line of receivers at $z=-2.5$ m. A sinusoidal deformation,

FIG. 7. The benchmark scattered pressure field solution (solid line) and the WSSC results (dashed line) for a point source located at $x_s=-1000$ m and $z_s=-5$ m and a line of receivers at $z=-2.5$ m.

$$z(x) = a \sin\left(\frac{2\pi x}{w}\right), \quad -5 \text{ m} \leq x \leq 5 \text{ m}, \quad (24)$$

is considered where $a=1.2$ m and $w=10$ m. As can be seen from Fig. 8, the agreement between the benchmark solution (solid line) provided by method II and the WSSC approach is excellent (scattered fields are shown). This gives us confidence that the WSSC approach is accurate for general deformations of the upper surface.

In Fig. 9 we compute a grid of values for the sinusoidal deformation of Eq. (24) and a point source located at $x=-15$ m and $z=-0.5$ m; this corresponds approximately to an angle of 88° with respect to the center of the scattering surface. In the first panel we have subtracted off the function,

$$\frac{i}{4}[H_0^1(kR) - H_0^1(k\tilde{R})]. \quad (25)$$

This perhaps does not make much physical sense for points within the outward deformation, but does emphasize the dif-
FIG. 8. The benchmark scattered pressure field solution: method II for a tapered plane wave incident at 70° ($g=9$ m) (solid line) for the sinusoidal deformation of the upper surface and the WSSC results (dashed line) for a line of receivers at $z=-2.5$ m.
FIG. 9. The upper panel shows the scattered pressure field (total–flat surface solution) and the bottom panel shows total pressure field for a point source located at $x=-15$ m and $z=-0.5$ m. The frequency is 1500 Hz.

ference between the field in the presence of the scattering surface and the field which would exist for the perfectly flat surface. In the second panel the amplitude of the total field is shown. The interference effects between the scattered and incident fields is evident in the half-space below and to the right of the scattering region.

We now repeat the half-space computations but for the source in a 15-m-deep waveguide. The bottom has a sound speed $c_p=1700$ m/s and $\rho=1.5$ g/cm³. There is an attenuation of 0.5 dB/λ. A set of four complex images is used to represent the reflected field from the seabed and this set is used to construct a sequence of images for the waveguide.[30] We construct the set to account for up to an including two seabed reflections. This set is then used in the computational code to replace the two-term half-space Green's function. For the bounded waveguide, energy will be incident upon the scattering region from a large distribution of angles. The scattered field (incident subtracted from total) and the total fields are shown in Fig. 10. Because of the interactions of the incident and scattered fields with seabed boundary, the resulting fields have a more complicated spatial structure than for the unbounded half-space. It is important to emphasize the ease with which the unbounded half-space scattering method was modified to include the effects of the waveguide propagation, simply by using the appropriate Green's function for the exterior of the scattering chamber. In this case, by using a complex image approximation it was very easy to simply add an extra loop to the half-space code to include the extra complex image positions.

IV. SUMMARY

In this paper we have described some of the issues associated with the modeling of scattering from a finite interval of surface roughness. In particular, for a distant point source or for an untapered plane wave with a shallow grazing angle (and, possibly, distant receiver points from the area of roughness) the extent of the computational domain will need to be large in order for a truncated integral equation approach to yield an accurate approximation. A tapered incident field can
FIG. 10. The upper panel shows the scattered pressure field (total-flat surface solution) and the bottom panel shows total pressure field for a point source located at $x=-15$ m and $z=-0.5$ m. The frequency is 1500 Hz. There is a bottom seabed at a depth of 15 m with $c_p=1700$ m/s, $\rho=1.5$ g/cm^3, and attenuation of 0.5 dB/λ.

be used in some situations to mitigate some of the truncation issues. Also, we showed that using the half-space Green's function to extrapolate the integral equation solution to receiver points could be advantageous. However, there remain cases (for example, a distant point source and distant receivers) where a truncated integral equation approach, even using the half-space Green's function for extrapolation, will not yield an accurate approximation unless a very large computational domain is used. The use of the half-space Greens' function in the BIEM allows one to restrict the integral equation to just the area of roughness and avoid these large computational domains. However, this approach is only valid if the deformation of the upper surface is only inward. For the more general case, we proposed a wave superposition/scattering chamber approach. This was shown to be accurate for all cases considered and has the advantage that the size of the computational domain does not depend upon the locations of the source or receivers. As well, we showed that it is easily extendable to the case of a waveguide with a flat bottom seabed.

Target phase: An extra dimension for fish and plankton target identification

Richard Barr[a)] and Roger F. Coombs[b)]

National Institute of Water and Atmospheric Research, Private Bag 14-901, Kilbirnie, Wellington, New Zealand

The acoustic signal backscattered from a fish in water, $\mathcal{L}_{bs}(f)$, at a frequency, f, differs from the incident signal in both magnitude, $|\mathcal{L}_{bs}(f)|$, and phase, $\arg[\mathcal{L}_{bs}(f)]$, and it has been common practice for many years to use the backscatter magnitude from individual fish as an aid to species identification. However, very little use has been made of the phase of the backscattered signal relative to that of the incident acoustic pulse. If the gross phase changes due to propagation through water are compensated for, the residual phase signature is found to contain useful target-specific information. The phase signature can be characterized by estimating the rate at which the echo phase changes, relative to the transmitted pulse, during the echo from a fish. Clear groups are produced when single fish targets from *in situ* data are plotted in complex target space (target strength versus target rate of change of phase) and this is explored here by computing the acoustic backscatter, in complex target space, from a series of simple large and small model fish targets, both with and without gas-filled swimbladders, using a Monte Carlo technique. It is shown that all the features found in the *in situ* data can be explained in terms of the size and attitude of the fish. The modeling was carried out at the frequency of 38 kHz, which pertained to the *in situ* data, and the specific results only apply to this frequency. However, the complex target approach is generally applicable to fish target strength analysis independently of frequency. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1979503]

I. INTRODUCTION

Historically, the acoustic identification of fish has tended to follow two different paths. One system of identification, which is performed at great range (>100 m), makes use of standard fishing industry echogram displays. The shape of fish *marks* on the echogram, their size, and distance from the sea bed or hills, etc. have all been used as indicators of specific fish types (LeFeuvre *et al.*, 2000; Rose and Legget, 1988; Scalabrin *et al.*, 1996). The advantage of this approach is that it can be used in *real time* while fishing. The disadvantage is that few features of fish shoals exhibit high species discrimination (Scalabrin *et al.*, 1996). The second approach is to locate a single fish on the edge of large schools and, by measuring their target strength *in situ*, use the magnitude of the target strength as an indication of the species. This technique necessitates deploying a transducer reasonably close to the fish (<100 m) so that single targets can be resolved (e.g., Do and Coombs, 1989). A useful extension to this technique is to perform the measurements at a number of different frequencies simultaneously and weight the responses on the different frequencies in order to optimize the species selectivity of the summed response (Kloser *et al.*, 2002).

The target strength, measured at a frequency f, is commonly defined (e.g., Medwin and Clay, 1998) in terms of the modulus of the complex acoustical backscattering length, $\mathcal{L}_{bs}(f)$,

$$\text{TS}(f) = 20 \log[|\mathcal{L}_{bs}(f)|/1 \text{ m}](\text{dB}). \tag{1}$$

Previous target identification studies using target strength have only used the modulus of the backscatter data as in Eq. (1). However, the backscattering length, $\mathcal{L}_{bs}(f)$, is a complex quantity and one can measure not only the amplitude of the backscattered pulse from a target compared to the incident pulse, $|\mathcal{L}_{bs}(f)|$, but also the phase, $\arg[\mathcal{L}_{bs}(f)]$. How this phase changes with elapsed time, or range, if we assume propagation in sea water, gives us a new dimension in fish target studies.

Experimentally, phase information has previously been used to determine the position of a target in the transducer beam (e.g., Ehrenberg, 1979) and to help discriminate between single and multiple targets (Soule *et al.*, 1995; 1996; 1997). In these cases, however, phase differences were measured between the different elements of a four-quadrant transducer. In this paper the phase of the echo from a target is determined by reference to the transmitted pulse. If the gross phase changes due to propagation through water are removed, the residual phase signature is found to contain useful target specific information. Barr *et al.* (2000) created a descriptor, the target rate of change of phase, which displayed such target specific characteristics largely independent of range. They defined the target rate of change of phase as the rate at which echo phase changed, relative to the trans-

mitted pulse, during the echo from the fish. Barr *et al.* (2000) also selected the maximum echo amplitude, and the rate of phase change, evaluated at maximum amplitude, to define a target in complex target space. Using the rate of change of phase as the new descriptor and referencing the scale to the time of the maximum echo amplitude effectively removes range effects and gives a parameter whose properties are dominated by the physical characteristics of the target. They then used this complex target strength information to discriminate, *in situ*, between different fish groups in which the magnitude of the target strength was the same but the phase response different.

Barr *et al.* (2000) based target identification largely on associations between trawl catches and expected acoustic responses from conventional target strength studies. The expected phase response of orange roughy, in particular, was based on some preliminary target modeling work, and this paper greatly extends this with the aim of increasing understanding of the observed acoustic responses by modeling the scattering from simple, but realistic, physical models of the fish and other scatterers found in trawls and other sampling devices.

II. DATA

The data were collected using NIWA's Computerised Echo Sounder Technology (Barr *et al.* 2000; Coombs *et al.*, 2003). In this system, signals received by the transducer are amplified and then digitized at 100 kHz and fed to a digital signal processor (DSP56002), where they are complex demodulated, filtered, and decimated to give a final sample rate of 10 kHz. The output voltage, A, from the receiver for any fish is, from Eq. (1), proportional to $|\mathcal{L}_{bs}(f)|$, where f is 38 kHz. We have characterized this using the maximum amplitude, A_{max}, of a received pulse. In our past target strength studies (e.g., Coombs and Barr, 2004) we have estimated A_{max} by locating the highest-amplitude sample in a pulse envelope and fitting a parabola to it and the two points to either side (three points in all). The target strength, in decibels, is derived from the square of the amplitude with calibrations referenced to a tungsten carbide sphere. Similarly, the signal phase also changes across a received pulse as a consequence of the range to the target and, more importantly, the acoustical properties of the target, $\arg[\mathcal{L}_{bs}(f)]$. As for amplitude, we fit phase change, ϕ, to a quadratic relationship with time, t, where

$$\phi = a + bt + ct^2. \tag{2}$$

Hence the rate of change of phase with time is

$$\frac{d\phi}{dt} = b + 2ct. \tag{3}$$

For a sequence of samples ($\Delta t = 100 \ \mu s$) at $t = -2, -1, 0, +1, +2$, where $t = 0$ is the time of the maximum amplitude, A_{max}, our rate of change of phase descriptor, ϕ'_{max}, is simply b from Eq. (3). Together, A_{max} and ϕ'_{max} describe a target in complex target space. To facilitate a comparison with the earlier work, we use the velocity of sound in seawater to convert the unit of rate of change of phase

from degrees per second to degrees per meter.

In Barr *et al.* (2000) we presented two plots of target strength versus the rate of change of phase derived from many thousands of *in situ* single targets. The recordings were made at short range (<100 m) and in deep water (≈ 800 m) on the Chatham Rise, about 1000 Km to the east of mainland New Zealand. The sounding frequency for all of these data was 38 kHz and the pulse length 12 cycles (0.32 ms). To cover more of the pulse, in estimating ϕ'_{max}, we used two samples to either side of the peak (five points in all). The predominant large fishes in the trawl catches from Barr *et al.* (2000) were orange roughy (*Hoplostethus atlanticus*) and black oreo (*Allocytus niger*). Small fishes such as myctophids (*Myctophum spp*) were often caught in the trawl meshes as were many other types of small organisms such as salps.

The two plots are reproduced here as the upper and lower panels of Fig. 1, which show clear groupings of the fish targets. The upper panel is from an oreo survey and has three clear target groups. The lower panel, from an orange roughy survey, shows four groups, although these are perhaps not quite so clear. Target group **a**, in the upper panel, was ascribed to black oreo, group **b** to myctophids, and group **c** was thought to be euphausids or other small planktonic targets. The data for this figure were collected at a location where trawl catches were predominantly of black oreo. The targets in the lower panel of Fig. 1 came from an area where catches were mainly of orange roughy and the arc-shaped feature **a** was ascribed to this species. The feature **b** was again attributed to myctophids and **d** to euphausids or other small sea creatures. Peak **c** was also provisionally assigned to orange roughy as a possible result of a failure in the single target detection algorithm. As noted in the Introduction, our aim is to reproduce similar target responses to those of Fig. 1 using simple fish models, and to determine how basic parameters of these models affect the target response. In the following discussions the plots of target strength versus the rate of change of the phase are referred to as plots in complex target space.

III. MODELING

A. Anatomically based acoustic backscatter models

We have characterized the trawl catches using black oreos, orange roughy, and myctophids and these three species are shown in Fig. 2 (from Paul, 1986). The bodies of the fish have been modeled as general spheroids and the swimbladders as prolate spheroids. The parameters of the model fish and the propagation media, applicable to a depth of 1000 m, are given in Table I. Unless otherwise stated, model parameters are all taken from Table I. The swimbladders of the myctophid and black oreo are assumed to be gas filled, while the orange roughy is assumed to have a swimbladder filled with wax esters (Phleger and Grigor, 1990). The data on the propagation medium, the orange roughy, and the black oreo are taken from Barr (2001) and on the myctophid from Marshall (1960). These models are intended to capture the essential acoustic scattering features of fish representing large and small species with gas-filled swimbladders and a large spe-

FIG. 2. Drawings of the three fish modeled in this study taken from Paul (1986). Note that the typical adult oreo and roughy are ≈35 cm in length, whereas adult myctophids are only ≈7.5 cm.
FIG. 1. Plots of acoustic target strength versus the target rate of change of phase (complex target space) (from Barr *et al.*, 2000). Upper panel: Data recorded during an oreo survey. Lower panel: Data recorded during an orange roughy survey.

cies with a wax-filled swimbladder; they are not meant to accurately model all the biological features of the fish. Myctophids in particular have very complicated swimbladder morphology that tends to shift from being entirely gas filled in juveniles to increasingly wax ester filled with age (Butler and Pearcy, 1972; Neighbors and Nafpaktitis, 1982). Morphology also varies between different species, and Butler and Pearcy (1972) grouped the swimbladders of eight myctophid species into three types: gas-filled, fat invested, and atrophied or reduced, although in all of these species, small specimens had thin-walled gas filled swimbladders.

We assume that all the dimensions of our fishes scale linearly and that the body proportions remain constant. For oreo and roughy modeling this seems reasonable since the

data in Fig. 1 were derived from adult fishes whose lengths had typical standard deviations of only 10%. Thus, scaling linearity is only required to hold good over a limited length range. The possible effects of the model limitations are discussed later.

The Kirchhoff method was used to evaluate the target strength of the spheroids (Medwin and Clay, 1998; Foote and Francis, 2002). The results have been found to be accurate when the acoustic wavelength is small compared to the length of the swimbladder or fish body (Foote and Francis, 2002). The technique should thus give acceptable accuracy for all the fish bodies studied here, but will be near the limits of its applicability for the small swimbladder of the myctophid. To calculate the backscatter from a tilted ellipsoid, containing a nonconfocal and ellipsoid core, is not a simple problem, and we have modeled the swimbladder and fish body separately following Furusawa (1988).

B. Fluid sphere models

Because many of the targets in Fig. 1 are likely to be small (groups **c** and **d**) and therefore at the limit of the applicability of the Kirchhoff method, an alternative modeling approach, appropriate to small scatterers, was also implemented. We assume that these small targets are much smaller than the wavelength of the incident acoustic radiation (4 cm for our *in situ* data). This means that the overall shape of the target is not as important as the volume in determining its scattering properties (Strasberg, 1953; Love, 1978). The

small prolate spheroid swimbladder of our myctophid (with an aspect ratio of 3:1) can be expected to have resonance frequency and peak target strength responses (in broadside orientation) to within 6% of those of a sphere of the same volume (Feuillade and Werby, 1994). We therefore take all our plankton model targets to be spherical and composed of fish flesh or gas-filled. As we have only acoustic information about the real targets, a spherical model seems a reasonable first approximation.

We used the approach of Anderson (1950) to determine the complex target strength of the spherical targets of fish flesh and Love (1978, 1993) for the spherical air bladders. Love (1978) derived an expression for the complex target strength of a gas bladder encased within a viscous, heat-conducting shell of fish flesh. However, in a later paper (Love, 1993) he showed that, for blue whiting, the outside diameter of the shell had little effect on the target strength and that thermal and surface tension effects were negligible. He went on to produce a simplified formula that is effectively that of Anderson (1950) with the addition of viscous damping in the flesh surrounding the gas bladder (Medwin and Clay, 1998). Although this model has the disadvantage that it only applies to the gas bladder oscillating in its fundamental mode, for the small targets considered here the sound radiation in higher-order modes is several orders of magnitude below that of the fundamental (Strasberg, 1953). Our spherical gas bladders (effectively bubbles) are therefore modeled using Love's (1993) simplified theory. This approach takes account of resonance in the gas bladder, while the Kirchhoff does not.

C. Generation of plots in complex target space

As noted above, the data in Fig. 1 were generated with a 38 kHz transmission of 12 cycles duration; this short pulse length being used to maximize resolution of single targets. By computing the complex spectrum, $P(f)$, of the pulse and assuming the transducer response, $T(f)$, to be the same as that given by MacLennan (1981), we can derive the complex response, $R(f)$, of a fish from Eq. (4) below:

$$R(f) = T(f)P(f)G(f), \qquad (4)$$

where $G(f)$ is an estimate of the complex target strength of the model fish, $\mathcal{L}_{bs}(f)$, of Eq. (1), evaluated using the Kirchhoff method. By taking the inverse Fourier transform of $R(f)$, and complex demodulating, we obtain the

pulse response of the model fish to insonification by the ping.

Figure 3 shows the pulse response of a model black oreo of 30 cm total length, when insonified in the dorsal aspect at zero tilt. The solid trace shows the amplitude response and the dashed trace the phase response. However, whereas the numerical results presented in Fig. 3 are continuous, the experimental pulse responses of Barr et al. (2000) were sampled at 10 kHz. As a result, measurements of the ping response, as plotted in Fig. 3, were only recorded every 7.5 cm (100 μs). Typical sample points at this resolution are shown by the open circles on the continuous amplitude and phase curves.

To simulate the in situ data in Fig. 1, we used Monte Carlo simulations assuming fish lengths and tilt angles in the fish population were normally distributed with mean length, L, and standard deviation, σ_L, and mean tilt, χ, with standard deviation, σ_χ. Fish were selected at random from this distribution, their ping response computed at a resolution of 7.5 cm and A_{max} and ϕ'_{max} estimated for each fish to give a single point. Many tens of thousands of points are needed to produce displays comparable to Fig. 1 and computation speed proved a limitation. To speed up the simulation, the algorithm used by Barr et al. (2000) was modified and the number of points used to fit the phase response reduced from five to three. From Fig. 3 it can be seen that reducing the number of points with the simulated responses will make little difference to the estimates of ϕ'_{max}. The simulation also allowed

for a uniform random movement of fish targets within the 7.5 cm resolution range.

IV. MODELING RESULTS

A. Black oreo

Figure 4 shows the complex target response for three black oreo simulations, where the mean length was taken to be 33.7 ± 1.8 cm and tilt angle $17 \pm 8°$ (Coombs and Barr, 2004), with the other parameters from Table I. The upper group of results, centered at ≈ -40 dB target strength and 0 deg/m rate of change of phase, is the result of modeling the combined effects of the swimbladder and the fish body. The shape of the group is very similar to, but somewhat less dispersed than, group **a** in the upper panel of Fig. 1, which was thought by Barr *et al.* (2000) to represent black oreo. The circles drawn around the groups in Figs. 1 and 4 have the same target strength and rate of change of the phase range to assist comparisons. It is possible that some of the extra spread in the *in situ* results is due to signal contamination by small targets at a level below that required to trigger rejection by the single target detection algorithms used.

The center group in Fig. 4 represents the response of the black oreo swimbladder alone. Comparing this with the combined response of the swimbladder and fish body above it, we can see that the main contribution of the fish body is to increase the spread in the rate of change of phase. The lowest trace in Fig. 4 is the response of the fish body alone and is typically ≈ 20 dB below that of the swimbladder. This ratio is much greater than that reported by Foote (1980) for cod and mackerel and is probably due to the difference in shape between these species. Oreos are much deeper (dorsal to ventral) in wavelength terms than cod, resulting in less coherence in the returned echo. The response of the fish body alone shows a very large spread on the phase axis for a very small change in target strength, producing an arc-shaped feature similar to curve **a** in the lower panel of Fig. 1, which
Barr *et al.* (2000) attributed to orange roughy. Based on the groupings in Figs. 1 and 4, we conclude that it is necessary to include the fish body when modeling the black oreo complex target strength.

Figure 5 shows the effects of different features of the black oreo model. The top group is a copy of the upper plot in Fig. 4 for a complete model of the fish body plus swimbladder. The standard deviations of the fish length and tilt angle distributions, from Coombs and Barr (2004), are shown beside each group. The second group in Fig. 5 uses the same complete fish model but the fish length has been fixed at 30 cm and only the tilt angle varied. It can be seen that the tilt alone is sufficient to cause the same spread in target strength and rate of change of phase as when both tilt and length vary, but the group shows a clearly defined structure. The third group down shows the effect of keeping the fish tilt angle constant at 0° and letting the fish length vary. This group has about the same phase spread as the upper two but the amplitude spread is reduced by a factor of 4. The bottom group in Fig. 5, for a fish of constant total length 30 cm and of constant tilt angle 0°, shows the target spread produced only by the 7.5 cm uncertainty in the start of digitization. The spread from this source is negligible in comparison with the variability in fish tilt and length. From Figs. 1 and 5 we conclude that black oreo tilt is of much more significance in determining target strength than fish length.

B. Orange roughy

The overall form of the target strength-length response of the spheroidal orange roughy body produced by the Kirchhoff method is almost identical to that generated by the slab-cylinder method of Clay and Horne (1994) [see Fig. 6(c) of Barr, 2001]. However, the magnitude is around 4 dB less for the Kirchhoff method. On the other hand, the target strength values for the swimbladder, with its assumed circular cross section, are within 1 dB when computed by the two different techniques. We believe the values given by the Kirchhoff

R. Barr and R. F. Coombs: Fish identification using target phase

FIG. 7. Orange roughy targets plotted in complex target space. Results are computed separately for the swimbladder and fish body. Note the increased *x*-axis spread compared to Fig. 6.

technique are to be preferred because the spheroidal model approximates the shape of an orange roughy better than the slab-cylinder model.

In order to compensate for the reduced contribution of the fish body to the total roughy target strength we have increased the contribution from the swimbladder to produce a target strength of similar magnitude to those measured experimentally (McClatchie *et al.*, 1999; Barr *et al.*, 2000). This has been accomplished by reducing the swimbladder tilt angle to 12° compared to the 18° assumed in Barr (2001). A close inspection of the frozen saggital section of the male orange roughy in Phleger and Grigor (1990) shows that while the rear half to two-thirds of the swimbladder is tilted ≈18° above the horizontal, the front half to a third is almost horizontal. A compromise tilt of 12° for the whole bladder therefore seems reasonable. With this tilt our simple model produces target strength values within 0.5 dB of the most recent *in situ* measurements (Doonan *et al.*, 2001), for roughy of ≈34.5 cm standard length.

The lower panel in Fig. 6 shows more than 4700 *in situ* targets plotted in complex target space recorded on the Chatham Rise in June 1999 at depths between 680 and 820 m. The upper panel shows 5000 targets produced using our spheroidal orange roughy model with parameters as given in Table I except for the swimbladder tilt angle, which was reduced to 12°, as described above. The only free parameters in the model were the model fish length and tilt distribution. To produce the results plotted in the upper panel of Fig. 6 required, a 0° mean fish tilt angle with a standard deviation of 2° and a fish length standard deviation of 0.5 cm. The tilt angle standard deviation appears unrealistically small at 2°, being only half that found to be necessary to model smooth oreo target strength distributions (Coombs and Barr, 2004) and a quarter that required for black oreos. The 0.5 cm fish length standard deviation required to fit the *in situ* data is also well below the 2.8 cm typical of roughy caught by trawling on acoustically surveyed marks by Barr *et al.* (2000). However, it must be remembered that our fish models are perfect spheroids. It is possible that by incorporating some irregularities on the surface of the fish model, as used, for example, by Clay (1991), larger standard deviations will be required to model the *in situ* data.

Figure 7 shows the individual contributions of the fish body and the swimbladder to the overall complex target strength presented in the upper panel of Fig. 6. Note that the range of the *x* axis in Fig. 7 is twice that in Fig. 6. It is clear from Fig. 7 that the dominant contributor to the arc-shaped phase response in Fig. 6 is the fish body, but that the very rapid phase variation for the fish body alone is moderated by the presence of the swimbladder. The dimensions of the swimbladder are much smaller in terms of acoustic wavelength than those of the fish body. The comet-like tail on the swimbladder response results from the variation in swimbladder response with tilt angle [see Fig. 6(a) of Barr 2001].

While the "dot plots" in Figs. 1, 6, and 7 give a rough idea of target distributions in complex target space, it is difficult to get any idea of relative target concentration. This
FIG. 8. *In situ* data recorded during the 1999 orange roughy survey. The targets are plotted in complex target space with the gray scale indicating the target density.

problem has been overcome in Fig. 8, where the *in situ* data for nine further target strength runs are plotted as gray shaded contours, equally spaced in the logarithm of target density. The highest target concentrations are white and the lowest black. All these data were recorded during the 1999 orange roughy survey, over marks that were later found by trawling to contain orange roughy. It was initially thought that the arc-like bands around −50 dB were necessarily the roughy but this feature, as described later, can also be produced by a different target type. The data in panels d44, d52, and d53 also show a clear group near −40 dB, probably produced by oreos. The weaker groupings (−60 to −70 dB) with large positive rates of phase change (100 to 150 deg/m) will be discussed later.

Figure 9 shows contours of target density in complex target space computed solely from our spheroidal orange roughy models. The results in each panel are computed for 10,000 roughy, described largely by the data in Table I, but with fish length (L) and fish tilt angles (χ) normally distributed with the parameters given in the respective panel. The arc-shaped group in the central panel (cl3) has a shape and size very similar to the arc-shaped plot in the center panel (d54) in Fig. 8, which appears to confirm the arc-shaped signature as orange roughy. However, there is still some doubt about the small spread in fish lengths (34.3±0.5 cm) needed to model the *in situ* data. The mean fish length determined from trawling, over the same path as the acoustic transects, was 34.2±2.7 cm, a spread some five times greater than in the model.

The models in Fig. 9 have been arranged to show the effects, in complex target space, of fish length, fish length

standard deviation, tilt angle, and tilt angle standard deviation. The three center panels, from left to right, show the effect of a 1.4 cm increase in mean fish length: as fish length increases, the peak in target density moves from positive to negative values of the rate of the change of phase. The three central panels running from bottom to top of Fig. 9 show the effect of increasing the standard deviation of the fish length. As might be expected from the effect of changing fish length, this increases the length of the arc.

Moving diagonally in Fig. 9 from top left to bottom right shows the effect of changing the mean fish tilt angle. This appears to have little effect on the arclength, but a significant effect on the spread of target strength with positive tilt angles, giving a larger spread. Moving diagonally in Fig. 9 from bottom left to top right shows the effect of increasing the fish tilt angle standard deviation, which in a similar fashion as previous, has only a slight effect on the arclength but produces an increased spread in target strength.

In summary, our simple orange roughy model is able to give a plausible explanation of the arc-shaped target distributions, as shown in the lower panel of Fig. 1, but seems to require fish distributions with unrealistically small standard deviations of fish length and tilt angle.

C. Myctophid

Figure 2 shows the shape of a typical myctophid in comparison with an orange roughy and a black oreo. Myctophids are much longer in comparison to their body depth than either oreos or roughy but the main difference is their size (see Table I); myctophids at around 7.5 cm are significantly
FIG. 9. Spheroidal model orange roughy targets plotted in complex target space with the gray scale indicating the target density.

smaller than the other two. "Myctophid" is used somewhat loosely here and is intended to include all small fishes with gas bladders. The aim of the myctophid model is to identify the target groups **b** in Fig. 1.

The myctophid target strength-length relationship from modeling is shown in Fig. 10. The computations assume all fish dimensions scale linearly but the target strength values, especially those of the swimbladder, are less reliable as the dimensions of the fish decrease and become comparable to
FIG. 10. Target strength of the model myctophid compared with the *in situ* target strength of groups **b** in Fig. 1.

the 38 KHZ wavelength ($\approx$4 cm). For fish lengths between 6 and 10 cm, the total fish target strength is almost constant at $\approx$$-53$ dB, independent of fish length. This constancy in target strength results from interference between sound reflected from the fish body and from the swimbladder and is within 0.5 dB of the value of -53.5 dB (the dashed horizontal line in Fig. 10) found by Barr *et al.* (2000) to be representative of more than 30 000 targets in groups such as **b** in Fig. 1, strong evidence that these are myctophid-like fishes. To further test this assignment, Monte Carlo analyses were made of the complex target strength of 5000 myctophid-like targets selected from fish distributions with different length and tilt angle distributions. Figure 11 shows the results for four different fish distributions. The upper group (inside the ellipse) was produced by myctophids with lengths uniformly distributed between 5.6 and 10.5 cm, swimming horizontally with zero tilt angle. The ellipse around the distribution has the same dimensions as the ellipse **b** in the lower panel of Fig. 1 and is located at the same position on the target strength scale. However, on the rate of change of phase scale (*x* axis) it is in a position intermediate between those of the ellipses in the upper and lower panels of Fig. 1.

Although this is a remarkably good fit, it is not clear how realistic the assumptions of uniform length distribution (5.6–l0.5 cm) and zero tilt angle are. While myctophid-like fishes have been caught in this length range in shallower waters on the Chatham Rise (McClatchie, 2002), the distributions were more Gaussian than uniform with a spread from 3-10 cm. The zero fish tilt angle required to fit the *in situ* data is unrealistic (Bone, 1973) and probably results from inad-
FIG. 11. Complex target space plots of four myctophid distributions with different length and tilt distributions.

FIG. 12. Complex target space plots of two simulated small target distributions. These targets have lengths uniformly distributed from 1% to 100% of the standard myctophid target (7.5 cm total length). The black dots apply to a gas bladder alone and the gray dots to a fish body alone. Targets are assumed to have zero mean tilt with a standard deviation of 5°.

equacies of the Kirchhoff method for targets small in comparison to the wavelength.

The complex target strengths of three further myctophid distributions are presented in Fig. 11. Comparing these with the uppermost group (uniformly varying length and fixed tilt), it is apparent that none accurately models the behavior of the observed fish distribution (groups **b** in Fig. 1). The second group from the top (fixed scale length of 7.5 cm and zero tilt angle with 2° standard deviation) clearly has too much spread in the target strength and insufficient spread in the rate of change of phase. Third from the top (both scale and tilt varying) produces a realistic spread in the rate of change of phase, but has too wide a spread in amplitude, especially for low values of the rate of change of phase. The lowest group (fixed fish tilt and scale length) clearly has insufficient spread in either amplitude or phase.

D. Small targets, Kirchhoff

To try and determine the practical limits of our myctophid model, we attempted to use it to reproduce the low target strength groups, **c** and **d**, in Fig. 1. We assumed that these targets were either gas bladders or fish flesh and that they were uniformly distributed within the length range from 1%–100% of our standard myctophid target (Table I) since this had a target strength at the upper limit of those in groups **c** and **d**. The black and gray patches in Fig. 12 show the complex target response of gas- and fish flesh- based "plankton," respectively. Although these cover the same target strength range as groups **c** and **d** in Fig. 1, they differ significantly with respect to phase. The *in situ* data show a clear progression of the increasing rate of change of phase with increasing target strength that is absent in the modeled results. The latter show the rate of change of phase to be almost constant and independent of target strength. As the majority of planktonic targets must be either flesh or gas
dominated, this is further evidence of the weakness of the Kirchhoff model for smaller targets.

E. Small targets, fluid sphere

In this section we present the results of the alternative fluid sphere model for small targets. The gray trace in the center and toward the bottom of Fig. 13 shows the response of 20 000 spherical fish flesh targets with radii uniformly distributed in the range 0.001–10.0 mm. The fish flesh and sea water parameters are those for the oreo body in Table I. The response is similar to that for the myctophid fish body in Fig. 12, with very little change in the rate of change of phase
FIG. 13. Complex target space plots of two theoretical small spherical target distributions. The gray dots apply to a uniform distribution of fish flesh targets of radii in the range 0.001 to 10.0 mm. The black dots apply to a uniform distribution of gas filled targets with radii in the range 0.001 to 3.6 mm.

for a large change in target strength. Neither set of fish-flesh target responses exhibit the same increase in rate of change of phase with increasing target strength shown by groups **c** and **d** in Fig. 1 and, if anything, they show the reverse trend. It is unlikely therefore, that any but the smallest targets in Fig. 1 could be of a similar density to fish flesh.

What then produces the weak targets, as in group **c**, in the upper panel of Fig. 1? The answer is in the black target response in Fig. 13. This shows the complex target strength of a uniform distribution of l0 000 spherical gas bubbles of radius 0.001 to 3.6 mm, located at a depth of 800 m. The bubbles are assumed to be surrounded by a medium of zero viscosity and so either Anderson's (1950) or Love's (1993) formulations can be used to compute the response and this comparison was made as a means of checking the validity of our calculations. For the first time we can now see a gradual increase in the target rate of change of phase with increasing target strength, suggesting that the small targets in Fig. 1 are produced by small gas inclusions in either plankton or fishes. The large and rapid change in phase about the maximum target strength in Fig. 13 is the result of resonance of the gas spheres near 38 kHz. The largest-amplitude response occurs near the zero rate of change of phase, typical of a resonant system.

Printed around the black response curve in Fig. 13 are markers giving the radius of the air bladder at that region of the plot. It can be seen that to model groups **c** and **d** in Fig. 1 (between −85 and −50 dB) requires gas bladders between 0.7 and 1.4 mm diameter.

It is possible that the arc-shaped curve **a**, in the lower panel of Fig. 1, thought to be orange roughy by Barr *et al.* (2000), might, in fact, be produced by the resonant swim-bladders of myctophids. As noted earlier, myctophids have a complicated swimbladder morphology, but all of the juveniles had thin-walled gas-filled swimbladders. From Butler and Pearcy (1972), a 23 mm specimen had a volume equivalent to that of a sphere of radius ≈0.5 mm, whereas from Marshall (1960) a 75 mm myctophid had a radius of ≈3.6 mm. Thus, most of the question-mark-shaped curve in Fig. 13 could also be produced by a group of myctophids of varying species and size and consequently so could groups **c** and **d** in the Fig. 1 Chatham Rise data.

The rate of change of phase for spheres of radius greater than ≈1.3 mm radius is almost zero and remains so up to a radius of 3.6 mm, the limit of the calculations. At the same time the target strength increases from around −55 to −50 dB. The bubble model thus produces target strengths with similar features to the myctophid model using the Kirchhoff method (Figs. 10 and 11), and it is reassuring that both techniques produce similar results. The target strength values at the upper limit of the bubble model's validity are in reasonable agreement with those of the myctophid model at the lower limit of its validity.

Barr *et al.* (2000) warned against attributing rapid changes in phase purely to targets without gas-filled swim-bladders like orange roughy because similar signatures were found at much shallower depths where there were no orange roughy. The center panel in Fig. 14 shows one such distribution in complex target space recorded over a thick scattering layer on the Chatham Rise at depths between 400 and 500 m. These results were attributed to very dense targets overwhelming the single target algorithm, especially when individual targets were spaced at multiples of the sounding wavelength, in a similar manner to that suggested by Soule *et al.* (1996). Effectively, two small targets such as myctophids, separated in the vertical direction, were thought to be mimicking the reflections from the upper and lower surface of a fish without a gas-filled swimbladder. However, we now think it more likely that these arc-shaped targets were produced by resonant air bladders in either myctophids or siphonophores. The upper and lower panels in Fig. 14 show the response in a complex target space of 10 000 gas-filled spheres, with radii uniformly distributed between 0.35 and 0.65 mm, immersed in fish flesh. The lower panels are for fish flesh with zero viscosity and the upper panel a viscosity of 2 kg m^{-1} s^{-1} (20 Poise).

It is clear from Fig. 14 that resonant gas-filled spheres have signatures very similar to those of the *in situ* acoustic targets. The model results in the upper panel of Fig. 14 match the target strength of the *in situ* data very well but slightly underestimate the total phase spread in the arc-shaped region. On the other hand, the arc-shaped region in the lower panel, which was computed ignoring the viscosity of the fish flesh, has target strengths that are ≈4 dB too large and overestimates the spread in the rate of change of phase. A fish flesh viscosity of 1.0 kg m^{-1} s^{-1} (10 Poise) fits the spread in the rate of change of phase of the *in situ* data almost exactly, but slightly overestimates the target strength. The slightly high values of the simulated target strength could result from the assumption that the gas bladders are spheres when they are actually prolate spheroids. The latter, with aspect ratios of 3:1 and 10:1 and the same volumes as the spheres, would have target strengths reduced by ≈0.5 and 1.5 dB, respectively (Feuillade and Werby, 1994; Ye, 1997).

Finally, Fig. 15 shows the effect of the depth of immersion in the ocean on the response of gas-filled spheres enclosed in fish flesh for depths of 100, 330, and 1000 m. The viscosity of the fish flesh has been taken as 1.0 kg m^{-1} s^{-1} which was the value found to best fit the *in situ* data (Fig. 14). It can be seen that at all depths the shape in complex phase space is roughly that of a question mark and that the target strength at resonance increases monotonically with depth. This is just a feature of the larger spheres needed to support resonance at greater depths. However, the rate of change of phase, and hence the Q of the resonance, maximizes at ≈330 m. The depth at which this occurs depends on the relative contributions to damping caused by reradiation (scattering) and viscous effects (see Medwin and Clay, 1998). The resonant radius, r_{res}, the sphere radius giving maximum target strength, and the zero rate of change of phase, is shown for each depth in Fig. 15.

V. DISCUSSION

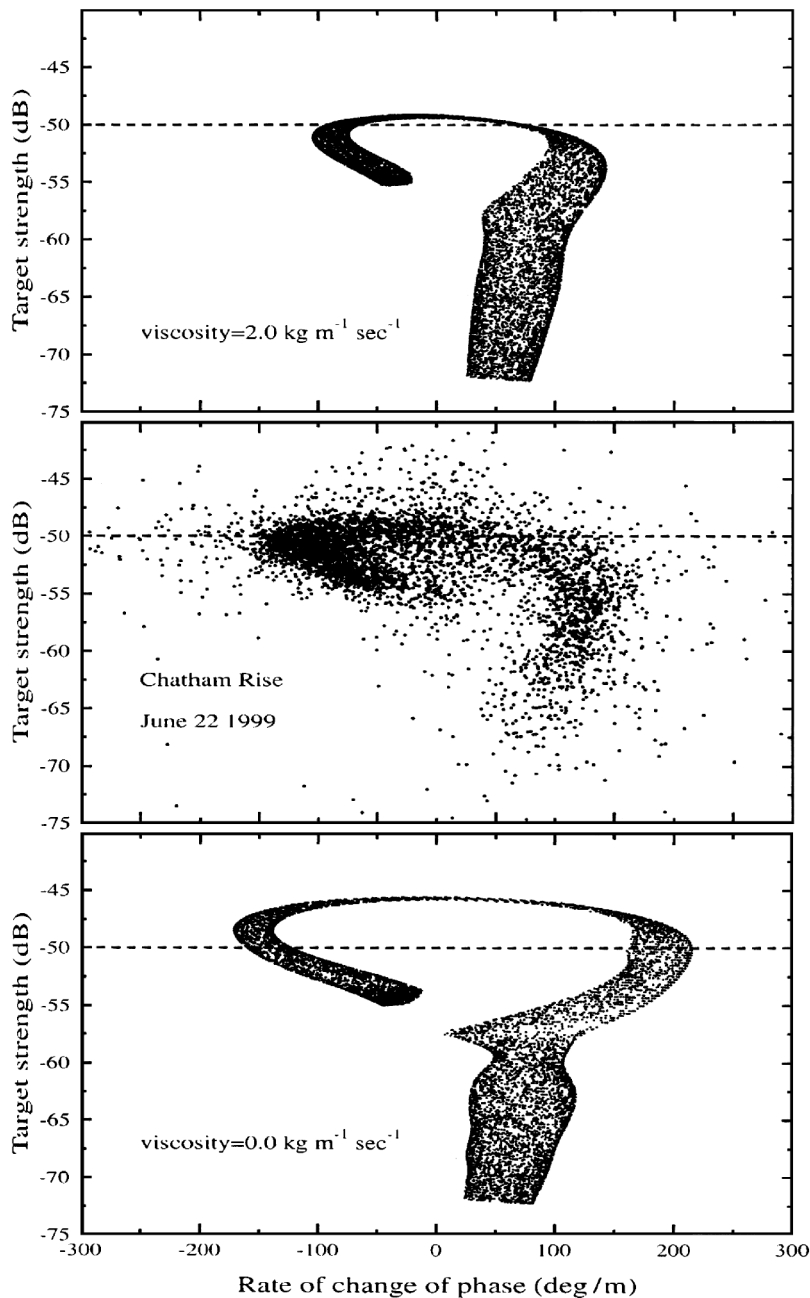
Our aim in this paper was to reproduce similar target responses to those in Fig. 1 using simple fish models, and to


FIG. 14. Center panel: complex target space plot of *in situ* data recorded in a midwater scattering layer at a depth of ≈400 m during the orange roughy survey. Upper and lower panels: complex target space plots of l0 000 small gas-filled spherical targets with radii uniformly distributed between 0.35 and 0.65 mm. The results in the lower panel are for gas spheres encased in fish flesh of zero viscosity. Those in the upper panel are for gas spheres encased in flesh of viscosity $2.0 \ \text{kg m}^{-1} \text{s}^{-1}$.

determine how the parameters of these models affect the target response—how successful were we and what practical insights have we gained?

The black oreo model, a typical large deepwater fish with a gas-filled swimbladder, provides a good fit to the *in situ* data. In this case, much of the greater part of the scattering is from the swimbladder and this is naturally shaped like a prolate spheroid and is large relative to the wavelength, so the result is not unexpected. Figure 5 shows that the tilt angle has a bigger effect on the target strength than the fish length, so to improve estimates of oreo target strength for biomass estimation, more information on fish attitudes in the wild is needed. The large influence of tilt probably results from the large offset angle of the swimbladder in the body (Coombs and Barr 2004) and its large size relative to the wavelength. The fish length was found to have

a greater effect on the phase response rather than the amplitude.

For orange roughy the results were less clear cut. The arc-shaped response results primarily from interference between the signals scattered from the upper and lower surfaces of the fish body, but is too great without the moderating effect of scattering from the swimbladder. With this fish model we have been able to realistically match the pattern of the *in situ* data with respect to both amplitude and phase. However, this was only possible by using a fish length distribution that was much smaller than that of the fish caught in trawl samples and it was also necessary to adjust the angle of the swimbladder in a somewhat arbitrary fashion. Orange roughy are much more complex scatterers than oreos. The contrast in scattering between the body and swimbladder (Fig. 7) is not large, the swimbladder is only approximately
FIG. 15. Complex target space plots of 10 000 small gas-filled spherical targets with radii uniformly distributed between the limits indicated showing how resonance changes with depth. r_{res} is the radius of the gas sphere that is resonant at the given depth. The gas spheres are encased in flesh of viscosity 1.0 kg m^{-1} s^{-1}.

spheroidal (Phleger and Grigor 1990) and there are significant deposits of wax esters in the head as well as the swimbladder. Thus, to better model orange roughy scattering it will be necessary to adopt an approach such as that of Macaulay (2002), who used finite difference modeling together with density information from CAT scans to model roughy. However, while this technique will remove the computational uncertainties, it will still have practical modeling problems associated with the need to recover specimens from great depth. The uncertainties in the orange roughy modeling perhaps creates some doubt as to whether the targets exhibiting rapid rates of phase change are in fact produced by orange roughy, and the small target results showed that a similar pattern could be produced by resonating gas bubbles.

The results for myctophids were also less clear cut than for oreos. We were able to reproduce target groups **b** in Fig.

1 effectively but only by assuming a zero tilt angle showing no variation. While the former is not unreasonable, the latter is unrealistic (Bone, 1973). This is almost certainly because these targets are small relative to the wavelength and the Kirchhoff method is at the limits of its applicability. While it is frustrating not to be able to accurately model complex target strength data with a realistic fish distribution model, the lack of agreement shows the value of the extra constraints placed on the fish models by having to simultaneously fit both amplitude and phase.

Our Kirchhoff modeling of small targets (between −50 and −80 dB in Fig. 1) duplicated the range of target strengths but not the trend in phase of increasing rate of change of phase with increasing amplitude evident in Fig. 1, again demonstrating the value of the extra dimension of phase to the analysis of target strength. Modeling small fish-flesh targets as fluid spheres gave similar results to Kirchhoff

and fitted only the weakest targets (≈ -80 dB in Fig. 1). Modeling small targets as spherical gas bubbles encased in viscous fish flesh was much more successful and was able to duplicate the trend of increasing rate of change of phase with increasing target strength. This model suggests that the gas spheres responsible for groups **c** and **d** in Fig. 1 have a maximum radius of ≈ 0.6 mm and gas bubbles of this size were found in siphonophores by Barham (1963), who suggested that they were probably responsible for a deep acoustic backscattering layer observed in the San Diego trough at the time the samples were collected. The bubble sizes were measured in the laboratory three weeks after the siphonophores were removed from deep water, and it is uncertain what the size of the bubbles was at great depth in the ocean, but it was probably smaller. Even so, our results suggest that group **d** in Fig. 1 could be siphonophores and these have been caught in sediment traps at depths of 300 and 1000 m on the Chatham Rise (Nodder, 2002), where the *in situ* data were collected. The resonant gas targets in Fig. 13 could also have been produced by small myctophids with spheroidal swimbladders of equivalent size. The diameter of these was 1.5 mm, which is a reasonable swimbladder dimension for some families of small myctophids, especially those invested with lipids (Butler and Pearcy, 1972; Neighbors and Nafpaktitis, 1982).

The gas bubble model also showed a region of very rapid phase change with a comparatively small-amplitude change, resulting from the acoustic resonance of the gas bubbles (Fig. 13). This signature is very similar to the arc-shaped pattern of the rate of change of phase that we have ascribed to orange roughy above (group **a** in the lower panel of Fig. 1). Of course, these two mechanisms are not mutually exclusive and both may be present in our *in situ* data. To further investigate this question, a more sophisticated approach will be needed, such as simultaneous measurements of complex target strength at multiple frequencies [similar to those made by Kloser *et al.* (2002) using amplitude only], or a sounding system using frequency modulated (chirp) pulsing techniques (Barr, 2001). New modeling techniques such as that of Macaulay (2002) should also help. However, regardless of the mechanism involved, these signatures with rapid phase variation again clearly show the value of the extra dimension provided by the phase component of the complex target strength.

To model resonant targets at shallower depths on the Chatham rise, it was found necessary to use a value of 1.0 kg m^{-1} s^{-1} (10 Poise) for the viscosity of the medium surrounding the gas bladder. This is significantly lower than the value of 500 Poise used by Love (1993) in modeling backscatter from blue whiting and is more similar to a thick oil rather than fish flesh, possibly suggesting that the swimbladder is surrounded by lipids of this viscosity rather than fish flesh as such.

A measurement of the complex target response is useful when estimating fish biomass acoustically. Large gas-filled swimbladders and small resonant bubbles can both exhibit similar amplitude responses leading to an overestimate of the abundance of the large fish when in the presence of smaller resonant targets. However, the clear difference between the phase responses of the two types of target show that it is possible to separate them using complex target plots. It may be that biomass estimates for some species will have to be made at multiple frequencies to avoid this resonant target problem.

This work also implies that fisheries acoustic systems used in this way must be calibrated with respect to phase as well as amplitude, using, for example, the response relative to that of a tungsten carbide calibration sphere. The phase response of all system components must also be considered, for example, both the amplitude and phase response of transducers are now known to change, sometimes significantly, with the depth of immersion in the ocean (Coombs *et al.*, 2003; Kloser, 1996).

All of this work was carried out at 38 kHz and the specific results apply only at that frequency. However, the rate of change of phase is applicable generally to all fish and plankton target strength work at all frequencies.

VI. CONCLUSIONS

The target rate of change of phase adds a valuable new dimension to studies of fish and plankton target strength and to acoustic biomass estimation of fish generally. Our results show that the patterns seen in the target strength-rate of change of phase plots of *in situ* data can be explained in terms of relatively simple models of fish of different sizes and with and without gas-filled swimbladders.

Statistical description of matched field processing ambiguity surfaces

Brian H. Tracey
MIT Lincoln Laboratory, 244 Wood Street, Lexington, Massachusetts 02420

The relationship between array design and ambiguity surface characteristics is not straightforward for matched field processing (MFP). Because MFP makes use of multipath propagation, ambiguities are a function of the environment as well as the array. This paper develops a statistical approach that seeks to provide an analytic link between array design and metrics describing the MFP output. Approximate expressions are derived for the probability distribution of power output across conventional MFP ambiguity surfaces. The validity of the expressions is examined through numerical simulation. This approach can be used as a design tool for comparing the expected performance of different array geometries. © 2005 Acoustical Society of America. [DOI: 10.1121/1.2000750]

I. INTRODUCTION

For plane-wave and range-focused beamforming, the relationship between array geometry and the array response is well understood.[1] Quantities such as array resolution and sidelobe levels can be calculated in a straightforward manner. A set of similar guidelines linking the array geometry to array response does not currently exist for matched field processing (MFP). MFP uses full-field propagation models to account for multipath when constructing steering vectors for beamforming.[2] A major difficulty in deriving guidelines is that the array response depends on the environment for MFP. Thus array design for MFP is often studied through numerical simulations. While these studies can be of significant value, analytic tools for array design are also desirable.

Since MFP seeks to exploit multipath, an ideal receive array would provide orthogonal sampling of the propagating normal modes. For a vertical line array (VLA), this means that the array should span as much of the water column as possible, with depth sampling sufficient for sampling the highest trapped mode.[3,4] Horizontal line arrays (HLAs) rely on mode orthogonality in the range dimension to separate the propagating modes, leading to requirements on array length.[5,6] The mode correlation matrix (MCM), which describes cross-talk between modes, provides a useful way to characterize an array's ability to resolve multipath. HLA and VLA geometries can be directly compared using metrics that describe the extent to which the MCM is diagonally dominant.[7,8]

MFP ambiguity surfaces are characterized by a complicated set of local maxima and minima that shift with source location and environmental parameters. As a result, they have often been described by statistical measures such as peak-to-average sidelobe ratio and deflection index.[9] The approach taken in several previous studies of MFP array design[7,8] is to simulate MFP output for different arrays, calculate statistics describing the ambiguity surfaces, and correlate these statistical measures with metrics describing the diagonality of the mode correlation matrix. In contrast, the work below seeks to develop an *analytic* link between mode resolution and a statistical description of the MFP ambiguity surface. The analytic approach can help give additional insight into the array design problem. The results below show how ambiguity surface statistics depend on the mode shapes and attenuations across the ranges and depth searched, in addition to the mode correlation matrix.

The first two sections below show the MFP ambiguity structure for several example arrays and present an expression relating the conventional MFP (CMFP) output to the mode correlation matrix. The following sections derive the predicted sidelobe distribution for narrow-band and broadband CMFP. Monte Carlo simulations are then used to explore the accuracy of the predictions as a function of array geometry. Criteria are developed to identify when good quantitative agreement can be expected. Examples below also suggest that the analytic approach can provide better qualitative ranking of array performance than commonly used metrics such as MCM diagonality.

II. DEPENDENCE ON ARRAY GEOMETRY

As motivation, the effects of array geometry on MFP are examined for a representative shallow water environment. Simulations were generated based on environmental data gathered for the Santa Barbara channel experiment (SBCX).[10] This environment consists of a 209-m-deep water column with a downward refracting sound speed profile, as shown in Fig. 1. The seabed in the SBCX site was described as a series of sediment layers, with properties given in Table I. The KRAKEN normal mode model[11] was used for the simulations, with the environment assumed to be range independent.

Simulations were carried out for four array geometries. Properties of the arrays are listed in Table II. The first array geometry was a vertical line array (VLA) spanning 80% of the water column. This array span is similar to those actually used during the SBCX data collection. A second VLA was modeled that spanned only 40% of the water column. Two
FIG. 1. Sound speed profile used for simulations, taken from SBCX measurements.

TABLE II. Parameters for arrays used in simulations. For vertical arrays, "depth" refers to the bottommost hydrophone in the array.

Type	No. of sensors	Spacing (m)	Length (m)	Depth (m)
80% VLA	50	3.4	166.6	208
40% VLA	50	1.7	83.3	208
1 km HLA	201	5	500	100
500 m HLA	101	5	1000	100

horizontal line arrays (HLAs), of 1 km and 500 m length respectively, were modeled. Both HLAs were oriented at endfire to the source, as multipath resolution and MFP performance are best for HLAs at this orientation. Narrow-band simulations were done for a frequency of 120 Hz. This frequency is in the range of projected tones used in SBCX and other MFP experiments.

Conventional, or Bartlett, MFP surfaces were generated to demonstrate the localization possible with each array. No environmental mismatch was introduced. The signal was normalized so that the peak of the ambiguity surface equaled one. The conventional MFP output power is given by

$$b(\Theta) = \left| \frac{\mathbf{p}_{\text{look}}^H(\Theta)}{|\mathbf{p}_{\text{look}}(\Theta)|} \cdot \frac{\mathbf{x}(\Theta_S)}{|\mathbf{x}(\Theta_S)|} \right|^2, \quad (1)$$

where $\Theta = (r, z, \theta)$ is the MFP steering direction in three dimensions, Θ_S is the source location, $\mathbf{x}$ is the data, and $\mathbf{p}_{\text{look}}$ is the predicted pressure field on the array. The vector $\mathbf{p}_{\text{look}}$ and its normalization are kept separate, rather than being combined into a replica vector $\mathbf{v}$, for use in calculations below. In the absence of mismatch, the data vector $\mathbf{x}$ is a scaled version of the replica vector at the source location.

Simulated CMFP surfaces are shown in Fig. 2. The simulated noise source was located at 70-m depth and at 10-km range from the center of the receiver array. The 80% spanning VLA provides a good localization of the source. Significant ambiguities exist for the other arrays.

While the two HLAs clearly have high sidelobes, two points are worth noting. First, the horizontal aperture provides azimuthal discrimination that is not available with the VLAs. If only a single source is present along each bearing, it may be possible to track the MFP output over time to

TABLE I. Parameters for geoacoustic model of SBCX test site: z=depth from surface; c_c=compressional sound speed; ρ=density; α_c =compressional wave attenuation.

z (m)	c_c (m/s)	ρ (g/cm^3)	α_c (dB/λ)
209	1607	1.95	0.37
309	1702	1.95	0.37
309	1862	1.98	0.035
609	2374	1.98	0.035
609	2374	2.03	0.04

localize the source even though an instantaneous MFP output is highly ambiguous. Adaptive beamforming and broadband processing can also help to reduce ambiguities.

The HLA simulations also show that sidelobe levels are lower near the surface than at depth. This results from a combination of two effects. First, the HLAs can better resolve the high-angle modes associated with surface sources, as these arrive at conical angles closer to broadside. Second, the downward-refracting sound speed profile traps the lowest-order modes at depth.

III. MODE CORRELATION MATRIX AND MFP OUTPUT

In this section the mode correlation matrix is defined and its link to the output of a Bartlett processor is shown. The acoustic source is assumed to be in the far field of an array of L sensors. The range r_i between each sensor and the source is given by

$$r_i = r_s + \Delta_i, \quad (2)$$

where r_s is the range from the source to the center of the array and Δ_i is the range increment to each sensor. For a perfectly straight VLA, $\Delta_i = 0$ for all sensors. For a uniform straight HLA, $\Delta_i(\theta) = (x_i - x_{\text{ref}})\cos \theta$, where x is distance along the array and θ is bearing to the source. Using a normal mode description of the sound field, the pressure received on sensor i is given by

$$p(r_i, z_i, \theta) = \frac{i\sqrt{2\pi} e^{-i\pi/4}}{\sqrt{r_s}} \sum_n \frac{\psi_n(z_s)\psi_n(z_i)}{\sqrt{k_n}} e^{ik_n[r_s + \Delta_i(\theta)]}, \quad (3)$$

where ψ_n is the mode shape for mode n, k_n is the horizontal wave number for the mode, and z_s and z_i are the source depth and ith receiver depth, respectively. For matched field processing, replica vectors describing the response of the array to every possible source location are generated. Assuming that no mismatch exists, the replicas may be generated by using Eq. (3), evaluated for all look directions (r, z, θ).

For the far-field case, complex modal correlation matrices can be defined that include the range differences between elements, but not the absolute range:

$$e_{nm} = \sum_{i=1}^{L} \psi_n(z_i)\psi_m(z_i) e^{i(k_n\Delta_i(\theta_s) - k_m^*\Delta_i(\theta))}. \quad (4)$$

Since the modes are orthogonal, the mode correlation matrix will be diagonal for a fully spanning VLA.

This definition can be used to rewrite the CMFP output power given by Eq. (1). First, Eq. (3) is used to express the data vector $\mathbf{x}$, neglecting mismatch [mismatch can be in-

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Brian H. Tracey: Statistics of matched field ambiguity surfaces   1373
FIG. 2. Simulated CMFP ambiguity surfaces in the SBCX environment for the arrays considered. A 120-Hz source is located at 10-km range and 70-m depth, oriented at endfire to the horizontal arrays. Although HLAs have much higher sidelobes, they also have an ability to separate sources based on bearing that VLAs do not.

cluded by perturbing the modal horizontal wavenumbers in Eq. (3)]. All terms involving the array geometry are combined using the mode correlation in Eq. (4). The remaining terms may be grouped together, giving the output as

$$b(\Theta) = \left| \sum_{n,m} Y_{nm} e_{nm} \right|^2, \quad (5)$$

where Y_{nm} contains all information about the source location and look direction:

$$Y_{nm} = \frac{2\pi}{\sqrt{k_n k_m}} \frac{\psi_n(z_s)\psi_m(z)e^{i(k_n r_s - k_m^* r)}}{|\mathbf{p}_{\text{look}}(\Theta)||\mathbf{x}(\Theta_S)|}. \quad (6)$$

The conjugates on mode eigenvalues ensure that attenuation is handled correctly.

Before proceeding, it is helpful to study the mode correlation matrix in more detail. Figure 3 shows mode correlation matrices for the arrays defined in Sec. II. The plots are normalized so diagonal elements are equal to one. Modes 15 and higher have high loss and do not contribute to the acoustic field at long range. As expected, the 80% spanning VLA provides excellent resolution of the modal arrivals, while increased cross-talk is seen for the 40% VLA and the two HLAs.

A basic difference in the mode correlation patterns for vertical and horizontal arrays is seen in Fig. 3. For VLAs, the cross-talk between modes remains roughly similar as mode number increases, while for HLAs cross-talk decreases with mode order. The improved resolution of HLAs for higher modes results because higher modes impinge on the array at steeper vertical angles. These modes therefore arrive at coni-

cal angles that are closer to broadside, where the array resolution is better, and can be more easily separated.

While Fig. 3 shows results for endfire, Eq. (4) applies for any bearing angle. As the look direction bearing and source bearing diverge, the values of all components in the mode correlation matrix will drop. This reflects the filtering of source energy introduced by the conventional beampattern of the mode filter. Thus Eq. (4) and the results in the following sections can be used to determine the output power statistics as a function of the azimuthal difference from the source.

IV. NARROW-BAND CMFP STATISTICS

Equation (5) above expressed CMFP output power in terms of cross-modal correlations. That relationship is used here to derive approximate analytical results for the probability distribution of matched-field sidelobes. A statistical approach is based on the following assumptions.

(i)   Statistics for the MFP surface are assembled by randomly sampling different MFP cells or "look directions." Thus the look direction can be treated as a random variable.

(ii)   The true source location is unknown, so the source depth and range are assumed to be random variables.

The look direction depths are assumed to be distributed with uniform probability over depths $[D_{l1}, D_{l2}]$, while the source depths are distributed over $[D_{s1}, D_{s2}]$. Both source ranges and look direction ranges are assumed to be uniformly distributed over the full MFP search space, from R to $R+\Delta R$.
FIG. 3. Far-field mode correlation matrices for the arrays considered. Note the difference in structure between horizontal and vertical arrays.

Given the assumptions above, the terms Y_{nm} from Eq. (5) are zero-mean complex random variables (note that the mode correlation terms e_{nm}, which depend on array geometry, are considered deterministic). A further assumption is made that the random terms Y_{nm} are Gaussian distributed. Because many such terms are summed, inaccuracies in this assumption are reduced by the central limit theorem. The Y_{nm} are zero-mean, so only their variance needs to be calculated. The variance of the real part of Y_{nm} is found as (see the Appendix)

$$\sigma_{nm}^2 = \frac{2\pi^2}{k_n k_m} \int \frac{\psi_m^2(z)\psi_n^2(z_s)}{|\mathbf{p}_{\text{look}}(\Theta)|^2 |\mathbf{x}(\Theta_S)|^2} \times e^{-2\alpha_n r_s} e^{-2\alpha_m r} p_{\mathbf{r}}(\mathbf{r}) \, d\mathbf{r}, \tag{7}$$

where $\mathbf{r}$ represents the independent random variables r_s, z_s, r, and z. A further assumption is required to represent the normalizing terms $|\mathbf{p}_{\text{look}}|^2$ and $|\mathbf{x}|^2$. For an array that resolves the modes well, off-diagonals will not contribute strongly to the intensity, and the norm-squared can be approximated by

$$|\mathbf{p}(\Theta)|^2 \approx \sum_{l=1}^{N_p} \frac{2\pi}{k_l} \psi_l^2(z) e_{ll} e^{-2\alpha_l r_{\text{mid}}}, \tag{8}$$

where N_p is the number of trapped (or proper) modes and r_{mid} is the mid-range of the MFP search region whose statistics are being calculated. This approximate normalization is discussed in more detail in the Appendix.

Numerical results below indicate that the assumption of a Gaussian distribution is reasonable. The approximation made in Eq. (8) appears to be a cause of inaccuracy for

arrays with limited vertical aperture. Unfortunately, a more accurate (but analytically tractable) approximation has not been identified.

The Appendix shows that the assumptions above result in the following expression:

$$\sigma_{mn}^2 \approx \frac{4\pi^2}{2k_n k_m} Z_m(D_{l1}, D_{l2}) Z_n(D_{s1}, D_{s2}) \times R_m(R, \Delta R) R_n(R, \Delta R), \tag{9}$$

where Z_m and R_m account for depth and range integrations. The range integral R_m accounts for mode attenuation over the range of the ambiguity surface:

$$R_m(R, \Delta R) = \frac{e^{-2\alpha_m R}}{2\alpha_m \Delta R} [e^{-2\alpha_m \Delta R} - 1], \tag{10}$$

while the depth integrals are given by

$$Z_m(D_1, D_2) = \int_{D_1}^{D_2} \frac{\psi_m^2(z) \, dz}{\Delta D \sum_{l=1}^{N_p} (2\pi/k_l) \psi_l^2(z) e_{ll} e^{-2\alpha_l r_{\text{mid}}}}, \tag{11}$$

where D_1 and D_2 are the lower and upper depths of integration, and $\Delta D = D_2 - D_1$. Separate integrals over depth are required for the source and replicas, as the region of possible source depths can be different than the MFP search region.

Equation (9) gives the variance for the real part of a single Y_{nm} term from Eq. (5). These terms are multiplied by e_{nm} and summed to give another complex zero-mean Gaussian random variable, denoted Y. The variances of the real and imaginary parts of Y are equal and are given by

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Brian H. Tracey: Statistics of matched field ambiguity surfaces   1375

$$\sigma_Y^2 = \sum_{n,m} \sigma_{nm}^2 |e_{nm}|^2. \tag{12}$$

Finally, the absolute value-squared is taken as shown in Eq. (5), yielding an exponential probability distribution:

$$P_{NB}(b) = \frac{1}{\mu} e^{-b/\mu}, \tag{13}$$

where

$$\mu = 2 \sum_{n,m} \sigma_{nm}^2 |e_{nm}|^2. \tag{14}$$

The interpretation of this result is that the ambiguity surface distribution is controlled by the amount of mode cross-talk, as measured by e_{nm}, weighted by a factor σ_{mn}^2 that captures the mode excitation and attenuation.

Equation (13) is an approximate result and can give non-physical behavior (i.e., nonzero probability of $b > 1$). A metric that describes its range of validity is therefore required. One useful approach is to require that the probability of non-physical behavior is below a threshold; for example $\Pr(b > 1) < 0.01$. This metric is demonstrated in the numerical results below.

Several results can be found directly from Eq. (13). The percentage of the ambiguity surface that has a value higher than some threshold γ is given by

$$\Pr(b > \gamma) = e^{-\gamma/\mu}. \tag{15}$$

For example, the fraction of the surface within 3 dB of the peak is found by setting $\gamma = 0.5$. Finally, the expected value of the exponential distribution is μ. This means that the average peak-to-sidelobe ratio, which has been used as a statistic for describing MFP ambiguity surfaces, is given by μ.

V. STATISTICS FOR INCOHERENT BROADBAND CMFP

When the source being localized has broadband energy, frequency averaging may be used to reduce ambiguities in the output. Frequency averaging is beneficial because the location of MFP ambiguities shifts over frequency while the true source location remains fixed. Thus high ambiguities at one frequency are averaged together with lower output at other frequencies. Linear averaging has been widely applied to MFP:[9,12]

$$I_{BB} = \frac{1}{M} \sum_{i=1}^{M} b(f_i). \tag{16}$$

Other options include averaging cross-frequency components[13] or averaging matched field outputs in decibels rather than in linear power.[14] Only linear averaging is analyzed here.

The results in Sec. IV can be used to find the PDF for broadband CMFP. In doing so, the assumption is made that the frequencies being averaged are spaced widely enough that their sidelobe locations can be treated as uncorrelated. Conditions for this to be true are discussed below. If more closely spaced frequencies are added, little benefit in terms

of sidelobe reduction will result. The PDF for the sum of M uncorrelated ambiguity surfaces is found using moment generating functions:

$$P(b) = \mathcal{L}^{-1} \left(\prod_{n=1}^{M} \mathcal{L}(P_{NB}(b|f_n)) \right), \tag{17}$$

where $\mathcal{L}$ denotes the Laplace transform. Using the transformed narrow-band distribution $\mathcal{L}(e^{-b/\mu}/\mu) = (1/\mu)[1/(s + 1/\mu)]$ along with the definition of the inverse transform, the PDF for the averaged surface is found as

$$P_{BB}(b) = \frac{M}{2\pi i} \int_{\gamma-i\infty}^{\gamma+i\infty} \left(\prod_{n=1}^{M} \frac{1}{\mu_n} \right) \left(\prod_{n=1}^{M} \frac{1}{s + 1/\mu_n} \right) e^{sbM} \, ds, \tag{18}$$

where the factors of M in the leading fraction and the exponent account for the number of frequencies being averaged. The narrow-band terms μ_n will vary with frequency and will be unique. The integral above can then be solved as a contour integration with each frequency giving rise to a simple pole in the complex plane. Summing the residues of these poles gives the final result:

$$P_{BB}(b) = M \left(\prod_{n=1}^{M} \frac{1}{\mu_n} \right) \sum_{n=1}^{M} \left(\prod_{m=1, m\neq n}^{M} \frac{\mu_m \mu_n}{\mu_n - \mu_m} \right) e^{-bM/\mu_m}. \tag{19}$$

Although the narrow-band coefficients μ_n are unique, they often vary slowly with frequency. This can give rise to numerical instabilities. If the μ_n are approximated as constant, the broadband distribution is a central χ^2 distribution with $2M$ degrees of freedom:

$$P_{BB}(b) = \frac{M}{\sigma_Y^{2M} 2^M \Gamma(M)} (bM)^{M-1} e^{-bM/2\sigma_Y^2}, \tag{20}$$

or, in terms of μ,

$$P_{BB}(b) = \frac{M}{\mu^M \Gamma(M)} (bM)^{M-1} e^{-bM/\mu}. \tag{21}$$

The higher-order χ^2 distributions are characterized by a reduced probability of either very large or very small values. Frequency averaging fills in the troughs of the sidelobes in addition to averaging down the peaks. The *average* peak to sidelobe ratio for this form of incoherent averaging is μ, the same as for narrow-band processing, but the shape of the distribution is different.

The derivation above assumes that the sidelobe locations are uncorrelated across frequency. Waveguide invariant arguments can be used to estimate the frequency spacing required for this to be true.[12,15] The migration of CMFP sidelobes with frequency is described by

$$\frac{\delta\omega}{\delta r} = \beta \frac{\omega}{r - R}, \tag{22}$$

where R is the true range to the source and β is the waveguide invariant. β is roughly 1 for many shallow water scenarios. For the CMFP sidelobes to shift by one CMFP range main lobe L_r, a frequency shift of

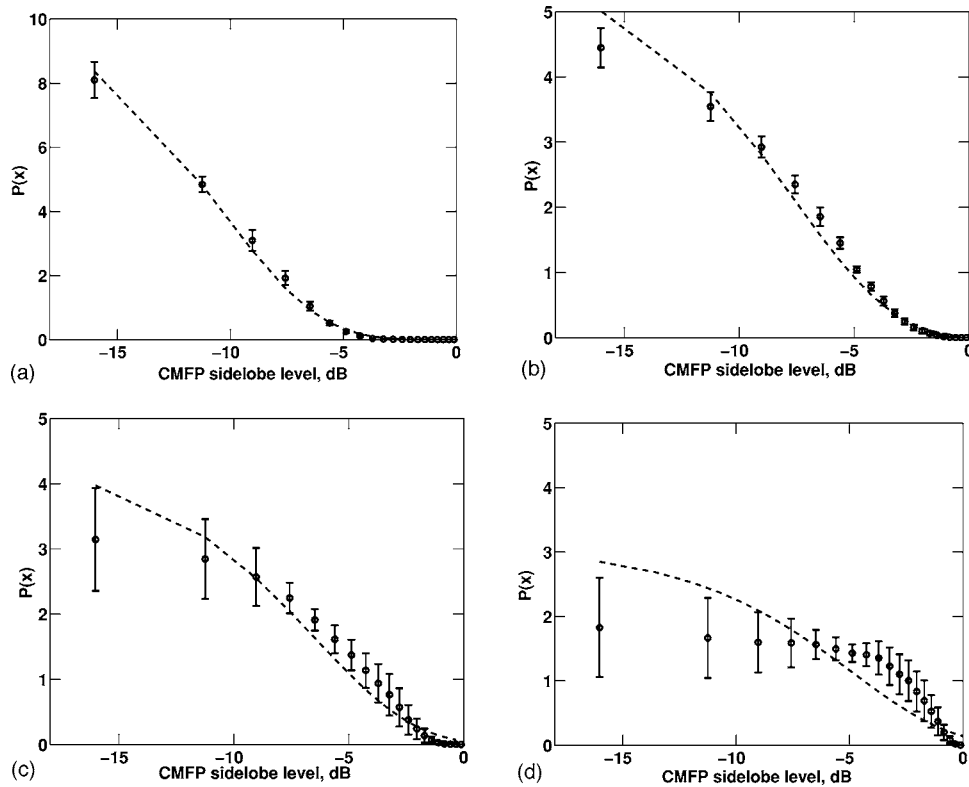
Brian H. Tracey: Statistics of matched field ambiguity surfaces


FIG. 4. Comparison of predicted PDFs (dashed lines) with distributions estimated from Monte Carlo runs. Histograms were generated for individual Monte Carlo runs and used to produce the averaged distribution ± one standard deviation. Agreement is close for the 80% spanning VLA and degrades as effective vertical aperture is reduced.

$$\Delta f \geqslant \frac{fL_r}{r - R} \qquad (23)$$

is required. The main lobe size in range is given by $L_r = 2\pi/(k_1 - k_N)$.[10] Since sidelobes shift faster with increasing distance from the source, frequency averaging reduces MFP levels away from the source more rapidly. Setting $r - R = 1$ km in Eq. (23) suggests, for the scenarios considered below, a frequency spacing of roughly 10 Hz. Adding frequencies at a finer spacing is not expected to help reduce ambiguities in the MFP output.

VI. NUMERICAL RESULTS

Simulations were carried out to test the results above. CMFP power was simulated for an ensemble of random source ranges and depths. The output power from these surfaces was used to generate histograms which were normalized to estimate PDFs. A mean distribution and standard deviations around it were calculated and are compared to the predicted distribution.

Figure 4 shows a comparison of simulated and predicted distributions for narrow-band CMFP. For these cases, the source and look direction depths and ranges were allowed to vary uniformly over the MFP search grid shown in Fig. 2. For the 80% spanning VLA the agreement to the overall shape is quite good. Of the arrays considered, this one best satisfies the assumption used to derive the approximate normalization in Eq. (8).

The match between predictions and simulation degrades for the less capable arrays. As discussed above, one possible

metric for the accuracy of Eq. (13) is the probability of non-physical outputs $[\Pr(b > 1)]$. This probability is calculated to be 1.1e-5 for the 80% spanning VLA, 0.003 for the 40% spanning VLAs, 0.0094 for the 1 km HLA, and 0.046 for the 500 m HLA. Reasonable matches to the analytic model are seen for cases where $\Pr(b > 1) < 0.01$. It is worth noting that the relevant parameter for mode cross-talk is the array length in wavelengths. Thus the agreement for the 500-m array at 240 Hz should be comparable to the agreement seen for the 1-km-long array at 120 Hz.

The simulations in Fig. 2 showed that the HLA apertures could provide some discrimination between surface and submerged depth zones. The ability of the analytic results to predict this is tested by restricting the look directions D_{l1} and D_{l2} in the calculation. A comparison between calculated and simulated results is shown in Fig. 5 for the 1-km-long HLA example. The "surface" depth zone is defined as 0–20 m, with the "submerged" zone defined as the rest of the water column. The analytic prediction is successful in predicting the surface/submerged trends in output power distribution.

Simulations are next used to examine the output distribution for incoherent broadband MFP. The analysis above showed that a simplification is possible if the narrow-band variances are fairly flat with frequency. These variances were examined and found to vary by less than 10% over the frequency range considered. cases considered. Thus Eq. (21), which assumes constant variance with frequency, was used for the calculation.

Figure 6 shows a comparison of the predicted and simulated distributions for incoherent broadband MFP. The calcu-
FIG. 5. Predicted PDF for depth zones [1–20 m] and [20–209 m] compared to Monte Carlo results, 1 km HLA. Predictions are shown with lines, while Monte Carlo results are shown with error bars. Near-surface zone results are shown as dashed lines, while submerged zone results are solid. Note improved agreement between the model and Monte Carlo for the near-surface zone due to improved sampling of the high-order modes.

FIG. 6. Comparison of predicted PDFs for incoherent broadband averaging with distribution estimated from Monte Carlo runs. Predictions are shown with dashed lines, while Monte Carlo results are shown with error bars.
FIG. 7. Average sidelobe level (μ parameter) for narrow-band CMFP versus frequency and array geometry. The improved resolution and increased number of modes at high frequencies act to reduce average sidelobe levels. For HLAs, the sidelobe levels calculated are for the source bearing (endfire) only; lower sidelobes are present on other bearings.

lations were done for the 1-km-long HLA for bandwidths of 20 and 40 Hz. As the bandwidth increases, the distribution becomes more peaked; both high sidelobes and deep nulls in the frequency-averaged output become less likely. It is interesting to note that the agreement between the predicted and simulated distributions is closer than it was in the narrow-band case. This is presumably because variations in the steering vector normalization average out over frequency, making the approximation in Eq. (8) more accurate.

VII. SIDELOBE LEVELS VERSUS APERTURE AND FREQUENCY

The numerical results above have helped to validate the analytic results derived. In this section the analytic results are used to compare performance of several arrays versus frequency. The derived mean sidelobe level μ is also compared to a metric measuring MCM diagonality for use as a predictor of array performance.

Figure 7 shows the average sidelobe ratio calculated for single-frequency CMFP. This ratio is given by the parameter μ from Eq. (13), assuming that source power is normalized to one. The ratio is calculated for a set of tones in the range 64–338 Hz that correspond to projected tones used in SBCX. For HLAs, the results shown are for the endfire beam only. Results are shown for the four arrays discussed above and for two shorter arrays: a 250-m-long HLA (101 phones at 2.5-m spacing) and a 20% spanning bottom-mounted VLA. A trend is seen toward lower sidelobe levels at higher frequencies, where more modes can be coherently summed to reduce ambiguities.

As discussed above, a useful criteria for quantitative accuracy of the predictions is that the probability of nonphysical results be less than some threshold. Discussion following Fig. 4 suggested a criteria of $\Pr(b > 1) < 0.01$, which corresponds to an average sidelobe level of −6.6 dB or less. A less restrictive criteria of $\Pr(b > 1) < 0.05$ would suggest reasonable agreement for arrays with average sidelobe level of −4.76 dB or lower.
FIG. 8. Diagonality coefficient calculated for mode correlation matrices (MCMs); more diagonal is better. This metric roughly tracks the relative performance of the different arrays, but does not account for the different structure of VLA and HLA MCMs.

Previous studies have used metrics describing the diagonality of the mode correlation matrix (MCM) to compare arrays. The importance of the mode correlation matrix was discussed above. One problem with using a diagonality metric is that the structure of the MCM is not captured.

The MCM can be described using the following metric, which compares the power in the matrix diagonal to the power in all matrix elements:

$$d = \frac{|\mathrm{diag}(\mathbf{E})|^2}{|\mathbf{E}|_{\mathrm{frob}}^2}, \tag{24}$$

where $\mathbf{E}$ is the MCM and "frob" indicates the Frobenius norm.

Figure 8 shows this metric for the arrays and frequency ranges shown above. This metric gives a ranking which is similar to that seen in Fig. 7, but some noticeable differences exist. The diagonality coefficient shows the 1-km HLA and 40% VLA as being extremely similar, with the 1-km HLA having a slightly more diagonal MCM. Figures 7 and 2 both show the 1-km HLA as having slightly *worse* performance, in spite of its higher diagonality. The explanation is that the MCM metric does not capture the MCM structure for HLAs, which typically have worse resolution for the low-order modes that can dominate submerged source response. In contrast, Eq. (13) weights the MCM values by factors that account for mode excitation and attenuation, leading to improved qualitative agreement with direct numerical ranking of array performance.

VIII. SUMMARY

This article has addressed the prediction of sidelobe levels for conventional matched field processing. An approach was developed for analytically predicting the distribution of output power in conventional MFP ambiguity surfaces as a function of array aperture and processing bandwidth. These investigations are intended to provide tools for MFP array design that complement the use of numerical simulations and array design trade studies.

APPENDIX: VARIANCE CALCULATION

In this appendix the variance of the Y_{mn} terms shown in Eq. (8) is calculated. This variance is used to calculate the parameter μ describing the exponential distribution for narrow-band CMFP.

To review, the quantities in the CMFP power output which are randomly varying under the assumptions listed in Sec. IV are collected into the term

$$Y_{nm} = \frac{2\pi}{\sqrt{k_n k_m}} \frac{\psi_n(z_s)\psi_m(z)e^{i(k_n r_s - k_m^* r)}}{|\mathbf{p}_{\mathrm{look}}(\Theta)||\mathbf{x}(\Theta_S)|}. \tag{A1}$$

The exponential terms in the random quantity Y_{nm} can be rewritten as

$$e^{i(k_n r_s - k_m^* r)} = e^{i\phi}e^{-\alpha_m r}e^{-\alpha_n r_s}. \tag{A2}$$

The phase associated with the random source and look direction ranges has been collected into a phase term $e^{i\phi}$. Although this phase actually depends on r and r_s, treating it separately separates out the very rapid fluctuation in phase from the much slower change in attenuation. Y_{nm} is a complex zero-mean random variable. Since the argument to the exponential can range over $0-2\pi$, the real and imaginary parts have equal variance, given by

$$\sigma_{nm}^2 = \frac{4\pi^2}{k_n k_m} \int \frac{\psi_m^2(z)\psi_n^2(z_s)}{|\mathbf{p}_{\mathrm{look}}(\Theta)|^2 |\mathbf{x}(\Theta_S)|^2}$$
$$\times \cos^2[\phi(r)]e^{-2\alpha_n r_s}e^{-2\alpha_m r}p_{\mathbf{r}}(\mathbf{r})\,d\mathbf{r} \tag{A3}$$

with $\mathbf{r}$ representing the independent random variables r_s, z_s, r, z, and ϕ, and $p_{\mathbf{r}}(\mathbf{r})$ representing their probability density function. The $\cos^2[\phi(r)]$ term comes from the real part of the complex exponential. A similar equation containing a $\sin^2[\phi(r)]$ term is obtained for the variance of the imaginary part. These terms both average to $\frac{1}{2}$, giving the result quoted in Sec. IV.

The normalization of the pressure fields is required next. For an array that resolves the modes well, off-diagonals will not contribute strongly to the intensity, and the norm-squared for the look direction vector is

$$|\mathbf{p}(\Theta)|^2 \approx \sum_l \frac{2\pi}{k_l}\psi_l^2(z)e_{ll}e^{-2\alpha_l r}. \tag{A4}$$

Attenuation acts to eliminate contributions from high angle modes, so almost all the contribution at longer ranges is from the trapped or "proper" modes. This allows a further simplification:

$$|\mathbf{p}(r,z)|^2 \approx \sum_{l=1}^{N_p} \frac{2\pi}{k_l} \psi_l^2(z) e_{ll} e^{-2\alpha_l r_{\text{mid}}}, \qquad (A5)$$

where r_{mid} is the mid-range of the MFP search region whose statistics are being studied. Numerical tests indicated that this further simplification did not introduce errors for the cases studied.

Next, the approximation in Eq. (A5) is substituted into Eq. (A4). Because the source location and look directions are independent random variables, integration over these variables can be done separately:

$$\sigma_{nm}^2 = \frac{4\pi^2}{k_n k_m} \left[\frac{1}{\Delta_{Dl}} \int_{D_{l1}}^{D_{l2}} dz \frac{\psi_m^2(z)}{\sum_{l=1}^{N_p} (a/k_l) \psi_l^2(z) e_{ll} e^{-2\alpha_l r_{\text{mid}}}} \right]$$

$$\times \left[\frac{1}{\Delta_{Ds}} \int_{D_{s1}}^{D_{s2}} dz_s \frac{\psi_n^2(z_s)}{\sum_{p=1}^{N_p} (a/k_p) \psi_p^2(z_s) e_{pp} e^{-2\alpha_p r_{\text{mid}}}} \right]$$

$$\times \left[\frac{1}{\Delta R} \int_{R}^{R+\Delta R} dr\, e^{-2\alpha_m r} \right]$$

$$\times \left[\frac{1}{\Delta R} \int_{R}^{R+\Delta R} dr_s\, e^{-2\alpha_n r_s} \right]. \qquad (A6)$$

The first two terms in brackets are the Z_m terms from Sec. IV, while the two range integrals can be evaluated to give the R_m terms. The equation above then gives the result quoted in Eq. (10).

Experimental demonstration of adaptive reverberation nulling using time reversal

H. C. Song, W. S. Hodgkiss, W. A. Kuperman, P. Roux, and T. Akal[a]
Marine Physical Laboratory, Scripps Institution of Oceanography, La Jolla, California 92093-0238

The concept of environmentally adaptive reverberation nulling using a time reversal mirror (TRM) recently has been described [Song *et al.*, J. Acoust. Soc. Am. **116**, 762–768 (2004)]. In this paper, monostatic reverberation nulling is demonstrated experimentally at 850 and 3500 Hz using data from a shallow water experiment conducted off the west coast of Italy in April 2003. The active transmission of a seafloor spatial null from a vertical source array is shown to result in the attenuation by 3–5 dB of prominent reverberation features with their levels being reduced to that of the more diffuse reverberation background. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1984990]

I. INTRODUCTION

Bottom reverberation severely limits the detection of low-speed targets by active sonar systems in a shallow water environment.[1] As a consequence of waveguide propagation, some regions of the seafloor are strongly ensonifed, resulting in high levels of backscatter observed at specific times by the receiver even if the seafloor is relatively flat over the region of interest. It would be desirable to avoid ensonifying the seafloor while at the same time maintaining coverage of the water column for target detection purposes.

Recently, a series of ocean acoustic experiments has been carried out confirming the robustness and potential utility of time reversal mirrors (TRM) in underwater acoustics.[2–4] The focusing capability of a TRM without *a priori* knowledge of the environment suggests two different approaches for active target detection in reverberation-limited environments. First, a TRM can focus acoustic energy on a target while shadowing the boundaries below and above the focus in a waveguide, thereby reducing reverberation. The resulting echo-to-reverberation enhancement has been demonstrated experimentally in shallow water using a TRM in the 3–4-kHz band.[5]

The other approach to enhance active target detection is reverberation nulling recognizing that focusing and nulling are complementary. Lingevitch *et al.*[6] recently have shown in simulation that backscattering from the rough water-bottom interface can serve as a surrogate probe source in time reversal. The concept is based on the fact that a time-gated portion of reverberation provides an estimate of the transfer function vector between a TRM array and the range cell along the bottom. The transfer function vector then could be used to refocus energy to the corresponding bottom interface. On the other hand, the idea behind reverberation nulling is to mini-

mize the acoustic energy incident on the boundary in a specific range cell while more energy is projected into the water column possibly illuminating targets. To achieve this, a weight vector which is in a complementary subspace orthogonal to the focusing vector is applied on the TRM prior to retransmission. A theoretical study of reverberation nulling is described in Ref. 7 along with numerical simulations.

As a companion to Ref. 7, this paper presents results of reverberation nulling from an April 2003 TRM experiment conducted in shallow water off the west coast of Italy. We are not aware of other mid-frequency, adaptive reverberation nulling approaches and related experimental results published in the literature. Section II briefly reviews the concept of reverberation nulling. Section III presents experimental results at 850 and 3500 Hz. Conclusions then follow in Sec. IV.

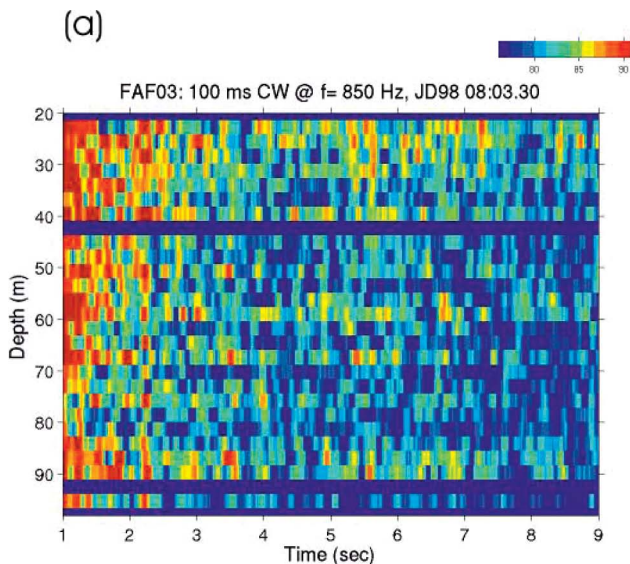
II. REVERBERATION NULLING: DESCRIPTION

The theory of reverberation nulling is described in detail in Ref. 7. In this section, we briefly overview the procedure for reverberation nulling. It is assumed that roughness at the water/bottom interface is the dominant backscattering mechanism and we confine our interest to narrow-band signals. It also is assumed that both the environment and bottom roughness are axisymmetric.

The fundamental idea behind reverberation focusing/nulling is based on the fact that a time-windowed segment of reverberation provides an estimate of the transfer function vector $\mathbf{h}(f)$ between a TRM array and the corresponding range cell along the bottom.[6] The reverberation then can be treated as a single (extended) source problem in array processing. This suggests that a single snapshot would permit obtaining an estimate of the transfer function vector when

---

[a] T. Akal was with NATO Undersea Research Centre, 19138 La Spezia, Italy.
FIG. 1. The FAF-03 experiment took place north of Elba Island, Italy. The monostatic reverberation portion of the experiment involving the SRA only was conducted in two different areas at two different frequencies: 850 and 3500 Hz. For 850 Hz, the SRA was moored about 6 nautical miles north of Elba in a relatively flat area of water depth 117 m (upper part). For 3500 Hz, the SRA was positioned closer to Elba (about 2 miles north) in water depth of 105 m having a shoaling bathymetry towards Elba (lower part with circles).

there is a strong reverberation return, i.e., the high reverberation-to-noise and/or reverberation-to-echo case. In fact, we will use a single snapshot to demonstrate reverberation nulling in Sec. III.


Typically, a single transducer does not have sufficient source level to induce significant backscattering so that simultaneous excitation (i.e., a beam) with maximum power is desirable. For instance, a broadside transmission refers to an excitation with equal amplitudes across the array element. Although one can use arbitrary beams, in practice it will be difficult to excite high-angle beams efficiently (which corresponds to the higher order modes) since this requires both a dense sampling and long aperture of the TRM array. Usually multiple snapshots $\mathbf{h}_i$ are collected from either different beams or repeated use of the same beam in order to construct a data covariance matrix $\mathbf{R} = \Sigma \mathbf{h}_i \mathbf{h}_i^{\dagger}$ where $\dagger$ denotes a conjugate transpose (Hermitian) operation.

Since focusing and nulling are complementary problems, the success of nulling depends on obtaining a transfer (focusing) vector. This can be done by selecting a time window as described in Ref. 7 which suggests a time window less than twice the signal pulse length. The time-gated reverberation then can reduce to a single source problem such that the effective rank of $\mathbf{R}$ is equal to 1. The complex conjugate of the first eigenvector spanning the signal subspace is used as a new excitation weight vector on the TRM for retransmission to focus the energy onto the range cell, i.e., $\mathbf{w}_{focus} = \mathbf{v}_1^{*}.$[7]

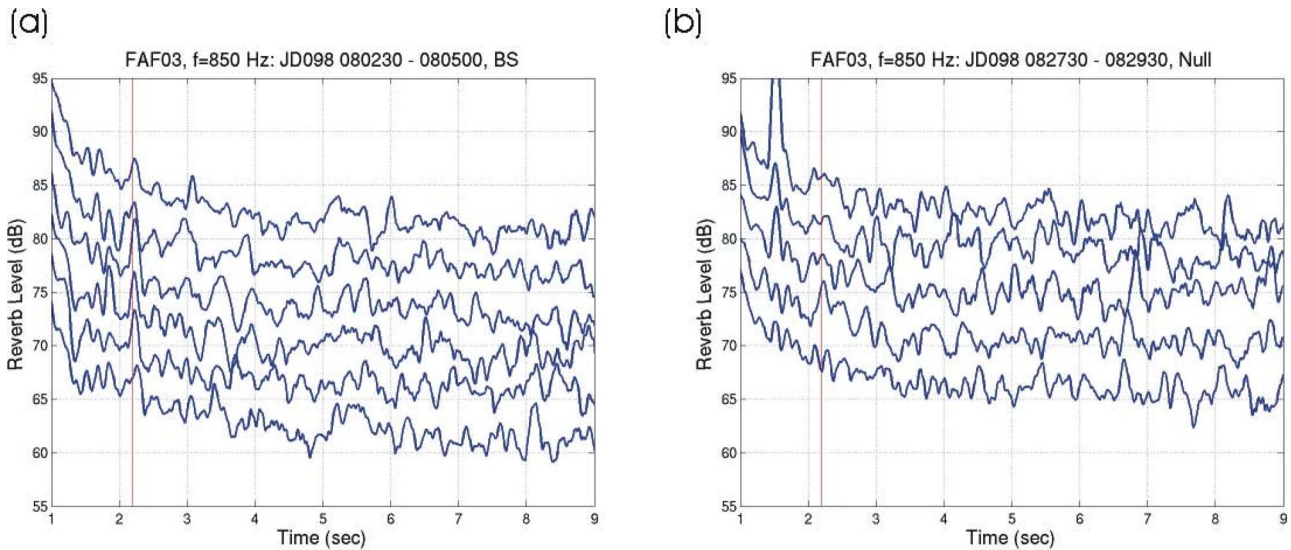
Once a focusing vector is obtained, nulling can be achieved by choosing an arbitrary vector in the $(N-1)$-dimensional noise subspace orthogonal to the one-dimensional focusing vector where N is the number of elements of the TRM array. The natural question is then how to select a nulling weight vector optimally in the sense that maximum energy is projected into the water column. Unfortunately, we cannot further optimize the nulling vector $\mathbf{w}_{null}$ since no other information is available from the reverberation return except the transfer function between the array and the corresponding range cell.
FIG. 2. (a) Monostatic reverberation return from an 850-Hz, 100-ms broadside transmission from the SRA. Four transducers (channels 1, 3, 21, and 29 numbered from the bottom) were not operating. (b) Reverberation time series obtained by incoherent averaging the active 25 channels. The reverberation is strong initially and decreases in about 7 s to the ambient noise level. Note the two strong reverberation returns at 2.2 s and 3.5 s.


FIG. 3. Ping-to-ping variability of reverberation returns from an 850-Hz, 100-ms transmission over several consecutive pings spaced every 30 s. For convenience, adjacent pings are displaced relative to one another by 4 dB and the upper curve represents the absolute level. (a) Broadside transmission and (b) reverberation nulling.

III. REVERBERATION NULLING: EXPERIMENT

A. Reverberation experiment

A time-reversal experiment was carried out in April 2003, north of Elba Island off the west coast of Italy (Fig. 1). The monostatic reverberation portion of the experiment involving the source-receiver array (SRA) was conducted at two different sites using two different frequencies, 850 and 3500 Hz, respectively. Figure 1 (upper part) shows the SRA located about 6 nautical miles north of Elba in a relatively flat area of water depth 117 m for the 850-Hz transmissions. For the 3500-Hz transmissions, the SRA was positioned closer to Elba (about 2 miles north) in water depth of 105 m having a shoaling bathymetry towards Elba as shown in Fig. 1 (lower part with circles). Both 850 and 3500 Hz SRAs had 29 transducers spanning a 78-m aperture with 2.786-m inter-element spacing. The SRAs covered the water column from
FIG. 4. Measurements of the sound speed profile were obtained from CTD casts taken by the *R/V Alliance* on JD98 (8 April) during the 850-Hz reverberation experiment. The SRA covered the water column from 20 to 98 m.

20 to 98 m. The vector time series transmitted by the SRA is normalized such that the maximum value across all elements and time is equal to the maximum source level of 182 and 178 dB *re* 1 μPa at 850 and 3500 Hz, respectively. A detailed description of the TRM hardware and 3500-Hz transducers can be found in Ref. 8. The SRAs were moored for stable operations on 8 April (JD98) for 850 Hz and 13 April (JD103) for 3500 Hz.

B. Reverberation nulling

The nulling experiments were conducted as follows.

(1) Transmit a 100-ms CW broadside transmission (BT) from the SRA at either 850 or 3500 Hz and record the returning reverberation time series.
(2) Select a time window of 100 ms corresponding to the range (or time) of interest and apply a Fourier transform at the center frequency of either 850 or 3500 Hz to obtain an estimate of the array transfer function vector $\mathbf{h}$ from the seafloor to the SRA elements. Thus, $\mathbf{h}^*$ is the focusing vector where * denotes a conjugate operation.
(3) A nulling weight vector $\mathbf{w}_{null}$ is obtained by projecting the broadside beam $\mathbf{e}$ onto the noise subspace such that

$$\mathbf{w}_{null} = [\mathbf{I} - \mathbf{h}^*\mathbf{h}^T/|\mathbf{h}|^2]\mathbf{e}, \qquad (1)$$

where $\mathbf{I}$ is an N-dimensional identity matrix, $\mathbf{e}$ is an N-dimensional column vector with entires equal to 1, and T denotes a transpose operation.
(4) Generate a vector time series from the excitation weight vector $\mathbf{w}_{null}$ (i.e., 100-ms CW with different amplitudes and phases across the array) and broadcast the resulting time series.

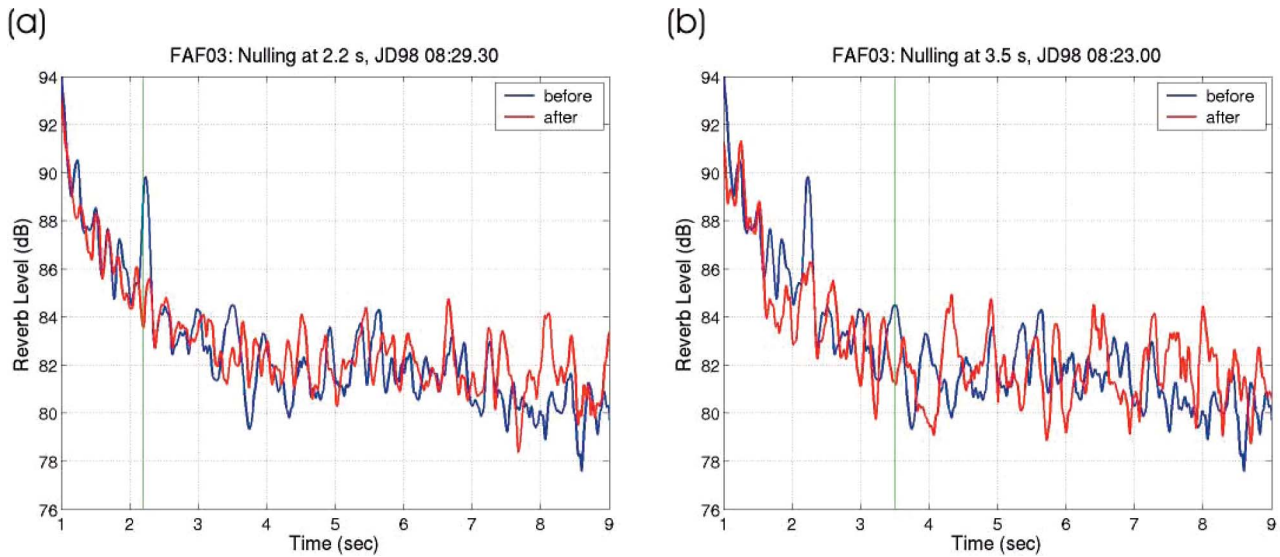
Note that steps 1 and 2 can be repeated by exciting the SRA with different beams or the same broadside beam at multiple times to construct a sample covariance matrix $\hat{\mathbf{R}} = (1/K)\sum \mathbf{h}_i\mathbf{h}_i^\dagger$ where K is the number of snapshots involved.


FIG. 5. Reverberation return resulting from a new excitation weight vector for nulling when applied to range windows at (a) 2.5 s and (b) 3.5 s, respectively. The original reverberation return from a broadside transmission in Fig. 2(b) is superimposed for comparison purposes. While (a) indicates as much as 5-dB reduction in the reverberation level compared to the background level at 2.2 s, (b) shows about 2-dB decrease. Note that suppression at a specific time increases the level at other times.

In our nulling experiment, however, we collected just a few reverberation returns from broadside transmissions and selected a single reverberation return which apparently exhibited a strong level at the range (or time) of interest for processing. In other words, a single snapshot was used to extract an estimate of the transfer function vector from the seafloor when there is a strong reverberation return, i.e., the high reverberation-to-noise case.

Note that there is freedom to choose any of the eigenvectors in the noise subspace or an arbitrary combination of them as described in Sec. II. In our nulling experiment, an additional constraint in step 3 has been imposed such that the nulling weight vector is the projection of the broadside beam onto the subspace spanning the noise eigenvectors. This was done for two reasons. First, one can compare the reverbera-

tion nulling resulting from the new weight vector with the original reverberation return from a broadside transmission. Second, a broadside beam will excite lower order modes efficiently given the aperture of the array and element spacing.

1. f = 850 Hz

Figure 2(a) shows a reverberation return from a 100-ms broadside transmission from the SRA which is selected out of six consecutive pings over the 3-min period in Fig. 3(a). For convenience, adjacent curves are displaced relative to one another by 4 dB and the upper curve represents the absolute level. Note the ping-to-ping variability illustrating the repeatability over the time period. During this measurement, four of the SRA transducers (channels 1, 3, 21, and 29 numbered from the bottom) were not operating properly and were disabled (thick horizontal blue lines) in Fig. 2(a). The reverberation time series displayed in Fig. 2(b) was obtained by incoherent averaging the active 25 channels. The reverberation is strong initially and decreases in about 7 s to the ambient noise level. Figure 4 shows the sound speed profiles collected during the reverberation experiment on 8 April.

For reverberation nulling, we concentrated on the two strong peaks around 2.2 and 3.5 s in Fig. 2(b). Resulting reverberation returns (after) due to a new excitation weight for nulling are shown in Figs. 5(a) and 5(b) when applied to 2.2 and 3.5 s, respectively. The original broadside transmission (before) is superimposed for comparison purposes. While Fig. 5(a) shows as much as 5-dB reduction in the reverberation level compared to the background at 2.2 s, Fig. 5(b) indicates the level at 3.5 s is reduced by about 3 dB. Note that suppression of reverberation at a specific time, however, increases the reverberation level at other times. Figure 3(b) indicates that reverberation nulling is maintained over four out of five pings in the 3-min period.
FIG. 6. Sound speed measurements on 13 April during the 3500-Hz reverberation experiment. The SRA covered the water column from 20 to 98 m. The profile is similar to a deep sound channel with the channel axis around 20 m.

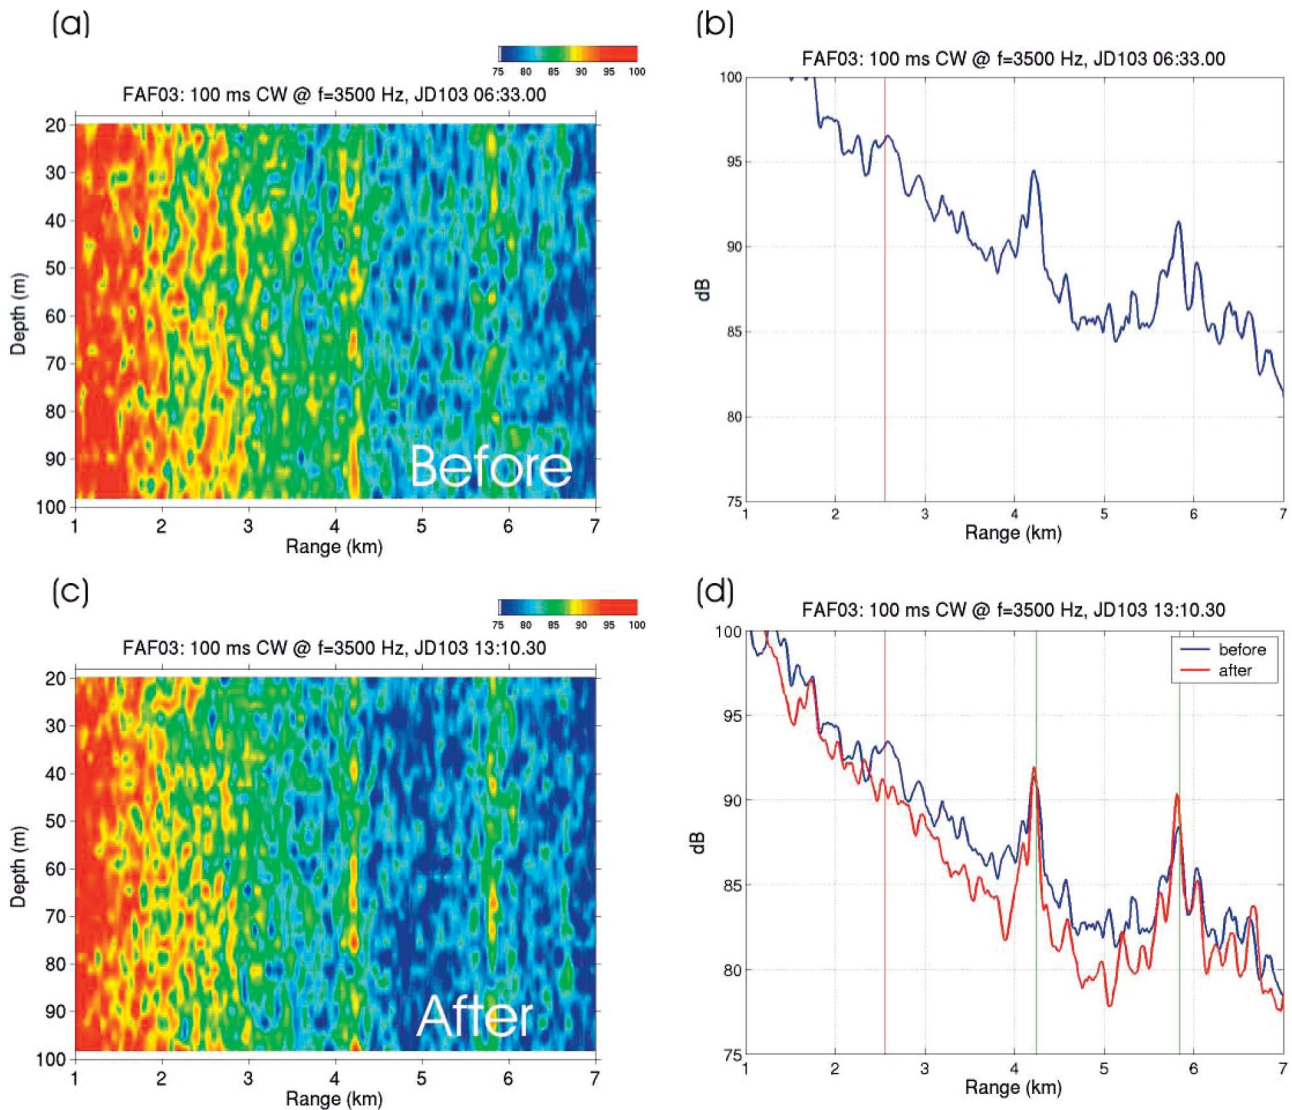
Song *et al.*: Experimental demonstration of reverberation nulling


FIG. 7. (a) Monostatic reverberation return (06:33:00) from a 3500-Hz, 100-ms broadside SRA transmission as a function of range (converted from time). (b) Reverberation level obtained by incoherent averaging across the channels. Due to the proximity of the SRA to Elba, the two prominent peaks around 4.25 and 5.85 km result from the interaction with Elba corresponding to the outer concentric circles denoted in the Fig. 1(b). The peak at 2.5 km, however, is due to a seamount at the corresponding range which is visible in the bottom topography in Fig. 1(b) denoted by a black circle. (c) and (d) Reverberation return after nulling (13:10:30). The reverberation level at 2.5-km range is reduced by about 3 dB to the background level. Note that the reverberation level at 5.8-km range has increased.

It is interesting to observe from Fig. 5 that the reverberation nulling intended for either 2.2 or 3.5 s leads to nulling at both times. This implies that the two peaks are related through the propagation characteristics of the waveguide.

2. f=3500 Hz

At 3500 Hz, the SRA was deployed in 105-m water depth close to Elba Island as shown in Fig. 1 (lower part). Figure 6 shows sound speed profiles collected during this portion of the experiment on 13 April which look similar to a deep sound channel with a channel axis around 20 m. A typical example of the reverberation return from a broadside transmission is shown in Fig. 7 while Fig. 8(a) shows ping-to-ping variability over the 3-min period as in Fig. 3. Figure 7(b) displays the incoherent average of the reverberation level across the SRA. Note that the time axis is replaced by range r using the relationship of $r=2t/c$ with $c=1500$ m/s.

As expected, the reverberation level at 3500 Hz is higher than the level at 850 Hz by about 10 dB at 3 s. Considering the transmitted source level at 3500 Hz which is 4 dB less than that at 850 Hz, the overall reverberation level is approximately 18 dB higher.

Due to the proximity of the SRA to Elba Island, the two prominent peaks around 4.25 and 5.85 km result from the interaction with Elba Island corresponding to the outer concentric circles denoted in Fig. 1. The broad peak at 2.5 km, however, is due to a seamount at the corresponding range which is visible in the bottom topography (black circle) shown in Fig. 1. Thus the peak at 2.5-km range provides a good candidate for reverberation nulling.

The results after implementing reverberation nulling are displayed in Figs. 7(c) and 7(d), indicating reduction of the reverberation level by about 3 dB to the background level at 2.5 km. On the other hand, the reverberation return from the

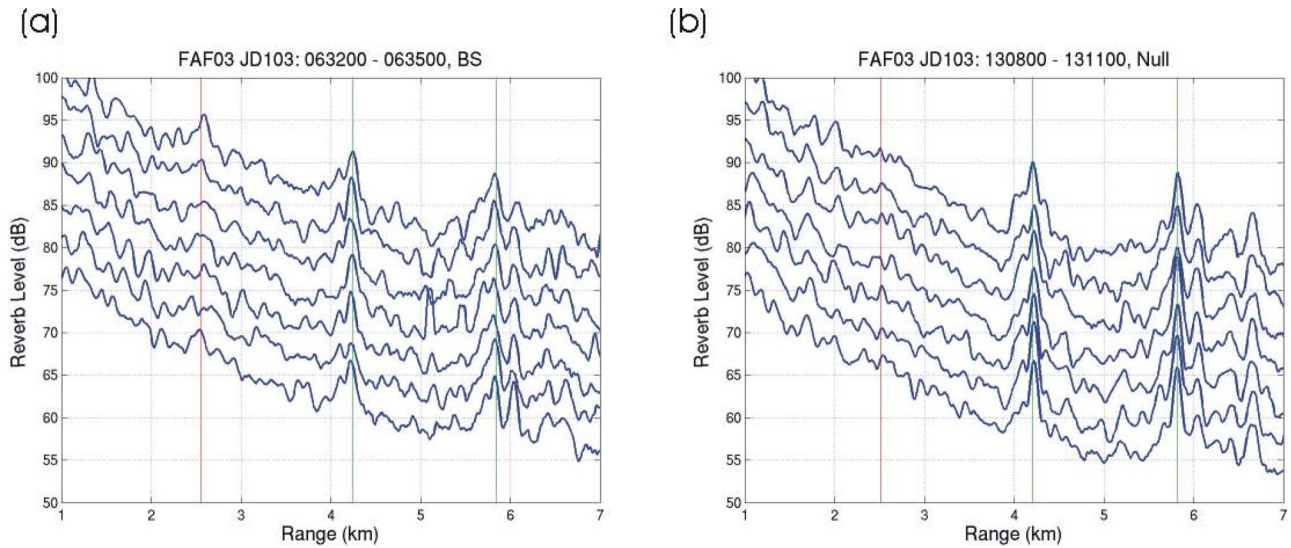
Song *et al.*: Experimental demonstration of reverberation nulling


FIG. 8. Ping-to-ping variability of reverberation returns from a 3500-Hz, 100-ms transmission over several consecutive pings spaced every 30 s. For convenience, adjacent pings are displaced relative to one another by 4 dB and the upper curve represents the absolute level. (a) Broadside transmission and (b) reverberation nulling.

interaction with Elba has increased at 5.8 km range. Figure 8(b) indicates that we can achieve reverberation nulling most of the time over the 3-min period. It should be mentioned that the reverberation level after nulling has been increased by 2.4 dB to facilitate comparison with the original broadside reverberation return. This has been done to accommodate the normalization described in Sec. III A where the normalized amplitudes for all of the elements are equal to 1 for a broadside transmission whereas only a single element has amplitude equal to 1 for reverberation nulling. Since the nulling experiment shown in Fig. 7(c) and 7(d) was conducted almost 7 h after the capture of the reference broadside reverberation return (06:33:00) in Fig. 7(a), it is interesting to observe a reverberation return from a broadside transmission right after nulling (13:10:30). Figure 9 suggests that the

reverberation structure at 13:28:00 remains unchanged with a consistent sharp peak at 2.5-km range.

IV. CONCLUSIONS

In this paper, the feasibility of reverberation nulling using a time reversal mirror without knowledge of the environment was demonstrated experimentally in shallow waters at two different frequencies. At 850 Hz, the reverberation level was reduced up to 5 dB. At 3500 Hz, the prominent reverberation return from a nearby seamount was reduced approximately 3 dB.

A continuous wave method for ultrasonic characterization of liquid materials

Yves Deblock,[a] Pierre Campistron, and Bertrand Nongaillard

IEMN-DOAE, UMR CNRS 8520, BP 69, Cite Scientifique, 59652, Villeneuve d'Ascq, France

This paper describes a method for measuring the velocity and attenuation of high-frequency sound waves traveling through liquid materials. This method is based on the measurement of the forward scattering parameter (S_{21}) of the acoustic system composed of two transducers and the liquid between them. The acoustic parameters are obtained from the analysis of S_{21} in the time domain. Various experiments using distilled water as the liquid sample have been carried out. They show the influence on the measurement sensitivity of receiver detection bandwidth, liquid thickness, and difference of temperature between the room and the test cell. The method was used for the measurement of the attenuation and velocity of mixtures of alcohol and water. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000771]

I. INTRODUCTION

Ultrasonic liquid characterization generally means sensitive measurement of the acoustic properties, i.e., velocity and attenuation coefficient, as a function of frequency. These properties are often related to viscoelastic mechanisms, which involve relaxation phenomena. Broadband frequency studies are of great use in understanding these phenomena.

Usually, one can distinguish two common ways for characterizing a liquid through purely ultrasonic measurements. The major difference lies in the excitation type of the ultrasonic devices: pulsed or continuous wave signals.

The pulse method, first described by Pellam *et al.*,[1] is often used in the biomedical field. Short bursts of ultrasonic waves travel out into the liquid from one transducer to another. The length of the pulses is sufficiently short to prevent overlapping of the different reflected waves in the system. The amplitude of the received pulse as a function of the distance between the transducers gives the attenuation coefficient of sound in the liquid. The pulse transit time as a function of the distance gives the sound velocity.

Interferometric methods that use continuous wave signals derive from optics and were introduced in the acoustic field by Pierce.[2] Standing waves are set up in the liquid between the transducer and a reflector (or another transducer). The detected signal of the transducer presents a succession of flat maxima and sharp minima as the distance between the transducer and the reflector is increased. The distance between successive minima or maxima is half the wavelength in the liquid, therefore the velocity can be determined. The attenuation is obtained from the decrease in the detected signal with the increase of the distance between the transducer and the reflector.

Many different techniques using the basic methods have been developed (see, for example, the comprehensive review of Breazeale *et al.*[3]). More recently a very powerful pulse

method has been developed by Kushibiki *et al.*:[4] attenuation and velocity of sound waves in liquids are obtained from very precise and well-established experimental procedures in the very- and ultra-high frequency ranges.

A method is proposed in this paper for the measurement of attenuation and velocity using continuous wave (CW) signals. This method uses a similar acoustic system as in Kushibiki's method but the velocity and the attenuation of sound waves are obtained from the measurement of the scattering parameter S_{21} of the acoustic system, using a network analyzer. The acoustic system is composed of the liquid sample inserted between the faces of two rods, having transducers on their opposite face. The advantage of this present method over other published methods lies in the ability to use a narrow bandwidth detection of S_{21} that improves the signal-to-noise ratio and makes the measurement of velocity and attenuation more sensitive.

II. MEASUREMENT PRINCIPLE

Figure 1 shows the acoustic system used to determine the velocity and the attenuation of sound waves in liquids. A transducer unit is composed of a rod having a transducer bonded to one end. It is shown in this section how the velocity and the attenuation are obtained from the measurement of the transfer function of the acoustic system (i.e., the scattering parameter S_{21}) using a vector network analyzer.

Briefly, a vector network analyzer consists of a sweeping signal source, a test set to separate forward and reverse test signals, and a multi-channel high-sensitivity receiver. The S-parameters of a network are obtained by comparing these test signals with a reference signal (amplitude ratio and phase difference). The reference signal is obtained by splitting the output signal.

When one transducer is driven by a continuous wave signal, standing waves are set up in the rods and the liquid. Assuming a one-dimensional model for the propagation of acoustic waves in the transducers, the rods, and the liquid, S_{21} can be written as

---

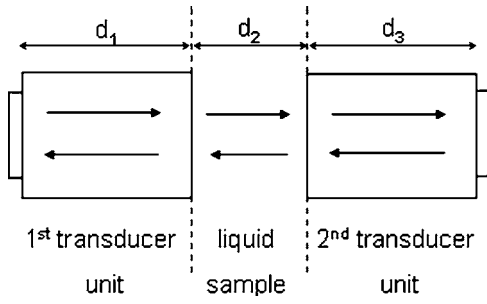
[a]Electronic mail: yves.deblock@iemn.univ-lille1.fr


FIG. 1. The schematic representation of the acoustic system for velocity and absorption coefficient measurements of liquid samples.

$$S_{21}(f) = \sum_{n,p,q} K_{npq} \exp[-\alpha(nd_1 + qd_3) - \alpha_l pd_2]$$

$$\times \exp(-j2\pi f t_{npq}) \tag{1}$$

with

$$t_{npq} = \frac{nd_1 + qd_3}{v} + \frac{pd_2}{v_l}. \tag{2}$$

The subscripts n, p and q are odd integers, corresponding to the number of trips the wave travels in the first rod, the liquid, and the second rod, respectively. v and v_l represent the acoustic velocity in the rod and the liquid, respectively. α and α_l represent the attenuation of waves in the rod and in the liquid, respectively. d_1 and d_3 are the rod lengths of the first and second transducer units. d_2 is the gap distance between the transducer units, that is, the liquid thickness. K_{npq} are coefficients that include electromechanical conversion effects of both transducers and the reflection and transmission coefficients of acoustic waves at the interfaces.

Over a narrow frequency range the coefficients K_{npq} and the absorption coefficients α and α_l can be assumed independent of the frequency compared with the complex exponentials $\exp(-j2\pi f t_{npq})$ of Eq. (1). Consequently the discrete inverse Fourier transform applied to $S_{21}(f)$ gives a series of discrete impulses convolved with the inverse Fourier transform of the rectangle window of measurement and $S_{21}(t)$ can be written as

$$S_{21}(t) = A_{npq} \sum_{n,p,q} \frac{\sin \pi(t - t_{npq})\Delta f}{\pi(t - t_{npq})\Delta f} \exp[j2\pi(t - t_{npq})f_{\text{cent}}] \tag{3}$$

with

$$A_{npq} = \Delta f K_{npq} \exp[-\alpha(nd_1 + qd_3) - \alpha_l pd_2]. \tag{4}$$

Δf is the frequency window over which the inverse Fourier transform is performed and f_{cent} is its center frequency.

$S_{21}(t)$ is a superposition of impulses having the shape of the $(\sin x)/x$ function, of amplitude A_{npq} and located at times t_{npq}. When the impulses are well separated from each other, the phase of $S_{21}(t)$ linearly increases versus time with a slope given by $2\pi f_{\text{cent}}$. Separation of the first impulse is achieved by selecting a frequency range that satisfies
FIG. 2. The experimental arrangement for velocity and attenuation coefficient measurements of liquid samples.

$$\Delta f > \max\left(\frac{v}{2d_1}, \frac{v_l}{2d_2}, \frac{v}{2d_3}\right). \tag{5}$$

On the other hand, Δf must be narrow enough to assume that the K_{npq} are independent of frequency. Δf has been estimated through experiments as

$$\Delta f < \frac{1}{10}W, \tag{6}$$

where W is the transducer bandwidth.

Finally the attenuation and the velocity of sound waves are obtained by measuring the variations of A_{111} and t_{111} of the first impulse of $S_{21}(t)$ as the liquid thickness is changed by Δd_2:

$$\alpha_l = \frac{\Delta A_{111\ \text{dB}}}{\Delta d_2}, \tag{7}$$

with $\Delta A_{111\ \text{dB}} = 20 \log(\Delta A_{111})$ and $\Delta A_{111} = A_{111}(d_2 + \Delta d_2)/A_{111}(d_2)$, and

$$v_l = \frac{\Delta d_2}{\Delta t_{111}} \tag{8}$$

with $\Delta t_{111} = t_{111}(d_2 + \Delta d_2) - t_{111}(d_2)$.

III. MEASUREMENT SYSTEM AND METHOD

Figure 2 shows a schematic drawing and a photograph of the main part of the measurement system. Both ultrasonic units are inserted in the inner cylinder of the cylindrical shaped tanks. The tanks are connected together and temperature regulated by water circulation. A cryostat holds the temperature of water constant in the tanks to within 0.1 °C. As it is shown in Fig. 2, a cavity is formed by the inner cylinder of
FIG. 3. An example of the scattering parameter S_{21} of the acoustic system as a function of frequency.

FIG. 4. The amplitude of the discrete inverse Fourier tranform of the scattering parameter shown in Fig. 3.

the lower tank and by the ultrasonic unit. This cavity constitutes the test cell for the liquid under investigation. The upper tank and its ultrasonic unit are fixed on a motorized z-axis stage of resolution 1 μm, allowing the distance between the transducer units to be set. The lower tank and its ultrasonic unit are fixed on a complex manual positioning stage including two goniometers and two x- and y-axis stages, which allows the parallelism and alignment between the ultrasonic units to be set.

An ultrasonic unit consists of a piezoelectric LiN_bO_3 plate bonded to one end of a SiO_2 rod. The plate thickness corresponds to one half wavelength of the longitudinal wave traveling in the plate at the resonant frequency. The plate diameter and the rod length are related in such a way that the limit between the Fresnel and Fraunhofer zones of the acoustic field in the rod corresponds to the rod length, and so the diffraction effects are minimized in the rod.

Four sets of ultrasonic units have been designed, capable of measurements from 20 to 100 MHz. Electrical matching of all transducers was done using two-reactance matching networks providing better electromechanical conversions. The complete description of the matching procedure has been given elsewhere.[5]

A network/spectrum analyzer (HP 4195A) was used, in the network mode, to measure the scattering parameter S_{21}. The frequency was swept over a span of Δf and 401 samples were measured and sent to a computer for processing. The inverse Fourier transform was calculated with a sampling resolution of 1 ns.

The mechanical positioning system plays a very important role in the measurement accuracy. First of all, alignment and parallelism are roughly adjusted by eye as the transducers are brought closer but without contact. Afterwards, fine adjustment is performed by maximizing the amplitude of the detected signal, using a radio frequency burst as the driving signal of the emitter transducer.

Figure 3 shows typical records of the components of S_{21}. In this experiment, two transducers of 21-MHz center frequency were used. The transducers were bonded to rods having lengths of 10 and 20 mm. The distance between the transducer units was arbitrarily set to 5.6 mm. Measurements
were done over a frequency range of 1.5 MHz, centered around 21 MHz. Figure 4 shows $|S_{21}(t)|$, the amplitude of the inverse Fourier transform of $S_{21}(f)$. Impulses come from multiple reflections of the acoustic waves in the two rods and in the water. They are identified by the times t_{npq} defined by Eq. (2). When the impulses are well separated from each other Eq. (3) predicts that the phase of $S_{21}(t)$ linearly increases versus time with a slope given by $2\pi f_{cent}$, and shifts correspondingly with the successive impulses. This must be checked by subtracting the phase $\phi(t) = 2\pi f_{cent}t$ from the phase of $S_{21}(t)$ and studying whether the resulting phase difference is constant. Figure 5 plots this difference around the first impulse. As expected the phase is roughly constant over the main lobe with shifts of π in the side lobes.

The attenuation and the velocity of sound waves in liquids are obtained by measuring the variations of A_{111} and t_{111} as the gap distance is changed by Δd_2, according to Eqs. (7) and (8). Finding the time corresponding to the absolute maxima of $|S_{21}(t)|$ is imprecise, thus t_{111} is redefined as the nearest time in the neighborhood of the maximum of $|S_{21}(t)|$ for which the phase goes through zero.
FIG. 5. The amplitude and subtracted phase of the discrete inverse Fourier transform of S_{21} observed on a small time range around the first transmitted impulse.

Deblock *et al.*: Method of ultrasonic characterization of liquids

IV. EXPERIMENTS AND DISCUSSIONS

The purpose of this section is to show the reliability of the measurement system. Acoustic properties of distilled water are well known over several experimental conditions and thus it was used as the test liquid.[6,7] Data reported here were not subjected to any mathematical process such as averaging. The various experiments which were performed show the important characteristics of the measurement method. The influence on the measurement accuracy of the bandwidth of the intermediate frequency filter of the network analyzer and the thickness of the liquid sample were studied. Efficiency of the temperature control system was tested.

As an example, the method was applied to the measurement of the acoustic properties of ethyl alcohol and water mixtures.

A. Influence of the bandwidth of the intermediate frequency filter

It is well known that reducing the bandwidth of a receiving system improves the signal-to-noise ratio and makes measurements more sensitive. In the current technique, the bandwidth narrowing effect is illustrated through the measurements of the variations of A_{111} and t_{111} as a function of the water thickness, for different bandwidths (RBW) of the intermediate frequency filter of the network analyzer. Four selectable bandwidths were chosen, ranging from 0.3 to 300 kHz, and experiments were performed at 21 MHz (the central frequency of a set of transducer units) and at a temperature of 18.6 °C. Results obtained using the 300- and 0.3-kHz bandwidths are plotted in Figs. 6(a) and 6(b) and Figs. 7(a) and 7(b), respectively, with the corresponding linear regression fits. A comparison of Fig. 6(a) with Fig. 7(a) clearly shows that narrowing the bandwidth causes a reduction in noise. The standard deviation of the fit decreases from 0.02 to 0.002 dB. However, the standard deviation of the fit is constant of the order of 3 ns irrespective of the selected bandwidth [cf. Figs. 6(b) and 7(b)].

The slopes of the linear regression fits give the absorption and the velocity of sound waves in water. Data of absorption and velocity and the parameters describing the linear regression, for various bandwidths, are summarized in Table I.

The measured absorption and velocity respectively decreases and increases as the detector bandwidth decreases. However, no clear explanation could be found to account for these evolutions. However, it is clear that the measured absorption and velocity using the narrowest detector bandwidth comes very close to the accepted literature values of absorption and velocity at 18.6 °C and 21 MHz, which are 0.1027 dB/mm and 1478 m/s, respectively. The small deviation from the accepted values is due to three factors: the misalignment and nonparallelism between the transducers and the accuracy of the z-stage mechanical displacement.

Great care must be taken in positioning the transducers. Imperfect alignment and parallelism produce different linear fits of the plots $(\Delta A_{111}, \Delta d_2)$ and $(\Delta t_{111}, \Delta d_2)$, providing different values of attenuation and velocity to be determined.
FIG. 6. Variations as a function of the liquid thickness Δd_2 (a) of the amplitude A_{111} of the first impulse and (b) of its transit time. The bandwidth (RBW) of the intermediate frequency filter and the temperature are set to 300 kHz and 18.6 °C, respectively.

B. Influence of the variation of thickness

The thickness variation of the liquid sample is of considerable importance for the accuracy of the measurement method. The larger the thickness, the better the accuracy. This is true as long as the signal-to-noise ratio of the measured parameter S_{21} is good. The attenuation and the velocity of sound waves were measured at various frequencies as a function of liquid thickness and compared with referenced data from Pinkerton[6] and Kroebel,[7] respectively. Relative errors on attenuation and velocity calculated from referenced and measured data are reported in Figs. 8(a) and 8(b), respectively. These measurements were performed using four pairs of transducer units and the 300-Hz bandwidth filter. Errors on both velocity and absorption decrease as the thickness variation increases up to 35 wavelengths. Above this thickness limit the errors become roughly constant to within 0.08% and 2.5%, respectively. Under this limit the error on attenuation decreases versus frequency since the attenuation, and ΔA_{111}, increase versus frequency. These errors are mainly attributed to the displacement accuracy of the z-axis stage.
FIG. 7. Variations as a function of the liquid thickness Δd_2 (a) of the amplitude A_{111} of the first transmitted impulse and (b) of its transit time. The bandwidth (RBW) of the intermediate frequency filter and the temperature are set to 0.3 kHz and 18.6 °C, respectively.

FIG. 8. Relative errors compared with Pinkerton data of absorption (a) and Kroebel data of velocity (b) as a function of liquid thickness normalized to the wavelength. The temperature is set arbitrarily to 23 °C.

C. Influence of the temperature control system

The cavity filled by the liquid sample is open to air in a way that is dependent on the transducer spacing. Thus it is difficult to keep it at a constant temperature, particularly when the temperature is several degrees different from the room temperature, and when the distance between the transducers units is changed. The velocity and the attenuation of sound waves were measured at the arbitrarily frequency of 58 MHz while the temperature of the liquid was changed from 5 °C to 50 °C. The variation of the thickness of the

[a]Standard deviation of the fit.
[b]Correlation coefficient.

liquid sample was set to 10 and 100 wavelengths, with a room temperature of 22 °C. Errors on both attenuation and velocity have been plotted as a function of the temperature difference between the room and the cavity in Figs. 9(a) and 9(b). Over a temperature range of about 30° around the room temperature, the control system is able to keep errors on attenuation and velocity lower than 5% and 0.4%, respectively.

D. Ultrasonic absorption and velocity in mixtures of ethyl alcohol and water

Storey[8] made measurements of absorption on mixtures of ethyl alcohol and water using a pulse mode method. For comparison, the same measurements were made using the current method and in addition velocity was also investigated.

The absorption coefficient and velocity were measured for mixtures with compositions ranging from pure water to 94% alcohol. For comparison with the data of Storey the quantity α/f^2 is plotted as a function of the composition of the liquid in Fig. 10(a). Velocity is plotted in Fig. 10(b).
FIG. 9. Relative errors compared with Pinkerton data of absorption (a) and Kroebel data of velocity (b) as a function of the temperature difference between the liquid sample and the room temperature. The frequency is set arbitrarily to 58 MHz.

As it was found by Storey, the quantity α/f^2 reaches a maximum at a composition between 20% and 30% alcohol. For pure water (0%) and pure alcohol (100%) α/f^2 is independent of frequency. At and around the maximum α/f^2 depends on the frequency.

The additional velocity measurements show that the velocity exhibits a maximum at a different composition between 15% and 20% alcohol. Whatever the composition, the velocity may be considered as frequency independent and only dependent on temperature.

V. CONCLUSION

A method for measuring the velocity and attenuation of sound waves in liquids has been developed. The specificity of this method consists in driving the emitter transducer in a continuous wave mode and using a detector of narrow bandwidth. This enhances the signal-to-noise ratio and makes measurements very sensitive. Various experiments using distilled water have been performed indicating the efficiency of this method. However, the resulting data does not constitute
FIG. 10. Variations as a function of the composition of alcohol and water mixtures, of the absorption (a) and the velocity (b).

intrinsic characteristics of the measurement method capability since they are liquid dependent. Finally some materials were investigated for which absorption was already measured by another method and in addition velocity was measured.

Polydisperse particle size characterization by ultrasonic attenuation spectroscopy for systems of diverse acoustic contrast in the large particle limit

Andreas Richter,[a] Frank Babick, and Siegfried Ripperger
Institut für Verfahrenstechnik und Umwelttechnik, TU Dresden, 01062 Dresden, Germany

Ultrasonic attenuation spectroscopy offers advantages over other spectrometric methods for the determination of suspension and emulsion size distributions. One advantage is the possibility of conducting measurements in highly concentrated or optically opaque dispersions. Models useable for the inversion of measured attenuation spectra to calculate particle size distributions are available and widely used, but their applied forms only allow for the characterization of particles smaller than 10 μm. In this paper, a methodology using the Faran model for elastic scatterers is examined in the region of micrometer-sized particles with respect to its suitability for the prediction of measured attenuation spectra and size distributions of various material combinations. All selected particle fractions and fluid materials were characterized independently from ultrasonic attenuation spectroscopy with respect to their material properties, size distributions, and shape. A comparison of measured and calculated attenuation spectra shows an acceptable agreement. The chosen methodology for particle sizing applications is further confirmed if a fit of the model to the measurement data is performed. In this approach, the solids volume fraction is treated as the only fit parameter. The findings indicate that the methodology is suitable for polydisperse particle size characterization for a wide range of acoustic contrast. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000773]

I. INTRODUCTION

Ultrasonic attenuation spectroscopy can be used to quantify dispersions with respect to particle or droplet size and concentration. It offers several advantages over other methods. First, because of favorable signal-to-noise ratios it can be applied to systems having high concentrations of dispersed material. Second, a wide range of particle or droplet sizes can be characterized, since several mechanisms contribute to the attenuation of sound. Some of the mechanisms are only valid in the region of nanometer-sized particles, while others dominate sound attenuation by suspensions with particles larger than 10 μm. This presence of more than one attenuation mechanism supports the distinction between attenuation spectra with respect to particle size. Finally, since the method is able to handle field applications where sample extraction or preparation (i.e., dilution) should be omitted, ultrasonic attenuation spectroscopy can be applied to online measurements.

Measurement devices and mathematical frameworks for the analysis of measured attenuation spectra to assess particle size information have been available for several years. Models for performing these analyses are well tested and commonly applied, although most of the established approaches are limited to the region of particle and droplet diameters below 10 μm, which is identified with the long wave regime

(for frequencies up to 100 MHz). The wave regime is determined by the wave number ka given by

$$ka = \frac{\pi d}{c_F}f = \frac{2\pi a}{c_F}f, \qquad (1)$$

where d is the particle diameter (or a the radius), c_F is the velocity of sound in the continuous phase, and f is the frequency of the sound wave. The long wavelength regime is characterized by $ka \ll 1$. Both of the models currently used for the analysis of attenuation results, the ECAH theory[1,2] and the coupled phase/cell models,[3,4] are only applied in the limit of this wave regime. Outside the long wavelength limit, other models for the mathematical description of sound attenuation exist.[5,6] One of these models, the Faran approach,[5] was developed to allow for the calculation of elastic scattering in the intermediate wave regime ($ka \approx 1$) for elastic immovable spheres, and attenuation measurements have been shown to be in agreement with the model for $ka \gtrsim 1$ in polystyrene-water suspensions with narrow distributions of particle size.[7,8] In these studies, model predictions were calculated under the implicit assumption that polydispersity can be expressed by linear superposition of the attenuation contribution of each size class. The observed good agreement between predictions and measured size and frequency dependency of attenuation support the validity of the assumption. This is a prerequisite for particle sizing applications, because it implies that the contribution to attenuation from different

[a]Electronic mail: ar5@rcs.urz.tu-dresden.de

size fractions could potentially be identified and separated. This study tries to present a combined approach for the calculation of size distributions from measured attenuation data in the large particle limit and relies on the superposition principle implicitly assumed by other works.

The purpose of this paper is twofold. First, the model framework for particle size characterization by ultrasonic attenuation spectroscopy in the intermediate wave regime is detailed. Aspects relevant to particle size extraction are outlined. Second, the validity of the combined approach is examined by comparing measured results obtained with an unaltered commercially available attenuation spectrometer to model predictions. The measurements were carried out for a wide range of material combinations to detail the influence of material properties on the validity of the combined approach. The discussion of the approach covers the agreement of measured attenuation spectra with prediction and the similarity between the polydisperse size distributions calculated from the very same measured ultrasonic attenuation and results obtained with an independent measurement technique.

II. ULTRASONIC ATTENUATION MODELING FOR PARTICLE SIZE CHARACTERIZATION

The theory developed by Epstein and Carhart,[1] which was later expanded by Allegra and Hawley[2] (ECAH theory), is based upon the description of the scattered thermal and hydrodynamic fields within and surrounding a single spherical particle. The model development is carried out by defining an infinite sum of scattering coefficients. These coefficients are defined by the interface between particulate and continuous phase. Boundary conditions at this interface are balances of impulse and heat exchange and introduce material properties to the model. The solution is given as a location-dependent pressure amplitude at large distances from the particle, from which expressions of attenuation in the far field can be derived.

In its original form, the ECAH theory is universal with respect to particle size and wavelength. Explicit formulations for the attenuation coefficient can be stated for the long wavelength or small particle size limit. Since the ECAH theory only considers single particles, the model is valid for low concentrations, for which the interaction of hydrodynamic, thermal, and elastic scattering fields between neighboring particles can be neglected (single scattering limit).

In contrast to the ECAH theory, the coupled-phase models[3,4] are generally able to correctly incorporate the interaction of thermal and hydrodynamic fields, but do not account for elastic scattering. Models of this type are based on formally combining particulate matter into a single phase which interacts with the continuous phase. For both of these abstract phases, balances of continuity, energy, and force can be stated and combined into a linear set of equations, under the assumption that time-dependent influences are negligible. The connection between the formal treatment of two separate phases and true dispersive state is usually achieved by the so-called "cell models." These models consider each particle and the surrounding medium as a single cell, with volume

fractions of dispersed and continuous phase chosen accord <>ing to the dispersion volume distribution. Consequently, the evaluation of acoustic field disturbances caused by the dispersion is carried out for a single average cell. Interactions between cells are incorporated by selecting suitable boundary conditions. Despite this seemingly more abstract approach, the coupled phase models are applied to the particle size characterization of nanosized suspensions.[4,9,10] The model is often preferred because of the more accurate reflection of the particle concentration influence even outside the single-scattering limit. However, because of the underlying abstract model formalism, only thermal and viscoinertial effects along with absorption within the phases are considered in coupled phase/cell models, which limits their applicability to the long wavelength region ($ka \ll 1$).

As stated above, the ECAH theory is based on the interaction of scattered, viscoinertial, and thermal fields with the surrounding medium. In contrast, if only elastic scattering (diffraction, refraction, and reflection) is assumed to govern the wave propagation, another type of model can be derived. This approach is relevant, if elastic scattering dominates the propagation of sound, which is the case in the intermediate wave regime ($ka \approx 1$). Models describing elastic scattering were derived by Faran[5] and Anderson.[6] Again, a set of equations derived from boundary conditions (differing in their nature from those in the ECAH theory) leads to the definition of scattering coefficients A_n. Depending on the properties of the particle-fluid combination, different expressions for A_n can be developed. The approach proposed by Faran[5] is suitable for the case of solid, elastic, immovable spheres. The scattering coefficients are expressed as[11]

$$A_n = - \sin \eta_n \cdot e^{-i\eta_n} = \frac{-i \tan(\eta_n)}{1 + i \tan(\eta_n)} \tag{2}$$

with

$$\tan \eta_n = \tan \delta_n(ka) \frac{\tan \alpha_n(ka) - (\rho_F/\rho_P)\tan \zeta_n(k_L a, k_T a)}{\tan \beta_n(ka) - (\rho_F/\rho_P)\tan \zeta_n(k_L a, k_T a)}, \tag{3}$$

$$\tan \delta_n(ka) = -j_n(ka)/n_n(ka), \tag{4}$$

$$\tan \alpha_n(ka) = -ka \cdot j'_n(ka)/j_n(ka), \tag{5}$$

$$\tan \beta_n(ka) = -ka \cdot n'_n(ka)/n_n(ka), \tag{6}$$

$$\tan \zeta_n(k_L a, k_T a) = -\frac{(k_T a)^2}{2}\left[\frac{\tan \alpha_n(k_L a)}{1 + \tan \alpha_n(k_L a)} - \frac{n^2 + n}{n^2 + n - 1 - (k_T a)^2/2 + \tan \alpha_n(k_T a)}\right]\Bigg/\left[\frac{n^2 + n - (k_T a)^2/2 + 2\tan \alpha_n(k_L a)}{1 + \tan \alpha_n(k_L a)}\right.$$

$$\left.-\frac{(n^2 + n)(1 + \tan \alpha_n(k_T a))}{n^2 + n - 1 - (k_T a)^2/2 + \tan \alpha_n(k_T a)}\right], \tag{7}$$

where the expressions of the wave numbers $k_L a$, $k_T a$, and ka are given by $k_L a = \pi d f / c_L$, $k_T a = \pi d f / c_T$, and $ka = \pi d f / c_F$ with c_L, c_T, and c_F denoting the velocity of the compressional (longitudinal) and shear (transversal) wave in the particle, and the compressional wave in the continuous phase, respectively. The quantities ρ_P and ρ_F are the densities of particle and continuous phase. The series j_n, n_n and j'_n, n'_n represent spherical Bessel and Neumann functions and their first-order derivatives. It is possible to deduce the sound velocities from the elastic properties of the medium, namely the modulus of elasticity E and Poisson number ν:

$$c_L = \sqrt{\frac{E(1 - \nu)}{\rho(1 + \nu)(1 - 2\nu)}}, \tag{8}$$

$$c_T = \sqrt{\frac{E}{2\rho(1 + \nu)}}. \tag{9}$$

Thus, the influence of material on the scattering coefficient and the scattering behavior for a known frequency and particle size can be expressed by the densities and the elastic properties. It implies that the knowledge of these properties is sufficient to determine the acoustical attenuation behavior of any particle-fluid system in the region of $ka \approx 1$.

If the dispersed system is not limited to wave numbers $ka \approx 1$ or above, viscoinertial and thermal attenuation need to be considered. Hay and Mercer[11] expanded the Faran approach by including viscoinertial effects in the same way as they appear in the ECAH theory, but the resulting scattering coefficients are significantly more complex.

In analogy to the ECAH theory, a term for the attenuation coefficient α can be stated which relates the scattering coefficients A_n to an amplitude or intensity decrease of a wave passing through a dispersed medium. Hay and Mercer[11] used the total absorption cross section, i.e., the sum of elastic scattering and intrinsic absorption by particles, defined by Morse and Ingard[12] in combination with Faran's coefficients A_n and state the following expression for the total attenuation coefficient for the dispersed phase:

$$\alpha = -\frac{3\phi}{2(ka)^2 a}\sum_{n=0}^{\infty}(2n + 1) \cdot \mathrm{Re}(A_n). \tag{10}$$

In Eq. (10) ϕ denotes the solids volume fraction.

III. ELASTIC SCATTERING BY POLYDISPERSE PARTICLE SYSTEMS

The expression following from the Faran model [Eq. (10)] describes the dependency of attenuation by elastic scattering on the wave number ka. This implies a dependency on both the particle diameter d (or radius a) and the frequency f. In its original form, Eq. (10) considers a monosized particle collective. However, in most cases of particle characterization, a polydisperse state of the system must be assumed.

Polydispersity is defined as the presence of more than one particle size.[13,14] This includes both monomodal and multimodal particle systems. The polydisperse state has been included in the discussion of the scattering formulation before.[7,8,15,16] In these studies the size distribution is treated as a number density or histogram function, which is a representation of the number fraction or particle concentration in each particle size class. For the following approach, the results are presented in a manner not fundamentally different from previous work, but in a way that separates the size distribution function from the particle volume concentration ϕ by using a particle volume based size distribution function.[14] This is an advisable form if size distribution and particle concentration should be treated separately.

Generally, a polydisperse state can be described by a vector of discrete particle sizes. The term "size" can be thought to be a more general description of a property of the particles, that is, a length measure. In the case of irregularly shaped particles, an average or equivalent diameter parameter is often used (i.e., diameter of the sphere having the same volume). Since this study primarily deals with spherical particles, the following derivation uses the sphere diameter as a measure of the particle size. Consider the vector $\mathbf{d} = (d_1, d_2, \ldots, d_v)$, where d_j represents a class-averaged particle diameter. Then $\mathbf{\Delta Q_3} = (\Delta Q_{3_1}, \Delta Q_{3_2}, \ldots, \Delta Q_{3_v})$ can be taken to be the volume-based size distribution vector describing the fraction of particles within each class.[14] Each value ΔQ_{3_j} defines the fraction of the overall particle volume belonging to the size class with diameter d_j. The associated requirement $\Sigma_v \Delta Q_{3_j} = 1$ emphasizes that the size distribution vector comprises a complete set of classes for a given polydisperse system. The index 3 denotes the fact that this is a volume-based treatment, as opposed to particle number-, length-, or area-based distributions (index 0, 1, 2).[14] $Q_3(d_j)$ is the cumulative distribution function. Its values $Q_3(d_j) = Q_{3_j}$ define the fraction of particles having a diameter smaller than d_j. Based on this notation the definition of the median particle diameter d_{50} can be expressed as $Q_3(d_{50}) = 0.5$, that is, 50% (by volume) of the particles in the distribution have a diameter smaller than d_{50}. The particle volume concentration in each size fraction j is $\phi \Delta Q_{3_j}$. The sum over these values again gives the overall volume concentration ϕ.

This work is based on the single scattering theory, where it is implicitly defined that the volume concentration and the attenuation are linearly related. Consequently, the attenuation coefficient α is found through superposition of the attenuation contribution by all size classes, for a continuous size distribution function and a discrete size distribution function according to Eqs. (11) and (12), respectively:

$$\alpha = -\frac{3\phi}{2}\int_0^{\infty}\frac{1}{(ka)^2 a}\sum_{n=0}^{\infty}(2n + 1)\mathrm{Re}(A_n)dQ_3, \tag{11}$$

$$\alpha = -\frac{3\phi}{2}\sum_{j=1}^{\nu}\frac{1}{(ka_j)^2 a_j}\sum_{n=0}^{\infty}(2n+1)\mathrm{Re}(A_n)\Delta Q_{3_j}. \qquad (12)$$

Hall[7] and Mobley[8] used a similar polydisperse model development for demonstrating that measurements in the ka range up to 7 can be described by Faran's approach to a high degree of accuracy. The authors derived the single scattering model from the Waterman-Truell multiple scattering formulation[17] in the domain of weak scattering density, which resulted in an expression equivalent to Eq. (12).

For this study, another consideration regarding the representation of the attenuation spectrum is applied. The quantity α is interpreted as a vectorial representation of attenuation. Each element of α corresponds to one of the values in a vector of discrete frequencies $\mathbf{f} = (f_1, f_2, \ldots, f_u)^T$. This assumption implicitly used by other works[7,8,15,16] is based on the application of ultrasonics techniques. It makes use of the fact that measurements obtained from digitized broadband signals or by a step-through process using narrow-band signals result in values at discrete frequencies with finite spacing. This consideration is advisable if model prediction spectra are to be compared to measurements.

Based upon the two considerations implicitly made by other authors (superposition due to polydispersity and vectorial representation of the attenuation spectrum), a matrix version of Eq. (10) can be stated. Attenuation by elastic scattering for a polydisperse particle collective and a vector of frequencies is expressed as

$$\boldsymbol{\alpha} = \phi \cdot \mathbf{K} \cdot \Delta \mathbf{Q}_3^T \qquad (13)$$

where $\mathbf{K}$ is a kernel matrix with elements given by

$$K_{i,j} = \frac{3}{2(ka_{i,j})^2 a_j}\cdot\sum_{n=1}^{n_{max}}(2n+1)\mathrm{Re}(A_{n_{i,j}}). \qquad (14)$$

The matrix $\mathbf{K}$ depends on the elements of the wave number matrix $\mathbf{ka}$, the vector of particle diameters $\mathbf{a} = \mathbf{d}/2$, and the matrix of scattering coefficients $\mathbf{A_n}$. The matrix $\mathbf{ka}$ is defined by $\mathbf{d}$ and $\mathbf{f}$ as

$$\mathbf{ka} = \mathbf{f}\cdot\mathbf{d}\frac{\pi}{c_F} = \begin{bmatrix} f_1 d_1 & \cdots & f_1 d_\nu \\ \vdots & & \vdots \\ f_u d_1 & \cdots & f_u d_\nu \end{bmatrix}\frac{\pi}{c_F} \qquad (15)$$

and thus the scattering coefficients A_n can be expressed as

$$\mathbf{A_n} = \begin{bmatrix} A_{n_{1,1}} & \cdots & A_{n_{1,\nu}} \\ \vdots & & \vdots \\ A_{n_{u,1}} & \cdots & A_{n_{u,\nu}} \end{bmatrix}. \qquad (16)$$

Each of the values $A_{n_{i,j}} = A_n(ka_{i,j})$ can be calculated according to Eqs. (2)–(7).

The formation of the matrix is the central principle for determining polydisperse particle size information from attenuation measurements.[9,18] This approach offers the possibility of obtaining a particle size distribution vector $\Delta \mathbf{Q}_3$ from a measured attenuation spectrum $\boldsymbol{\alpha}$ as the solution to the linear system of equations set up by Eq. (13). Besides numerical inversion of $\mathbf{K}$, one possible strategy for finding such a solution vector consists of estimating a best-fit representation $\Delta \mathbf{Q}_{3_{fit}}$, under the assumption that $\Delta \mathbf{Q}_{3_{fit}}$ conforms to a predetermined function type. Naturally, the selected function type greatly impacts the fit quality. In the case of monomodal continuous size distributions, a common choice is a log-normal size distribution.[19–21] The density distribution function $q_3 = dQ_3/dd$ (or $q_3 = \Delta Q_3/\Delta d$ in discretized form) for this function type is

$$q_3(d) = \frac{1}{\sigma_{ln}\sqrt{2\pi}d}\exp\left[-\frac{1}{2}\left(\frac{\ln(d/d_{50})}{\sigma_{ln}}\right)^2\right]. \qquad (17)$$

In this case, the task of determining the best-fit representation $\Delta \mathbf{Q}_{3_{fit}}$ (based on a log-normal size distribution) is reduced to estimating the defining parameters, namely median diameter d_{50} and standard deviation σ_{ln}.

If measured attenuation spectra $\boldsymbol{\alpha}_{\mathbf{meas}}$ of suspensions are to be compared to model predictions $\boldsymbol{\alpha}$, it is necessary to account for the absorption of sound within the continuous phase. When assuming linear superposition, the total suspension attenuation $\boldsymbol{\alpha}_{\mathbf{tot}}$ can be calculated by adding the attenuation in the pure continuous phase $\boldsymbol{\alpha}_{\mathbf{F}}$, weighted according to the solids volume fraction, to the model predictions for the dispersed phase $\boldsymbol{\alpha}$:

$$\boldsymbol{\alpha}_{\mathbf{tot}} = \boldsymbol{\alpha} + (1-\phi)\cdot\boldsymbol{\alpha}_{\mathbf{F}}. \qquad (18)$$

IV. EXPERIMENTAL MATERIAL AND SETUP

Based upon the material properties defining elastic scattering according to Eqs. (2)–(9) (density, modulus of elasticity, and Poisson number), several particle substances were selected. Among the materials chosen, glass represents a class of materials having properties similar to those of minerals. Two fractions of glass particles manufactured by Potters-Ballotini GmbH Kirchheimbolanden, one with a mean diameter of 60 μm and another with a mean of 200 μm, were available for analysis.

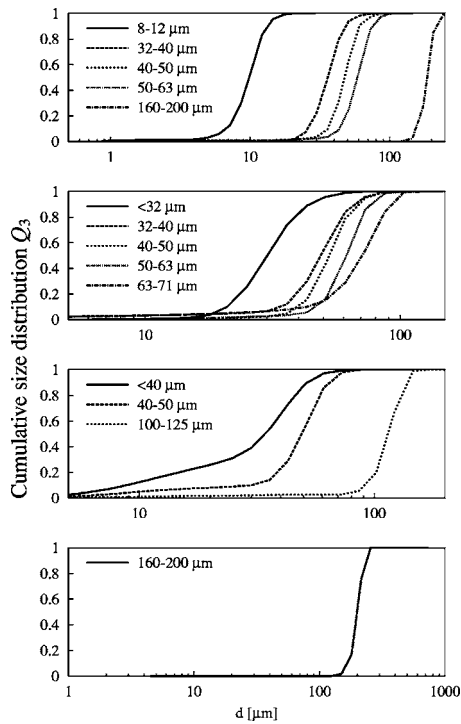
Richter et al.: Large particle ultrasonic attenuation spectroscopy   1397


FIG. 1. Cumulative size distributions Q_3 as functions of particle diameter d of particulate materials used in the attenuation and particle size comparison. From top to bottom, the size distributions show glass, aluminum, tin, and polystyrene.

Aluminum and tin were selected as examples of metallic particulate matter and obtained from Nanoval GmbH, Berlin, and TU Bremen, respectively. Finally, a sample of polystyrene particles (Duke Scientific) was chosen to represent the class of polymer particles. Table I lists material properties of all particulate materials that underwent analysis.

All particle samples were split into fractions of narrow width by a combination of sieving and air separation. The aim of this separation step was to create well-defined particle size distributions and to cover a broad range of values for ka. The applied sieve mesh sizes define and denote the diameter fractions (Table IV). To obtain independent particle size distributions of the resulting fractions, a laser diffraction spectrometer (HELOS, Sympatec GmbH) was utilized. Reference size distributions are detailed in Fig. 1. Furthermore, each fraction was evaluated by scanning electron (SEM) and light microscopy to confirm particle shape and surface properties (i.e., roughness). Although materials with spherical shape were selected, up to 10% of all fractions contained aspherically shaped particles.

Most particle fractions were examined in more than one continuous phase fluid. During this study, water, ethanol, and a NaCl solution (20% NaCl by weight) were used in the preparation of the suspensions. Using more than one continuous phase fluid further diversifies the material combinations and allows for an evaluation of the material property sensitivity. Additionally, this approach allows for conclusions to be drawn regarding the impact of unfavorable properties such as surface roughness and particle shape. These effects should contribute to the same extent in different particle-fluid combinations. Table II lists elastic properties of the continuous phase materials used in this study.

[a]Own measurement.

An acoustic spectrometer model DT-1200 (Dispersion Technology[22]) was utilized for the measurement of experimental attenuation spectra of the material combinations. This device allows the measurement of attenuation at up to 18 specified discrete frequency values in the range from 3 to 99 MHz. Both the number and the spacing (i.e., linear, logarithmic) of the frequencies can be adjusted. For the present work, the full range and number of frequencies was used and a logarithmic distribution selected [$\mathbf{f} = (3, 3.69, 4.53, \ldots, 99)^T$ MHz, $\ln(f_{i+1}/f_i) = 0.2057$]. The measurement chamber of the device contains a fixed and a movable broad-band transducer, allowing for settings of different gap widths between sound emitter and receiver. For each of the frequencies selected for the measurement, the device cycles through a defined number of gap widths between the emitter and the receiver. At each setting (frequency and gap width), a pulsed signal is generated. First, a frequency synthesizer generates a continuous wave signal. A field-programmable gate array (FPGA) controlled by a host computer then generates a transmit gate. This transmit gate is used by a gated amplifier to form a pulsed RF signal from the continuous wave signal. A power amplifier increases the peak power and the resulting signal is passed to the transducer.

Signal reception is carried out by measuring wave intensity during time frames corresponding to the mean sound travel time. This is done in the following manner: The detected RF input signal is passed to a wideband RF amplifier having a programmable gain set by the FPGA, which allows only pulses arriving within a predetermined time interval to pass. The resulting signal is connected to a quadrature mixer which demodulates the received signal, providing analog pulses proportional to the in-phase and quadrature components of the received RF pulse, respectively. After a filter step and A/D conversion, the digitized peak amplitudes of the quadrature signals upon an A/D strobe command are passed through a digital signal processor that accumulates

data from a large number of pulses and generates statistical data on a given pulse set, and finally the data are routed to the computer bus.

The intermediate result of the measurement at different gap widths and frequencies is a matrix of signal intensity and its fluctuation. Statistical analysis of the signal fluctuation at each measurement point (frequency, gap width) and an averaging procedure are applied to extract the signal strength values. These values form an attenuation vector which corresponds to the discrete frequencies. The resulting attenuation values are divided by the frequency at which they were obtained and stored in a database ($\alpha_{\mathrm{meas}}/\mathbf{f}$ having units of dB/cm/MHz). These database values were employed in the subsequent study. During the measurement, the factory settings of the device remained unchanged. Neither signal conditioning nor our own processing of sound signal data was applied.

To confirm that attenuation measurements in the suspensions are reliable and reproducible, measurements of attenuation in pure liquids were performed and compared to established tabulated data. Table III shows good agreement between the tabulated and the measured data and can be seen as evidence that the device is capable of reproducing known results and is an appropriate tool for this study. Nevertheless, device specifics such as bandwidths of the individual signals or signal wave forms were not accessible during the study and must be seen as a source of influence when discussing attenuation results.

Because settling velocities in suspensions of particles larger than 10 μm are comparably high, precautions had to be taken to prevent sedimentation and to ensure constant concentration levels in the measurement chamber. This was achieved by continuously circulating the suspensions upwards through the measurement chamber past the sensor. Additionally, since material properties such as density and modulus of elasticity are temperature-dependent values, a heat exchanger was installed. Using this device, the suspension temperature was kept at a constant value of 25 °C. A schematic of the setup is depicted in Fig. 2.

The attenuation spectrum of the pure continuous phase was measured at the beginning of each measurement campaign. To this same sample of the continuous phase, the particle system was added. Solids volume fractions ϕ in the

measurement compartment were adjusted by adding small amounts of particle material until the desired concentration was obtained. The particle concentration was measured by extracting samples of 1 ml via pipette, which were analyzed for their solids weight fraction using a thermobalance (Mettler Toledo HG53 Halogen Moisture Analyzer). After the solids fraction had been established at the desired value by repeated addition of particle material and subsequent concentration measurement, the suspension attenuation measurement runs were started. Each examination of material combinations with each of the diameter fractions was repeated at least four times, in order to evaluate variations. For a comparison of the resulting attenuation spectra, mean and standard deviation of the measurement repetition were determined. At each of these four repeat measurements one concentration sample was taken. Although the concentration was carefully adjusted, fluctuations of the resulting solids volume concentrations ϕ occurred in all cases.

V. COMPARISON OF ATTENUATION SPECTRA MEASUREMENT TO PREDICTION

Measured attenuation spectra α_{meas} were compared with the corresponding calculations. Only the mean and standard deviation of the attenuation measurements along with the mean nominal concentration values were used for the evaluation of the model framework. Predictions of the sound attenuation spectrum were obtained by calculating α_{tot} [Eq. (18)]. The fraction of the attenuation caused by elastic scattering α was computed according to Eq. (13), using particle size distributions ΔQ_3 determined from laser diffraction spectroscopy (Fig. 1) and material properties listed in Tables I and II. These calculations rely on the scattering coefficient range from A_1 to A_{40}, which was found to be an optimal compromise between calculation time and exactness. Higher coefficient orders did not result in an accuracy increase greater than the round-off errors introduced by the numerical computation.

Figure 3 compares the measured attenuation spectra obtained for glass particles in water at volume fractions of 1% to the corresponding model predictions. All graphs display attenuation as $\alpha/\mathbf{f}$ versus ka. For these and all following graphical comparisons of attenuation spectra, the distribution median diameter d_{50} obtained from the laser diffraction measurements [the value of d for which $Q_3(d)=0.5$, see Fig. 1] was used in the calculation of the abscissa data. The division by $\mathbf{f}$ accentuates the oscillations in the region of $ka>3$.

When comparing attenuation spectra for different fractions of the same material (Fig. 3), it appears that function extremum locations coincide, and that the shape of the curve is reproduced. The presentation of attenuation as a function of ka emphasizes the normalization inherent in the use of the wave number. Deviations should be attributed to the different relative size distribution span. For size distributions comprised of a broader diameter range, attenuation spectra appear smoother due to superposition of attenuation by different portions of the particle size spectrum.

Judging by the attenuation functions, the agreement between model and measured results is adequate. For all glass particle fractions, the shape of the measured curve is re-
FIG. 3. Measured (dots) and calculated (lines) ultrasonic attenuation spectra of glass fractions in water, $\phi=1$ Vol-%. The wave number ka was calculated using the mean diameter d_{50} of the laser diffraction results and the frequency vector **f**.

flected by the calculations (see Fig. 3). Similar results for all other examined material combinations are shown in Fig. 4. All graphs emphasize the effect of normalization introduced by the wave-number-dependent function (shape and magnitude of attenuation spectra of different fractions match regardless of material combinations).

Despite this good agreement, size distribution functions of the smaller fractions measured by laser diffraction show the presence of particles with diameters smaller than 5 μm. This size region exhibits attenuation by viscoinertial interac-

tion between continuous and dispersed phase. This can be observed in the corresponding attenuation spectra by declining slopes with increasing values of ka in the region of $ka=0.1$. This effect is apparent for glass particles in ethanol or in NaCl solution [Figs. 4(a) and 4(b)]. The prediction curves do not exhibit this increase, since the mechanism of viscoinertial attenuation is not included in the calculations.

Two device-dependent factors may have had an influence on the measured results. Both relate to the discrete step-through-frequency method of acquiring the data. First, the

Polystyrene-water	160–200	0.74	0.29	4.46×10^{-4}	2.71×10^{-2}

spectral coverage may have been too wide to reproduce attenuation peaks which are narrow in frequency, leading to peaks being missed. Furthermore, the width of the generated pulse in time may have been too large. If the frequency bandwidth of the ultrasonic pulse is as wide or wider than the frequency width of the peak, it may not be properly resolved.

The result obtained with the polystyrene-water system exposes some limits of the measurement, even though the general shape of the curve is in agreement with the prediction. For this sample, the calculated and the measured spectra have the same order of magnitude. For higher wave numbers these spectra even coincide. However, a number of predicted oscillations in the low ka range are not reproduced by the measurement results. The possible reasons for this result are threefold. First, a detailed inspection of the calculations reveals that the frequency spacing employed in the study does not allow for a finer resolution of the attenuation function. Second, size distributions based on laser diffraction can be expected to span a greater width than actually present. An indication of this (algorithm-induced) result can be found

from a comparison of the sieve mesh sizes used for fractioning (Table IV, column "diameter fraction") to the laser diffraction size distributions (Fig. 1). The laser diffraction results extend to diameters well beyond the sieve mesh size. Finally, the tone burst created by the device at each frequency may be too wide to resolve the peaks even though its center frequency is in line with the peak. This can be problematic when the peaks of the attenuation curve are narrow, which is the case for the polystyrene calculations.

VI. DISCREPANCY BETWEEN MODEL AND MEASUREMENT

As stated above, the agreement between model prediction and measurement is good for all material combinations. Nonetheless, there appears to be a systematic trend to higher measured attenuation values compared with the model predictions. When examining Figs. 3 and 4 it appears that a simple scaling (such as a multiplication with a constant factor for all attenuation values of a spectrum) could lead to an even better agreement between model and prediction. On
FIG. 5. Measured (dots) and calculated (lines) ultrasonic attenuation spectra of glass fractions in water. Calculations were carried out by using best-fit solids volume concentration values. Compare to Fig. 3. The wave number ka was calculated using the mean diameter d_{50} of the laser diffraction results and the frequency vector $\mathbf{f}$.

examination of the model [Eq. (13)] it can be concluded that such a scaling parameter could be expressed in the form of a modified solids volume concentration. Equation (10) expresses attenuation as linearly dependent in the factor ϕ.

To investigate the hypothesis of a scaling-dependent influence, the model [Eq. (13)] was subjected to a parameter estimation procedure. During this step the solids volume fraction ϕ was treated as a variable while all other parameters (material properties, size distribution) remained at the previously defined values. The graphs in Fig. 5 were obtained by a least squared error fit of Eq. (13) in combination with Eq. (18) to the measured attenuation data, with ϕ being the only fit parameter. Figure 5 shows that with best-fit concentration values, better agreement between measured and predicted attenuation functions can be achieved.

To quantify the agreement between measured and predicted best-fit curves, the coefficients of variation can be examined. Therefore, the coefficient of variation of measurement and fit s^2 was calculated according to

$$s^2 = \frac{\sum_{i=1}^{n} (\alpha_{tot_i} - \alpha_{meas_i})^2}{n-1}.$$ (19)

This coefficient was compared to the average measurement variance σ^2 as presented in Eq. (20):

$$\sigma^2 = \frac{1}{n} \sum_{i=1}^{n} \sigma_i^2.$$ (20)

Each value σ_i corresponds to the variance from the repeated measurements m_i at the frequency f_i, as shown in Eq. (21):

$$\sigma_i^2 = \frac{\sum_{k=1}^{m_i} (\alpha_{meas_{i,k}} - \bar{\alpha}_{meas_i})^2}{m_i - 1}.$$ (21)

Table IV lists values of σ^2 and s^2 along with nominal and approximated volume fractions for the studied material combinations. For all examined cases, σ^2 and s^2 have a comparable order of magnitude, which implies that the agreement of the estimation (using the best fit concentration values) is not significantly different from the random error obtained during the repeated attenuation measurements. For every examined case, the solids volume fraction fit caused an improvement of the agreement between prediction and measured result. The details of the curves are well reproduced (i.e., locations as well as magnitudes of the extrema, for glass-water 160–200 μm, see Fig. 5).

It is noteworthy that the best-fit volume fractions are larger by a factor of 1 to 1.4 in comparison with the measured values (see Table IV). One explanation for the observed deviation could be a method-dependent influence. In fact, the solids volume fraction showed variations between consecutive repeat measurements, even though great effort had been made to maintain constant solids volume fractions in the measurement chamber. It is possible that the method used for sampling the suspension for concentration analysis leads to lower values than the actual concentration. It can be speculated that gravitational settling removed particles from the pipette in the very moment the sampling was carried out, resulting in a sampling volume with a smaller particle fraction compared to the measurement chamber. These types of systematic procedural errors cannot be ruled out.

A second interpretation relies on the assumption that the data acquisition by the spectrometer results in generally higher attenuation values. However, measurements for pure liquids (see Table III) do not indicate that there is a general trend to higher attenuation values. Furthermore, the measuring device was specifically developed for particle sizing applications and its capabilities have been repeatedly confirmed.[4,9,18,23] It is not possible to provide a conclusive evaluation of device influence in this experiment, since the data used for the study was accessed as provided by the spectrometer, that is, without further consideration of the signal processing. As pointed out before, the spectral coverage and frequency resolution may have influenced the results.

Finally, in the event that device- or method-dependent effects are not responsible for the observed deviation, it is possible that effects of multiple scattering may be present in the measured attenuation spectra. However, Hall[7] and Mobley[8] stated that measurements can be considered to be in the single scattering region if the following condition applies:

$$c_{MH} = \frac{\phi 12}{k^2 d^3} |f(\theta)| \ll 1 \quad (\theta = 0 \text{ or } \pi).$$ (22)

In Eq. (22) the scattering length f is defined by

$$f = \frac{i}{k} \sum_{n=0}^{\infty} (2n + 1) A_n P_n(\cos \theta).$$ (23)

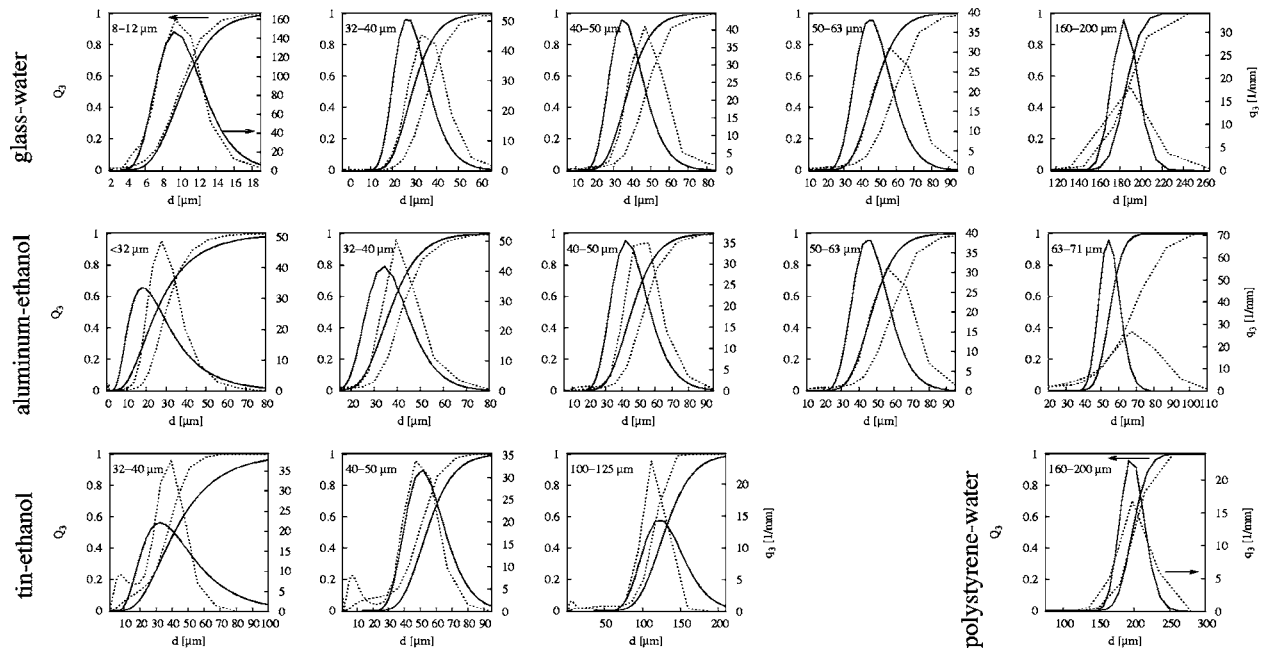
For all of the measurements in the present study this criterion is satisfied, since the values c_{MH} do not exceed 10^{-5}. Regardless of its origin, the discrepancy between model and measurement does not invalidate the approach using the


FIG. 6. Cumulative (Q_3) and density size distributions (q_3) as functions of the particle diameter d, obtained by laser diffraction spectrometry (dashed line) and from measured attenuation data (solid line) for the studied material combinations, $\phi=1$ Vol-%. The values based on the attenuation data were calculated by best-fit approximation based on a long-normal size distribution function.

Faran model, because the difference appears to be remediable by a simple scaling of the data.

VII. PARTICLE SIZE DISTRIBUTIONS

The validity of the approach for polydisperse particle sizing applications in the intermediate wave regime was evaluated by estimating particle size distributions by performing a best-fit of the parameters of the log-normal size distribution function q_3 [Eq. (17)]. Since the selected value of the solids volume fraction ϕ was found to influence the agreement between model and measured results, this parameter was considered as a third variable of the fit process (besides the mean diameter d_{50} and the standard deviation σ_{ln}). An implementation of the Levenberg-Marquardt approximation algorithm was applied to determine the best-fit values.

Figure 6 depicts the resulting log-normal size distributions along with their counterparts measured by laser diffraction spectrometry. The results are shown for selected material combinations of all examined particle size fractions. Each graph contains both the cumulative size distribution Q_3 and the density distribution q_3 as functions of particle diameter d. A compilation of best-fit values for all measured attenuation spectra is listed in Table V. To quantify the goodness of fit of the parameter estimation results, the variance between measured attenuation spectra and the estimated spectra based on the best-fit size distributions was computed. Variance values are listed in Table V besides fit results and sieving mesh sizes.

Judging by the agreement between the graphical representation of the best-fit size distributions, it appears that the estimates are comparable to the laser diffraction results. This is the case for both the mean values and distribution widths. In every case, the order of the size fraction is correctly re-

produced, since the median diameter d_{50} is comparable to sieving mesh sizes (Table V, column "diameter fraction") and laser diffraction (Fig. 6). Distribution widths of ultrasonic attenuation and laser diffraction results are similar, even if mean values do not agree (Fig. 6, glass-water $32-40$ μm, $40-50$ μm, $50-63$ μm; aluminum-ethanol <32 μm, $32-40$ μm, $40-50$ μm, $50-63$ μm).

For some cases, mean values of the best-fit are smaller, although of the same order of magnitude as the measured values. In select cases, the widths of the calculated distribution do not match the measured widths (glass-water $160-200$ μm, aluminum-ethanol $63-71$ μm, tin-ethanol $100-125$ μm, polystyrene-water). In most of these cases, the σ_{ln} values result in narrower calculated distributions. As stated above, this is mainly caused by shortcomings of the laser diffraction result interpretations.

In many of the observed measurements, the fit variance values listed in Table V are of comparable order of magnitude as the average measurement variance, indicating good fit results of the calculations. For some results, the success of the approximation procedure as expressed by the variance was found to be greatly influenced by the best-fit starting values. For one measurement, glass $8-12$ μm in ethanol, the algorithm did not converge regardless of the starting values. It is possible that the squared error function (to be minimized by the Levenberg-Marquardt algorithm) did not expose a distinct global minimum because of the monotonous character of the attenuation function. The presented approach for the polydisperse case is monotonous for the smaller size fractions examined in this work [i.e., compare Figs. 3(a), 4(a), and 4(b), fraction with diameters $8-12$ μm].

Additionally, a general feature of the fit approach needs to be considered when evaluating the fit results. The log-normal size distribution excludes a wide range of size distri-

TABLE V. The numerical results of the approximation of a log-normal size distribution to the measured attenuation data. The value d_{50} describes the average particle diameter, while σ_{ln} is the standard deviation of the distribution. σ^2 and s^2 are the coefficients of variation of the measurement and of measurement and fit, respectively.

bution types (i.e., multimodal distributions). In cases where the log-normal distribution is inappropriate, flawed size distributions are calculated if this function type is applied anyway. This may have been the case with some fractions, especially for those where a significant small particle fraction (diameter $d < 5$ μm) is present (Fig. 1, tin 32–40 μm).

Finally, the parameter estimation is a second indication in favor of the assumption of a scaling-dependent discrepancy between attenuation model and measured result. In some cases, the best-fit concentrations are twice as large (see Table V). When evaluating this result it needs to be considered that the parameter fit process used to find these concentration values involves three parameters. Otimization processes depending on more parameters are characterized by more degrees of freedom. For ill-posed fit problems, this results in a greater uncertainty for each of the fit values when compared to a fit of a single value, as carried out for the comparison of the attenuation spectra (Sec. V). Thus, the fit values reported in Table V can be expected to show a larger deviation from the nominal values. Nevertheless, any deviation between nominal measurements and estimate values indicates either a problem with measurement setup and method, or an incorrectly modeled influence of the concentration. Despite these shortcomings, the results are an indication that the size distributions calculated from measured attenuation spectra are appropriate representations of the dispersed systems.

VIII. CONCLUSION

In this work, a possible approach for ultrasonic attenuation spectroscopy for particle size characterization in the intermediate wave regime was outlined and evaluated. A methodology relying on the Faran elastic scattering model was cast for the polydisperse case and a vector of frequencies and compared to measured data. Various combinations of particulate and continuous phase were experimentally studied with respect to their sound attenuating behavior in the region of elastic scattering. A commercially available attenuation spectrometer designed for particle characterization was used for the measurement of attenuation. The measured polydisperse attenuation spectra for a vector of discrete frequencies were found to correlate with model predictions for the polydisperse case. By studying materials with diverse acoustic contrast, the influence of material properties on the validity of the approach was examined. The only material properties necessary for a complete description of the suspension were the densities and elastic properties of its components.

The measurements resulted in attenuation values higher than those predicted by theory. The deviation was found across the whole frequency region and for all material combinations. To evaluate the nature of the deviation, the solids volume concentration was treated as a variable and subjected to a fit process. As a result of the best-fit procedure, agreement between model and measurement result was further increased. By evaluating the measurement results, it can be concluded that the measurement setup or the experimental procedure are likely sources of the deviation.

Particle size distributions associated with the measured attenuation spectra were compared with those obtained by an independent method (laser diffraction) for additional validation of the approach. For all measured attenuation spectra, size distributions were calculated by a best-fit approximation. The resulting distributions were found to agree with the laser diffraction size distributions in the limit of shortcomings of each method. Deviations present in the distribution results must be addressed and discussed in the light of the applied measurement technology. Furthermore, the validity of the methodology should be confirmed through the application of additional polydisperse size distribution types, i.e., bi-modal suspensions. Nevertheless, the findings indicate that a methodology using the Faran model for elastic scattering is applicable to particle size measurements in the intermediate wave regime, and that size distributions can be inferred from measured attenuation spectra in the large particle limit.

A small, high performance fiber optic microphone has been designed, fabricated, and tested. The device builds on a previous design utilizing a thin, seven-fiber optical probe, but now adds a micromachined 1.5 μm thick silicon diaphragm active element. The resulting sensor head is thin (several millimeters) and light, and the overall microphone system is less expensive than conventional microphones with comparable performance. Measurements in the laboratory using a standard free-field technique at high frequencies, an enclosed calibrator at lower frequencies, and pseudostatic pressure changes demonstrate uniform broadband response from near dc (0.01 Hz) up to near 20 kHz. The measured microphone internal noise is nearly flat over this band and does not exhibit noticeable levels of $1/f$ noise. Over the audible portion of this band, the minimum detectable pressure is determined to be 680 μPa per root Hz with further reductions possible using lower noise/higher power light sources and/or improvements in the diaphragm. In contrast to conventional high-performance microphones, there is no need for preamplifier packages close to the relatively small sensor head resulting in much lower acoustic scattering cross sections. This attribute, together with high performance, low cost, and immunity to emi, makes the microphone ideal for multielement array applications. [DOI: 10.1121/1.2000749]

I. INTRODUCTION

Since the initial surge of interest in fiber optic sensors some 20 years ago, the development of fiber optic microphones has made slow but steady progress. This interest has been connected with one or more of the advantages that such optically based sensors are perceived to possess over conventional capacitive technology. These include immunity to electromagnetic interference, safety in hazardous, explosive environments, material component compatibility with hostile environments, and the absence of troublesome capacitive effects at low frequencies requiring expensive, bulky preamps at the sensor head. Up to the present time, only interferometric fiber optic microphones have been demonstrated having threshold detectabilities $P_{\min}$ comparable to those of the best electrical microphones. While interferometric sensors can be made to achieve very low threshold levels, they are somewhat complex and costly. Our interest here is in achieving a noninterferometric, optical intensity-based microphone with a very low sound detection threshold. He and Cuomo (1992) have presented analysis indicating that optical microphones based on reflection from a membrane should be possible having $P_{\min}$ levels below 100 μPa/$\sqrt{\text{Hz}}$. This paper reports on the development of a noninterferometric fiber optic microphone based on their concept which now approaches the state-of-the-art threshold performance of many commercially available conventional microphones while delivering all the usual advantages connected with optical versus electrical

based sensing. In addition, these optical microphones are considerably smaller, lighter, and cheaper than the conventional high performance devices.

The starting point for this new fiber optic microphone is a small, light, low-cost device reported by Bucaro and Lagakos (2001) which was designed for acoustic active control systems, applications which typically do not require sensors with low threshold detectability. This device in turn was inspired by the much earlier work of He and Cuomo (1991), who introduced the first multifiber probe lever microphone, Hu *et al.* (1992), who developed the first experimental fiber optic microphone based on this idea, and Zuckerwar *et al.* (1995), who in reporting a high-temperature fiber-optic microphone presented a thorough analysis of the various components of the device. Each of these devices, including that reported here, is based on the principle illustrated in Fig. 1. Here an optical fiber probe carries light to a reflective diaphragm and some of the reflected light is recaptured by an adjacent fiber which transmits this optical signal to a photodetector. Motion of the reflector normal to the fiber's end in response to an acoustic pressure linearly modulates the light level recaptured by the collection fiber so that the photodetector current contains a signal proportional to the varying acoustic pressure disturbance at the diaphragm. The fiber optic microphone reported by Bucaro and Lagakos (2001) utilized a bundle of seven fibers similar to that first reported by He and Cuomo (1991) with the central fiber transmitting light to the reflective diaphragm and six outer fibers hexagonally arranged about the central fiber collecting the reflected light. This sensor was small (1.5 cm³), light (1.3 g), cheap ($\sim \$ 25$), and achieved a modest threshold detectability of 16 mPa/$\sqrt{\text{Hz}}$. This latter number is to be contrasted with that

achieved by (low noise) broadband conventional microphones, one example of which is the Bruel & Kjaer (BK) 4180 capacitive device which has a threshold detectability of 158 $\mu Pa/\sqrt{Hz}$. The goal of this effort was to realize a noninterferometric fiber optic microphone having the overall characteristics of that reported by Bucaro and Lagakos (2001) but with a significant decrease (~two orders of magnitude) in the minimum detectable acoustic level so as to approach that of conventional microphones such as the above-mentioned BK device.

In the following sections, we present a short theoretical background which informs how we have chosen to design the new fiber optic microphone, give fabrication details, provide measurement results establishing the microphone's performance, and conclude with remarks indicating the impact this new technology should have.

II. THEORETICAL BACKGROUND

Treatment of the response of the fiber optic microphones of interest here naturally splits into two parts—that associated with the fiber bundle probe and that with the mechanical design and attachment of the reflective diaphragm.

A. Fiber probe

Considerable analysis has been presented in each of the above-quoted references regarding the optical fiber probe. The work includes one, two, and seven fiber bundle designs. In each case, one attempts to maximize the light level modulation for a given diaphragm displacement by the choice of optical fiber bundle parameters as well as the probe-diaphragm separation distance. Generally speaking, as discussed by He and Cuomo (1991) increasing the number of fibers in the bundle results in designs with increased performance. On the one hand, a seven-fiber probe design is preferred over one with fewer fibers because of its superior sensitivity. On the other hand, compared to higher fiber count designs, its natural hexagonal arrangement of outer fibers with one at the center leads to a compact, simple, relatively thin and cost-effective probe. The parameters of an individual fiber can be optimized using the theoretical expressions also given by He and Cuomo (1991). Briefly, their results call for favoring larger fiber core radii, larger fiber numerical apertures, and smaller fiber claddings. Ultimately, a trade-off is made among sensitivity, complexity, and cost—the last of which is moderated by choosing from commercially available fibers. The probe used by Bucaro and Lagakos (2001) and described in detail by Lagakos and Bucaro (2001), which uses a bundle of seven fibers each having a 0.37 numerical aperture, a 15 μm cladding, and a 200 μm core, was designed making these tradeoffs in the context of a
light-weight, miniature, inexpensive microphone. Accordingly, we consider this fiber bundle probe to be near optimum for our purpose and use this design (shown in Fig. 2) for our new device.

B. Diaphragm reflector

In designing a diaphragm consistent with low threshold detectability, it is useful to consider similar diaphragms used in current commercial low noise electrical microphones. In these devices, the diaphragm is a thin metal or metallized plastic foil which is set under significant tension. The purpose of the tension, T, is to increase the microphone bandwidth and to maintain a flat diaphragm surface. The diaphragm response is dominated by this tension, and the diaphragm is modeled as a membrane. The static (low frequency) displacement, X, at the center of the diaphragm produced by a uniform applied pressure P is

$$X = \frac{Pr^2}{4T},\qquad(1)$$

where r is the diaphragm radius.

The application of MEMS technology to production of microphone diaphragms offers a much wider choice of parameters. In particular, a wide bandwidth can be achieved by making r small. Also, thin, flat silicon or silicon nitride diaphragms can be made with minimum tension. When T is small the diaphragm is modeled as a clamped plate, as described in the following. The heart of the major breakthrough reported here in the fiber optic microphone is associated with the mechanical design and details of such a low tension small, thin reflective diaphragm. Consider the response of a thin circular disc of thickness t, radius r, Young's modulus E, and Poisson ratio σ to a dynamic pressure P. For various mounting conditions the center displacement X is given as

$$X = \frac{3Pr^4 H}{16Et^3},\qquad(2)$$

where for example H is given by $1 - \sigma^2$ and $4(1 - \sigma^2)$ for the clamped and freely supported attachment conditions respectively.

The minimum detectable pressure, defined to be that for a signal to noise ratio S/N=1 in a band Δf, can be estimated [He and Cuomo (1992)] by realizing that the signal S is given in terms of the displacement by $X(\partial W_{op}/\partial X)D$, where W_{op} is the recaptured reflected light intensity and D is the photodetector sensitivity:

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Bucaro *et al.*: Miniature fiber optic microphone   1407

$$P_{\min} = \frac{16Et^3N\sqrt{\Delta f}}{3r^4(1-\sigma^2)D\left(\frac{\partial W_{op}}{\partial X}\right)}. \qquad (3)$$

Here N is the rms noise, including shot noise, thermally driven diaphragm vibration, detector and LED noise, etc. Clearly, a low detection threshold requires sufficiently low N; and what is possible practically will be discussed later. However, as can be seen in Eq. (3), significant reduction in $P_{\min}$ should be possible simply through tailoring the dimensions and mechanical properties of the diaphragm. While attempting to achieve a significant reduction through a corresponding reduction in diaphragm stiffness through E is not practical, capitalizing on the strong dependence on diaphragm dimensions can be very effective. The fourth power dependence of $P_{\min}$ on r is attractive, and recognizing that the fiber optic microphone reported by Bucaro and Lagakos (2001) utilized a 6-mm-diam diaphragm, we project that $P_{\min}$ can be reduced by a factor of 100 by increasing the diaphragm diameter to 19 mm. This, however, results in a microphone large by today's standards (although still smaller than some high performance conventional microphones) with significant disadvantages for most applications, particularly for those involving arrays of microphones. On the other hand, $P_{\min}$ also has a strong dependence on the thickness t, and the required reduction in this parameter is attractive in that it can also move the device toward smaller size.

One obvious way in which to achieve a significant reduction in diaphragm thickness is through the use of micromachining techniques. Interestingly, these fabrication methods have been exploited for some time in conventional, capacitive microphones. Scheeper *et al.* (1994) have presented an excellent treatment of this subject and have demonstrated significant improvements in capacitive microphone performance by decreasing the thickness of the silicon nitride diaphragm using micromachining.

With reference to Fig. 2, for the new fiber optic microphone design we estimate the potential drop in $P_{\min}$ associated with a practically realizable decrease in the diaphragm thickness. We take the diaphragm diameter to be 1.6 mm, roughly the diameter of the seven-fiber probe. Our experience suggests that a practical diaphragm thickness is in the neighborhood of 1 to 2 μm. For 1.5 μm thickness and the above diameter, the ratio r^4/t^3 is 2×10^8 compared to 4×10^6 in the original fiber optic microphone of Bucaro and Lagakos (2001). This and Eq. (3) imply a reduction of $P_{\min}$ by a factor of 50 for the new design which would achieve our goal of ~two orders of magnitude reduction in the threshold detectability.

III. FINAL DESIGN, FABRICATION, AND ASSEMBLY

The overall fiber optic microphone design is shown in Fig. 3. Light of wavelength 850 nm from a light emitting diode (LED model Optek OPF370A) is coupled into the central fiber of a seven multimode fiber bundle and propagates to the well-polished end of this input fiber. Upon exiting the fiber, the light propagates a short distance in air
FIG. 3. Overall fiber optic microphone schematic.

(~200 μm) and is reflected by the diaphragm back into the bundle where six receiving fibers surrounding the transmitting fiber carry the recaptured light to a *PIN* photodiode (SD 100-41-21-231). The LED is driven by a current supply (100 mA current and 1 V) which requires about 100 mW of power. The transmitting and receiving multimode fibers are identical commercially available fibers with a 200 μm glass core, a 230 μm plastic clad, a 500 μm Tefzel plastic coating, and a 0.37 numerical aperture. The LED is mounted on a commercially available ST connector (slightly modified) which is then coupled to the ST connector on which the transmitting fiber is mounted. At the output end of the bundle, the ends of the six receiving fibers are coupled to a single 600 μm core fiber using another standard ST connector. This fiber is finally connected to a *PIN* silicon photodiode, mounted on a modified ST connector similar to that used for the LED.

The diaphragm was fabricated by utilizing bulk micromachining techniques as illustrated in Fig. 4. Silicon-on-insulator (SOI)$\langle100\rangle$ wafers with 1.5 μm device layer thickness and 1 μm buffered oxide (BOX) thickness were used as a starting material. Prior to micromachining, a protective SiO_2 layer (1 μm) was deposited on the front side of the device layer by plasma-enhanced chemical vapor deposition (PECVD). The same PECVD technique was then used to build a 4-μm-thick silicon oxide layer on the back side of the wafer. This relatively thick oxide was covered with a photoresist layer (~5 μm) and patterned using contact optical lithography and a subsequent CF_4-based reactive ion etch. As a result of the patterning step, circular openings (with diameter 1.6 mm, approximately the outer diameter of the optical fiber bundle) were created in the back side SiO_2 layer to allow exposure of the silicon wafer to a subsequent deep reactive ion etch (DRIE). The remaining oxide film formed a high-resistance mask which served to protect those parts of the wafer intended to become the frame of the diaphragm (see Fig. 2). A Bosch DRIE process featuring high etch rate, very high anisotropy (nearly vertical walls), and high selectivity (ratio of Si etch rate to that for SiO_2) was utilized to etch cylindrical channels originating at the circular openings in the back side oxide and penetrating through the entire thickness of the Si wafer, stopping at the bottom surface of the BOX layer. At the completion of the DRIE step, a suspended circular diaphragm was created comprised of the silicon device layer sandwiched between the BOX oxide at the bottom and the protecting PECVD oxide on the top. A short

   2.8 mm

wet etch in hydrofluoric acid (HF) was used to dissolve both oxide layers thus yielding a relatively low stress single-crystal Si diaphragm.

It is well known that in thin films residual stress can play a large role in the dynamic mechanical response. If our circular diaphragm is under tension T, the displacement response predicted by Eq. (2) is altered. For low tension values, the response is modified in the following way (Bickley, 1933):

$$X = \frac{3Pr^4H}{16Et^3}\left[1 - \frac{5T(1-\sigma^2)r^2}{6Et^3}\right]. \qquad (4)$$

It is interesting to ask at what diaphragm tension would the displacement be reduced by say 10% because of the second term in Eq. (4). Setting the second term in brackets equal to 0.1 and solving for T yields a tension of 0.13 N/m. Accordingly, as a rough rule we attempt to achieve micromachined diaphragms in which the residual tension is not significantly larger than this value.

We estimated the level of residual stress present in the finished diaphragms by the presence and number of optical fringes observed in the image of the diaphragm in white light. Typical diaphragms we fabricated exhibited less than one optical fringe across their diameter. Considering the dimensions of our diaphragm, we estimate this to be consistent with a tension of 0.04 N/m, a value lower than the 0.13 N/m goal derived earlier.

As illustrated in Fig. 4, the finished 1.5-µm-thick silicon diaphragm together with its 500-µm-thick frame to which it is rigidly attached is easily broken from the overall wafer by

the application of some weak forces. Under observation with a microscope, this 2.8 mm structure is then placed over the sensor end of the fiber probe and attached to the end of the stainless steel tubing using a two-component, hard epoxy adhesive applied to the end of the tubing.

In the final structure, the actual distance between the diaphragm and the fiber probe end face is an important parameter in determining the final sensitivity. Before diaphragm attachment, this distance was predetermined and set using the procedure outlined by Bucaro and Lagakos (2001) wherein a controlled micrometer translation stage is used to vary the distance between the fiber bundle (within the stainless steel tubing) and a fixed mirror mounted on a piezoelectric transducer at the end of the outer stainless steel tubing. Both the ac and dc displacement sensitivity ($\partial W_{op}/\partial X$) in Eq. (3) can be measured in this way versus the gap separation allowing the fiber bundle to be fixed with respect to the supporting tubing so that the sensitivity is maximum.

IV. MEASUREMENTS

Measurements to determine the dynamic, broadband response of the fiber optic microphone were carried out using two systems, a dynamic pressure calibrator over the low frequency portion of the band and a standard open-air, speaker technique over the high frequency segment. We arranged the measurements so that there was a small region of overlap for the two techniques. In addition, we measured the pseudo-static response (change in optical signal over ~100 s period) to small step changes in pressure (water height changes) using a 6.4-mm-i.d. U-shaped plastic tubing to which the microphone diaphragm end was attached.

The low frequency measurements were made over the band 30–1000 Hz by placing the sensor in a Bruel & Kjaer (BK) pressure calibrator, type 4221, together with a standard calibration microphone. The latter was a BK 4938 sensor with a 2669 BK preamplifier and a 2690 BK amplifier. A broadband chirp pulse covering the band was applied to the calibrator, and the output signals from the fiber optic and calibration microphones were recorded and stored in a Macintosh computer using a ML 750/M Power Lab recorder.

A speaker setup was used to measure the fiber optic microphone over the higher frequency band, 900 Hz–25 kHz. This technique used a free-field configuration in which the sound source (a high-fidelity loudspeaker) was mounted on a pedestal with the fiber optic microphone attached to a vertical supporting rod. Both the source and the microphone were positioned so that the nearest reflecting surfaces in the room were at least 1.5 m away. The loudspeaker was driven with a gated sinusoidal signal, whose duration was sufficiently short so that the direct sound signal from the speaker to microphone and echoes from surrounding reflecting surfaces could be separated in time. The fiber optic microphone was removed after recording the response signals and replaced by the BK calibration microphone at the identical location to provide the absolute pressure levels required to calibrate the fiber optic microphone response. At the highest frequency measured (25 kHz), the acoustic wavelength is
FIG. 5. Laboratory measured fiber optic microphone response vs frequency (—) cw free-field; (- - -) BK 4221 pressure calibrator; and (↔) pseudo-static measurements.

still much larger than the microphone diameter, and we assume the measured free-field response to be the same as the pressure response.

The fiber optic microphone response measured over the entire band is shown in Fig. 5 in units of mV/Pa which have been converted directly from W/Pa upon multiplication by the photo-detector sensitivity $D = 1.1 \times 10^6$ V/W for our detector package. We also recorded the intrinsic noise level of the microphone in a quiet room (ambient acoustic levels $\ll 100$ μPa), and this is shown in Fig. 6. (This can be converted to Pa/$\sqrt{\text{Hz}}$ upon division by the microphone sensitivity shown in Fig. 5.)

V. DISCUSSION

As can be seen (Fig. 5), the microphone exhibits a reasonably flat, broadband response to frequencies approaching 20 kHz, above which a large resonance dominates. We also notice that the pseudostatic response is virtually identical to that measured dynamically below 1 kHz. The small fluctuations observed in the frequency response above 1 kHz (measured in an open laboratory) are, for the most part, related to ambient noise in the laboratory. This is contrasted to the virtually noise-free measurements made at lower frequencies within the shielded calibrator. One can notice above this noise level, however, a small, broad peak just above 10 kHz. This is in fact associated with the first resonance of the disk-
FIG. 6. Measured microphone intrinsic noise levels vs frequency.

like diaphragm. The resonance frequencies and associated mode shapes of circular disks, which depend on E, t, r, and σ, are easily predicted [see, for example, Soedel (1981)]. For our diaphragm parameters, the first resonance is predicted to occur at 10.1 kHz and involves radially symmetric vibration. This resonance response peak is in fact just visible in the response curve of Fig. 5. The next resonant response predicted is that for the so-called 0,1 mode which is an antisymmetric vibration whose nodal line is located along the disc diameter. The resonance frequency is predicted to be 21.2 kHz, which coincides almost exactly with the frequency of the large response peak seen in Fig. 5. A relatively large sensor response (compared for example to that from the first vibrational mode) is to be expected for the 0,1 mode as can be understood from the following consideration. The deflection in this mode results in a tilting of the diaphragm plane about its diameter (along which most of the probing light is incident), and this motion is considerably more effective at changing the light level captured by the outer ring of receiving fibers than motion of the diaphragm normal to its plane.

We would like to determine to what extent the diaphragm fabrication and attachment procedures have produced a sensitivity as predicted by Eq. (2) In particular, from Eq. (2) one sees that the diaphragm response to pressure P is given by $(\partial X/\partial P) = 3 \ r^4(1 - \sigma^2)/(16 \ Et^3)$. For our intended diaphragm dimensions ($r = 8 \times 10^{-4}$ m and $t = 1.5$ μm) and using the available elastic parameters for silicon ($E = 14.5 \times 10^{10}$ Pa and $\sigma = 0.245$), this predicts $(\partial X/\partial P) = 1.47 \times 10^{-7}$ m/Pa. Since the microphone sensitivity in W/Pa is given by $(\partial X/\partial P) \times (\partial W_{\text{op}}/\partial X)$, $(\partial X/\partial P)$ can be extracted from the measurements by using the value for sensitivity shown in Fig. 5 and dividing by $(\partial W_{\text{op}}/\partial X)$ measured for the probe. This latter parameter was determined by mounting the probe on a micrometer translation stage and placing it in close proximity to a mirror mounted on a piezoelectric transducer as described by Bucaro and Lagakos (2001). The displacement amplitude of the vibrating mirror was obtained from the output of a small reference accelerometer (Endevco 2250A) mounted close to the mirror. For our gap separation, $\partial W_{\text{op}}/\partial X$ is found to be 6.35×10^{-1} W/m. This gives $(\partial X/\partial P) = 3.46 \times 10^{-8}$ m/Pa. Thus the experimental value for $(\partial X/\partial P)$ is about four times lower than that predicted by Eq. (2).

At the present time, the exact source(s) for this reduced diaphragm sensitivity is not certain. One could surmise that it may involve a combination of effects. These would include: (1) diaphragm thickness variation or uncertainty; (2) silicon material parameter variations; (3) increased tension in the attached diaphragm; (4) a decreased effective diaphragm diameter resulting from the flow of adhesive onto the perimeter of the diaphragm; (5) the neglect of effects associated with the entrapped air in the cavity between the diaphragm and fiber bundle end; and (6) neglect of the crystal diaphragm anisotropy.

Unlike the case for the first four issues above, the quantitative impact of the entrapped air on the sensitivity of our actual microphone can be accurately determined since we know the required parameters. This air is confined between the diaphragm and the end surface of the optical fiber bundle,

and it can be modeled as an isothermal film squeezed by the motion of the diaphragm. This model was originally developed by Crandall (1918) and recently applied by Hansen *et al.* (2000) to micromachined transducers. An approximate solution of the squeeze-film equations is obtained assuming piston motion of the diaphragm and a free boundary with the atmosphere at the edge of the fiber bundle. The force of the air on the diaphragm consists of two components: (1) a component in phase with velocity which dissipates energy like a resistance, R_{air}; (2) a component in phase with the diaphragm displacement that stores energy through compression of the gas, like a spring with a stiffness constant, S_{air}. An important parameter of the air film is $\beta = (12\,\mu\omega/P_0)^{1/2}(r/h)$, where ω is the angular frequency of vibration, μ is the viscosity of the air, P_0 is atmospheric pressure, r is the diaphragm radius, and h is the gap between the diaphragm and fiber optic bundle. When $\beta \ll 1$ the expressions for the equivalent resistance and stiffness of the air film are

$$R_{air} = \frac{3\pi\mu r^4}{2d^3} \quad S_{air} = \frac{3\pi\mu^2 r^6}{P_0 d^5}. \tag{5}$$

An exact but more complicated solution for the air motion was developed by Zuckerwar (1978). However, Eq. (5) is sufficient for our estimates, presented in the following, for the effect of the air on the diaphragm response.

The above-noted expressions are used to calculate R_{air} and S_{air} at a frequency of 10 kHz, to determine the effect of the air on the fundamental resonance of the diaphragm (resonance frequency $\omega_0 \cong 2\pi \times 10^4$ rad/s). For the fiber optic microphone in this study the parameters in Eq. (5) are: $R_{air} = 4.3 \times 10^{-6}$ Ns/m, and $S_{air} = 9.66 \times 10^{-5}$ N/m. The air stiffness, S_{air}, can be compared with the stiffness of the diaphragm, defined as S_m= applied pressure/average diaphragm deflection = $192\pi D_b/r^2$, where D_b is the bending stiffness of the diaphragm. The calculated $S_m = 52$ N/m, and it is seen that $S_{air} \ll S_m$. Apparently, because the gap d between the diaphragm and the end of the fiber bundle is relatively large (200 μm), the air in this gap can move freely and does not impede the motion of the diaphragm. We conclude that the trapped air is not responsible for the drop in sensitivity. We also point out that the present design does not include a capillary vent for pressure equilibration on the two sides of the diaphragm, a technique often used in microphone designs. An estimate of the backpressure resulting from motion of the diaphragm to pressure P for our cavity size gives $P \times 10^{-4}$ and suggests that equilibration is not necessary.

Having estimated R_{air}, we can also determine whether the breadth of the first resonance peak can be attributed to the trapped air. The quality factor for the fundamental resonance, Q_{air}, corresponding to the above-noted air resistance can be estimated from $Q_{air} = m\omega_0/R_{air}$ where m is (approximately) the mass of the diaphragm. From the above, with $m = 6.9 \times 10^{-9}$ kg, the calculated $Q_{air} \sim 10^2$. This relatively high value of the quality factor shows that the air resistance is small and cannot account for the observed width $Q^{-1}\omega_0/2\pi$ of the fundamental resonance. Apparently, the

mechanical properties of the diaphragm itself and its attachment material are responsible for the relatively high damping of the fundamental.

At the present time, we do not know accurately the parameters required to determine the contributions of effects numbered (1)–(4) to the decrease in sensitivity. Regarding (1) and (2), diaphragm thickness and material property variation or uncertainty, our experience indicates that the micromachining process and the high quality of the silicon wafers utilized result in thickness variations of no more than ±0.3% and uncertainties no more than ±3%; Young's modulus variations of no more than ±10%; and Poisson ratio uncertainties of less than ±10%. Given the dependence of sensitivity on these parameters indicated in Eq. (2), these uncertainties could lead to sensitivity differences of 9%, 10%, and 1% for thickness, Young's modulus, and Poisson ratio, respectively. Taking the largest of each of these would account for only about 20 % of the sensitivity drop.

We can obtain a very rough estimate of what diaphragm tension would lead to a factor 4 drop in the sensitivity using Eq. (4). [The estimate is rough since Eq. (4) is accurate only for small tensions.] Setting the bracketed term equal to 1/4 gives a value of 0.72 N/m for the tension, a value some 20 times higher than our estimate based on the number of optical fringes seen from white light reflected from the unattached diaphragms. While the attachment process itself can lead to increased tension, we do not think an increase by a factor of 20 is likely, nor do we see any significant change in the fringe pattern associated with the attached diaphragm.

Next, we consider the possibility of decreased effective diaphragm diameter resulting from the flow of adhesive onto its perimeter. Given the strong fourth power dependence of the sensitivity on diaphragm radius, it would only take enough material sufficient to constrain an outer annulus of width of only 29% the original radius to produce the entire effect. Microscopic observation of the external diaphragm surface of the microphone showed no such adhesive flow. However, we are not able to observe the diaphragm underside in order to draw any conclusion.

Finally, regarding crystal anisotropy, we have not yet developed an expression equivalent to Eq. (2) for this case. We are thus unable at this time to calculate the magnitude of this effect. We note, however, that the variation in E and σ for $\langle 100 \rangle$ and $\langle 111 \rangle$ silicon wafers as measured by Franca and Blouin (2004) is $\sim$36% and 25%, respectively; and since the sensitivity is proportional to E^{-1} and to $(1-\sigma^2)$, it does not seem likely that anisotropic elastic properties will account for the observed sensitivity decrease.

Further work will be carried out in order to determine to what extent each of these effects [numbered (1)–(4) and (6)] is in fact contributing to the factor of 4 decrease of the microphone dynamic sensitivity.

Next we discuss the minimum detectable pressure P_{min} defined to be the acoustic level at which the S/N per $\sqrt{Hz}$ is one. The intrinsic noise level, which is determined for our sensor by the LED light and power source (with 150 μW on the detector), can be seen in Fig. 6 to be $\sim$17 pW/$\sqrt{Hz}$ above 30 Hz and is nearly independent of frequency. From Fig. 5 we can see that at 5 kHz the acoustic sensitivity is

measured to be −152 dB re: W/Pa. This gives a minimum detectable pressure of −215.4 dB re:W/$\sqrt{\text{Hz}}$+152 dB re: W/Pa=−63.4 dB re: Pa/$\sqrt{\text{Hz}}$ or 680 μPa/$\sqrt{\text{Hz}}$. (We also note that this level is an order of magnitude higher that the ambient acoustic levels in the quiet room.)

The fact that the intrinsic noise level of the microphone is determined by the LED/power source was established by noting that the same noise level was observed when the LED/detector system was monitored before integration into the microphone (using the same 150 μW optical power level) and that the detector specified noise level is much lower. The current microphone uses a relatively inexpensive LED, and we note that more expensive light sources are available with significantly lower noise levels. How far below the 680 μPa/$\sqrt{\text{Hz}}$ threshold level one could achieve with this replacement depends upon the other noise mechanisms at play in the microphone [see, for example, Zuckerwar *et al.* (2003) and He and Cuomo (1992)]. These noise sources include detector noise, mechanical noise associated with thermally generated diaphragm vibration, and photon noise.

This last noise source, which is the fundamental limit regarding the optical components of our microphone, can be estimated straightforwardly. In this case, over the band Δf the mean square noise current $\langle i^2 \rangle$ is given by $2eD\,W_{\text{op}}\Delta f$, with e the electronic charge. We then have

$$P_{\min} = \sqrt{2e\Delta f \frac{W_{\text{op}}}{D}} \bigg/ \left(\frac{\partial W_{\text{op}}}{\partial P} \right), \qquad (6)$$

which for our parameters gives $P_{\min}=360$ μPa/$\sqrt{\text{Hz}}$.

As can be seen, the limiting LED noise is not far above the photon noise limit for our power level on the detector, i.e., 150 μW. However, were we able to attain the theoretical diaphragm sensitivity (with the additional factor of 4), the minimum detectable pressure would decrease to 90 μPa. In addition, higher power and lower noise LEDs are available, and with a source having 10 times the power (and noise ≤ shot noise limit), $P_{\min}$ could reach 28 μPa.

Ultimately, background diaphragm motion will determine whether these levels can be attained. We have estimated the levels of thermally generated diaphragm noise associated with the moderate amount of internal damping of the diaphragm and its attachments as manifested in the Q of the first resonant peak. This is simply estimated using Nyquist's relation [Callen and Welton (1951)] as discussed by Gabrielson (1993) which gives $A^{-1}\sqrt{4k_B T\omega_0 m\Delta f/Q}$ for the noise equivalent pressure, where A and m are the diaphragm area and mass, k_B is Boltzmann's constant, T the temperature, and ω_0 the resonance frequency. For our parameters, we find that this yields noise pressures less than 1 μPa/$\sqrt{\text{Hz}}$, which are well below the noise levels discussed earlier.

The current design demonstrates an inexpensive, miniature fiber optic microphone with a threshold detectability 24 times lower and a diameter a factor of 2 smaller than its progenitor device reported by Bucaro and Lagakos (2001). Its limiting noise is that associated with the LED source, whose power spectrum is nearly flat (versus $1/f$) down to very low frequencies (∼0.01 Hz). This leads to an inexpensive, broadband, sensitive microphone covering frequencies from about 20 kHz down below subhertz. We also note that if one could achieve the theoretical diaphragm sensitivity and employ higher power/lower noise LEDs, threshold detectabilities would approach within an order of magnitude that of the best conventional device we could identify, namely the 25-mm-diam Bruel & Kjaer #4146 [Gabrielson (1993)].

The fiber optic microphone threshold detectabilities identified earlier—680 μPa/$\sqrt{\text{Hz}}$ achieved in the present design, 90 μPa/$\sqrt{\text{Hz}}$ were we to achieve the diaphragm sensitivity predicted by Eq. (2), and 28 μPa/$\sqrt{\text{Hz}}$ for the higher power/low noise source and optimized diaphragm—approach and attain, respectively, those levels of performance achieved by some of the best broadband conventional microphones. However, unlike these conventional high performance counterparts, large expensive preamps connected directly to the fiber optic microphone head are not required. In addition, the current fiber optic microphone (2.8 mm diameter and 13 mm length) is significantly smaller than most of the other high performance devices, and it uses inexpensive optical and electrical components whose total costs can be well below $100.

The high performance fiber optic microphone reported here can be expected to find application in many areas. However, this is especially true where a nonelectrical, miniature, light-weight, and/or inexpensive sensor head is required. In this regard, perhaps the highest payoff of this technology will be in the design and implementation of microphone arrays where sensor head and cabling size, cost, and acoustic cross section are most important. We also note that in such an array a single light source can be shared by a number of microphones, N_{mic}, without drastically impacting the threshold sensitivity achieved in the present device. In this case, the minimum detectable pressure for each microphone would be increased by the factor $\sqrt{N_{\text{mic}}}$.

Properties of transducers and substrates for bulk acoustic wave resonators and sensors are described. These resonators utilize one-dimensional thickness vibrations of structures consisting of a low-loss substrate crystal surmounted by a thin active piezoelectric film that drives the composite in resonant modes to achieve gigahertz frequencies. The structures considered include oblique orientations of the substrate, leading to generation of coupled elastic modes in the composite. A modified Christoffel-Bechmann (CB) formalism is presented to calculate acoustic wave speeds and displacements in the piezoelectric film transducer and the substrate. The CB method also yields the piezoelectric coupling coefficients of arbitrarily oriented piezofilms, for electric fields impressed either along the thickness or laterally. The calculations apply generally to transducer and substrate crystals of any symmetry class. The piezoelectric portion is then made specific for films of class 6 mm (wurtzite structure) with arbitrary orientation on the substrate, and the substrate calculations are specified for class $\bar{3}m$ materials, but apply also to any substrate with $3m$ or 32 symmetry. Zinc oxide and sapphire are used in an example of the acoustic resonator structure. [DOI: 10.1121/1.1985076]

I. INTRODUCTION

Acoustic resonators, filters, and actuators are key enabling components which find numerous applications in communications and in sensors. These frequency control and selection components are members of a class of generic network elements that possess the superiority of low acoustic loss, small size, and attractive thermal characteristics.

The quartz resonator, introduced in the 1920s, is the prototypic element of this class. With perhaps the single exception of the 32 kHz wristwatch crystal, applications have steadily pushed upper frequency limits, primarily to achieve higher system bandwidths. In the 1940s, 30 MHz was considered the industrial limit. Today, applications demand gigahertz capabilities. To achieve these frequencies, acoustic resonances utilize thickness vibrations of thin films and plates. These bulk acoustic wave (BAW) devices are capable of handling relatively high levels of power, with low noise performance. At the upper frequency ranges, composite structures are commonly used. These consist of a thin active piezoelectric layer deposited on a robust, high acoustic quality factor (Q) substrate, and are often referred to as HBAWs (high frequency BAWs),[1] or thin-film resonators (TFRs).[2]

TFR substrate candidates include silicon, diamond, quartz, lithium niobate, gallium arsenide, and sapphire (corundum). Each of these materials possesses beneficial characteristics. Among them sapphire has extremely low acoustic loss, high thermal conductivity, and is readily available commercially.

The focus of this paper is the development of a modified Christoffel-Bechmann (CB) formalism to calculate acoustic wave velocities, displacements, and piezoelectric coupling of arbitrarily oriented composite transducer structures, composed of piezoelectric thin films on a substrate. ZnO on sapphire structures are used as the example, however, the calculations apply generally to transducer and substrate crystals of any symmetry class.

II. CHRISTOFFEL-BECHMANN METHOD

A. Overview

We treat the case of simple thickness modes of homogeneous, but arbitrarily anisotropic thin plates, films, and composites driven piezoelectrically. This is a one-dimensional approximation, with no lateral variations in motion. It has proven to be adequate in many practical situations, and permits most salient features to be simply described. General background is found in Ref. 3.

There are two methods in general usage for treating the case of plane acoustic wave propagation in crystals, from which the solution to this problem is composed. In the plate-coordinate method, the relevant elastic, piezoelectric, and dielectric material coefficients are transformed to the rotated coordinate system specifying the orientation of the film or plate. In the CB method, the transformation involves instead

Plane-Coordinate Method

Christoffel-Bechmann Method

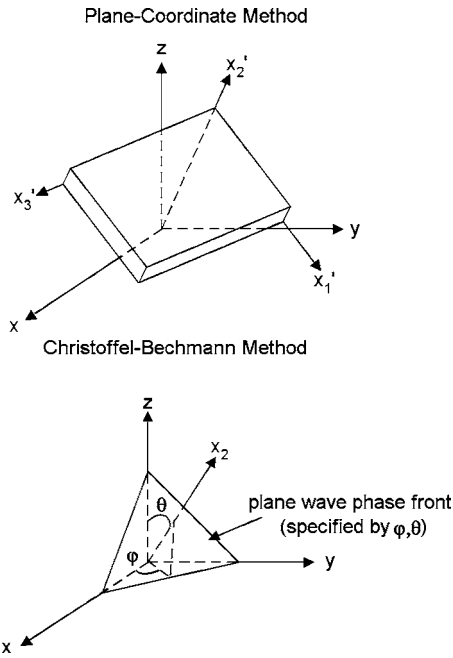
plane wave phase front
(specified by φ,θ)


FIG. 1. Schematic representations of the rotations used for the plate-coordinate and Christoffel-Bechmann methods. In the plate-coordinate method (x,y,z) are the crystallographic axes, (x'_1,x'_2,x'_3) are the plate axes, and the (x'_1,x'_3) plane coincides with the phase front. In the Christoffel-Bechmann method, (x,y,z) are the crystallographic axes, x_2 is the propagation direction, and the plane wave phase front is specified by φ and θ.

only the coordinate representing the direction of propagation of the plane waves with respect to the crystallographic axes. It is therefore simpler than the first method. Figure 1 is a schematic representation of the rotations involved in these two methods. Either method yields the wave velocities that determine the resonance frequencies, the directions of particle motion for each mode, and the usual thickness excitation piezoelectric coupling coefficients. When lateral excitation is used, the electric field is imposed along a transverse axis, and additional coefficients are required to be calculated. The procedure for doing this has been known using the plate-coordinate method. Here we provide the computationally simpler CB method to encompass lateral excitation, and obtain therefrom the lateral piezocoupling coefficients for oblique orientations of films and plates. These will be specialized in subsequent sections for particular crystal classes to classify the acoustic behavior of materials for the purposes of analyzing device performance.

B. Christoffel-Bechmann elastic wave formalism

George Green, in an 1839 paper, derived equations containing 21 coefficients that today we recognize as those governing acoustic plane wave propagation in crystals. Christoffel, in 1877, published a long article in which he cast the equations in terms of strain instead of stress, and gave them a form that is still used. Cady introduced piezoelectric effects,[4] and Bechmann used them to augment Christoffel's method.[5] Here we sketch the CB method, to include the case where the electric field driving the motion is lateral to the

direction of the advancing phase front. We then apply the extended method to the simple thickness modes of films with arbitrary piezoelectric symmetry.

The method starts by assuming that acoustic plane waves are propagating in a specified direction with respect to the crystallographic axes of the material. If such waves are subsequently confined as standing waves between the major surfaces of a thin plate or film, one refers to the ensuing motion as simple thickness modes. We adopt the IEEE Standards[6,7] defining both the crystallographic axial set, and the notation $(YXwlt)\varphi/\theta/\psi$ specifying the orientation of a film or plate aligned with a rotated coordinate set of axes. Thickness is taken along the rotated X_2 axis, which is the direction of plane wave progression. The angle set φ, θ, and ψ specifying the three rotations leads to a rotation matrix (α). Normally, the film is piezoelectrically driven by electrodes placed on the major surfaces, creating an electric field in the thickness direction; this is called thickness excitation (TE). When the exciting field lies in the plane of the film, the situation is referred to as lateral excitation (LE). We assume that the lateral electric field is impressed along the rotated X_1 axis.

With the specification of φ, θ, and ψ, elements of the matrix (α) are determined as

$$\alpha_{11} = [\cos\varphi\cos\psi - \sin\varphi\sin\theta\sin\psi], \tag{1}$$

$$\alpha_{12} = [\sin\varphi\cos\psi + \cos\varphi\sin\theta\sin\psi], \tag{2}$$

$$\alpha_{13} = [-\cos\theta\sin\psi], \tag{3}$$

$$\alpha_{21} = [-\sin\varphi\cos\theta], \tag{4}$$

$$\alpha_{22} = [\cos\varphi\cos\theta], \tag{5}$$

$$\alpha_{23} = [\sin\theta], \tag{6}$$

$$\alpha_{31} = [\cos\varphi\sin\psi + \sin\varphi\sin\theta\cos\psi], \tag{7}$$

$$\alpha_{32} = [\sin\varphi\sin\psi - \cos\varphi\sin\theta\cos\psi], \tag{8}$$

$$\alpha_{33} = [\cos\theta\cos\psi]. \tag{9}$$

The CB method takes $\alpha_n = \alpha_{2n}$, the elements of the second row of (α), and $\zeta_n = \alpha_{1n}$, the elements of the first row of (α). Then, using the full tensor forms of the elastic, piezoelectric, and dielectric constants, the following quantities are formed:

$$\Gamma_{jk} = c_{ijkp}\alpha_i\alpha_p, \tag{10}$$

$$\Xi_k = e_{nkp}\alpha_n\alpha_p, \tag{11}$$

$$\varepsilon'_{22} = \varepsilon_{in}\alpha_i\alpha_n, \tag{12}$$

$$\Gamma^*_{jk} = \Gamma_{jk} + \Xi_j\Xi_k/\varepsilon'_{22}. \tag{13}$$

The second term in Eq. (13) is the piezoelectric stiffening term. The quantities appropriate to LE are now formed:

$$\Lambda_k = e_{nkp}\zeta_n\alpha_p, \tag{14}$$

$$\varepsilon'_{12} = \varepsilon_{in}\zeta_i\alpha_n, \tag{15}$$

$$\varepsilon'_{11} = \varepsilon_{in}\zeta_i\zeta_n. \tag{16}$$

The stiffnesses c_{ijkp} are those at constant electric field, c^E_{ijkp}, and the dielectric permittivities ε_{ij} are those at constant elastic strain, ε^S_{ij}. Where these quantities appear in the following, the standard Voigt contraction for the indices has been applied.

Next, the eigenvalue equation

$$|\Gamma^*_{jk} - c\,\delta_{jk}| = 0 \tag{17}$$

is solved. It determines three piezoelectrically stiffened eigenstiffnesses, c_m, yielding the elastic velocities $v_m = (c_m/\rho)^{1/2}$, and corresponding eigenvectors $\gamma^{(m)}$, specifying the directions of particle displacement for each mode m, with respect to the crystallographic axes. By tradition, $m=a,b,c$, corresponds, respectively, to the quasi-extensional, the fast-, and slow-quasi-shear modes. Apart from the wave speeds, v_m, that determine the resonance frequencies of the film, and the angles

$$\delta_m = \cos^{-1}(\gamma^{(m)}_k\alpha_k) \tag{18}$$

that describe the deviations of the particle motions with respect to the propagation axis, the most important practical quantities associated with the vibrational modes are the values of the piezoelectric coupling factors, $k(\text{TE})_m$, and $k(\text{LE})_m$. These are obtained as follows. For the TE case:

$$e^0_m(\text{TE}) = \gamma^{(m)}_n\Xi_n, \tag{19}$$

$$k_m(\text{TE}) = |e^0_m(\text{TE})|/(\varepsilon'_{22}c_m)^{1/2}. \tag{20}$$

For the LE case:[2]

$$e^0_m(\text{LE}) = \gamma^{(m)}_n\Lambda_n, \tag{21}$$

$$e^{00}_m(\text{LE}) = e^0_m(\text{LE}) - \{\varepsilon'_{12}/\varepsilon'_{22}\}e^0_m(\text{TE}) \tag{22}$$

$$= \gamma^{(m)}_n\{\Lambda_n - (\varepsilon'_{12}/\varepsilon'_{22})\Xi_n\}, \tag{23}$$

$$\varepsilon^0_{11} = [\varepsilon'_{11} - (\varepsilon'_{12})^2/\varepsilon'_{22}], \tag{24}$$

$$k_m(\text{LE}) = |e^{00}_m(\text{LE})|/(\varepsilon^0_{11}c_m)^{1/2}. \tag{25}$$

III. MATERIALS IN CLASS 6mm

A. General

For the piezoelectric film component of high frequency bulk acoustic wave resonator (HBARs), materials of symmetry group 6mm represent attractive choices, because of their strong piezo-coupling factors and low cost. Materials belonging to symmetry class 6mm (wurtzite crystal structure) include zinc oxide (ZnO) and members of the lead zirconate titanate (PZT) family of polarized ferroelectric ceramics. Other representatives include barium titanate, and some binary semiconductors, e.g., AlN, GaN, and InN in the III-V system, and BeO, α-ZnS, CdS, and CdSe in the II-VI system.[8] The Van Dyke matrix[9] for class 6mm is given in Table I. For this class, the angle φ is irrelevant, so the X cut

TABLE I. Van Dyke matrix for symmetry class 6mm. ($c_{12}=c_{11}-2c_{66}$; $[c]$ is $[c^E]$; $[\varepsilon]$ is $[\varepsilon^S]$.)

$$\begin{bmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 & 0 & 0 & e_{31} \\ c_{12} & c_{11} & c_{13} & 0 & 0 & 0 & 0 & 0 & e_{31} \\ c_{13} & c_{13} & c_{33} & 0 & 0 & 0 & 0 & 0 & e_{33} \\ 0 & 0 & 0 & c_{44} & 0 & 0 & 0 & e_{15} & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 & e_{15} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & e_{15} & 0 & \varepsilon_{11} & 0 & 0 \\ 0 & 0 & 0 & e_{15} & 0 & 0 & 0 & \varepsilon_{11} & 0 \\ e_{31} & e_{31} & e_{33} & 0 & 0 & 0 & 0 & 0 & \varepsilon_{33} \end{bmatrix}$$

(film normal along X_1) is equivalent to the Y cut (film normal along X_2), and in Eqs. (14)–(16), the ζ_k are, in general:

$$\zeta_1 = \cos\psi, \tag{26}$$

$$\zeta_2 = \sin\theta\sin\psi, \tag{27}$$

$$\zeta_3 = -\cos\theta\sin\psi. \tag{28}$$

Thin-film resonators are most often fashioned with the polar direction along the film normal, producing a thickness-stretch (extensional) motion. Sometimes the polar axis is made to lie in the plane of the film, resulting in a thickness-shear mode of vibration. In both cases, the driving voltage is impressed across two electrodes placed on the major surfaces. This situation can be generalized in two simple ways, by permitting both the polar axis and the exciting electric field directions to be non-collinear, and to be oblique to the thickness. There have been few reports of transducers with oblique orientation because of perceived difficulties in manufacture. New materials and technologies can be expected to ease this impediment in the future. Alternative electroding arrangements can provide oblique driving fields.

The point group symmetry 6mm results in several simplifications of the general case treated in the last section, even when the polar axis is oblique. First, the gamut of allowable orientations is limited. For the most general type of crystal, the one-dimensional vibrational characteristics follow from specification of the two angles that determine a plane in space. For 6mm symmetry, however, the basal plane is isotropic, so the angle of longitude is irrelevant, and only the single angle of latitude is meaningful. ("Latitude" in this usage refers to the angle between the film normal and the direction of the polar axis.) Second, one of the shear modes always remains a pure mode, regardless of angle, that is, it is not coupled to any other motion; the other two modes are generally coupled together.

Regarding the direction of the electric field driving the motion, the traditional electroding scheme, where the electrodes are placed on the film major surfaces, is referred to as "thickness excitation" because the resulting field points along the film thickness. One may alternatively configure the electrode system to the sides, producing a lateral field in the plane of the film. Lateral excitation is more commonly used for driving g bars than plates or films. By a combination of

b	c_{66}^E	$c_b^E=c_{66}^E\cos^2\theta+c_{44}^E\sin^2\theta$	c_{44}^E degenerate mode
c	$\bar{c}_{44}=c_{44}^E+(e_{15})^2/\varepsilon_{11}$	$\bar{c}_c$	c_{44}^E degenerate mode

TABLE III. Piezocoupling factors for thickness modes of Y-cut crystals of symmetry class 6 mm.

Mode	TE	LE(E_1)	LE(E_3)	LE(ψ)
a	0	0	$|e_{31}|\,(\varepsilon_{33}c_{11}^E)^{-1/2}$	$|e_{31}\sin\psi|\,(\varepsilon_{11}^o c_{11}^E)^{-1/2}$
b	0	0	0	0
c	$|e_{15}|\,(\varepsilon_{11}\bar{c}_{44})^{-1/2}$	0	0	0

electroding arrangements, it is possible to produce a composite driving electric field that is neither parallel nor perpendicular to the film normal. The analysis, however, shows that the problem must be broken down into the two canonical forms of TE and LE, and each is treated separately, because the effective material coefficients involved are somewhat different for each form.

B. Method of CB applied to the wurtzite structure

Many III-V and II-VI crystals have point group symmetry 6mm, the wurtzite structure. The piezoelectric matrix contains three independent coefficients, e_{15}, e_{31}, and e_{33}. Orientations in this symmetry class are limited in their variety to a single rotation about any axis normal to the polar axis. A synopsis of the behavior of films or plates of class 6 mm material piezoelectrically driven in simple thickness modes is given in the following. The polar axis is denoted P; P' is the direction of projection of P onto the plane of the film, and $\tilde{n}$ is the direction of the film normal.

For P parallel to the film normal (Z cut), all modes are pure, with the shears degenerate. TE drives only the extensional mode. LE drives only the shear mode, and displacement is along the LE field direction.

For P in the plane of the film (Y cut), all three modes are pure, with one shear mode having displacement along P, and the other having displacement in the plane, but normal to P. TE drives only the shear mode having motion along P; its effective stiffness is $\bar{c}_{44}=c_{44}^E+e_{15}^2/\varepsilon_{11}$. LE drives only the extensional mode, providing there is a component of E_{lateral} along P; its effective stiffness is c_{11}^E.

When the unique axis P is neither parallel nor perpendicular to the film normal, one shear mode remains pure, and inert to TE (polarized perpendicular to both P and to the film normal). It may be either the "b" or "c" mode, depending on the material and angle. The other two modes are coupled, and TE drives both. All three modes, the pure shear and the two coupled modes, are driven by LE if E_{lateral} is neither normal nor parallel to P'. If E_{lateral} is normal to P', only the pure shear mode, polarized normal to P' (and therefore along E_{lateral}), is driven by LE. If E_{lateral} is parallel to P', only the two coupled modes are driven by LE (since they both have components of displacement along E_{lateral}), and the motions are normal to that of the inert pure shear mode, i.e., in the plane containing P' and the film normal.

For a rotated cut, with P oblique to the film normal, the pure shear perpendicular to both P' and $\tilde{n}$ is driven by LE (for a rotated Y cut, the required E is E_1); although k(LE) goes to zero at the Y cut. At the Y cut ($\theta=0°$) the stiffness is

c_{66}^E; for the Z cut, it is c_{44}^E. For θ between 0° and 90°, the stiffness for this pure mode transforms as $(c_{66}^E\cos^2\theta+c_{44}^E\sin^2\theta)$.

The coupled shear and extensional modes (in the plane of P' and $\tilde{n}$), for a rotated cut, are driven by LE (for a rotated Y cut, the required E is E_3'). At the Y cut, the mode coupling ceases, and k(LE) drives the a mode only. At the Z cut, the mode coupling likewise ceases, but now k(LE) drives the degenerate shear polarized normal to P with isotropic azimuthal piezocoupling; the displacement is along the applied field. At the Y cut, the a mode stiffness is c_{11}^E; for the Z cut, it is $\bar{c}_{33}=c_{33}^E+e_{33}^2/\varepsilon_{33}$. For θ between 0° and 90°, the stiffness for this mode transforms in a somewhat complicated manner.

The above-mentioned results are detailed in the following tables. Table II gives the effective elastic stiffnesses for the three modes of Y-cut, rotated-Y-cut, and Z-cut, class 6 mm piezoelectrics. Tables III–V give the piezocoupling factors for the three modes of Y-cut, Z-cut, and rotated-Y-cut, class 6 mm piezoelectrics, respectively. In Tables III and V, the additional abbreviations and relations hold:

$$e_a^0(\text{TE}) = [\gamma_2^{(a)}\Xi_2 + \gamma_3^{(a)}\Xi_3], \tag{29}$$

$$e_a^0(\text{LE}) = [\gamma_2^{(a)}\Lambda_2 + \gamma_3^{(a)}\Lambda_3], \tag{30}$$

$$e_c^0(\text{TE}) = [\gamma_2^{(c)}\Xi_2 + \gamma_3^{(c)}\Xi_3], \tag{31}$$

$$e_c^0(\text{LE}) = [\gamma_2^{(c)}\Lambda_2 + \gamma_3^{(c)}\Lambda_3], \tag{32}$$

where

$$\Xi_2 = (e_{15} + e_{31})\cos\theta\sin\theta, \tag{33}$$

$$\Xi_3 = [e_{15}\cos^2\theta + e_{33}\sin^2\theta], \tag{34}$$

$$\Lambda_2 = [e_{15}\sin^2\theta - e_{31}\cos^2\theta]\sin\psi, \tag{35}$$

$$\Lambda_3 = (e_{15} - e_{33})\cos\theta\sin\theta\sin\psi, \tag{36}$$

$$|e_a^{00}(\text{LE})| = |e_a^0(\text{LE}) - (\varepsilon_{12}'/\varepsilon_{22}')e_a^0(\text{TE})|$$
$$= |(\gamma_2^{(a)}\Lambda_2 + \gamma_3^{(a)}\Lambda_3) - (\varepsilon_{12}'/\varepsilon_{22}')(\gamma_2^{(a)}\Xi_2 + \gamma_3^{(a)}\Xi_3)|, \tag{37}$$

TABLE IV. Piezocoupling factors for thickness modes of Z-cut crystals of symmetry class 6mm.

Mode	TE	LE(E_1)	LE(E_3)	LE(ψ)
a	$|e_{33}|\,(\varepsilon_{33}\bar{c}_{33})^{-1/2}$	0	0	0

TABLE V. Piezocoupling factors for thickness modes of rotated-Y-cut crystals of symmetry class $6mm$.

Mode	TE	LE(E_1)	LE(E_3')	LE(ψ)
a	$\lvert e_a^0 \rvert \, (\varepsilon_{22}' \bar{c}_a)^{-1/2}$	0	$\lvert e_a^{oo} \rvert \, (\varepsilon_{11}^o \bar{c}_a)^{-1/2}$	$\lvert e_a^{oo} \rvert \, (\varepsilon_{11}^o \bar{c}_a)^{-1/2}$
b	0	$\lvert e_{15} \sin\theta \rvert \, (\varepsilon_{11} c_b^E)^{-1/2}$	0	$\lvert e_{15} \sin\theta \cos\Psi \rvert \, (\varepsilon_{11}^o c_b^E)^{-1/2}$
c	$\lvert e_c^0 \rvert \, (\varepsilon_{22}' \bar{c}_c)^{-1/2}$	0	$\lvert e_c^{oo} \rvert \, (\varepsilon_{11}^o \bar{c}_c)^{-1/2}$	$\lvert e_c^{oo} \rvert \, (\varepsilon_{11}^o \bar{c}_c)^{-1/2}$

$$\lvert e_c^{00}(\mathrm{LE}) \rvert = \lvert e_c^0(\mathrm{LE}) - (\varepsilon_{12}'/\varepsilon_{22}') e_c^0(\mathrm{TE}) \rvert$$
$$= \lvert (\gamma_2^{(c)}\Lambda_2 + \gamma_3^{(c)}\Lambda_3) - (\varepsilon_{12}'/\varepsilon_{22}')(\gamma_2^{(c)}\Xi_2 + \gamma_3^{(c)}\Xi_3) \rvert. \tag{38}$$

For the Y cut, $\gamma^{(a)} = [0,1,0]$ and $\gamma^{(c)} = [0,0,1]$, and for the Z cut, $\gamma^{(a)} = [0,0,1]$ and $\gamma^{(c)} = [0,1,0]$, but for rotated orientations, a two-dimensional eigenvalue problem must be solved. The matrix consists of the elements Γ_{22}^*, Γ_{23}^*, and Γ_{33}^* where

$$\Gamma_{22}^* = [c_{11}\cos^2\theta + c_{44}\sin^2\theta$$
$$+ (e_{15}+e_{31})^2 \cos^2\theta \sin^2\theta/\varepsilon_{22}'], \tag{39}$$

$$\Gamma_{33}^* = [c_{44}\cos^2\theta + c_{33}\sin^2\theta$$
$$+ (e_{15}\cos^2\theta + e_{33}\sin^2\theta)^2/\varepsilon_{22}'], \tag{40}$$

$$\Gamma_{23}^* = [\cos\theta \sin\theta][(c_{13}+c_{44}) + (e_{15}+e_{31})[e_{15}\cos^2\theta$$
$$+ e_{33}\sin^2\theta]/\varepsilon_{22}']. \tag{41}$$

The eigenvalues are $\bar{c}_a$ and $\bar{c}_b$ and

$$\gamma^{(a)} = [0, \gamma_2^{(a)}, \gamma_3^{(a)}], \tag{42}$$

$$\gamma^{(c)} = [0, \gamma_2^{(c)}, \gamma_3^{(c)}] \tag{43}$$

are the eigenvectors.

The rotated permittivities are

$$\varepsilon_{11}' = \varepsilon_{11} + \Delta \cos^2\theta \sin^2\psi, \tag{44}$$

$$\varepsilon_{12}' = -\Delta \cos\theta \sin\theta \sin\psi, \tag{45}$$

$$\varepsilon_{22}' = \varepsilon_{11}\cos^2\theta + \varepsilon_{33}\sin^2\theta, \tag{46}$$

$$\varepsilon_{11}^0 = \varepsilon_{11}' - (\varepsilon_{12}')^2/\varepsilon_{22}'$$
$$= \varepsilon_{11} + \Delta\cos^2\theta\sin^2\psi(1 - \Delta\sin^2\theta/\varepsilon_{22}'), \tag{47}$$

where

$$\Delta = (\varepsilon_{33} - \varepsilon_{11}). \tag{48}$$

For $\varepsilon_{33} \neq \varepsilon_{11}$, ε_{11}^0 is a function of ψ (albeit usually a weak one), so k_m (LE) is not strictly proportional to $\lvert\cos(\psi)\rvert$. If $(\varepsilon_{11}-\varepsilon_{33})=0$, then it is cosinusoidal in ψ; as the difference widens, the departure grows. The ε_{11}^0 variation is independent of considerations of piezoelectricity, and applies to all uniaxial crystals, for rotations in the basal plane.

The considerations given here for crystal class $6mm$ apply equally to members of crystal class $4mm$, which includes some of the newer single-crystal ferroelectrics. Both classes possess identical Van Dyke matrices, with the exception that in $4mm$ c_{12} is an independent constant.

C. Piezoelectric ZnO thin films

Zinc oxide (ZnO) is a wide band gap (3.37 eV) II-VI semiconductor with strong piezocoupling. Through proper doping to achieve high resistivity, it can be made a piezoelectric material with strong piezoelectric coupling coefficients. It can also be made highly conductive to serve as an electrode in certain HBAR configurations.[10] It is capable of being deposited on technologically important substrates as lattice-matched, oriented thin films by a variety of techniques, such as molecular-beam epitaxy, metalorganic chemical vapor deposition, metalorganic vapor phase epitaxy, and various types of sputtering. Measured elastic, piezoelectric, and dielectric values are given in Tables VI(a) and VI(b) for film and bulk growth; Ref. 13 contains ZnO temperature coefficients.

Of particular interest is the capability of growing oriented films of ZnO and its alloys on various facets of crystal sapphire. Depending on the particular application, it may be advantageous to orient the transducer polar axis either normal to the film thickness (appropriate to TE), or in the plane of the film (for LE). For measured orientations of ZnO grown on various planes of sapphire, see Ref. 14, and references therein, as well as Ref. 15.

We have found[10,16] that the alloy $Mg_xZn_{1-x}O$ retains the $6mm$ piezoelectric character for $x < 0.33$ to 0.35, and, for

$$

greater x values, transforms to the nonpiezoelectric cubic rocksalt point group $m3m$ characteristic of silicon and diamond. Moreover, depending on the facet upon which the film is grown, this new ternary composition allows either TE and LE to be utilized, with higher acoustic velocities, and only a slight diminution of the piezocoupling, from the pure ZnO value. Material constants for $Mg_xZn_{1-x}O$ may be adequately calculated by transforming the constants of MgO from the rocksalt to the wurtzite phase, and using Vegard's law (parameters of substitutional solid solutions vary linearly between the values for the components) to combine the wurtzite ZnO and MgO constants.[10] In addition to ZnO and $Mg_xZn_{1-x}O$ compositions, the $6mm$ nitrides, such as GaN[17] and AlN, show considerable future promise as piezoelectric transducers for HBAR/TFR devices.

IV. MATERIALS IN CLASS $3m$

In this section we address some acoustic properties of materials in symmetry class $3m$, and apply the CB formalism to Y cuts of the strongly piezoelectric refractory oxides lithium niobate and lithium tantalate. The Van Dyke matrix for class $3m$ is shown in Table VII. Material values for $LiNbO_3$ and $LiTaO_3$ are found in Ref. 18; pertinent subsets are listed in Tables VIII(a) and VIII(b).

According to the IEEE orientational definitions, a Y cut is specified by $(YX1)\theta=0$, and $\alpha_2=1$. With the matrix elements from Table VII inserted in Eqs. (10)–(13), along with the $LiNbO_3$ values from Tables VIII(a) and VIII(b), the piezoelectrically stiffened gammas are

$$\Gamma_{11}^* = \Gamma_{11} + (\Xi_1)^2/\varepsilon_{11}^S = c_{66}^E = 72.09 \text{ GPa}, \qquad (49)$$

$$\Gamma_{22}^* = \Gamma_{22} + (\Xi_2)^2/\varepsilon_{11}^S = c_{11}^E + (e_{22})^2/\varepsilon_{11}^S = 213.43 \text{ GPa}, \qquad (50)$$

$$\Gamma_{33}^* = \Gamma_{33} + (\Xi_3)^2/\varepsilon_{11}^S = c_{44}^E + (e_{15})^2/\varepsilon_{11}^S = 93.45 \text{ GPa}, \qquad (51)$$

$$\Gamma_{23}^* = \Gamma_{23} + (\Xi_2\Xi_3)/\varepsilon_{11}^S = -c_{14}^E + (e_{22}e_{15})/\varepsilon_{11}^S$$
$$= 14.30 \text{ GPa}, \qquad (52)$$

$$\Gamma_{13}^* = \Gamma_{13} + (\Xi_1\Xi_3)/\varepsilon_{11}^S = 0, \qquad (53)$$

$$\Gamma_{12}^* = \Gamma_{12} + (\Xi_2\Xi_1)/\varepsilon_{11}^S = 0. \qquad (54)$$

Setting the Eq. (17) determinant

$$|\Gamma_{jk}^* - c\delta_{jk}| = \begin{vmatrix} (\Gamma_{11}^* - c) & 0 & 0 \\ 0 & (\Gamma_{22}^* - c) & \Gamma_{23}^* \\ 0 & \Gamma_{23}^* & (\Gamma_{33}^* - c) \end{vmatrix} \qquad (55)$$

equal to zero yields the stiffness eigenvalues. By inspection, one root is $c=c_{66}^E$; this is the elastic stiffness of the pure shear mode. The corresponding velocity is

$$v_{\text{pure-shear}} = (c_{\text{pure-shear}}/\rho)^{1/2} = (c_{66}^E/\rho)^{1/2} = 3940.6 \text{ m/s}. \qquad (56)$$

The rest of the determinant gives the quadratic for the effective stiffnesses of the quasi-shear and quasi-extensional modes:

$$(\Gamma_{22}^* - c)(\Gamma_{33}^* - c) - (\Gamma_{23}^*)^2 = 0, \qquad (57)$$

yielding

$$c_{\text{quasi-ext}} = 215.11 \text{ GPa}, \qquad (58)$$

$$c_{\text{quasi-shear}} = 91.77 \text{ GPa}, \qquad (59)$$

and

$$v_{\text{quasi-ext}} = (c_{\text{quasi-ext}}/\rho)^{1/2} = 6806.8 \text{ m/s}, \qquad (60)$$

$$v_{\text{quasi-shear}} = (c_{\text{quasi-shear}}/\rho)^{1/2} = 4446.0 \text{ m/s}. \qquad (61)$$

The piezocoupling calculations follow from Eqs. (18) to (25), and are listed in Table IX for both TE and LE excitations of Y-cut lithium niobate and lithium tantalate.

FIG. 2. Growth habits of crystalline sapphire (symmetry class $\bar{3}m$), showing the natural *a*, *r*, and *n* facets, and basal plane *c*. *X* is the digonal axis, *Z* the trigonal axis, and *Y-Z* is the mirror plane.

V. MATERIALS IN CLASS $\bar{3}m$

Sapphire (α-Al_2O_3, corundum, alumina, ruby, emery) belongs to symmetry point group $\bar{3}m$; other members of this class include hematite (Fe_2O_3), and calcite ($CaCO_3$). Some salient physical characteristics are listed in Table X. Sapphire is a technologically popular and important crystal, particularly it is a primary substrate for growing the wide band gap semiconductor GaN. It has the same elastic stiffness matrix as lithium niobate (class $3m$) and quartz (class 32). Its Van Dyke matrix is that of Table VII with the piezoelectric $[e]$ entries set to zero. It possesses a trigonal rotatory inversion axis (Z) with mirror plane. Three equivalent secondary axes, lying 120° apart, are chosen parallel to the diad axes. *X* coincides with any one of the secondary axes, and *Y* is perpendicular to *Z* and *X* to form a right-hand coordinate system.[6,7] Growth habits of crystalline sapphire, showing the natural *a*, *r*, and *n* facets, and basal plane *c* are seen in Fig. 2. In the crystallographic literature, an *a* face is referred to as a "second-order prism." Similarly, *r* and *R* faces are referred to as "positive and negative rhombohedrals," respectively.

Three mirrors lie in the planes the normals to the *a* faces make with the *Z* axis, and divide adjacent *n* facets. A mirror plane is designated *m*, and called a "first-order prism." The normal to an *r* face lies in the (*Y-Z*) mirror plane. The *r* and *R* planes in sapphire are akin to the *BT* and *AT* (rotated-*Y*-cuts) of quartz;[19] wave propagation is perpendicular to the digonal axis, and at an angle to the trigonal axis.

TABLE X. Room temperature physical characteristics of sapphire.

Quantity	Unit	Value
Mass density	kg/m^3	3982
Molecular weight		101.96
Debye temperature	K	1033.9
Melting temperature	K	2325±5°
Specific heat capacity	J/(K mol)	79.45
Thermal conductivity	W/(m K)	K_1=25.2
		K_3=23.1
Lattice parameters	nm	a=0.475 70
		c=1.298 77
Morphological axial ratio	$\rho=c/2a$	1.365 11
Mohs hardness		9
The Miller indices used here for sapphire are pertinent to the morphological axial ratio ($c/2a$). Some authors and vendors use the ratio (c/a), and this can be a source of confusion. For example, $(1,0,\bar{1},1)$ specifies an *r* plane (with an angle of 57.62° between its normal and the *c*-plane normal) if the ratio ($c/2a$) is used, but would specify an *R* plane (with an angle of 38.25° between its normal and the *c*-plane normal) if (c/a) were to be used. The presence of c_{14} in the Van Dyke matrix gives a polarity to the *X* axis that depends on the sign of c_{14}. We take c_{14} to be negative, which determines the sign of the angle θ for rotated-*Y*-cuts, $(YX1)\theta$. The *r* plane occurs for positive θ values, and the *R* plane for negative θ values with this convention. In the following labeling of the planes, which establishes a concordance between some of the planes in sapphire and the nomenclature used to describe quartz, the morphological axial ratio ($c/2a$) is used to identify the planes in accordance with Belyaev,[20]

c plane: $(0,0,0,1) \sim Z$ cut,

m planes: $(1,0,\bar{1},0);(0,1,\bar{1},0);(\bar{1},1,0,0);(\bar{1},0,1,0);$

$\times (0,\bar{1},1,0);(1,\bar{1},0,0) \sim Y$ cut,

r planes: $(1,0,\bar{1},1);(\bar{1},1,0,1);(0,\bar{1},1,1)$

$\sim BT$ cut(r closer to Z cut);rotated $-Y-$ cut,

R planes: $(\bar{1},0,1,2);(1,\bar{1},0,2);(0,1,\bar{1},2)$

$\sim AT$ cut(R closer to Y cut);rotated $-Y-$ cut,

a planes: $(2,\bar{1},\bar{1},0);(\bar{1},2,\bar{1},0);(\bar{1},\bar{1},2,0) \sim X$ cut,

n planes: $(2,2,\bar{4},3);(\bar{2},4,\bar{2},3);(\bar{4},2,2,3);(\bar{2},\bar{2},4,3);$

$\times (2,\bar{4},2,3);(4,\bar{2},\bar{2},3) \sim$ rotated $-X-$ cuts.

Much work has been reported on various features of sapphire and its characterization.[20,21] An extensive review of extant literature leads us to conclude that the best present-day values for the elastic stiffnesses of sapphire, and their temperature variation are those of Goto *et al.*;[22] these are given in Table XI(a) for room temperature. The thermoelastic values of White and Roberts[23] in Table XI(b) are similarly to

TABLE XI. (a) Sapphire elastic stiffnesses and temperature coefficients (RT) and (b) sapphire thermoelastic coefficients (RT).

(a)		c_{11} (GPa)	c_{33} (GPa)	c_{44} (GPa)	c_{66} (GPa)	c_{13} (GPa)	c_{14} (GPa)	(c_{12}) (GPa)	ρ (MPa/K)	Ref.
	c_{ij}	497.3	500.9	146.8	167.25	116.0	−21.90	162.8	3982	22

$^a T_c = (\partial c/\partial T)/c$.

be preferred. In general, the stiffnesses are about five times those of quartz,[19] but the velocity anisotropy is much less because $c_{11}=c_{22}\approx c_{33}$ and $c_{44}=c_{55}\approx c_{66}$.

Application of the CB formalism of Sec. II discloses the following behavior for different orientations:

X cut ($\alpha_1=-1, \alpha_2=0, \alpha_3=0$): Propagation along X; $\Gamma_{11}=c_{11}$ uncoupled longitudinal wave with motion along X axis; two coupled shear waves.

Y cut ($\alpha_1=0, \alpha_2=1, \alpha_3=0$): Propagation along Y; $\Gamma_{11}=c_{66}$ uncoupled shear wave, with motion along X axis; coupled quasi-shear and quasi-longitudinal waves.

Z cut ($\alpha_1=0, \alpha_2=0, \alpha_3=1$): Propagation along Z; three uncoupled waves, longitudinal motion along Z axis; two degenerate shear waves with motions perpendicular to Z.

Rotated-Y-cut ($\alpha_1=0, \alpha_2=\cos\theta; \alpha_3=\sin\theta$): Propagation perpendicular to X; Γ_{11} uncoupled shear wave, with motion along X axis; coupled quasi-shear and quasi-longitudinal waves.

Rotated X cut ($\alpha_1=-\cos\theta, \alpha_2=0, \alpha_3=\sin\theta$), or any arbitrarily doubly rotated cut ($\alpha_1=-\sin\varphi\cos\theta; \alpha_2=\cos\varphi\cos\theta; \alpha_3=\sin\theta$): Propagation perpendicular to Y; three coupled quasi-shear and quasi-longitudinal waves.

Table XII contains the acoustic velocities and direction cosines for plane wave propagation in various directions in sapphire. The angles θ for the r, R planes are the complements of the 57.62° and 38.25° values mentioned earlier. The columns headed (−r) and (+R) contain calculations for θ values that are the negatives of those for these planes; this is done to show how little acoustic anisotropy is present for the rotated-Y-cut values ($\varphi=0$) given; this lack is maintained for all general doubly rotated cuts ($\varphi\neq 0$) in sapphire. The direction cosines referred to the crystallographic coordinates (γ) are related to those referred to the plate coordinates (β) by the transformation $\beta_{ik}=\alpha_{ij}\gamma_{jk}$.

VI. COMPOSITE RESONATORS

A. Single-mode HBARs

The foregoing has considered the acoustic behavior of piezofilm transducers and substrates separately. In this sec-

tion the mode structure of composites formed by joining the layers is briefly considered. Virtually all of the HBAR structures constructed to date utilize a single acoustic mode. In the standard ZnO/Al_2O_3 configuration, the zinc oxide is deposited on a sapphire face cut perpendicular to its trigonal axis (c plane); the ZnO is found to grow with its polar axis normal to this face. The trigonal axis of the sapphire and the hexagonal (polar) axis of the zinc oxide are therefore parallel. Piezoelectric excitation of the ZnO film by an electric field in its thickness direction (TE) drives the pure longitudinal mode in the ZnO, as discussed in Sec. III. This pure mode couples energy into the sapphire by virtue of the mechanical attachment of the film to the substrate. Within the sapphire substrate, it is found that a pure longitudinal plane wave is allowed. It propagates along the Z axis of the sapphire. Thus the single driven mode in the zinc oxide gives rise to only a single wave type in the sapphire. The two other pure shear waves in the ZnO and the two other pure shear waves in the sapphire are unexcited. If the sapphire substrate bearing the ZnO film is terminated at its other end by a plane parallel to the film, then the longitudinal wave will be reflected thereat, and the device is regarded as a resonator supporting motions of a single mode type.

Alternatively, using the same ZnO-sapphire configuration, piezoelectric excitation of the piezofilm by an X-directed electric field in the plane of the film-substrate interface (lateral excitation, LE), drives a pure shear mode in the ZnO, which couples to pure shear motion in the sapphire. The two other pure modes in the ZnO (one longitudinal, and one shear) and the two pure waves in the sapphire (again, one longitudinal, and one shear) are unexcited.

In either of these TE or LE cases, the undriven wave types are irrelevant to the electrical characteristics of the device measured between the two electrodes. The resulting situation is that of a single piezoelectrically driven mode in the film mechanically driving a single piezoelectrically inert mode in the substrate by the surface tractions at the film-substrate interface. These single-mode to single-mode resonator cases are of some complexity, but have been treated previously in the literature.[1]

However, for other orientations of the piezoelectric film and substrate, a plurality of modes will be excited in general, even in the one-dimensional simple thickness mode approximation. While the ensuing mode structure is rendered more complicated with these orientations, the opportunities for utilization of the resulting multi-mode spectrum is also enhanced. Not only may new types of multi-mode HBARs and TFRs be constructed, but one may also use the increased gamut of possibilities in reverse, to infer the elastic properties of newly developed but poorly characterized substrate materials such as langasite and its isomorphs.[24] Family members include: langasite ($La_3Ga_5SiO_{14}$); langanite ($La_3Ga_{11/2}Nb_{1/2}O_{14}$); and langatate ($La_3Ga_{11/2}Ta_{1/2}O_{14}$). These class 32 crystals offer the promise of exceedingly low acoustic loss, combined with excellent temperature behavior.

B. Multi-mode HBARs

The CB formulation of Sec. II discloses the possibilities arising in the more intricate and interesting case where a single mode is piezoelectrically driven in a film of ZnO deposited on a planar substrate of sapphire as before, but where four modes (two in each medium) are coupled by the mechanical boundary conditions at the interface. This situation arises when the ZnO/sapphire components assume different crystallographic orientations, and leads to enlarged prospects for producing novel and practical devices. In one such demonstrated device,[10] the structure consists of $Al/Mg_xZn_{1-x}O/n+\text{-}ZnO$ on an r-plane sapphire plate, where Al and the n-type doped ZnO thin film serve as top and bottom electrodes, respectively.

For $Mg_xZn_{1-x}O$ films grown on $r\text{-}Al_2O_3$ substrates, the orientational relationship is $(11\bar{2}0)Mg_xZn_{1-x}O\|(01\bar{1}2)Al_2O_3$ and $[0001]Mg_xZn_{1-x}O\|[01\bar{1}1]Al_2O_3$. Thus the $Mg_xZn_{1-x}O$ films have their c axis in the growth plane, and perpendicular to the $\bar{3}mX$ axis. As a consequence, piezoelectric excitation of the $Mg_xZn_{1-x}O$ film by an electric field in its thickness direction (TE), drives the pure shear mode in the film, which mechanically forces the two elastically coupled modes (quasi-longitudinal and quasi-shear) in the sapphire. This, in turn, leads to additional mechanical coupling with the pure longitudinal mode in the $Mg_xZn_{1-x}O$ via the mechanical boundary conditions at the interface.

Application of an electric field in the plane of the $Mg_xZn_{1-x}O$ film (LE) drives piezoelectrically the pure longitudinal mode in the film. The two elastically coupled modes (quasi-longitudinal and quasi-shear) in the sapphire substrate are thereby forced. This, in turn, leads to further coupling with one of the pure shear modes in the $Mg_xZn_{1-x}O$ via the mechanical boundary conditions at the interface.

Table XIII gives the excitation possibilities arising when ZnO or MgZnO is deposited on various facets of sapphire (or any class $\bar{3}m$, $3m$, or 32 material). It is formed using the results of the CB analysis of Sec. II. Although multi-mode HBARs may be fashioned from any oblique orientations of sapphire, the use of r- or R-plane (rotated-Y-cut) material appears at present to be most desirable because of commercial availability. Table XIV gives the excitation possibilities arising when a Y-cut crystal of class $3m$ is used as the piezoelectric excitation layer. Examples include a Y-cut $LiNbO_3$ crystal bonded to sapphire for resonant ultrasound spectroscopy, or a $LiNbO_3$ or $LiTaO_3$ thin film deposited on a sapphire substrate.

TABLE XIII. Acoustic modes excited in thin-film ZnO/Al_2O_3 composite.[a]

| Substrate Al_2O_3 Orientation | Thin film ZnO | Excitation method | | | |
| | | Thickness (TE) | | Lateral (LE) | |
		ZnO	Al_2O_3	MgZnO	Al_2O_3
c plane	c plane	p L	p L	p S	p S
r,R planes	a plane	p S	p S, q-L, q-S	p L	q-L, q-S

[a]Angle between $LiNbO_3$ X_1 axis and the X_1' axis of Al_2O_3 substrate.
[b]Two coupled shear modes.

VII. CONCLUSIONS

We have presented the Christoffel-Bechmann method for calculating acoustic wave speeds and coupling coefficients of arbitrarily oriented piezoelectric plates and films, for electric fields impressed either along the thickness or laterally. The formalism has been applied to characterize the generic behavior of plate composites consisting of a crystal substrate surmounted by a piezoelectric film that drives the structure in resonant modes as part of a high stability oscillator or low loss filter circuit. The calculations apply generally to crystals of any class. The piezoelectric portion is made specific for films of crystal class $6mm$ with arbitrary orientation on the substrate, and the substrate calculations are specified for class $\bar{3}m$ materials because these combinations appear to encompass the most desirable current material classes, although the $\bar{3}m$ results apply also to any substrate crystal in the $3m$ or 32 crystal classes. Zinc oxide and sapphire have been used in an example of the acoustic resonator structure.

Many applications of active sound transmission control (ASTC) require lightweight partitions, high transmission loss over a broad frequency range, simple control strategies, and consistent performance for various source and receiving space conditions. In recent years, researchers have begun to investigate active segmented partitions (ASPs) because of their potential to meet such requirements. This paper provides a theoretical and numerical analysis of four ASP module configurations that are candidates for these applications. Analogous circuit methods are used to provide normal-incidence transmission loss and reflection coefficient estimates for their passive and active states. The active control objective for each configuration is to induce global vibration control of various transmitting surfaces through direct vibration control of a *principal* transmitting surface. Two characteristic single-composite-leaf (SCL) configurations are unable to use the strategy effectively. However, design adjustments are investigated to improve their performances. Two double-composite-leaf (DCL) configurations use the strategy much more effectively to produce efficient global control of transmitting surface vibrations and achieve high transmission loss over a broad frequency range. This is achieved through a minimum volume velocity condition on the *source* side of each module. One DCL configuration enhances module isolation in full ASP arrays while satisfying other design and performance criteria. © 2005 Acoustical Society of America. [DOI: 10.1121/1.1992767]

LIST OF SYMBOLS

B = Magnetic flux density in magnet air gap of moving-coil actuator

c = Speed of sound in fluid medium

C_{Mn} = Effective mechanical compliance of nth module element

C_{Mmn} = Effective mechanical compliance coupling mth and nth module elements ($m \neq n$)

$\hat{e}_g$ = Complex open-circuit voltage amplitude of electrical control source (signal generator)

f = Frequency

G_A = Acoustic ground (ambient reference pressure)

G_M = Mechanical ground (zero reference velocity)

I = Roman numeral representing source side of module

II = Roman numeral representing transmitting side of module

j = $\sqrt{-1}$

k = Acoustic wave number, $= \omega/c$

$\tilde{k}$ = Complex acoustic wave number accounting for propagation losses, $= k - j\alpha$

L = Effective cavity length in double-composite-leaf modules

l = Effective length of voice coil conductor in magnet air gap of moving-coil actuator

L_E = Electrical inductance of voice coil in moving-coil actuator

m = Integer index representing given module element, = 1, 2, 3, or 4

M_{Mn} = Effective mechanical mass of nth module element

n = Integer index representing given module element, = 1, 2, 3, or 4

$\hat{p}_i$ = Complex amplitude of constant normally incident acoustic pressure[1]

$\hat{p}_r$ = Complex amplitude of normally reflected acoustic pressure, $= \hat{p}_i - (\rho_0 c/S)\hat{U}_I$

$\hat{p}_t$ = Complex amplitude of normally transmitted acoustic pressure, $= (\rho_0 c/S)\hat{U}_{II}$

R = Complex pressure-amplitude reflection coefficient, $= 1 - (\rho_0 c/S)(\hat{U}_I/\hat{p}_i)$

R_E = Electrical resistance of voice coil in moving-coil actuator

R_g = Output resistance of electrical control source (signal generator)

R_{Mn} = Effective mechanical resistance of nth module element

R_{Mmn} = Effective mechanical resistance coupling mth and nth module elements ($m \neq n$)

S = Total cross-sectional area of ASP modules and hypothetical source and receiving space plane-wave tubes, $= S_1 + S_2 = S_3 + S_4$

S_n = Cross-sectional area of nth module element

TL = Normal-incidence sound transmission loss, $= 10 \log(1/\tau)$

$\hat{u}_n$ = Complex normal velocity amplitude of nth module element

$\hat{U}_\mathrm{I}$ = Volume velocity on side I (source side) of module

$\hat{U}_\mathrm{II}$ = Volume velocity on side II (transmitting side) of module

Z_{A1} = Acoustic impedance substitution for waveguide two-port network, $= j(\rho_0 \omega / \tilde{k} S) \tan(\tilde{k} L/2) \approx j(\rho_0 c / S) \tan(k L/2)$

Z_{A2} = Acoustic impedance substitution for two-port waveguide network, $= -j(\rho_0 \omega / \tilde{k} S) \csc(\tilde{k} L) \approx -j(\rho_0 c / S) \csc(k L)$

Z_{A3} = Acoustic impedance substitution, $= Z_{A1} + Z_{A2} + (\rho_0 c / S)$

Z_{A4} = Acoustic impedance substitution, $= Z_{A3} - [Z_{A2}^2 (Z_{M3} S_4^2 + Z_{M4} S_3^2 + Z_{M34} S^2)] / [(Z_{M3} S_4^2 + Z_{M4} S_3^2 + Z_{M34} S^2) Z_{A3} + Z_{M3} Z_{M4} + (Z_{M3} + Z_{M4}) Z_{M34}]$

Z_E = Isolated electric impedance of moving-coil actuator and electrical control source output, $= R_g + R_E + j\omega L_E$

Z_{Mn} = Effective mechanical impedance of nth module element, $= \begin{cases} j\omega M_{Mn}; \ n=1, \text{for module configurations 1 and 4} \\ R_{Mn} + j[\omega M_{Mn} - (1/\omega C_{Mn})]; \quad \text{otherwise} \end{cases}$

Z_{Mmn} = Effective mechanical impedance coupling mth and nth module elements $(m \neq n)$, $= R_{Mmn} + (1/j\omega C_{Mmn})$

α = Total thermoviscous absorption coefficient for acoustic losses in module cavities[2]

δ = In-plane width of thin transmitting surface

ρ_0 = Ambient density of fluid medium

σ_{Mn} = Effective mass surface density of nth element, $= M_{Mn}/S_n$

τ = Sound power transmission coefficient

ω = Angular frequency, $= 2\pi f$

I. INTRODUCTION

An active segmented partition (ASP) is a contiguous array of interconnected modules or elements that are actively controlled to reduce sound transmission between a source space and a receiving space. While limited investigations of ASPs have been conducted over the past few years,[3–16] in-depth comparative analyses of individual ASP module configurations are still needed to better understand their behaviors and to establish those that produce the highest transmission loss using simple control strategies.

A discrete ASP module is a complete subsection of an array, consisting of an integrated arrangement of active and passive components that are often acoustically and structurally small. If a module is well designed and controlled, it interacts with adjacent modules and supporting structures to yield effective control of sound transmission through the entire partition. Moreover, because an ASP typically consists of several identical modules, individual module design governs overall partition performance, as does the method of control, the method of structural support, and the method of module interconnection. Inadequate attention to any of these details

can lead to serious performance limitations (at least over substantial bandwidths) or relegate the approach to use with impractical control schemes.

Much of the past research in active sound transmission control (ASTC) has focused on difficulties of simultaneously controlling distributed structural and fluid media, and has essentially dismissed active vibration control of partitions as an effective means of controlling sound transmission.[17–22] The research has instead emphasized restructuring of distributed partition modes (rather than suppression of modes) to produce normal surface velocity distributions that transmit inefficiently into receiving spaces.[23] Nevertheless, researchers have found that effective reduction of sound transmission is generally accomplished by both partition modal amplitude reduction and modal restructuring,[24] with the weight of each mechanism depending upon specific geometric and structural-acoustic parameters.[5,25–27] As a result, the notion that active suppression of partition vibration yields ineffective control of sound transmission should not necessarily be applied as a generalization to all types of partitions.

Many complexities of distributed partition ASTC that have discounted vibration control methods result from a common condition in which secondary control force or moment distributions fail to match corresponding distributions produced by primary incident pressure disturbances. However, local physical conditions differ significantly for partitions segmented into small, discretely controlled components. In the case of ASPs, primary and secondary force distributions may be constrained to match more closely on key module surfaces, permitting more efficient simultaneous control of partition vibration and sound transmission. Moreover, efficient global control of transmitting surface vibrations produces sound transmission control applicable to many types of source and receiving spaces—to both their near fields and far fields.

Past ASTC research has also emphasized the behavior and positional optimization of error sensors and actuators in conjunction with active partitions and their surroundings. However, transducer positional optimization schemes are often based on unreliable assumptions of system time invariance. While adaptive controllers are able to modify and optimize control filters for time-varying systems, *a priori* optimized transducer locations must necessarily remain fixed and nonadaptive. What is needed, therefore, is a physical ASTC strategy that performs well for a variety of source and receiving spaces and remains essentially unaffected by their time-varying physical changes.

In recent years, the authors have identified several research considerations to address such needs and to otherwise improve the practicality and performance of ASTC systems. Other efforts have provided tools to conceptualize, model, and evaluate ASP modules, and have led to the proposal of seven criteria for their design and performance.[7,11–13,16] While some research efforts have shown that ASPs may be used to control transmitted volume velocity, sound power, total potential energy, or other receiving space field quantities (typically through elaborate multichannel sensing and

control), the seven criteria suggest that a much simpler scheme based on localized module vibration control may be advantageous.

This paper provides a comparative theoretical and numerical investigation of four ASP modules that were identified as candidates to satisfy the criteria. It explores their salient properties and a practical vibration-based scheme to control them. It compares normal-incidence transmission loss and reflection coefficient estimates for the modules in their passive and active states. The transmission loss estimates are well suited for comparison with classical normal-incidence transmission loss formulations. The analysis reveals basic problems and performance limitations for some configurations, and provides recommendations that may be used to enhance their effectiveness. It also identifies mechanisms of higher-performance vibration-controlled ASPs to enhance the viability of ASPs as ASTC solutions.

The underlying active control objective for each module is to induce global vibration control of its various transmitting surfaces by directly minimizing normal vibration of its *principal* transmitting surface. The analysis shows why single-composite-leaf (SCL) ASP modules are typically unable to use this simple strategy effectively. It then introduces two double-composite-leaf (DCL) modules that use the strategy much more effectively to produce efficient global vibration control of transmitting surfaces and achieve high transmission loss over a broad frequency range. One module is especially noteworthy in that it is designed to enhance implementation of full ASP arrays while satisfying the seven design and performance criteria mentioned above.

The investigation explores physical configurations of individual ASP modules rather than complete ASP arrays. However, it does so while acknowledging basic array requirements and characteristics. Results are derived assuming the use of moving-coil actuators, but they are representative of results based on other transducer formats. One-dimensional acoustic fields, lumped mechanical elements, analogous electro-mechano-acoustic circuits,[28,29] and time-harmonic excitation and control are employed to efficiently model and evaluate the configurations. Relevant assumptions and simplifications are made to limit otherwise unwieldy circuit diagrams to planar (though still somewhat complicated) forms. These steps are carried out carefully to avoid detracting from key module characteristics.

The following sections present theoretical developments for the four module configurations and numerical examples to illustrate their characteristic behaviors. They also discuss additional ASP module limitations and capabilities from a general standpoint.

II. SELECTED ASP MODULE CONFIGURATIONS

A. Configuration 1: Single composite leaf (SCL) with a surrounding finite-impedance interstice

The first module configuration is shown in Fig. 1. It includes an actuator with its diaphragm and a surrounding interstice to which the actuator frame is connected. Little consideration has previously been given to the effects that actuator control has on supporting ASP structures such as
FIG. 1. Isolated view of ASP module configuration 1. An actuator diaphragm vibrates freely but snugly within the frictionless interstice opening. Both the actuator diaphragm and the interstice are assumed to vibrate as pistons in normal translational rigid-body modes. Plane waves are normally incident and reflected in the source space, and normally transmitted in the receiving space. The model isolates effects of acoustic forces and reactive motor forces on the interstice. (After Ref. 7.)

this interstice. A common tacit assumption is that supporting structures have infinite impedance. However, this notion is invalid for actuators supported by many partition elements. When exposed finite-impedance elements form transmitting interstitial components, their vibrations can pose significant ASTC problems.

The supporting interstice is assumed to form a single lumped-element system around the periphery of the actuator diaphragm with effective mechanical mass, compliance, and resistance. The diaphragm is assumed to vibrate freely but snugly within its frictionless opening such that no sound can transmit through an intervening crack. Although lumped mechanical resistance and compliance elements are shown on opposite sides of the diaphragm and interstice, they are assumed to apply uniformly over the pertinent cross sections. The interstice and diaphragm are assumed to vibrate only in normal translational rigid-body modes, so the entire transmitting surface area of the module is composed of piston-like elements. The actuator magnet and frame are considered to be acoustically unobtrusive lumped masses that firmly attach to the interstice and vibrate in unison with it.

As suggested by the dashed horizontal lines in the drawing, the semi-infinite source space (side I) and receiving space (side II) are assumed to behave as one-dimensional low-frequency fields, such as those constrained by rigid-walled plane-wave tubes. A constant incident pressure wave impinges normally upon the module from the source space while another wave reflects normally back into the source space. A transmitted wave propagates normally into the receiving space, which has the same characteristic impedance as the source space.

1. Equivalent circuit modeling and analytical results

An equivalent circuit representing the complete system under time-harmonic excitation and control is shown in Fig. 2 (see the List of Symbols for clarification of labels). The circuit includes four ideal area gyrators that couple the me-
FIG. 2. Multiple-domain equivalent circuit representing ASP module configuration 1. (After Ref. 7.)

chanical mobility portion of the circuit to the acoustic impedance portions, the latter representing the source and receiving spaces. The control voltage input and combined electric impedance of the signal generator and actuator have been carried through an ideal transformer from the electric impedance domain to the mechanical mobility portion of the circuit.

Normal velocity amplitudes of the actuator diaphragm ($\hat{u}_1$) and the surrounding interstice ($\hat{u}_2$) may be derived directly from the circuit by (1) writing the defining equations for the ideal gyrators and ensuring they are satisfied with appropriate flow and potential senses; (2) writing the equations of motion in all physical domains using Kirchhoff's flow law (i.e., writing the nodal equations for all nodes except the ground reference nodes); and (3) solving the simultaneous algebraic equations for the velocities. Four nodal equations for the model reduce to two coupled equations of motion for the diaphragm and interstice, yielding the two complex amplitudes. They are functions of both incident pressure and electrical input voltage

$$\hat{u}_1 = \frac{2\hat{p}_i\left\{ Z_{M2}S_1 + \left[Z_{M12} + \frac{(Bl)^2}{Z_E} \right]S \right\} + \hat{e}_g\frac{Bl}{Z_E}(2\rho_0cS_2 + Z_{M2})}{\left[2\frac{\rho_0c}{S}S_1^2 + Z_{M1} + Z_{M12} + \frac{(Bl)^2}{Z_E} \right]\left[2\frac{\rho_0c}{S}S_2^2 + Z_{M2} + Z_{M12} + \frac{(Bl)^2}{Z_E} \right] - \left[2\frac{\rho_0c}{S}S_1S_2 - Z_{M12} - \frac{(Bl)^2}{Z_E} \right]^2},$$ (1)

$$\hat{u}_2 = \frac{2\hat{p}_i\left\{ Z_{M1}S_2 + \left[Z_{M12} + \frac{(Bl)^2}{Z_E} \right]S \right\} - \hat{e}_g\frac{Bl}{Z_E}(2\rho_0cS_1 + Z_{M1})}{\left[2\frac{\rho_0c}{S}S_1^2 + Z_{M1} + Z_{M12} + \frac{(Bl)^2}{Z_E} \right]\left[2\frac{\rho_0c}{S}S_2^2 + Z_{M2} + Z_{M12} + \frac{(Bl)^2}{Z_E} \right] - \left[2\frac{\rho_0c}{S}S_1S_2 - Z_{M12} - \frac{(Bl)^2}{Z_E} \right]^2}.$$ (2)

The total volume velocity produced by the vibrating surfaces is the same on both sides of the module:

$$\hat{U}_I = \hat{U}_{II} = \hat{u}_1S_1 + \hat{u}_2S_2 = \frac{2\hat{p}_i\left\{ Z_{M1}S_2^2 + Z_{M2}S_1^2 + \left[Z_{M12} + \frac{(Bl)^2}{Z_E} \right]S^2 \right\} + \hat{e}_g\frac{Bl}{Z_E}(Z_{M2}S_1 - Z_{M1}S_2)}{\left[2\frac{\rho_0c}{S}S_1^2 + Z_{M1} + Z_{M12} + \frac{(Bl)^2}{Z_E} \right]\left[2\frac{\rho_0c}{S}S_2^2 + Z_{M2} + Z_{M12} + \frac{(Bl)^2}{Z_E} \right] - \left[2\frac{\rho_0c}{S}S_1S_2 - Z_{M12} - \frac{(Bl)^2}{Z_E} \right]^2}.$$ (3)

This result is used to determine the transmitted pressure, sound power transmission coefficient, transmission loss, and source-side pressure-amplitude reflection coefficient under both passive and active conditions.

Under open-circuit passive conditions, $Z_E \rightarrow \infty$ and the inverse transmission coefficient becomes[30]

$$\frac{1}{\tau} = \left| \frac{\left(2\frac{\rho_0c}{S}S_1^2 + Z_{M1} + Z_{M12} \right)\left(2\frac{\rho_0c}{S}S_2^2 + Z_{M2} + Z_{M12} \right) - \left(2\frac{\rho_0c}{S}S_1S_2 - Z_{M12} \right)^2}{2\frac{\rho_0c}{S}(Z_{M1}S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2)} \right|^2.$$ (4)

The reflection coefficient becomes

$$R = 1 - 2\frac{\rho_0 c}{S}\left[\frac{Z_{M1}S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2}{\left(2\frac{\rho_0 c}{S}S_1^2 + Z_{M1} + Z_{M12}\right)\left(2\frac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}\right) - \left(2\frac{\rho_0 c}{S}S_1 S_2 - Z_{M12}\right)^2}\right]. \tag{5}$$

As stated in Sec. I, the active control strategy for the configuration is to minimize the normal velocity of its principal transmitting surface: the actuator diaphragm. Equation (1) demonstrates that it may be driven to zero (assuming sufficient actuator power handling and linear response) using the following input control voltage:

$$\hat{e}_g = -2\hat{p}_i \frac{Z_E}{Bl}\left\{\frac{Z_{M2}S_1 + \left[Z_{M12} + \frac{(Bl)^2}{Z_E}\right]S}{2\rho_0 c S_2 + Z_{M2}}\right\}. \tag{6}$$

However, forces due to the impinging incident wave, coupling, and reaction of the actuator motor against the finite impedance interstice will cause it to vibrate with velocity amplitude

$$\hat{u}_2 = \frac{2\hat{p}_i(S_1 + S_2)}{2\rho_0 c S_2 + Z_{M2}}. \tag{7}$$

The force due to incident pressure on the actuator diaphragm is accordingly transferred by the actuator motor to the surrounding interstice. The residual volume velocity $\hat{U}_{\mathrm{II}} = \hat{u}_2 S_2$ leads to the controlled inverse transmission coefficient

$$\frac{1}{\tau} = \left|1 + \frac{Z_{M2}}{2\rho_0 c S_2}\right|^2. \tag{8}$$

Significantly, this expression is the same as that resulting from a *passive* single-leaf partition with mechanical impedance Z_{M2} and transmitting surface area S_2, instead of total surface area $S = S_1 + S_2$.

When the interstice is mass controlled, the reciprocal transmission coefficient becomes

$$\frac{1}{\tau} \approx 1 + \left(\frac{\omega \sigma_{M2}}{2\rho_0 c}\right)^2, \tag{9}$$

which corresponds to the normal-incidence mass law for a homogeneous single-leaf partition of surface density σ_{M2}. Notably, the interstice mass M_{M2} includes the mass of the actuator magnet and frame. Hence, this result shows that when the interstice is mass controlled, the active control scheme provides no added benefit to that which could be achieved by a *passive* module constructed solely of the interstitial material with a mass equivalent to that of the actuator magnet and frame added to it.

Equation (8) reveals several other noteworthy properties. First, it indicates that the transmission loss of the controlled module depends upon the interstice surface area and not the diaphragm surface area. Second, it shows that the transmission loss is independent of the actuator diaphragm mass. Hence, the configuration could employ any piston-like diaphragm with appropriate dimensions. Third, it demonstrates that transmission loss increases with increased interstice im-

pedance. For a lightweight ASP, the interstice does not necessarily have to be massive to have high impedance in the direction normal to the partition. It might be oriented so that it is deeper from the source side to the receiving side and proportionately narrower in the plane of the partition. This would significantly increase stiffness in the direction normal to the partition without increasing mass. It would also produce the simultaneous benefit of decreasing the transmitting interstice surface area S_2, which as seen in Eq. (8) would increase transmission loss even more.

Another important property of the controlled configuration is its pressure-amplitude reflection coefficient R as seen from the source space. If $|R| > 1$, the module adds energy to the semi-infinite one-dimensional field, at least relative to that encountered in the presence of a perfectly rigid boundary. On the other hand, if $|R| < 1$, it absorbs at least a portion of the incident energy.[31] Thus, to avoid exacerbating noise levels in the primary field, a desirable requirement might simply be that $|R| \leq 1$. The reflection coefficient determined from the residual volume velocity $\hat{U}_{\mathrm{I}}$ is

$$R = \frac{Z_{M2}}{2\rho_0 c S_2 + Z_{M2}}, \tag{10}$$

which satisfies this requirement. In the high-frequency limit (i.e., when the interstice is fully mass controlled), $R \to 1$.

Based on these analyses, it appears that if one could make the interstitial surface area vanishingly small and its normal stiffness extremely large, the sound transmission through the controlled module would become correspondingly small. However, Sec. II B discusses an important detail that has been neglected and that significantly limits the performance of realizable SCL configurations.

2. Numerical example

Table I provides several numerical values for a representative example of the configuration. The parameters are used with Eqs. (4) and (8) to generate normal-incidence transmis-

TABLE I. Parameter values used in the numerical example for ASP module configuration 1.

FIG. 5. Isolated view of ASP module configuration 2. An actuator diaphragm is connected to a surrounding resilient suspension, which is connected on its opposite side to a stiffened interstice. The surround is represented with lumped mechanical elements. The model isolates effects of acoustic forces and diaphragm forces on the resilient surround. (After Ref. 7.)

sion loss curves for passive and active conditions, as shown in Fig. 3. As the curves demonstrate, control of sound transmission is poor for both states at lower audible frequencies. However, performance gradually improves to modest levels at higher frequencies. Active control produces a 9-dB improvement over passive control at these higher frequencies, but it performs no better at very low frequencies and actually performs worse in the narrow band centered at 58 Hz.

The values in Table I are also used with Eqs. (5) and (10) to provide a similar comparison of source-side reflection coefficient moduli under passive and active conditions (see Fig. 4). In both Figs. 3 and 4, curve dips correspond to resonances of vibrating module elements. The dip centered at 87 Hz for the passive condition corresponds to the resonance of the resiliently mounted diaphragm. Because the diaphragm motion is minimized via active control, this dip vanishes in the active state. The dip centered at 20 Hz for both passive and active conditions corresponds to the dominant resonance of the interstice (with the mounted actuator).

B. Configuration 2: Single-composite leaf (SCL) with a surrounding suspension

The analysis of the first module configuration assumed the actuator diaphragm vibrated freely but snugly within the

FIG. 4. Source-side reflection coefficient modulus for ASP module configuration 1 under open-circuit passive and active conditions (calculated using numerical values from Table I).

surrounding interstice opening so that no sound could transmit through an intervening crack. In practice, this idealized behavior would be extremely difficult to achieve. An airtight seal between an actuator diaphragm and a surrounding interstice would be realized with a mechanical connection. This connection must be resilient to produce sufficient suspension compliance and reduce undesirable mechanical coupling between adjacent ASP elements (a presumed requirement for controller simplification). A compliant airtight suspension with finite transmitting surface area is therefore introduced between the diaphragm and interstice as shown in Fig. 5. This suspension is analogous to the surround of a typical moving-coil loudspeaker. When used in conjunction with an adequately spaced rear suspension (e.g., a spider), it forms a composite dual suspension that significantly restricts diaphragm motion to translational rigid-body motion. As a transmitting surface, a surrounding suspension possesses degrees of vibrational freedom that may be difficult to control. Since it responds somewhat independently to impinging sound waves, a knowledge of its behavior is crucial to understand the performance of the module when the normal velocity of the transmitting diaphragm is minimized through actuation.

1. Equivalent circuit modeling and analytical results

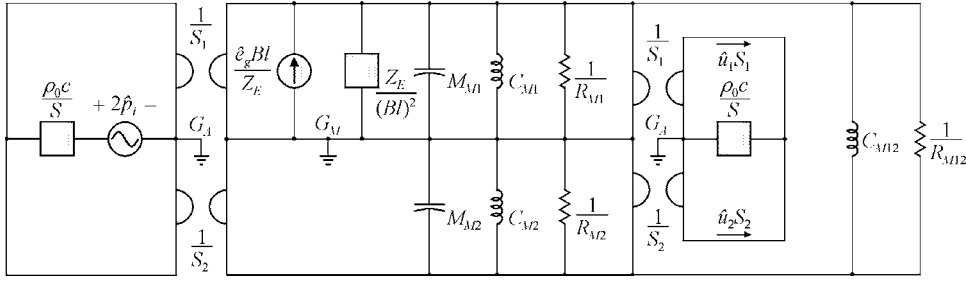
For this model, the interstice is assumed to have infinite stiffness in the direction normal to the partition plane, and its in-plane area is assumed to be negligible.[33] As a result, dominant effects of the suspension are well isolated and a useful representation of the module is given by the equivalent circuit in Fig. 6. The surrounding suspension is modeled as a lumped mass connected between the actuator diaphragm and the rigid interstice with compliance and resistance on both sides. Solving the circuit as described in Sec. II A 1, produces the following normal surface velocities for the diaphragm and surround:


FIG. 6. Multiple-domain equivalent circuit representing ASP module configuration 2. (After Ref. 7.)

$$\hat{u}_1 = \frac{2\hat{p}_i(Z_{M2}S_1 + Z_{M12}S) + \hat{e}_g\dfrac{Bl}{Z_E}\left(2\dfrac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}\right)}{\left[2\dfrac{\rho_0 c}{S}S_1^2 + Z_{M1} + \dfrac{(Bl)^2}{Z_E} + Z_{M12}\right]\left(2\dfrac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}\right) - \left(2\dfrac{\rho_0 c}{S}S_1S_2 - Z_{M12}\right)^2}, \tag{11}$$

$$\hat{u}_2 = \frac{2\hat{p}_i\left\{\left[Z_{M1} + \dfrac{(Bl)^2}{Z_E}\right]S_2 + Z_{M12}S\right\} - \hat{e}_g\dfrac{Bl}{Z_E}\left(2\dfrac{\rho_0 c}{S}S_1S_2 - Z_{M12}\right)}{\left[2\dfrac{\rho_0 c}{S}S_1^2 + Z_{M1} + \dfrac{(Bl)^2}{Z_E} + Z_{M12}\right]\left(2\dfrac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}\right) - \left(2\dfrac{\rho_0 c}{S}S_1S_2 - Z_{M12}\right)^2}. \tag{12}$$

The total volume velocity is then

$$\hat{U}_\mathrm{I} = \hat{U}_\mathrm{II} = \frac{2\hat{p}_i\left\{\left[Z_{M1} + \dfrac{(Bl)^2}{Z_E}\right]S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2\right\} + \hat{e}_g\dfrac{Bl}{Z_E}(Z_{M2}S_1 + Z_{M12}S)}{\left[2\dfrac{\rho_0 c}{S}S_1^2 + Z_{M1} + \dfrac{(Bl)^2}{Z_E} + Z_{M12}\right]\left(2\dfrac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}\right) - \left(2\dfrac{\rho_0 c}{S}S_1S_2 - Z_{M12}\right)^2}. \tag{13}$$

While this configuration is notably different than configuration 1, its analytical representations for passive $1/\tau$ and R are identical to those given in Eqs. (4) and (5) (except that the definition of Z_{M1} differs as shown in the List of Symbols). The control voltage required to drive the normal diaphragm velocity $\hat{u}_1$ to zero is

$$\hat{e}_g = -2\hat{p}_i\frac{Z_E}{Bl}\left(\frac{Z_{M2}S_1 + Z_{M12}S}{2\dfrac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}}\right). \tag{14}$$

When it is applied, the normal surround velocity becomes

$$\hat{u}_2 = \frac{2\hat{p}_i S_2}{2\dfrac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}}. \tag{15}$$

The resulting volume velocity for the controlled condition then produces the inverse transmission coefficient

$$\frac{1}{\tau} = \left|1 + \frac{Z_{M2} + Z_{M12}}{2\dfrac{\rho_0 c}{S}S_2^2}\right|^2. \tag{16}$$

If the surround becomes mass controlled, $Z_{M2} + Z_{M12} \approx j\omega M_{M2} = j\omega\sigma_{M2}S_2$ and the inverse transmission coefficient becomes

$$\frac{1}{\tau} \approx 1 + \left(\frac{\omega\sigma_{M2}}{2\rho_0 c}\right)^2\left(\frac{S}{S_2}\right)^2. \tag{17}$$

The reflection coefficient for the controlled configuration is given by the relationship

$$R = \frac{Z_{M2} + Z_{M12}}{2\dfrac{\rho_0 c}{S}S_2^2 + Z_{M2} + Z_{M12}}. \tag{18}$$

This once again satisfies the requirement that $|R| \leqslant 1$ and in the high-frequency limit, $R \to 1$.

The results given above indicate that the ways to reduce sound transmission through the resilient surround are (1) to reduce its relative surface area and (2) to increase its mechanical impedance. However, increasing its mechanical mass, stiffness, or resistance has important disadvantages. Dramatically increasing its mass is not a good option if one is trying to minimize overall partition mass. The amount that its stiffness or resistance can be increased will likewise be restricted if the surround is to remain sufficiently resilient. Thus, although these quantities may be increased within prescribed limits, the most important approach to reducing

T. W. Leishman and J. Tichy: Active segmented partition modules

FIG. 7. Normal-incidence transmission loss for ASP module configuration 2 under open-circuit passive and active conditions (calculated using numerical values from Table II).

FIG. 8. Source-side reflection coefficient modulus for ASP module configuration 2 under open-circuit passive and active conditions (calculated using numerical values from Table II).

transmission through the surround is to minimize its exposed surface area. This too has practical limitations.

2. Numerical example

Figure 7 uses the analytical results and the parameter values listed in Table II to provide a numerical comparison of the module transmission loss under open-circuit passive and active conditions. Figure 8 provides a similar comparison of the source-side reflection coefficient moduli. In the passive curves of both figures, deep dips centered at 27 Hz are caused by the dominant resonance of the resiliently suspended diaphragm. The shallower and broader dips centered near 235 Hz are produced by the dominant surround resonance. Active control minimizes diaphragm motion, resulting in significant improvement to transmission loss at lower frequencies. However, since the surround remains free to vibrate, the dips near 235 Hz persist. In addition, from 125 to 225 Hz, active control produces transmission loss that is less than that produced by passive control. A comparison of Figs. 3 and 7 also reveals that this active module configuration performs better than configuration 1 at low frequencies (i.e., below 125 Hz) but worse at higher frequencies.

TABLE II. Parameter values used in the numerical example for ASP module configuration 2.

C. Configuration 3: Double-composite leaf (DCL) with acoustic transmitting surface actuation

The preceding sections have provided useful guidelines to increase transmission loss through interstices and actuator diaphragm assemblies. However, they have also shown that the vibration-controlled SCL modules are significantly limited in the ASTC performance they can achieve. Because of this limitation and other problems associated with their incorporation into ASP arrays, the authors chose to explore several other module configurations.[13]

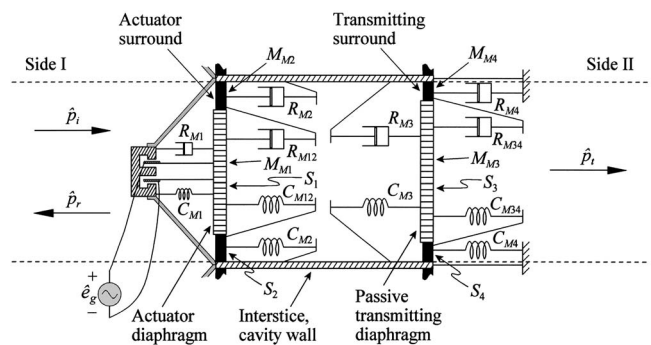
One noteworthy configuration is depicted in Fig. 9. It is a DCL arrangement that incorporates many of the ideas discussed for the preceding configurations but also adds interesting new features. It includes an actuator with a piston-like diaphragm and surround. The actuator frame is rigidly mounted to a stiffened surrounding interstice. Because the interstice impedance normal to the partition is extremely large (assumed to be infinite) and the exposed transmitting surface area is very small, its vibration and contribution to sound transmission are considered negligible. The actuator


FIG. 9. Isolated view of ASP module configuration 3. An actuator diaphragm is connected to a surrounding resilient suspension, which is connected on its opposite side to a stiffened interstice. The surround is modeled with lumped mechanical elements. A passive transmitting diaphragm is similarly supported by a surrounding resilient suspension and a spaced rear suspension. The source and transmitting sides of the module are separated and acoustically coupled by a small isolated cavity. The model demonstrates useful methods mechano-acoustic actuation and segmentation.
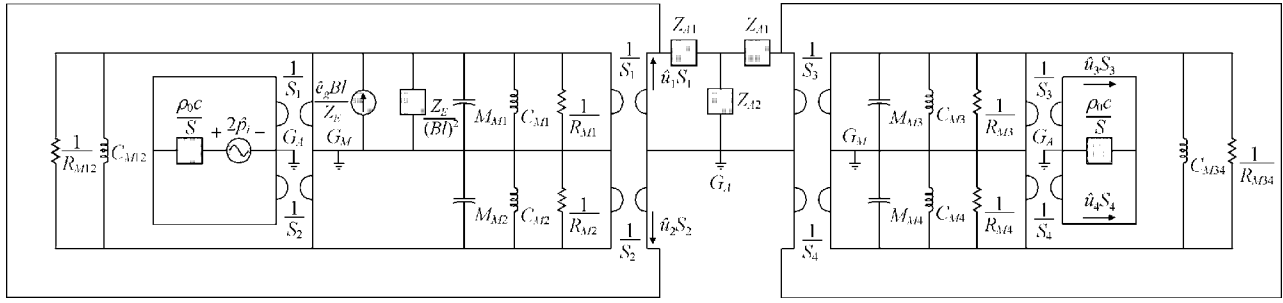

FIG. 10. Multiple-domain equivalent circuit representing ASP module configuration 3.

drives a small sealed cavity to *acoustically* actuate a passive piston-like diaphragm and surround. Both transmitting surfaces are significant. A primary focus of the model is to evaluate the effects of transmitting surround vibration when the module is passive and when its transmitting diaphragm vibration is minimized via active control. As suggested in Sec. II B, performance limitations imposed by transmitting surrounds are difficult to control passively and are therefore of considerable interest. The exposed surface area of the surround may be chosen to be small and its impedance may be chosen to be as large as possible within prescribed limits. The transmitting diaphragm is modeled with connection to both the resilient surround and a spaced rear suspension, the combination helping to constrain its rigid-body translational motion.

1. Equivalent circuit modeling and analytical results

A planar equivalent circuit representing the configuration is shown in Fig. 10. Excitation, radiation, and coupling in the acoustic impedance portions of the circuit are again represented for one-dimensional fields. The simplification neglects higher-order modes and certain near-field coupling effects in the cavity (both of which may merit further analysis), but it acceptably represents cross-sectional spatially averaged field quantities.

Nine nodal equations from the circuit reduce to four coupled equations of motion for the actuator diaphragm, actuator surround, transmitting diaphragm, and transmitting surround, yielding normal surface velocities that are again functions of both incident pressure and electrical input voltage. The velocities of the first two elements combine with their surface areas to produce the following source-side volume velocity:

$$\hat{U}_{\mathrm{I}} = \frac{2\hat{p}_i\left\{\left[Z_{M1} + \dfrac{(Bl)^2}{Z_E}\right]S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2\right\} + \hat{e}_g\dfrac{Bl}{Z_E}(Z_{M2}S_1 + Z_{M12}S)}{\left\{\left[Z_{M1} + \dfrac{(Bl)^2}{Z_E}\right]S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2\right\}Z_{A4} + \left[Z_{M1} + \dfrac{(Bl)^2}{Z_E}\right]Z_{M2} + \left\{\left[Z_{M1} + \dfrac{(Bl)^2}{Z_E}\right] + Z_{M2}\right\}Z_{M12}}. \tag{19}$$

The normal surface velocities of the transmitting diaphragm and surround are

$$\hat{u}_3 = \hat{U}_{\mathrm{I}}\left[\frac{Z_{A2}(Z_{M4}S_3 + Z_{M34}S)}{(Z_{M3}S_4^2 + Z_{M4}S_3^2 + Z_{M34}S^2)Z_{A3} + Z_{M3}Z_{M4} + (Z_{M3} + Z_{M4})Z_{M34}}\right], \tag{20}$$

and

$$\hat{u}_4 = \hat{u}_3\left(\frac{Z_{M3}S_4 + Z_{M34}S}{Z_{M4}S_3 + Z_{M34}S}\right). \tag{21}$$

These velocities also combine with their surface areas to produce the transmitting volume velocity

$$\hat{U}_{\mathrm{II}} = \hat{U}_{\mathrm{I}}\left(\frac{Z_{A3} - Z_{A4}}{Z_{A2}}\right). \tag{22}$$

Under open-circuit passive conditions, the inverse transmission coefficient then becomes

$$\frac{1}{\tau} = \left|\frac{[(Z_{M1}S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2)Z_{A4} + Z_{M1}Z_{M2} + (Z_{M1} + Z_{M2})Z_{M12}]Z_{A2}}{2\dfrac{\rho_0 c}{S}(Z_{M1}S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2)(Z_{A3} - Z_{A4})}\right|^2, \tag{23}$$

and the source-side reflection coefficient becomes
FIG. 11. Normal-incidence transmission loss for ASP module configuration 3 under an open-circuit passive condition (calculated using numerical values from Table III). The predicted infinite transmission loss produced by active control is not plotted.

TABLE III. Parameter values used in the numerical example for ASP module configuration 3.

Parameter	Value	Parameter	Value
Bl	5 T·m	R_E	6 Ω
c	343 m/s	R_g	0.1 Ω
C_{M1}	400 μm/N	R_{M1}	2 kg/s
C_{M2}	200 μm/N	R_{M2}	2 kg/s
C_{M3}	400 μm/N	R_{M3}	2 kg/s
C_{M4}	200 μm/N	R_{M4}	2 kg/s
C_{M12}	200 μm/N	R_{M12}	2 kg/s
C_{M34}	200 μm/N	R_{M34}	2 kg/s
L	25 cm	S	400 cm^2
L_E	0.5 mH	S_1	325 cm^2
M_{M1}	175 g	S_2	75 cm^2
M_{M2}	5 g	S_3	325 cm^2
M_{M3}	175 g	S_4	75 cm^2
M_{M4}	5 g	ρ_0	1.21 kg/m^3

$$R = 1 - 2\frac{\rho_0 c}{S}\left[\frac{Z_{M1}S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2}{(Z_{M1}S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2)Z_{A4} + Z_{M1}Z_{M2} + (Z_{M1} + Z_{M2})Z_{M12}}\right]. \tag{24}$$

As seen from Eq. (20), the control strategy of minimizing normal vibration of the transmitting diaphragm is accomplished by driving the *source-side* volume velocity to zero such that $\hat{u}_1 S_1 = -\hat{u}_2 S_2$. Solving Eq. (19) for the required control voltage yields

$$\hat{e}_g = -2\hat{p}_i \frac{Z_E}{Bl}\left\{\frac{\left[Z_{M1} + \frac{(Bl)^2}{Z_E}\right]S_2^2 + Z_{M2}S_1^2 + Z_{M12}S^2}{Z_{M2}S_1 + Z_{M12}S}\right\}. \tag{25}$$

Inspection of Eqs. (21) and (22) further reveals that this voltage and the resulting zero source-side volume velocity simultaneously drive the transmitting surround velocity and the transmitting volume velocity to zero. Thus, with the interstice free from vibration (or otherwise producing negligible sound transmission), the transmission loss of the controlled configuration tends (within modeling constraints) to infinity (i.e., $1/\tau \to \infty$). The source-side reflection coefficient becomes $R = 1$.

2. Numerical example

Figure 11 provides an example of the open-circuit passive transmission loss of the module using the parameters listed in Table III. (The predicted infinite transmission loss is not shown for the active state.) A comparison of passive and active source-side reflection coefficient moduli is given in Fig. 12. The curves show multiple dips corresponding to resonances of the interacting module elements for the open-circuit passive state. Some of these effects are characteristic of common double-leaf partitions, while others result specifically from segmentation. The narrow dip centered at 705 Hz corresponds to the first cavity resonance. The broader dip, centered at about 235 Hz, corresponds to the source-side sur-

round resonance (compare Figs. 7 and 8). As with most passive double-leaf constructions, transmission loss is relatively high at high frequencies, but poor at very low frequencies. Nevertheless, active control produces a substantial increase in transmission loss at all frequencies as long as the module dimensions are small compared with the acoustic wavelength.

D. Configuration 4: Double-composite leaf (DCL) with resilient actuator support

An enhanced DCL configuration is shown in Fig. 13. While it is similar to configuration 3 in many respects, it incorporates a few distinguishing features that improve its integration and control in extended ASP arrays. The actuator frame in configuration 3 was rigidly mounted to the interstice, which was assumed to have infinite impedance. In practice, the interstice impedance would be large but finite.
FIG. 12. Source-side reflection coefficient modulus for ASP module configuration 3 under open-circuit passive and active conditions (calculated using numerical values from Table III).
FIG. 13. Isolated view of ASP module configuration 4. An actuator diaphragm vibrates freely but snugly within a frictionless support panel opening. The support panel vibrates similarly within a surrounding interstice opening and is connected to the stiffened interstice by a resilient suspension. A passive transmitting diaphragm is supported by a surrounding resilient suspension and a spaced rear suspension, both modeled with lumped mechanical elements and connected on their opposite sides to the interstice. The source and transmitting sides of the module are separated and acoustically coupled by a small isolated cavity. The model demonstrates useful methods of mechano-acoustic actuation, segmentation, and isolation. (After Ref. 7.)

The reaction of the actuator frame against the interstice would then force it to vibrate to some degree. Configuration 4 accordingly adds a measure of isolation between the actuator and interstice through an inertial support panel. The actuator frame is rigidly mounted to the panel, but the panel is attached to the interstice via a resilient connection. The panel is characterized as a lumped-element piston that vibrates snugly within the frictionless interstice opening. The actuator diaphragm is likewise assumed to vibrate freely but snugly as a piston within the frictionless panel opening, with mechanical resistance and compliance coupling it to the actuator frame.

Sound transmission into the cavity through intervening cracks or surrounds is basically inconsequential. In practice, resilient surrounds must be incorporated with the actuator diaphragm and support panel. However, their areas are neglected here (as with configuration 1) to allow modeling with a planar equivalent circuit. This simplification is acceptable for the source-side elements because, as seen from the analysis of configuration 3, the control condition that minimizes transmitting surface vibrations is a zero source-side volume velocity. Vibration control of the principal transmitting surface and small-cavity acoustic coupling of the transmitting surfaces to the source-side surfaces ensure that the condition is essentially satisfied for any number of source-side surfaces. Hence, the actuator diaphragm and support panel are considered to be the only significant source-side surfaces without much loss in generality.

As with configuration 3, the single actuator controls vibrations of both the transmitting diaphragm and its surround through acoustic actuation. Although the concept of acoustic actuation of *distributed* double-leaf partition cavities is not new,[34–38] important distinctions of this configuration make its actuation and behavior unique in several ways. First, when incorporated into an array, several of these modules form an extended partition that is structurally segmented into isolated elements on both its source side and transmitting side. Both the actuator support panel suspension and the transmitting diaphragm suspension help reduce mechanical coupling to the interstice and adjacent modules. Second, the distinctive pair of diaphragms (actuator diaphragm and transmitting diaphragm) and the actuator support panel vibrate as discrete translation pistons. Third, the actuator diaphragm and support panel produce a zero volume velocity condition on the source side of the cavity. Fourth, the actuator and other elements are configured to produce local cross-sectional symmetries. Fifth, the overall partition cavity is segmented by the interstices into acoustically small cavities. This last characteristic has the important effect of *constraining* primary (noise) and secondary (control) pressure distributions within each cavity, and therefore upon the inner faces of the transmitting diaphragms and surrounds. The pressure distributions are thus compelled to match more closely, yielding improved active control performance.

In reality, acoustic pressure within a cavity is never completely uniform and becomes less uniform with increasing frequency. However, if the transmitting diaphragm is constrained to vibrate only as a translational rigid body, it will respond to the total *spatially averaged* pressure over its cavity-side face. Control of its normal velocity will produce an advantageous effect: the same actuation that minimizes its vibration via spatially averaged pressure will also suppress vibration of the transmitting surround over a broad frequency range. Accordingly, the approach of the configuration is not merely one of acoustic cavity actuation, but an important combination of mechano-acoustic isolation, actuation, and segmentation.

1. Equivalent circuit modeling and analytical results

An equivalent circuit representing the configuration is shown in Fig. 14. Its nine nodal equations again reduce to four coupled equations of motion for the actuator diaphragm, actuator support panel, transmitting diaphragm, and transmitting surround. The velocities and surface areas of the first two elements yield the source-side volume velocity

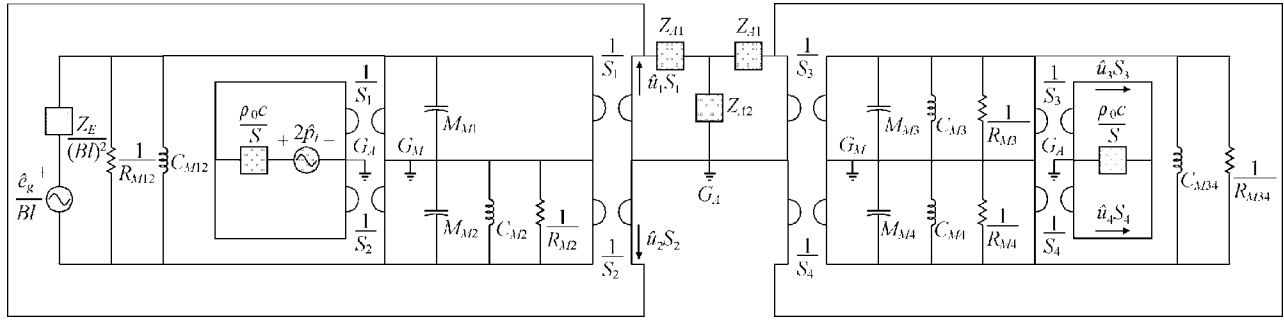
$$\hat{U}_I = \frac{2\hat{p}_i\left\{ Z_{M1}S_2^2 + Z_{M2}S_1^2 + \left[Z_{M12} + \frac{(Bl)^2}{Z_E} \right]S^2 \right\} + \hat{e}_g\frac{Bl}{Z_E}(Z_{M2}S_1 - Z_{M1}S_2)}{\left\{ Z_{M1}S_2^2 + Z_{M2}S_1^2 + \left[Z_{M12} + \frac{(Bl)^2}{Z_E} \right]S^2 \right\}Z_{A4} + Z_{M1}Z_{M2} + (Z_{M1} + Z_{M2})\left[Z_{M12} + \frac{(Bl)^2}{Z_E} \right]}. \quad (26)$$


FIG. 14. Multiple-domain equivalent circuit representing ASP module configuration 4. (After Ref. 7.)

Using this result, $\hat{u}_3$, $\hat{u}_4$, and $\hat{U}_{\text{II}}$ are represented as shown in Eqs. (20)–(22). Although the source-side elements are quite different than those of configuration 3, the open-circuit passive representations for $1/\tau$ and R are also identical to those given in Eqs. (23) and (24) (except for the difference in Z_{M1}, as defined in the List of Symbols).

The normal transmitting diaphragm velocity may be driven to zero with the following actuator control voltage:[39]

$$
\hat{e}_g = -2\hat{p}_i \frac{Z_E}{Bl} \left\{ \frac{Z_{M1}S_2^2 + Z_{M2}S_1^2 + \left[Z_{M12} + \frac{(Bl)^2}{Z_E} \right] S^2}{Z_{M2}S_1 - Z_{M1}S_2} \right\}.
$$

(27)

As indicated earlier, this voltage simultaneously drives the transmitting surround velocity and transmitting volume velocity to zero through the source-side condition $\hat{u}_1 S_1 = -\hat{u}_2 S_2$.[40] The transmission loss thus tends (within modeling constraints) to infinity and the source-side reflection coefficient takes on the constant value of $R = 1$. While this reflection coefficient does not reduce acoustic energy in the semi-infinite source space, it does not add energy to the space above that which would occur with a completely rigid boundary.

2. Numerical example

Figure 15 provides an example of the open-circuit passive transmission loss of the module using the parameters
FIG. 15. Normal-incidence transmission loss for ASP module configuration 4 under an open-circuit passive condition (calculated using numerical values from Table IV). The predicted infinite transmission loss produced by active control is not plotted.

listed in Table IV. A comparison of passive and active source-side reflection coefficient moduli is given in Fig. 16. Because of the similarity in module constructions, the curves are similar in some respects to those given in Figs. 11 and 12. Differences follow from the changes to the source-side module elements. Once again, active control produces a considerable increase in transmission loss at all frequencies in which the module dimensions are small compared with the acoustic wavelength.

3. Design and performance criteria

This module configuration satisfies the seven design and performance criteria mentioned in Sec. I. First, it is designed to utilize simple localized sensors and actuators. This characteristic is important because consistent local control mechanisms allow the module to perform similarly despite changes in adjacent source and receiving spaces. It also allows the module to be self-contained with the possibility of decentralized control. Second, its design and control enable efficient global reduction of normal transmitting surface vibrations (although interstice vibration and transmission are controlled passively). While multiple actuation mechanisms are usually required to control multiple transmitting surface vibrations, this configuration permits efficient control of two vibrating surfaces using only a single actuator. Furthermore, because the control is induced by minimizing vibration of a single transmitting surface, the configuration simplifies error sensing.

TABLE IV. Parameter values used in the numerical example for ASP module configuration 4.

Parameter	Value	Parameter	Value
Bl	5 T·m	R_E	6 Ω
c	343 m/s	R_g	0.1 Ω
C_{M2}	200 μm/N	R_{M2}	3 kg/s
C_{M3}	400 μm/N	R_{M3}	2 kg/s
C_{M4}	200 μm/N	R_{M4}	2 kg/s
C_{M12}	500 μm/N	R_{M12}	1 kg/s
C_{M34}	200 μm/N	R_{M34}	2 kg/s
L	25 cm	S	400 cm^2
L_E	0.5 mH	S_1	75 cm^2
M_{M1}	7 g	S_2	325 cm^2
M_{M2}	325 g	S_3	325 cm^2
M_{M3}	175 g	S_4	75 cm^2
M_{M4}	5 g	ρ_0	1.21 kg/m^3

FIG. 16. Source-side reflection coefficient modulus for ASP module configuration 4 under open-circuit passive and active conditions (calculated using numerical values from Table IV).

Third, the configuration may be constructed using appropriate lightweight materials. To ensure lumped-element behavior, key structural elements should be acoustically small and stiffness controlled over frequencies of interest. Fourth, the configuration adds no sound energy to a one-dimensional semi-infinite source space, at least compared to that encountered with a completely rigid boundary. Fifth, the configuration can accommodate simple passive enhancements and function as a hybrid active–passive device. One enhancement of particular interest is the addition of porous absorptive material to the module cavity to improve passive high-frequency transmission loss. The module could then function as an active device at low frequencies, then "cross over" into effective passive control at higher frequencies.

Sixth, the configuration uses small, isolated, lumped-element components with constrained fields and vibrational motions to reduce problems with controllability, observability, and spillover. Seventh, its segmentation and isolation minimize coupling between adjacent partition modules to simplify control requirements and increase the feasibility of decentralized control.

III. ADDITIONAL DISCUSSION OF CAPABILITIES AND LIMITATIONS

The idealized behavior of each module configuration is unavoidably affected by nonideal physical conditions. Some performance limitations result from nonideal vibrational responses. Controlled transmitting components may have residual vibrations or fail to vibrate as ideal rigid bodies. Bending or rotational rigid-body modes ("rocking modes") of transmitting surfaces complicate the behaviors of modules and may reduce their effectiveness. They also affect the assumed accuracy of uniform or spatially averaged pressures employed in equivalent circuits.

Residual vibrations of narrow transmitting surfaces include those of exposed interstices and transmitting diaphragm surrounds. When radiating into a semi-infinite three-dimensional receiving space, these surfaces are similar to baffled annular pistons or strips. Studies of such radiators[41,42] indicate that radiation from a thin interstice or surround becomes very inefficient when its in-plane width δ becomes very small compared to wavelength, i.e., $k\delta \ll 1$. Further-

more, it can be shown[41] that reducing δ while holding the characteristic cross-sectional dimension a of a module constant has greater impact on radiation reduction than reducing a by the same factor with δ held constant. Moreover, with a fixed-dimension array of many modules, minimizing δ remains the only practical method of surface area reduction.

Three of the module configurations in this investigation were assumed to incorporate narrow interstices with infinite impedance in the direction normal to the plane of the partition. If a narrow interstice has finite impedance and does vibrate to a degree, its radiation into a receiving space will be inherently inefficient. However, its vibration will also force limited vibration of the adjacent transmitting diaphragm and surround. Despite this problem, the normal vibration of the principal transmitting surface is still controlled with appropriate actuation.

When translational motion of a transmitting rigid body is effectively reduced, low-amplitude residual rocking may persist. Nevertheless, if a baffled transmitting face of a rigid body rocks symmetrically with respect to its center point (i.e., with odd symmetry), it produces zero net volume velocity. Modules should accordingly be designed to ensure that any residual transmitting surface vibrations fall into this category. When transmitting faces of an ASP are small compared to wavelength, such consistent reduction in volume velocity provides beneficial reduction in sound transmission.[9,10,43] Notably, the method described here is more than just volume velocity control involving large, spatially dependent surface velocities. Instead, the approach produces sound transmission control in two steps. First, it significantly suppresses normal vibration of efficiently transmitting modes. Second, it leaves only low-amplitude residual vibration with a distribution that transmits inefficiently into the receiving space.

The ASP design and performance criteria discussed in Sec. II D 3 require that normal vibrations of *all* transmitting surfaces be minimized to the greatest extent possible. Because module configurations 3 and 4 were found to accomplish the task well, they are expected to simultaneously reduce transmission into both receiving space near fields and far fields. However, near fields produced by narrow residually vibrating surfaces and rocking surfaces possess reactive acoustic energy that cannot be wholly neglected. Such residual vibrations must be carefully considered when listeners or acoustic receivers are positioned close to partitions.

Simultaneous control of the source-side reflection coefficient or the source-space sound field may be desirable while an ASP is engaged in controlling sound transmission. Additional actuation mechanisms may be incorporated into modules to help provide this control or help control residual interstice vibration.[13] While the requirements to accomplish these additional tasks make the problem more complex, the concepts could find application in certain sound transmission problems.

It is anticipated that carefully designed ASP modules will function effectively in complete ASP arrays using simple adaptive controllers. Decentralized controllers may require reduction of coupling between adjacent partition modules to weaken cross-coupling control paths (i.e., trans-

fer functions between actuators and error sensors of neighboring modules).[44] Of the module configurations presented in this investigation, configuration 4 appears to be most capable of producing effective isolation.

IV. CONCLUSIONS

This work has provided a theoretical and numerical investigation of several vibration-controlled modules for use in active segmented partitions (ASPs). These partitions consist of physically segmented arrays of acoustically and structurally small modules that may be regulated using adaptive controllers. The control objective for each module was to induce global control of its various normal transmitting surface vibrations by directly minimizing normal vibration of its *principal* transmitting surface. In some cases, passive means were used to control interstitial surface vibrations. Analyses of the modules were realized using electro-mechano-acoustic circuits. While certain simplifying assumptions were required to make the circuits manageable, they clearly demonstrated important module behaviors. Transmission loss estimates from the analyses are well suited for comparison with classical normal-incidence transmission loss formulations.

The investigation has revealed the inability of two characteristic single-composite-leaf (SCL) configurations to simultaneously control vibration of their transmitting diaphragms, resilient suspensions, and partition interstices under the active control scheme. A numerical example showed that the first configuration produced poor active sound transmission control (ASTC) at low frequencies and moderate ASTC at high frequencies. Another example showed that the second configuration improved low-frequency performance but at the expense of high-frequency performance. In both cases, the introduction of active control was shown to *decrease* transmission loss below passive levels at some frequencies.

Despite these limitations, the investigation provided useful recommendations to enhance ASTC capabilities of these and other vibration-controlled configurations. They suggest that lightweight ASPs should incorporate interstices with very high impedance in the direction normal to the partition. Interstitial widths should also be very narrow in the plane of the partition. Resilient transmitting suspensions that connect stiff diaphragms to interstices should likewise be thin in the plane of the partition and have reasonably large impedances (within prescribed limits to maintain desired resiliency).

Two double-composite-leaf (DCL) configurations were introduced that utilize distinctive combinations of acoustic actuation and mechano-acoustic segmentation. In their passive states, both show transmission loss characteristics typical of double-leaf partitions but add other characteristics unique to their segmented natures. In their active states, they efficiently and globally control transmitting surface vibrations to produce high transmission loss over a broad frequency range. Moreover, because of their localized control mechanisms, their performances remain relatively unaffected by typical time-varying changes to surrounding environments. The second of the two configurations incorporates special segmentation and isolation to reduce coupling between adjacent partition modules and enhance the effectiveness of extended arrays using simple decentralized controllers.

This work has shown that appropriate vibration control of properly configured ASP modules can yield effective local control of sound transmission. When incorporated into full partition arrays, these modules have the potential to enhance the practicality and performance of ASTC systems through their straightforward design, implementation, actuation, error sensing, and application to many sound transmission problems.

[1] When appropriate (e.g., for analogous circuit modeling), spatially averaged acoustic pressures and particle velocities may be assumed over relevant cross-sectional areas.

[39] This equation corrects Eq. (13) in Ref. 7. Equations (14) and (15) of that paper also have minor errors that may be corrected by solving for $\hat{u}_1$ and $\hat{u}_2$ under general conditions (as outlined in the present paper), then substituting the control voltage.

[40] The concept of minimizing volume velocity into the cavity leads to another possibility for localized error sensing. If the cavity is sufficiently small, it may be feasible to minimize acoustic pressure at a point within the cavity to produce the desired reduction of volume velocity and subsequent control of transmitting surface vibrations. However, the scheme is slightly precarious; it is possible to minimize acoustic pressure at a point in the cavity while the transmitting diaphragm is still vibrating. If small interstice vibrations or extraneous sources in the receiving space cause the transmitting diaphragm to vibrate, the acoustic pressure minimization would not necessarily eliminate sound transmission through the diaphragm and surround. In addition, if a pressure error sensor happened to be located at an uncontrolled pressure node in the cavity, the error signal might not be sufficiently observable and control complications could arise.

Individual modules intended for active segmented partitions should be carefully analyzed before they are advanced as viable tools for active sound transmission control. In this paper we present experimental evaluations of two vibration-controlled modules: a single-composite-leaf (SCL) configuration and a double-composite-leaf (DCL) configuration. Experimental apparatuses and procedures are introduced to assess their normal-incidence transmission losses over a bandwidth from 40 to 1970 Hz. The average transmission loss of the passive SCL module is found to be 21 dB. If its transmitting diaphragm acceleration is minimized through active control, transmission loss increases somewhat at lower frequencies but decreases at higher frequencies, producing no increase in the average value. The average transmission loss of the passive DCL module is found to be 43 dB. After its transmitting diaphragm acceleration is actively minimized, the transmission loss increases substantially at all frequencies (especially at low frequencies), to produce an average value of 77 dB. Thus, while both configurations have the same underlying control objective, the DCL module yields a 56 dB average improvement over the SCL module through simple configurational changes. An alternative control scheme is investigated that minimizes acoustic pressure in the DCL module cavity, but it is found to be less effective. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1992747]

I. INTRODUCTION

An active segmented partition (ASP) consists of an array of interconnected modules or elements with active and passive components that are configured and controlled to reduce sound transmission. Proper design, control, and evaluation of individual modules are crucial if ASPs are to provide effective control of sound transmission over useful bandwidths. In the past, research of ASPs has been obscured by more extensive research in other areas of active sound transmission control (ASTC).[1] It has nevertheless been pursued by a few researchers, who have seen its potential to enhance sound isolation capabilities of existing segmented partition structures, reduce partition masses, simplify active control requirements, and enhance ASTC in other ways.

Acousticians have long recognized the need for more efficient control of sound transmission through lightweight partitions, particularly at low frequencies. Some have anticipated that the active control of partitions would help fulfill this need because of its typical low-frequency benefits. However, difficulties encountered in the control of distributed structural and fluid media have imposed serious limitations on both the performance and practicality of many ASTC systems. Several criteria have been proposed to address these limitations, suggesting that properly implemented ASPs could provide needed ASTC improvements.[2,3]

Most researchers advocating ASPs in the past have done so to propose a means of controlling sound transmission through fuselage structures into aircraft cabins.[4–10] This concept is appealing because interior fuselage trim panels already exist as segmented partition elements. Others have suggested ASPs to control sound transmission through lightweight machinery enclosure walls[11,12] (a concept reminiscent of earlier passive techniques[13]). The authors of this paper have explored many different ASP configurations for general applications and ASTC improvements.[2,3,14–17]

While past research efforts have provided useful contributions to ASPs and their advancement, they have often lacked in-depth analyses and comparisons of module configurations, control methods, and associated ASTC performances. Recent theoretical work has filled some of these gaps through the exploration of several distinct module configurations.[2,3,17] However, a presentation of related experimental results is needed to validate theoretical predictions, to further compare the configurations, and to establish those capable of producing very high transmission loss using simple control strategies.

Sound isolation capabilities of experimental ASP implementations have often remained ambiguous to readers of the literature. Apparent shortcomings related to their performance and consistency have limited their acceptance or utility for many applications. However, uncertainty surrounding their capabilities has arisen in part because irregular measurement techniques are often used to quantify sound isolation of active partitions. While it is true that their measure-

ments are somewhat unique and must account for special conditions produced by active control,[18] they should reasonably conform to recognized norms, providing a meaningful evaluation of actual transmission loss capabilities. Experimental methods have been developed as part of this work to address these needs.

The research reported in this paper was undertaken to increase general understanding of ASPs and to provide greater insight into individual module configurations, their performance capabilities, and their limitations. It was also intended to substantiate theoretical predictions for two specific ASP module configurations. The first incorporated a single electromechanically actuated diaphragm with a surrounding airtight suspension (compare configuration 2 in Ref. 17). Theoretical work predicted that this single-composite-leaf (SCL) configuration would show significant transmission loss deficiencies. The second involved an electroacoustic actuator driving an isolated cavity and thereby actuating a passive transmitting diaphragm with a surrounding airtight suspension (compare configuration 3 in Ref. 17). Theoretical work predicted that this double-composite-leaf (DCL) configuration would perform much better than the first, achieving very high transmission loss over a broad bandwidth while satisfying several other design and performance criteria.[2,3,17]

Several experimental tools were developed to evaluate the modules and their control schemes. The underlying control objective for each was to minimize sound transmission through global reduction of transmitting surface vibrations, using only simple actuation and error-sensing techniques.

In the following sections we describe the experimental methods used in the research effort. We then present results and analyses of measured normal-incidence transmission losses for the two modules in their passive and active states. The results are compared to theoretical predictions and transmission losses of six passive benchmark partitions for further experimental validation and insight.

II. EXPERIMENTAL METHODS

A. Transmission loss measurement system

Normal-incidence acoustic properties of ASP modules may be readily determined using plane-wave tubes and the two-microphone transfer function technique developed by Chung and Blaser.[20,21] The common uses of these tools for the measurement of absorptive materials and acoustic filters naturally extend to the measurement of an electromechanoacoustic device separating a source tube and receiving tube.[3,14,15,22] The approach may be used to decompose the upstream and downstream fields adjacent to an ASP module into normally incident, reflected, and transmitted components, producing reliable transmission loss measurements. The possible residual reflection from an anechoic receiving tube termination suggests a need to decompose the downstream field into traveling-wave components using downstream microphones.

Figure 1 depicts the plane-wave tube system developed for the measurement of ASP modules and passive benchmark partitions in this work. It is shown with an arbitrary partition
FIG. 1. Experimental system for measuring normal-incidence transmission loss of an individual partition module (ASP module or passive benchmark structure). The arrangement is shown with an arbitrary partition positioned between the source tube and receiving tube.

positioned between the source tube and receiving tube. Time-averaged sound power incident upon a partition $\langle W_i \rangle_t$ and transmitted through the partition $\langle W_t \rangle_t$ are detected using the upstream and downstream microphone pairs. The transmission loss then follows from the expression

$$\text{TL} = 10 \log \left(\frac{\langle W_i \rangle_t}{\langle W_t \rangle_t} \right). \tag{1}$$

Both tubes were constructed of heavy plastic with 10.1 cm inside diameters.[23] The source tube had an overall length of approximately 1 m. The receiving tube consisted of a measurement section and an anechoic termination section. The termination was designed following empirical concepts[24] and validated[25] using the two-microphone transfer function technique.[26] It was a pyramidal wedge cut from a block of 25.6 kg/m^3 open-cell polyurethane foam rubber, tapering over a 91 cm span from its apex to its 10.1 cm diameter circular base. Its tip was supported by a thin wire set a small distance from the apex to prevent it from sagging. The circular base was a 25 cm thick continuous extension of the wedge, backed by an 18 cm thick air cavity filled with loose glass-wool insulation and capped with a heavy cast-iron plug. In overall length, the anechoic termination was approximately 134 cm. Its measured cutoff frequency (above which its normal-incidence pressure-amplitude reflection coefficient modulus was consistently $|R| \leq 0.10$) was approximately 135 Hz. However, its absorption coefficient α exceeded 0.5 down to 40 Hz. The usable length of the receiving tube measurement section, from a given partition face to the anechoic wedge tip, was approximately 184 cm.

The source tube excitation loudspeaker was driven by an amplified swept sinusoid, stepped at 1 Hz increments below the cutoff frequency of the first tube cross mode (1990 Hz). Many partitions introduced boundary conditions that resulted in significant axial source tube resonances. However, acoustic pressure was measured by a measurement reference microphone at the source-side face of each partition to ensure that its level was maintained at a nearly constant value over frequency. This was accomplished through automatic level control of the excitation signal. The process ensured sufficiently linear behavior of the source tube sound field and its transducers, and maintained an adequate transmission loss signal-to-noise ratio at all frequencies of interest. Nevertheless, because of the automatic control, the excitation loud-

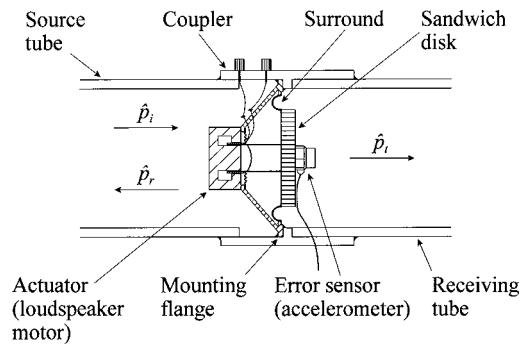
speaker vibrated more vigorously at some frequencies (i.e., at source tube antiresonance frequencies) than at other frequencies (i.e., at source tube resonance frequencies). Structure-borne flanking transmission consequently became more conspicuous near antiresonance frequencies.

A block diagram of the measurement system, its transducers, and electronics is shown in Fig. 2. Rough placements of microphones and accelerometers are suggested in the figure. More specific placements are discussed below and shown in subsequent figures. Holes were drilled into the tops of the source and receiving tubes to accept microphones at key positions and multiple spacings. This enabled broadband decomposition of the fields within established error constraints.[26,27] The microphones were regularly calibrated to each other and to a standard reference microphone using switching[20,26] and uniform-pressure calibration techniques.

As seen from the figure, three microphones were actually used to probe the source tube. The microphone positioned closest to the partition (approximately 1 cm upstream) was the measurement reference microphone mentioned earlier. The other two microphones were a relatively calibrated pair used to determine the one-dimensional acoustic properties in the source tube. The rightmost microphone of the pair was fixed 30 cm (approximately 3 tube diameters) from the end of the tube. This distance provided a margin beyond the common single-diameter rule,[26] allowing a greater decay of strongly reflected higher-order modes and ensuring the plane


wave mode became more predominant at the microphone pair. The leftmost microphone of the pair was positioned at one of two upstream positions to provide either a 7.0 or 42.0 cm microphone spacing for valid measurements at higher or lower frequencies, respectively. A second relatively calibrated microphone pair was used in a mirror-image configuration on the opposite side of the partition to probe the receiving tube. A usable measurement bandwidth of approximately 40 to 1970 Hz was made possible through the combination of measurements made with the two spacings. A few passive properties of ASP modules were evaluated at frequencies below 40 Hz. Error conditions did not fall into the ideal range for these frequencies,[27] but they were considered reasonable for the purposes of this study. Other details of the measurement system, control system, and electronics are discussed in Ref. 3.

B. ASP modules

1. Single-composite-leaf (SCL) module

The first experimental ASP module was adapted from a moving-coil loudspeaker, as shown in Fig. 3. The loudspeaker diaphragm was replaced by an aluminum honeycomb sandwich disk with a 7 cm diameter and an 11 g total mass. Because its first bending mode frequency (for a free-edge condition) was determined to be well above the cutoff frequency of the first plane-wave tube cross mode, the disk was assumed to behave as a rigid body over the frequency range of interest. A small 1.3 g acrylic tube was glued between the existing voice-coil former and disk to enable its direct electromechanical actuation. The inner edge of the existing half-roll doped-cloth surround was glued to the back face of the disk around its periphery. The loudspeaker frame incorporated large openings, making it somewhat unobtrusive to incident waves.

The loudspeaker mounting flange was trimmed to fit snugly within a heavy PVC plastic tube coupler and firmly adhered to the inner coupler surfaces to produce an airtight seal between the source tube and receiving tube. The coupler was likewise joined to the source tube and receiving tube with airtight seals. An accelerometer was mounted to the center of the transmitting face of the disk as an error sensor. When the module was excited by normally incident waves, a control signal could be applied to the actuator terminals to
FIG. 4. Double-composite-leaf (DCL) ASP module, shown with accelerometers mounted to the hardened actuator diaphragm dust dome and to the passive transmitting diaphragm. The module coupler housings are attached via a resilient airtight connection to reduce structure-borne flanking transmission from the source tube to the receiving tube. Compare configuration 3 of Ref. 17.

minimize the normal acceleration of the disk. In its uncontrolled state, the actuator terminals were simply open circuited. Electro-mechano-acoustic parameters for the module (defined in Ref. 17) were determined using common electric impedance testing techniques,[28] acoustical testing techniques,[22] direct measurements,[3] and published specifications.

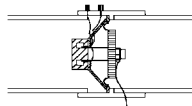
2. Double-composite-leaf (DCL) module

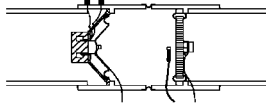
The second experimental ASP module is depicted in Fig. 4. It was constructed using the same type of loudspeaker as in the first module, but with the original diaphragm assembly still intact. The diaphragm dust dome was coated with several layers of epoxy to provide a sufficiently rigid surface for accelerometer mounting. A miniature accelerometer was mounted to the dome to observe its vibrational behavior. In this configuration, the loudspeaker functioned as an electroacoustic actuator driving a small acoustic cavity (11.3 cm diameter and 9.1 cm nominal length) between its own diaphragm and a passive transmitting diaphragm. The latter consisted of a 19 g stiff aluminum honeycomb sandwich disk supported by a dual surrounding suspension. The suspension consisted of two half-roll butyl 50 rubber surrounds that were firmly glued to the peripheries of the front and back disk faces. An accelerometer was mounted to the center of the transmitting face as an error sensor. A small microphone was also positioned in the cavity to observe the enclosed field or to act as an alternate error sensor. Electro-mechano-acoustic parameters for the module (defined in Ref. 17) were again determined using a variety of methods.

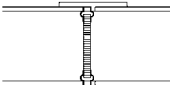
As with the first module, the actuator and transmitting diaphragm assemblies were carefully fitted and adhered within tube coupler housings with airtight seals. The couplers were also joined to the source tube and receiving tube with airtight seals. However, because of complications arising from flanking transmission during very high transmission loss measurements, the two couplers were typically spaced by about 1 cm and joined with a resilient airtight connection. The connection reduced structure-borne flanking trans-

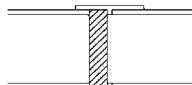
mission into the receiving tube, most of which resulted from mechanical source tube vibrations induced by the excitation loudspeaker or control actuator.

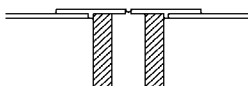
Once the module was excited by normally incident waves, a control signal was applied to the actuator terminals to minimize either normal acceleration of the transmitting diaphragm or acoustic pressure at a specified point within the cavity. In its uncontrolled state, the actuator terminals were open-circuited.

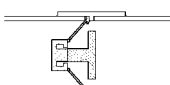
C. Passive benchmark partitions


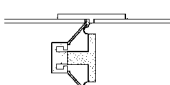












As a means of validating results provided by the measurement system, the active and passive transmission losses of the experimental ASP modules were compared with transmission losses of several passive benchmark partitions. Table I summarizes the designs and experimental purposes of the various active and passive structures.

Benchmark partition 1 was an open tube (no structure), expected to provide very little if any measurable transmission loss. Benchmark partition 2 was the isolated passive transmitting diaphragm assembly from the DCL ASP module. The transmission loss of this diaphragm was expected to behave like that of a single-leaf partition with effective mass, compliance, and resistance over an appreciable bandwidth.

Benchmark partition 3 incorporated a single 2.5 cm thick, 11.3 cm diameter solid steel plug spanning the entire cross section of a PVC plastic or steel tube coupler, sealed around its periphery to the inner surfaces of the coupler. The coupler was firmly connected and sealed to both the source and receiving tube. While the structure had no readily predictable transmission loss behavior, it was expected to provide a high transmission loss benchmark with significant structural flanking paths. Benchmark partition 4 (also shown in Fig. 5) incorporated a pair of sealed steel plugs—one in a PVC coupler and one in an adjacent steel coupler. As with the DCL ASP module, one coupler was mounted and sealed to the source tube and the other was mounted and sealed to the receiving tube. They were typically separated from each other by a 1 cm spacing and joined with a resilient airtight connection. This resulted in a plug spacing of approximately 4 cm. The arrangement provided a very high transmission loss benchmark. The resilient connection could also be removed so that the couplers could be firmly connected or separated by a large distance (e.g., 50 cm). Additional physical separation further reduced direct and flanking transmission, providing an extremely high transmission loss, near or exceeding the highest measurable transmission loss of the experimental system.

Benchmark partition 5 was an arrangement similar in basic form to the SCL ASP module (see Fig. 3). However, the transmitting diaphragm, surround, voice-coil assembly, and spider were removed from the actuator and replaced with a heavy steel plug (see Fig. 6). The diameter of the plug face was the same as the diameter of the transmitting aluminum honeycomb sandwich disk. The diameter of the plug shaft was approximately the same as the diameter of the voice-coil former and extension. The base of the shaft was firmly affixed to the actuator magnet structure. Since the resilient sur-

round was removed, a direct but constricted sound transmission path was introduced around the perimeter of the plug.

Benchmark partition 6 was nearly identical to benchmark partition 5, except that the resilient surround was once again mounted. As shown in Fig. 6, its inner edge was glued to the steel plug and its outer edge was glued to the actuator frame. This mounting again established the airtight seal between the source and receiving tubes and provided an approximate passive means of evaluating sound transmission through the surround alone.

D. Measurement capabilities and limitations

Measurements and analyses of the first four passive benchmark partitions were conducted to verify that the mea-

surement system functioned as expected and to identify some of its capabilities and limitations. The open tube (benchmark partition 1) showed little if any transmission loss (never exceeding 0.4 dB) over the measurement bandwidth. The isolated passive transmitting diaphragm assembly (benchmark partition 2) closely followed its theoretically predicted behavior as a single-leaf partition. The single and dual steel plug partitions (benchmark partitions 3 and 4) demonstrated the high transmission loss measurement capabilities of the system, but also exposed certain limitations. Maximum reliable transmission loss values were limited by flanking transmission, electronic cross-talk, ambient acoustic noise, electronic noise, etc. Benchmark partition 3 yielded a
FIG. 5. Passive benchmark partition 4: a pair of spaced 2.5 cm thick solid steel plugs spanning the entire cross sections of the tube couplers to which they are sealed. The couplers are shown as being attached to each other by a resilient airtight connection to reduce structure-borne flanking transmission from the source tube to the receiving tube.
FIG. 6. Passive benchmark partition 6: a modified SCL module with a steel plug replacing the transmitting diaphragm assembly. The surround is intact.
FIG. 7. Measured transmission losses for passive benchmark partition 4 (see Fig. 5). Measurement results are shown for three distinct coupler interconnection conditions.

transmission loss ranging from approximately 50 dB at the lowest measurement frequencies to approximately 70 dB at the highest frequencies, with an average value of 60 dB.[29] However, the transmission loss curve had several significant undulations over frequency that corresponded to decreases and increases in structural flanking transmission near the axial source tube resonance and antiresonance frequencies, respectively (see Sec. II A).

Many of the same flanking transmission effects were evident (especially below 700 Hz) for the dual steel plug partition (benchmark partition 4) when the couplers were rigidly connected. When the couplers were spaced with the resilient connection between them, these effects largely disappeared below 1350 Hz and the measurable transmission loss dramatically increased. The value ranged from approximately 70 dB at the lowest frequencies to approximately 90 dB above 500 Hz, with an average transmission loss of 86 dB. If the resilient connection was removed and the couplers were widely separated with no mechanical connection at all, a significant increase in the measured transmission loss occurred at only the lowest frequencies, below about 160 Hz. In this case, the transmission loss ranged from approximately 80 dB at the lowest frequencies to approximately 90 dB at the highest frequencies, producing only a slightly higher average value. Transmission loss plots for the three coupler conditions are shown in Fig. 7.

The benchmark partitions also increased the understanding of the experimental ASP modules. As discussed in Sec. III A 2, measurements of benchmark partitions 5 and 6 were particularly useful for increasing understanding of the SCL module. Other validations of the measured module properties are discussed in Ref. 3.

The transmission loss curves in Fig. 7 demonstrate a degree of random fluctuation at decibel values above about 80 dB. In such a high decibel range, measurement limitations could be caused by electronic cross-talk between measured signals or an insufficient electroacoustic signal-to-noise ratio. A series of measurements specifically demonstrated that electronic cross-talk could impact the associated downstream signals—at least near 200 Hz, 350 Hz, and in the band between 500 and 1000 Hz.[3] Electroacoustic noise in the downstream measurements included ambient noise and self-noise

of the microphones and their accompanying electronics. Because of the signal processing methods used in the measurements, the upstream incident intensity level was intended to exceed the transmission loss by an amount greater than the associated background intensity level at all frequencies of interest. For partitions with extremely high transmission loss, this could pose a significant problem. The incident intensity level had to be limited to prevent clipping of source-space microphone signals and other system nonlinearities. A level of approximately 124 dB (re 10^{-12} W/m^2) was chosen, producing a maximum transmission loss signal-to-noise ratio from roughly 80 dB at the lowest frequencies to 100 dB at the highest frequencies. The average value over the measurement bandwidth was approximately 95 dB.[3]

A comparison of the measured transmission loss of benchmark partition 4 (with resilient connection) to the maximum measurable values (limited by either electronic crosstalk or transmission loss signal-to-noise ratio) revealed that the partition pushed the dynamic limits of the measurement system—especially between 500 and 800 Hz. However, at most other frequencies, the system was capable of measuring its average 86 dB transmission loss with sufficient margin. Other measurement limitations and sources of measurement error are considered elsewhere.[3,22,26,27]

E. Measurement challenges posed by adaptive control

Additional experimental challenges needed to be surmounted to perform accurate transmission loss measurements of the ASP modules under adaptive control. Simultaneous (and sometimes conflicting) dynamic range requirements dictated by the measurement system and the adaptive controller had to be consistently satisfied. The adaptive controller also had to remain stable and maintain an adequate rate of convergence as it tracked the swept-sinusoidal stimulus.

1. Simultaneous dynamic range requirements

As seen in Fig. 2, several components of the measurement system shared signals with the adaptive controller. The challenging simultaneous dynamic range requirements of the components became further complicated by the fact that the measurement system utilized multiple signal channels and a large bandwidth. To maximize usable dynamic ranges, it was necessary to optimize signal path gain structures. The analyzer automatically adjusted every A/D input range with internal amplification circuits; they were checked, adjusted, and recorded with each swept-sine step. However, the adaptive controller had no automatic gain control for its A/D inputs. The associated signals had to be independently conditioned and optimized to ensure that the controller dynamic range capabilities could be met.

As indicated above, the ambient acoustic and electronic noise present in the receiving tube measurements required the source tube to be sufficiently but not excessively driven to bring transmitted acoustic energy above the noise floor. This was a primary reason why the stimulus signal level was adjusted over frequency to maintain a nearly constant sound pressure level at the source-side face of the partitions. The

process necessitated frequency-dependent compensation for the excitation loudspeaker sensitivity and strong source tube resonances. However, the same signal driving the excitation loudspeaker power amplifier also drove the adaptive controller reference input. Thus, because of the extreme amplitude adjustments needed to satisfy the constant sound pressure level requirement, the varying signal level essentially pushed the adaptive controller input to its dynamic limits. Had the signal at the input been maintained at a consistent optimal level, the dynamic range of transmission loss measurements would have suffered. Thus, the ideal requirements of the measurement system and adaptive controller were essentially at odds with one another.

The solution chosen to remedy this problem involved both the use of the measurement reference microphone discussed earlier and the multichannel dbx 1046 compressor/limiter, which conditioned the controller reference input signal (see Fig. 2). The latter was set with an infinite compression ratio and a threshold that maintained a nearly constant controller reference input level over the entire measurement bandwidth. Another channel of the compressor/limiter was used to explore dynamic range control of the ASP module error signals.[30]

Because of the automatic stimulus signal level adjustments, the excitation loudspeaker required protection from being overdriven at some frequencies. This was accomplished by specifying a fixed maximum stimulus signal level in the swept-sine control. The output signal of the reference microphone was also maintained at a maximum level that ensured that the sound pressure at all other source-space microphones would remain high, but without overdriving them or their accompanying electronic circuitry.

2. Tracking of the swept-sine stimulus

Another experimental challenge involved the ability of the adaptive controller to track rapid changes in the stepped-sinusoidal excitation of the measurement system. With measurements spanning nearly 2000 Hz with 1 Hz step intervals, overall measurement durations could be quite long. It was therefore desirable to adjust the sweep rate to be as fast as possible and the settling time after each step to be as short as possible. However, the adaptive controller had to be able to track the sweep, adapting rapidly and stably within the settling times.

As the stimulus frequency approached axial source tube resonance frequencies, the adaptive controller typically took much longer to adapt after each 1 Hz frequency increment. This was likely due to dramatic changes in system amplitudes and phases near these frequencies. On occasion, it was necessary to increase settling times or pause measurements and increase adaptive controller convergence parameters to shorten convergence times with each step.

III. RESULTS

The experimental ASP modules were tested under the various conditions summarized in Table II. Three measure-

TABLE II. Measurement conditions for the experimental ASP modules.

ASP Module	Mode	Error Signal	Error Signal Compression
SCL	Passive	N/A	N/A
	Active	Transmitting diaphragm acceleration	No
		Transmitting diaphragm acceleration	Yes
DCL	Passive	N/A	N/A
	Active	Transmitting diaphragm acceleration	Yes
		Cavity pressure, behind diaphragm center	Yes
		Cavity pressure, behind diaphragm periphery	Yes

ments were conducted for the SCL module and four for the DCL module. The following sections provide additional details of these measurements and their results.

A. Single-composite-leaf (SCL) module

The SCL module depicted in Fig. 3 was evaluated under two basic conditions. First, its behavior was measured in its passive mode, with the actuator terminals open circuited. Subsequently, its normal transmitting diaphragm acceleration was minimized through adaptive control. The acceleration control was first achieved without error signal compression, then with error signal compression. The following paragraphs report measurements and observations for the module under the various conditions. They also compare evaluations of passive benchmark partitions 5 and 6 introduced in Sec. II C.

1. Passive mode

Figure 8 shows the measured normal-incidence transmission loss for the passive module plotted against the transmission loss for the active module (discussed below). Passive and active theoretical predictions are also plotted using analytical results[17] and module parameters. The minimum
FIG. 8. Measured transmission losses for the SCL ASP module in its passive mode (actuator terminals open circuited) and in its active mode (transmitting diaphragm acceleration minimized). The measured curves are plotted against theoretical predictions for the two modes.

value of the passive transmission loss curve corresponds to the diaphragm assembly resonance frequency at approximately 28 Hz. Below this frequency, the assembly becomes stiffness controlled. Between about 50 and 500 Hz, it appears to behave as a mass-controlled single-leaf partition; its value consistently rises at approximately 6 dB per octave.[31] One might expect the device to remain mass controlled at higher frequencies, but this behavior clearly breaks down above 500 Hz. The transmission loss drops from a maximum of 32 dB at 500 Hz to 14 dB at about 1220 Hz. It then rises again gradually, but to a value no greater than 20 dB. The dip centered at 1220 Hz corresponds to the primary resonance of the damped surround. When averaged over the entire measurement bandwidth, the transmission loss of the passive module is approximately 21 dB.

2. Transmitting diaphragm acceleration control

The normal acceleration of the module diaphragm was effectively minimized through direct electromechanical actuation. As indicated earlier, this actuation could be adaptively controlled either with or without compression of the acceleration error signal. Despite improvements in error signal reduction provided by compression,[32] transmission losses produced by the module were essentially identical in either case.

The actively controlled transmission loss shown in Fig. 8 generally agrees with the corresponding theoretical prediction, except at the lowest frequencies. The measured curve decreases with undulation from moderate values (e.g., 35 dB) at low frequencies to a minimum value of 13 dB at 1220 Hz. The curve then rises by approximately 1 dB per 100 Hz increase to a value of about 20 dB at 1970 Hz. The average transmission loss over the entire measurement bandwidth is again 21 dB. Thus, on average, the actively controlled module offers no benefit over the passively controlled module. However, below 350 Hz, it does offer useful improvement. Between 40 and 350 Hz, the average transmission loss is 33 dB, compared to the 24 dB average of the uncontrolled module. At the lowest frequencies, active control produced a 20 to 30 dB improvement over the passive transmission loss results.

As predicted theoretically, the uncontrolled module provided better transmission loss than the controlled module between about 350 and 1300 Hz. Above 1300 Hz, the controlled and uncontrolled states produced essentially identical results. Theoretical analysis suggested that these high-frequency active performance limitations are caused by uncontrolled surround vibrations.[17] Passive benchmark partitions 5 and 6 were evaluated to validate this assertion. Benchmark partition 5 provided means of evaluating the constriction effects of the module magnet structure, frame, and rigid transmitting diaphragm core. Benchmark partition 6 was identical to benchmark partition 5, except that it added the flexible airtight surround (see Fig. 6). Measured transmission losses of the two benchmark partitions are compared in Fig. 9.

Without the surround, the transmission loss of benchmark partition 5 was very small. Over the measurement bandwidth, its average value was only 1 dB. It produced a
FIG. 9. Measured transmission losses for passive benchmark partitions 5 and 6 (see Fig. 6). Both are modified SCL modules with a steel plug replacing the transmitting diaphragm assembly. Benchmark partition 5 is configured without a surround while benchmark partition 6 is configured with a surround.

transmission loss plateau of just under 2 dB between 750 and 1275 Hz. At higher and lower frequencies, the transmission loss tapered to values closer to those of the open tube, with an average transmission loss of less than 0.2 dB. The transmission loss of benchmark partition 6 was quite similar to that of the acceleration-controlled ASP module shown in Fig. 8. These measurements accordingly confirm that the module surround was an important partition element with a resonant transmission loss minimum near 1200 Hz.

B. Double-composite-leaf (DCL) module

The DCL module depicted in Fig. 4 was evaluated under three basic conditions. It was first measured in its passive mode, with its actuator terminals open circuited. It was next measured in its first active mode, with its normal transmitting diaphragm acceleration minimized through acoustic actuation. It was subsequently measured in its second active mode, with its enclosed cavity pressure minimized at a point through acoustic actuation. For the second active mode, the error signal was first produced by a microphone located on the chamber axis, centered about 1 cm behind the transmitting diaphragm. The microphone was then moved to a position about 1 cm from the edge of the chamber, approximately 1 cm behind the transmitting diaphragm surround. Because of the success of error signal compression with the SCL module, the compressor/limiter was again used to process the module error signals (see Fig. 2). In the following sections we provide evaluations of the module under the various conditions.

1. Passive mode

The measured normal-incidence transmission loss for the passive DCL module is shown in Fig. 10. A theoretical curve based on analytical results[17] and module parameters is also shown for comparison. The dip in the curve to its minimum value near 35 Hz is well predicted by the theoretical curve and is caused by the impedances of the actuator and transmitting diaphragm assemblies. Transmission loss is characteristically poor in the surrounding spectral region. Al-
FIG. 10. Measured transmission losses for the DCL ASP module in its passive mode (actuator terminals open circuited) and in its first active mode (transmitting diaphragm acceleration minimized). The measured passive curve is plotted against a theoretical prediction.

FIG. 11. Measured acceleration error signal attenuation produced by a single-channel filtered-x controller with the DCL ASP module. The result is plotted against an attenuation curve for the cavity pressure immediately behind the center of the transmitting diaphragm under acceleration control.

though the average transmission loss over the entire measurement bandwidth is 43 dB, it is only 10 dB between 40 and 200 Hz. These low-frequency limitations are typical of passive partitions.

The dip near 200 Hz in the measured curve corresponds approximately to the mass-air-mass resonance frequency of the passive double-leaf partition.[31] Immediately above this dip, the transmission loss increases at slightly more than 20 dB per octave, as anticipated for frequencies just above the resonance. As the frequency continues to increase, one might expect the transmission loss to continue rising at a rate of about 18 dB per octave. However, the trend stops at approximately 720 Hz, at a maximum value of 58 dB. The reduction of the transmission loss above this frequency (following primarily from the presence of the actuator diaphragm surround) suggests a limitation to the idealized double-leaf partition behavior that might be ascribed to the passive module. From 720 to 950 Hz, transmission loss gradually recedes to approximately 47 dB, where it temporarily levels off. Near 1890 Hz, a pronounced dip to a value of 38 dB corresponds to the first axial resonance frequency of the enclosed cavity.

2. Transmitting diaphragm acceleration control

Once the normal acceleration of the transmitting diaphragm was minimized via active control, the transmission loss of the module dramatically increased over the entire measurement bandwidth (see Fig. 10). It increased by an average of 34 dB and by more than 70 dB at some lower frequencies. The transmission loss was not infinite, as predicted by limited theoretical modeling,[17] but it was substantial. Its general value gradually increased from about 70 dB near 40 Hz to over 90 dB near 725 Hz. Above 725 Hz, it decreased until it dropped to roughly 60 dB at the highest measurement frequencies. The average over the entire measurement bandwidth was approximately 77 dB. From 40 to 200 Hz, the average was 73 dB—a 63 dB improvement over the corresponding average under passive conditions. Between 40 and 1125 Hz, the average transmission loss was 82 dB.
As shown in Fig. 11, the active attenuation of the normal acceleration error signal ranged from a low of about 50 dB at some frequencies to more than 80 dB at several frequencies below 200 Hz. (Such high values for the 12-bit controller I/O system were made possible in part by error signal compression.) The attenuation notably decreased between the lowest frequencies and 750 Hz. Above 750 Hz, it again increased until it leveled off at roughly 64 dB. The average reduction over the entire measurement bandwidth was 64 dB.

The attenuation of the cavity pressure directly behind the center of the transmitting diaphragm is also shown in Fig. 11 as a result of the acceleration control scheme. It clearly follows the acceleration attenuation up to about 750 Hz, but continues its decline at higher frequencies, dropping well below the acceleration attenuation curve. It eventually dips to a conspicuous minimum of 13 dB centered near 1800 Hz. The center frequency of this dip coincides closely with the cutoff frequency of the first cavity cross mode. At frequencies above the dip, the cavity pressure attenuation again rises to approximately 35 dB. On average, cavity pressure attenuation over the measurement bandwidth is 45 dB, a full 19 dB less than the corresponding average acceleration attenuation.

Another noteworthy characteristic of the controlled module involves the normal acceleration at the center of the *actuator* diaphragm. Under controlled conditions, its mean-square value was found to decrease from its passive mean-square value below 800 Hz. However, above 800 Hz, it actually *increased* in order to minimize the normal transmitting diaphragm acceleration. The greatest increase in its mean-square acceleration occurred at approximately 1850 Hz. Theoretical work has indicated that the transmitting diaphragm acceleration control is accomplished by minimizing the source-side volume velocity into the cavity.[2,3,17] Although the rigid body motion of the actuator diaphragm could not be guaranteed over the entire measurement bandwidth, the fact that the relative central diaphragm acceleration increased with increasing frequency suggests that the diaphragm had to counteract at least one other transmission path into the cavity. A principal candidate for such a path was the resilient diaphragm surround.
FIG. 12. Measured transmission losses for the DCL ASP module in three active modes: (1) transmitting diaphragm acceleration control, (2) cavity pressure control with the error microphone centered behind the transmitting diaphragm, and (3) cavity pressure control with the error microphone directly behind the transmitting diaphragm surround.

FIG. 13. A comparison of measured transmission losses for the SCL and DCL ASP modules in their passive and acceleration-controlled active modes.

3. Cavity acoustic pressure control

a. Central cavity position Figure 12 shows that when acoustic pressure was controlled at the central position behind the transmitting diaphragm, the module transmission loss characteristics were very similar to those attained under transmitting diaphragm acceleration control. The average transmission loss over the measurement bandwidth was again 77 dB.

The error signal reduction for this scheme was also similar to that produced by the acceleration control scheme over most of the measurement bandwidth. The average attenuation was again 64 dB. This stands in contrast to the 45 dB average pressure reduction realized under acceleration control at the same cavity position. Over a small bandwidth centered at approximately 180 Hz (near the passive mass-air-mass resonance frequency of the module) there was a significant difference between the error signal attenuation of the two control schemes. Acoustic pressure reduction under cavity pressure control was approximately 12 dB less than acceleration reduction under transmitting diaphragm acceleration control. Acoustic pressure was even reduced more through acceleration control at these frequencies than through cavity pressure control.

As one might anticipate, normal transmitting diaphragm acceleration was substantially reduced under the cavity pressure control scheme because of an attendant decrease in the source-side volume velocity into the cavity. This reduction was nearly identical to the cavity pressure reduction under transmitting diaphragm acceleration control over most of the measurement bandwidth (see Fig. 11). Its average attenuation of 43 dB was about 2 dB lower than the cavity pressure attenuation under acceleration control. The most pronounced difference between the two attenuation curves was again concentrated in the small spectral region centered near the passive mass-air-mass resonance frequency. Relative to cavity pressure reduction under acceleration control, acceleration reduction under cavity pressure control suffered a 13 dB dip in this region. Thus, although the two control schemes demonstrated similar behaviors, the acceleration control scheme was slightly more effective.
b. Peripheral cavity position Figure 12 also shows that the controlled transmission loss of the module suffered more significantly after the error microphone was moved from behind the center of the transmitting diaphragm to a peripheral position behind its surround. The transmission loss followed that generated under acceleration control and that generated under centered cavity pressure control up to about 600 Hz. However, above 600 Hz, its relative transmission loss significantly decreased, dropping from roughly 85 dB at 600 Hz to about 50 dB at 1970 Hz. The average value over the entire measurement bandwidth was 68 dB—a full 9 dB lower than that achieved under the other two schemes. The approach also produced a more pronounced dip to 27 dB near 1850 Hz. Interestingly, the transmission loss was even 12 dB lower at that frequency than that produced by the module in its passive state.

Error signal attenuation for this latter scheme once again resembled that of the acceleration control scheme, except near 180 Hz. At that frequency, its relative attenuation dropped by approximately 15 dB. Average attenuation over the measurement bandwidth was 63 dB. The attenuation of normal transmitting diaphragm acceleration was similar to that achieved by the centered cavity pressure control scheme up to about 400 Hz. However, above 400 Hz, it dropped until it became roughly 20 dB less than that achieved by the former scheme over the remaining measurement bandwidth. The attenuation dip centered at 1800 Hz (see Fig. 11) also shifted up slightly to a center frequency of 1850 Hz. The average diaphragm acceleration reduction over the entire measurement bandwidth was 29 dB—a full 14 dB less than that achieved when pressure was minimized at the central cavity position.

IV. DISCUSSION

Figure 13 compares the transmission loss curves for the two ASP modules in their passive and active acceleration-controlled states. While both modules utilized the same basic control objective, the DCL module yielded an average transmission loss improvement of 56 dB over the SCL module.

This significant improvement followed from a simple configurational difference that produced very high transmission loss over a broad frequency range.

Experimental results indicated that both normal transmitting diaphragm acceleration control and centered cavity pressure control of the DCL module yielded similar transmission losses. Both schemes performed best at frequencies well below the cutoff frequency of the first cavity cross mode and the first cavity axial resonance frequency. Assuming the transmitting diaphragm behaved as a translational piston, one would expect diaphragm acceleration control to be less sensitive to error sensor location than cavity pressure control. This assertion is partly supported by the degraded experimental results for cavity pressure control when the error microphone was displaced to the periphery of the cavity. Transmitting diaphragm acceleration control also provided slightly superior error signal reduction than either cavity pressure control scheme.

Many of the results described for the cavity pressure control scheme give evidence of acoustic wave effects increasing in the cavity with increasing frequency. Since these effects make the scheme less consistent at higher frequencies, error microphone placement must be optimized to reduce their impact. Another detrimental aspect of the scheme appears at lower frequencies near the mass-air-mass resonance frequency of the module. As indicated in Ref. 17, cavity pressure control is slightly precarious because it is possible to minimize acoustic pressure at a point in the cavity while the transmitting diaphragm is still vibrating. If an error microphone is positioned near an uncontrolled cavity pressure node, control complications may arise. Because of these limitations of the pressure control scheme, acceleration control might be considered the more effective strategy for the module.

The transmission loss of the SCL module was relatively low at most frequencies. As a result, limitations posed by flanking transmission, electronic cross-talk, and noise were not generally significant during its measurements. With the module rigidly attached to both the source tube and receiving tube, Figs. 7 and 8 suggest that flanking transmission may only have caused a slight effect on the measured transmission loss in a narrow frequency band near 90 Hz.

Because of the very high transmission loss produced by the DCL module, one might question whether the measurement system could accurately evaluate its full transmission loss capabilities. In Sec. II D we indicated that measurement constraints due to flanking transmission, electronic cross-talk, and noise posed significant limitations. To further consider the impact of these limitations, the transmission loss of the acceleration-controlled DCL module is plotted again in Fig. 14, against the transmission loss signal-to-noise ratio[3] and the transmission loss for benchmark partition 4 with its resilient coupler connection. An inspection of the curves reveals that the transmission loss of the DCL module was generally within the transmission loss signal-to-noise ratio, although it pushed these limits at some frequencies. The DCL module also pushed the limits suggested by the benchmark partition up to about 1150 Hz. However, above 1150 Hz, its transmission loss receded, creating a significant margin.
FIG. 14. A comparison of the measured transmission loss of the DCL ASP module under transmitting diaphragm acceleration control to (1) the measured transmission loss of benchmark partition 4 with a resilient coupler connection (see Fig. 5) and (2) the transmission loss signal-to-noise ratio.

Results from Sec. II D suggest that the benchmark partition transmission loss may have been slightly corrupted by flanking transmission below about 160 Hz (see Fig. 7). An inspection of Fig. 14 suggests that the low-frequency portions of the measured ASP module transmission loss may also have been corrupted. However, an additional comparison of Fig. 7 suggests that effects of flanking transmission could have been much worse had the two module sections not been mechanically isolated through their resilient connection.

Transmission loss for the benchmark partition could also have been slightly corrupted by electronic cross-talk between upstream and downstream signals—most predominantly in the spectral region between 500 and 1000 Hz. Once again, this possibility could have implications for the DCL module. Since identical adaptive controller convergences could not be guaranteed for consecutive measurements, upstream and downstream acoustic pressures were measured simultaneously. Otherwise, the effects of electronic cross-talk might have been further reduced.

As shown in Figs. 8 and 10, the measured and theoretically predicted transmission loss curves for the ASP modules have been found to agree within reason. This provides useful validation of the models presented in Ref. 17. Measured and theoretically predicted source-side reflection coefficients of the modules have also been found to agree.[3,17]

V. SUMMARY AND CONCLUSIONS

Experimental methods have been developed to assess the normal-incidence transmission losses of individual active segmented partition (ASP) modules over a bandwidth from 40 to 1970 Hz. The methods fulfill simultaneous dynamic range requirements of a measurement system and an adaptive controller while addressing adaptive controller stability and convergence. Steps were taken to evaluate and reduce flanking transmission, electronic cross-talk, ambient acoustic noise, and electronic noise—all of which limited the maximum reliably measured transmission loss of the system. The module measurements were validated by comparing their

measured transmission losses to theoretical predictions and measured transmission losses of passive benchmark partitions with predictable or extreme behaviors.

Two experimental ASP modules were created to substantiate theoretical predictions of their behaviors. The first was a single-composite-leaf (SCL) configuration with an electromechanically actuated diaphragm and a resilient surround. The second was a double-composite-leaf (DCL) configuration with an electroacoustically actuated cavity bounded by a passive transmitting diaphragm and a resilient surround. The underlying active control objective for each was to induce global reduction of its normal transmitting surface vibrations through simple actuation and error sensing.

A filtered-x adaptive controller successfully controlled both modules over the entire measurement bandwidth as they were excited by a swept-sinusoidal stimulus. Electronic signal compression was found to increase error signal attenuations, sometimes to exceptional values for the 12-bit controller I/O system. Nevertheless, actual transmission loss performances of the modules depended more significantly upon their physical configurations and control schemes.

Under active transmitting diaphragm acceleration control, the low-frequency transmission loss of the SCL module increased somewhat over its passive transmission loss, but the high-frequency transmission loss decreased, leaving the average value unchanged. The decline in high-frequency performance was apparently caused by uncontrolled surround vibrations. Under similar control, the transmission loss of the DCL module increased substantially at all frequencies. Increases at low frequencies were particularly noteworthy. Flanking transmission, electronic cross-talk, and noise may have had some influence on the measurement of its very high transmission loss values.

The adaptive controller was also used in an alternative control scheme to minimize acoustic pressure at discrete points within the DCL module cavity. Transmitting diaphragm acceleration control was found to be slightly more effective than cavity pressure control when the error microphone was centered directly behind the transmitting diaphragm. It was found to be much more effective than cavity pressure control when the microphone was moved to the periphery of the cavity. Inefficiencies of the cavity pressure control scheme stem from acoustic wave effects in the cavity at higher frequencies and other problems related to error signal observability. Transmitting diaphragm acceleration control and cavity pressure control both performed best at frequencies well below the cutoff frequency of the first cavity cross mode and the frequency of the first axial cavity resonance.

Under active control, the mean-square acceleration at the center of the DCL module actuator diaphragm actually increased from its passive value at higher frequencies. This increase was apparently required to counteract one or more transmission paths into the module cavity (other than the central part of the diaphragm itself) and to reduce the source-side volume velocity. The actuator surround was a likely candidate for an alternative path into the cavity.

While both modules used the same underlying control objective, the DCL module yielded an average transmission loss that was 56 dB higher than that of the SCL module. This substantial improvement was accomplished through a simple configurational change that required no more complicated actuation or error sensing. While both modules improved low-frequency transmission loss through active control, the DCL module consistently provided much higher transmission loss over the entire measurement bandwidth. It therefore proved to be the better candidate for ASP applications.

Additional work is required to assess normal-incidence transmission loss characteristics of other ASP module configurations and multiple modules mounted in ASP arrays. Oblique and random-incidence transmission loss measurements should also be conducted for these modules and arrays.

[18]One easily overlooked complication in the measurement of active partitions involves the impact of actuation upon both the receiving space and source space sound fields. When comparing passive and active control conditions for a partition, a change to either field has impact on the measured transmission loss. Another complication involves the interaction between active partitions, as secondary sources of sound, and primary sources of sound in the source space (Ref. 19). Other complications are discussed in this paper.

[29]Arithmetic decibel averages are used in this paper. Because they are based on fixed 1 Hz frequency increments, these averages are most easily visualized with transmission loss plots that use linear frequency scales.

[30]When used for error signal processing, the compressor/limiter was adjusted to send the adaptive controller consistently high error signal levels throughout the adaptation processes. With sinusoidal excitation and a compression ratio of approximately 8:1, it allowed adaptation to proceed without significant effect on convergence or stability. It also enabled the adaptive controller to significantly improve its error signal reductions (Ref. 3).

[31]F. J. Fahy, *Sound and Structural Vibration: Radiation, Transmission, and Response* (Academic Press, New York, 1985).

[32]Without the use of the compressor/limiter, the average acceleration reduction over the measurement bandwidth was approximately 63 dB. With its use, the value increased to approximately 66 dB—a 3 dB improvement. However, between 20 and 100 Hz, the compressor/limiter produced an average improvement of 10 dB, while between 200 and 600 Hz it produced an average improvement of 9 dB. Over the remainder of the bandwidth, the compressed and uncompressed error signals yielded similar reductions, with a few exceptions. Error signal compression might be considered for the enhancement of adaptive controllers with inadequate dynamic ranges, at least when used with sinusoidal stimuli.

Linear independence method for system identification/secondary path modeling for active control

Benjamin J. Kim[a)] and David C. Swanson

Applied Research Laboratory and Graduate Program in Acoustics, The Pennsylvania State University, P.O. Box 30, State College, Pennsylvania 16804

A method for noninvasive system identification/secondary path modeling has been developed for single- and multi-channel filtered-*x* least-mean-square (LMS)-based active noise control (ANC). The problem of on-line secondary path modeling is recognized as one of linear dependence associated with an underdetermined system, a one-equation/two-unknown problem in which the highly correlated primary source and secondary source contributions to the error signal are not readily distinguishable. The method resolves this uniqueness issue by introducing a second equation with similar unknowns. The critical linear independence of the two equations, hence the proposed designation, is achieved with a single perturbation of the control filter output, thereby rendering the system solvable. This secondary path modeling strategy was implemented using an innovative real-time DSP control architecture and tested on a "transducerless" system devised to investigate behavior of ANC algorithms. Results of narrowband, broadband, and multi-channel tests reveal response estimates that are accurate in both magnitude and phase; bias due to primary noise and other secondary sources is notably absent in the obtained secondary path models. The rapidity with which the system is identified can also contribute to the stability and performance of filtered-*x* LMS-based controllers. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1992727]

I. INTRODUCTION

The filtered-*x* least-mean-square (FXLMS) algorithm is easily the most widely used and studied adaptive algorithm in feedforward active noise control (ANC) due in no small measure to its relative simplicity, proven robustness, and ease of implementation.[1–6] An extension of the venerable LMS algorithm conceived by Widrow and Hoff in 1959,[7,8] the FXLMS algorithm was developed (by Morgan in 1980 and independently by Widrow *et al.* and Burgess in 1981)[9–11] to accommodate the electro-acoustic feedforward or secondary path inherent in ANC systems (see Fig. 1). Accommodation would entail filtering the reference or *x* signal with a response estimate or model of the composite secondary path prior to performing the cross correlation in the LMS recursion (hence the designation "filtered-*x*"). This prefiltering would compensate for the delay in the feedforward path by effectively time aligning the reference and error signals, allowing for a usable gradient estimate and thus rendering the LMS method practicable for ANC.

Obtaining the necessary secondary path response estimates requires that the FXLMS adaptive filter be partnered with a secondary path modeler, preferably one that is not only accurate in its measurement of the "plant" response but adaptive in order to track any changes that the path might undergo during system operation. Given that the stability and performance of the (otherwise robust) FXLMS algorithm depend almost entirely on the quality of the plant models, it is a rather uncompromising arrangement. The secondary path modeler must *lead* the adaptive control filter with response

estimates that sufficiently reflect the path at the time of the filter updates, else the controller can diverge. For a time-varying environment, this ideal modeler—one that is both accurate and adaptive—is preferred. To this end, secondary path modeling continues to be a focus of research in active control.

The level of accuracy that secondary path modelers should attain for stable FXLMS operation has been analyzed extensively.[9,12–14] With a tonal reference the FXLMS algorithm is stable provided the phase of the response estimate is within ±90° of that of the true plant response at the disturbance frequency. Numerical results suggest that errors of ±40° hardly affect the convergence of the algorithm;[9] beyond ±40°, however, convergence slows with adaptation actually "stalling" as phase errors approach ±90°. The convergence coefficient, or step size, can be reduced to help with stability but doing so can further slow adaptation and limit convergence. Errors in the magnitude of the response estimate, considered more forgiving than its phase counterpart, can also cause instability but can be rectified by an appropriate adjustment of the step size (in proportion to the inverse of the error).[5] This rescaling of step sizes based on error, however, is deemed unfeasible as it requires knowledge of the true plant response which if known would certainly be used in lieu of the estimated response. Nevertheless, the findings establish that secondary path models need only be sufficiently accurate—not necessarily exact—for a FXLMS controller to perform satisfactorily. It is therefore desirable that secondary path modelers demonstrate consistency in meeting such tolerances.

The adaptive requirement for the ideal modeler assumes an on-line secondary path modeling implementation. The

FIG. 1. Secondary path (and primary path) in feedforward ANC system. Secondary path extends from the control filter output to the error sensor input (includes the digital-to-analog and analog-to-digital converters).

secondary path response can be estimated off-line prior to ANC operation and is usually done in the absence of primary noise. In most practical cases, however, the primary noise cannot be switched off. Moreover, the secondary path can be time varying which may render the initial model obsolete and unusable by the FXLMS controller. It follows that there are two basic approaches to on-line secondary path modeling: invasive and noninvasive. The former, often referred to as active system identification, involves the injection of interrogatory signals such as uncorrelated random noise through the control path, a technique known as additive random noise.[15] Besides the counterproductive nature of injecting auxiliary noise for the purposes of noise control, this technique suffers from misalignment in the secondary path response estimate due to residual noise[1] and typically long convergence times if convergence is achieved at all.[4] Variations on this approach have been suggested that attempt to alleviate these problems.[16–18]

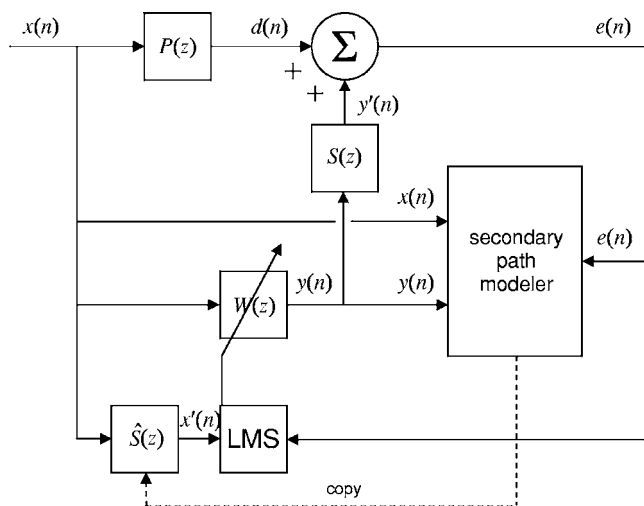
The preferred on-line modeling approach is thus noninvasive wherein the control signals are used to perform secondary path modeling (see Fig. 2), an approach often referred to as passive system identification. One such method employs an extended least squares technique whereby the


FIG. 2. Noninvasive secondary path modeler within FXLMS framework. $W(z)$, $P(z)$, $S(z)$, and $\hat{S}(z)$ represent the z transforms of the control filter, primary path, secondary path, and secondary path response estimate, respectively.

primary path and secondary path are simultaneously modeled in an "overall" fashion (the primary path modeling would aid in removing from the secondary path response estimate the bias due to primary noise).[19–21] The minimization of the difference between its estimated and measured error signals, however, yields solutions for the primary and secondary path models that are not necessarily unique.[4–6,19] This was observed by Kim in a "two-trial test", the results of which are given in Fig. 3.[22] In this real-time implementation, the primary and secondary path response estimates were recorded upon minimization of both the modeling error and error signal (a 1-kHz sinusoid). The results are indicative of an underdetermined system and can account for the observed instability of FXLMS-based control systems utilizing the overall modeling technique.[22–24] Kuo and Jiang suggested a procedural modification of this overall modeler wherein the primary and secondary path responses are estimated serially rather than in parallel in a "stage switching" process.[25] Numerous on-line noninvasive secondary path modeling methods have been proposed.[4,26–32] The difficulties associated with on-line secondary path modeling have led some to explore alternatives to the FXLMS algorithm, i.e., adaptive algorithms that do not require an explicit model of the plant.[33–39]

In this paper, a new method for system identification/secondary path modeling is presented. The difficulty in identifying the secondary source contribution within the error signal is first sketched in a physical and algebraic context. This description serves then as the point of departure for the development of the frequency-domain-based linear independence method for secondary path modeling. The methodology is formulated for single-channel system identification for both narrowband (single- and multiple-frequency)[22,40] and broadband signals, then generalized for multi-channel system identification. The proposed method is implemented atop a real-time frequency-domain FXLMS controller within the framework of a novel DSP control architecture, and tested on linear "transducerless" ANC systems devised for straightforward analysis of ANC algorithm behavior. Tests were conducted for both periodic and stochastic signals. To quantitatively assess the performance of the new method, particularly in how it manages a changing plant, all secondary path models are compared with the true plant models.

II. THE LINEAR INDEPENDENCE METHOD

A. Underlying problem in on-line secondary path modeling

Modeling of the secondary path is essentially a transfer function measurement of the path between the output of the digital controller that feeds the control source and the input of the error sensor. What renders such a routine measurement nontrivial in active control is the infiltration of primary noise through the secondary path during the identification process as this introduces bias in the secondary path response measurement. In most ANC applications, it is unlikely that the primary noise source can be switched off for system identification purposes (such as electrical transformers and air-
FIG. 3. Two-trial results for overall modeling algorithm. Note relative phases of response estimates and scale of y axes for $\hat{s}[n]$.

plane engines). Many times the secondary path model obtained off-line does not reflect the path during system operation (as in fan-induced duct noise).

The predicament is clear when considering the superposition of two sinusoids of like frequency each with some specified amplitude and phase, a superposition which results in a third sinusoid of equal frequency with corresponding amplitude and phase. If the object was to find the first two sinusoids with knowledge of only the third, even the casual observer would recognize that it is not possible. In fact, an infinite set of sinusoids exists (at the given frequency) that can yield the third sinusoid. It is this correlation that makes on-line secondary path modeling the challenge it has been: it disallows the ability to correctly distinguish the secondary noise contribution in the error signal which when known aids in the accurate determination of the secondary path response. Determining what two numbers make up a specified sum such as in the equation $P+S=1$ summarizes the inherent problem algebraically.

In any single-channel ANC system where source-to-reference feedback is negligible, the time-domain equation relating the physical contributions of the primary noise source and the secondary noise source to the error signal is

$$[x(n) * p(n)] + [y(n) * s(n)] = e(n), \tag{1}$$

where $*$ denotes linear convolution; $x(n)$ and $y(n)$ are the reference and filter output signals, respectively; $p(n)$ and $s(n)$ represent the primary and secondary path impulse responses, respectively; and $e(n)$ is the error signal. The quantity $[x(n)*p(n)]$ corresponds to the primary source contribution to the error signal $e(n)$ [reference signal $x(n)$ traverses primary path $p(n)$] while the quantity $[y(n)*s(n)]$ corresponds to the secondary source contribution [control filter output $y(n)$ traverses secondary path $s(n)$]. The filter output is related to the reference signal as in the equation

$$y(n) = \sum_{l=0}^{L-1} w_l(n)x(n-l), \tag{2}$$

where $w_l(n)$ is the lth coefficient of a length L finite impulse response (FIR) filter. Applying the Fourier transform to Eq. (1) gives

$$[X(k)P(k)] + [Y(k)S(k)] = E(k), \tag{3}$$

where k denotes the kth frequency bin. $X(k)$, $Y(k)$, and $E(k)$ are transforms of the readily observable quantities $x(n)$, $y(n)$, and $e(n)$, respectively, that are obtained via blocks of

time-aligned data, or "snapshots". The unknowns are $P(k)$ and $S(k)$, the primary path and secondary path transfer functions, respectively. For the purposes of comparison, Eq. (3) can be rewritten as

$$\{XP + YS = E\}_k. \tag{4}$$

The similarity between the aforementioned "$P+S=1$" example and Eq. (4) is now evident. For given data set $\{X,Y,E\}$ there exists an infinite set of solutions for P and S.

B. Formulation

The insufficiency of one equation in determining a unique solution for the requisite secondary path response estimate $\hat{S}(k)$ was made salient in the last section. The formulation of the linear independence method begins with the notion that it may be possible to locate the correct set $\{\hat{P}(k),\hat{S}(k)\}$ within the infinite pool of estimates that satisfy Eq. (3) by introducing another equation with a similar set of unknowns. Taking two consecutive snapshots of data allows for a set of two equations with two unknowns,

$$X_A(k)P(k) + Y_A(k)S(k) = E_A(k), \tag{5a}$$

$$X_B(k)P(k) + Y_B(k)S(k) = E_B(k), \tag{5b}$$

where $\{X_A(k),Y_A(k),E_A(k)\}$ corresponds to the first snapshot of data and $\{X_B(k),Y_B(k),E_B(k)\}$ corresponds to the second snapshot of data. $Y_A(k)$ and $Y_B(k)$ represent the control filter outputs according to the equations

$$Y_A(k) = W_A(k)X_A(k), \tag{6a}$$

$$Y_B(k) = W_B(k)X_B(k), \tag{6b}$$

where $W(k)$ is the FFT of the filter's impulse response. Linear independence of the two equations [Eqs. (5a) and (5b)] is achieved by ensuring the inequality

$$W_A(k) \neq W_B(k). \tag{7}$$

Primary and secondary paths are assumed to remain stationary in between and during snapshots. The solution is thus

$$\hat{P}(k) = \frac{E_A(k)Y_B(k) - Y_A(k)E_B(k)}{X_A(k)Y_B(k) - Y_A(k)X_B(k)}, \tag{8a}$$

$$\hat{S}(k) = \frac{X_A(k)E_B(k) - E_A(k)X_B(k)}{X_A(k)Y_B(k) - Y_A(k)X_B(k)}. \tag{8b}$$

This formulation can be conveniently written in matrix form beginning with Eqs. (5a) and (5b):

$$\begin{bmatrix} E_A \\ E_B \end{bmatrix}_k = \begin{bmatrix} X_A & Y_A \\ X_B & Y_B \end{bmatrix}_k \begin{bmatrix} P \\ S \end{bmatrix}_k. \tag{9}$$

Matrix algebra gives

$$\begin{bmatrix} \hat{P} \\ \hat{S} \end{bmatrix}_k = \begin{bmatrix} X_A & Y_A \\ X_B & Y_B \end{bmatrix}_k^{-1} \begin{bmatrix} E_A \\ E_B \end{bmatrix}_k, \tag{10}$$

and inversion of the square matrix results in the equation

$$\begin{bmatrix} \hat{P} \\ \hat{S} \end{bmatrix}_k = \left\{ \frac{1}{X_A Y_B - Y_A X_B} \begin{bmatrix} Y_B & -Y_A \\ -X_B & X_A \end{bmatrix} \right\}_k \begin{bmatrix} E_A \\ E_B \end{bmatrix}_k. \tag{11}$$

This is equivalent to Eqs. (8a) and (8b).

1. Narrowband noise

Narrowband signals may render the 2×2 matrix in Eq. (10) noninvertible for the unexcited FFT bins where, again, k denotes the FFT bin number. These unexcited bins contain zeros, thus the inversion of these matrices would result in null sets of solutions. Although it may be feasible to add low-level broadband noise to excite these bins, spectral leakage prohibits the direct inversion of even the matrices that are associated with frequency bins corresponding to the narrowband signal.[22]

Since the FXLMS algorithm requires only the secondary path response estimate $\hat{S}(k)$, Eq. (8b) will be considered from this point forward though the method outlined in the following can be applied to estimate the primary path $\hat{P}(k)$ (valid for single-channel only). Noting that FFTs are made up of complex numbers, a routine complex conjugate multiply done on this expression yields

$$\hat{S}(k) = \frac{[X_A(k)E_B(k) - E_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*}{[X_A(k)Y_B(k) - Y_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*}, \tag{12}$$

where * denotes complex conjugate. The denominator is now real valued. For narrowband signals the denominator is still zero for the unexcited frequency bins. The numerator is a spectrum that happens to preserve all phase information related to the secondary path response. More simply, the numerator is *correct in phase*. For sinusoidal (single-frequency) signals the numerator need only be scaled in magnitude by a single factor to yield an approximate, if not exact, plant estimate. Two methods of numerator scaling are suggested. One method uses the total power of the spectrum in the denominator to scale the numerator for which case utilizing Parseval's theorem would be appropriate. The other method uses the peak value of the spectrum in the denominator. For sinusoidal signals the equations are thus

$$\hat{S}(k) = \frac{[X_A(k)E_B(k) - E_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*}{\{[X_A(k)Y_B(k) - Y_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{power}} \tag{13a}$$

and

$$\hat{S}(k) = \frac{[X_A(k)E_B(k) - E_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*}{\{[X_A(k)Y_B(k) - Y_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{peak}}. \tag{13b}$$

An extension of this procedure yields the general solution for multiple-frequency narrowband signals. The spectrum is divided into subbands, each subband spanning bins associated with each sinusoid. Each subband in the numerator is then scaled by the peak value or power within the corresponding subband in the denominator. Thus Eqs. (13a) and (13b) can be generalized to accommodate multiple-frequency signals like so:

$$\hat{S}_{B1}(k) = \frac{\{[X_A(k)E_B(k) - E_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{B1}}{\{[X_A(k)Y_B(k) - Y_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{power\ or\ peak,B1}}, \tag{14a}$$

$$\hat{S}_{B2}(k) = \frac{\{[X_A(k)E_B(k) - E_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{B2}}{\{[X_A(k)Y_B(k) - Y_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{power\ or\ peak,B2}}, \tag{14b}$$

$$\vdots$$

$$\hat{S}_{BN}(k) = \frac{\{[X_A(k)E_B(k) - E_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{BN}}{\{[X_A(k)Y_B(k) - Y_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*\}_{power\ or\ peak,BN}}, \tag{14c}$$

where B stands for "band" and N denotes the Nth subband containing the Nth frequency signal. The sinusoidal case is a subset of this solution. This is similar to the scaling of bin-dependent step sizes described by Swanson for controlling multi-frequency narrowband noise using the frequency-domain FXLMS algorithm.[41] Where to divide the spectrum can be determined using peak recognition, a spectral processing and analysis tool that is used extensively in such areas as condition-based maintenance, speech recognition, and mass spectroscopy.

Care must be taken when performing the spectral multiplies in Eq. (14) to guard against circular convolution/correlation, or wraparound, errors. The overlap-save method is preferred for its simplicity whereby time series data are appropriately buffered and pre-/post-zero padded prior to transforming and multiplying. This method is described in detail by Shynk,[42] Reichard, and Swanson.[41,43] For a frequency-domain FXLMS implementation, a control filter of length L necessitates a secondary path response estimate of length $2L$ to carry out the cross spectrum in the LMS update. To yield a $2L$-length secondary path response estimate, data snapshots of lengths $4L$ and $8L$ are needed to properly execute Eq. (14) in this regard. This is summarized in Table I. Longer snapshots can be taken as long as the final time-domain secondary path model is truncated to meet the $2L$ length requirement. A comprehensive step-by-step procedure for implementing the linear independence method equation is given in the Appendix.

2. Broadband noise

Due to the stochastic nature of broadband noise, time averaging is required. The transfer function estimates $\hat{P}(k)$ (for single-channel systems) and $\hat{S}(k)$ are thus calculated according to the equations

$$\hat{P}(k) = \frac{1}{q}\sum_{i=1}^{q} \frac{E_{A,i}(k)Y_{B,i}(k) - Y_{A,i}(k)E_{B,i}(k)}{X_{A,i}(k)Y_{B,i}(k) - Y_{A,i}(k)X_{B,i}(k)}, \tag{15a}$$

$$\hat{S}(k) = \frac{1}{q}\sum_{i=1}^{q} \frac{X_{A,i}(k)E_{B,i}(k) - E_{A,i}(k)X_{B,i}(k)}{X_{A,i}(k)Y_{B,i}(k) - Y_{A,i}(k)X_{B,i}(k)}, \tag{15b}$$

where q is the number of averages. It is assumed here that the secondary path contains a delay no longer than that in the primary path in order to meet the causality constraint for broadband feedforward control systems. Although not necessary for random noise signals, the overlap-save method can be applied nonetheless to ensure that the secondary path response estimate is free of any circular convolution errors.[41] Note that the expressions in Eq. (15) do not incorporate the scaling methodology suggested for narrowband signals.

As stated in the previous section, the lengths of the data snapshots can be varied as long as the secondary path response estimate length requirement is met. Particularly for broadband noise, longer data snapshots provide better resolution and generally yield greater accuracy in the truncated impulse response.

TABLE I. Summary of lengths of relevant quantities relative to control filter length for frequency-domain FXLMS controller and proposed secondary path modeler.

Quantity	Description	Length
w	Control filter	L
s	Secondary path response estimate	$2L$
x_A, y_A, e_A	First data snapshot	$8L$ or $4L$
x_B, y_B, e_B	Second data snapshot	$4L$ or $8L$

3. Multi-channel system identification

Secondary path modeling for multi-channel active control systems presents an even greater challenge due to the additional canceling sources contributing to the control region. Imposing linear independence via the control filter makes a control source physically "audible" to an error sensor regardless of the ambient noise in the control field. This makes the proposed method ideal for multi-channel use where the control field of each error can contain contributions from multiple sources. Sequential and orderly "perturbation" of the control sources in the multi-channel system (in a round robin fashion) allows each of the error sensors to observe and identify the contribution from each secondary source. The equation for multi-channel linear independence secondary path modeling is

$$\hat{S}_{ij}(k) = \frac{X_A(k)E_{B,i}(k) - E_{A,i}(k)X_B(k)}{X_A(k)Y_{B,j}(k) - Y_{A,j}(k)X_B(k)}, \tag{16}$$

where i indicates the ith error sensor and j the jth secondary source. The jth source is perturbed to obtain the path models associated with that particular source. For example, in a two-input/two-output configuration, source 1 is perturbed to obtain path models $\hat{S}_{11}$ and $\hat{S}_{21}$, and source 2 is perturbed to obtain $\hat{S}_{12}$ and $\hat{S}_{22}$. The expression is evaluated in the manner described in the last two sections depending on the characteristics of the noise signal. Again, solving for $\hat{P}(k)$ is not possible in a coupled multi-channel configuration (primary sources cannot be perturbed, therefore bias due to other sources in the system cannot be removed).

C. Notes on implementation

1. Imposing linear independence and on-line modeling

Imposing linear independence forces two lines that are otherwise parallel to intersect. For the two lines defined by Eqs. (5a) and (5b), adjusting the filter coefficients so that $w_B(n) \neq w_A(n)$ changes the slope of the second line relative to the first allowing them to cross. The common point is $(P(k), S(k))$ and it is of course the coordinate $S(k)$ that secondary path modeling targets. Clearly there are countless ways in which this inequality condition can be met. There are, however, important considerations. The linear independence method works by perturbing a secondary source output so that an error sensor physically "hears" the secondary source within the highly correlated noise. Too small a perturbation and the error sensor may not detect the change in the system. This corresponds to an exceedingly shallow intersection of the two lines and, algebraically, a near-singular matrix in Eq. (9). For real systems, the finite precision of the DSP and limited dynamic range of system components in effect broaden and give the otherwise infinitely thin lines width. Though very slight, at such shallow angles this can cause the crossing point to become indistinct. The worst case is that the lines remain parallel despite an intended perturbation.

Thus a minimum perturbation is necessary to achieve unambiguity. This minimum perturbation is measurable and varies with the system.

Even with minimum perturbation considered, there are still countless ways in which one can perturb the control output. A relatively simple method entails adjusting the magnitude of the current control filter coefficients to generate the second set of filter coefficients according to the equation

$$w_B(n) = (1 + \varepsilon)w_A(n), \tag{17}$$

where ε is a real number (positive or negative) except zero. ε should be sufficient in magnitude to make the two-line intersection unambiguous. If it is too large, however, excessive changes in the control source output can result which may be undesirable. The linear independence method can be applied in this manner whenever secondary path models need updating. It can also be performed repeatedly before each and every update of the control filter. When the error signal is minimized, however, the constant perturbations can contribute residual noise. This can be alleviated by setting a threshold below which system identification is not performed.

It is possible to utilize the intrinsic FXLMS updating of the control filter for system identification. Data snapshots would be those taken before and after a filter update. Reference and error signal data from the second snapshot would be used with the newly generated secondary path model to calculate the gradient estimate (this second snapshot would then serve as the first snapshot for the next modeling). The control filter is updated and a new second snapshot taken. This process would be repeated. When the error signal is minimized, however, the changes in the control filter may not be sufficient to yield well-conditioned data sets as described earlier. This again can be alleviated by setting a threshold for the error signal magnitude below which system identification is not performed. A more robust option would be to monitor the *changes* in the control filter (if a change does not result in a perturbation that exceeds the minimum perturbation, then a secondary path model would not be calculated).

This exploitation of the FXLMS adaptation works for single-channel narrowband control and yields a true on-line modeler since "the control system is kept in operation during this repeated measurement" of the secondary path response.[6] For multi-channel implementations, it is arguable whether or not the linear independence method, or any method that is perturbation based, constitutes an on-line modeler since the controller must be suspended momentarily while the individual control sources are perturbed. For broadband ANC as well, the necessary averaging requires that the FXLMS updates be suspended until enough averages have been performed to yield adequate models. Depending on the characteristics of the noise to be canceled, the number of channels, and implementation, the linear independence method may or may not technically constitute on-line modeling. However, the method does effectively remove measurement bias without having to switch off the primary noise and secondary noise sources which can be viewed as requisite for on-line modeling.

2. Update rate and minimum time constraint

Time delays present in the feedforward path should be considered in the implementation of adaptive active noise controllers. The electro-acoustic secondary paths can have delays on the order of milliseconds (it can take that amount of time for any change in the control source output to appear at the error sensor input). If a controller updates itself within this delay period, it can be thought of as running blindly for those iterations. Data used for one update should reflect the change imposed from the previous update, else it is a wasted effort and stability can be compromised.[44] Also of concern is the transients introduced into the system by the altering of the control filter. The FXLMS algorithm and the proposed secondary path modeler are based on linear time invariance, therefore these transients should be allowed to decay out before subsequent measurements are taken.[1,44] This minimum waiting period depends on the system. For infinitely damped or nonreverberant systems this waiting period equals roughly the propagation delay between the control source and the error sensor. For lightly damped or reverberant systems this waiting period equals the propagation delay plus the time it takes for reverberations to decay out. The waiting period is defined as $\tau_{\text{prop+trans}}$ where "prop" denotes propagation and "trans" denotes transients. A block FXLMS implementation (a frequency-domain version is described later) lends itself naturally for filter update rate control and linear independence secondary path modeling.

The linear independence method assumes that the control system is unchanged in between and during the two snapshots required for the modeling. For narrowband noise, as stated in Sec. II B 1, a total of $12L$ data points is required to calculate the response estimate ($8L$ points for one set and $4L$ points for the other set). This amounts to $(12L)f_s^{-1}$ s where f_s is the sampling rate. Allowing the system to reach steady state after perturbation adds additional time. Thus, for the proposed method the minimum time requirement for secondary path modeling is

$$\tau_{\text{min}} = \frac{12L}{f_s} + \tau_{\text{prop+trans}}. \tag{18}$$

The situation is clearly different for broadband signals since averaging is required. The minimum time can vary depending on the desired resolution and accuracy. Increasing the number of averages can yield a more accurate secondary path model but will increase the minimum time for system identification. Larger data blocks can enhance resolution of the model (model can be truncated to appropriate length for x-filtering) but that too will increase the minimum time. Since system identification is best performed as quickly as possible, the specification of these parameters will involve a balancing act of sorts and will depend on the system and application. One implementation is described later in Sec. IV A 4.

III. EXPERIMENTAL SETUP

A. Control architecture and hardware

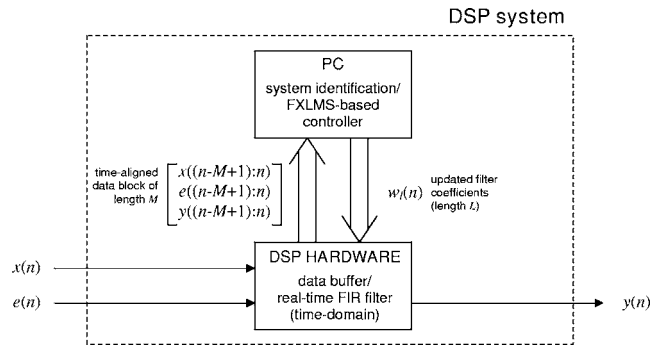
Normally, DSP system boards are programmed to handle all signal processing tasks, i.e., filtering, calculations and up-


FIG. 4. DSP control architecture for block processing implementation, single channel.

dates to the control filters, system identification if any, etc. For evaluation, troubleshooting, and debugging purposes, this implementation can be cumbersome due to the difficulty in monitoring the processing of the signals. It can be considerably more cumbersome when hardware is programmed in assembly. An innovative DSP control architecture was designed and implemented that is advantageous with respect to ease of use, signals analysis, and operator control.

Figure 4 depicts the control architecture. Signal processing tasks are assigned to both the DSP system board and the PC in which it operates. The DSP board doubles as a real-time filter and data buffer: it performs time-domain filtering on the reference signal using the filter weights "handed over" by the PC, and stores in a circular buffer the incoming signal data $x(n)$ and $e(n)$ and the control output data $y(n)$. The PC meanwhile downloads data from this buffer (data block size specified by the user), uses the data to calculate the control filter coefficients, and uploads the new filter weights to the DSP board. This not only lightens the computational load on the DSP permitting it to operate at higher sample rates and/or run longer filters, this sharing of information with the PC allows the user easy access to data for efficient signals analysis and troubleshooting using relatively syntax-free tools such as MATLAB. It is even possible to do real-time signal processing (minus the control filtering) with a tool such as MATLAB depending on the software and hardware configuration.

The key advantage to this control architecture with specific regards to FXLMS control and linear independence system identification is the relative ease with which one can adjust the control filter coefficients and the rate at which the filter is updated. While this is fundamental to the proper implementation of the proposed linear independence method, it is conducive to the stability of the FXLMS algorithm particularly when applied to systems that have large secondary path delays[44] and/or are lightly damped where transients introduced into the control field can linger.

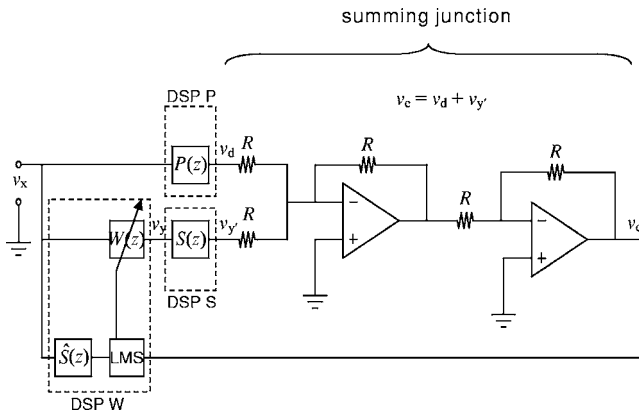
The DSP hardware used for the following tests comprised of Spectrum DSP32C system boards based on the WE® DSP chip. Each has two 16-bit analog I/O channels onboard with a ±3-V range on both the input and output. Each board, programmed in assembly, was optimized to run a 128-tap filter (128 coefficients) at 24 kHz. The multiplexed circular buffer held 131 072 samples of each of the two in-


FIG. 5. Transducerless ANC test circuit, single channel. Measured impulse responses can be uploaded to filters **P** and **S** to simulate real environments.

FIG. 6. Transducerless ANC test circuit, two channel. Channels are coupled.

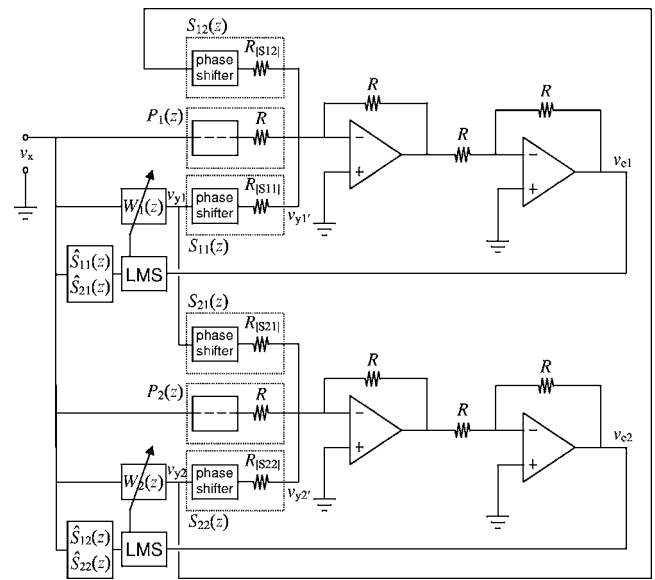
puts and control output, approximately 5.46 s worth of data (at 24 kHz). The cutoff frequency (-3 dB) was set at 9 kHz for the low-pass reconstruction and antialiasing filters. The PC ran on a 200-MHz Intel Pentium processor; Microsoft Visual C/C++ v6.0 was used for the necessary programming and operation of the DSP hardware. The reference signals were taken from a Hewlett Packard 35670A Dynamic Signal Analyzer.

B. The transducerless ANC test system

Op-amp-based transducerless ANC test systems were developed for controlled real-time testing of ANC algorithms. A schematic of the single-channel test system is given in Fig. 5. The summing junction acts as the point of interference between the desired and control signals, albeit in the electrical rather than the usual acoustical domain. There are several key advantages to such a test system: (1) it allows control over most system variables which aids in better understanding algorithm behavior; (2) it allows the testing of active noise controllers without having to go on-site or build large physical systems; (3) it ensures reproducibility over time; and (4) it is inexpensive. A notable feature of this test system is the interchangeable primary and secondary paths made possible by the insertion of digital filters at the appropriate points in the circuit. DSP **P** and DSP **S** help shape the primary and secondary paths, respectively. Like the control filter in DSP **W**, **P** and **S** are FIR filters that operate according to the equations

$$d(n) = \sum_{l=0}^{L-1} p_l(n)x(n-l), \tag{19a}$$

$$y'(n) = \sum_{l=0}^{L-1} s_l(n)y(n-l), \tag{19b}$$

the coefficients of which, namely $p_l(n)$ and $s_l(n)$, are determinable by the user. Each filter has a length of 128 and is run at 24 kHz. One can conceivably insert measured impulse responses of real systems into these filters to simulate those systems.


A schematic for the two-channel transducerless ANC test system is given in Fig. 6. Here, in addition to a second summing junction for the second channel, circuit paths were added to couple the two channels as indicated by S_{12} and S_{21} in the figure. Due to the limited number of DSP system boards, analog phase shifters were inserted to allow phase variation of sinusoidal signals in the secondary paths.[45] Magnitudes are determined by the resistor values at the inputs of the summing junctions.

C. LMS control filter implementations

A frequency-domain version of the normalized leaky FXLMS algorithm was implemented for the single-channel controller, expressed as

$$W_{m+1}(k) = \nu W_m(k) - \alpha_m(k)R_m^*(k)E_m(k), \tag{20}$$

where

$$R_m(k) = X_m(k)\hat{S}(k) \tag{21}$$

is the filtered-x signal spectrum, ν is the leakage factor, and $\alpha_m(k)$ is the convergence coefficient. The following frequency-domain normalized leaky multiple-error FXLMS algorithm[6] was implemented for the two-channel test:

$$W_{1,m+1}(k) = \nu W_{1,m}(k) - \alpha_{1,m}(k)\{R_{m,11}^*(k)E_{1,m}(k)$$
$$+ R_{m,21}^*(k)E_{2,m}(k)\}, \tag{22a}$$

$$W_{2,m+1}(k) = \nu W_{2,m}(k) - \alpha_{2,m}(k)\{R_{m,12}^*(k)E_{1,m}(k)$$
$$+ R_{m,22}^*(k)E_{2,m}(k)\}, \tag{22b}$$

where

$$R_{m,ij}(k) = X_m(k)\hat{S}_{ij}(k) \tag{23}$$

and i and j indicate the ith sensor and jth secondary source. For these tests ν was set to 0.999. Assuming the secondary path model is phase accurate the prefiltering operation in Eqs. (21) and (23) time aligns the reference and error

signals to allow for a valid cross spectrum in the gradient estimate. Again, care must be taken to avoid circular convolution/correlation errors. The FFT quantities needed for proper evaluation of these expressions using the overlap-save method are summarized below:

$$W_m(k) = \mathrm{FFT}[w_{mL}(0) \cdots w_{mL}(L-1) \, 0 \cdots 0], \tag{24}$$

$$R_m(k) = \mathrm{FFT}[r(mL-L) \cdots r(mL-1)$$
$$r(mL) \cdots r(mL+L-1)], \tag{25}$$

$$E_m(k)$$
$$= \mathrm{FFT}[0 \cdots 0 \, e(m2L+2L-L) \cdots e(m2L+2L-1)], \tag{26}$$

$$\hat{S}_m(k) = \mathrm{FFT}[s_{m2L}(0) \cdots s_{m2L}(2L-1) \, 0 \cdots 0], \tag{27}$$

$$X_m(k) = \mathrm{FFT}[x(m2L-2L) \cdots x(m2L-1)$$
$$x(m2L) \cdots x(m2L+2L-1)], \tag{28}$$

where L is the length of the control filter.

The convergence coefficient $\alpha_m(k)$ for the narrowband tests was made frequency *in*dependent so that

$$\alpha_m = \frac{\tilde{\alpha}}{[\Pi_{rr,m}(k)]_{\max}}, \tag{29}$$

where $\tilde{\alpha}$ is a normalized step size, $\Pi_{rr,m}(k)$ is the power spectral density of the filtered-x signal, and $[\Pi_{rr,m}(k)]_{\max}$ is the maximum absolute value in the power spectral density vector. This was done to sidestep the problems of spectral division mentioned in Sec. II B 1, namely those of spectral leakage and division by zero for unexcited frequency bins.[41] Each of the two FXLMS update equations in Eq. (22) uses a convergence coefficient that is scaled by the larger maximum of the two power spectral densities in its respective equation. The convergence coefficient for the broadband tests was made frequency dependent so that

$$\alpha_m(k) = \frac{\tilde{\alpha}}{\Pi_{rr,m}(k)}, \tag{30}$$

where, again, $\tilde{\alpha}$ is the normalized step size and $\Pi_{rr,m}(k)$ is the filtered-x signal power spectral density.[6] For both narrowband and broadband tests, the normalized step size $\tilde{\alpha}$ was set to 0.9.

IV. RESULTS AND DISCUSSION

Presented in this section are five tests that demonstrate the implementation and efficacy of the linear independence method. Efficacy of a secondary path modeler is best demonstrated by comparing its response estimates with the true models. The true models were obtained using the following adaptive modeler:

$$\hat{S}_{m+1}(k) = \hat{S}_m(k) + \alpha_m Y_m^*(k) E_m^y(k). \tag{31}$$

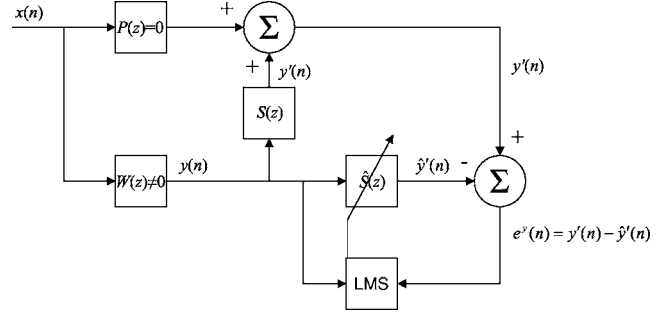
The corresponding block diagram is given in Fig. 7. Equation (31) is a basic LMS recursion that estimates the secondary path in an off-line fashion. The primary noise is made


FIG. 7. Block diagram of LMS filter used in determining true secondary path model.

quiet by a simple disconnect in the transducerless ANC test circuit to allow for an unbiased secondary path model.

A. Single channel

The transducerless ANC test circuit pictured in Fig. 5 was used for the following single-channel tests. For both the narrowband and broadband tests, a pure delay of 100 samples was inserted into the primary path via the filter in DSP **P**; $P(z)$, the z transform of the primary path, was approximately z^{-100}. This was done primarily to allow for causality for the broadband test (causality is of little concern for narrowband signals). For the narrowband tests four impulse responses were generated using random numbers each with length 128 and range -0.2 to 0.2; these would be inserted into DSP **S** to shape the secondary path. The impulse responses and their respective magnitude and phase responses are shown in Fig. 8 and are labeled S1, S2, S3, and S4. While these do not represent responses of real systems, their value lies in the variation in phase and magnitude as the impulse responses are "swapped out". The secondary path modeler would have to cope with the changes in the path regardless of authenticity. For the broadband test pure delays were manufactured for the secondary paths so that $S(z) \approx \{z^{-10}, z^{-25}, z^{-50}, z^{-75}\}$.

1. Single frequency, changing secondary path

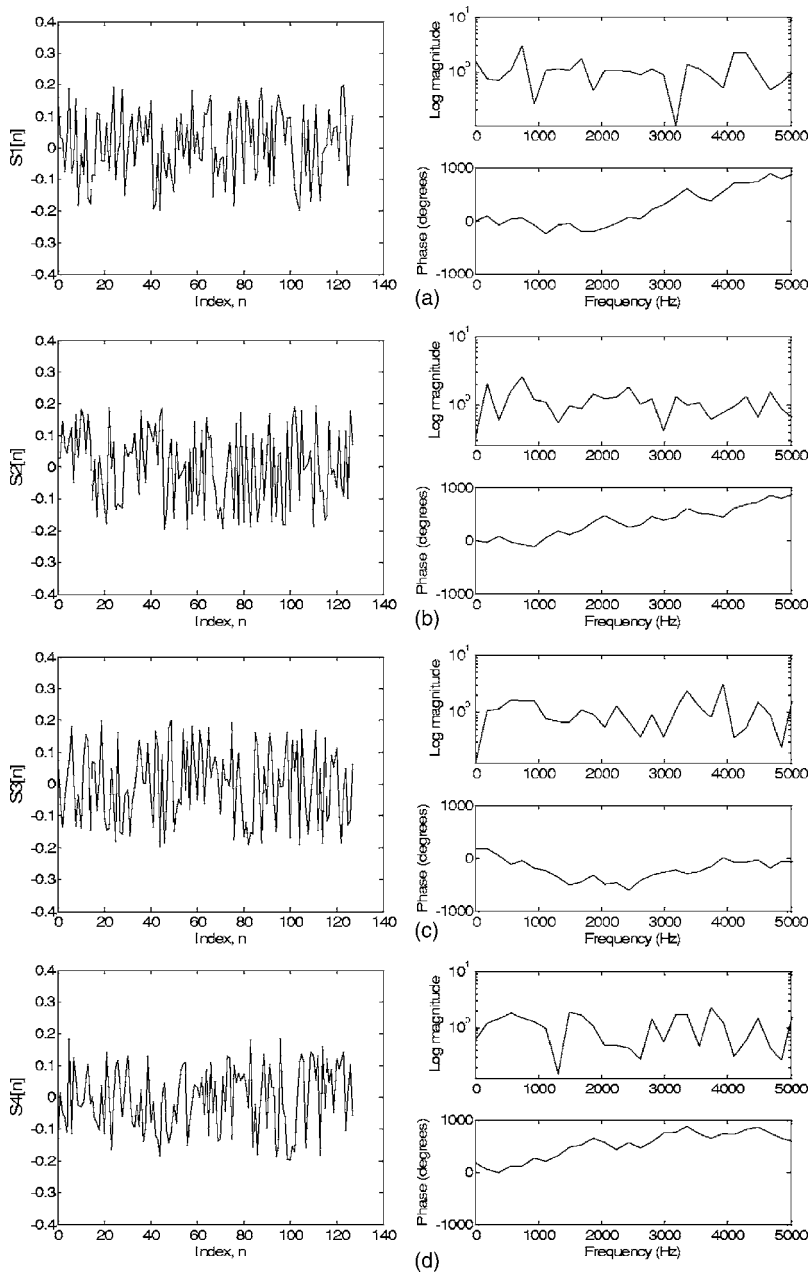
A sinusoidal signal of frequency 1 kHz and amplitude 1 V_p was used for the reference signal with the desired signal derived from this reference. DSP **S** is initialized with secondary path S1. Noise cancellation performance is given in Fig. 9. At ANC system startup, the control filter is zeroed $[W_A(z)=0]$ resulting in no secondary source output. A snapshot of data is taken (iteration 0); the control filter is then adjusted so that $W_B(z)=0.1$; a second snapshot is taken that reflects the change in the control field (iteration 1); the control filter is set back to zero; the secondary path model is calculated. The model is then used by the FXLMS filter for 14 iterations. The secondary path is then interchanged with S2 after iteration 15. A snapshot of data is taken (iteration 16), then the control filter coefficients present at iteration 16 are multiplied by 1.1 ($\varepsilon=0.1$) prior to acquisition of the second data set so that $w_B(n)=1.1w_A(n)$. This multiplication by 1.1 is done for the subsequent secondary path modeling for paths S3 and S4. This particular value of ε was chosen for no


FIG. 8. Random number generated secondary path impulse responses of length 128 and their respective magnitude and phase responses: (a) S1, (b) S2, (c) S3, and (d) S4.

reason other than to ensure that the perturbation would be visible in the noise cancellation performance plots.

Figure 9 compares the noise cancellation of the controller using three different secondary path models: (1) the true model, (2) the model obtained by scaling the numerator by denominator power, and (3) the model obtained by scaling the numerator by denominator peak value. The respectable performance of the controller—attenuation of ~50 dB after only ten iterations—can be attributed to the high accuracy of the secondary path models, revealed in Fig. 10, as well as the controlled update rate. In this near-infinitely damped system with negligible propagation delay, ten iterations (two for "sys id" and eight for FXLMS adaptation) corresponds to 0.15 s or 150 ms ($12L$ samples for sys id and $2L \times 8$ samples for FXLMS adaptation where $L=128$). Phases are exact while magnitudes are very closely approximated to the true magnitude. The models obtained using the peak scaling method are acceptable because they are consistent—consistently be-
FIG. 9. Cancellation performance of 1-kHz sinusoid in changing secondary path.
FIG. 10. Secondary path model comparison for 1-kHz sinusoid in changing path: (a) $\hat{s}_1$, (b) $\hat{s}_2$, (c) $\hat{s}_3$, and (d) $\hat{s}_4$. Models reveal phase delays of (a) 11, (b) 18, (c) 21, and (d) 16 samples. Amplitude of 0.0078 corresponds to unity gain.

low the actual magnitude—and therefore require no rescaling of step size to maintain FXLMS controller stability that an otherwise overestimated magnitude can compromise.

Phase delay information can be readily extracted from the plots of these single-frequency secondary path models. The center point or peak of the leftmost crest serves as the reference point. The distance from this point to the y axis is the phase delay in samples. In Fig. 10(a), the first crest is centered at approximately index 11 indicating an 11-sample phase delay in the path *at 1 kHz*. This phase delay changes according to the secondary path as observed in the other models in the figure. Note that phase delay is ambiguous within an additive constant of $2\pi N$ rad where N is any integer. Extracting absolute magnitude response requires knowledge of the FFT size. Here, an amplitude of 0.0078 corresponds to unity gain.

Before continuing, it is worthwhile to review why the secondary path models in Fig. 10 do not resemble the random number generated impulse responses in Fig. 9, e.g., why $s_1[n] \neq S1[n]$. Because the control signal is being used to estimate the secondary path, the models can reflect only those frequencies present in that signal. As Fig. 10 illustrates only the response at 1 kHz is estimated, not a broad frequency range. The same holds true for the control filters: filter weights will reflect only those frequencies present in the system. Thus the system will need to be reidentified when there is a change in frequency content (the control filter must correspondingly adapt to the new frequencies). This is the motivation for the next test.

2. Stationary secondary path, shifting frequency

Noninvasive secondary path modelers use the control signals to perform system identification, therefore any change in the frequency content will require the modeler to

reidentify the system to reflect the current frequencies. For this test, the frequency of the reference signal (still 1 V_p amplitude) was shifted from 1 to 4 kHz in 1-kHz steps. The secondary path was made stationary (path S1 was used throughout the test). The ANC performance is shown in Fig. 11. The procedure for imposing linear independence and adapting the control filter (14 iterations) is identical to that used for the first test. The secondary path response estimates are revealed in Fig. 12. As in the prior test, the phases correspond exactly with those of the actual models. The magnitudes are similar to the results of the last section.

3. Multiple frequency, changing secondary path

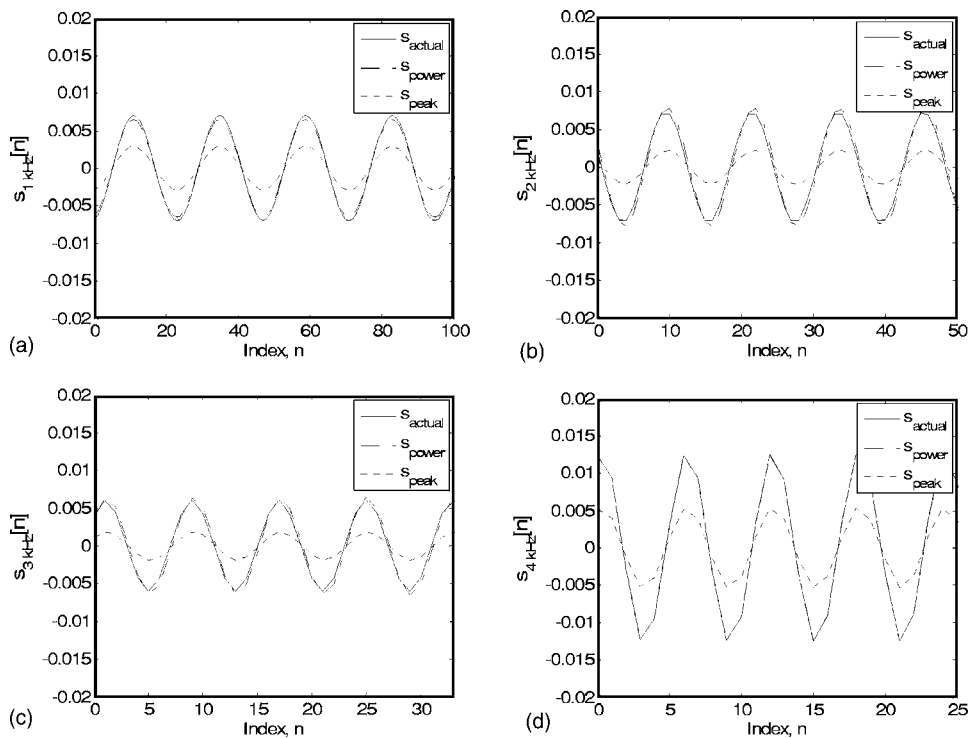
Two-frequency signals were used to validate the multiple frequency generalization of the linear independence
FIG. 11. Cancellation performance of changing frequency in stationary secondary path.


FIG. 12. Secondary path model comparison for changing frequency in stationary path: (a) $\hat{s}_{1\text{ kHz}}$, (b) $\hat{s}_{2\text{ kHz}}$, (c) $\hat{s}_{3\text{ kHz}}$, and (d) $\hat{s}_{4\text{ kHz}}$. method. Peak recognition capability would assist in dividing the frequency spectrum into the appropriate subbands particularly in systems where the frequencies are time varying. Validation of the proposed method, however, does not require such capability. Subbands can be set *a priori* if the frequencies in the control system are unchanging. This is what is done here.

The two frequencies used for this test were 1 and 2 kHz, each with amplitude 0.5 V_p (lowered from 1 V_p to avoid clipping of the A/D and D/A converters). The spectrum was divided into two subbands at the midpoint between the two peaks with each subband accommodating its respective sinusoid. The procedure for imposing linear independence is

identical to that used in the previous tests. For the FXLMS adaptation, 30 iterations are allowed after the modeling of each secondary path.

Figure 13 shows the cancellation performance for the two-frequency error signal and Fig. 14 reveals the secondary path models. Again, the models scaled using the peak subband values have magnitudes that are consistently less than that of the true magnitudes. The models scaled by power generally have magnitudes that vary relative to the true magnitudes. This is an artifact of the spectrum subbanding where frequency bins that contribute to the power of one sinusoid can lie in an adjacent subband. The contributions of these outlying bins are generally small, hence the correspondingly small variations in the magnitude. Again, the phase is accurate.

4. Random noise, changing secondary path

Random noise, band limited at 6.4 kHz, was used for the broadband test. The controller was programmed to execute the linear independence method using 1024- and 2048-sample data blocks (overlap-save method was utilized). The resulting secondary path impulse response is 512 points long but would be truncated to 256 points (longer time data increases the resolution of the FFTs, resulting in more accurate secondary path impulse responses). Fifty averages were performed. Rather than impose linear independence 50 times, however, which would require the control filter to be adjusted twice that number of times (w_A to w_B and back to w_A), only one adjustment was made in between two snapshots, each snapshot of sufficient length to provide for 50 data windows of lengths 1024 and 2048 with 50% overlap. The first and second snapshots are thus 26 112 and 52 224 samples in

FIG. 13. Cancellation performance of two-frequency signal (1 and 2 kHz) in changing secondary path.
FIG. 14. Secondary path model comparison for two-frequency signal in changing path: (a) $\hat{s}_1$, (b) $\hat{s}_2$, (c) $\hat{s}_3$, and (d) $\hat{s}_4$.

length or 1.088 and 2.176 s, respectively. Of course, this assumes no change in the secondary path during the sys id period.

Figure 15 shows the time history of the error signal for this test. For the initial secondary path modeling, $W_A(z)=0$ and $W_B(z)=0.1$ as was done for the previous tests. For all subsequent modeling, $W_B(z)$ was set equal to zero for the second snapshot. In the figure, this is reflected in the sudden decrease in amplitude during each sys id period as only the primary source is contributing to the error signal during the latter half. This was done to improve performance of the cancellation system where less noise is preferred. Imposing linear independence in a manner similar to that in the other tests would sustain the high level of noise in the control field during the relatively lengthy sys id period of 3.264 s. Upon

FIG. 15. Cancellation performance of random noise in changing secondary path.

modeling the secondary path, the FXLMS algorithm is iterated 256 times before the secondary path is interchanged. The amount of cancellation ranges from 30 to 40 dB across the passband.

Figure 16 reveals the secondary path impulse response estimates and also the primary path impulse response estimate as determined by the linear independence method. The primary path impulse response estimate indeed reflects the 100-sample delay yielded by the filter in DSP **P**; the secondary path impulse response estimates reflect the pure delays of 10, 25, 50, and 75 samples imposed by DSP **S**.

B. Multi-channel

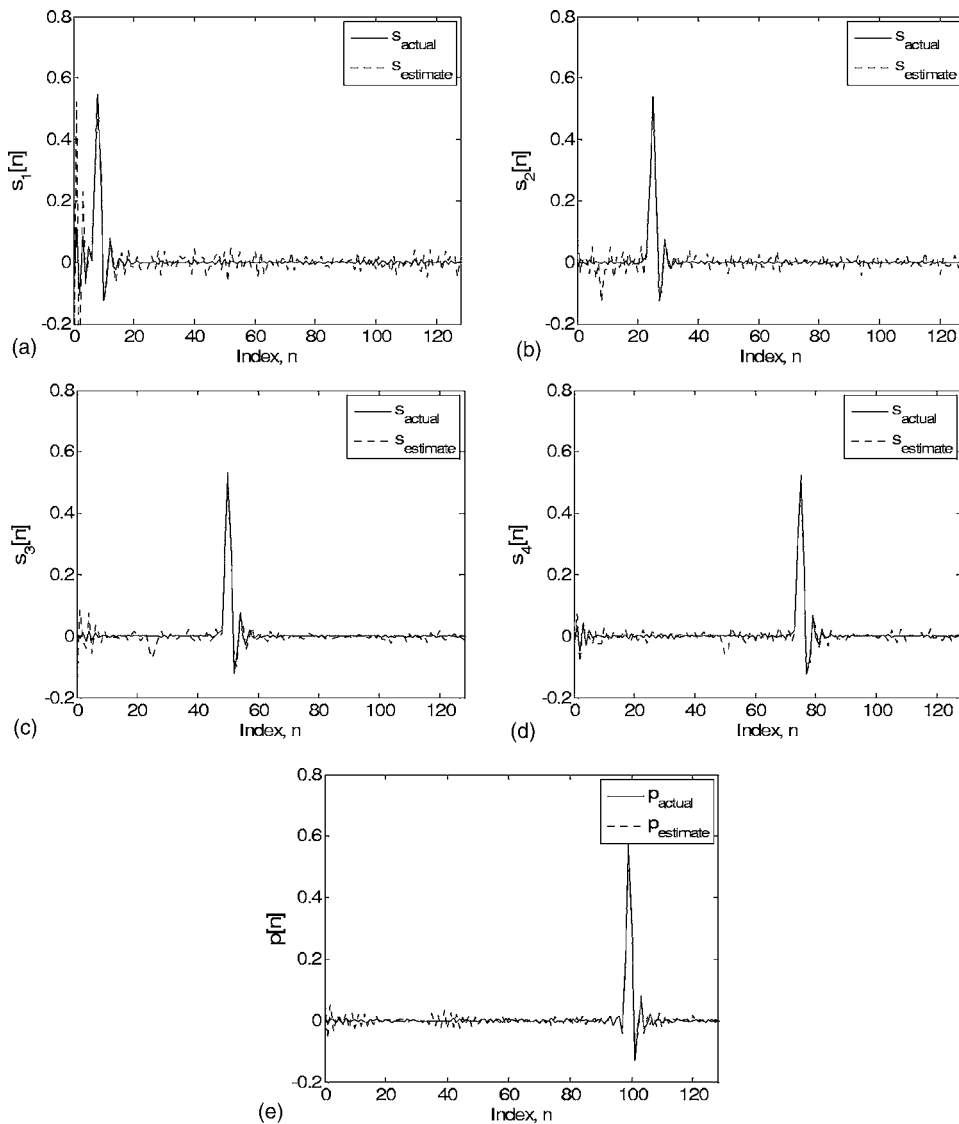
The two-channel transducerless ANC test circuit pictured in Fig. 6 was used for this final test. The primary paths for both channels were such that $P_1(z)=P_2(z)=1$ (no delay or gain) making $d(n)=x(n)$. The resistor values which determine the magnitudes of the paths were set as follows: $R=R_{|S11|}=R_{|S22|}=10$ kΩ, $R_{|S12|}=20$ kΩ, and $R_{|S21|}=50$ kΩ. This translates to a magnitude response of unity for the direct secondary paths (control source 1 to error sensor 1, control source 2 to error sensor 2); a magnitude of 0.5 for the coupled path from control source 2 to error sensor 1; and a magnitude of 0.2 for the coupled path from control source 1 to error sensor 2. These values were chosen to fall within the secondary path magnitude constraints of the multiple-error FXLMS algorithm.[6] They yield a small eigenvalue spread for the matrix $\mathbf{S}^H\mathbf{S}$ (H denotes Hermitian or conjugate transpose) that would allow for relatively straightforward convergence (large eigenvalue spreads are generally indicative of ill-conditioned systems). For the specified paths the eigenvalue set is {0.9, 1.1}. An inverter was used to set the phase of S_{21}


FIG. 16. Secondary path model comparison: (a) 10-sample pure delay, (b) 25, (c) 50, and (d) 75; primary path model comparison: (e) 100-sample pure delay.

to 180°; the phases of S_{11}, S_{12}, and S_{22} were set at random. The reference signal was sinusoidal with a frequency of 1 kHz and amplitude 1 V_p.

Figure 17 shows the cancellation performance using the
FIG. 17. Two-channel cancellation performance.

proposed secondary path modeling method. The points at which linear independence was imposed are indicated by the arrows. The control output for channel 1 was adjusted first to model S_{11} and S_{21}, then channel 2 to model S_{12} and S_{22}. The secondary path response estimates scaled by power (instead of the peak denominator value) were used for the cancellation shown in the figure. Only 15 iterations or so of the LMS algorithm were necessary to achieve 50 dB of cancellation for both channels. This again is attributable to the accuracy of the secondary path models revealed in Fig. 18. Their magnitudes can be further verified from the resistor values used. The amplitudes of the coupled paths 2-1 and 1-2 are respectively $\frac{1}{5}$ and $\frac{1}{2}$ that of the direct paths, which corresponds exactly to the secondary path magnitudes imposed by the resistors (amplitude of 0.0078 corresponds to unity gain).

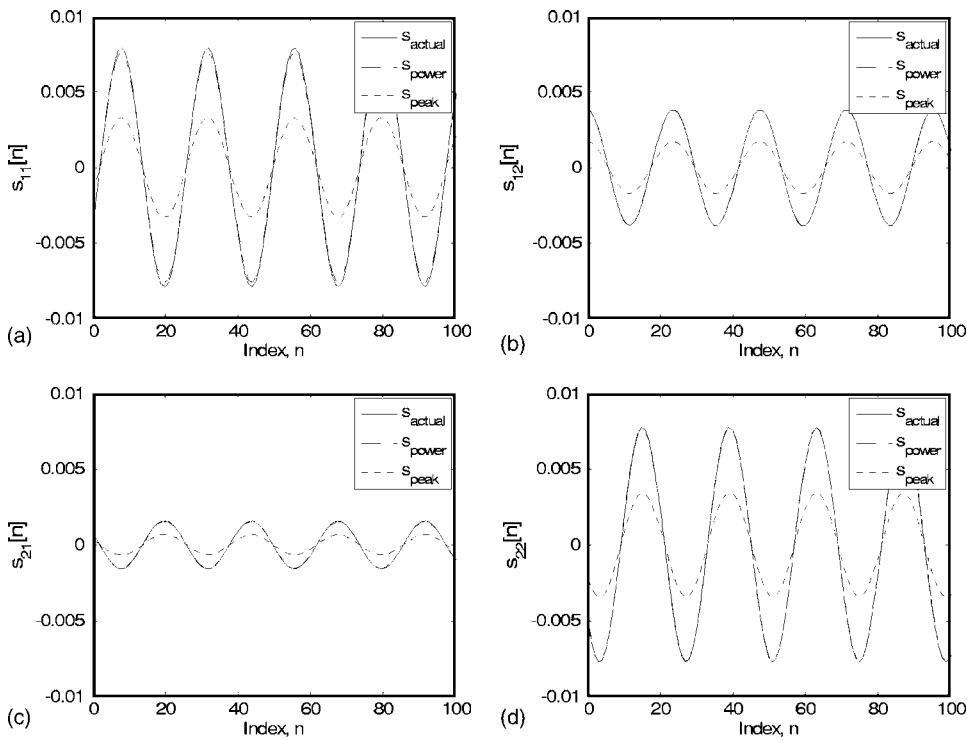
It is deemed critical that in coupled multi-channel, multiple-error FXLMS-based ANC systems the secondary paths be identified as accurately as possible. As stated previously, the performance of the multiple-error FXLMS algorithm depends greatly on the relative magnitudes of the secondary paths as the eigenvalue spread of the matrix $\mathbf{S}^H\mathbf{S}$ determines the convergence. In addition, the rate of conver-


FIG. 18. Secondary path model comparison for direct and coupled paths: (a) $\hat{s}_{11}$, (b) $\hat{s}_{12}$, (c) $\hat{s}_{21}$, and (d) $\hat{s}_{22}$. Models reveal phase delays of (a) 8, (b) 23, (c) 20, and (d) 15 samples. Amplitude of 0.0078 corresponds to unity gain.

gence is limited by the step size which is governed by the maximum eigencomponent of $\mathbf{S}^H\mathbf{S}$.[4] The relative phases between the secondary paths also play a significant role in the convergence of the algorithm.[46–48] In short, accurate secondary path response estimates would aid tremendously in the analysis of robustness of multi-channel ANC systems.

It is interesting to note the phase of path S_{21} which subtly exposes a delay contributed by the DSP system board inputs and outputs (D/A and A/D converters, reconstruction and antialiasing filters). The left-most trough should be centered at index 0 which would correspond to the 180° phase shift imposed by the inverter. Instead it is centered at index 8 indicating an eight-sample phase delay in the control path. Measurement of the DSP hardware revealed a linear phase delay of about 7.6 samples, or 317 μs, relative to the 24-kHz sampling rate.

V. CONCLUSIONS

A system identification methodology has been introduced that reduces the linear dependence problem associated with on-line noninvasive secondary path modeling to a solvable system of two equations and two unknowns. Achieving linear independence of such a system is the critical feature of the method, hence the proposed designation. The procedure requires two consecutive snapshots of $\{x(n), e(n), y(n)\}$ data, both made linearly independent by a deliberate perturbation of the control output in between snapshots. Physically, the perturbation makes the control source discernable relative to the primary noise and other noise sources in the control system. Narrowband tests reveal secondary path models that are exact in phase and closely approximated in magnitude compared to the true models. Impulse response estimates obtained from the broadband tests were nearly identical to the true impulse responses. The results demonstrate the efficacy of the proposed linear independence method in removing the encumbering measurement bias due to primary noise and other control field contributions. Its appeal and value lie in its mathematical simplicity and physical intuitiveness.

APPENDIX: IMPLEMENTING THE MODELING EQUATION

The following is a detailed procedure for implementing the linear independence secondary path modeling equation $\hat{S}(k)$

$$= \frac{[X_A(k)E_B(k) - E_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*}{[X_A(k)Y_B(k) - Y_A(k)X_B(k)][X_A(k)Y_B(k) - Y_A(k)X_B(k)]^*},$$

(A1)

where $X(k)$, $Y(k)$, and $E(k)$ are transforms of time domain vectors $x(n)$, $y(n)$, and $e(n)$, respectively, and subscripts A and B correspond to time-aligned data snapshots reflecting control filters w_A and w_B, respectively. Of particular concern is how to effectively utilize the overlap-save method to avoid circular convolution/correlation errors due to wraparound when performing the numerous spectral multiplications in Eq. (A1).[22,40] The procedure assumes that time data vectors are arranged such that the oldest sample is first and the newest sample is last (from left to right). It also assumes a control filter of length L. Step 9 is a relatively key step.

(1) Take 8L-length snapshot of aligned time data. This first snapshot is the set $\{x_{A,8L}, y_{A,8L}, e_{A,8L}\}$ which contains reference, filter output, and error signal vectors, respectively, and corresponds to control filter w_A.

(2) Adjust control filter such that $w_B \neq w_A$.

(3) Wait for transients to decay out, i.e., for the system to return to steady state.

(4) Take another snapshot of data of length 4L. Second snapshot is the set $\{x_{B,4L}, y_{B,4L}, e_{B,4L}\}$ (corresponds to control filter w_B).

(5) Take 8L-point discrete Fourier transform (DFT) of first data set. This set is now $\{X_{A,8L}, Y_{A,8L}, E_{A,8L}\}$. It may be necessary to zero 0-Hz frequency bins to eliminate any DC offset in DFTs.

(6) *Post*-zeropad each vector in second data set with 4L zeros. Take 8L-point DFT. This set is now $\{X_{B,8L(zp)}, Y_{B,8L(zp)}, E_{B,8L(zp)}\}$ where "zp" stands for "zeropadded." Again, it may be necessary to zero 0-Hz frequency bins to eliminate any DC offset in DFTs.

(7) Compute $X_{A,8L}E_{B,8L(zp)} - E_{A,8L}X_{B,8L(zp)}$. The resultant quantity will be referred to as U_{8L}.

(8) Compute $X_{A,8L}Y_{B,8L(zp)} - Y_{A,8L}X_{B,8L(zp)}$. The resultant quantity will be referred to as V_{8L}.

(9) Take inverse DFT of U_{8L} to give u_{8L}. Keep *last* **2L** points of u_{8L}, pre-pad with 2L zeros, and take 4L-point DFT to yield $U_{4L(zp)}$.

(10) Take inverse DFT of V_{8L} to give v_{8L}. Discard first 4L points, or left half of v_{8L}, and take 4L-point DFT to yield V_{4L}. Take complex conjugate of V_{4L} to get V_{4L}^{*}.

(11) The expression for the secondary path model is now

$$S_{4L} = \frac{U_{4L(zp)}V_{4L}^{*}}{V_{4L}V_{4L}^{*}}.$$

For single-frequency narrowband noise the numerator can be scaled by either the power or peak value of the spectrum in the denominator. Evaluate expression.

(12) Take inverse DFT of S_{4L} to give s_{4L}. Discard last 2L points of s_{4L} to give s_{2L}. s_{2L} is the 2L-point time-domain secondary path response estimate.

Control strategies for active noise barriers using near-field error sensing

Arthur P. Berkhoff[a]

TNO Science and Industry, PO Box 155, 2600AD Delft, The Netherlands, and University of Twente,
PO Box 217, 7500AE Enschede, The Netherlands

In this paper active noise control strategies for noise barriers are presented which are based on the use of sensors near the noise barrier. Virtual error signals are derived from these near-field sensor signals such that reductions of the far-field sound pressure are obtained with the active system. The performance of the control algorithm is compared for far-field error signals, near-field error signals, and virtual far-field error signals, with and without additional reference sensors. The virtual error signals are obtained by using separate transfer functions for the primary sources and secondary sources. These separate transfer functions are determined in such a way that the necessity of the separation of the virtual sensors for the primary field and for the secondary field can be judged by direct comparison. The systems are evaluated for independent broadband and randomly positioned primary sources, changing source spectra, moving sources, and configurations involving a nonvanishing wind speed. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1992787]

I. INTRODUCTION

Recently, active noise barriers for reduction of traffic noise have been considered.[1,2] The goal of the active noise barriers is to reduce the sound-pressure level at a distance from the noise barrier, such as on the facades of houses. Microphones at these positions can be used in order to create error signals to be minimized by the controller.[2] In another configuration, microphones were placed directly near the active noise barrier.[1] This leads to obvious advantages due to the absence of sensors at inconvenient positions. Another advantage is that the primary sources are essentially diffraction sources on top of the noise barrier. If the secondary sources are placed near the top of the noise barrier, then the influence of wind is more or less the same for the primary sources and the secondary sources. This can lead to a possibly more robust system with respect to fluctuations of the wind. However, minimization of the near-field sound pressure does not necessarily lead to a reduction of the far-field sound pressure (e.g., Fig. 7 in Ref. 3). Another concern is the possibility to implement the systems in real time. A system where all sensors and loudspeakers of the complete noise barrier are coupled and combined in a single multi-input multioutput controller is clearly impossible. Still another aspect is the influence of moving sources on the performance of the system.[4–6] Considering the above, the main objectives for the design of the active noise barrier are (1) no microphones near buildings should be used but only microphones near the active noise barrier; (2) the system has to be suitable for moving noise sources; (3) the system should consist of modules that work more or less independently by using a limited amount of information from other parts in the system in order to reduce communication bandwidth and hardware

resources. In this paper the first two items will be addressed; only a single module will be considered, which can have multiple inputs and multiple outputs.

An important aspect of the present work is the application of a virtual sensor. Virtual sensors have been discussed in a general control framework by Albertos and Goodwin.[7] A virtual sensor for active noise control has been described by Munn *et al.*[8] An important observation is that for many active control applications the contributions from the primary source have to be separated from the contributions of the secondary source. For the near-field sensor, this separation has been described by Garcia-Bonito *et al.*[9] If the virtual sensor and the near-field error sensor are at very different positions, then this separation should be done for both the near-field sensor and the virtual sensor, as described by Popovich[10] and Roure.[11] The basic idea is to subtract the contribution of the actuator from the near-field sensor, leading to an estimate of the contribution of the primary source on the near-field sensor, and then to predict the primary farfield signal by a suitable transfer function. The estimate of the total far-field signal is then obtained as the sum of the estimated far-field contributions of the primary and secondary sources. Yuan[12] added a second near-field sensor in order to make it less sensitive to transmission zeros at the sensor location in resonating environments.

The present results are for a multi-input, multioutput, multireference system for random, broadband noise. Although the description of Ref. 10 is principally suitable for multichannel systems, no multichannel results are known to the present author. As compared to Ref. 11, the present results give an extension for random, broadband noise instead of harmonic noise. A further difference is that the transfer function between the secondary source and the far-field sensor is split in two parts, in contrast with Refs. 10 and 11, where a single transfer function is used. This was done for two reasons: first, the transfer functions which make an esti-

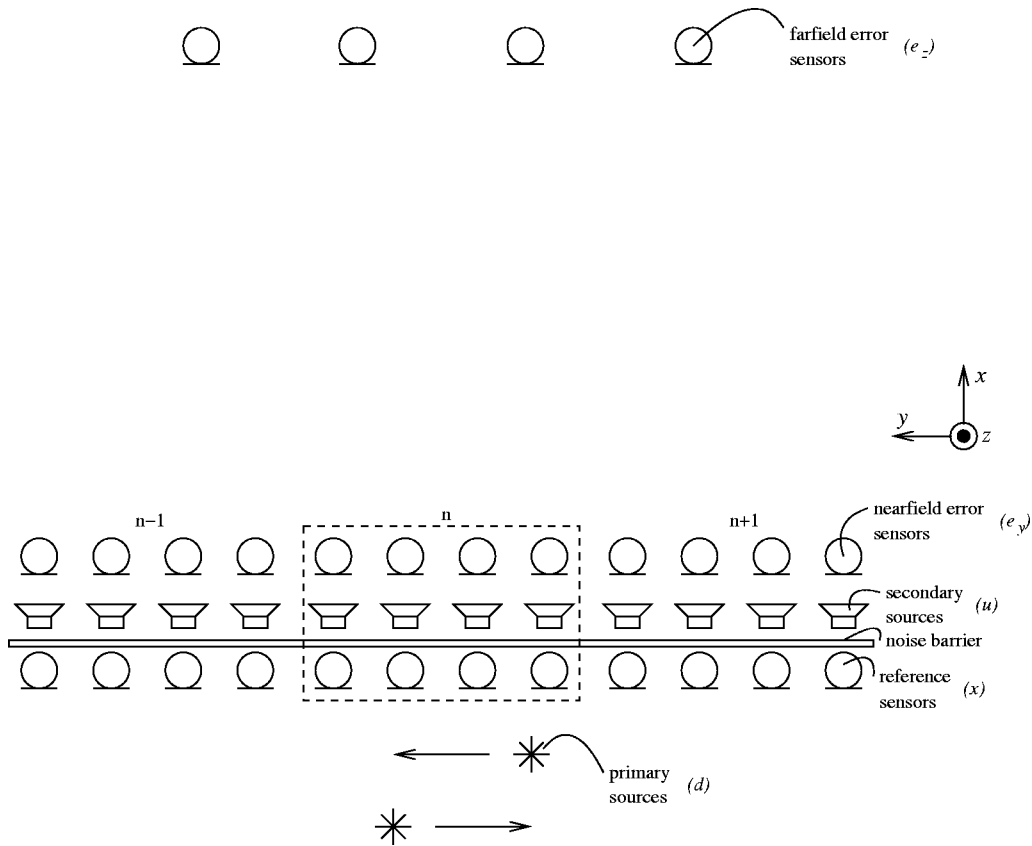

FIG. 1. Configuration of an active noise control system for reduction of noise at the position of the far-field sensors by using information derived from near-field error sensors.

mate of the far-field-from the near-field signals are then treated in a similar way for the primary sources as for the secondary sources. Second, the virtual sensors are based on the assumption that the path from the near field to the far field does not change. It is interesting to have an idea of the differences between the virtual sensors for the primary source and the secondary source. If, for example, these virtual sensors would have some similarity, then we could modify the primary virtual sensor and secondary virtual sensor by the same amount, for example adapting for a changing wind direction or speed. In this work the two multichannel virtual sensors will be compared and some conclusions will be drawn. In order to assess the performance of the proposed virtual sensor scheme, it will be compared with some other active control schemes.

II. DESCRIPTION OF THE SYSTEM

A proposed configuration of the system can be found in Fig. 1. The system consists of reference sensors (microphones), secondary sources (loudspeakers), and near-field error sensors (microphones). In an initial calibration phase far-field error sensors (microphones) also can be used in order to determine the transfer functions for the virtual sensors. A single section n of the active noise barrier is considered (Fig. 1). In order to assess the stability and performance of the active noise barrier, including the interactions between different subsystems, the sensors and sources of adjacent sections also should be taken into account.

A. Reduction of the far-field sound pressure using measurement of near-field quantities

One of the aspects of the system is that virtual error signals are derived from the near-field error sensors. These virtual error signals should represent the far-field pressure at a sufficient number of discrete positions in the angular sector of interest, or more generally, the acoustic degrees of freedom in that angular sector.[13] In the configuration, we distinguish the following components: the primary disturbance d, reference signals x, actuator control signals u, near-field error signals e_y, and far-field error signals e_z such that, in the z-transform domain

$$\begin{bmatrix} x(z) \\ e_y(z) \\ e_z(z) \end{bmatrix} = \begin{bmatrix} G_{dx}(z) & G_{ux}(z) \\ G_{dy}(z) & G_{uy}(z) \\ G_{dz}(z) & G_{uz}(z) \end{bmatrix} \begin{bmatrix} d(z) \\ u(z) \end{bmatrix}. \tag{1}$$

The action of the control operator W is described by

$$u(z) = W(z)x(z). \tag{2}$$

We seek to minimize the cost function

$$J = \|e_z\|_2^2 + \beta\|W\|_2^2, \tag{3}$$

where the term with β is used for regularization by penalizing the magnitude of W. The norm for a general causal transfer function matrix $A(z)$ which, using time τ, corresponds to an impulse response matrix $A(\tau)$, is defined as[14]

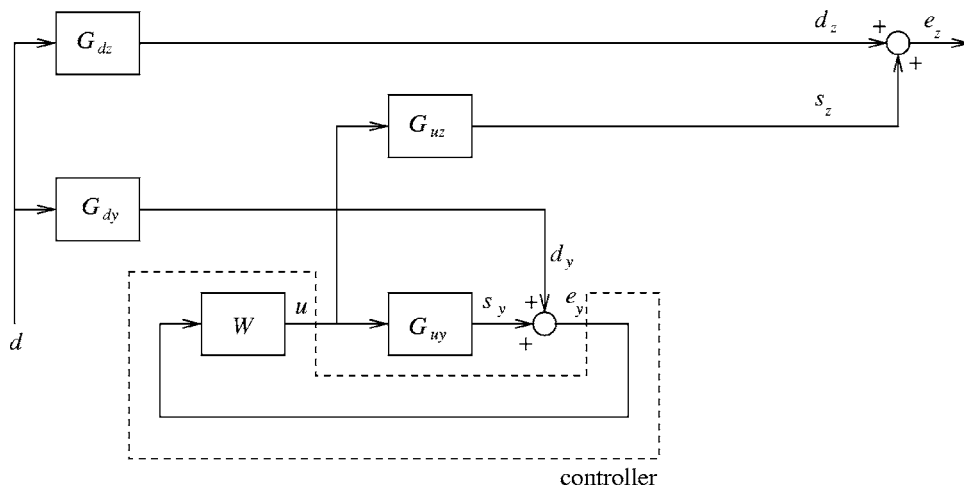
Arthur P. Berkhoff: Near-field sensing for active noise barriers


FIG. 2. Schematic representation of a system which directly minimizes e_y in a feedback configuration.

$$\|A\|_2 = \left[\int_0^\infty \mathrm{tr}\, A^T(\tau)A(\tau)\mathrm{d}\tau \right]^{1/2}, \qquad (4)$$

where tr is the trace of a matrix. The norm for a stochastic signal vector $a(\tau)$ is defined as

$$\|a\|_2 = [\mathrm{tr}\, \mathsf{E}\{a^T(\tau)a(\tau)\}]^{1/2}, \qquad (5)$$

where E is the expected value. Lower-case variables denote vectorial quantities, whereas upper-case variables denote matrices. The assumption is that G_{ux} is compensated in the controller, leading to a control structure based on internal model control.[15]

A relatively simple approach for the reduction of far-field sound pressure is to try to reduce the sound pressure near the noise barrier.[1] A disadvantage of this system is that a reduction of the near-field pressure does not necessarily lead to a reduction of the far-field pressure. This holds for both feedback configurations (Fig. 2) and feedforward configurations (Fig. 3). An improved technique could be based on the estimation of the far-field error signals e_z (which are assumed to be unavailable when the system is operational) from the near-field error signals e_y. A rather straightforward approach is to design a single transfer function H_{yz} which makes a real-time estimate of e_z from measured data e_y (see Fig. 4). From the simulations it will be seen that the maximum performance with such a transfer function is limited by

the fact that we are dealing with two sets of sources, the primary sources and the secondary sources. These two sets of sources have a very different nature and lead to rather different requirements for the transfer function H_{yz}. One significant difference, for example, is that the near-field sensors are, located at a distance from the primary sources, while the near-field sensors are, by definition, in the near field of the secondary sources. A compromised H_{yz} designed for the two sets of sources simultaneously did not give satisfactory results because of the relatively large prediction errors. The prediction errors for the compromised design were of similar magnitude as the off-diagonal prediction errors in Table I. So, although a single transfer function H_{yz} may have acceptable performance in some systems, such as active panels,[16] it does not lead to sufficient performance in the present systems for active noise barriers.

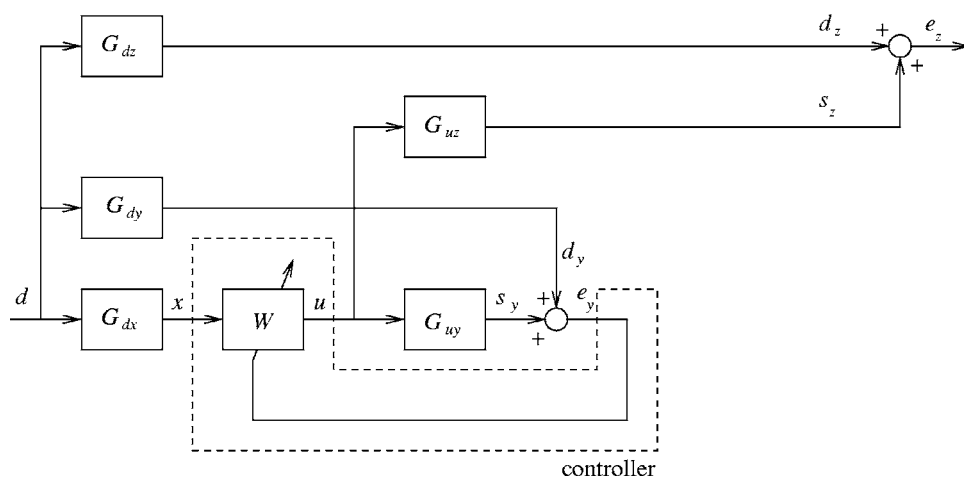
Therefore, a new strategy was devised in which the primary sources and the secondary sources were treated separately. The actual contributions on e_y and e_z consist of a part due to the primary signal and a part due to the secondary signal. As the transfer functions from the primary source and secondary source to both e_y and e_z are quite different, these contributions are taken into account separately. Therefore, in accordance with Eq. (1), we define G_{dy} as the transfer function between primary source and near-field error sensor, G_{dz} as the transfer function between primary source and far-field


FIG. 3. Schematic representation of a system which directly minimizes e_y in a feedforward configuration.
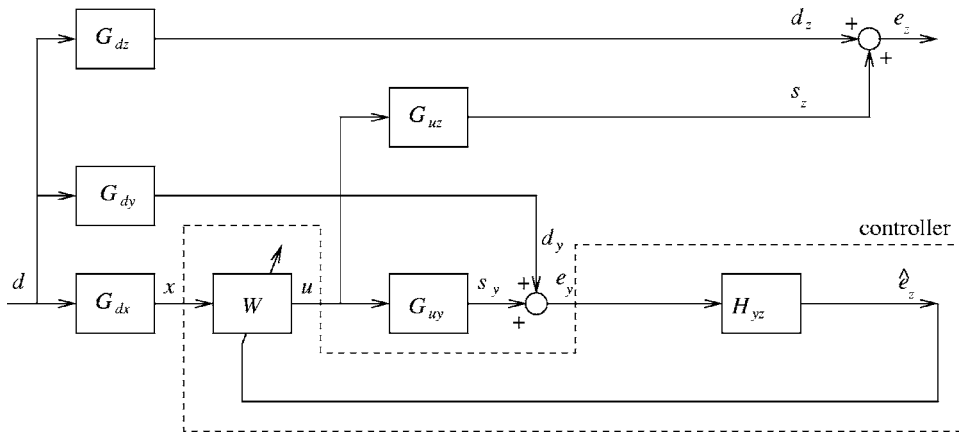

FIG. 4. Schematic representation of a system which makes an estimate $\hat{e}_z$ of the far-field error signals e_z based on a single transfer function H_{yz}.

error sensor, G_{uy} as the transfer function between secondary source and near-field error sensor, and G_{uz} as the transfer function between secondary source and far-field error sensor. The far-field signal e_z can be expressed as

$$e_z(z) = d_z(z) + s_z(z), \tag{6}$$

in which the primary signal d_z is given by

$$d_z(z) = G_{dz}(z)d(z), \tag{7}$$

and the secondary signal s_z is given by

$$s_z(z) = G_{uz}(z)u(z). \tag{8}$$

The estimate $\hat{d}_z$ of the signal d_z is derived from an estimate $\hat{d}_y$ of the primary near-field error signals as follows:

$$\hat{d}_z(z) = H_{yz}^d(z)\hat{d}_y(z), \tag{9}$$

where H_{yz}^d is obtained from system identification. The estimate $\hat{d}_y$ is obtained by subtracting the secondary signal from the measured signal e_y

$$\hat{d}_y(z) = e_y(z) - \hat{s}_y(z), \tag{10}$$

where $\hat{s}_y$ is an estimate of the secondary signal on the near-field error sensors, which is given by

$$\hat{s}_y(z) = \hat{G}_{uy}(z)u(z). \tag{11}$$

An estimate $\hat{s}_z$ of the contribution of the secondary sources on the far-field sensors is given by

$$\hat{s}_z(z) = H_{yz}^s(z)\hat{s}_y(z), \tag{12}$$

where H_{yz}^s is also obtained from system identification. Finally, the estimate $\hat{e}_z$ of the far-field sensor can be obtained from the summation of the estimates of the primary sources and secondary sources

$$\hat{e}_z(z) = \hat{d}_z(z) + \hat{s}_z(z). \tag{13}$$

The estimate $\hat{e}_z$ can be written as

$$\hat{e}_z(z) = H_{yz}^d(z)\hat{d}_y(z) + H_{yz}^s(z)\hat{s}_y(z)$$
$$= H_{yz}^d(z)e_y(z) + [H_{yz}^s(z) - H_{yz}^d(z)]\hat{G}_{uy}(z)u(z). \tag{14}$$

The near-field error signal is given by

$$e_y(z) = d_y(z) + s_y(z). \tag{15}$$

Therefore, using

$$d_y(z) = G_{dy}(z)d(z), \tag{16}$$

and

$$s_y(z) = G_{uy}(z)u(z), \tag{17}$$

the estimate $\hat{e}_z$ can be written as

$$\hat{e}_z(z) = H_{yz}^d(z)[G_{dy}(z)d(z) + G_{uy}(z)u(z)]$$
$$+ [H_{yz}^s(z) - H_{yz}^d(z)]\hat{G}_{uy}(z)u(z). \tag{18}$$

In the case of perfect modeling, we have $G_{uy}(z) = \hat{G}_{uy}(z)$. Then, the above expression reduces to

$$\hat{e}_z(z) = H_{yz}^d(z)G_{dy}(z)d(z) + H_{yz}^s(z)G_{uy}(z)u(z). \tag{19}$$

If the secondary sources are close to the diffraction sources, and if they radiate in a similar way, then we have $H_{yz}^d = H_{yz}^s = H_{yz}$, leading to

$$\hat{e}_z(z) = H_{yz}(z)[G_{dy}(z)d(z) + G_{uy}(z)u(z)] = H_{yz}(z)e_y(z). \tag{20}$$

B. System diagram and comparison with other systems

The complete block diagram of the system is shown in Fig. 5. It can be seen that two separate transfer functions H_{yz}^d and H_{yz}^s are used, which together are able to reconstruct the pressure e_z in the far field. For purposes of comparison, some existing systems will be described. Figure 4 shows a system using a single transfer function, H_{yz}. Figure 3 shows a system where the basic strategy is to minimize the near-field pressure, using a feedforward controller, as before. Figure 2 shows a system in which the near-field pressure is directly

TABLE I. Estimation accuracy of the near-field–far-field predictors H_{yz}^d and H_{yz}^s on far-field sensor 1 for different calibration sources.

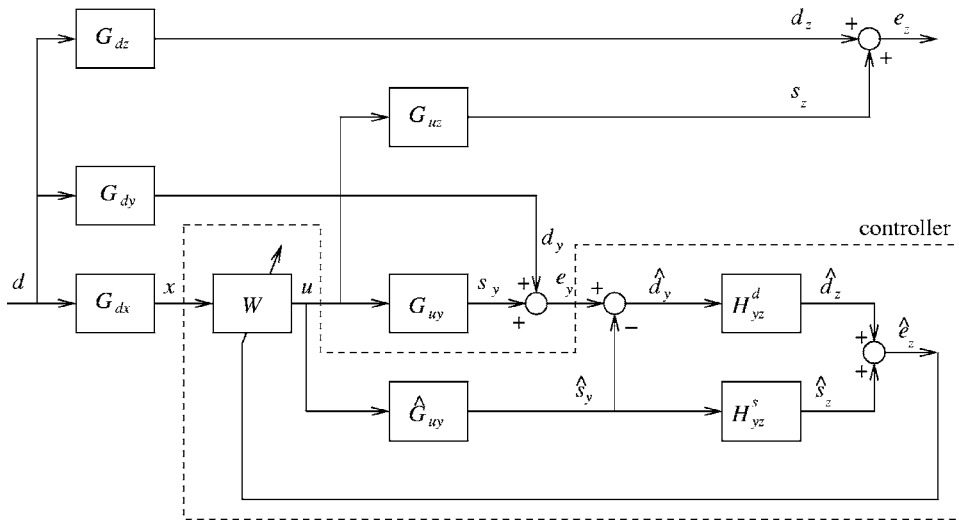
Calibration sources	H_{yz}^d, estimation error [dB]	H_{yz}^s, estimation error [dB]
Sources in primary source region	−14.6	10.5
Secondary sources	−2.6	−36.3


FIG. 5. Schematic representation of a system which makes an estimate $\hat{e}_z$ of the far-field error signals e_z.

fed back to the controller, where the basic strategy is also to minimize the near-field pressure. In the present application, reduction of the near-field pressure is very different from minimizing the far-field pressure. The simulations in subsequent section will show that the configuration of Fig. 5 performs substantially better than the configurations of Figs. 2 and 3. The configuration of Fig. 5 also performs substantially better than the configuration of Fig. 4 because of the reason mentioned in Sec. II A.

Changes in the secondary path are critical for stability robustness and performance robustness. The performance robustness for single-channel active noise control systems including the effects of wind has been analyzed in Ref. 17. In the configuration of the latter paper, the error sensor should be considered to be in the far field of the secondary source due to the relatively large distance of 20 m. The propagation distances involved in the secondary path are considerably reduced if near-field sensors are used instead of the far-field sensors. Therefore, it is expected that the reduced change of the propagation path has a positive effect on the stability robustness of the system. Furthermore, if the primary sources are effectively diffraction sources on top of a noise barrier,

and if the secondary sources are close to these diffraction sources, then we obtain a system in which a large part of the possibly varying transmission path is common to both the primary signals and the secondary signals. This results in an expected improved performance robustness with respect to changes in wind, temperature, etc.

Equation (20) suggests that, if H_{yz} has a sufficiently flat frequency response, minimizing e_y in principle would be sufficient to reduce $\hat{e}_z$. This only holds if the primary sources are coincident with the secondary sources. In practical situations it is very difficult to exactly realize the condition $H_{yz}^d = H_{yz}^s = H_{yz}$. Differences are caused by, for example, the distributed nature of the primary (diffraction) sources, while the secondary sources are concentrated sources. These different behaviors are especially seen on the near-field sensors. Also, the exact position of the primary sources may be difficult to determine. Therefore, for a practical implementation a more general approach is required in which the estimation of the primary path and the estimation of the secondary path are treated separately. For the estimation of the primary transfer functions we define a region with identification sources.
FIG. 6. (Color online) Comparison of a primary far-field signal with an estimate obtained from the near-field sensor signals.
FIG. 7. (Color online) Comparison of a secondary transfer function to the far field with an estimate obtained from the near-field sensor signals.

Furthermore, only those near-field pressure distributions that contribute to the far field, as governed by the transfer functions H_{yz}, should be controlled. If e_y is minimized directly then usually only sound-pressure reductions in the near field are obtained. An additional reduction of the order of H_{yz} can lead to systems that are potentially more robust, have less spillover, and require less actuator effort.

In order to be able to compute the virtual error signals, an initial calibration phase is assumed in which sources are placed at random positions in the region where the primary noise sources are to be expected. The estimate of the primary

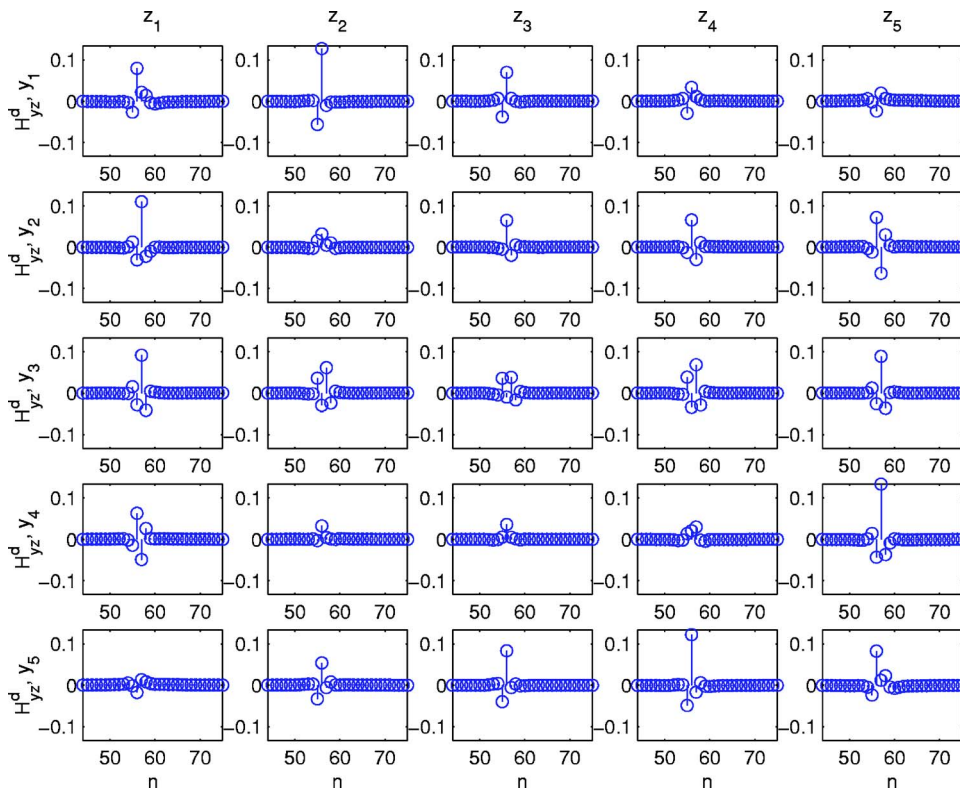
signal on one of the far-field sensors is shown in Fig. 6. The estimate of one of the secondary source transfer functions to the far field as estimated from the secondary transfer functions to the near-field sensors is shown in Fig. 7. In the present case 50 calibration sources have been used and three independent primary sources (an example of this can be found in Sec. III A, Fig. 13). The identification procedure is based on the solution of the equations resulting from an assumed multi-input, multioutput finite impulse response model leading to a block-Toeplitz structure.[18] In order to improve the stability of the solution, the mean-square value


FIG. 8. (Color online) Impulse response matrix H_{yz}^d as a function of sample index n; a row represents the impulse response of a particular near-field sensor and a column denotes the impulse response of a particular farfield sensor.
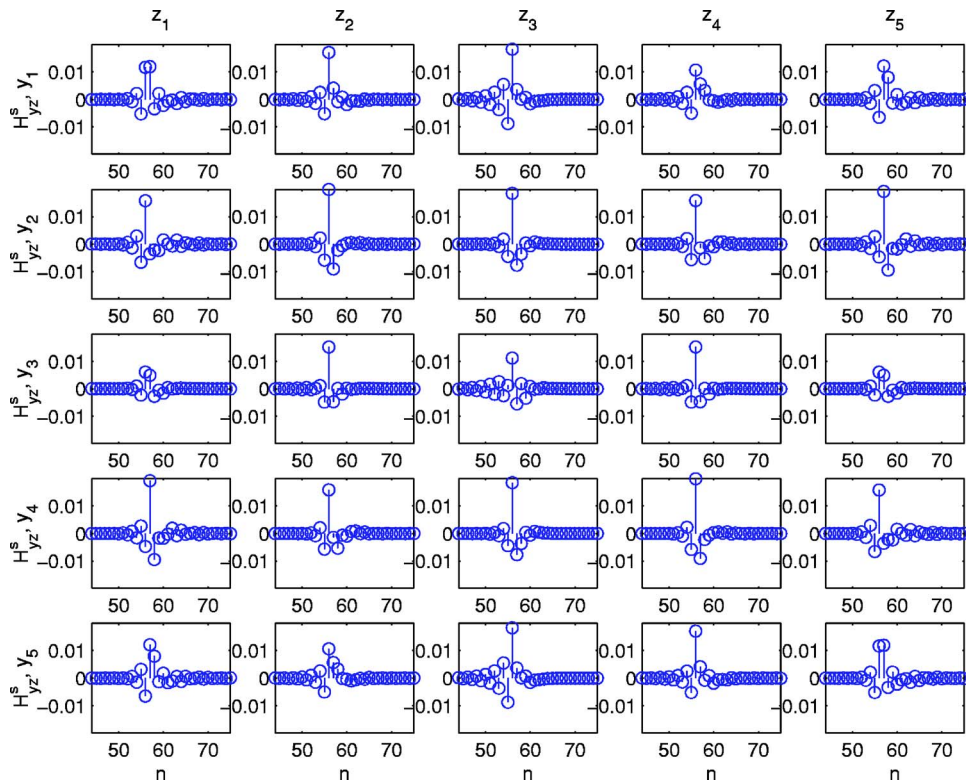

FIG. 9. (Color online) As Fig. 8, except that H_{yz}^s is shown.

of the coefficients of the FIR model are weighted with a normalized coefficient weighting factor $\beta' = 10^{-2}$ as compared to the mean-square prediction error of the far-field pressure. This value of β' was obtained by reducing the value of β' until the prediction error for primary signal validation data did not reduce anymore. The prediction error was obtained with validation data from an independent set of primary sources at random positions in the same region as

FIG. 10. Reduction of the broadband sound pressure for three independent broadband primary noise sources in which the error signal equals the near-field pressure; the primary sources are at $x=-4.5$ m (black asterisks), the reference sensors at $x=-0.5$ m (black circles), the secondary sources at $x=0.5$ m (black asterisks), the near-field error sensors at $x=1$ m (black circles), and evaluation microphones in the far field at $x=20$ m (blue circles).

for the solution of the system of equations. It has been found that the estimation errors did not significantly change with the number of primary sources, provided the primary sources were within the region used for calibration.

Although the transfer functions H_{yz}^d and H_{yz}^s relate the signals from identical near-field sensors and identical far-field sensors, they should be obtained from separate identification procedures, as mentioned previously. The necessity of this is demonstrated in Table I, which gives the estimation results on far-field sensor 1 for different combinations of calibration sources and the two transfer functions, H_{yz}^d and H_{yz}^s. It can be seen that the estimator H_{yz}^d only gives accurate results if the calibration sources are placed in the same region as where the primary sources are to be expected. The same holds for H_{yz}^s, which is only accurate if the calibration sources are taken to be the secondary sources. The differences between H_{yz}^d and H_{yz}^s can be seen in Figs. 8 and 9. One particular difference is that the magnitude of H_{yz}^d is higher than the magnitude of H_{yz}^s. This is caused by the strong near-field behavior and corresponding reactive components of the sound pressure which do not propagate to the far field.

The virtual sensor descriptions are based on a multi-input, multioutput model, and therefore allow for the prediction of far-field signals due to multiple uncorrelated sources in the pertinent source region. However, uncorrelated sources outside the pertinent source region could reduce the accuracy of the far-field estimate. In principle, because of the multi-channel description, the virtual sensors could be designed in such a way that the error of the far-field estimate inside the source region would be minimized while, simultaneously, minimizing the sensitivity for disturbing sources outside that source region. Although numerical tests have shown that this

FIG. 11. As Fig. 10, except that the error signal equals the far-field pressure.

is a useful approach, the design procedure for the virtual sensors in the rest of the paper will be limited to the minimization of the far-field prediction error, either for the sources inside the primary source region, resulting in H_{yz}^d, or for the secondary sources, resulting in H_{yz}^s.

III. RESULTS

Examples will be given in the form of a simulated section of an active noise barrier.

A. Comparison of different configurations

The first example is a purely active noise barrier, as in Ref. 19 (i.e., without passive noise barrier), in which the error signal equals the pressure as measured on microphones near the secondary sources, assuming the control structure of Fig. 3. In the present case the distance (in the x direction) between the error sensors and the secondary sources in 0.5 m. In addition, five reference sensors are used, which are positioned, as seen from the secondary sources, 1 m toward
FIG. 12. As Fig. 11, except that no separate reference sensors are used.
FIG. 13. As Fig. 10, except that the error signal equals the virtual far-field pressure; the sources as used for the identification of H_{yz}^d and H_{yz}^s are indicated by green asterisks.

the primary sources. The primary noise sources are three independent broadband noise sources which are at a distance of 5 m from the secondary sources and at 0.15 m from each other. The sound pressure in the far field is evaluated with five microphones at $x=20$ m. The horizontal distance between these microphones, in the y direction, is 1.5 m. The method for designing the broadband controller of Eq. (2) which minimizes the cost function of Eq. (3) has been described previously.[18] The sampling frequency is $f_s=1$ kHz, the number of controller coefficients for each control filter equals 128, and the normalized regularization parameter β equals 0; the distance between the secondary sources is 0.3 m, as are the distances between the reference sensors and the error sensors. All transducers and sources are at a height $z=2$ m. Figure 10 shows the configuration and the resulting sound pressure in the x,y plane. It can be seen that sound-pressure reductions are mainly obtained near the error sensors. The reduction at the error sensors is 24.2 dB, but the reduction in the far field is much less, being 1.9 dB.

If the error sensors are moved to the far field, *viz.*, to the positions of the evaluation microphones, then the reductions in the far field become much higher. The average reduction of the error signal and consequently the reduction at the evaluation microphones now becomes 11.3 dB, which is limited by the causality constraint. Again, the control structure of Fig. 3 applies, but with the additional simplification $e_y=e_z$. The results are shown in Fig. 11.

TABLE II. Average reductions of the error signals and the far-field pressure signals for different configurations.

Error signal	Error signal, av. reduction [dB]	Far-field pressure, av. reduction [dB]
Near-field pressure (Fig. 10)	24.2	1.9
Far-field pressure (Fig. 11)	11.3	11.3
Far-field pressure, no reference sensors (Fig. 12)	3.5	3.5
Virtual far-field pressure (Fig. 13)	11.6	9.0

TABLE III. Average reductions of the error signals and the far-field pressure signals for three different primary source configurations with the same controller coefficients, using 32 coefficients, showing the influence of modified positions combined with a modified spectrum for the primary sources as well as the influence of a moving source.

Error signal	Error signal, av. reduction [dB]	Far-field pressure, av. reduction [dB]
Nominal primary sources	12.8	10.6
New primary sources, modified positions, modified spectrum	11.0	11.4
Moving source	9.4	11.0

In the third simulation the effect of a removal of separate reference sensors is demonstrated. In order to demonstrate this, the reference sensors are now shifted to the position of the near-field error microphones; the error signal equals the far-field pressure. The result is shown in Fig. 12. It can be seen that the reduction of the error signal (3.5 dB) and consequently the reduction of the sound-pressure level in the far field (3.5 dB) is considerably less than in Fig. 11. Hence, the use of separate reference sensors giving time-advanced information of the noise sources is necessary if significant noise reductions are to be obtained.

In the last simulation we show the result in case the error signal equals virtual far-field signals, using the same microphone positions as in Fig. 10 and using the control scheme of Fig. 5. The transfer functions H_{yz}^d and H_{yz}^s, as well as $\hat{G}_{uy}$, are determined from off-line system identification. The sources as used in the identification phase are positioned in the region where the primary noise sources are to be expected (see Fig. 13). It can be seen that the resulting far-field sound-pressure reductions are slightly less than in Fig. 11, being 9.0 dB. However, the far-field sound-pressure reductions are considerably higher than obtained with the near-field error

sensors as used in Fig. 10. The reduction of the error signals is approximately equal in case of minimizing the virtual error signals, being 11.6 dB, and in case of minimizing the true far-field error signals (11.3 dB). The numerical results for these four cases are collected in Table II. It can be seen that the sound-pressure reductions have a ripple in the x direction. It has been found that this ripple can almost be eliminated while keeping the same noise reductions by a proper regularization, e.g., by increasing β from 0 to 0.01.

B. Robustness

Robustness of the controllers was evaluated for the following cases: for a different order of the controller, for a new set of primary sources in the same region as for the nominal case, for a change of the primary spectrum as compared to the nominal case, and for a moving source. Robustness was also checked for situations with wind, which is described in Sec. III C.

1. Change of primary source spectrum

The influence of a simultaneous change of the positions of the primary sources and a changing primary spectrum is shown in Table III. Here, the distance between the secondary sources is 0.5 m, as are the distances between the reference sensors and the error sensors. The modified primary spectrum was obtained by applying a fourth-order bandpass filter with Butterworth characteristic with lower and upper cutoff frequencies of 0.15 and 0.35 f_s, respectively, to the primary source signals. It can be seen that, with the modified primary source positions and spectrum, there is even a slight improvement of the performance on the far-field evaluation microphones from 10.6 to 11.4 dB.
FIG. 14. (Color online) Configuration for the simulation of the performance of a combined passive and active noise barrier; the passive noise barrier is positioned at $x=10$ m and has a height of 3 m; the active system consists of double rows of reference microphones (dots at $x=9.5$ m, $z=2$ m, and $z=3$ m), double rows of loudspeakers (diamonds at $x=10$ m, $z=2.5$ m, and $z=3.5$ m) and double rows of near-field error microphones (dots at $x=10.5$ m, $z=2$ m, and $z=3$ m). Of the total of 10×11 microphone positions in the far field at $x=35$ m, 3×5 positions are used for the virtual sensors (indicated by dots). The primary sources are randomly positioned in the region -1.5 m$\leq y\leq1.5$ m, $0\leq z \leq1$ m $-0.5\leq x\leq0.5$ m (indicated by triangles).
FIG. 15. Noise reduction in dB(A) at the 10×11 microphones at $x=35$ m (Fig. 14), without wind.

2. Moving sources

In this case a single source emitting random broadband noise was moving from $x=1$ m to $x=-0.91$ m during a simulation period of 512 samples. The performance for this moving source can also be found in Table III. The same controller coefficients were used as for the other two cases in Table III. The radiation characteristics of the moving sources were simulated by taking into account the Doppler shift as well as the changing radiation characteristics depending on the direction of the movement.[20]

C. Influence of wind for a simulated noise barrier

In a subsequent simulation study, several features were added in order to be able to analyze somewhat more realistic
FIG. 16. Noise reduction in dB(A) at the 10×11 microphones at $x=35$ m (Fig. 14), with wind of 5m/s in the x direction.

situations involving a passive noise barrier having a height of 3 m. The components of the active reduction system were placed near the top of the noise barrier (Fig. 14). In this case double rows were used for the reference microphones, the loudspeakers, and the near-field microphones. This was done to have more control in the height direction z, leading to effective noise reductions over extended heights. The identification procedure was as before, where the calibration sources in the primary source region were statistically independent from the real primary noise sources; they also had different positions. The simulation of the passive noise barrier was based on a ray-tracing model which includes the effects of wind[21] for $x \geq 10$ m. Also, the transfer functions from sources to microphones were based on this ray-tracing model. The effect of the wind can be seen in the transfer functions by shorter impulse responses due to the reduced propagation speed (not shown). The source spectrum was obtained from measured traffic noise, where the traffic consisted of 30 percent trucks and 70 percent cars. The sampling frequency was 3.6 kHz. The performance for the case of no wind can be seen in Fig. 15. In view of Fig. 14, it can be seen that the noise reduction is maximum for the region where the virtual microphones are positioned. If a wind of 5 m/s in the positive-x direction was used, then the performance of the system, using the same transfer functions H_{yz}^d and H_{yz}^s as with no wind, is as shown in Fig. 16. It can be seen that the noise reductions at the virtual microphones in Fig. 16 are somewhat lower as compared to Fig. 15, but still significant. So, although the virtual sensors for the primary sources and the secondary sources are very different (see, for example, Figs. 8 and 9), the system seems to be quite robust with respect to changes in the transfer function between the noise barrier and the far-field microphones. In this paper only wind directions perpendicular to the noise barrier were taken into account. Subsequent robustness studies should also consider wind directions parallel to the noise barrier.

IV. CONCLUSIONS

Simulations have shown that additional reference sensors at the incidence side of an active noise barrier are required if large sound-pressure reductions for broadband noise are to be obtained at relatively large distances from the noise barrier. Furthermore, the control system should be based on the minimization of the far-field sound pressure, which can be either a measured far-field sound pressure or a virtual far-field sound pressure. If virtual sensors are used then the contributions of the primary sources and the secondary sources should be treated separately. Finally, although the virtual sensors for the primary sources and the secondary sources are very different, a system in which all transducers are positioned near a noise barrier seems to be relatively robust with respect to changes in the propagation characteristics between noise barrier and the region where reductions are to be obtained.

The effects of simple coupled volume geometry on the objective and subjective results from nonexponential decay

David T. Bradley[a] and Lily M. Wang

University of Nebraska-Lincoln, Architectural Engineering Program, Peter Kiewit Institute, Omaha, Nebraska 68182-0681

This project focuses on the individual and interactive acoustic effects of three architectural parameters on the double slope profile from a simple coupled volume system created in the computer modeling program ODEON. The three variables studied are the volume ratio between the main and secondary spaces, the absorption ratio between the two spaces, and aperture size. The resulting energy decay profiles are analyzed using T_{30}/T_{15} coupling coefficient ratios and Bayesian analysis. Coupling coefficient results show general trends in the effects of the three architectural parameters that match previous research results and the predominant interactive effect between the three variables involving a large coupled volume. Similar results are suggested by the Bayesian analysis based on the newly developed quantifiers, decay ratio and ΔdB, although a more complex relationship among the variables may exist at larger volume ratios. A subset of the simulated sound fields have been auralized and used to conduct psychoacoustic testing. The subjective testing results indicate that perceived reverberation increases with greater coupled volume size and aperture size, correlating well with objective results. The outcomes also suggest that higher perceived reverberation coincides with larger decay ratios and smaller ΔdB values. Subjective results based on clarity showed no significant effects. © *2005 Acoustical Society of America.*

I. INTRODUCTION

Coupled volume geometries have been used in several modern concert halls, including Festival Hall in Tampa, FL; the Great Hall in Hamilton, Ontario; Lucerne Concert Hall in Lucerne, Switzerland; the Myerson-McDermott Hall in Dallas, TX; and Verizon Hall in Philadelphia, PA. Architectural acousticians have been particularly interested in halls that utilize coupled volume systems because of their potential for creating a nonexponential energy decay. This paper focuses on the effort to articulate more clearly the effect of certain architectural parameters on the nonexponential decay in coupled volume spaces, both from objective and subjective viewpoints. Objectively the authors explore new ways of quantifying the phenomenon of nonexponential decay, while subjective psychoacoustic tests have been conducted to learn more about its perception.

A system utilizing coupled volumes typically consists of two or more spaces that are connected through an acoustically transparent opening known as a coupling aperture. When the secondary space exhibits a decay time that is longer than that of the main space, sound energy will be fed back into the main space by the auxiliary volume. This late-arriving energy results in the phenomenon known as the double slope decay.

A coupled volume system consisting of two spaces is shown in Fig. 1, where V_i is the volume of the ith space, A_i is the total surface area of the ith space, S is the surface area of the coupling aperture separating the two spaces, and P is the power of the sound source in room 1. Also, α_i is defined as the average absorption coefficient of the ith space, c as the speed of sound, and E_i as the energy density in the ith space. The power balance equations for the two rooms can be written as

$$P - \frac{A_1\alpha_1 cE_1}{4} - \frac{ScE_1}{4} + \frac{ScE_2}{4} = 0 \qquad (1)$$

$$-\frac{A_2\alpha_2 cE_2}{4} - \frac{ScE_2}{4} + \frac{ScE_1}{4} = 0. \qquad (2)$$

These equations give us the steady state response of the system. By setting $P=0$, we can obtain the differential equations representing the reverberant sound decay in the two spaces:

$$\frac{c}{4}(A_{1S}E_1 - SE_2) = -V_1\frac{dE_1}{dt}, \qquad (3)$$

$$\frac{c}{4}(-SE_1 + A_{2S}E_2) = -V_2\frac{dE_2}{dt}, \qquad (4)$$

where $A_{iS}=A_i\alpha_i+S$, and exponential decay is assumed such that

$$E_i = E_{i0}e^{-2\delta t}, \qquad (5)$$

where E_{i0} is the initial energy density in the ith space and δ is the decay constant of the space. By substituting Eq. (5) into Eqs. (3) and (4), and simplifying, we can rewrite the system of equations in matrix form:

[a]Electronic mail: dbradley@mail.unomaha.edu
FIG. 1. Plan view of a coupled volume system used in theoretical development.

$$\begin{bmatrix} \left[\left(\frac{c}{4}\right)A_{1S} - 2\delta V_1\right] & -\left(\frac{c}{4}\right)S \\ -\left(\frac{c}{4}\right)S & \left[\left(\frac{c}{4}\right)A_{2S} - 2\delta V_2\right] \end{bmatrix} \cdot \begin{bmatrix} E_{10} \\ E_{20} \end{bmatrix} = 0. \quad (6)$$

This system can only be valid for a single value of δ if the ratio E_{10}/E_{20} is the same for both equations, which requires the determinant of the coefficients of E_{10} and E_{20} to equal zero, producing the following polynomial equation:

$$4V_1V_2\delta^2 - \left(\frac{c}{2}\right)(A_{1S}V_2 + A_{2S}V_1)\delta + \left(\frac{c^2}{16}\right)(A_{1S}A_{2S} - S) = 0. \quad (7)$$

The eigenvalues of this quadratic equation give the decay constants for each room, δ_1 and δ_2, as a function of the volumes, surface areas, and absorptions of the two rooms, and the speed of sound. The decay time (T_i) for room i alone can then be calculated from δ_i using

$$T_i = \frac{6.9}{\delta_i} \quad (8)$$

in S.I. units.

To visualize the reverberant process as a temporal phenomenon, it is helpful to plot the sound level as a function of time. Cremer et al.[1] give the relationship between T_i, E_{i0}, and a reference sound energy density, E_{ref}, as

$$L_i(t) = -\left(\frac{60}{T_i}\right)t + 10 \log_{10}\left(\frac{E_{i0}}{E_{ref}}\right), \quad (9)$$

where $L_i(t)$ is the sound pressure level in the ith space. The early and late temporal components of the decay in the first room can be derived from this equation. For the case where $\delta_1 > \delta_2$, the early portion is dominated by the autonomous effects of room 1 and the late portion is driven by the effects of room 2 on room 1, given by the following:

$$L_{1early}(t) = -\left(\frac{60}{T_1}\right)t + 10 \log\left(\frac{E_{10}}{E_{ref}}\right), \quad (10)$$

$$L_{1late}(t) = -\left(\frac{60}{T_2}\right)t + 10 \log\left(\frac{E_{21}}{E_{ref}}\right), \quad (11)$$

where the initial energy density in room 1 caused by the energy transferred from room 2 to room 1 is given as

$$E_{21} = k_1 k_2 E_{10} \quad (12)$$

and k_1 and k_2 are coupling factors characterizing the transfer of energy between the rooms based on their geometry and absorption, defined as
FIG. 2. Representative energy decay curve of a space exhibiting a double slope profile.

$$k_1 = \frac{S}{A_{1S}}, \quad k_2 = \frac{S}{A_{2S}}. \quad (13)$$

The term E_{ref} in Eqs. (10) and (11) may be chosen to be equal to E_{10}, thereby normalizing the sound level in room 1, $L_1(t)=0$ dB at $t=0$. Then substitution of Eqs. (12) and (13) into Eq. (11) and further simplification yields the following early and late decay equations for room 1:

$$L_{1early}(t) = -\left(\frac{60}{T_1}\right)t, \quad (14)$$

$$L_{1late}(t) = -\left(\frac{60}{T_2}\right)t - 10 \log\left(\frac{A_{1S}A_{2S}}{S^2}\right). \quad (15)$$

These equations are in $y=-mx+b$ form, from which we can see that the early and late portions of the decay are two lines, each with a slope and y intercept that can be calculated from geometrical parameters of the coupled volumes. The above-mentioned theoretical development is a modified version of that given in Cremer et al.[1] For a more detailed description of this analysis, the reader is referred to Refs. 1–5.

The above-mentioned results allow for the decay slope of the main room in a coupled volume system to be analyzed based on its two temporal components, early decay and late decay. Many room acousticians believe that a steep early decay slope allows for a high level of perceived clarity, whereas a shallow late decay slope leads to a more lingering reverberance.[4] Clarity describes the definition of a sound in a space, or how easily different parts of a sound signal can be differentiated from one another. Reverberance describes the fullness of tone, and refers to sound energy that persists in a room after a sound is suddenly stopped. Both clarity and reverberance are desired quantities in concert hall acoustics, but seem to have contradictory decay slope criteria. This apparent contradiction may be alleviated in coupled volume systems because $L_1(t)$ and $L_2(t)$, which can exhibit differing slope characteristics, dominate the decay at different times. Figure 2 shows a representative decay outline for this situation, where $L_1(t)$ is shown by the dashed line and $L_2(t)$ by the solid line.

This so-called double slope decay, or double slope effect (DSE), shown by the bold lines in Fig. 2, may result in high clarity and reverberation. The term DSE will be used in this paper to refer to the phenomenon in which the secondary decay is longer than the first, and in which it dominates the

decay profile during the latter portion of time. Although coupled volume systems can be designed to exhibit a variety of acoustic effects, both with and without DSE, this work will focus on those which incorporate auxiliary volumes external to a main space connected through apertures specifically designed to obtain DSE. The authors refer to such systems as dedicated coupled volume systems.

II. PREVIOUS RESEARCH

As can be seen from the above-noted theoretical development, the DSE in a coupled volume system is affected by several variables, namely main volume size, coupled volume size, aperture size, and level of absorption in the two spaces. The effects of these variables, as well as source-receiver positions and the relationship between theoretical and computational analyses of coupled systems, have been explored to a limited degree in previous studies.

Eyring conducted a study of several coupled room configurations in an attempt to develop empirical modifications to theoretical formulas.[6] Eyring's configurations examined three distinct variables: absorption in both rooms, aperture size, and the source-receiver positions. Specifically, Eyring found that the double slope effect is most noticeable when a large absorptive room is coupled with a smaller live room. Additionally, for his particular configurations, Eyring posited that the coupled volume effect occurs only for absorption coefficients of less than 0.07 in the coupled room. Finally, he suggested that DSE only occurs when the source and receiver are placed in the same room, particularly, the less reverberant room. This work began to shed light on the relationship between the architectural parameters of the system and the DSE; however, more systematic analysis of these variables was needed.

Harrison and Madaras utilized computer modeling of coupled volumes to study the effects of aperture size and coupled volume size.[7] They quantified the coupled volume effect with a ratio of T_{30}/T_{15}, referred to as the "coupling coefficient." This ratio gives the relationship between two different portions of the reverberant decay. T_{30} is defined as the decay time from -5 to -35 dB in the energy decay function, multiplied by a factor of 2, such that T_{30} is on the same order of magnitude as T_{60}. Similarly, T_{15} is given as the decay time from -5 to -20 dB, multiplied by a factor of 4. Although T_{30}/T_{15} is an adequate indicator of DSE, it does not rigorously differentiate between different double slope profiles. Particularly, a specific coupling coefficient can be used to describe several different double slope profiles. This ambiguity compromises the effectiveness of this descriptor as a metric of the DSE.

Harrison and Madaras showed that T_{30}/T_{15} is maximized for smaller aperture opening sizes and generally increases exponentially with increasing coupled volume sizes. The researchers also pointed out that the shape, location, and configuration of the aperture openings had noticeable, but less significant effects on the acoustic performance than did the volume of the coupled space and aperture size.

Ermann and Johnson studied how the architectural variables, aperture size, and coupled volume absorption affect the decay slope of a coupled system.[8] To quantify the coupled volume effect, the investigators used the ratio of T_{60}/T_{15}, referred to as the "coupling constant," which is a slight variation on Harrison and Madaras' coupling coefficient. This ratio has problematic issues, similar to the coupling coefficient, namely that it is not a rigorous measure of DSE. Additionally, this method obtains a T_{60} value from a straight line fit, which is a poor representation of the actual double sloped decay function and could lead to great inaccuracies. Thus, coupling constant is only a rough indicator of DSE.

The Ermann and Johnson study showed that having an average absorption coefficient in the coupled space less than 0.02 ($\bar{\alpha} < 0.02$) produced significantly higher coupling constants than $0.02 < \bar{\alpha} < 0.05$. The coupling constant approached infinity as $\bar{\alpha}$ decreased to zero, and asymptotically approached unity for $\bar{\alpha} \geqslant 0.10$. The results regarding the effect of aperture size indicate that the coupling constant peaks when the aperture size is 1% of the total main volume surface area, while the coupled volume effect declines dramatically for aperture sizes larger than 1% of the total main volume surface area.

Summers extended the earlier theoretical work into the computational domain using CATT Acoustic computer models of coupled spaces.[9] His work analyzed the limits of statistical models by comparing them to computer modeled results, subsequently making refinements to the basic formulas of statistical coupling. Results showed that high levels of coupling caused large deviations between statistical predictions and computational values. Additionally, the results showed that all assumptions for single rooms, such as a diffuse sound field with even distribution of absorption, must hold true in the coupled system so that theoretical and computational methods may agree.

Research on subjective perception of nonexponential decays has also been undertaken. Atal *et al.* conducted an investigation to determine the correlation between the subjective feeling of reverberation and nonexponential decays.[10] In this study, nonexponential decays were produced by manipulating reverberated signals obtained from computer-simulated reverberators using combfilters connected in parallel. The decays exhibited a flat response across frequency, indicating that each normal mode had an equal decay rate. The researchers carried out pairwise comparison subjective tests between classic exponential decays and the artificially generated nonexponential decays. The reverberation time corresponding to the exponential decay chosen as most similar to a particular nonexponential decay was designated as the subjective reverberation (T_s). The investigators found that this T_s was highly correlated with a new reverberation time metric $T(160 \text{ ms})$. $T(160 \text{ ms})$ was found by fitting a straight line through the first 160 ms of the nonexponential decay and extrapolating to 60 dB down. This result indicates that the most important factor in determining the subjective evaluation of reverberation in nonexponential decays is the early temporal content of the decay. Further investigation, though, found that introducing the complexity of frequency dependence found in typical concert halls confounded the

correlation between the subjective impression of reverberation and the early portion of non-exponential decay.

Picard also constructed a series of artificial nonexponential decays by splicing together pairs of impulse responses exhibiting exponential decay profiles.[11] Subjective testing was conducted in an effort to determine just noticeable differences between exponential and nonexponential decays. The results showed that subjects could more easily perceive a difference between the decays when the y intercepts of the two slopes were minimized. Additionally, difference perception increased as the difference between the two slopes in the nonexponential decays was increased. In the study, Picard suggested a quantitative descriptor for nonexponential decay based on the amount of energy from the latter secondary decay that is added above the original exponential decay.

Ermann conducted a similar subjective perception study, using computational geometric acoustics modeling to generate exponential and nonexponential decays.[12] The results from subjective tests utilizing these decays corroborated those found by Picard, showing that subjects are more likely to recognize a difference between two decay curves when the difference between the first and second slopes in the nonexponential decay is increased.

The research in this paper uses room acoustic computer modeling techniques to extend the work on quantifying the effect of coupled room geometry by more comprehensively analyzing the individual and interactive effects of three architectural parameters found to be significant in previous work: the volume ratio between the main and secondary spaces, the absorption ratio between the two spaces, and the aperture size. In this paper, the coupling coefficient is used to compare against previous research, and new DSE quantifiers are additionally introduced to differentiate the nonexponential decays with greater precision. The study then continues to extend the previous work by correlating subjective responses with the coupled geometry itself. Together, the objective and subjective analyses help to provide a better understanding of how architectural parameters affect DSE in coupled volume systems.

III. DEVELOPMENT OF NEW DSE QUANTIFIERS

A. Decay ratio and ΔdB

As discussed previously, the coupling coefficient obtained from the ratio of T_{30}/T_{15} does not uniquely represent the double slope effect apparent in an energy decay curve associated with a coupled volume system, and thus may not accurately indicate its perception. A more accurate method of characterizing the DSE may be achieved by analyzing the decay as a composite of two distinct slopes. The energy decay curve shown in Fig. 2 will be used as an illustrative example. The steep slope characterizing the early decay, shown as a dashed line in Fig. 2, will be referred to as slope 1. The shallower slope representative of the late decay, depicted as a solid line in Fig. 2, will be referred to as slope 2 (noise floor is disregarded during slope calculation). A time decay, which is inversely proportional to the slope, can be

calculated for each line, giving Decay1 and Decay2. The quotient of the two time decay quantities will be defined as a parameter called decay ratio:

$$\text{decay ratio} = \frac{\text{Decay 2}}{\text{Decay 1}} = \frac{T_{60_2}}{T_{60_1}}. \tag{16}$$

A second parameter, ΔdB, can be defined by the difference between the y intercepts of each of the two slopes. The dB level of slope 1 is given by the starting level of its energy decay curve. The dB level of slope 2 is found by extending the slope to the ordinate and determining the level at time zero of its energy decay curve. ΔdB is found by subtracting the second level from the first. In the earlier theory section, the early and late decay functions were normalized such that

$$\Delta dB = 10 \log\left(\frac{A_{1S}A_{2S}}{S^2}\right). \tag{17}$$

The decay ratio and ΔdB provide more information about the double slope characteristic of a particular energy decay curve than the coupling coefficient; thus, they can be used to more distinctly describe the DSE produced by a coupled volume system. Additionally, if one of the decay rates is specified, then the DSE may be uniquely defined.

Previous subjective research indicated that the difference between exponential and nonexponential decays was more easily perceived when the two slopes of the nonexponential decays were more different,[11,12] and when the y intercepts of the two slopes were minimized.[11] Note that these two trends correspond to the two proposed quantifiers: more perceptible DSE with larger decay ratio and smaller ΔdB.

The calculation of decay ratio and ΔdB requires four quantities from an energy decay function: the two slopes of the decay, and the y intercepts of those slopes. Obtaining these data from virtual and real coupled volume rooms can prove to be problematic. Particularly, determining the presence of nonexponential decay from visual inspection of the energy decay curve resulting from the Schroeder backwards integration method can be difficult. This is because background noise can alter the shape of the Schroeder curve, depending on the upper time limit of integration.[13] An analytical method is necessary to obtain accurate slope and relative dB level data for the new DSE quantifiers. One such method can be found through the use of Bayesian statistics.

B. Bayesian analysis

Xiang and Goggans developed Bayesian analysis for use in room acoustics and specifically for studying multirate decay impulse responses.[13,14] Bayesian model-based parameter estimation is used to produce an algorithm for the evaluation of multirate decay functions. The method allows for the estimation of the number of decay rates present in a multirate decay curve without requiring an initial guess on the number of slopes inherent in the decay. Additionally, this analysis can be used to determine the parameters of the decay profile, namely the slopes of the decays and ordinate intercepts of those slopes. Bayesian analysis also provides a major improvement over the classical least-squares approach. In the least-squares method, the initial estimations of parameters

TABLE I. Dimensions of main and coupled volumes with volume ratio percentage values used in computer model configurations.

	l (m)	w (m)	h (m)	V(m³)	Ratio level	Percentage of main volume
Main	34	28	26	24752		
Coupled 1	21	18	13	4914	1	20%
Coupled 2	23	22	17	8602	2	35%
Coupled 3	26	24	20	12480	3	50%

that describe an impulse response must be relatively close to actual values for iteration convergence to occur. The Bayesian method avoids this problem, as careful estimates of the initial values are not required.

In Xiang and Goggans' work, the Bayesian analysis method is shown to be a suitable approach to predicting the decay rates from sound energy decay functions. There is found to be little dependence on the upper time limit of integration or signal to noise ratio. Bayesian analysis can therefore be used to determine the slopes and intercepts in a multirate decay function, and when applied to double slope decay data, it yields the values necessary to calculate the parameters of decay ratio and ΔdB.

IV. COMPUTATIONAL ANALYSIS

This research project uses computer modeling of room acoustics to determine the individual and interactive effects of three architectural parameters on DSE: the volume ratio between the main and secondary spaces, the absorption ratio between the two spaces, and the aperture size. These three variables were modified in a simplified coupled volume system composed of two rectangular boxes connected through one acoustically transparent aperture. The coupled system was realized as a three-dimensional space and studied using the ODEON v5 computational modeling program.[15,16] Although it is beyond the scope of this paper to verify computer modeling as a tool to study DSE, ongoing work by the authors has validated this methodology.[17]

The ranges of values for the architectural parameters in question were developed based on data from existing halls that utilize dedicated coupled volume systems in their design. Additionally, consideration was taken from the values given by the spaces studied in the previous research mentioned earlier.

The first architectural parameter, volume ratio, quantifies the size of the coupled volume with respect to that of the main volume, and is represented as a percentage in this research. Existing dedicated coupled volume halls reviewed for this study have volume ratios ranging from 28% to 50%. Therefore, three volume ratios closely matching this range have been used in this study: 20%, 35%, and 50%. In the computer models, the main volume was held constant at 24 752 m³, and the coupled volume was varied to obtain the respective volume ratio percentage. Details are provided in Table I.

The second architectural parameter is the absorption ratio. This ratio depicts the equivalent absorption area in the coupled volume as a percentage of the equivalent absorption area in the main volume. The equivalent absorption area in each space, with units of m²-sabins, is calculated by multiplying its total surface area by its average absorption coefficient, which in this study has been applied uniformly to all surfaces in the space. Absorption ratio percentage values range from 3% to 14% in the existing halls reviewed for this study; four levels across this range have been modeled. The main volume's absorption coefficient in the computer models was held constant at 0.25. Since the surface area in the coupled space changes as its volume changes, the resulting absorption coefficients in the coupled space varied across volume ratio in order to achieve the desired absorption ratio. Values for the four levels of absorption ratio used in this study, labeled as a, b, c, and d, and the respective coupled volume absorption coefficients are shown in Table II.

The final varying parameter is aperture opening size. In this study, aperture opening size is defined as the surface area of the opening between the main and coupled volumes, given as a percentage of the available aperture area. The available aperture area is defined by the surface area of the intersection of the two volumes, which equals the surface area of one face of the coupled volume, and thus varies with each volume ratio. Five percentages of this available area have been used for the aperture opening size, as shown in Table III. The aperture opening size can also be given as a percentage of the main volume surface area, a quantity commonly used in earlier research; those corresponding percentages are also listed in Table III.

Varying the three parameters resulted in a total of 60 different combinations. Each combination was created as one of 60 model configurations in the ODEON program. Figure 3 shows a representative model configuration.

In addition to the previously listed absorption coefficients, the surfaces in each computer model were assigned a uniform scattering coefficient of 0.3. This value is usually a

satisfactory, average scattering coefficient for use in room acoustic computer modeling,[15,16] although with a low level of geometric model detail, as used in this study, it may result in a less diffuse sound field.[18] Each of the 60 models was processed in ODEON to produce an impulse response for each configuration. An omni-directional source was used with an impulse response length of 4000 ms and 1705 rays. Generally, a higher number of rays will lead to denser reflection information in the impulse response, since more rays are able to travel in and out of the secondary space. Current research incorporating computer modeling of coupled volume spaces shows a tendency to use a higher number of rays,[19] and future research should further follow this issue in a more systematic way. For the study discussed here, though, inspection of ray-tracing graphics in ODEON produced satifactory results showing that a sufficient amount of rays had traveled between the main and secondary spaces.

Objective measures, such as T_{15} and T_{30} values, were subsequently extracted from each impulse response. Finally each impulse response was evaluated with Bayesian analysis to obtain its decay slopes and y intercepts.

V. COMPUTATIONAL RESULTS

A. Coupling coefficient results

The coupling coefficients for the 60 models were found by calculating the respective T_{30}/T_{15} ratios. These coupling coefficients are plotted as a function of absorption ratio and aperture size for the three volume ratios in Fig. 4. A few general trends can be noted regarding the individual effects of the architectural parameters on the quantifier, coupling coefficient.
Looking across volume ratio levels, we see that coupling coefficient generally increases as the size of the coupled volume increases. This effect is in accordance with physical expectations. A larger coupled volume would allow sound energy to dissipate more slowly, feeding back into the main volume over a longer period of time, increasing the late energy in the main volume.

Across absorption ratio, coupling coefficient is shown to decrease as the level of absorption in the coupled volume increases. Again, this result is corroborated by the behavior of sound in the physical world. For larger values of α in the coupled volume, sound energy would be absorbed more rapidly. Therefore, the disparity between the early and late energy would decrease due to the smaller amount of late energy being fed back into the main hall.

Finally, in observing the general effect of aperture size, note that coupling coefficient peaks at a particular opening size for each volume/absorption combination, which is typically a small percentage of the total surface area of the main volume. In the physical world, smaller aperture sizes would force sound energy from a relatively reverberant coupled volume to leak back into the main volume more slowly, thus increasing the late decay time. Aperture sizes that are too small, however, would reduce the probability of the sound reentering the space before dissipation, and would therefore decrease the chances of obtaining a double slope decay profile. These observations are in line with the results found in previous research.

FIG. 4. Coupling coefficient data for all 60 configurations.
FIG. 5. Computer modeled and theoretical decay ratio and ΔdB data for volume ratio 1.

The results in Fig. 4 also provide insight into the interactions between the three parameters studied. Note that larger coupled volumes with aperture sizes approximately 10%–20% of the available aperture area (or roughly 1% of main volume's surface area) produce high coupling coefficient values. This effect is maximized with lower absorption ratios. A small volume ratio, though, only results in higher coupling coefficients if the absorption ratio is also quite low. In summary, the coupled volume size seems to have the largest effect on coupling coefficient; if it is not large enough, then high coupling coefficient can only be achieved with very low absorption ratios.

B. Decay ratio and ΔdB results

The results based on the newly suggested parameters of decay ratio and ΔdB, determined from Bayesian analysis, are more difficult to interpret than the coupling coefficient results because they provide more information about the double slope decay curves that has not been well-linked to subjective perception of DSE yet. The black data points and lines in Figs. 5–7 show the computer modeled results, with each graph representing a different volume ratio. The ΔdB values shown are normalized by dividing each value by the average ΔdB value across all configurations: 10.5 dB. This normalization was conducted in order to display the ΔdB data in the same range as the decay ratio data; this procedure has no influence on the overall trend of the data.
FIG. 6. Computer modeled and theoretical decay ratio and ΔdB data for volume ratio 2.
FIG. 7. Computer modeled and theoretical decay ratio and ΔdB data for volume ratio 3.

For the smallest volume ratio 1 (Fig. 5), decay ratio and ΔdB follow the same pattern across configurations with the majority of cases demonstrating decay ratio values of one and ΔdB values of zero. Such decay ratio and ΔdB values indicate an energy decay function from which the Bayesian analysis detected no double slope. In general, the results from this volume ratio suggest that smaller coupled volume sizes do not readily produce DSE. A nonexponential decay curve seems to be found at lower and higher aperture sizes, but not in a consistent or expected fashion across the cases. It is possible that the simplified geometry or selection of calculation parameters have compromised the results in these cases.

For volume ratio 2 (Fig. 6), decay ratio and ΔdB follow the same general pattern with all combinations of aperture size and absorption ratio producing some degree of nonexponential decay. Both decay ratio and ΔdB values peak at 10%–20% of the available aperture area (or roughly 1% of the main volume's surface area) for each absorption ratio. These results match the coupling coefficient trends in Fig. 4 for this volume ratio and those obtained from previous research.

As with volume ratio 2, the results for largest volume ratio 3 (Fig. 7) show all combinations of aperture size and absorption ratio producing some degree of nonexponential decay; however, the decay ratio and ΔdB do not behave similarly across configurations for this large coupled volume size. For example, there is a distinct difference at 10% aperture opening for the lower absorption ratios. Decay ratio and ΔdB do not necessarily have to show the same trends, though; as a matter of fact, that is why decay ratio and ΔdB are being suggested as more accurate quantifiers in this paper. Having both of these descriptors provides a more distinct description of nonexponential decays within coupled volume systems. Figure 8 demonstrates a number of cases of different combinations of decay ratios and ΔdB, where decay ratio may be large while ΔdB small and vice versa. What remains unclear at this point is how these different nonexponential decays are perceived. Subjective testing is required to study further how decay ratio and ΔdB may be linked to perception of DSE.

The theoretical derivation given earlier in this paper showed how decay ratio and ΔdB can be calculated from

knowledge of the geometrical parameters. These theoretical values have been calculated for each of the 60 configurations used in the computer simulations, and are shown by the gray data points and dashed lines in Figs. 5–7. The theory expects decay ratio to decrease as aperture size increases, decrease as absorption ratio increases, and increase as the coupled volume increases. Recall that previous research found that non-exponential decays with larger decay ratios were more easily differentiated from exponential decays; the theory finds that larger decay ratios are obtained with smaller aperture openings, smaller absorption ratios, and larger volumes (with some values off the y-axis range in Figs. 6 and 7). The computer modeled decay ratio data generally matches these trends, but not completely across all configurations. The main differences are that the computer modeled behavior at the smallest aperture openings always demonstrates smaller decay ratios. Also the computer modeled results do not show a clear increase in decay ratio when increasing from volume ratio 2 to 3.

The theoretical ΔdB values decrease as aperture opening increases, increase as absorption ratio increases, and decrease as the coupled volume increases. Recall that previous research found that nonexponential decays with smaller ΔdB were more easily differentiated from exponential decays; the theory finds that smaller ΔdB are obtained with larger aperture openings, smaller absorption ratios, and larger volumes. The computer modeled ΔdB results show similar tendencies for aperture size and volume, but the trend with absorption ratio is not found.

The differences between the theoretically expected decay ratio and ΔdB values and the computer modeled results obtained from Bayesian analysis could be due to the following factors. Summers' work indicated that results between computer models and statistical theory deviate when diffuse fields are not achieved, and also when there is a high level of coupling.[9] The computer modeling parameters, particularly the scattering coefficient and number of rays used, may have detracted from the diffuseness of the generated sound fields.

Another limitation in both the theory and the computer modeling analysis involves the behavior at small aperture openings. In the physical world, impedance effects at the boundary and considerations of wavelength compared to opening size could reduce the decay ratio values, so that the high values of decay ratio predicted theoretically would be invalid. Furthermore, high decay ratios are usually accompanied by higher uncertainty values in the Bayesian analysis, as explained by Xiang et al.[20]

Although the decay ratio and ΔdB results from theory and from Bayesian analysis of the computer modeled impulse responses do not perfectly match, it is still of interest to use the simulated results to learn more about the subjective perception of DSE.

VI. SUBJECTIVE ANALYSIS

To help reach the goal of having an objective measure of DSE that correlates to subjective response, psychoacoustic testing has been conducted. Another purpose of this testing was to determine the effect of the architectural parameter variation on subjective response to DSE. A subset of the impulse responses generated in the computational phase of this study was used in the subjective testing phase. The subset consisted of the sound fields simulated in the combinations of the volume ratio and aperture opening size variables, producing 15 impulse responses in total. The absorption ratio for these combinations was held constant at the lowest level of 3%, since lower levels are most likely to produce DSE according to theory and previous research. Subjects were asked to rate the perceived reverberation and clarity from a series of sound tracks. These two acoustic qualities were chosen as the subjective variables because DSE is allegedly related to having both high reverberance and clarity. Combining the results from subjective perception of these two qualities would indicate the broader psychoacoustic response to DSE.

Auralizations were produced in ODEON by convolving the impulse responses for each configuration with an anechoic music sample. The anechoic piece used in this study was a selection from Beethoven's 9th symphony performed by the Osaka Philharmonic Orchestra.[21] A KEMAR head related transfer function was applied to the convolved impulse responses in ODEON. A series of 15 sound tracks were created from the 15 configurations. The tracks were presented over headphones to 30 human test subjects, and the presentation order was randomized to reduce bias error. Subjects were members of the University of Nebraska community, with the majority being between 20 and 30 years of age. Each subject was determined to have normal hearing thresholds in both ears. Most of the subject pool indicated that they had limited exposure to classical music, such as that played during the testing.

Subjects were given a brief training session that covered the definitions of the acoustical qualities of reverberation and clarity. After the training period, subjects were asked to rate each track on a 9 point scale for reverberation (dead to live) and clarity (unclear to clear).

VII. SUBJECTIVE RESULTS

This study used a repeated measures design with two independent variables: volume ratio with three levels, and aperture size with five levels. There were two dependent variables: perceived reverberation and perceived clarity.

A two-way repeated measures ANOVA was performed on these data. Results indicate that there was a significant effect of volume ($p < 0.0001$) and aperture size ($p < 0.0001$) on perceived reverberation. Additionally, perceived reverberation showed a significant effect due to the interaction between volume and aperture size ($p = 0.028$). There were no observed significant effects on perceived clarity. Figures 9 and 10 show the statistically estimated mean values of perceived reverberation and perceived clarity for each combination of volume and aperture size.

The nonparallel lines in Fig. 9 do indicate a reaction between the independent variables, volume ratio, and aperture size. In other words, as both independent variables change, the perceived reverberation results change in a manner different from when the independent variables are changed separately. It appears that the main cause of the nonparallel lines is the volume ratio 2 data in the midrange of aperture opening sizes tested, implying that this is a region where the subjects may find it difficult to differentiate between their perceptions of reverberation.

Post-hoc pairwise Bonferroni comparison tests revealed that, for perceived reverberation, volume ratios 2 and 3 were significantly different from volume ratio 1. Additionally, for perceived reverberation, the 10%, 20%, and 40% openings significantly differed from the 2% opening. Also, the 20% and 40% openings significantly differed from the 5% opening ($p < 0.05$ for all significant tests).

In summary, the volume ratio and aperture size have been found to affect perceived reverberation in this study. Listeners generally perceived a higher reverberation as volume and aperture size were increased independently. Figure 11 shows the objective early decay time (EDT) results from the computational analysis of the impulse responses of each model. These data show a clear tendency for EDT to increase as volume and aperture size are increased. The early portion of the reverberant decay has long been regarded as a good indicator of subjective impression of reverberance.[22,23] Therefore, comparative analysis between the EDT values and the subjective response to reverberance shows good agreement between the objective and subjective results.

The lack of significant effects with clarity is most likely due to the nature of the simplified forms of the modeled coupled volume systems. Clarity may be objectively quantified by the clarity index, a ratio of early to late sound energy received at a given position in a space. The clarity index is given in dB as

$$C_{80} = 10 \log\left(\frac{\int_{t=0}^{80 \text{ ms}} g^2(t)dt}{\int_{t=0}^{\infty} g^2(t)dt} \right), \tag{18}$$

where $g(t)$ is the impulse response of the space in time. This measure is affected greatly by early reflections. In this study, the models were comprised of two simple rectangular boxes, a geometry that does not produce a high number of early reflections that are distinguishable from other reflections. As the coupled space's volume and the aperture size are changed, the early reflections are unfortunately not directly influenced. Objective clarity (C_{80}) results from the 60 configurations studied in this paper are shown in Fig. 12. The greatest differences in the C_{80} values were found when comparing across volume ratios, giving an average difference of 0.68 dB, which is on the order of the just noticeable difference: $0.67 \pm 0.13 \ dB$.[24] These objective results

FIG. 12. Objective clarity (C_{80}) values for the subset of configurations used in subjective testing.

TABLE IV. Computer modeled decay ratio and ΔdB data, and statistically estimated perceived reverberation data for volume ratio 3 and five aperture opening size percentages.

Aperture size (%)	Decay ratio	ΔdB	Statistically estimated reverb
2	2.00	0.58	4.30
5	3.16	1.40	4.27
10	1.64	1.53	5.30
20	2.46	0.60	5.03
40	2.94	0.72	5.63

suggest no perceptual change in clarity across configurations, agreeing with the subjective results obtained.

The original hypothesis of the authors was that higher perceived reverberation and perceived clarity resulted from nonexponential decay curves that demonstrated greater degrees of nonexponential decay, and that this degree of nonexponential decay could be objectively quantified by coupling coefficient or more precisely with the new combination of decay ratio and ΔdB. Unfortunately, since perceived clarity did not result in any significant results in this study, it is not possible at this time to delve further into the prospect of nonexponential decays producing both high reverberation and high clarity.

Even though the perceived clarity results are not obvious, comparison of the perceived reverberation results to the coupling coefficient, decay ratio, and ΔdB results show very good correlations. As indicated previously, volume ratios 2 and 3 produced statistically higher perceived reverberation values than volume ratio 1. These larger volume ratios also produced higher values of coupling coefficient, decay ratio, and ΔdB than volume ratio 1. The same is true for the subjective results of aperture size; aperture sizes around 20% produced significantly higher perceived reverberation values than those from the lower apertures of 2% and 5%. For volume ratio 2, these larger aperture sizes generally produced higher values of coupling coefficient, while the decay ratio and ΔdB results were more varied depending on the volume ratio.

Recall that the decay ratio and ΔdB data from volume ratio 3 of the computer simulations exhibited different trends across aperture opening size (Fig. 7). To analyze how each of the new quantifiers may relate to subjective perception of reverberation, a comparison of the volume ratio 3 data is made against the statistically estimated means of reverberation from the subjective tests (Table IV). Comparing cases that were found to be significantly different from the Bonferroni tests, we see that in comparing the 2% and 20% cases, decay ratio increases while ΔdB remains about the same, correlating to higher perceived reverberation. Similarly in comparing the 2% and 40% cases, decay ratio increases while ΔdB increases slightly, again correlating to higher perceived reverberation. Comparing the 5% and 20% cases, de-

cay ratio and ΔdB both decrease, resulting in higher perceived reverberation. A comparison of the 5% and 40% cases shows decay ratio decreasing slightly and ΔdB decreasing a larger amount, producing higher perceived reverberation. Comparison between 2% and 10%, however, shows a different trend not expected from previous research; decay ratio decreases and ΔdB increases, producing higher perceived reverberation. The authors believe this anomaly may be due to the issues discussed earlier with the computer modeling, concerning the diffuseness and density of the reflection diagram.

In summary, the results mostly confirm findings from previous research: larger decay ratios and smaller ΔdB values generally lead to greater perceived reverberation. It still remains unclear, though, which of the two parameters has the more severe influence on DSE overall, since no significant relationships were found with perceived clarity ratings.

VIII. CONCLUSIONS AND FUTURE WORK

Computer modeling results for 60 coupled volume configurations with varying volume ratio, absorption ratio, and aperture size have been studied objectively using coupling coefficient and the new parameters of decay ratio and ΔdB. There is a general increase in coupling coefficient as coupled volume size increases, a general increase in coupling coefficient as coupled volume absorption decreases, and coupling coefficient peaks at a particular opening size for each volume/absorption combination. Coupling coefficient results also suggest that among the three parameters, having larger coupled volume sizes is the most significant in producing higher coupling coefficient values. Smaller coupled volume sizes can only achieve high coupling coefficients if the absorption ratio is also very low. The proposed parameters of decay ratio and ΔdB provide more specific information about each nonexponential decay curve, and have been found to show similar trends as coupling coefficient. However, the new parameter data for the highest volume ratio tested were harder to interpret without further information about subjective perception.

Subjective testing using the results from 15 of the configurations showed a general increase in perceived reverberance with increasing volume and aperture size. Higher perceived reverberance also matched well with objective coupling coefficient results, and generally with higher decay ratios and lower ΔdB values. No significant effects on perceived clarity were found, which may be due to the lack of distinguishable early reflections in the simplified geometry studied. Due to the lack of this significant effect, further

extrapolation by combining the subjective results of reverberation and clarity could not be carried out to determine overall subjective response to DSE.

Further study in this area could focus on advancing a metric for describing DSE that will allow for the effects of the architectural parameters on coupled volume systems to be more clearly understood. Several issues can be improved in ongoing work. The simplified geometry of the models may have adversely affected the results due to the lack of strong early reflections. Consequently, models with more realistic geometries can be built to produce results that better articulate the clarity of the systems. Additionally, certain computer modeling calculation parameters may have had an adverse effect on the results. The number of rays used, for example, could have been significantly higher, allowing for a more accurate exploration of the coupled volume geometry. Future work could incorporate these modifications, and more concrete conclusions regarding DSE prediction and perception may be made with further research.

The ability of computational geometrical acoustics to accurately model energy decay in systems of coupled rooms is investigated both theoretically and experimentally. Unlike single-volume rooms, coupled rooms have reflection density that is not described by a single quadratic function of time. It is shown that tail-correction procedures used by beam-axis-tracing algorithms, which assume quadratic growth of reflection density, can lead to inaccurate predictions in coupled rooms. Further, beam-axis tracing implemented as ray tracing with a growing detection sphere is susceptible to error in coupled rooms when the detection sphere extends into adjacent subrooms. Marked error is anticipated in those cases for which the source and receiver are in the less reverberant of two rooms and is expected to be most severe for (1) small coupling apertures and (2) receiver positions near boundaries between subrooms. Errors are demonstrated by comparison of computational geometrical acoustics predictions with scale-model measurements made in a two-room coupled system. A revised beam-axis/ray-tracing algorithm is investigated that circumvents possible error mechanisms by switching to ray tracing for the late part of the decay. Comparisons with scale-model measurements indicate that the revised algorithm is able to predict energy decay accurately in coupled rooms. © 2005 Acoustical Society of America. I. INTRODUCTION

Computational modeling of sound fields in rooms using software based on geometrical acoustics (GA) is now commonplace among researchers and practitioners in the field of architectural acoustics. As a result, GA software is being applied to an ever-increasing variety of room types—many of which were never anticipated when the software algorithms were first developed. Of the nontraditional room types being modeled, systems of coupled rooms are of particular interest because of growing use of such geometries in the design of auditoria (see, e.g., Chaps. 2 and 3 of Ref. 1). However, the accuracy of certain computational GA algorithms is compromised when applied to coupled rooms.[2–5] Based on comparisons between predictions of GA models and acoustical measurements of coupled-room systems, prior studies have suggested that ray-tracing and beam-axis-tracing algorithms require many more rays or beam axes, relative to the numbers required for single-volume rooms, to accurately predict sound fields in systems of coupled rooms.[4,5] Authors have also reported that methods that algorithmically generate the late portion of the decay curve in order to extend the duration beyond the truncation time of a computational GA algorithm (a technique that is distinct from the tail-correction procedures discussed below) can lead to errors when applied to coupled rooms.[5,6]

This paper presents an investigation of the ability of the previously developed commercial GA software CATT-Acoustic (v. 7.0 and above), which is based on a randomized form of the widely used beam-axis paradigm,[7,8] to accurately predict sound fields in coupled rooms in the high-frequency region for which wave effects primarily consist of surface scattering. (Recognizing the severe limitation of pure-specular methods, randomized beam-axis tracing stochastically redirects the direction of beam axes on reflection to account for frequency-dependent surface scattering, in the same manner as ray tracing.) Systems of coupled rooms composed of large, reverberant enclosures, such as those encountered in concert halls equipped with reverberation chambers, are primarily addressed. Assumptions inherent to the algorithm are described together with the conditions under which they can be violated. Though the algorithm has been validated in single-volume rooms by comparison of predictions with measurements,[9] comparisons of predictions with scale-model measurements indicate that the algorithm displays systematic error when applied to certain systems of coupled rooms. To address this, a modified algorithm is in-

---

vestigated, which, by comparison with the same scale-model measurements, is shown to accurately model sound fields in systems of coupled rooms.

II. BEAM-AXIS TRACING

A. Background

As stated in the Introduction, the work described is this paper is largely directed toward the high-frequency region for which surface scattering is the only significant wave effect and sound fields can be accurately modeled by GA. Two primary methods have been traditionally used for the computational modeling of sound fields in rooms according to the laws of GA. Of these, the image-source model[10,11] is a deterministic pure-GA model that, when applied to coupled rooms, displays no limitations unique to that room configuration.[6] (It is, however, flawed in all geometries by an inability to model nonspecular reflection. It is further limited by its computational complexity to computing only low-order reflections or reflections in simple geometries.) The second method, ray tracing,[12] is computationally less demanding, but subject to systematic geometrical errors.[13] Beam-axis tracing,[7,8] a variant of ray tracing that approximately models the propagation of divergent beams (either having triangular or circular faces), offers certain advantages, while still being subject to similar errors.

Hybrid methods have been developed that combine aspects of ray-tracing and image-source models.[2,9,14–16] In these hybrid models, rays or beam axes are used either to transport energy, as in the conventional ray-tracing approach, or to efficiently probe the geometry and locate potential image sources. Because of their foundation in (specular only) ray tracing and beam-axis tracing, these techniques are also subject to systematic geometrical errors.

Recently, interest has renewed in beam-tracing algorithms in which the intersections of beam faces with multiple surfaces are modeled exactly.[17–19] Because these models are formally identical in their predictions to the image-source model, they likewise have no limitations unique to coupled rooms. At present, such models are limited to rooms that can be modeled by a moderate number of polyhedra [i.e., those without highly faceted surfaces (see p. 753 of Ref. 19)], and also suffer from inability to model nonspecular reflection. Moreover, the computational complexity of even the most recent of these models[19] remains exponential in reflection order, suggesting that the high-order-reflection calculations required to model reverberation may be impractical in some cases.

B. Mechanisms of energy-detection error

Beam tracing is most often applied approximately, by tracing only the central axes of the beams—so-called beam-axis tracing. This approach offers the advantage of decreased computing time by covering the 4π steradians outwardly visible from the source more efficiently than ray tracing (i.e., fewer beam axes are needed than rays due to the increased detection probability of a beam face relative to a ray). However, it can result in incorrect detections of energy arrivals at receivers in the late part of the decay, which must be ad-

dressed by a tail-correction procedure. The two primary mechanisms by which energy is incorrectly detected are discussed below.

First, if only the axes of beams are traced, it is possible that a surface that would interact with a portion of the outgoing wavefront represented by one of the beam faces will not be accounted for because it will not interact with the axis of the beam. The area of the beam face grows over time and gives a measure of the spatial-detection uncertainty. When the beam face is on the order of the area of representative room surfaces and larger, significant numbers of geometrically valid reflections are unaccounted for. This error mechanism can be viewed as spatial undersampling due to the divergence of the rays representing the axes of the cones.[13] As a result of this, an increasing number of geometrically valid reflections are undetected as time increases.[15,16] In beam-axis tracing, unlike ray tracing, this results in an increasing loss of detected energy arrivals over time due to the explicit reduction of the energy of each beam axis to account for spherical divergence, which it is not balanced by geometrically invalid detections. However, these undetected reflections can be naturally compensated for by relaxing the geometrical detection criteria with time to allow an increasing number of reflections to be detected that are *almost* geometrically valid.[9,16]

A second source of error results if the size of the beam face at late times exceeds the size of the total room such that each reflection is detected by all receivers, regardless of whether the arrival is physically possible or not. The particular form that this error takes depends on the algorithm used to model beam-axis tracing. In a single-volume room, the observed reflection density $n(t)$ asymptotically approaches a constant value[15]

$$\lim_{t \to \infty} n(t) = \frac{\pi c M \beta \langle \overline{\ell} \rangle^2}{4V}, \tag{1}$$

where t is time, c is the speed of sound, M is the number of beam axes, β is an empirically derived factor depending on the shape of the beam faces and their overlap (which has an analytical expression for Gaussian shaded beams of circular cross section[15]), and $\langle \overline{\ell} \rangle$ is the mean-free path length.

It should be noted that if beam axes are used to find image sources in the hybrid method and the geometrical validity of these sources is checked, some valid image sources (the amount increasing over time) will be missed, and a tail-correction procedure will likewise be needed.

In contrast with beam-axis tracing, pure ray tracing needs no correction of the energy levels of the arrivals in the computed echogram (energy impulse response) because the effect of undetected geometrically valid reflections is balanced by the effect of multiple and geometrically invalid arrivals,[13,15] though the consequence of this is that the tail of the decay has unnaturally low reflection density growth and, unless the receiver sphere is large, shows greater run-to-run variation.

C. Tail correction

Tail-correction procedures required by beam-axis tracing have been typically developed for use in single-volume rooms. Consequently, the assumptions of these procedures need not be valid in systems of coupled rooms. Three approaches presented in the literature are considered here. Each of these approaches relies on applying an energy correction to the arrivals that are detected. As such, these tail-correction algorithms assume that the detections are representative of all correct arrivals, including those that are not detected. Detection is essentially a random process and, for numbers of beam axes that would be adequate in a single-volume room, but are not in a system of coupled rooms, the actual number of detections in the late part can be small enough to produce large run-to-run fluctuation in the predicted decay rate.

1. Reflection growth

Following an image-source argument,[20] the observed reflection growth (or *reflection density*), $n(t)$, in a single-volume rectangular room can be shown to be, asymptotically, equal to the late-time expected value $\tilde{n}(t)$, which is quadratic in time following the expression

$$\tilde{n}(t) = \frac{dN}{dt} \approx \frac{4\pi c^3 t^2}{V}, \tag{2}$$

where N is the number of reflections received up to a time t and V is the volume of the room. Vorländer[21] has plausibly argued that this result for the true asymptotic behavior of $\tilde{n}(t)$ is general for any room shape under the assumptions of exponential decay from steady state and isotropic incidence of sound on the receiver. A number of authors[16,22] have further suggested that a quadratic growth of reflection density occurs, at least approximately, in an even broader class of rooms (see Appendix G of Ref. 1 for further discussion). Failure to detect late-time arrivals can therefore be addressed by assuming quadratic growth of reflections and accordingly increasing the energy of those late reflections that *are* detected according to the growth rate determined by a least-squares fit to the early portion of the decay.[16] This is the approach to tail correction used by CATT-Acoustic (v. 7.0 and above).

2. Analytic expressions

Lehnert and Blauert[22] have proposed a method in which the energy of the arrivals is increased by a factor inversely proportional to the detection probability after the growth rate of the observed reflection density drops below the rate expected and becomes approximately constant in time. A similar approach[23] assumes a smooth transition from the behavior of the algorithm, described by Eq. (2), to the late behavior, described by Eq. (1), and multiplies the energy of arrivals by the reciprocal of the resulting expression for the expected growth rate,

$$n(t) = \frac{4\pi c^3 t^2}{V} \left[1 - \exp\left(-\frac{t_c^2}{t^2} \right) \right], \tag{3}$$

where $t_c \propto \sqrt{M/\beta}$ is the intersection point in time of the expected reflection growth rate with the constant asymptotic rate.[15]

3. Sources of error

All of these methods of tail correction require the assumption that Eq. (2) is correct or, at least, $\tilde{n}(t) \propto t^2$. Decay of energy in a rectangular parallelepiped room with nonuniform absorption and insufficient surface scattering is nonexponential[24] (i.e., yields a nonlinear decay curve) yet displays a quadratic growth in reflection density.[20] Thus, assuming quadratic growth of reflection density is not equivalent to assuming exponential decay of energy. But it is not always accurate to make the assumption of quadratic reflection growth in other cases. In particular, the true asymptotic value of reflection growth $\tilde{n}(t)$ in a system of coupled rooms is not necessarily described by Eq. (2).

It is primarily quadratic but time-variant reflection growth, rather than nonquadratic reflection growth, that, by violating the assumptions of tail-correction procedures, leads to errors in predictions using GA algorithms in coupled rooms. In single-volume rooms the method-dependent observed $n(t)$ deviates from the predicted value given by Eq. (2) initially, but later in time is well described by the quadratic function. In coupled rooms, this behavior is not observed. Instead, for the computational GA algorithm, room geometry, and aperture sizes studied here, the following behavior is observed. If source and receiver are in the same subroom, the initial behavior of $n(t)$ is approximately what it would be in an uncoupled room of the same volume. As time progresses, $n(t)$ gradually transitions to approximately behave as though in a single-volume room having the same volume as the entire coupled system. (See Fig. 7 for an illustration.) If the source and receiver are in different subrooms, $n(t)$ initially increases very slowly in time. As in the prior case, $n(t)$ transitions at later times to approximate the behavior of a large single-volume room, though the curve observed in the system of coupled rooms is displaced laterally relative to the curve predicted for a single-volume room due to the slower initial buildup of reflection density in the system of coupled rooms. (See Fig. 12 for an illustration.)

The result of $n(t)$ that transitions between two quadratic functions of time, as in the case of the source and receiver in the same subroom, is that a tail-correction algorithm will attempt to adjust the energy of detected arrivals based on an estimated reflection density that may be either too high or too low. The consequences are essentially the same in the case of source and receiver in different subrooms: tail correction is based on an inaccurate estimate of $\tilde{n}(t)$. In this case it is a particular problem if the form of $\tilde{n}(t)$ is estimated from the early portion of the computed response, as this results in an estimate of $\tilde{n}(t)$ that will be much too small to yield useful tail correction.

D. Other considerations

A second error source unique to coupled-room geometries can occur for certain implementations of beam-axis tracing. In single-volume rooms, increasing size of circular beam faces is equivalent to increasing radii of detection spheres surrounding receivers. Therefore, certain computational models (such as CATT-Acoustic) implement beam-axis tracing as ray tracing with spherical receivers that increase in radius with time.[16] This presents no problem for single-volume rooms because the case in which the detection sphere exceeds the size of the room and $n(t)$ approaches a constant value corresponds to the case in which the beam face exceeds the size of the room. However, in coupled rooms, the growing detection sphere has two distinct points of transition. The first is its extending into one or more of the adjacent subrooms, resulting in a change in $n(t)$. The second is its exceeding the size of the entire coupled system, which yields constant $n(t)$. The first point of transition may be marked by an upward shift in the level of the decay curve, particularly in those cases for which the energy density of the adjacent subroom is significantly higher. Thus, the level increase of the error is expected to be greatest in systems that are weakly coupled (roughly speaking, those in which subrooms are coupled by small apertures), and should be earlier in time (higher in level) for receivers near boundaries between subrooms.

III. DESCRIPTIONS OF ALGORITHMS TESTED

A. Original algorithm

In this study, the GA software CATT-Acoustic is investigated. CATT-Acoustic (v. 7.0 and above) is based on the randomized tail-corrected cone-tracing (RTC) algorithm.[9] Reflections are treated by beam-axis tracing with a circular beam face (cone-axis tracing), but with the image-source method used to calculate all geometrically valid first- and second-order reflections. First-order nonspecular reflections are treated by the creation of secondary "diffuse reflection sources" radiating according to Lambert's law.[16] Higher-order reflections are treated by randomization of the cone direction according to the probabilistic interpretation of Lambert's law.[24] In the Lambert model, a scattering coefficient s is defined as the fraction of energy that is not specularly reflected. Surface absorption is modeled by the angle-independent power absorption coefficient α, which represents the fraction of the incident energy that is absorbed by the surface.

Tail-correction assumes a quadratic growth rate of reflection density, as described in Sec. II C 1. The algorithm assumes that $n(t)$ is proportional to t^2 and defines the constant of proportionality by fitting a straight line to the initial portion of $\sqrt{n(t)}$, the length of this portion being dependent on the number of cone axes used. Corrections are performed individually for each receiver so that varying rates of reflection growth throughout the room are accommodated. For single-volume rooms the corrections predict the decay curve rather accurately, even for a small number of cone axes, as shown in Fig. 1 (see also Fig. 3 of Ref. 16).
FIG. 1. Spatial ensemble averages of decay curves in the closed room 1 of the coupled system shown in Fig. 2 (configured as a single-volume room) as predicted by the RTC algorithm using 3000, 30 000, and 150 000 cones are shown in (a). Though the square root of the observed reflection growth rates $\sqrt{n(t)}$ (solid lines) shown in (b) tend toward constant slope predicted by Eq. (1) (dotted lines), the tail-correction procedure of RTC, based on a linear least-square estimate of $\sqrt{n(t)}$ (dashed line), is robust to changes in the number of cones.

B. Modified algorithm

The assumption of quadratic growth in reflection density can fail for certain systems of coupled rooms, as described in Sec. II C 3. To address this, a modified form of the RTC algorithm has been developed. The new algorithm behaves as RTC until any one of the expanding detector spheres contacts one of the surface boundaries. From that point on, rather than applying tail correction, the radius of each detection sphere is held fixed and the detection procedure at each receiver is altered to that of ray tracing (i.e., the propagation law of r^{-2} is addressed by changes in detection probability due to ray divergence, rather than explicit reduction of the energy associated with each ray).[13,22] No tail-correction procedure is necessary, but the number of rays traced must be large enough that the ray density, throughout the time that the size of the detection sphere is fixed, is sufficient to insure adequate probability of detection.[13,22] This new algorithm was first implemented as a user-selected option ("late part ray trace") in the commercial distribution of CATT-Acoustic with version 8.0b, and is also used in other cases (such as when a room includes semitransparent surfaces) for which the reflection growth cannot be assumed quadratic.

IV. SCALE-MODEL EXPERIMENTS

A. Apparatus and methods

In order to assess the accuracy of the algorithms under the most controlled conditions, measurements were carried out in a schematic 1:10 scale-model representation of a concert hall with an auxiliary coupled room, shown in Fig. 2.

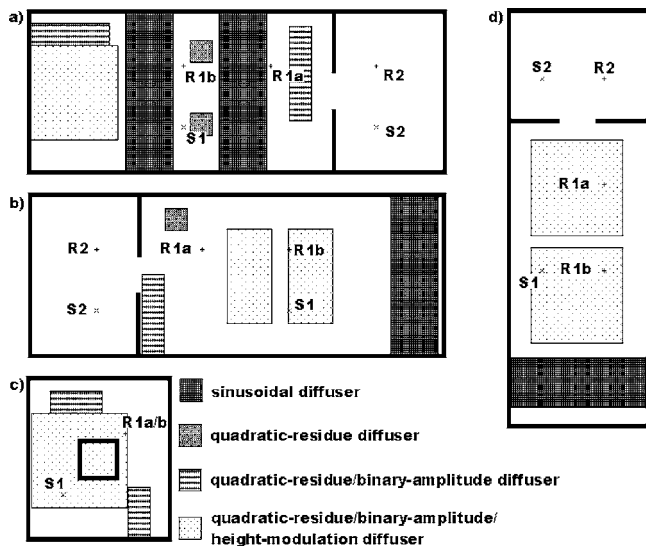
The scale model was constructed from $\frac{5}{8}$-in.-thick medium-density fiberboard (MDF), which was first painted and then spray coated with two layers of polyurethane. Audience absorption was simulated by 2-in.-thick foil-backed fiberglass batting placed on the floor of the primary room. Wide-bandwidth surface scattering was provided by 30-cm


FIG. 2. Schematic representation of the scale model of two coupled rooms. Transverse (a, b) and lateral (c) sections are shown together with overhead plan (d). Source (x) and receiver (+) positions are indicated together with diffuser locations.

lengths of the commercial product RPG FlutterFree®, a seven-element quadratic-residue diffuser[25] with design frequency 5000 Hz model scale (500 Hz full-scale equivalent). The samples used were constructed of milled cedar and spray coated with two layers of varnish. In addition to being used in groups of three to form (nearly) square panels, the quadratic-residue diffusers were also used as elements of larger binary-amplitude diffusers[26] with design frequencies of 1114 and 1715 Hz model scale (111.4 and 171.5 Hz full-scale equivalent), based on 11- and 13-element Barker sequences. A photograph of a diffuser consisting of two 13-element Barker sequences is shown in Fig. 3. Binary amplitude diffusers were constructed on $\frac{1}{4}$-in.-thick plywood sheeting, which was also spray coated with two layers of varnish. Variation in the design frequency of the binary-amplitude diffusers was accomplished by using wooden spacers of two different thicknesses to adjust the depths of the wells formed between the quadratic-residue diffusers. By grouping binary-amplitude diffusers of different design frequencies together, some additional surface-height modulation with spatial period $\Lambda=60$ or 120 cm was obtained. Additional surface scattering was provided by sinusoidal surfaces of formed polyvinyl-chloride (PVC) plastic having $\Lambda=7.5$ cm and peak amplitude $\Xi=0.9$ cm.

A 1:10 scale dodecahedron loudspeaker (edge length 20 mm, driver diameter 13 mm) was used as the sound
FIG. 3. Photograph of a diffuser panel consisting of two 13-element Barker sequences with design frequencies 1114 Hz (top) and 1715 Hz (bottom) with individual elements formed of quadratic-residue diffusers.

source. Measurements of far-field directivity indicate that the loudspeaker is omnidirectional to within ±5 dB over the entire frequency range of interest. Omnidirectional microphones with $\frac{1}{8}$-in. diaphragms were used as receivers. For measurements, they were mounted with the diaphragms oriented parallel to the floor. Modeling the microphones as a piston at the end of a long tube (see, e.g., Ref. 27) gives the prediction that they will differ from ideal omnidirectional response by less than ±2 dB over the entire frequency range of interest.

Computer-generated sweeps were used as excitation signals.[28] A combination of pre- and postequalization was used to address frequency dependence in the power response of the loudspeaker and maximize the signal-to-noise ratios (S/N) of the measured impulse responses by accounting for the spectrum of the background noise and the attenuation due to air absorption.[28] Coherent averaging of five sequentially repeated measurements provided an additional gain in S/N. Comparison between averaged and unaveraged decays indicated that the decay process was sufficiently repeatable that averaging did not suppress the decay.

Because the purpose of the model was to test the algorithms rather than to model a full-scale space, neither nitrogen nor air drying was used to compensate for the additional propagation loss. Rather, the increased dissipation of the air at scaled frequencies, as computed by ISO 9613-1,[29] was modeled in the software based on measurements of atmospheric conditions made at approximately 30-min intervals. For each octave band, the dissipation coefficient used was the mean of the coefficients calculated for each frequency in the band rather than the coefficient calculated for the center frequency—the difference being significant at high frequencies.

B. Characterization and calibration

1. Absorption coefficients

As suggested by Polack *et al.*,[30] the absorption coefficients $\alpha(f)$ of the wall surfaces were measured in a 1:10 scale-model reverberation room (with geometry modeled after a validated full-scale room) constructed entirely of the same material as the auditorium model. Instead of estimating the absorption coefficient from the measured reverberation time by inverting a statistical model of energy decay (such as Sabine's), the direct-inversion method based on the computational GA proposed in Ref. 31 was used because it was believed to be more accurate. The absorption coefficients of the fiberglass batting and the individual quadratic-residue diffusers were also measured by this method in conjunction with a deep well[32] of height 8 cm. Absorption coefficients of larger objects (diffusers) were measured in the concert-hall model configured as a single-volume room, following the procedure proposed in Ref. 31.

2. Scattering coefficients

Because scattering coefficients $s(f)$ often have little effect on the rate of decay in small, proportionate rooms that are sufficiently mixing,[33] such as the nonrectangular scale-model reverberation room used here, $s(f)$'s were estimated

TABLE I. Mean absorption coefficients $\bar{\alpha}$ and mean scattering coefficients $\bar{s}$ are reported for both subrooms of the scale model for each of four full-scale-equivalent octave bands measured. Values reported are geometrical averages, calculated with rooms configured as isolated single-volume rooms (both $\bar{\alpha}$ and $\bar{s}$ are functions of aperture area when the rooms are coupled).

	125 Hz	250 Hz	500 Hz	1000 Hz
$\bar{\alpha}_1$	0.244	0.214	0.209	0.199
$\bar{\alpha}_2$	0.055	0.061	0.057	0.031
$\bar{s}_1$	0.295	0.284	0.198	0.093
$\bar{s}_2$	0.120	0.120	0.080	0.060

from decay curves measured in the auditorium model following the procedure proposed in Ref. 31. This is a much more approximate approach than the method described in ISO/DIS 17497-1 (Ref. 34), but one necessitated because the diffusers were too large to be rotated (as required) within either the reverberation-room model or the concert-hall model.

3. Adjustments

Both $\alpha(f)$ and $s(f)$ were iteratively adjusted to match predictions of RTC to decay-curve measurements made in each room of the concert-hall model when isolated from the adjacent room. However, determining $\alpha(f)$ and $s(f)$ by minimizing the error between either the predicted and measured reverberation time or the gross shapes of the predicted and measured decay curves is an ill-conditioned problem. Thus, while this iterative-adjustment procedure does remove most effects of uncertainty in $\alpha(f)$ and $s(f)$ (as discussed below), it does not ensure that the parameters used are exactly those of the actual materials. While this could be problematic if the model were to be used to predict detailed aspects of the sound field or changes associated with fine variations in source and receiver position, for the assessment of gross characteristics of the decay curve it is sufficient. Mean absorption and scattering coefficients for each of the two rooms of the scale model, calculated from the values used in the geometrical acoustics computations, are reported in Table I.

C. Uncertainty

The primary source of uncertainty in the comparison between the computed and measured results are uncertainties in the input parameters of the computer model: absorption and scattering coefficients of surfaces, air-dissipation coefficient (as calculated from temperature, relative humidity, and barometric pressure), directionality of sources and receivers, source and receiver locations, and room dimensions. Monte Carlo error analysis is required to estimate the uncertainty in the GA computer-model predictions resulting from the uncertainty in the input parameters,[35] but would be prohibitive here given the number of input parameters. In Ref. 35, such computations were performed for the same geometry with simplified boundary conditions and give some indication of the expected uncertainty given uncertainty in the inputs.

Nonetheless, for the comparisons conducted here, the uncertainty discussed above is less germane than in a conventional prediction scenario because input parameters have been iteratively adjusted in order to match the predictions of

the algorithms to the measurements conducted in each of the subrooms when configured as an isolated room. The uncertainty which is germane is that resulting from stochastic variations between individual measurements or prediction runs. Measurement uncertainty is small: $\ll 1$ dB difference between averaged and unaveraged decay curves in the time region before noise begins to affect the shape of the decay curve. Likewise, run-to-run fluctuations of the GA algorithms were found to be small ($\ll 1$ dB) for the number of cones/rays used in these simulations.[35]

D. Results and discussion

Depending on source and receiver positions, a number of different cases for testing the prediction algorithms can be defined. The notation S1R2, for example, represents the case in which the source is in room 1 and the receiver is in room 2. Because of symmetry of Green's functions, S1R2 is formally identical to the S2R1, assuming that both source and receiver are omnidirectional. However, reciprocity need not hold for errors that may arise due to the computational GA algorithm. Source ($\times$) and receiver ($+$) positions are shown in Fig. 2. One representative source position was used in each room. Two receiver positions were used in room 1, 1a near the aperture, and 1b away from the aperture. A single receiver was used in room 2.

Figures 4, 6, 8, 9, 11, 13, and 15 compare the predictions of both the original RTC algorithm (denoted by RTC) and the new algorithm (here denoted by RAY) with measured decay curves for various source-receiver combinations in each of four full-scale-equivalent octave bands: 125, 250, 500, and 1000 Hz, full-scale equivalent. Geometrical acoustic computations were carried out using both RTC and RAY algorithms with 30 000, 150 000, and 300 000 cones/rays. Truncation times for the computations were chosen to exceed the maximum time value of interest.

To assist visual comparison between the computed decay curves and the measured decay curves, noise subtraction[36] was used when Schroeder integrating the measured decay curves. In some cases, and particularly for the highest frequency band considered, noise subtraction is unable to completely remove the effects of noise. Consequently, some of the measured decay curves that are displayed show a decreasing slope at late times that is not representative of the actual behavior of the sound field in the room.

For the particular apertures chosen, the wavelengths of the frequency bands studied are small enough that diffraction is not a significant concern ($ka > 2.8$ in all cases, where $k = 2\pi/\lambda$ and $2a$ is the edge length of the square apertures; see, e.g., Ref. 37).

1. S1R1

For the S1R1a case, using 30 000 cones/rays, the predictions of the RTC algorithm are poorly matched to the scale-model measurements, while the RAY algorithm accurately predicts measured decay curves, as shown in Fig. 4. The RTC algorithm predicts an unphysical break in the decay curve, occurring between 1 and 2 s. This break culminates in
FIG. 4. For source-receiver condition S1R1a and coupling area of 50 m², decay-curve predictions of the RTC algorithm (dotted lines) and the revised (RAY) algorithm (dashed lines) using 30 000 cones/rays are compared with scale-model measurements (solid line) in full-scale-equivalent octave bands 125 Hz (a), 250 Hz (b), 500 Hz (c), and 1000 Hz (d). a decay curve of nearly constant decay rate for $t > 2$ s. Figure 5 indicates that predictions of the RTC algorithm first depart from scale-model measurements at $t \approx 0.6$ s, which corresponds to the onset of tail correction. Also shown in Fig. 5, as the detection sphere extends into room 2, there is an abrupt jump in detected energy due to falsely detected arrivals. The level of the error due to these false detections decreases with increasing frequency, as shown in Fig. 4. This is largely due to the increased influence of air dissipation at these higher frequencies.

Increasing the number of cones/rays decreases the initial size of the detection sphere such that the onset of the error

due to the detection sphere extending into room 2 is shifted to a later point in time, as shown in Figs. 6 and 7. Similarly, moving the receiver farther from the boundary between the subrooms shifts the onset of the error to a later point in time by increasing the size of the detection sphere necessary to extend into the adjacent subroom, as illustrated by comparison of Fig. 8 with Fig. 6.

While increasing the number of cones/rays or moving the receiver farther from the boundary between the subrooms can effectively eliminate errors in the predictions of the RTC algorithm due to the detection sphere extending into the ad-

FIG. 5. On the left axis, the decay-curve prediction of the RTC algorithm (dotted line) and the revised (RAY) algorithm (dashed line) using 30 000 cones are plotted together with the scale-model measurement (solid line) in the 125-Hz full-scale-equivalent octave band.

FIG. 7. For source-receiver condition S1R1a and coupling area of 50 m², the square root of reflection density $\sqrt{n(t)}$ as computed by the RTC algorithm using 150 000 cones (solid line) is plotted on the right axis and compared with the linear estimate used by RTC for tail correction (dotted line). Values of $\sqrt{n(t)}$ predicted by Eq. (2) are plotted assuming $V = V_1$ (triangles) and $V = V_1 + V_2$ (circles). On the left axis, the decay-curve prediction of the RTC algorithm (dotted line) and the revised (RAY) algorithm (dashed line) using 150 000 cones are plotted together with the scale-model measurement (solid line) in the 125-Hz full-scale-equivalent octave band.
FIG. 8. For source-receiver condition S1R1b and coupling area of 50 m^2, decay-curve predictions of the RTC algorithm (dotted lines) and the revised (RAY) algorithm (dashed lines) using 30 000 cones/rays are compared with scale-model measurements (solid line) in full-scale-equivalent octave bands 125 Hz (a), 250 Hz (b), 500 Hz (c), and 1000 Hz (d). Insets show the differences in level between predictions and measurement: $\Delta L_p(t) = L_p(t)_{\text{computed}} - L_p(t)_{\text{measured}}$.

FIG. 9. For source-receiver condition S1R2 and coupling area of 50 m^2, decay-curve predictions of the RTC algorithm (dotted lines) and the revised (RAY) algorithm (dashed lines) using 30 000 cones/rays are compared with scale-model measurements (solid line) in full-scale-equivalent octave bands 125 Hz (a), 250 Hz (b), 500 Hz (c), and 1000 Hz (d). Insets show the differences in level between predictions and measurement: $\Delta L_p(t) = L_p(t)_{\text{computed}} - L_p(t)_{\text{measured}}$. The measured curve in the 1000-Hz octave band shows the effect of noise at late times.

jacent subroom, differences between the predictions of the RTC algorithm and the RAY algorithm remain, as shown in Figs. 6 and 8. In general, RAY predictions are better matched to the scale model measurements than RTC predictions. The reason for this is the faulty assumption of the RTC algorithm that $n(t)$ at late times in a subroom of a coupled system can be predicted from $n(t)$ at early times. (Conversely, it should be noted that, in single-volume rooms, this approach is more robust to common user errors, such as incorrect entry of geometry, than those based on the volume of the room because the effective acoustical volume is easily derived from the observed reflection growth rate whereas this volume can be difficult to compute numerically from a poorly drawn model.) Reflection density, as estimated by RTC, is too high at late times, as Fig. 8 shows. Consequently, the energy density is predicted to be too high. The least-square estimate of $n(t)$ calculated by RTC is nearly $4\pi c^3 t^2 / V_1$, where V_1 is the volume of room 1. However, at late times, $n(t)$ is better described by $4\pi c^3 t^2 / (V_1 + V_2)$, where V_2 is the volume of room 2.

2. S1R2

When the source and receiver are in different rooms, the observed error is of a different character. For the S1R2 case, using 30 000 cones/rays, the decay rate is consistently under-predicted by the RTC algorithm, as shown in Fig. 9. The early part of the decay, dominated by reflections associated with room 1, does not well predict the greater reflection density of the late part of the decay, which is dominated by reflections associated with room 2, as shown in Fig. 10. A break in the decay curve, similar to that observed in the S1R1 cases, occurs when the detection sphere extends into room 1 ($t > 1.25$ s). The level difference at this break is smaller than those observed in the S1R1 cases because the mean energy density of room 1 is lower than the mean en-

ergy density of room 2. Increasing the number of cones/rays from 30 000 to 150 000 decreases the detection sphere size, shifting the error to a later point in time. However, the estimate of reflection growth rate is still determined from the early part of the decay and, therefore, continues to underpredict the reflection density in the late decay. Consequently, the energy level of the decay curve is underpredicted by the RTC algorithm. In contrast, the RAY algorithm yields predictions of consistent accuracy.

3. S2R1

For the S2R1 case, the nature of the error differs from that observed for the converse S1R2 case, indicating that
FIG. 10. For source-receiver condition S1R2 and coupling area of 50-m^2, the square root of reflection density $\sqrt{n(t)}$ as computed by the RTC algorithm using 30 000 cones (solid line) is plotted on the right axis and compared with the linear estimate used by RTC for tail correction (dotted line). On the left axis, the decay-curve prediction of the RTC algorithm (dotted line) and the revised (RAY) algorithm (dashed line) using 30 000 cones are plotted together with the scale-model measurement (solid line) in the 125-Hz full-scale equivalent octave band.
FIG. 11. For source-receiver condition S2R1a and coupling area of 50 m^2, decay-curve predictions of the RTC algorithm (dotted lines) and the revised (RAY) algorithm (dashed lines) using 30 000 cones/rays are compared with scale-model measurements (solid line) in full-scale-equivalent octave bands 125 Hz (a), 250 Hz (b), 500 Hz (c), and 1000 Hz (d). Insets show the differences in level between predictions and measurement: $\Delta L_p(t) = L_p(t)_{\text{computed}} - L_p(t)_{\text{measured}}$.

reciprocity does not hold for errors due to the algorithm. For 30 000 cones/rays, decay curves predicted by RTC display an error similar to that observed for the S1R1 cases; they have a break after which the curve is displaced upward in level due to the detection sphere extending into room 2. This is illustrated in Figs. 11 and 12 for the receiver position near the aperture (S2R1a). Increasing the number of rays shifts the point of the break later in time, as observed for the S1R2 case. For the S2R1b case, with the receiver further from the aperture, similar effects are found, but, as in the S1R1b case, they occur later in time.
FIG. 12. For source-receiver condition S2R1a and coupling area of 50 m^2, the square root of reflection density $\sqrt{n(t)}$ as computed by the RTC algorithm using 30 000 cones (solid line) is plotted on the right axis and compared with the linear estimate used by RTC for tail correction (dotted line). Values of $\sqrt{n(t)}$ predicted by Eq. (2) are plotted assuming $V=V_1$ (triangles), $V=V_2$ (squares), and $V=V_1+V_2$ (circles). On the left axis, the decay-curve prediction of the RTC algorithm (dotted line) and the revised (RAY) algorithm (dashed line) using 30 000 cones are plotted together with the scale-model measurement (solid line) in the 125-Hz full-scale-equivalent octave band.
FIG. 13. For source-receiver condition S2R2 and coupling area of 50 m^2, decay-curve predictions of the RTC algorithm (dotted lines) and the revised (RAY) algorithm (dashed lines) using 30 000 cones/rays are compared with scale-model measurements (solid line) in full-scale-equivalent octave bands 125 Hz (a), 250 Hz (b), 500 Hz (c), and 1000 Hz (d). Insets show the differences in level between predictions and measurement: $\Delta L_p(t) = L_p(t)_{\text{computed}} - L_p(t)_{\text{measured}}$.

4. S2R2

The S2R2 case differs from the prior cases in that both reflection density and decay level behavior are predominantly controlled by room 2. Using 30 000 cones/rays, the algorithms both predict the decay curve with little error, as shown in Fig. 13. For the first 20 dB of decay, the RAY algorithm is marginally more accurate than the RTC algorithm, which slightly overpredicts the level of the decay curve. Increasing the number of cones/rays to 150 000 alters the predicted decay curves very little. The observed reflection density, shown in Fig. 14, indicates that the RTC estimate of $n(t)$ is too high at large time. Reflection density
FIG. 14. For source-receiver condition S2R2 and coupling area of 50 m^2, the square root of reflection density $\sqrt{n(t)}$ as computed by the RTC algorithm using 30 000 cones (solid line) is plotted on the right axis and compared with the linear estimate used by RTC for tail correction (dotted line). On the left axis, the decay-curve prediction of the RTC algorithm (dotted line) and the revised (RAY) algorithm (dashed line) using 30 000 cones are plotted together with the scale-model measurement (solid line) in the 125-Hz full-scale-equivalent octave band.
FIG. 15. For source-receiver condition S1R1a and coupling area of 70.7 m², decay-curve predictions of the RTC algorithm (dotted lines) and the revised (RAY) algorithm (dashed lines) using 30 000 cones/rays are compared with scale-model measurements (solid line) in full-scale-equivalent octave bands 125 Hz (a), 250 Hz (b), 500 Hz (c), and 1000 Hz (d). Insets show the differences in level between predictions and measurement: $\Delta L_p(t)$ $= L_p(t)_{\text{computed}} - L_p(t)_{\text{measured}}$.

FIG. 16. For source-receiver condition S1R1a and coupling area of 70.7 m², the square root of reflection density $\sqrt{n(t)}$ as computed by the RTC algorithm using 30 000 cones (solid line) is plotted on the right axis and compared with the linear estimate used by RTC for tail correction (dotted line). On the left axis, the decay-curve prediction of the RTC algorithm (dotted line) and the revised (RAY) algorithm (dashed line) using 30 000 cones are plotted together with the scale-model measurement (solid line) in the 125-Hz full-scale-equivalent octave band.

initially follows $4\pi c^3 t^2/V_2$ and then transitions to $4\pi c^3 t^2/(V_1+V_2)$. As a result of this, RTC increases the energy of late detections by too large a factor and marginally overpredicts the level of the decay curve. Increasing the number of cones cannot improve the error of the RTC algorithm in this case.

It is notable that at the point in time when the detection sphere extends into room 1, there is little influence on the decay curve predicted by RTC because both the reflection density and the energy density in room 1 are sufficiently lower than those of room 2.

5. Aperture area

Doubling the area of the aperture results in relations between computer-model predictions and measured decay curves similar to those observed for the smaller aperture, as shown in Fig. 15 for S1R1a case and 30 000 cones/rays. In those cases for which a break occurs in the RTC predictions, such as the case shown, the onset time of the break is (inevitably) the same as that observed for the small-aperture case though the level difference is smaller, confirming the speculation of Sec. II B 3. The subrooms are more strongly coupled by the larger aperture such that their respective energy densities are less disparate than they were in the more weakly coupled small-aperture condition. Thus, while the increase in detected reflections that occurs when the detection sphere extends into room 2 (as shown in Fig. 16) is similar to that observed for the small-aperture condition, the effect on the decay curve is smaller in level.

6. Discussion

The results discussed above suggest that prediction errors of the RTC algorithm observed in coupled rooms have two components. The first is the overprediction or underpre-

diction of decay energy/rate due to a changing reflection-growth rate, which violates the assumption of the tail-correction algorithm. The second is an erroneous break in the predicted decay rate due to the penetration of the detection sphere into the adjacent subroom that results in false detections and sometimes causes an abrupt upward shift in level of the decay curve. Comparisons of computational GA predictions with scale-model measurements have shown that the RAY algorithm, by circumventing the error mechanisms of the RTC algorithm, yields accurate predictions of decay curves in coupled rooms.

The accuracy of the RAY algorithm has been independently confirmed by comparison of predictions with reverberation-time measurements made in a cathedral comprising two large, reverberant rooms.[38] The comparisons, conducted by Martellotta et al.[38] (and reported in Chap. 6 of Ref. 1), show that RAY is able to predict spatial averages of T15 and T30 in the room not containing the source to within 5%, while RTC is not.

V. CONCLUDING REMARKS

Tail-correction procedures for beam-axis tracing can fail in certain cases when applied to the prediction of sound fields in systems of coupled rooms. This is partly due to the almost-universal assumption that reflection density is quadratic in time. In systems of coupled rooms reflection density is ultimately quadratic in time, but is not described by a single quadratic function through time. As a result, algorithms that assume reflection density is quadratic in time can inaccurately predict decay curves in systems of coupled rooms. These errors have been demonstrated by comparison of the predictions of a particular cone-axis-tracing algorithm (CATT-Acoustic v. 7.0 and above) with scale-model measurements of a two-room coupled system.

A second error, which has likewise been demonstrated by comparison with scale-model measurements, results from penetration of a detector sphere into an adjacent subroom. This error is unique to cone-axis tracing implemented as ray tracing with a growing detection sphere. It is most severe when the receiver is near a boundary between subrooms (causing error to occur earlier in time) or when the adjacent subroom has greater energy density than the subroom containing the receiver (causing greater error in decay-curve level).

A revised beam-axis-tracing algorithm, which addresses the problems of prediction in coupled rooms, has been investigated. The revised algorithm (introduced in CATT-Acoustic v 8.0b and above) uses a conventional ray-tracing algorithm for the late part of the decay, making tail-correction procedures unnecessary (because ray tracing inherently compensates for the failure to detect certain paths by detecting other, geometrically invalid paths) and preventing penetration of detector spheres into adjacent subrooms. This new algorithm has been shown to yield accurate predictions in the scale model used here and should have no intrinsic limitation when applied to any system of coupled rooms.

While the revised algorithm is more accurate than the original RTC algorithm when applied to systems of coupled rooms, the RTC algorithm remains preferable when applied to single-volume rooms. For single-volume rooms, both algorithms yield similar decay-curve predictions. However, the RTC algorithm yields results that are more stable and generally requires fewer beam axes. Further, RTC is preferable for auralization because it yields echograms that have a natural (quadratic) growth of reflection density, while the revised (RAY) algorithm does not at times after the radius of the detection sphere is held fixed.

For thin nonlocally reacting porous layers, a method derived from the work of [Chien and Soroka, J. Sound Vib. **43**, 9–20 (1975)] has been used to localize the pole of the reflection coefficient located at a complex angle close to $\pi/2$ and to measure the surface impedance at this angle. Measurements are performed with a small source/receiver separation. The method is used in the present work to measure the surface impedance of acoustically thick porous layers of high flow resistivity. Simulations show that the measured impedance, which is related to a complex angle close to $\pi/2$ like for thin porous layers, is close to the impedance at grazing incidence. It is also shown that for semi-infinite layers the method provides a measure of the Brewster angle of the medium. Measurements of the cosine of the complex angle and of the related impedance on two granular media of high flow resistivity, Ottawa sand and glass beads, are in a reasonable agreement with predictions for frequencies above 1 kHz for a source/receiver separation of 30 cm. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1979447]

I. INTRODUCTION

In the present work, a method previously developed to evaluate the surface impedance of thin porous layers[1,2] is used for acoustically thick porous layers of granular porous materials with a high flow resistivity. An acoustically thick porous layer is characterized by a strong damping of the waves when they propagate from one side to the opposite side of the layer. If the frame is motionless, this condition corresponds to Im $k_1 l \gg 1$, where l is the thickness of the layer and k_1 is the wave number in the air that saturates the frame. The quantity Im k_1 increases with frequency and with the flow resistivity of the medium. Many porous media, concretes, soils, and some sound absorbing media, exist in layers with large or semi-infinite thickness. The method developed here consists of a very simple experimental setup that allows for the *in situ* measurement of the surface impedance on samples with an area around 1 m^2, using frequencies larger than 1 kHz.

The method is based on the classical expression of the reflected monopole field close to grazing incidence. This expression is widely used for outdoor ground impedance measurements with large source receiver offsets.[3] This underlying equation is only valid if the reflection coefficient has a pole θ_p for some value of the angle of incidence θ that is close to $\pi/2$. Let Z and $Z_s(\theta)$ be the characteristic impedance of the free air, and the surface impedance of the layer, respectively. It is shown in Sec. II that $\cos \theta_p = -Z/Z_s(\theta_p)$. For thin layers, one pole can be present close to $\pi/2$ because $|Z_s|/Z \gg 1$ when l is sufficiently small. For thick layers the condition $|Z_s|/Z \gg 1$ is obtained when the flow resistivity is sufficiently large.

Thick porous layers can have an impedance very close to the one of a semi-infinite layer. The pole for a semi-infinite layer has properties very different from the ones of the pole related to a thin layer. It is recalled in this paper that the pole θ_p and the zero θ_z of the semi-infinite layer are related to opposite cosines, $\cos \theta_p = -\cos \theta_z$. There are strong analogies between the zero of the semi-infinite acoustic layer and the Brewster angle of total refraction of electromagnetic waves.[4] In Sec. II the theory for thin layers is reviewed as well as the approach used for pole localization and impedance measurement. In Sec. III the theory is modified to describe semi-infinite layers. Simulated measurements are performed in Sec. IV to illustrate the main limitations of the Chien and Soroka model and our method. Measurements of reduced impedance on Ottawa sand and glass beads are compared to theoretical predictions. Section V contains the conclusions.

II. THEORETICAL BACKGROUND

A. Generalization of the work by Chien and Soroka to the case of thin porous layers

A classical method of measuring porous ground surface impedance is based on the expression of the reflected monopole field pressure obtained by Chien and Soroka.[5] For locally reacting media the reflected pressure is given by[5]

$$p_r = \frac{\exp(ikR_1)}{R_1}[v(\cos \theta_0) + (1 - v(\cos \theta_0))F(p_e)], \quad (1)$$

where $F(p_e)$ is given by
FIG. 1. Sketch of the experiment, the monopole source S, its image S', and the receiver at M above the porous layer.

$$F(p_e) = 1 + i\sqrt{\pi}p_e \exp(-p_e^2)\text{erfc}(-ip_e), \qquad (2)$$

and p_e is the numerical distance given by

$$p_e = \left(\frac{1}{2}ikR_1\right)^{1/2}\left(\frac{Z}{Z_s} + \cos\theta_0\right). \qquad (3)$$

A sketch of the measurement setup is presented in Fig. 1. R_1 is the distance from the image source S' to the receiver at M, R_2 is the distance from the source S to the receiver, r is the horizontal distance from the source to the receiver, z_1 and z_2 are the heights of the source and the receiver above the impedance surface, θ_0 is the specular angle of incidence, v is the reflection coefficient, Z and k are the characteristic impedance and the wave number in the free air, and Z_s is the surface impedance of the porous medium. The notation θ_0 is used for the specular angle of incidence related to a point source and θ for the angle of incidence of a plane wave. In the present work the time dependence is $\exp(-i\omega t)$. In general, the reflection coefficient for a plane wave at an angle θ, on a locally reacting medium, is given by

$$v(\cos\theta) = \frac{Z_s - Z/\cos\theta}{Z_s + Z/\cos\theta}. \qquad (4)$$

A pole of the reflection coefficient exists at a complex angle of incidence θ_p given by

$$\cos\theta_p = -\frac{Z}{Z_s}. \qquad (5)$$

Equations (3) and (4) can be rewritten using Eq. (5) as

$$p_e = \left(\tfrac{1}{2}ikR_1\right)^{1/2}(-\cos\theta_p + \cos\theta_0) \qquad (6)$$

and

$$v(\cos\theta) = \frac{\cos\theta + \cos\theta_p}{\cos\theta - \cos\theta_p}. \qquad (7)$$

Equation (1) is valid, as indicated in Ref. 5, for $kR_1 \gg 1$ and if both the pole θ_p and the specular angle θ_0 are close to $\pi/2$, which implies near grazing incidence and $|Z/Z_s| \ll 1$. When Eqs. (1), (2), (6), and (7) are used, it appears, like in the work by Brekhovskikh and Godin[6] for similar equations, and in previous works,[1,2] that the evaluation of Z_s from pressure measurements using Eq. (1) is primarily an evaluation of $\cos\theta_p$ followed by the evaluation of Z_s using Eq. (5).

The case of nonlocally reacting surfaces was not considered by Chien and Soroka.[5] For nonlocally reacting porous layers with a motionless frame, Z_s is dependent on the angle of incidence and Eq. (5) is replaced by

$$\cos\theta_p = -\frac{Z}{Z_s(\theta_p)}. \qquad (8)$$

The angle-dependent surface impedance for a layer of thickness l is given by

$$Z_s(\theta) = \frac{iZ_1}{\phi\cos\theta_1}\cot(k_1 l \cos\theta_1), \qquad (9)$$

where Z_1 and k_1 are the characteristic impedance and the wave number of the air saturating the porous medium, ϕ is the porosity, and θ_1 is the refraction angle. The refraction angle θ_1 is given by

$$\cos\theta_1 = \left(1 - \frac{1}{n^2} + \frac{\cos^2\theta}{n^2}\right)^{1/2}, \qquad (10)$$

where $n = k_1/k$ is the index of refraction. For thin nonlocally reacting layers, there are an infinite number of poles with a large imaginary part.[2] One pole, θ_p, will exist close to $\pi/2$ if, in Eq. (8), $Z/|Z_s(\theta_p)| \ll 1$. It has been shown in Ref. 1 that for nonlocally reacting thin porous layers with a motionless frame, Eqs. (1) and (2) can be used to evaluate the reflected field p_r, but Eq. (6) must be used for the numerical distance with $\cos\theta_p$ given by Eq. (8). The impedance Z_s that can be obtained from pressure measurements over thin layers from Eqs. (1)–(3) is $Z_s(\theta_p)$, close to $Z_s(\pi/2)$.

B. Pole localization and impedance measurement for thin porous layers

The method of Allard et al.[1] is based on Eq. (1). An equivalent version of Eq. (1) is used where v and p_e are replaced by their expressions given by Eqs. (6) and (7). The use of Eq. (7) for v is an approximation if the layer is not locally reacting, but this approximation is justified if $|\theta_0 - \theta_p|$ is sufficiently small such that the surface impedances $Z_s(\theta_p)$ and $Z_s(\theta_0)$ are not noticeably different. Equation (1) can be rewritten

$$p_r = \frac{\exp(ikR_1)}{R_1}\left[1 - \sqrt{2\pi kR_1}\exp\left(\frac{3\pi i}{4}\right)\right.$$

$$\left. \times\cos\theta_p \exp(-p_e^2)\text{erfc}(-ip_e)\right]. \qquad (11)$$

In this equation, $\cos\theta_p$ [or $Z_s(\theta_p)$] is the one parameter that characterizes the porous layer. A measurement of the reflected pressure field p_r is obtained by measuring the total field successively over the porous layer (p_t^l) and over a rigid impervious surface (p_t^r) at the same distances z_1, z_2, and r. Measurements are performed at small source-receiver distance, from 20 to 30 cm, close to grazing incidence to satisfy the condition θ_0 close to $\pi/2$. The total fields p_t^r and p_t^l with a point source of unknown amplitude K are given by

$$p_t^r = K\left[\frac{\exp(ikR_1)}{R_1} + \frac{\exp(ikR_2)}{R_2}\right], \qquad (12)$$

Hickey et al.: Impedance and Brewster angle measurement

TABLE I. Parameters for the porous materials

Parameters	Ottawa sand	Glass beads	Material 3
porosity ϕ	0.393	0.41	0.95
flow resistivity σ (N m^{-4} s)	94000.0	150000.0	40000.0
thermal permeability k_0' (m^2)	0.6×10^{-9}	3.8×10^{-10}	1.2×10^{-9}
viscous dimension Λ (μm)	32.4	26.5	50.0
thermal dimension Λ' (μm)	97.2	79.5	150.0
tortuosity α_∞	1.54	1.5	1.1
thickness l (cm)	8.0	3.0	8.0

$$p_t^l = K\left[p_r + \frac{\exp(ikR_2)}{R_2} \right]. \tag{13}$$

The reflected pressure field p_r is evaluated from the measured ratio p_t^l/p_t^r using

$$p_r = \frac{p_t^l}{p_t^r}\left[\frac{\exp(ikR_1)}{R_1} + \frac{\exp(ikR_2)}{R_2} \right] - \frac{\exp(ikR_2)}{R_2}. \tag{14}$$

From Eq. (11) $\cos \theta_p$ is given by

$$\cos \theta_p = [1 - R_1 p_r \exp(-ikR_1)]/[(2\pi kR_1)^{1/2}$$
$$\times \exp(3\pi i/4)\exp(-p_e^2)\mathrm{erfc}(-ip_e)], \tag{15}$$

At small source receiver distances, and for small $|\cos \theta_p - \cos \theta_0|$, the numerical distance p_e is generally small. The term $\mathrm{erfc}(-ip_e)$ can be approximated for small argument as

$$\mathrm{erfc}(-ip_e) = 1 + \frac{2i}{\sqrt{\pi}}p_e\left(1 + \frac{p_e^2}{3} + \frac{p_e^4}{2!5} + \frac{p_e^6}{3!7} + \cdots \right), \tag{16}$$

where p_e is given by Eq. (6). Simple iterative methods[1,2] can be used to evaluate $\cos \theta_p$ with Eqs. (6) and (15) when p_r is evaluated using Eq. (14) from measurements of p_t^r and p_t^l. The surface impedance $Z_s(\theta_p)$ with θ_p close to $\pi/2$ is obtained from Eq. (8).

Measured $\cos \theta_p$ are generally close to the predicted values obtained with the motionless frame model. The full Biot theory[7,8] must be used when frame resonances are excited. It has been verified experimentally[1,2] that for thin porous layers with $|k_1 l| \ll 1$, the pole θ_p close to $\pi/2$ has a Re $\sin \theta_p > 1$ and a surface wave contribution can exist at large numerical distances. The z_2 dependence of the surface wave related to the pole is $\exp(ikz_2 \cos \theta_p)$ with Im $\cos \theta_p > 0$, Re $\cos \theta_p < 0$, Im $\cos \theta_p \gg -$Re $\cos \theta_p$. The wave exponentially decreases with the distance z_2 from the porous surface. It is related to a trapped mode in the porous layer.[9] The reflection of electromagnetic TM waves by a thin grounded dielectric presents a strong analogy with this case.[4,9]

III. POLES AND ZEROS OF THE REFLECTION COEFFICIENT FOR SEMI-INFINITE LAYERS

Two granular media with a high flow resistivity, Ottawa sand and glass beads, are studied. The grain size distribution of the sand has a broad peak around 0.5 mm. The second medium is a mixture of glass beads of diameters ranging from 355 to 425 μm. The parameters that characterize both materials to be used in the predictions are given in Table I.
FIG. 2. Predicted modulus of the reflection coefficient at 4 kHz for a semi-infinite layer of Ottawa sand.

Tortuosity α_∞ and characteristic dimensions Λ and Λ' have been evaluated from time of flight ultrasonic measurements[10] under the simplifying hypothesis $\Lambda' = 3\Lambda$. Porosity and flow resistivity have been measured with the methods described in Refs. 11 and 12. Reasonable values of the thermal permeability are used. The thickness of the sand layer is $l = 8$ cm. The surface impedance is predicted by using the model of Johnson et al.[13] for the effective density ρ_1 and the model suggested by Lafarge[14] for the incompressibility χ_1 of the equivalent fluid. In Eq. (9), $k_1 = \omega(\rho_1/\chi_1)^{1/2}$ and $Z_1 = (\rho_1\chi_1)^{1/2}$. For frequencies higher than 1 kHz, the surface impedance of the layer given by Eq. (9) is very close to the surface impedance of the semi-infinite sand layer Z_s^∞ given by

$$Z_s^\infty = Z_1/(\phi \cos \theta_1). \tag{17}$$

The modulus of the reflection coefficient for the semi-infinite layer, calculated at 4 kHz from Eqs. (4) and (17) as a function of the angle of incidence θ, is shown in Fig. 2. A minimum in the reflection coefficient exists at $\theta_m = 1.365$. The unique pole for a semi-infinite layer is located at θ_p such that

$$\sin \theta_p = \left[\frac{(\rho_1/(\rho_0\phi))^2 - n^2}{(\rho_1/(\rho_0\phi))^2 - 1} \right]^{1/2} \tag{18}$$

and

$$\cos \theta_p = -\left[\frac{n^2 - 1}{(\rho_1/(\rho_0\phi))^2 - 1} \right]^{1/2}, \tag{19}$$

where ρ_0 is the air density and n is the index of refraction. Comparing the predicted $\cos \theta_p = -0.203 + i2.9 \times 10^{-2}$ from Eq. (19) to $\cos \theta_m = 0.204$ shows that it is opposite to Re $\cos \theta_p$ to a good approximation. This is due to the structure of the reflection coefficient v in Eq. (4). A given $\sin \theta_p$ is related to two opposite values for $\cos \theta$: $\cos \theta_p$, which is related to a zero of the denominator, and $\cos \theta_z = -\cos \theta_p$, which is related to a zero of the numerator, and a zero of v. The zero and the pole are related to opposite $\cos \theta$. The imaginary part of $\cos \theta_p$ is small and $|\cos \theta_z - \cos \theta_m|$ is small, thereby the localization of the minimum. The strong analogies between this zero and the zero of the reflection coefficient of a semi-infinite dielectric

layer (or a conducting layer of sufficient thickness) for electromagnetic transverse magnetic waves are discussed in Ref. 9. For the electromagnetic waves, the zero corresponds to the Brewster angle of the medium, and the hypothetical surface wave related to the pole is the Zenneck wave.[4] This wave does not exist at large numerical distances because $\mathrm{Re}\sin\theta_p < 1$. Raspet and Baird[15] have shown that $\mathrm{Re}\sin\theta_p < 1$ is not always true for semi-infinite porous layers described using the empirical laws of Delany and Bazley.[16] However, this condition has always been verified for semi-infinite porous layers when the causal equivalent densities and incompressibilities of the present work are used, and for the measurements described in the next section. However, we have not found any general proof that $\mathrm{Re}\sin\theta_p < 1$. A zero and a pole related to the same $\sin\theta_p$ is a general consequence of Eq. (4) and exist also for thin layers, but in this case $\mathrm{Re}\sin\theta_p > 1$, and there is no real angle θ_m close to θ_z. For semi-infinite layers, the complex Brewster angle can be partially localized with the Tamura method[17] of measuring the reflection coefficient at oblique incidence, from the minimum of the modulus of the reflection coefficient, but $\mathrm{Im}\cos\theta_p$ is not directly measurable with this method.

If the frame displacements are taken into account, another pole is present for porous frames saturated by a light fluid,[18,19] which is very close to the Rayleigh pole. The velocity of the Rayleigh waves in porous foams[20] is much smaller than the sound speed in air, and the pole is related to a complex angle of incidence far from $\pi/2$. This is probably the case for the unconsolidated media in the present study where no manifestation of this pole has been observed.

IV. VALIDITY OF THE METHOD FOR THICK LAYERS

A. Simulations

Equations (1)–(3) or the equivalent formulation with Eq. (11) gives an asymptotic estimation of the reflected field which is valid only for sufficiently large kr. A simulated measurement of $\cos\theta_p$ for a semi-infinite layer of sand using Eq. (15) is performed for $r=15$ cm, $z_1=z_2=0.5$ cm. The pressure p_r is calculated without approximations using the Sommerfeld integral[6]

$$p_r = ik \int_0^\infty \frac{q\,dq}{\mu} v(\mu) J_0(kqr) \exp(ik\mu(z_1+z_2)), \qquad (20)$$

where $\mu = \sqrt{1-q^2}$, $\mathrm{Im}\,\mu \geqslant 0$. The reflection coefficient v is given by Eq. (4) and the surface impedance Z_s by Eq. (9). The first test concerns the asymptotic behavior of the approximate expressions, Eq. (1) or (11). For the test, a layer of Ottawa sand of thickness $l=8$ cm, described by the parameters given in Table I, is used. The exact $\cos\theta_p$ is compared to the result of the simulated measurement for $r=15$ cm, $z_1=z_2=0.5$ cm, as a function of frequency in Fig. 3. The difference between the exact value and the simulated measurement slowly increases when frequency decreases. At 500 Hz, $kr=1.4$, the exact value and the simulated measurement remain surprisingly close to each other. The second test concerns the fact that as indicated in Ref. 5, Eq. (1) and then Eq. (11) are valid only for θ_0
FIG. 3. $\cos\theta_p$ as a function of frequency for a layer of Ottawa sand of thickness $l=8$ cm. Prediction:———; simulated measurement $r=15$ cm, $z_1=z_2=0.5$ cm:---.

close to $\pi/2$. In Fig. 4 the exact value and the simulated measurement are compared at 4 kHz for $r=15$ cm, and $z_1=z_2$ varying from 0.25 to 2.5 cm. The real part of $\cos\theta_p$ is predicted with a good precision over the whole interval, but the error on $\mathrm{Im}\cos\theta_p$ becomes considerable for $z_1+z_2 > 2$ cm. A simulation has been performed to test the validity of the method for large $\cos\theta_p$. For semi-infinite layers, $|\cos\theta_p|$ is a decreasing function of the flow resistivity. In order to increase $|\cos\theta_p|$ a porous medium with a lower flow resistivity, $\sigma=40\,000$ N m^{-4} s, and a thickness $l=8$ cm, has been used in the simulation. The parameters which characterize the material, denoted as material 3, are given in Table I. The simulated measurement of $\cos\theta_p$ and the exact value are compared in Fig. 5 for $z_1=z_2=5$ mm, $r=15$ cm, and frequencies varying from 0.5 to 5 kHz. The error in $\mathrm{Im}\cos\theta_p$ can be important at high frequencies when $|\cos\theta_p|$ is too large, similar to the case for a large $\cos\theta_0$. A last point concerns the result of the measurements, when the measurement has been performed with a good precision on a material with a high flow resistivity. A large flow resistivity is related to a weak dependence of the surface impedance on the angle of incidence and the results of outdoors measurements around grazing incidence are generally considered as surface impedances at normal incidence. In Fig. 6 the simulated measurement of $Z_s(\theta_p)/Z$ for a layer of thickness $l=8$ cm of Ottawa sand
FIG. 4. $\cos\theta_p$ at 4 kHz for a layer of Ottawa sand of thickness $l=8$ cm. Prediction:———; simulated measurement $r=15$ cm, 0.5 cm$<z_1+z_2$ <5 cm:---.

with $z_1=z_2=5$ mm, $r=15$ cm is compared to the predicted
reduced impedances at normal and at grazing incidence.
The predicted measurement in the high-frequency range is
noticeably different from the impedance at normal inci-
dence and close to the impedance at grazing incidence.

B. Measurements

Measurements have been performed on two granular
media, a layer of Ottawa sand of thickness $l=8$ cm and a
layer of glass beads of thickness $l=3$ cm. The source is a
pipe fed by a compression driver. The internal diameter of
the pipe is 4 mm. The receiver is a $\frac{1}{4}$-in. Bruel and Kjaer
microphone. Different source-receiver distances have been
used, ranging from 15 to 30 cm. As shown in Fig. 4, the
systematic error on Im $\cos \theta_p$ can be important if z_1+z_2 is too
large. Some measurements have been performed with the
source very close to the surface (z_1 small). In this case there
was a systematic dependence of the result on the source re-
ceiver distance, probably due to the fact that the source is not
an ideal point source and is modified when it is too close to
the reflecting surface. A distance of 3 mm between the pipe
and the surface was sufficient to avoid this systematic effect.
The sound emission at the end of the pipe is not noticeably
modified for this distance when the rigid impervious surface
is replaced by the porous layer. Predictions of $\cos \theta_p$ for the
sand and measurements for $r=30$ cm, $z_1=4$ mm, and z_2

$=8$ mm are presented in Fig. 7. At 0.5 kHz, the error on
Re $\cos \theta_p$ is large. This error is smaller at higher frequencies,
but the measured Im $\cos \theta_p$ is systematically larger than the
predicted one. Measurements with the same geometry and
predictions of the reduced surface impedance $Z_s(\theta_p)/Z$ of the
layer of glass beads are presented in Fig. 8. At 1 kHz, the
error on Im $Z_s(\theta_p)/Z$ is large. This error becomes smaller at
higher frequencies and a good agreement between prediction
and measurement is obtained. At frequencies higher than
1 kHz a good order-of-magnitude measurement of $\cos \theta_p$ and
$Z_s(\theta_p)$ can be obtained for the studied materials, which have
a fairly high surface impedance. Higher surface impedances
could probably be measured with a source that more closely
approximates a point source.

V. CONCLUSION

A method previously developed to evaluate the surface
impedance of thin porous layers close to grazing incidence
and with small source-receiver distances is used for thick
layers of granular porous materials with a high flow resistiv-
ity. The evaluated impedance is the only acoustical param-
eter needed to predict the reflected monopole pressure field
for specular angles of incidence close to $\pi/2$. For a locally
reacting surface the evaluated impedance is the surface im-

pedance independent on the angle of incidence. For a thick porous layer with a high flow resistivity, simulations show that the evaluated impedance is close to the impedance at grazing incidence and can noticeably differ from the impedance at normal incidence. There is a pole of the reflection coefficient at the complex angle of incidence associated to the evaluated impedance. For sufficiently thick porous layers this pole is related in a straightforward way to the Brewster angle of the medium, and impedance measurement simultaneously leads to an evaluation of the pole and the Brewster angle. Measurements of the surface impedance close to grazing incidence can be performed on materials with a large flow resistivity for areas of about 1 m², at frequencies larger than 1 kHz, with a very simple experimental setup. The evaluation is performed with a classical expression of the reflected monopole field close to grazing incidence. This expression which is widely used for outdoors ground impedance measurements with large source receiver distances is shown to be applicable to smaller source receiver distances at higher frequencies for acoustically thick porous layers.

ACKNOWLEDGMENTS

APPENDIX: DERIVATION OF REFLECTED PRESSURE

The general formulation of the "reference integral method" by Brekhovskikh and Godin[6] is used in Ref. 1 to adapt the pole subtraction method for the case of nonlocally reacting porous layers with a finite thickness. The asymptotic expression Eq. (11) for the reflected pressure p_r has been obtained, and the different approximations which can lead to the simplified expressions Eqs. (1), (2), (6), and (7) for thin porous layers are indicated. The calculation of Ref. 1 can be simplified for the case of semi-infinite layers. The reflection coefficient [Eq. (A2) in Ref. 1] can be written

$$v = 1 - 2\sqrt{n^2 - q^2}\left[\sqrt{n^2 - q^2} + \frac{Z_1}{\phi Z}n\sqrt{1 - q^2}\right]^{-1}, \quad (A1)$$

where $q = \sin \theta$ and $F(q)$ is now given by

$$F(q) = -2\sqrt{\frac{q(n^2 - q^2)}{1 - q^2}}\left[\sqrt{n^2 - q^2} + \frac{Z_1}{\phi Z}n\sqrt{1 - q^2}\right]^{-1}. \quad (A2)$$

Let $G(q)$ be the factor in brackets in Eq. (A2). The new parameter a [Eq. (A11) in Ref. 1] is given by

$$a = -2\sqrt{\frac{q_p(n^2 - q_p^2)}{1 - q_p^2}}\frac{1}{G_q'(q_p)}, \quad (A3)$$

$$G_q'(q_p) = -\frac{q_p}{\sqrt{n^2 - q^2}} - \frac{Z_1}{\phi Z}n\frac{q_p}{\sqrt{1 - q_p^2}}. \quad (A4)$$

When $|n|$ is sufficiently large, θ_p given by Eqs. (18) and (19) is close to $\pi/2$ and the first term on the right-hand side of

Eq. (A4) can be neglected. Then a can be written, like in Ref. 1,

$$a = 2Z/(Z_s(\theta_p)\sqrt{q_p}), \quad (A5)$$

and p_r has the same expression as in Ref. 1,

$$p_r = \frac{\exp(ikR_1)}{R_1}$$
$$\times \left\{v(\cos \theta_0) + \frac{Z\sqrt{\sin \theta_0}}{Z_s(\theta_p)\sqrt{\sin \theta_p}\sin[(\theta_p - \theta_0)/2]}C\right\}, \quad (A6)$$

$$C = 1 + i\sqrt{\pi}s_p\sqrt{kR_1}\exp(-kR_1s_p^2)\mathrm{erfc}(-i\sqrt{kR_1}s_p), \quad (A7)$$

$$s_p = \exp\frac{i\pi}{4}\sqrt{2}\sin\frac{\theta_p - \theta_0}{2}. \quad (A8)$$

In Eq. (A6), $Z/Z_s(\theta_p)$ can be replaced by $-\cos \theta_p$. If θ_0 and θ_p are close to $\pi/2$, $(\sin \theta_0/\sin \theta_p)^{1/2}$ can be removed in Eq. (A6) and in Eq. (A8) $\sin((\theta_p - \theta_0)/2)$ can be replaced by $(\cos \theta_0 - \cos \theta_p)/2$. The term $-2\cos \theta_p/(\cos \theta_0 - \cos \theta_p)$ corresponds to $1 - v$ in Eq. (1). The conditions of validity of Eq. (1) are, like in Ref. 5, θ_0 and θ_p close to $\pi/2$.

The dominating method of measuring sound intensity in air is based on the combination of two pressure microphones. However, a sound intensity probe that combines an acoustic particle velocity transducer with a pressure microphone has recently become available. This paper examines, discusses, and compares the two measurement principles with particular regard to the sources of error in sound power determination. It is shown that the phase calibration of intensity probes that combine different transducers is very critical below 500 Hz if the measurement surface is very close to the source under test. The problem is reduced if the measurement surface is moved further away from the source. The calibration can be carried out in an anechoic room. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1984860]

I. INTRODUCTION

The most successful method of measuring sound intensity in air is the "two-microphone" (or "*p-p*") method, which makes use of two closely spaced pressure microphones and relies on a finite-difference approximation to the sound pressure gradient.[1] Both the IEC standard on instruments for the measurement of sound intensity[2] and the corresponding North American ANSI standard[3] deal exclusively with *p-p* measurement systems. The alternative "*p-u*" method, which involves combining a pressure microphone with a particle velocity transducer, has been hampered by the absence of reliable transducers for the acoustic particle velocity; see, e.g., the historical overview in Ref. 1. The situation is different in underwater acoustics since "in water, direct measurement [of the acoustic particle velocity] is simple,"[4] and several *p-u* measurement systems have recently been developed; see, e.g., Refs. 4,5. This paper is concerned with air acoustics. Some years ago a micromachined transducer called the "Microflown" became available for measurement of the acoustic particle velocity in air,[6] and an intensity probe based on this device in combination with a small pressure microphone is now in commercial production.[7,8] Yet another method based on determining the sound pressure from an approximation to the divergence of the particle velocity (the "*u-u*" method, which involves six velocity transducers)[9] has, to the authors' knowledge, never been used in air.

The purpose of this paper is to compare, discuss, and examine the main limitations of the *p-u* and the *p-p* measurement principles in sound power determination under very difficult measurement conditions.

II. THE *p-p* MEASUREMENT PRINCIPLE

The *p-p* measurement principle employs two pressure microphones. The particle velocity component in the direction of the axis of the probe is obtained by a finite-difference approximation to the pressure gradient in Euler's equation of motion, and the sound pressure is simply the average of the two pressure signals. The most important limitations of this measurement technique are caused by the finite difference approximation, scattering and diffraction, and instrumentation phase mismatch.

The accuracy of the finite-difference approximation and the effect of scattering and diffraction obviously depend on the geometry of the microphone arrangement. Several configurations are possible, but in the early 1980s it was shown experimentally that the face-to-face configuration with a solid "spacer" between the two microphones is particularly favorable.[10] Much later it was discovered that the effect of scattering and diffraction not only tends to counterbalance the finite-difference error but in fact for a certain length of the spacer almost perfectly cancels it under virtually any sound field condition encountered in practice.[11] A practical consequence is that the upper frequency limit of a sound intensity probe based on two 1/2 in. microphones separated by a 12 mm spacer in the face-to-face arrangement is about 10 kHz, which is about an octave higher than the frequency limit determined by the finite-difference approximation.[11] The combination of 1/2 in. microphones and a 12 mm

spacer is now regarded as optimal, and longer spacers are only used when the focus is exclusively on low frequencies.[12]

Unless the measurement is compensated for phase mismatch the microphones for measurement of sound intensity with the *p-p* method have to be phase matched extremely well, and state-of-the-art sound intensity microphones are matched to a maximum phase response difference of 0.05° below 250 Hz and a phase difference proportional to the frequency above 250 Hz (say, 0.2° at 1 kHz).[13] The proportionality to the frequency is a consequence of the fact that phase mismatch in this frequency range is caused by differences between the resonance frequencies and the damping of the two microphones.[14]

It can be shown that a small phase mismatch error φ_{pe} gives rise to a bias error that can be approximated by[15,16]

$$\hat{I}_r \simeq I_r - \frac{\varphi_{pe}}{k\Delta r}\frac{p_{\mathrm{rms}}^2}{\rho c} = I_r\left(1 - \frac{\varphi_{pe}}{k\Delta r}\frac{p_{\mathrm{rms}}^2/\rho c}{I_r}\right), \quad (1)$$

where I_r is the "true" intensity (unaffected by phase mismatch), $\hat{I}_r$ is the biased estimate, p_{rms} is the rms value of the sound pressure, k is the wave number, Δr is the microphone separation distance, ρ is the density of air, and c is the speed of sound. This expression shows that the effect of a given phase error is inversely proportional to the frequency and the microphone separation distance and is proportional to the ratio of the mean square sound pressure to the sound intensity. If this ratio is large then even the small phase errors mentioned earlier will give rise to significant bias errors. Because of phase mismatch it will rarely be possible to make reliable measurements below, say, 80 Hz, except under very favorable semi free-field conditions unless a longer spacer than the usual 12 mm spacer is used.[17]

The ratio of the phase error to the product of the frequency and the microphone separation distance can be measured (usually in the form of the so-called "pressure-residual intensity index"[1]) by exposing the two pressure microphones to the same pressure in a small coupler.[1–3] Modern sound intensity analyzers automatically determine the ratio of the mean square pressure to the intensity during the intensity measurements.[18] Thus one has a clear indication of whether the bias error is serious or not.

The global version of Eq. (1) is found by integrating the normal component over a surface that encloses a source. The result is[16,19]

$$\hat{P}_a = \int_S \hat{\mathbf{I}} \cdot d\mathbf{S} \simeq P_a\left(1 - \frac{\varphi_{pe}}{k\Delta r}\frac{\int_S (p_{\mathrm{rms}}^2/\rho c)dS}{\int_S \mathbf{I} \cdot d\mathbf{S}}\right), \quad (2)$$

where P_a is the "true" sound power of the source within the surface and $\hat{P}_a$ is the biased estimate. The ratio of the surface integral of the mean square pressure to the surface integral of the intensity (in decibels) is known as the pressure-intensity index of the measurement.[1]

Calibration of *p-p* sound intensity measurement systems involves calibrating the two pressure microphones with a pistonphone in the usual manner and determining the pressure-residual intensity index in a small coupler driven by a wide-band signal as mentioned earlier.[1]

III. THE *p-u* MEASUREMENT PRINCIPLE

A. General considerations

A *p-u* sound intensity measurement system combines two fundamentally different transducers. The sound intensity is simply the time average of the instantaneous product of the pressure and particle velocity signal,[1]

$$I_r = \langle pu_r \rangle_t = \tfrac{1}{2}\mathrm{Re}\{pu_r^*\}, \quad (3)$$

where $\langle \rangle_t$ indicates time averaging, and the latter expression is based on the complex representation of harmonic variables. However, irrespective of the measurement principle used in measuring the particle velocity there is one fundamental problem: the pressure and the particle velocity transducer will invariably have different phase responses.[1] One must compensate for this "*p-u* phase mismatch," otherwise the result may well be meaningless. In fact even a small residual *p-u* mismatch error can have serious consequences under certain conditions. This can be seen by introducing such a small phase error, φ_{ue}, in Eq. (3). The result is[20]

$$\begin{aligned}\hat{I}_r &= \tfrac{1}{2}\mathrm{Re}\{p\hat{u}_r^*\} = \tfrac{1}{2}\mathrm{Re}\{pu_r^* e^{-j\varphi_{ue}}\}\\ &= \mathrm{Re}\{(I_r + jJ_r)(\cos\varphi_{ue} - j\sin\varphi_{ue})\} \simeq I_r\\ &\quad + \varphi_{ue}J_r,\end{aligned} \quad (4)$$

where

$$\hat{u}_r = u_r e^{j\varphi_{ue}} \quad (5)$$

is the particle velocity estimate, and

$$J_r = \tfrac{1}{2}\mathrm{Im}\{pu_r^*\} = \mathrm{Re}\{I_r + jJ_r\} \quad (6)$$

is the reactive intensity.[21,22] Whereas the (active) intensity describes the net flow of sound energy the reactive intensity describes the nonpropagating part of the energy, which is merely flowing back and forth, corresponding to the instantaneous particle velocity being in quadrature with the sound pressure. Many sources have strongly reactive near fields at low frequencies where they mainly generate evanescent waves. Near such a source the air is essentially moving back and forth as if it were incompressible.[1] Equation (4) demonstrates that even a small uncompensated *p-u* phase mismatch error will give rise to a significant bias error when $J_r \gg I_r$. On the other hand it also shows that substantial *p-u* phase errors can be tolerated if $J_r \ll I_r$. For example, even phase mismatch of 35° gives a bias error of less than 1 dB under such conditions. In other words, the phase calibration is critical when measurements are carried out under near field conditions, but not at all critical if the measurements are carried out in the far field. The "reactivity" (the ratio of the reactive to the active intensity) indicates whether this source of error is of concern or not.

The global version of Eq. (4) is found by integrating over a surface that encloses a source,[20]
FIG. 1. The two heated wires of the Microflown particle velocity transducer.

FIG. 2. A Microflown 1/2 in. sound intensity probe. The particle velocity sensor can be seen on the solid cylinder to the right; the electret microphone is mounted inside the other cylinder.

$$\hat{P}_a = \int_S \text{Re}\{(\mathbf{I} + j\mathbf{J})(\cos \varphi_{ue} - j \sin \varphi_{ue})\} \cdot d\mathbf{S} \simeq P_a$$

$$+ \varphi_{ue} \int_S \mathbf{J} \cdot d\mathbf{S}$$

$$= P_a \left(1 + \varphi_{ue} \frac{\int_S \mathbf{J} \cdot d\mathbf{S}}{\int_S \mathbf{I} \cdot d\mathbf{S}} \right), \tag{7}$$

and this shows that uncompensated *p-u* phase mismatch is a potential source of error when the reactivity (which in the global case is the ratio of the surface integral of the reactive intensity to the surface integral of the active intensity) is large. This will typically occur at low frequencies when the measurement surface is close to the source. Thus the reactivity is an important field indicator for *p-u* probes. By contrast the pressure-intensity index is not relevant for *p-u* probes, as also pointed out by Fahy.[1]

Calibration of *p-u* sound intensity measurement systems involves exposing the probe to a sound field with a known relation between the pressure and the particle velocity, for example a plane propagating wave or a simple spherical wave.[1] Fahy is rather pessimistic about such calibration techniques, though; he says, "At best this is a check, and not an accurate means of calibration."[1]

B. The Microflown intensity probe

The MF particle velocity transducer consists of two short, thin, closely spaced wires of silicon nitride coated with platinum and heated by a dc current to about 300 °C;[6–8] see Fig. 1. The resistance of the wires depends on the temperature. An acoustic particle velocity signal in the perpendicular direction changes the temperature distribution instantaneously, because one of the wires will be cooled more than the other by the airflow, and this difference in resistance is measured with a bridge circuit that provides a signal proportional to the particle velocity. At low frequencies the sensitivity of this device increases 6 dB per octave. Between 100 and 1 kHz the frequency response is relatively flat. Between 1 and 10 kHz there is a rolloff of 6 dB per octave caused by diffusion effect related with the distance between the two wires, and above 10 kHz the sensitivity decreases an additional 6 dB per octave because of the thermal heat capacity of the wires. The particle velocity transducer is combined with a small electret condenser microphone in the 1/2 in. sound intensity probe shown in Fig. 2. The velocity trans-

ducer is mounted on a small, solid cylinder, and the condenser microphone is mounted inside another, hollow cylinder. The geometry of this arrangement increases the velocity and thus the sensitivity of the velocity transducer.

IV. DISCUSSION

Inspection of Eqs. (2) and (7) shows that *p-p* and *p-u* sound intensity measurement systems are affected differently by extraneous noise. Sources outside the measurement surface do not contribute to the surface integral of the "true" intensity [in the the denominator of the second term on the right-hand side of Eq. (2)], but they increase the surface integral of the mean square pressure (the numerator of the second term), from which it follows that even a very small phase error imposes restrictions on the amount of extraneous noise that can be tolerated in sound power measurements with a *p-p* sound intensity measurement system. (This conclusion was anticipated by Pascal as early as in 1981.[23]) By contrast, sources outside the measurement surface do not in general increase the reactivity [the second term on the right-hand side of Eq. (7)], and thus they do not in general increase the error due to *p-u* phase mismatch.

High values of the pressure-intensity index can occur in the entire frequency range;[11] therefore *p-p* phase mismatch can be of concern also at high frequencies. On the other hand very reactive sound fields are unlikely to occur except at low frequencies;[16] therefore *p-u* phase mismatch will generally be a problem only at low frequencies, and it will usually improve the situation to move away from the source.

The simple expedient of reversing a *p-p* probe makes it possible to eliminate the influence of *p-p* phase mismatch, because the intensity changes sign but the error does not.[24,25] Unfortunately, most *p-p* intensity probes are not symmetrical and therefore not suitable for real measurements with the probe reversed. By contrast the MF probe can easily be reversed. However, reversing a *p-u* probe simply changes the sign of the result, including the bias error, as easily seen from Eq. (4).[26] In other words, there is no simple way of getting rid of the phase error of a *p-u* probe; it must be calibrated with sufficient accuracy.

V. EXPERIMENTAL RESULTS

A. Free-field calibration

To validate the foregoing considerations and examine the performance of the MF sound intensity probe some experiments have been carried out. Initially the device was tested in the small anechoic room at DTU at a position 2 m from a small loudspeaker. A Brüel & Kjær (BK) "pulse" analyzer of type 3560 in one-third octave mode was used in all measurements. First the directional response of the particle velocity sensor was measured in the vertical and in the horizontal plane, and found to be in reasonable agreement with the expected cosine behavior in the entire frequency range. Next, the pressure response was measured; it was found to be in fair agreement with the response of a 1/2 in. free-field microphone of type BK 4191 up to 6.3 kHz. And finally the frequency response between the pressure and the velocity signal of the device was determined. This response, which took values over an interval of almost 30 dB and 140° in the frequency range from 50 Hz to 10 kHz, served as a correction factor to the cross spectrum in subsequent intensity measurements.

In the first place it was assumed that the probe had been exposed to a plane propagating wave in the velocity calibration measurement. However, as soon as the velocity calibration was applied to sound power measurements it became apparent that 2 m distance from the source is not enough to ensure plane wave conditions at low frequencies. Thus the measurement was repeated in the large anechoic room at DTU at positions 2, 3, and 4 m from the loudspeaker. This room is very good at frequencies down to 50 Hz.[27] The velocity calibration was corrected for the "near field effect," that is, the factor in parentheses in the expression for the relation between the particle velocity and the pressure generated by a monopole,

$$u_r(r) = \frac{p(r)}{\rho c}\left(1 + \frac{1}{jkr}\right). \tag{8}$$

Figure 3 shows the amplitude and phase corrections measured at 2 and 4 m distance, with and without the near field effect taken into account. (The corrections measured at 3 m distance are similar.) Below 200 Hz it is clearly necessary to correct for the near field effect even at a distance of 4 m. The fact that the corrected calibration curves differ from each other below 100 Hz simply demonstrates that a loudspeaker is not a monopole.

In what follows the active and the reactive intensity has been estimated in one-third octave bands using

$$\hat{I}_r = \text{Re}\left\{\frac{S_{\hat{p}\hat{u}}H_{pu}}{H_{\hat{p}\hat{u}}|H_{p\hat{p}}|^2}\right\}, \tag{9}$$

$$\hat{J}_r = -\text{Im}\left\{\frac{S_{\hat{p}\hat{u}}H_{pu}}{H_{\hat{p}\hat{u}}|H_{p\hat{p}}|^2}\right\}, \tag{10}$$

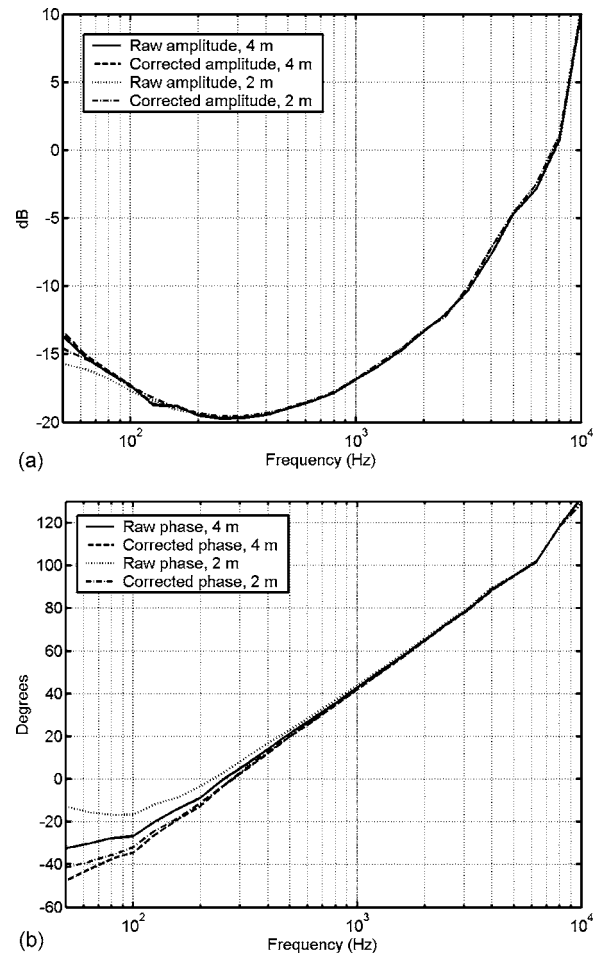
where $S_{\hat{p}\hat{u}}$ is the cross spectrum between the two signals from the MF probe, $H_{\hat{p}\hat{u}}$ is the ratio of the velocity to the pressure from the calibration measurement, H_{pu} is the corresponding theoretical value of the ratio of the velocity to the pressure


FIG. 3. Amplitude (a) and phase (b) calibration of the velocity signal relative to the pressure signal, measured at 2 and 4 m distance in an anechoic room, with and without correction for the finite distance to the loudspeaker.

[from Eq. (8)], and the pressure correction,$H_{p\hat{p}}$, takes account of fact that the pressure sensitivity of the device is not completely flat. The pressure correction is shown in Fig. 4.

B. Sound power measurements

The next experiments took place in a large hall where the sound power of a "sound source" of type BK 4205 was
FIG. 4. Pressure correction of the MF probe.
FIG. 5. Large and small measurement surface and the BK 4205 sound source.

FIG. 7. Ratio of reactive to active intensity on two surfaces enclosing the BK 4205 sound source.

measured by scanning over a surface enclosing the source with two different intensity probes, the MF probe and a *p-p* probe of type BK 3599 with microphones of type BK 4181. The two channels of the BK *p-p* sound intensity measurement system were much better matched than required of "class 1" systems by the IEC standard;[2] see Ref. 28. The reactive intensity was also measured. Two different measurement surfaces were used, one with an area of 5 m[2], and a very small one with an area of about 0.4 m[2] (see Fig. 5), and each measurement was repeated using a different scanning pattern. The repeatability was found to be very good in all cases.

Figure 6 shows the results of the four sound power measurements. The results determined with the MF probe have been processed using the presumably most accurate phase and amplitude calibration function, the one determined at 4 m distance and corrected for the near field effect. As can be seen all four measurements are in good agreement up to 6.3 kHz. At 8 and 10 kHz the MF probe overestimates slightly, perhaps because the pressure response of the device depends on the direction of incidence whereas the pressure calibration has been determined for axial incidence, or perhaps because the geometry of the arrangement affects the particle velocity. No influence of the measurement surface can be seen, in spite of the fact that the sound field on the small surface very

close to the source is strongly reactive at low frequencies, as demonstrated by Fig. 7. The fluctuations in the measured reactivity at high frequencies on the large measurement surface are of no concern. In this frequency range the reactive intensity decays rapidly with the distance to the source, and thus it takes very small values on the large measurement surface.[16,26] Besides, measuring reactive intensity in a predominantly active sound field with a *p-p* measurement system requires extremely accurate amplitude calibration.[29]

That the phase calibration of the *p-u* probe can be critically important is demonstrated by Fig. 8, which shows the error of the sound power measurements with the MF probe on the two measurement surfaces with the velocity calibration measured at 2 and 4 m distance, without and with correction for the finite distance to the loudspeaker in the calibration measurement. The reference is the measurement with the BK probe on the large surface. It is apparent that the reactive sound field on the small measurement surface amplifies the influence of *p-u* phase mismatch, as predicted by Eq. (7).

The BK 4205 sound source is an enclosed loudspeaker,

FIG. 6. Sound power of the BK 4205 sound source, measured with a BK intensity probe and with a MF intensity probe on two different measurement surfaces.
FIG. 8. Estimation error of the MF probe using different phase calibrations. A measurement with a BK intensity probe on the large measurement surface is used as the reference.
FIG. 9. Dipole source inside a very small measurement surface.

FIG. 11. Sound power of the dipole, measured with a BK intensity probe and with a MF intensity probe on two different measurement surfaces.

which is a well-behaved source. To examine the performance of the MF probe under more severe conditions the sound power of a dipole has been determined using an extremely small measurement surface with an area of 0.2 m². The dipole was constructed by mounting two loudspeaker units against each; see Fig. 9. Placed on concrete floor this source generated an exceptionally reactive sound field on the small measurement surface below 500 Hz, as shown in Fig. 10. In this case the BK probe produced negative intensity values at 50 and 63 Hz; hence the missing part of the corresponding curve. However, the "true" average intensity on the small surface can be calculated from the average intensity on the large surface. The MF data on the small surface were affected by residual p-u phase mismatch, as will become apparent in what follows.

Figure 11, which corresponds to Fig. 6, shows the results of sound power measurements with the two devices on the two measurement surfaces. Again, missing parts of the curves indicate meaningless negative sound power estimates. The two probes are in good agreement on the large measurement surface except for the overestimation of the MF probe at 8 and 10 kHz, as before. It can also be seen that the BK probe performs reasonably well except at 50 and 63 Hz on the small surface, considering the difficulties in measuring on such a small surface with the somewhat bulky probe. However, on the small surface the MF probe obviously has problems at low frequencies.

Figure 12, which corresponds to Fig. 8, shows the error of the MF results determined using the various calibrations. As can be seen, enormous errors occur when the small measurement surface is used, confirming once again that the phase calibration of the device is critically important when it is used in strongly reactive sound fields.

Finally it should be mentioned that the influence of strong background noise from sources outside the measurement surface has been examined. However, no significant difference between the performance of the p-p and the p-u measurement system under such conditions was observed.[28] As shown in Sec. II such background noise amplifies the error due to p-p phase mismatch, but with the very well-matched p-p intensity probe used in these measurements this effect could not be detected. The only effect of the noise was increased random errors, in all probability caused by the fact that the approximation to the surface integral in sound power measurement becomes more critical the higher the level of extraneous noise.

FIG. 12. Estimation error of the MF probe using different phase calibrations. A measurement with a BK intensity probe on the large measurement surface is used as the reference.
FIG. 13. Original and adjusted phase calibration.

C. Improved phase calibration

Not everybody has easy access to a large anechoic room of high quality; therefore it has been examined whether one can improve a free-field calibration made too close to the loudspeaker simply by manual adjustment of the phase calibration until the error that occurs in a very reactive sound field disappears. Figure 13 shows the modified phase correction, and Fig. 14 shows the result of such a procedure in the frequency range from 50 to 200 Hz. The starting point was the phase calibration measured at 2 m distance and corrected for the phase angle between pressure and particle velocity due to the finite distance on the assumption that the loudspeaker was a perfect monopole. The adjustment must be made in small steps. Below 100 Hz a phase increment of 0.1° has drastic consequences for the measurement on the small surface (the intensity estimate can change its sign, for example), confirming again that the phase calibration is critically important under such conditions. Modifying the phase calibration so as to remove the overestimation in the results on the small measurement surface at low frequencies has a very limited effect on the results determined on the large measurement surface, and also, not shown, a very modest influence on the measurement of the sound power of the BK
4205 using the large surface, but a positive influence on the (fairly small) error in the measurement of the sound power of the BK 4205 made on the small surface (not shown).

Obviously this method cannot take account of errors in the *amplitude* calibration. However, these errors are quite small, cf. Fig. 3(a), and their effect do not depend on the sound field conditions.

VI. CONCLUSIONS

The *p-u* sound intensity measurement principle has been examined theoretically and experimentally, and compared with the established *p-p* method with particular regard to the influence of phase mismatch on sound power estimation. It is more difficult to calibrate *p-u* intensity probes than *p-p* intensity probes, and whereas *p-p* phase mismatch in conventional *p-p* measurement systems can be almost eliminated by reversing the intensity probe, probe reversal has no effect on the influence of *p-u* phase mismatch in measurements with *p-u* measurement systems. Strongly reactive sound fields exacerbate the influence of *p-u* phase mismatch, but have no influence on the effect of *p-p* phase mismatch. Such sound field conditions are reflected in a high value of the reactivity, that is, the ratio of the surface average of the reactive intensity to the surface average of the active intensity. This will rarely be a problem above 500 Hz, and can be avoided simply by moving the measurement surface further away from the source under investigation. By contrast, background noise from sources outside the measurement surface increases the influence of *p-p* phase mismatch, but has no influence on the effect of *p-u* phase mismatch. Such background noise is reflected in a high value of the pressure-intensity index. This problem can occur in the entire frequency range.

The experimental part of the investigation was carried out with a *p-u* sound intensity probe produced by Microflown. The results show that it is possible to measure sound power reliably with the Microflown intensity probe from 50 Hz to 6.3 kHz if strongly reactive near fields, which tend to make the phase calibration very critical, are avoided. The measurements have also shown that it is possible to expand the range of measurement to near field conditions if the phase can be calibrated with sufficient accuracy below 500 Hz; at higher frequencies the phase calibration is less critical. The calibration can be carried out in a large anechoic room, and the extreme sensitivity to *p-u* phase mismatch in very reactive sound fields can even be turned to advantage by adjustment of the phase correction until the error disappears.

Data-based mode extraction with a partial water column spanning array

S. C. Walker,[a] Philippe Roux, and W. A. Kuperman
Marine Physical Laboratory of the Scripps Institution of Oceanography,
University of California—San Diego, La Jolla, California 92093-0238

In a shallow ocean waveguide the acoustic field can be characterized by depth-dependent modes propagating in range with an associated propagating wavenumber. Though recently developed methods for determining the modes from recorded acoustic data alone without ocean or bottom modeling have shown promise, they are only applicable when the acoustic field is sampled over the entire water column. This paper presents a method for determining the acoustic modes from measured data alone when the field is sampled over only a portion of the water column. The method requires broadband sources at many ranges, e.g., a moving source, in order to construct the frequency-wavenumber (f-k) structure of the waveguide. Because modal propagation is dispersive, the modes are characterized by a discrete set of wavenumbers that vary continuously with frequency. Due to the discreteness of the modal wavenumbers, it is possible to isolate the modes in the f-k domain and extract them individually with a singular value decomposition (SVD). Because the modes are extracted individually the full-spanning and degeneracy limitations of the SVD are removed. Theory, simulation, and laboratory data confirm the process. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1993149]

I. INTRODUCTION

The normal mode structure of an ocean waveguide is not only fundamental to describing propagation, but also provides opportunities for various types of array and signal processing.[1] In range-independent environments, matched mode or mode filtering methods[2–4] offer an effective alternative to more general matched field methods[5] that tend to be computationally costly and highly sensitive to environmental mismatch. Matched mode methods apply a knowledge of the modal components of the field to measured data over a vertical array of sensors. Typically, the modal components are constructed from theory using parameters derived from a detailed knowledge of the environment. The difficulty and high cost of obtaining the necessary environmental information has motivated research into the development of model-free methods for determining the modes of acoustic propagation. Of particular interest are methods that can be directly applied to acoustic data measured on a vertical line array (VLA) without any *a priori* information. Current research strategies range from active methods involving feedback between a pair of VLAs[6] to passive methods in which a VLA is used to accumulate information from acoustic sources and/or noise in the environment.[7–10] This paper demonstrates that, under certain conditions, normal modes can be extracted passively from the received acoustic field in a waveguide without a full water column spanning array, without environmental information and without any modeling.

We introduce a method for determining the acoustic modes of propagation from sound received on a partial-spanning VLA from a horizontally moving source. The method involves a combination of masking individual modal dispersion curves contained in a frequency-wavenumber (f-k) analysis of the data, and a subsequent singular value decomposition (SVD). The method is related to earlier work by Frisk and Lynch[11] in which they Hankel transformed (over range) acoustic data (at a single frequency) recorded on a single receiver from sources spanning a range aperture at a single depth in order to estimate the Green's function characterizing the shallow ocean waveguide. Extending this idea to broadband signals measured at many depths using the receivers of the VLA leads to a comprehensive knowledge of the depth-dependent f-k structure of the waveguide. By combining this knowledge with the physics of modal dispersion, it possible to overcome the inherent limitations to the applicability of other SVD based methods; namely singular value degeneracy and the full-spanning requirement.

SVD methods are based on the premise that the equation describing the decoupled full-spanning cross spectral density matrix (CSDM) of the frequency domain acoustic field is isomorphic to its SVD. Existing SVD methods rely on range, frequency, and ambient noise ensemble averaging to decouple the modes in the CSDM.[9,10] In this paper we introduce a frequency-wavenumber (f-k) modal dispersion curve isolation, or mode isolation (MI), scheme for decoupling the modes in the CSDM. By decomposing the acoustic field into its wavenumber components, it is possible to isolate the modes in the f-k domain prior to formation of the CSDM. Our scheme involves the formation of several CSDMs, each of which contains significant contributions from only one modal component of the acoustic field. Then a SVD is applied to each f-k averaged CSDM in order to extract each modal depth dependence one at a time. Not only does this eliminate the ambiguities arising from singular value degen-

---

[a]Electronic mail: shane@physics.ucsd.edu

eracies, it frees the SVD from its fully spanning constraint so that modes can be extracted over any portion of the water column for any sound speed profile.

Section II reviews the theory of SVD-based mode extraction. The conditions under which the SVD of the CSDM is expected to be isomorphic to the depth-dependent modes are discussed in Sec. II C. The range-averaged form of the CSDM introduced in Ref. 9 is used as an example. As well, the limitations of the SVD are addressed, namely those involving singular value degeneracies and normalization over a partial half-space. (Throughout this paper, the term "half-space" is meant to refer to all media below the surface of the water, i.e., the water column and all bottom layers.) The MI method is introduced and its advantages over other SVD methods are discussed in Sec. II D. Mode extraction results for both simulated and laboratory data are presented in Sec. III.

II. THEORY: SVD MODE EXTRACTION FROM VLA DATA

In this section we explicitly develop the relationship between acoustic data on an array, normal mode expansions, and the SVD process. After presenting this analysis, we then formally develop our extraction method.

A. Normal mode theory applied to the VLA pressure field

Normal mode theory states that the single frequency component, at angular frequency ω_j, of pressure field $p(z', z_q, \omega_j, r_h)$, at receiver point $(z = z_q, r = 0)$ in a range-independent waveguide with depth-varying density, $\rho(z)$, due to a time-varying pressure signal originating from point source, $S(t - t_0)$, located at the source point $(z = z', r = r_h)$ is given by

$$P_{qhj}(z') \equiv p(z', z_q, \omega_j, r_h)$$
$$= \frac{\sqrt{2\pi}e^{i\pi/4}}{\rho(z')} \sum_{m=1}^{M} \frac{\phi_m(z', \omega_j)\phi_m(z_q, \omega_j)}{\sqrt{k_m(\omega_j)r_h}} e^{-ik_m(\omega_j)r_h} \widetilde{S}(\omega_j).$$
$$(1)$$

Here M is the number of propagating modes supported by the environment, $\widetilde{S}(\omega_j)$ represents the Fourier transform of $S(t - t_0)$

$$\widetilde{S}(\omega_j) \equiv \frac{1}{2\pi} \int_{-\infty}^{+\infty} S(t - t_0)e^{-i\omega_j t}\, dt, \quad (2)$$

and $k_m(\omega_j)$ is the modal wavenumber. The $\phi_m(z_q, \omega_j)$ are the normalized, orthogonal depth-dependent mode functions satisfying

$$\int_0^{D'} \frac{\phi_m(z_q, \omega_j)\phi_m(z_q, \omega_j)}{\rho(z_q)}\, dz_q \equiv \delta_{mn}. \quad (3)$$

Rigorously, δ_{mn} represents a Kronecker-delta function when D' spans the entire half-space. The variables z_q, ω_j, and r_h are subscripted in order to facilitate the connection between the theoretical discussions in the continuous limit to follow and their discretized experimental implementations. Explic-
FIG. 1. Experimental setup. VLA composed of Q transducers at depths z_q (open circles) located at range $r = 0$ records acoustic field from sources at ranges $r = r_h$ and depth z'. The acoustic fields from sources at the same depth for many ranges (closed circles) are recorded individually.

itly, discretization is introduced to describe the experimental situation shown in Fig. 1 such that z_q is the depth of the qth VLA receiver element, r_h is the range of the hth source, and ω_j is the jth signal frequency component. Under an integral, a subscript serves as a label on a continuous variable. Under a summation, a subscript serves as a proper index. Functions of subscripted independent variables may also adopt the subscripted notation. Two notable examples are

$$k_m(\omega_j) \to k_{mj}, \quad \phi_m(z_q, \omega_j) \to \phi_{qmj}.$$

B. The SVD

Any $Q \times Q$ complex matrix $\mathbf{A}$ can always be written as a product of matrices such that

$$\mathbf{A} = \mathbf{USV}^\dagger, \quad A_{qq'} = \sum_{\alpha=1}^{N} u_{q\alpha}s_{\alpha\alpha}v_{\alpha q'}^*, \quad (4)$$

where $\mathbf{U}$ and $\mathbf{V}$ are unitary matrices, $\mathbf{V}^\dagger$ is the complex conjugate transpose of $\mathbf{V}$, and $\mathbf{S}$ is a diagonal matrix whose elements are the singular values of $\mathbf{A}$ and are positive. N is the number of rows of $\mathbf{Q}$ (and $\mathbf{V}$). $\mathbf{U}$ and $\mathbf{V}$ are unique when the singular values are nondegenerate. Performing a SVD on $\mathbf{A}$ yields $\mathbf{U}$, $\mathbf{V}$, and $\mathbf{S}$. By design, the SVD implementation we use orders the column vectors of $\mathbf{U}$ and $\mathbf{V}$ according to their respective singular values, with the vector corresponding to the greatest singular value appearing in the first column, the vector corresponding to the next highest singular value in column 2, and so forth.

C. The SVD of the decoupled CSDM and the normal modes

The SVD-based mode extraction algorithms defined in Refs. 8 and 9 involve the formation of the spatial cross-spectral density matrix (CSDM), $\mathbf{C}$, as the outer product of the complex frequency domain pressure field, $\mathbf{P} \equiv P_{qhj}(z')$ data array, with its complex conjugate transpose (for either constant h or constant j), $\mathbf{P}^\dagger$, averaged over range and/or frequency. In general, $\mathbf{C}$ is a complex $Q \times Q$ matrix where Q is the number of elements on the VLA. In accordance with Sec. II B, $\mathbf{C}$ may be written as a product of matrices $\mathbf{U}$, $\mathbf{V}$, and $\mathbf{S}$. Under the proper conditions, an isomorphism exists between some of the columns of $\mathbf{U}$ and some of the propagating depth-dependent modes. The remainder of this section briefly summarizes the connection between the SVD of the

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Walker *et al.*: Shallow water mode extraction   1519

CSDM and the depth-dependent modes using the range averaging or multiple range (MR) method of Ref. 9 as an example.

In the MR method, the CSDM, $\mathbf{C}^{MR}$, is defined as an average over ranges,

$$\mathbf{C}^{MR} \equiv \langle \mathbf{P}\mathbf{P}^{\dagger} \rangle^{MR},$$
(5)

$$C_{qq'}^{MR} = \frac{1}{H}\sum_{h=1}^{H} P_{qhj}(z')P_{hq'j}^{*}(z') = \sum_{m,n=1}^{M,M} \phi_{qmj}\phi_{nq'j}^{*}\delta_{mn}^{MR},$$

where

$$\delta_{mn}^{MR} \equiv \frac{2\pi|\widetilde{S}_{j}|^{2}\phi_{mj}(z')\phi_{nj}^{*}(z')}{H\rho^{2}(z')\sqrt{k_{mj}k_{nj}}}\left(\sum_{h=1}^{H}\frac{e^{-ik_{mnj}r_{h}}}{r_{h}}\right),$$
(6)

$$k_{mnj} \equiv k_{mj} - k_{nj}.$$
(7)

The MR method utilizes the information from a single frequency component, ω_{j}, of many acoustic pressure fields recorded at points z_{q} on the receiver VLA. The pressure fields are accumulated sequentially from sources at many ranges, r_{h}, all at the same depth z'. For a single frequency (constant j) then, $P_{qhj}(z')$ are the elements of a $Q \times H$ matrix for Q VLA elements and H range samples. For the case of adequate range sampling over a sufficiently large aperture, the summation over range in Eq. (6) results in the term in parentheses approaching an unnormalized Kronecker-delta function in the indices m and n. In this case, δ_{mn}^{MR} approaches a diagonal matrix so that Eq. (5) reduces to the approximation

$$C_{qq'}^{MR} \approx \sum_{m=1}^{M} \phi_{qmj}\phi_{mq'j}^{*}\delta_{mm}^{MR}.$$
(8)

Comparison to Eq. (4) makes explicit the isomorphism between the matrices $\mathbf{U}$ and $\mathbf{V}$ and the depth-dependent modes, ϕ_{qmj}, as well as the isomorphism between the singular values and the diagonal elements δ_{mm}^{MR},

$$U_{q\alpha} \equiv \vec{U}_{\alpha} \leftrightarrow \vec{\phi}_{mj} \equiv \phi_{qmj}, \quad s_{\alpha\alpha} \leftrightarrow \delta_{mm}^{MR}.$$
(9)

As the quantity δ_{mm}^{MR} is proportional to the intensity of mode m, the modes will be ordered according to their intensities measured at the VLA. Therefore, column 1 of the matrix $\mathbf{U}$ (and $\mathbf{V}$ as well), $\vec{U}_{1}$, returned by applying a SVD to the CSDM, is isomorphic to the depth-dependent mode of greatest intensity normalized to unity, and so forth. This isomorphism is valid only for modes which are completely decoupled from all other modes, i.e., for modes m for which δ_{mn}^{MR} approaches a Kronecker-delta function for all $n \neq m$. CSDM mode decoupling depends on the total number of sources, H, the span in range, or range aperture, of the sources, Δr, and the sampling interval of the sources, dr.[8,9]

Applying similar reasoning to a frequency-averaged form of the CSDM, a method we refer to as the frequency averaging or multiple frequency (MF) method, an isomorphism can be established between the frequency-averaged acoustic modes and the SVD column vectors in the case of limited bandwidth where the frequency-averaged acoustic modes are an adequate approximation to the true frequency-dependent modes. Proceeding further, it is possible to improve mode decoupling, and hence the mode extraction results, by combining the MR and MF methods. This hybrid method, MRMF, applies the SVD to a time- and range-averaged form of the CSDM to extract the modes.

CSDM mode decoupling is a necessary but not sufficient condition for the extraction of a given mode. For the case of degenerate singular values, $\mathbf{U}$ and $\mathbf{V}$ are not unique. Specifically, all column vectors of $\mathbf{U}$ whose corresponding singular values are degenerate are not unique. Hence, an isomorphism cannot be established between these vectors and any of the depth-dependent modes. As well, because $\mathbf{U}$ is unitary, the isomorphism is valid only when the matrix formed by the set of modes, $\mathbf{\Phi}_{j} \equiv \{\phi_{qmj}\}$ (the subscript j is included in reference to the MR case where a single frequency component is considered), is unitary. This is only true when $\mathbf{\Phi}_{j}$ spans the entire half-space, otherwise, $\Sigma_{q=1}^{Q}\phi_{mqj}\phi_{qnj}$ is not diagonal. This requires that the VLA cover the entire water column and that none of the propagating modes penetrate significantly into the bottom. Not only are the range, frequency, and ambient noise averaging techniques so far proposed in the literature constrained by the full-spanning requirement, but they are also hampered by degeneracy limitations (see Sec. II B).

As a final note, because $\mathbf{U}$ is comprised of Q columns, Q is the maximum number of modes that can be extracted. All the modes can be extracted when $Q \geq M$.

D. Using the f-k structure of the waveguide to extract the normal modes

In this section we augment the utility of range and frequency information in SVD-based methods by considering the underlying physics of modal dispersion in the f-k domain. Not only will such considerations allow us to overcome the degeneracy limitations of the earlier methods, but they also make it possible to extract all the depth-dependent modes projected over a partially spanning VLA.

The mode isolation (MI) method capitalizes on an extra bit of information not considered by the previously discussed mode extraction algorithms: namely, the model wavenumber pattern of an f-k dispersion representation. By accumulating the frequency domain VLA pressure fields from sources at many ranges all at the same depth, it is possible to apply a Fourier transformation over range as well as time. We note that the source ranges need not be evenly spaced.[12] In the case of varying sampling interval, the sampling intervals must be known. The range-wavenumber transformation results in the frequency-wavenumber structure of the waveguide projected over the VLA. This information is useful because in a horizontally stratified waveguide the modal wavenumbers are discrete and localized in the f-k domain, making it possible to isolate the modes (depending on the wavenumber resolution) from one another so that their depth dependence may be extracted individually. The effect of the isolation process is to reweight each isolated mode such that its effective excitation is much greater than the effective excitations of the other modes. This ensures that, upon apply-

ing the SVD to the isolated mode CSDM, the column vector of $\mathbf{U}$ corresponding to the greatest singular value, denoted here as $\vec{U}_1$, is associated with the isolated mode. By design, the SVD calculates the orthogonal column vectors of $\mathbf{U}$ sequentially according to their singular value. As each vector is calculated, it is constrained to be orthogonal with respect to each and every previously calculated vector. Because $\vec{U}_1$ is calculated first, it is not constrained by the orthogonalization process. Rather, it is merely normalized to unity over the spanning space. Furthermore, in the infinite wavenumber resolution limit ($\Delta r \rightarrow \infty$), the mode isolation process guarantees $\vec{U}_1$ to be nondegenerate. As a result, we conclude that $\vec{U}_1$ is isomorphic to the isolated depth-dependent mode projected over the VLA, regardless of the amount of the water column spanned by the VLA.

The remainder of this section is dedicated to the characterization of the MI process in a quantitative framework. Taking the discrete Fourier transform over the sampled ranges of the pressure field, we define the f-k domain VLA pressure field

$$\widetilde{P}_{qh'j}(z') \equiv \sum_{h=1}^{H} P_{qhj}(z') e^{-i\widetilde{k}_{h'} r_h}. \tag{10}$$

$\widetilde{k}_{h'}$ represents the wavenumber conjugate to the range, r_h. Because it is assumed that all the recorded pressure fields originate from the same source depth, the explicit depth dependence of the f-k domain pressure field shall be suppressed for the remainder of the paper. Substituting Eq. (1) and rearranging yields

$$\widetilde{P}_{qh'j} = \frac{\sqrt{2\pi} e^{i\pi/4}}{\rho(z')} \sum_{m=1}^{M} \frac{\phi_{mj}(z')\phi_{qmj}}{\sqrt{k_{mj}}} \widetilde{S}_j \gamma_{mh'j}, \tag{11}$$

where all the wavenumber-dependent phase factors have been included in $\gamma_{mh'j}$,

$$\gamma_{mh'j} \equiv \sum_{h=1}^{H} e^{-i(\widetilde{k}_{h'} + k_{mj})r_h}. \tag{12}$$

For constant range sampling interval, dr, $\gamma_{mh'j}$ reduces to the classical array diffraction result,

$$\gamma_{mh'j} = e^{-i(\widetilde{k}_{h'} + k_{mj})R_0} \frac{\sin((\widetilde{k}_{h'} + k_{mj})Hdr/2)}{\sin((\widetilde{k}_{h'} + k_{mj})dr/2)}, \tag{13}$$

where R_0 is the range of the nearest source (at $r=r_1$). The relevance of this result is that $\gamma_{mh'j}$ is peaked around $\widetilde{k}_{h'} = -k_{mj}$. Equation (13) demonstrates explicitly the dependence of the wavenumber resolution of the f-k pressure field on the range aperture, $\Delta r = Hdr$. $\gamma_{mh'j}$ approaches a delta function, $\gamma_{mh'j} \rightarrow \delta(\widetilde{k}_{h'} + k_{mj})$, in the infinite wavenumber resolution limit ($\Delta r \equiv |r_H - r_1| \rightarrow \infty$). For each q then, we recognize $\widetilde{P}_{qh'j}$ to be the f-k diagram of modal propagation at depth z_q defining the frequency-dependent wavenumber characteristics of the propagating depth-dependent modes. In the f-k domain, the modes appear as distinct, localized curvilinear regions centered on lines defined by $\widetilde{k}_{h'} = -k_{mj}$. The
FIG. 2. Depth-averaged modulus of the f-k structure of a simulated waveguide. Propagating modes appear as localized dark curves. (a) Unrotated f-k structure. (b) Rotated f-k structure. (c) Magnified rotated f-k structure showing the mode 4 mask region (black lines). Simulated waveguide parameters: Pekeris waveguide, $D=15$ m, $c_w=1500$ m/s, $c_b=1800$ m/s, $\rho_b =1800$ kg/m³, $dr=2$ m, $\Delta r=1$ km, $r_c=3$ km (r_c is the range to the center of the range aperture), and $z'=15$ m.

localization is a consequence of the discreteness of the modal wavenumber spectrum. Figure 2(a) shows an example of the discrete wavenumber spectrum of a simulated ocean Pekeris waveguide. All f-k domain dispersion figures show the depth-averaged modulus of the spectrum. Because the modal wavenumbers are localized in the f-k domain, it is possible to isolate them. The isolation is accomplished by means of a 2D mask applied in the vicinity of a given mode projected over all VLA elements.

At this point, it is convenient to introduce a modification to our transformation procedure that facilitates the mode isolation process. We emphasize that this modification in no way affects the analysis of the underlying waveguide dispersion physics. Returning to Eq. (10), we introduce a frequency-dependent weighting factor (in parentheses) and define the rotated pressure field

$$\hat{\widetilde{P}}_{qh'j} \equiv \sum_{h=1}^{H} P_{qhj}(e^{i\widetilde{k}_j r_h}) e^{-i\widetilde{k}_{h'} r_h}. \tag{14}$$

Analogously to Eq. (12), the wavenumber-dependent complex phase dependence of the rotated pressure field is

$$\gamma_{mh'j} \equiv \sum_{h=1}^{H} e^{-i(\widetilde{k}_{h'} + k_{mj} - \hat{k}_j)r_h}. \tag{15}$$

As before, for the case of constant range sampling, Eq. (15) reduces to the array diffraction result similar to Eq. (13), only it is peaked about $\widetilde{k}_{h'} = \hat{k}_j - k_{mj}$. The weighting factor transforms the f-k dispersion structure according to the choice for $\hat{k}_j$. The transformation is arbitrary. For example, choosing $\hat{k}_j$ equal to a constant results in a simple translation in wavenumber of the dispersion structure. For our purposes, we find it convenient to define $\hat{k}_j \equiv k_{1j}$ where k_{1j} is the frequency-dependent mode 1 wavenumber. This choice of transformation effectively rotates the f-k structure such that mode 1 curve appears at $\widetilde{k}_{h'} \approx 0$ for all frequencies. We approximate the mode 1 wavenumber $k_{1j} \approx \omega_j/v_{g1}$, where v_{g1} is a frequency independent approximation to the mode 1 group velocity, $v_{g1}=1500$ m/s over the bandwidth.[13] Because the modal wavenumber spectrum density increases as mode number decreases, modal wavenumbers of modes 1 and 2 will be the most difficult to resolve, and, therefore, the most difficult to isolate. This choice of rotation facilitates

the isolation of the low-order modes by rendering them nearly vertical. Figure 2(b) shows the rotation applied to the f-k structure of Fig. 2(a). In this example using simulated shallow ocean waveguide data, all five propagating modes are well resolved in wavenumber.

Referring to the f-k dispersion structure, the mask of mode ν is defined as the set of $\tilde{k}_{h'}$ for which

$$\hat{k}_j - k_{\nu j} - \epsilon_\nu \leq \tilde{k}_{h'} \leq \hat{k}_j - k_{\nu j} + \epsilon_\nu \qquad (16)$$

for each frequency component of interest. The width (in wavenumber) of the mode ν mask is determined by the quantity ϵ_ν. The mask width, and hence ϵ_ν, should be large enough that the mask contains all the important features of mode ν, but still small enough that it does not incorporate significant features of adjacent modes. We adopt the notation $\{X\}_\nu$ to represent the mode ν masking operation applied to the quantity X where X is a synthesis of modal components, $X = \sum_{m=1}^{M} x_m$. Because it is an isolation operation, the masking operation conceptually behaves similarly to the Kronecker delta function, $\delta_{m\nu}$. It isolates the mode ν component of quantity X, $\{X\}_\nu \approx x_\nu$. Applying the masking operation to the rotated f-k pressure field yields

$$\{\hat{\tilde{P}}_{qh'j}\}_\nu \approx \frac{\sqrt{2\pi} e^{i\pi/4}}{\rho(z')} \frac{\phi_{\nu j}(z') \phi_{q\nu j}}{\sqrt{k_{\nu j}}} \tilde{S}_j \gamma_{\nu h'j}. \qquad (17)$$

This form for the masking operation applied to the pressure field is valid in the limit that $\gamma_{mh'j} \rightarrow \gamma_{\nu h'j}$ over the mask region [the region defined by condition (16)]. This is indeed the case when mode ν is well isolated and a mask containing only mode ν can be defined unambiguously. That is, as long as the wavenumber resolution is adequate to render mode ν distinct from its neighboring modes, $\nu-1$ and $\nu+1$, in the f-k domain, the dominant contribution to the pressure field, and hence the CSDM, within the mask comes from mode ν.

Because the depth dependence of the modes is unaffected by the transformation process $(r \rightarrow k)$, it is not necessary to transform back from wavenumber to range in order to form the CSDM. Defining the mask such that there are the same number of wavenumber elements, H', for each frequency, $\{\hat{\tilde{P}}_{qh'j}\}_\nu$ is a $Q \times H' \times J$ array which can be used to form the CSDM directly. J here is the number of frequency components included in the mask. The CSDM is then defined as the double sum over the mode ν mask region

$$C_{qq'} = \frac{1}{H'J} \sum_{h',j=1}^{H'J} \{\hat{\tilde{P}}_{qh'j}\}_\nu \{\hat{\tilde{P}}_{qh'j}\}_\nu^*. \qquad (18)$$

Notice the sum over range is replaced by a sum over the wavenumbers defined by the mask.

Because the CSDM involves frequency averaging, care must be taken in establishing an isomorphism between the modes and the column vectors of the SVD matrix $\mathbf{U}$. Rigorously, the isomorphism is only valid when the depth dependence of the modes can be considered frequency independent. In practice this means that the frequency must be limited to a bandwidth over which the modal depth dependence is nearly constant. In this case the extracted modes can

be thought of as an average over the bandwidth, $\phi_{q\nu j} \rightarrow \langle \phi_{q\nu} \rangle$, so that upon substitution by Eq. (17), Eq. (18) takes the form

$$C_{qq'} = \langle \phi_{q\nu} \rangle \langle \phi_{\nu q'}^* \rangle \tilde{\delta}_\nu, \qquad (19)$$

where

$$\tilde{\delta}_\nu \equiv \frac{2\pi \langle \phi_\nu(z') \rangle \langle \phi_\nu^*(z') \rangle}{H'J\rho^2(z')} \left(\sum_{h',j=1}^{H'J} \left(\frac{|\tilde{S}_j|^2}{\sqrt{k_{\nu j} k_{\nu j}}} \right) \gamma_{\nu h'j} \gamma_{\nu h'j}^* \right). \qquad (20)$$

Clearly then, when mode ν is well resolved in wavenumber [as is the case with mode 4 in Fig. 2(c)], performing the singular value decomposition of $\mathbf{C}$ yields the matrix $\mathbf{U}$ such that the column vector $\vec{U}_1$ is isomorphic to the frequency-averaged depth-dependent mode ν with corresponding singular value s_{11} proportional to $\tilde{\delta}_\nu$,

$$U_{q1} \leftrightarrow \langle \phi_{q\nu} \rangle, \quad s_{11} \leftrightarrow \tilde{\delta}_\nu. \qquad (21)$$

In the case where the masked mode is not well resolved in wavenumber, it is not possible to define a mask that contains only mode ν and the SVD will not work for this mode.

To determine the resolvability of the modal wavenumbers, we consider the range/wavenumber relations of numerical Fourier transform implementations such as the fast Fourier transform (FFT),

$$\Delta r = \frac{2\pi}{d\tilde{k}}, \quad dr = \frac{2\pi}{\Delta\tilde{k}}. \qquad (22)$$

The mode ν wavenumber will be well resolved when the rotated wavenumber sampling interval is much less than the minimum interval separating adjacent modes within the bandwidth, $d\tilde{k} \ll |k_{\nu j} - k_{(\nu-1)j}|_{min}$. This condition determines the minimum range aperture required to resolve mode ν, Δr_ν, in wavenumber,

$$\Delta r_\nu \gg \frac{2\pi}{|k_{\nu j} - k_{(\nu-1)j}|_{min}}. \qquad (23)$$

Because $|k_{\nu j} - k_{(\nu-1)j}|_{min}$ decreases as ν decreases, this effectively sets a lower limit on the lowest mode that is extractable for a given range aperture. At the other end of the spectrum, the width of the rotated wavenumber domain, $\Delta\tilde{k}$, of the f-k diagram determines the highest-order mode appearing in the f-k structure. Then the upper limit on ν that is extractable for a given range sampling interval is set by the condition

$$dr = \frac{2\pi}{|k_{\nu j} - k_{1j}|_{max}}. \qquad (24)$$

In the context of ocean applications, the range aperture needed to resolve mode ν (in the low mode order limit, $\nu \ll 2D/\lambda_w$) is governed by the inequality

$$\Delta r_\nu \geqslant \frac{8D^2}{\lambda_w(2\nu-1)}. \tag{25}$$

Here D is the water depth, and $\lambda_w \equiv f_0/c_w$ is the acoustic wavelength in the water (characterized by sound speed c_w) at frequency f_0. For example, in order to extract all the propagating modes excited by a moving broadband source radiating at a central frequency of 150 Hz in a 100-m-deep waveguide, the source would have to cover greater than 8 km in range aperture. However, extracting modes 3 and greater would require only $\frac{1}{5}$ the range aperture. The sampling interval requirement can be written in terms of physical parameters as $dr \approx \lambda_w(c_b/|c_b-c_w|)$. For water and bottom sound speeds $c_w = 1500$ m/s and $c_b = 1800$ m/s, the sampling interval can be as large as 18 m ($=6\lambda_w$).

III. RESULTS: APPLICATION OF THE MI METHOD TO DATA

In this section we include comparisons of the depth-dependent mode extraction results of the MRMF and MI methods. Mode extractions using both simulated and experimental data are shown. The simulated mode extractions are useful because they allow us to compare the extracted modes with the true modes used to generate the simulated pressure fields. The experimental mode extractions provide a demonstration that the MI mode extraction method is experimentally applicable, a crucial first step proof of concept for shallow ocean applications. In the following sections, the vectors returned by the SVD operation are called SVD vectors. This is done in order to differentiate them from the theoretical modes used to generate the simulation. This differentiation also serves to emphasize that these objects are not always faithful representations of (isomorphic to) the true modes of acoustic propagation.

The effectiveness of range averaging (MR) and ambient noise decoupling SVD methods over a full-spanning array have been demonstrated.[9] Except for degeneracy limitations, our work shows that the MRMF technique works as well as the MI method when applied to data over a full spanning array. Therefore, we shall not dwell on full-spanning applications, and instead discuss the more interesting case of partial-spanning applications.

A. Comparison of MI and MRMF methods applied to a partial-spanning VLA simulation

Range and frequency-averaging CSDM decoupling scheme SVD methods, such as the MR, MF, and MRMF methods, have been applied to experimental data. The success achieved by such methods has been demonstrated to be limited by the constraints mentioned in Sec. II C, namely the degree of mode decoupling in the CSDM, the degeneracy of the singular values, and the full-spanning requirement. Of these, the latter is by far the most stringent constraint. Whereas some of the modes may be successfully extracted under conditions in which only some of the modes are decoupled and some of the modes are degenerate, these methods fail to extract any of the modes when the VLA does not span the entire water column. The MI technique, on the other
FIG. 3. Depth-averaged modulus of the rotated f-k structure of a simulated waveguide. Propagating modes appear as dark gray curved regions. Modes are enumerated for clarity. Modes 2, 4, and 6 were weakly excited by the source. Hence, they appear to be missing. The mode 7 mask is shown (solid black lines) as an example. Simulation parameters: Pekeris waveguide, $D = 60$ m, $c_w = 1500$ m/s, $c_b = 1800$ m/s, $\rho_b = 1800$ kg/m^3, $dr = 20$ m, $\Delta r = 2$ km, $r_c = 3$ km, and $z' = 30$ m.

hand, can extract all modes for which the wavenumber resolution is adequate over a partial-spanning array. In this section we use simulation to demonstrate the MRMF and MI methods' respective abilities to extract the depth-dependent modes of acoustic propagation over a partial-spanning VLA. Because the data is simulated it is possible to compare the extracted modes to theory.

We simulated the VLA pressure fields resulting from distant broadband (400–600 Hz) sources in a shallow ocean Pekeris waveguide characteristic of near shore environments of interest. The water depth was 60 m. The VLA consisted of 33 evenly spaced elements with element 1 at a depth of 12 m and element 33 at depth 44 m. The resulting f-k dispersion is shown in Fig. 3. Clearly, there are many propagating modes. The first 12 modes are labeled for clarity. Modes 2, 4, and 6 are weakly excited and do not appear on the dispersion plot. This results from the source depth being chosen to be at the midpoint of the water column.

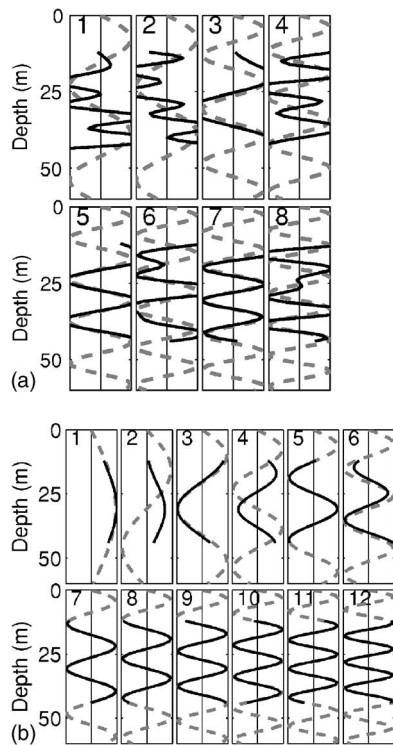
Figure 4(a) shows the SVD vectors produced by the MRMF method applied to the simulated pressure field. The MRMF SVD vectors were matched to all the theoretical modes. Each SVD vector is plotted with its closest matching theoretical mode. On the other hand, as seen in Fig. 4(b), when it comes to extracting depth-dependent modes projected over only a portion of the water column, the MI method performs remarkably well. Whereas in the MRMF case we do not automatically know to which mode a given SVD vector corresponds, in the MI case we know which mode we are attempting to extract. As the wavenumber separation between the modes decreases, each mask contains increasing residuals from adjacent modes. If the mode for which the mask is defined is weakly excited compared to an adjacent mode, the extraction process will result in a mix of adjacent modes. As a result, we see that the weakly excited modes (2, 4, and 6) are not well extracted. The remaining modes are well extracted, with one caveat. It is possible to properly determine mode 1 in this example only because mode 2 is absent. Otherwise, due to the limited wavenumber resolution, it would not have been possible to isolate mode 1 from mode 2.


FIG. 4. Comparison of MRMF and MI method mode extractions using simulated pressure field data over part of water column (12–44 m). (a) Depth-dependent modes extracted using the MRMF method. (b) Depth-dependent modes extracted using MI method. The SVD vectors (solid lines) are plotted with the theoretical modes (dashed lines) used to generate the data. Each numbered panel shows one SVD vector along with corresponding theoretical mode. In the MRMF case only the real components of the eight best matching MRMF SVD vectors are shown along with their best matching theoretical modes. Simulation parameters: same as Fig. 3.

B. MI method applied to experimental data

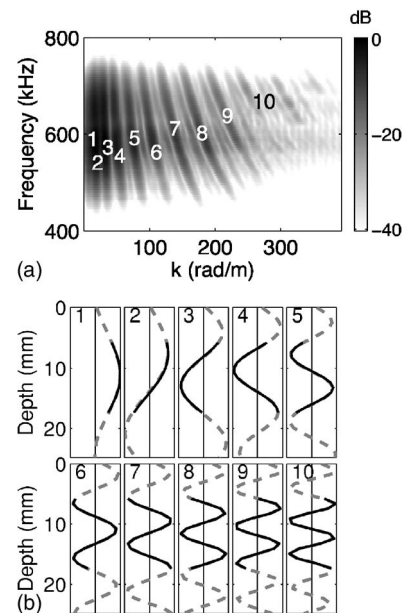
Figure 5 shows mode extraction results of the MI method applied to experimental data. The experiment was designed to mimic a typical shallow ocean range-independent environment at approximately a 1:10 000 scale. Whereas ocean environments of interest typically involve ranges on the order of kilometers, depths on the order of tens of meters, and wavelengths on the order of meters, the experimental ranges were on the order of a meter (ranges between 390 and 900 mm), the experimental depth was on the order of tens of millimeters ($D \approx 27$ mm), and the acoustic wavelength was on the order of millimeters ($\lambda \approx 2.5$ mm). The waveguide consisted of approximately 27 mm ($\approx 10.5\lambda$) of fresh water over a homogenous sand bottom. A vertical line array (VLA) measured the pressure fields individually from $H=301$ identical broadband ultrasonic sources (400 kHz bandwidth at 600 kHz carrier frequency) located at evenly spaced range intervals between 390 and 990 mm ($\approx 160 - 400\lambda$). The VLA consisted of $Q=31$ evenly spaced hydrophones spanning most of the water column (see Fig. 1). The absolute depths of the array elements were unknown. The minimum and maximum source ranges were constrained by the physical dimensions of the waveguide apparatus. The water depth and source frequency were chosen to produce ten propagating modes in a regime where the wavenumber resolution produced by the range aperture would be adequate


FIG. 5. MI method mode extraction results using ultrasonic experimental pressure field data over full-spanning (VLA elements 1–31) and partial-spanning (elements 8–22) VLAs. (a) Depth-averaged modulus of the rotated f-k structure of the experimental waveguide. Propagating modes appear as dark gray curved regions. Modes are enumerated for clarity. (b) MI SVD vectors from partial-spanning VLA data are indicated with solid lines. Full-spanning VLA SVD vectors appear as dashed lines. Only modes 1–10 are shown. Experimental parameters: fresh water over sand bottom, $D =27$ mm, $c_w \approx 1490$ m/s, c_b unknown, ρ_b unknown, $z' \approx 26$ mm, $dr =1$ mm, $\Delta r=600$ mm, and $r_c=690$ mm.

for resolving most of the modal wavenumbers. The source depth was chosen to be near the bottom to ensure that all the modes would be excited by the source. As seen in the resulting f-k diagram of Fig. 5(a), there were indeed ten propagating modes, seven of which were well isolated. Figure 5(b) shows the MI SVD vectors resulting from both full-spanning (dashed lines) and partial-spanning (dark lines) VLA geometries. The full spanning case utilized data from all 31 VLA elements, while the partial-spanning extraction used data from elements 8–22 ($\approx 6-17$ mm). Excluding mode 1, the full-spanning SVD vectors appear remarkably sinusoidal. Furthermore, the partial-spanning SVD vectors coincide perfectly with the corresponding portions of the full-spanning vectors. As mentioned, this would not be the case for the MRMF method. The wavenumber resolution was not adequate to isolate modes 1 and 2 (and perhaps mode 3).

IV. SUMMARY AND DISCUSSION

We have demonstrated the conditions under which the singular value decomposition (SVD) of a cross-spectral density matrix (CSDM) is expected to yield column vectors that are isomorphic to the depth-dependent modes of acoustic propagation. Typically, in order for the isomorphism to be valid (*i*) the CSDM must sample the entire half-space [the vertical line array (VLA) over which acoustic data is recorded must at least span the entire water column]; (*ii*) the modes must be decoupled in the CSDM; and (*iii*) the singular values returned by the SVD must be nondegenerate. The constraints posed by these conditions limit the applicability

of the current collection of SVD and eigenvalue decomposition mode extraction methods in the literature. The full spanning requirement alone is a formidable constraint to overcome in ocean applications. Add to this the degeneracy limitation, which arises whenever two or more modes arrive at the VLA with nearly equal intensities, and it is unlikely that such techniques will have significant practical applications in the ocean.

In order to address these shortcomings, we introduced a variation on the current SVD methods which incorporates a knowledge (by measurement) of the dispersion characteristics of the waveguide environment. Because the modes are dispersed and localized in the frequency-wavenumber (f-k) domain, it is possible to isolate and deal with them individually. Our mode isolation (MI) technique proved effective at extracting the modes of acoustic propagation over a VLA covering only a portion of the water column. In addition, because the modes are extracted individually, the MI technique does not suffer from degeneracy limitations.

The MI method is subject to two constraints: the soft constraint that the bandwidth be limited to a regime in which the depth dependence of the modes is weakly frequency dependent, and the hard constraint imposed by the available range aperture. The latter constraint, related to the CSDM mode decoupling requirement mentioned in (*ii*) above, determines the wavenumber resolution. It is the wavenumber resolution that dictates whether or not a given modal wavenumber will be well localized in the f-k domain. The MI technique is expected to perform well when the modes are well localized in the f-k domain regardless of the sound speed profile.

As a practical matter, it is worth mentioning that it is not necessary to determine the absolute ranges of the sources under the condition that they are evenly spaced. In this case transforming to wavenumber leads to the same fundamental f-k modal dispersion. Any error in estimating the range interval between the sources results only in a simple linear wavenumber scaling of the modal dispersion. In ocean applications, time gating the acoustic signal from a passing ship traveling at a constant velocity far from its closest point of approach might fulfill our requirement of evenly spaced acoustic sources. A misestimation of the ship's velocity would result in a linear scaling of the ranges and would not adversely affect the application of the MI mode extraction technique.

The high sidelobe level of the ambiguity surface has been a major drawback of matched field processing in ocean waveguides compared to the free space beamforming. In this paper, a contrast-maximized optimization scheme that enhances the contrast between the acoustic power output of the source region and the power output of the total region of interest is presented. The method utilizes the signal vectors determined from the contrast-maximizing formulation. Through numerical simulation and oceanic data analysis, the presented algorithm is shown to be effective in improving the contrast between the target and the averaged background sidelobe level. It was also shown that, even when the resolution of the source region in conventional matched field processing is degraded due to severe bottom attenuation, the resolution of the source is not affected in the contrast-maximized method. The same principle and method can be applied to the time-reversal processing to maintain the focal size in an ocean environment with high bottom attenuation. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1993131]

I. INTRODUCTION

Matched field processing (MFP) is an approach for localizing acoustic sources by comparing acoustic data with solutions of the wave equation. MFP can also be viewed as a generalized beamforming technique that takes advantage of the spatial structure of the sound field of a signal propagating in the ocean to provide improved localization performance compared to the conventional plane wave beamformer.[1] One of the advantages associated with the use of the MFP is that the ambiguity surface provides the localization result in range and depth terms, while the plane wave beamformer gives only the direction.

However, since the matched field processor exploits the spatial complexities of the acoustic field in the waveguide, the ambiguity surface produced by MFP typically contains, in addition to the signal peak, false peaks or sidelobes, which make the localization of an acoustic source ambiguous. The conventional MFP (CMFP) in an ocean waveguide tends to suffer from higher sidelobe levels than the conventional beamforming in free space, where the sidelobe level is around 13 dB less than the mainlobe level.

In order to avoid the ambiguity or to reduce the sidelobe effects, incoherent and coherent processors are widely used.[2–6] Sidelobe effects are additionally mitigated by using adaptive MFP (AMFP)[7–10] which minimizes the beamformer energy interfering with the signal by imposing a constraint that a signal in look-direction is passed without distortion.

The purpose of this paper is to present a method to suppress the sidelobe level of ambiguity surface produced by MFP in an ocean waveguide. In order to achieve lower side-lobes level, an adaptivity was introduced to find the signal vector to be correlated, or to be beamformed in the case of plane wave beamforming. The signal vector was determined from an optimization scheme to maximize the contrast between the source region and the search region of interest. The same principle has been applied to the generation of an acoustically bright spot in active noise control based on the contrast-maximizing optimization scheme using multiple sources in a free space.[11] In this paper, an optimization method for contrast maximization was extended to MFP in an ocean waveguide. The same principle and method can be applied to the time-reversal processing in order to reduce the focal size in an ocean waveguide with high bottom attenuation.

The remainder of this paper is organized as follows. In Sec. II, the two optimization schemes, maximization of power and contrast, are reviewed and the issues in waveguides are discussed. The simulated results of MFP in an ocean waveguide are presented and discussed in Sec. III. In Sec. IV, ocean acoustic data are analyzed to show the effectiveness of the contrast-maximized method in MFP. Section V summarizes the work.

II. THEORY

The conventional MFP is reviewed in Sec. II A, and then reformulated from the view point of power-optimization problem in Sec. II B. Finally, the theory on the contrast-maximized optimization method in MFP is presented.

In order to demonstrate the applicability of the contrast-maximized optimization method in MFP, two regions were defined as shown in Fig. 1. The search region was denoted as V_t, and the source region as V_s, which was assumed included inside V_t.

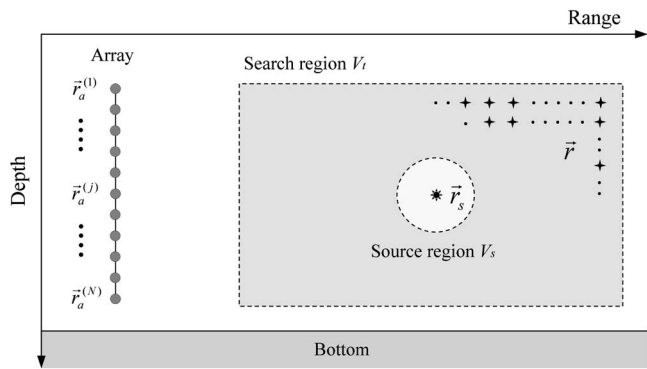

FIG. 1. (Color online) Schematics of acoustic regions in an ocean wave-guide.

A. Review of the conventional MFP

Defining the received acoustic pressure at the jth array element as $d(\vec{r}_a^{(j)}|\vec{r}_s)$ in frequency domain, MFP can be formulated as a correlation process between the replica generated from the propagation model and the data measured at an array:

$$P(\vec{r}) = \sum_{j=1}^{N} d^*(\vec{r}_a^{(j)}|\vec{r}_s) g(\vec{r}|\vec{r}_a^{(j)}) = \mathbf{d}^+ \mathbf{g}(\vec{r}|\mathbf{r}_a) = \mathbf{d}^+ \mathbf{w}, \qquad (1)$$

where the subscripts a and s denote the array and source, respectively, and $g(\vec{r}|\vec{r}_a^{(j)})$ represents the normalized Green's function at the arbitrary location $\vec{r}$ propagated from the jth array element location $\vec{r}_a^{(j)}$ as shown in Fig. 1. The number of the array elements is denoted as N. The superscripts $(\ )^*$ and $(\ )^+$ denote complex conjugate and Hermitian transpose, respectively. In a vector notation, the data vector, $\mathbf{d}$, and the replica vector, $\mathbf{w}$, which is mathematically equivalent to the normalized Green's function $\mathbf{g}$, are $(N \times 1)$ column vectors. Note that the position vectors are written in *italic* letters with arrows and column vectors and matrices are written in boldface letters.

B. Conventional MFP as a power optimization problem

Now, in order to introduce the "acoustical contrast" concept to MFP, the space-averaged power output is defined as the acoustical brightness of a given region. Replacing the signal vector $\mathbf{d}$ by $\mathbf{x}$, which is a more generalized form of the data vector to be correlated with the replica vector, the space-averaged power output σ_s and σ_t in the regions V_s and V_t can be formulated as

$$\sigma_s = \frac{1}{V_s} \int_{V_s} P(\vec{r}) P^*(\vec{r}) \, dV = \mathbf{x}^+ \mathbf{R}_s \mathbf{x}, \qquad (2)$$

$$\sigma_t = \frac{1}{V_t} \int_{V_t} P(\vec{r}) P^*(\vec{r}) \, dV = \mathbf{x}^+ \mathbf{R}_t \mathbf{x}, \qquad (3)$$

where

$$\mathbf{R}_s = \frac{1}{V_s} \int_{V_s} \mathbf{g}(\vec{r}|\mathbf{r}_a) \mathbf{g}^+(\vec{r}|\mathbf{r}_a) \, dV = \frac{1}{V_s} \int_{V_s} \mathbf{w}\mathbf{w}^+ \, dV, \qquad (4)$$

$$\mathbf{R}_t = \frac{1}{V_t} \int_{V_t} \mathbf{g}(\vec{r}|\mathbf{r}_a) \mathbf{g}^+(\vec{r}|\mathbf{r}_a) \, dV = \frac{1}{V_t} \int_{V_t} \mathbf{w}\mathbf{w}^+ \, dV. \qquad (5)$$

Each element of $\mathbf{R}_s$ and $\mathbf{R}_t$ represents the spatial correlation of the Green's functions, $\mathbf{g}$, in the two regions produced by each array element. It is worth noting that the correlation value in Eq. (2) has a maximum at the point source, where V_s is given by a point located at $\vec{r}_s$. For this reason, $\mathbf{R}_s$ is the covariance matrix of the replica vector for the acoustic field at the array propagated from the sources. In a similar way, the covariance matrix $\mathbf{R}_t$ can be constructed from replica vectors derived from the propagation model as shown in Eq. (5).

The conventional matched field processor or the Bartlett processor can be considered as a power optimization scheme, which gives a maximum power in a source region for given input power. In order to have maximum power at the source region, the problem can be stated as

$$\max_{\mathbf{x}} \sigma_s = \mathbf{x}^+ \mathbf{R}_s \mathbf{x} \ \text{subjected to} \ P_0 = \mathbf{x}^+ \mathbf{x}. \qquad (6)$$

The above equation may also be formulated as a pure (unconstrained) optimization problem using a form known as the Rayleigh quotient.[12,13] Therefore, maximizing the σ_s under given input power constraint is equivalent to maximizing the following ratio:

$$\alpha = \frac{\sigma_s}{P_0} = \frac{\mathbf{x}^+ \mathbf{R}_s \mathbf{x}}{\mathbf{x}^+ \mathbf{x}}. \qquad (7)$$

The ratio α represents the quantity of space-averaged output power generated in the source region by unit input power. The optimum data vector $\mathbf{x}_\alpha$, which maximizes the Rayleigh quotient in Eq. (7), corresponds to the eigenvector having the largest eigenvalue of $\mathbf{R}_s$. In conventional MFP, the optimum data vector $\mathbf{x}_\alpha$ reduces to the unprocessed data vector at the array $\mathbf{d}$ with a rank equal to one.

C. MFP as an acoustical contrast optimization problem

While the optimization problem in Sec. II B is to maximize the correlation in the source region, another optimization scheme to maximize the contrast between the source region and the search region can be formulated. The derivation of the contrast-maximized matched field processor is very similar to that of the maximum signal-to-interference ratio (SIR) for adaptive beamforming.[13]

The signal vector can be chosen to directly maximize the contrast between the source region and the search region. Assuming that $\mathbf{R}_s$ and $\mathbf{R}_t$ are known [which are the cross-spectral density matrix calculated from the replica vector in Eqs. (4) and (5)], we may choose to maximize the ratio of the space-averaged power output in the source space (σ_s) and the space-averaged power output in the search space (σ_t). That corresponds to the maximization of the following cost function:
FIG. 2. (Color online) Setup for numerical simulation in the Pekeris waveguide.

$$\beta = \frac{\sigma_s}{\sigma_t} = \frac{\mathbf{x}^+\mathbf{R}_s\mathbf{x}}{\mathbf{x}^+\mathbf{R}_t\mathbf{x}}. \tag{8}$$

This function, expressed as the ratio of two quadratic forms, essentially determines the ratio of the spaced-averaged output power in V_s to that in V_t (Fig. 1) and is well known as Rayleigh quotient. Now the problem is reduced to the determination of the optimum signal vector, which maximizes the Rayleigh quotient. Taking the derivative of Eq. (8) with respect to $\mathbf{x}$ and setting it to zero, we obtain

$$\mathbf{R}_s\mathbf{x} = \beta\mathbf{R}_t\mathbf{x}, \tag{9}$$

which appears to be a joint eigenproblem. The value of β is bounded to the minimum and maximum eigenvalues of the symmetric matrix $\mathbf{R}_t^{-1}\mathbf{R}_s$. The signal vector that maximizes β is given by the following form:

(a)

(b)
FIG. 3. (Color online) Simulation results. (a) Ambiguity surfaces by conventional MFP. (b) Ambiguity surfaces by contrast maximized MFP.

(a)

(b)
FIG. 4. (Color online) Ambiguity surfaces as function of range for point source case: (a) unnormalized plot and (b) normalized plot. The solid and dashed lines represent results by conventional MFP and contrast maximized MFP, respectively.

Shin and Kim: Matched field processing with contrast maximization
FIG. 5. (Color online) Simulation results for various bottom attenuation. (a), (c), and (e) were with the conventional signal vector. (b), (d), and (f) were with a contrast signal vector. The attenuation for (a) and (b) is $0\text{dB}/\lambda$, and $0.5\text{dB}/\lambda$, for (c) and (d), $1.0\text{dB}/\lambda$, for (e) and (f).

$$(\mathbf{R}_t^{-1}\mathbf{R}_s)\mathbf{x}_\beta = \beta_{\max}\mathbf{x}_\beta. \qquad (10)$$

The solution to the above Eq. (10) is well known and is equal to the eigenvector corresponding to the maximum eigenvalue of $\mathbf{R}_t^{-1}\mathbf{R}_s$. Thus, if the pressure fields produced by each control source can be predicted within V_t, which is inherently assumed in MFP, it is possible to construct the covariance matrix $\mathbf{R}_s$ and $\mathbf{R}_t$ based on Eqs. (4) and (5). Now, the optimal signal vector $\mathbf{x}_\beta$ obtained from the data vector $\mathbf{d}$ can be calculated and used as the signal vector to be correlated in the contrast-maximized optimization scheme.

In summary, we define the variables and state how they

are found. The data vector measured at the array is denoted as $\mathbf{d}$, and the processed data vector to be used for a different optimization scheme, such as contrast maximization, is expressed as $\mathbf{x}$. The processed data vectors, $\mathbf{x}_\alpha$ and $\mathbf{x}_\beta$, in Secs. II B and II C, represent the generalized data vectors for conventional MFP and contrast-maximized MFP and can be calculated from the eigenanalysis. Finally, the covariance matrices $\mathbf{R}_s$ and $\mathbf{R}_t$ are found from Eqs. (4) and (5), respectively.

III. SIMULATION IN AN OCEAN WAVEGUIDE

In Secs. II B and II C, two types of signal vector were considered. One is the conventional data vector $\mathbf{x}_\alpha$, which

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005   Shin and Kim: Matched field processing with contrast maximization   1529
FIG. 6. Variation of (a) peak value and (b) PBR as functions of the bottom attenuation. The solid and dashed lines represent results by conventional and contrast signal vector, respectively.

gives a maximum power in a source location for given input power of $\mathbf{x}^+\mathbf{x}$. The other is the contrast signal vector $\mathbf{x}_\beta$, which is to maximize the contrast between the finite region containing source and the entire search region. In this section, we show that the peak-to-background resolution (PBR) of a contrast-maximized matched field processor with the contrast signal vector is improved by about 3 dB compared to the Bartlett processor.

The experimental setup for a numerical simulation is shown in Fig. 2. The center frequency of the sound source was 500 Hz with unit strength. The field was sampled by a vertical line array containing 17 hydrophones spaced 5 m apart ranging from 10 to 90 m in depth. The ambiguity surfaces were computed for source ranges between 5.5 and 6.5 km away from the array and at source depths of 10 to 90 m. As propagation model, KRAKEN[14] was used throughout the simulation.

A. Statistical quantification of the ambiguity surface

To quantify the performance of overall sidelobe reduction or background suppression for two types of signal vectors, a measure of peak value (P) relative to mean background level (μ) was used. It was called peak-to-background resolution (PBR) and was defined as[15]

$$ \text{PBR} = 10 \log_{10}\left(\frac{P-\mu}{\mu}\right) \text{ dB}, \tag{11} $$

where the mean background level was calculated by excluding source region. We did not infer statistical behavior from them, but merely used them as a measure of "goodness."

B. Interpretation and analysis

Figure 3(a) shows the ambiguity surface produced by the conventional signal (data) vector in the case of the point source. The main peak was seen at the true source location: 50-m depth and 6000-m range. A value of PBR=9.60 dB was obtained for this surface. Figure 3(a) was compared with Fig. 3(b), which is the ambiguity surface obtained by contrast-maximized optimization scheme. Figure 3(b) clearly illustrates that the main peak was still accurately located at the true source location, and additionally the size of the source resolution was greatly improved. Also, it can be seen that PBR is about 12.03 dB, and therefore has improved by about 3 dB.

Figure 4 shows the ambiguity surface as a function of range for the Bartlett processor (solid line) and the contrast method (dashed line) in the case of point source. This figure describes the important difference between two optimization techniques. In Fig. 4(a), the power output of the contrast-maximized processor is approximately 5 dB lower than the power output of the Bartlett processor at the source location. This was due to the fact that the contrast-maximized technique did not maximize the power output at the source location, but maximized the contrast between the two regions. Figure 4(b) shows that the contrast-maximized processor had an excellent sidelobe suppression in an average sense compared to the Bartlett processor.

C. Effect of bottom attenuation

The physical principle on the size of resolution for time-reversal mirror (TRM)[16] is the same as the MFP. While a propagation model was used to match the source-generated sound fields in MFP, the time-reversed signal was physically backpropagated to the original source position using a source-receiver array in a TRM. Hence, the focal size realized with a TRM can be considered as the maximum achievable resolution of a conventional MFP for a given waveguide.

The excited acoustic field can be decomposed into modes, and each mode propagates with its own group speed. During the propagation between the source and the array, some high-order modes that had more interactions with the ocean bottom were removed by waveguide attenuation. The

Shin and Kim: Matched field processing with contrast maximization
FIG. 7. The location and bathymetry for SwellEx-96 Event 59.

focal size or the resolution[11] of a MFP was determined by the remaining effective modes. The focal size in depth and range can be estimated roughly as

$$\Delta_z \approx \frac{D}{M}, \tag{12}$$

$$\Delta_R \approx \frac{2\pi}{k_1 - k_2}, \tag{13}$$

where D is the water depth, M is the number of effective modes, and k_1 and k_M are the horizontal wave numbers of the first and last effective modes, respectively. The vertical resolution is determined by the mode functions while the horizontal resolution is determined by the difference of wave numbers that is the smallest *interference pattern* of the acoustic field. The waveguide attenuation increases the focal size by reducing the number of effective modes. As a consequence, the ambiguity surface is expected to become more blurry and to have higher sidelobes than in the ideal lossless situation.

In this section, the result of numerical experiments on the effects of bottom attenuation on the size of resolution cell and the sideobe level is presented. For simulation purposes, the bottom attenuation was varied between 0 and 1 dB/λ under the point source assumption, while keeping all other parameters unchanged as shown in Fig. 2.

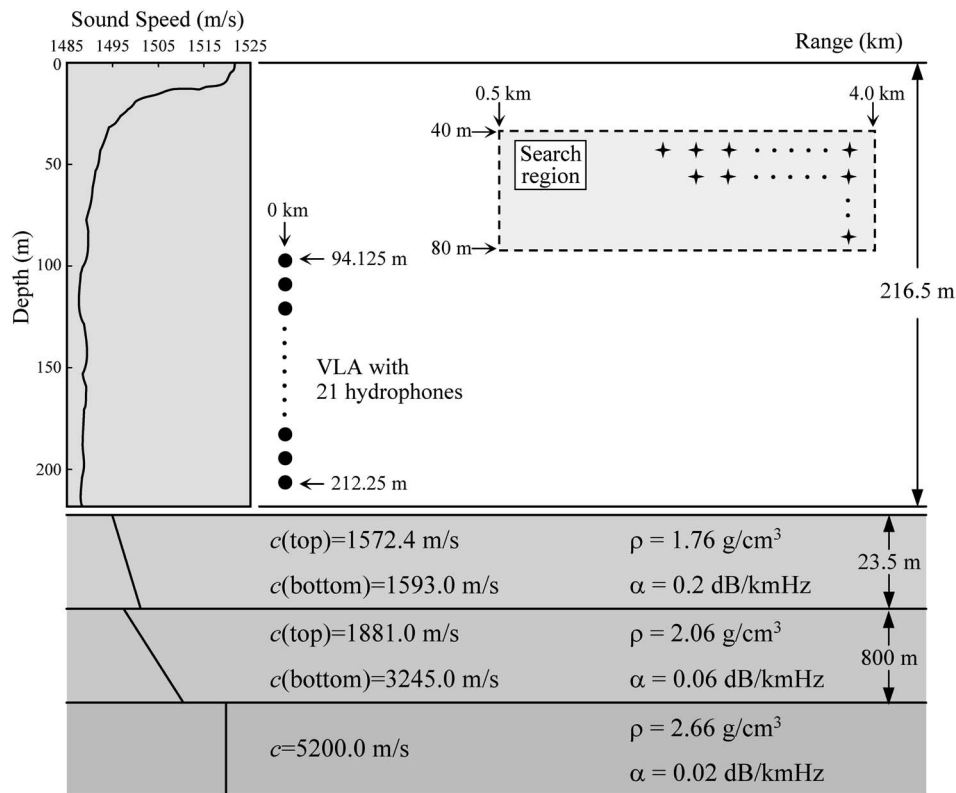
Figure 5 shows the ambiguity surface produced by the Bartlett processor for three bottom attenuation cases. The results by the conventional MFP are shown in Figs. 5(a), 5(c), and 5(e): the depth and range focal size increased with increasing bottom attenuation. The results by the contrast-maximized MFP, illustrated in Figs. 5(b), 5(d), and 5(f), show that there was no changes of focal size although the bottom attenuation increased. Figure 6 shows the peak value and PBR where the bottom attenuation varied from 0 to 1 dB/λ. The solid and dashed lines represent the results by the conventional MFP and the contrast-maximized MFP, respectively. In Fig. 6(a), the peak values by the conventional processor do not change with the attenuation, but the peak values by the contrast-maximized processor rapidly fall down approximately −9 dB at 1-dB/λ attenuation. However, in Fig. 6(b), the PBR by contrast-maximized processor is consistently greater than PBR by the conventional processor. Therefore, it was concluded that the contrast-maximized MFP suppressed the sidelobe levels by about 3 dB when compared to the conventional MFP.


FIG. 8. (Color online) The sound speed profile and geoacoustic parameters for replica vector calculation.

IV. APPLICATION TO OCEANIC DATA

This section describes the application of the contrast-maximization technique to the SwellEx-96 data[17] to verify the applicability of the technique to the matched field processing in a shallow water waveguide. In Sec. IV A, the description of the experiment is given. In Sec. IV B, the results of the contrast-maximized technique in MFP are presented and the quantitative analysis utilizing PBR is described.

A. Description of SWellEx-96 Event 59

The detailed description of the experiment can be found in Ref. 17. Figure 7 shows a plan view of the SwellEx-96 experiment with towed source ship. The solid circle marks on Fig. 7 shows the track of the towed source every 5 min. In order to apply the contrast-maximization technique, the following eight frequencies were used: 49, 64, 79, 112, 130, 148, and 166 Hz. The field was sampled by a vertical line array containing 21 hydrophones spaced 5 m apart and ranging from 94.125 to 212.25 m in depth. The towed source was located between 0.5 and 4 km from the array and at a depth of 60 m.

The KRAKEN[14] normal mode program was used to generate the matched field replica vectors. The depth covered in generating the replica vector was 40 to 80 m with 1-m increment and the range covered was 0.5 to 4 km with 20-m increment. The sound speed profile and relevant parameters used in creating the replica vectors are shown in Fig. 8.

B. Data analysis

In order to track the underwater acoustic source, the ambiguity surface at estimated source depth was displayed based on the procedure described in Ref. 12. First, the ambiguity surfaces for range versus depth were constructed for each frequency and the surfaces were incoherently summed over the eight frequency components. Then, the frequency average of the ambiguity surface was generated for every time step and was displayed at the estimated source depth.

Figure 9(a) shows the ambiguity surface from the Bartlett processor at estimated source depth and Fig. 9(b) illustrates the results of the Bartlett processor with contrast signal vector. The source trajectory is clearly visible in both figures. However, the ambiguity surface from the Bartlett processor had higher sidelobes than the contrast-maximized Bartlett processor.

In order to perform the quantitative analysis of each ambiguity surface, PBR was calculated over the search region for every time step as shown in Fig. 10. The mean background level was calculated by excluding the 100-m range ×10-m depth surrounding the peak location. Figure 10 displays the variation in PBR from 0 to 30 min, for ambiguity surfaces. The solid and dashed lines refer to the PBRs by the conventional and the contrast signal vector, respectively. Figure 10 shows that the PBR significantly improved by about 2 dB.

(a)

(b)
FIG. 9. (Color online) Plot of MFP-derived range versus time obtained from the eight pilot tones along the source track at that source depth with the peak MFP correlation: (a) Bartlett MFP and (b) Bartlett MFP with contrast signal vector.

V. CONCLUSION

A concept of contrast-maximized optimization was introduced to the matched field processing (MFP) in order to
FIG. 10. Variation of PBRs as functions of the time using Bartlett incoherent broadband MFP. The solid and dashed lines represent results of PBRs by conventional and contrast signal vector, respectively.

reduce the sidelobe level of ambiguity surfaces. The signal vectors were determined from an optimization scheme to maximize the relative space-averaged power in the source region to that in the search region of interest. The application of the developed algorithm to numerical simulation and ocean experimental data showed that the peak-to-background resolution (PBR) is improved by about 3 dB. It was also observed that, even when the resolution of the source region in conventional matched field processing was degraded due to severe bottom attenuation, the resolution of the source was not affected in the contrast-maximized method. The same principle and method can be applied to the time-reversal processing to maintain the focal size in an ocean environment with high bottom attenuation.

The inverse-scattering problem and global convergence

Stephen J. Norton

Geophex, Ltd., 605 Mercury Street, Raleigh, North Carolina 27603

In solving nonlinear inverse-scattering problems an iterative approach is usually required, particularly if the nonlinearity is strong. A typical approach is to use a descent algorithm to minimize a global error norm, such as the mean-square error, to arrive at a set of parameters that best predicts the data based on an assumed model of the unknown scattering object. In minimizing the error norm, the possibility of converging to a local minimum can lead to false solutions. A different strategy is proposed that is not based on gradient descent which, at least in principle, should avoid local minima and converge to the true solution (the global minimum). A simple inverse-scattering problem is used as an illustration. © *2005 Acoustical Society of America.*

Pages: 1534–1539

I. INTRODUCTION

Nonlinear inverse-scattering problems can generally be solved only by iteration when the nonlinearity is strong. The usual strategy is to estimate the unknown scattering distribution (or a set of parameters that model the distribution) by iteratively minimizing an error functional. A common choice is the mean-squared difference between the actual observations and observations predicted on the basis of solutions to the forward-scattering problem. For highly nonlinear problems (e.g., when multiple scattering is significant), local minima in the error functional can lead to erroneous solutions. Here we propose a strategy that, in principle, avoids local minima. To illustrate the problem, suppose $\mathbf{p}$ denotes a vector of parameters that models an unknown scattering potential and let $u_m(\mathbf{p})$, $m=1,2,\ldots,M$, represent a set of M observations predicted on the basis of an assumed $\mathbf{p}$, where m could denote measurements, say, at different positions or frequencies. The field quantity $u_m(\mathbf{p})$ can be computed by solving the forward-scattering problem given $\mathbf{p}$. Now denote by $u_m(\mathbf{p}^{(true)})$ the set of actual observations, where $\mathbf{p}^{(true)}$ is the true parameter vector that we wish to determine. A common approach is to estimate $\mathbf{p}^{(true)}$ by searching for a $\mathbf{p}$ that minimizes the mean-square error

$$\mathcal{E}(\mathbf{p}) = \frac{1}{2} \sum_{m=1}^{M} [u_m(\mathbf{p}) - u_m(\mathbf{p}^{(true)})]^2. \qquad (1)$$

When minimizing $\mathcal{E}(\mathbf{p})$ by gradient descent, this approach will yield a solution whenever the gradient of $\mathcal{E}(\mathbf{p})$ vanishes, that is, whenever

$$\frac{\partial \mathcal{E}(\mathbf{p})}{\partial p_n} = \sum_{m=1}^{M} [u_m(\mathbf{p}) - u_m(\mathbf{p}^{(true)})]\frac{\partial u_m(\mathbf{p})}{\partial p_n} = 0, \qquad (2)$$

for all p_n, $n=1,2,\ldots,N$, where p_n are the components of $\mathbf{p}$. As discussed below, this is not always guaranteed to be the point $\mathbf{p}$ for which

$$u_m(\mathbf{p}) - u_m(\mathbf{p}^{(true)}) = 0 \qquad (3)$$

holds for all m. When (3) holds, we have presumably found the true solution (the global minimum), but when (2) holds, a

false solution (or local minimum) may occur, for reasons to be discussed. The approach described in this paper is based on a numerical solution to the system of nonlinear equations defined by (3) using a multi-dimensional Newton's method. When Newton's method converges, it typically finds the global minimum or else fails to converge. For theoretical reasons, when convergence occurs, Newton's method generally will not converge to a local minimum. The Appendix describes a modification of Newton's method that can improve stability, that is, widen the domain of starting values for which Newton's method converges.

In developing a nonlinear inverse-scattering algorithm, a key task in devising an iterative approach is the calculation of the derivatives of the observed field with respect to the parameters, p_n, that model the scattering object. Here we employ the adjoint method, as described in Sec. II (see Ref. 1 for a more detailed discussion of the application of the adjoint method to inverse-scattering problems). Section III describes the multi-dimensional Newton's method, and Secs. IV and V illustrate the technique with a simple example.

By way of illustration, we consider here a simple one-dimensional inverse Helmholtz problem, although the basic approach can be generalized to higher dimensions and to the time domain. Let $\gamma(x,\mathbf{p})$ denote a one-dimensional scattering potential, where $\mathbf{p}$ is a vector of parameters that models the potential. Our objective is to determine $\mathbf{p}$. The 1-D Helmholtz equation is

$$\frac{d^2u(x)}{dx^2} + k^2u(x) + \gamma(x,\mathbf{p})u(x) = S(x), \qquad (4)$$

where $u(x)$ is an appropriate field quantity, k is the wave number in the absence of the scatterer ($\gamma=0$), and $S(x)$ is the source. The components of $\mathbf{p}$ might, for example, represent the coefficients in some convenient basis expansion of $\gamma(x,\mathbf{p})$, i.e.,

$$\gamma(x,\mathbf{p}) = \sum_{n=1}^{N} p_n\phi_n(x), \qquad (5)$$

where $\phi_n(x)$ are a set of suitable basis functions, although more general parametrizations are also possible.[1]

Note that the field depends on both the wave number k and the parameter vector $\mathbf{p}$, and we will sometimes indicate this by writing $u(x,k,\mathbf{p})$. As before, denote by $u(x,k,\mathbf{p}^{(true)})$ the observed field, where $\mathbf{p}^{(true)}$ signifies the true set of parameters. Our task is to find $\mathbf{p}^{(true)}$ from the scattered field observed at some point, x_0, outside the scattering domain. In our example, we shall assume that M measurements are made at different frequencies ω_m or, equivalently, at M wave numbers $k_m = \omega_m/c$, where c is the sound speed in the homogeneous background medium (i.e., when $\gamma = 0$). Then, in the above notation used in (1), the predicted observations are $u_m(\mathbf{p}) \equiv u(x_0, k_m, \mathbf{p})$ and the actual observations are $u_m(\mathbf{p}^{(true)}) \equiv u(x_0, k_m, \mathbf{p}^{(true)})$.

II. PROPAGATION OF DERIVATIVES

In any iterative scheme, we begin by guessing the parameter vector, $\mathbf{p}$, and then, on the basis of our guess, we predict the observation, $u(x_0, k, \mathbf{p})$, and compare it to the actual observation, $u(x_0, k, \mathbf{p}^{(true)})$. A common approach, as described below, is to use a least-squares norm. We describe later an alternative to least-squares estimation. In either case, however, to update our estimate of $\mathbf{p}$, we require the partial derivatives, $\partial u(x_0, k, \mathbf{p})/\partial p$, where p is one component of $\mathbf{p}$. For brevity, we abbreviate $u(x,k,\mathbf{p})$ by $u(x)$ below. To compute $\partial u(x_0)/\partial p$ at the observation point x_0, we employ the adjoint field, $u^\dagger(x)$, defined as the solution to

$$\frac{d^2 u^\dagger(x)}{dx^2} + k^2 u^\dagger(x) + \gamma(x,\mathbf{p})u^\dagger(x) = \delta(x - x_0). \quad (6)$$

Now differentiate (4) with respect to p, where for brevity we write $u_p(x) \equiv \partial u(x)/\partial p$. This gives

$$\frac{d^2 u_p(x)}{dx^2} + k^2 u_p(x) + \gamma(x,\mathbf{p})u_p(x) = -\frac{\partial \gamma(x,\mathbf{p})}{\partial p}u(x). \quad (7)$$

Thus, $u_p(x)$ obeys a Helmholtz equation with the "source" given by the term on the right of (7). We wish to compute the derivative of the observed field, $u(x_0)$, with respect to p. To do this, note that

$$\frac{\partial u(x_0)}{\partial p} \equiv u_p(x_0) = \int_{-\infty}^{\infty} u_p(x)\delta(x - x_0)dx. \quad (8)$$

Substituting the left-hand side of (6) into (8) gives

$$\frac{\partial u(x_0)}{\partial p} = \int_{-\infty}^{\infty} u_p(x)\left[\frac{d^2 u^\dagger(x)}{dx^2} + k^2 u^\dagger(x) + \gamma(x,\mathbf{p})u^\dagger(x)\right]dx. \quad (9)$$

Integrating by parts twice results in

$$\frac{\partial u(x_0)}{\partial p} = \int_{-\infty}^{\infty}\left[\frac{d^2 u_p(x)}{dx^2} + k^2 u_p(x) + \gamma(x,\mathbf{p})u_p(x)\right]u^\dagger(x)dx. \quad (10)$$

Substituting (7) into (10) finally gives

$$\frac{\partial u(x_0)}{\partial p} = -\int_{-\infty}^{\infty}\frac{\partial \gamma(x,\mathbf{p})}{\partial p}u(x)u^\dagger(x)dx. \quad (11)$$

If, for example, we substitute the scattering model (5) into (11), we obtain on letting $p = p_n$, the derivative of the observed field with respect to p_n:

$$\frac{\partial u(x_0)}{\partial p_n} = -\int_{-\infty}^{\infty}\phi_n(x)u(x)u^\dagger(x)dx. \quad (12)$$

The key result (11) can also be derived by writing the solution to (7) with the aid of the Green's function, $g(x|x')$, which solves

$$\frac{d^2 g(x|x')}{dx^2} + k^2 g(x|x') + \gamma(x,\mathbf{p})g(x|x') = \delta(x - x'), \quad (13)$$

to obtain

$$u_p(x) = -\int\frac{\partial \gamma(x',\mathbf{p})}{\partial p}u(x')g(x|x')dx'. \quad (14)$$

Comparing (6) and (13), we see that $u^\dagger(x) = g(x_0|x)$, which shows that (11) and (14) are the same after setting $x = x_0$ in (14). However, we prefer to define the adjoint field, $u^\dagger(x)$, as the solution to (6), where the observation point, x_0, is defined as the location of the source of this field.

III. ITERATIVE ALGORITHMS AND THE LOCAL MINIMUM PROBLEM

In the above problem, we denoted the observations by $u(x_0, k_m, \mathbf{p}^{(true)})$, where $\mathbf{p}^{(true)}$ is the true set of parameters. For brevity, we write this as $u^{(obs)}(k_m)$. For a given parameter estimate, $\mathbf{p}$, we can simulate the observations, denoted $u(x_0, k_m, \mathbf{p})$, by using a forward algorithm to solve (4). Below we abbreviate $u(x_0, k_m, \mathbf{p})$ by $u(k_m, \mathbf{p})$. In the usual least-squares approach, we seek the solution, $\mathbf{p}$, that minimizes the mean-square error

$$\mathcal{E}(\mathbf{p}) = \frac{1}{2}\sum_{m=1}^{M}[u(k_m, \mathbf{p}) - u^{(obs)}(k_m)]^2. \quad (15)$$

Solutions occur when the gradient of $\mathcal{E}(\mathbf{p})$ vanishes, that is, when the partial derivatives of $\mathcal{E}(\mathbf{p})$ all vanish:[2]

$$\frac{\partial \mathcal{E}(\mathbf{p})}{\partial p_n} = \sum_{m=1}^{M}[u(k_m, \mathbf{p}) - u^{(obs)}(k_m)]\frac{\partial u(k_m, \mathbf{p})}{\partial p_n} = 0, \quad (16)$$

for $n = 1, 2, \ldots, N$. Convergence to a global minimum will occur from any point within some domain of $\mathbf{p}$ provided that the matrix of second derivatives of $\mathcal{E}(\mathbf{p})$ is positive definite everywhere within that domain. This matrix is

$$\frac{\partial^2 \mathcal{E}(\mathbf{p})}{\partial p_i \partial p_j} = \sum_{m=1}^{M}\left\{\frac{\partial u(k_m, \mathbf{p})}{\partial p_i}\frac{\partial u(k_m, \mathbf{p})}{\partial p_j} + [u(k_m, \mathbf{p})\right.$$
$$\left. - u^{(obs)}(k_m)]\frac{\partial^2 u(k_m, \mathbf{p})}{\partial p_i \partial p_j}\right\}. \quad (17)$$

In general, the second term on the right is responsible for local minima, if they occur. This term vanishes if $u(k_m, \mathbf{p})$ is linear in $\mathbf{p}$, leaving only the first term, resulting in a positive

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Stephen J. Norton: Nonlinear inverse scattering   1535

definite $\partial^2 \mathcal{E}(\mathbf{p})/\partial p_i \partial p_j$. In the latter case, $\mathcal{E}(\mathbf{p})$ is quadratic in $\mathbf{p}$, implying the existence of a unique global minimum.[3] An additional point can be made by writing (16) as the matrix equation

$$\sum_{m=1}^{M} e_m(\mathbf{p}) J_{mn}(\mathbf{p}) = 0, \tag{18}$$

where $e_m(\mathbf{p}) \equiv u(k_m, \mathbf{p}) - u^{(obs)}(k_m)$ and $J_{mn}(\mathbf{p})$ is the Jacobian matrix

$$J_{mn}(\mathbf{p}) = \frac{\partial u(k_m, \mathbf{p})}{\partial p_n}. \tag{19}$$

Generally speaking a global minimum will occur at a point $\mathbf{p}$ when (18) holds and the Jacobian, $J_{mn}(\mathbf{p})$, is full rank at $\mathbf{p}$. This then guarantees that $e_m(\mathbf{p}) = 0$ for all m at the point $\mathbf{p}$. A local minimum can occur at a point $\mathbf{p}$ whenever the gradient vanishes [i.e., when (18) holds at $\mathbf{p}$] and when $J_{mn}(\mathbf{p})$ is less than full rank at $\mathbf{p}$. Then (18) can hold while $e_m \neq 0$ for one or more m, signifying a local minimum at $\mathbf{p}$.

We now consider an approach that, in principle, avoids local minima, which is based on solving the system of M nonlinear equations

$$u(k_m, \mathbf{p}) = u^{(obs)}(k_m), \quad m = 1, 2, \ldots, M, \tag{20}$$

for the unknown vector $\mathbf{p}$. If a solution to (20) exists, the following approach should, in principle, avoid converging to a local minimum in the error surface $\mathcal{E}(\mathbf{p})$. We solve (20) using Newton's method, as follows. Newton's method also has the added theoretical benefit of second-order convergence, whereas gradient descent using the mean-square error gradient (16) provides only first-order convergence.

Denote the jth estimate of $\mathbf{p}$ by $\mathbf{p}^{(j)}$. We then Taylor expand $u(k_m, \mathbf{p}^{(j+1)})$ about the point $\mathbf{p}^{(j)}$. We then have, to first order in $\mathbf{p}^{(j+1)} - \mathbf{p}^{(j)}$,

$$u(k_m, \mathbf{p}^{(j+1)}) = u(k_m, \mathbf{p}^{(j)}) + \sum_{n=1}^{N} J_{mn}(p_n^{(j+1)} - p_n^{(j)}), \tag{21}$$

where J_{mn} is the Jacobian matrix which, in view of (11), then can be computed from

$$J_{mn} \equiv \frac{\partial u(k_m, \mathbf{p}^{(j)})}{\partial p_n} = -\int_{-\infty}^{\infty} \frac{\partial \gamma(x, \mathbf{p}^{(j)})}{\partial p_n} u(x, k_m) u^{\dagger}(x, k_m) dx. \tag{22}$$

As noted, J_{mn} is evaluated at $\mathbf{p}^{(j)}$. Now let $\mathbf{J}$ denote the matrix whose elements are J_{mn} and $\mathbf{u}(\mathbf{p})$ an M component vector whose elements are $u(k_m, \mathbf{p})$, $m = 1, 2, \ldots, M$. Newton's method is obtained by setting $\mathbf{u}(\mathbf{p}^{(j+1)}) = \mathbf{u}^{(obs)}$ in (21), which gives an equation for $\mathbf{p}^{(j+1)}$ in terms of $\mathbf{p}^{(j)}$:

$$\mathbf{u}^{(obs)} - \mathbf{u}(\mathbf{p}^{(j)}) = \mathbf{J}(\mathbf{p}^{(j+1)} - \mathbf{p}^{(j)}). \tag{23}$$

This linear system can be solved for $\mathbf{p}^{(j+1)}$, or, symbolically,

$$\mathbf{p}^{(j+1)} = \mathbf{p}^{(j)} - \mathbf{J}^{-1} [\mathbf{u}(\mathbf{p}^{(j)}) - \mathbf{u}^{(obs)}], \tag{24}$$

which is Newton's method in N variables. If there are more measurements, M, than unknowns, N, the system (23) is overdetermined, in which case, for example, the generalized inverse can be used to solve (23). To this end, the system

(23) is premultiplied by the transpose of $\mathbf{J}$, giving

$$\mathbf{J}^T [\mathbf{u}^{(obs)} - \mathbf{u}(\mathbf{p}^{(j)})] = \mathbf{J}^T \mathbf{J}(\mathbf{p}^{(j+1)} - \mathbf{p}^{(j)}), \tag{25}$$

and the update formula (24) now becomes

$$\mathbf{p}^{(j+1)} = \mathbf{p}^{(j)} - (\mathbf{J}^T \mathbf{J})^{-1} \mathbf{J}^T [\mathbf{u}(\mathbf{p}^{(j)}) - \mathbf{u}^{(obs)}], \tag{26}$$

where $(\mathbf{J}^T \mathbf{J})^{-1} \mathbf{J}^T$ is the generalized inverse.

Press *et al.*[4] point out that the Newton step defined by (24) is always a descent direction on the error surface $\mathcal{E}(\mathbf{p}) = [\mathbf{u}(\mathbf{p}) - \mathbf{u}^{(obs)}]^2/2$. To show this, abbreviate the step as $\delta \mathbf{p} = \mathbf{p}^{(j+1)} - \mathbf{p}^{(j)}$; then

$$\nabla \mathcal{E}^T \delta \mathbf{p} < 0, \tag{27}$$

which follows by noting that $\nabla \mathcal{E}^T = (\mathbf{u}(\mathbf{p}^{(j)}) - \mathbf{u}^{(obs)})^T \mathbf{J}$ and then from (24)

$$\nabla \mathcal{E}^T \delta \mathbf{p} = -|\mathbf{u}(\mathbf{p}^{(j)}) - \mathbf{u}^{(obs)}|^2 < 0. \tag{28}$$

The same argument can be used to show that the step implied by (26) is also a descent direction. Press *et al.*[4] use the fact that each Newton step is a descent direction to devise a strategy for adaptively modifying the step size if $\mathcal{E}(\mathbf{p})$ is not reduced at each iteration. In their approach, one backtracks along the descent direction if the current step fails to reduce the error $\mathcal{E}(\mathbf{p})$. Note, however, that the descent direction defined by (24) [or (26)] is not the same descent direction defined by the gradient of $\mathcal{E}(\mathbf{p})$ given by (16) in solving the least-squares problem. In the Appendix, we outline a modified Newton's method based on the idea of continuation.[5] In that approach, the Newton iteration is reformulated as a differential equation in $\mathbf{p}$ whose solution progresses continuously from a known solution, $\mathbf{p}_0$, to the desired solution. The idea here is to enlarge the domain of starting values from which global convergence succeeds.

IV. EXAMPLE: TWO-PARAMETER INVERSE PROBLEM

As an illustration, we consider a simple inverse Helmholtz problem with two unknown parameters. Although the problem is simple and artificial, it does succeed in showing how the Newton iteration converges to the global minimum, whereas mean-square minimization converges, from the same starting value, to a local minimum.

We consider a one-dimensional problem with a potential step of unknown magnitude and unknown location. The step occurs at the point $x = a$ and beyond the step the wave number is β. We wish to determine the parameters a and β from two measurements. The field $u(x)$ then obeys the following Helmholtz equation:

$$\frac{d^2 u(x)}{dx^2} + k^2 u(x) + (\beta^2 - k^2) H(x - a) u(x) = 0, \tag{29}$$

where k is the wave number to the left of the step and $H(x)$ is the unit step function. We assume a field $\exp(ikx)$ is incident on the step from the left. The total field is then of the form

$$u(x) = e^{ikx} + R e^{-ikx}, \quad x < a, \tag{30}$$

$$u(x) = Te^{i\beta x}, \quad x > a. \tag{31}$$

Imposing the boundary conditions of continuity of the field and its derivative at $x = a$ yields the coefficients R and T:

$$R = \frac{k - \beta}{k + \beta} e^{2ika}, \tag{32}$$

$$T = \frac{2k}{k + \beta} e^{i(k-\beta)a}. \tag{33}$$

The potential function $\gamma(x, \mathbf{p})$ for this problem is

$$\gamma(x, \mathbf{p}) = (\beta^2 - k^2) H(x - a) \tag{34}$$

and its derivatives with respect to a and β are

$$\frac{\partial \gamma(x, \mathbf{p})}{\partial a} = -(\beta^2 - k^2) \delta(x - a), \tag{35}$$

$$\frac{\partial \gamma(x, \mathbf{p})}{\partial \beta} = 2\beta H(x - a). \tag{36}$$

To compute the derivatives of the observed field at an observation point x_0 (where we assume $x_0 < a$) using (11), we need the adjoint field which, in this case, solves

$$\frac{d^2 u^\dagger(x)}{dx^2} + k^2 u^\dagger(x) + (\beta^2 - k^2) H(x - a) u^\dagger(x) = \delta(x - x_0). \tag{37}$$

Solving this equation, we find that the adjoint solution is given by

$$u^\dagger(x) = -\frac{i}{2k} u(x) e^{-ikx_0}, \tag{38}$$

for $x \geq x_0$, where $u(x)$ is given above in (30) and (31). Substituting $u(x)$ and $u^\dagger(x)$ into (11), we obtain for the derivatives of the observed field

$$\frac{\partial u(x_0)}{\partial a} = (\beta^2 - k^2) u(a) u^\dagger(a), \tag{39}$$

$$\frac{\partial u(x_0)}{\partial \beta} = -2\beta \int u(x) u^\dagger(x) dx. \tag{40}$$

Integrating (40), we finally obtain

$$\frac{\partial u(x_0)}{\partial a} = 2ik \left[\frac{k - \beta}{k + \beta} \right] e^{i2ka} e^{-ikx_0}, \tag{41}$$

$$\frac{\partial u(x_0)}{\partial \beta} = -\frac{2k}{(k + \beta)^2} e^{i2ka} e^{-ikx_0}. \tag{42}$$

As a check, these can be obtained by directly differentiating (30) with respect to β and a after setting $x = x_0$.

V. SIMULATION

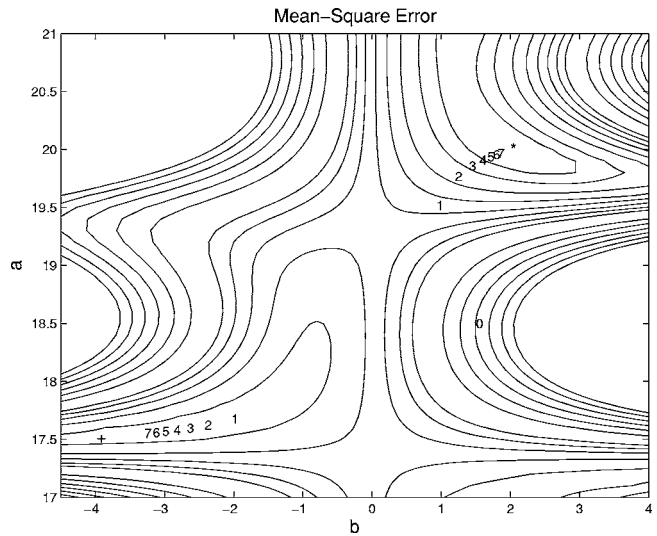
Using the example of the last section, we devise a problem with both local and global minima. Starting from the same initial guess, $\mathbf{p}$, we show that the Newton iteration converges to the global minimum, whereas a steepest-


FIG. 1. Contour plot of mean-square error surface. The $*$ and $+$ signify, respectively, global and local minima, with the starting value for both algorithms identified by the 0. Newton's method converges to the global minimum and the method of steepest descent converges to one of many local minima. For Newton's method, the numbers label single iterations, whereas for steepest descent, each number stands for 1000 iterations.

descent algorithm that minimizes the mean-square error converges to a local minimum. The data consist of observations made at two frequencies (i.e., two values of k). In particular, the backscattered field is

$$u(x, k) = e^{ikx} + R e^{-ikx}, \tag{43}$$

where from (32) $R = [(k - \beta)/(k + \beta)]\exp(2ika)$. Recall that a is the location of a step discontinuity and β is the wave number beyond this step. Let us define as our unknowns a and $b \equiv (k - \beta)/(k + \beta)$ and let our data consist of the real part of the backscattered field observed at x_0 with wave numbers k_1 and k_2; that is, we measure

$$u_R(x_0, k_1) = \cos(k_1 x_0) + b \cos(2k_1 a - k_1 x_0),$$

$$u_R(x_0, k_2) = \cos(k_2 x_0) + b \cos(2k_2 a - k_2 x_0),$$

with a and b the unknowns.

This particular problem has multiple minima. We set the true parameter values to $a = 20$ and $b = 1$, and let $x_0 = 0$, $k_1 = 0.7$, and $k_2 = 0.1$. In an attempt to recover the parameters a and b, we applied both iterative algorithms, steepest descent and Newton's method, using the same initial starting point: $a = 18.5$ and $b = 1.5$. Figure 1 shows the paths of convergence of both algorithms on a contour plot of the mean-square error surface $\mathcal{E}(a, b)$, where the global minimum is marked by $*$ and a local minimum is marked by $+$. The starting value is identified by 0. For this particular example, Newton's method converges to the global minimum and the steepest-descent method converges to the local minimum. One can check that the Jacobian is full rank at the global minimum, but singular at the local minimum. The numbers in the figure denote single iterations of Newton's method (converging to

∗), where each number in the steepest-descent path (converging to +) stands for 1000 iterations. Thus, we see that steepest descent converges exceedingly slowly in this example. A more efficient descent algorithm, such as the conjugate-gradient method, would converge more rapidly, although once again to the local minimum.

VI. DISCUSSION AND CONCLUSION

We propose a method for solving nonlinear inverse-scattering problems that, in principle, should avoid the problem of convergence to local minima. In the simple example described in the last section, the author found that the basic Newton iteration, without the modification suggested by Press *et al.*,[4] either converged to the global minimum or failed to converge, depending on the starting values of the parameters. In the limited number of tests conducted, the algorithm never converged to a local minimum. On the other hand, the steepest-descent algorithm either failed to converge, converged to a local minimum, or occasionally converged to the global minimum, again depending on the starting parameters. To develop a more robust Newton algorithm, the modification suggested by Press *et al.* or a similar strategy might be used, particularly for higher dimensional problems. If no exact solution to (20) exists due to noise in the data or inaccuracies in the model, an algorithm needs to be devised to yield an approximate solution under these conditions. For example, a stabilized Newton iteration along the lines of the generalized update formula (26) should converge to a "reasonable" solution given uncertainties in the data or model. The latter formula is less likely to fail due to an ill-conditioned Jacobian. Another potentially promising approach is the continuation method outlined in the Appendix.

The purpose of this paper is to suggest a strategy for avoiding false solutions associated with local minima. However, the numerical issues of nonconvergence and stability associated with a multi-dimensional Newton's method are beyond our scope here. These issues will require further study for the development of a truly robust inverse-scattering algorithm.

APPENDIX: "MORPHING" A KNOWN SOLUTION INTO AN UNKNOWN SOLUTION

Ortega and Rheinboldt[5] describe a technique known as the method of continuation, in which the Newton iteration starts from the solution of a known problem and is allowed to continuously evolve toward the solution of the desired problem. The idea is both to increase the domain of starting values that leads to convergence to the global solution and to provide a more robust algorithm than the basic Newton iteration. Here we outline this approach and refer the reader to Ref. 5 for details and a discussion of convergence criteria. In view of (20), we can redefine our original problem as the task of finding the zeros, $\mathbf{p}$, of a system of equations $F(k_m, \mathbf{p}) = 0$, given by

$$F(k_m, \mathbf{p}) \equiv u(k_m, \mathbf{p}) - u^{(obs)}(k_m) = 0, \quad m = 1, 2, \ldots, M, \tag{A1}$$

in which a standard multi-variable Newton's method would be used. Letting $\mathbf{F}(\mathbf{p})$, $\mathbf{u}(\mathbf{p})$, and $\mathbf{u}^{(obs)}$ denote vectors of M components, this can be written

$$\mathbf{F}(\mathbf{p}) \equiv \mathbf{u}(\mathbf{p}) - \mathbf{u}^{(obs)} = 0. \tag{A2}$$

Suppose we consider instead the problem of finding the zeros of

$$\mathbf{F}(\mathbf{p}, \tau) \equiv \mathbf{u}(\mathbf{p}) - \mathbf{u}^{(obs)} + (\tau - 1)[\mathbf{u}(\mathbf{p}_0) - \mathbf{u}^{(obs)}] = 0, \tag{A3}$$

where τ varies between 0 and 1 and $\mathbf{p}_0$ is a set of starting parameters. The idea is to start the iteration at a known solution defined when $\tau = 0$, that is, $\mathbf{F}(\mathbf{p}_0, 0) = 0$ [which follows from (A3)] and end at the desired solution when $\tau = 1$, that is, $\mathbf{F}(\mathbf{p}, 1) = 0$ [which is (A2)]. When τ varies from 0 to 1, we see that the solution to (A3) varies continuously from $\mathbf{p}_0$ to $\mathbf{p}_1$, where $\mathbf{p}_1$ is the solution to (A2), that is, the desired solution. Note that $\mathbf{p}$ is a function of τ, which we signify by writing $\mathbf{p}_\tau$. An iterative algorithm can be devised (as τ varies from 0 to 1) by differentiating (A3) with respect to τ. This gives

$$\mathbf{J}(\mathbf{p}_\tau) \frac{d\mathbf{p}_\tau}{d\tau} + \mathbf{u}(\mathbf{p}_0) - \mathbf{u}^{(obs)} = 0, \tag{A4}$$

where $\mathbf{J}$ is the Jacobian defined by (22), which leads to the differential equation

$$\frac{d\mathbf{p}_\tau}{d\tau} = -\mathbf{J}(\mathbf{p}_\tau)^{-1}[\mathbf{u}(\mathbf{p}_0) - \mathbf{u}^{(obs)}], \tag{A5}$$

with the initial condition $\mathbf{p}_0$. If we discretize τ by writing τ_k, where $k = 0, 1, \ldots, N$, (A5) can be approximated using, for example, the simple integration scheme of Euler. Letting $\mathbf{p}_k$ denote $\mathbf{p}_{\tau_k}$, this results in

$$\mathbf{p}_{k+1} = \mathbf{p}_k - (\tau_{k+1} - \tau_k)\mathbf{J}(\mathbf{p}_k)^{-1}[\mathbf{u}(\mathbf{p}_0) - \mathbf{u}^{(obs)}]. \tag{A6}$$

Note the resemblance to Newton's method as defined by (24). The difference, however, is that the quantity in square brackets in (A6) is not updated at each iteration, as is done in (24), as well as the presence of the weighting $(\tau_{k+1} - \tau_k)$. As before, each iteration requires a solution to the forward and adjoint scattering problems to compute the Jacobian. Since the above integration scheme may require more iterations than Newton's method, we may sacrifice computational efficiency for the benefit of widening the domain of convergence. Note also from (24) that Newton's method will fail at any point where the determinant of the Jacobian vanishes. However, a more sophisticated integration scheme than Euler's method applied to (A5) should be able to pass through these singular points, provided the singularities are integrable (alternatively the integration path $\mathbf{p}_\tau$, $0 \leq \tau \leq 1$, through parameter space can be deformed around these points). The above arguments suggest that a method based on integrating (A5) using an adaptive integration algorithm, although computationally more costly, may well be more stable than a simple Newton's iteration, but a study of this approach is beyond our scope.

[1]S. J. Norton, "Iterative inverse-scattering algorithms: Methods for comput-ing the Frechet derivative," J. Acoust. Soc. Am. **106**, 2653–2660 (1999).
[2]If we define $F_n(\mathbf{p}) = \partial \mathcal{E}(\mathbf{p})/\partial p_n$, local minima will occur for zeros of the system of nonlinear equations

$$F_n(\mathbf{p}) = 0, \quad n = 1, 2, \dots, N.$$

However, as pointed out in Ref. 4, these equations are the components of the gradient of a scalar and are not independent. In fact, they obey the $N(N-1)/2$ integrability conditions

$$\frac{\partial F_n(\mathbf{p})}{\partial p_m} = \frac{\partial F_m(\mathbf{p})}{\partial p_n},$$

which follows from the definition of $F_n(\mathbf{p})$. For N equations in N unknowns, these conditions imply, generally speaking, the possibility of multiple solu-tions to the first equation in this footnote and thus multiple local minima.

A general mathematical approach was proposed to study phenomenological models of the inner-hair-cell and auditory-nerve (AN) synapse complex. Two models (Meddis, 1986; Westerman and Smith, 1988) were studied using this unified approach. The responses of both models to a constant-intensity stimulus were described mathematically, and the relationship between model parameters and response characteristics was investigated. The mathematical descriptions of the two models were essentially equivalent despite their structural differences. This analytical approach was used to study the effects of adaptation characteristics on model parameters and of model parameters on adaptation characteristics. The results provided insights into these models and the underlying biophysical processing. This analytical method was also used to study offset adaptation, and it was found that the offset adaptation of both models was limited by the models' structures. A modified version of the synapse model, which has the same onset adaptation but improved offset adaptation, is proposed here. This modified synapse model produces more physiologically realistic offset adaptation and also enhances the modulation gain of model AN fiber responses, consistent with AN physiology. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1993148]

I. INTRODUCTION

The inner-hair-cell (IHC) and auditory-nerve (AN) complex is a critical element in the peripheral auditory system that converts a mechanical signal (the response of the cochlea to sound) into a neural signal. Physiological studies (Westerman and Smith, 1984; Rhode and Smith, 1985; Westerman, 1985) have provided insight into the temporal dynamics of IHC-AN synaptic processing. The response of an AN fiber to a constant-intensity tone burst is typified by very rapid firing at the onset that declines with time, rapidly at first and then more slowly over a period of tens of milliseconds. The AN response after the offset of the stimulus (cessation of the stimulus) is greatly reduced relative to the spontaneous response and slowly recovers over several tens of milliseconds (Harris and Dallos, 1979; Westerman, 1985). Since the amplitude of the receptor potential of the IHC produced by a constant-amplitude stimulus (for example, a high-frequency tone) is essentially constant (Russell and Sellick, 1978), adaptation is believed to occur at the level of the transmitter release process in the IHC-AN synapse. Recent physiological studies (Moser and Beutner, 2000) provide direct evidence for the idea of adaptation at the IHC-AN synapse. The adaptation process in the IHC-AN synapse results in greater sensitivity to transient stimuli than to steady-state stimuli and underlies other temporal aspects of AN responses. These properties also limit some aspects of temporal coding of stimulus envelopes. For example, offset adaptation may be responsible in part for the psychophysical phenomenon of forward masking (Harris and Dallos, 1979).

IHC-AN synaptic adaptation is very complex. Its characteristics depend on stimulus intensity, duration, and previous stimulation history. Synaptic adaptation (Fig. 1) (Harris and Dallos, 1979) at the onset of AN responses to tone bursts is usually characterized functionally by two exponential components (Westerman and Smith, 1984; Rhode and Smith, 1985; Westerman, 1985):

$$R_{on}(t) = A_{sus} + A_r e^{-t/\tau_R} + A_{st} e^{-t/\tau_{ST}}, \qquad (1)$$

where A_r and A_{st} are the components of rapid and short-term adaptation, τ_R and τ_{ST} are the respective decay time constants, and A_{sus} is a steady-state component. Adaptation at the offset of the stimulus can also be described as an exponential recovery component, with a different time constant than the onset, after a "deadtime" period, or a period of very low probability of firing:

$$R_{off}(t) = \begin{cases} 0; & t < t_0 \\ A_{sp}(1 - e^{-(t-t_0)/\tau_{sp}}) \end{cases}, \qquad (2)$$

where A_{sp} is the spontaneous rate, t_0 is the deadtime period, and τ_{SP} is the recovery time constant of the offset responses. Other measurements that have helped characterize AN adaptation processes include responses to increments or decrements in stimulus intensity with an ongoing tonal background (Smith and Zwislocki, 1975;

---

FIG. 1. Schematic diagram of the response of an AN fiber to a toneburst (Harris and Dallos, 1979; Westerman, 1985). The onset response of the AN fiber can be described as a sum of two exponential components [see Eq. (1)], and the offset response can be fit with a single exponential recovery function after a deadtime [Eq. (2)].

FIG. 2. Schematic diagram of two synapse models (Meddis, 1988; Westerman and Smith, 1988). (a) In the Westerman model [see Eqs. (6) and (7)], three transmitter reservoirs are cascaded, each with their own concentration and volume. The transmitter diffuses from global to local and then from local to immediate reservoirs. The output of the synapse model, S_{out}, is determined by the product of the concentration in the immediate reservoir and the diffusion permeability from the immediate reservoir into the synaptic cleft. (b) In the Meddis model [Eqs. (3)–(5)], the transmitter in the cleft is either lost or reprocessed by the reprocessing store (w). The free transmitter pool receives the transmitter from the reprocessing store or from a global factory and releases the transmitter into the cleft (c) with instantaneous release probability density k. The model synapse output is proportional to the amount of transmitter left in cleft (Meddis, 1988) or the rate of transmitter released into the cleft (Sumner et al., 2002).

Smith et al., 1985). Adaptation characteristics also differ for fiber types with different spontaneous rates (Rhode and Smith, 1985). The diversity and complexity of IHC-AN synaptic adaptation provide a challenge for the successful modeling of synapse dynamics (Hewitt and Meddis, 1991).

The mechanisms that give rise to synaptic adaptation can be due either to the depletion of a readily released presynaptic pool of neurotransmitter (Moser and Beutner, 2000) or the desensitization of the postsynaptic receptors (Raman et al., 1994). The adaptation at IHC-AN synapse has often been modeled using multiple reservoirs of a neurotransmitter, with diffusion out of the cell and between reservoirs within the cell (Furukawa and Matsuura, 1978; Schwid and Geisler, 1982; Smith and Brachman, 1982; Meddis, 1986; Westerman and Smith, 1988; Ross, 1996). Each diffusion step is controlled by a permeability parameter, and at least one of the permeabilities in these models is determined by the stimulus (presumed to be controlled by IHC calcium concentration, intracellular IHC voltage, or equivalently, stimulus intensity). Adaptation of the synaptic output in these models depends on the reduction of the driving force for the diffusion of the synaptic material (transmitter) from the cell into the synaptic cleft (Fig. 2). Mathematically, low-pass filters are used to implement the replenishment and diffusion mechanisms between different transmitter reservoirs. These models can be implemented using either a cascade of low-pass filters or parallel low-pass filters, depending on the interconnection of the reservoirs.

The variation of adaptation characteristics across AN fibers makes it desirable to have different sets of model parameters to predict individual AN fiber responses more accurately, but determining these parameters is tedious. Compared to analytical solutions, the exhaustive search of a multidimensional parameter space using numerical methods is very time consuming, and the parameters may be trapped by local minima in the cost function. In addition, simulation

results may not give insight into a particular model; that is, quantitative relationships between the model parameters and adaptation properties may not be revealed by the exercise of fitting the parameters to a single fiber response, and the difference between different models may not be fully understood.

During the past twenty years, two IHC-AN synapse models with different structures have been developed independently and actively in a series of studies (Meddis, 1986, 1988; Westerman and Smith, 1988; Meddis et al., 1990; Carney, 1993; Zhang et al., 2001; Sumner et al., 2002). Both of these models are very successful in simulating the onset adaptation responses of the AN fibers to some extent. For the model proposed by Westerman and Smith (1988), equations were derived to determine the model parameters from the desired shape of the onset of the peri-stimulus time (PST) histogram. A recent study (Zhang et al., 2001) detailed how these parameters can be derived for different types of AN fibers. For the model proposed by Meddis (1986), the analytical relationship between steady-state responses and model parameters was described in a later study (Meddis et

al., 1990). This model was further explored in a recent study (Sumner *et al.*, 2002) to simulate the rate-level functions of low-, medium-, and high-spontaneous-rate AN fibers by changing parameters in the transmitter-release control function (that is, the stage that determines how the model IHC voltage affects the transmitter release permeability in the adaptation model) and synapse model parameters. However, the studies of other model adaptation characteristics (e.g., amplitudes and time constants of adaptation components) are limited by the sets of parameters provided by the authors (e.g., Hewitt and Meddis, 1991; Sumner *et al.*, 2002), which makes it difficult to understand the relationship between these parameters and different adaptation properties. Also, the difference in adaptation responses for these models, and whether the difference is a result of the different model structures or the different model parameter values, have not been clarified.

In this article, we use a unified approach to consider two models, that of Meddis (1986) and of Westerman and Smith (1988) (we will refer to the latter as the Westerman model). Since the essential architecture of the synapse model under investigation (interconnection of the synaptic reservoirs) has not been changed in the newer versions of these models (Zhang *et al.*, 2001; Sumner *et al.*, 2002), the results from this study are also applicable and beneficial to understanding the more recent versions of these models (see Sec. VI). In our approach, both models can be described as circuits of interconnected low-pass filters. In this framework, the responses of each model to a constant-intensity stimulus can be determined analytically, and relationships between the response characteristics and model parameters can be established. This mathematical method clarifies the differences and similarities between the two models, leading us to the conclusion that, despite their different structures, the two models are essentially the same. In addition, because the model equations provide better insight into the model structure, we can easily derive the model parameters on the basis of the desired adaptation properties.

There has been less attention paid to the modeling of offset adaptation at the IHC-AN synapse. It is difficult to find a common physiological explanation for both onset and offset adaptation because of the difference in their respective characteristic functions. Simulation results from models (Sumner *et al.*, 2003) have also not provided insights concerning the relationship between onset and offset adaptation.

We use our analytical approach to study the relationship between onset and offset adaptation in the Westerman and Meddis models. The model response characteristic function of offset adaptation is the same as that of onset adaptation, and is limited by the model parameters used to specify the desired onset adaptation. A modification for both models is then proposed; the modified model has the same onset adaptation but improved offset adaptation. The onset and offset adaptation responses are based on same physiological assumption in this modification. The modified offset adaptation enhances the modulation gain of the model AN fiber responses to modulated stimuli, consistent with AN physiology (Joris and Yin, 1992).

II. PHYSIOLOGICAL INTERPRETATION OF THE MEDDIS AND WESTERMAN SYNAPSE MODELS

In this section, we provide our physiological interpretation of the two models and explain how onset adaptation is achieved in both models. The similarities and differences between the two models are compared qualitatively here; their underlying physiological assumptions are further discussed in Sec. VI.

The model proposed by Meddis (1986, 1988) has three neurotransmitter reservoirs that are specified by the number of synaptic transmitters in the reservoir and arranged in a cycle: The immediate store (q); the synaptic cleft (c); and the reprocessing store (w) (see Fig. 2). New transmitter in the immediate store is either manufactured from the factory at a rate of $y[M-q(t)]$, where M is the amount of neurotransmitter in the global store), provided by a reprocessing store [at a rate of $xw(t)$], or released from the immediate store into the synaptic cleft at a rate of $k(t)q(t)$. The transmitter in the cleft is either lost at a rate of $lc(t)$ or recycled at a rate of $rc(t)$. The transmitter replenishment and release in the model can be described by the following equations:

$$\frac{dq}{dt} = y(M - q(t)) + xw(t) - k(t)q(t), \tag{3}$$

$$\frac{dc}{dt} = k(t)q(t) - (l + r)c(t), \tag{4}$$

$$\frac{dw}{dt} = rc(t) - xw(t). \tag{5}$$

The model synapse output is a value proportional to the rate of transmitter release into the cleft, $k(t)q(t)$. The instantaneous release probability, $k(t)$, is the only stimulus-dependent variable in the model and is usually specified as a function of intracellular IHC voltage (defined as V_{IHC}, referenced to the IHC resting potential). Rapid adaptation after onset is the result of the depletion of the synaptic transmitters in the immediate store, and is mainly limited by the instantaneous release probability, $k(t)$. Short-term adaptation is the result of the depletion of synaptic materials available for recycling process, and is mainly limited by the reuptake rate [$rc(t)$], reprocessing rate [$xw(t)$], and the fraction of synaptic material in the cleft available for recycling, $r/(1+r)$. The replenishment of the synaptic transmitter from the global factory into the immediate store, $y[M-q(t)]$, contributes the model's steady-state response.

In the Westerman model, the transmitter reservoir is characterized by the volume, V, and concentration, C, of the synaptic material in the reservoir. The model (Fig. 2) has three reservoirs (global, local, and immediate) of synaptic material, connected in series by a diffusion path. The diffusion rate of synaptic material between reservoirs (from global to local, and then from local to immediate) is determined by the permeability (P) and by the concentration difference between the reservoirs. The governing equations for the transmitter release between these reservoirs are

$$V_I \frac{dC_I(t)}{dt} = -P_L C_I(t) - P_I(t)C_I(t) + P_L C_L(t), \tag{6}$$

and

$$\frac{dC_L(t)}{dt} = \frac{P_G C_G}{V_L} + \frac{P_L}{V_L}C_I(t) - \left(\frac{P_L + P_G}{V_L}\right)C_L(t), \tag{7}$$

where C_I, C_L, and C_G are the immediate, local, and global reservoir concentrations; V_I and V_L are the immediate and local reservoir volumes; and P_L and P_G are the permeabilities between the local and immediate and between global and local reservoirs, respectively.

The small immediate store (V_I, C_I) in the Westerman model is directly comparable with that in the Meddis model (q). The release permeability $P_I(t)$ is the same as $k(t)$ in the Meddis model, which is the only parameter determined by the input sound stimulus. The synapse output is a value proportional to the rate of transmitter released from the immediate store $[P_I(t)C_I(t)]$ into the synaptic cleft, similar to $k(t)q(t)$ in Meddis model. The Westerman model has the following characteristic function:

$$C_I(t) = \Phi_0' + \Phi_1' e^{-t/\tau_1'} + \Phi_2' e^{-t/\tau_2'}, \tag{8}$$

where the values of τ_1', τ_2', and Φ_0', Φ_1', Φ_2' can be calculated from Eqs. (6) and (7) (see Westerman and Smith, 1988). The primes in the parameter names distinguish these variables from those used in original Meddis model [see Eq. (13) below]. Note that the characteristic function here is the same as that of the onset responses of AN fibers [Eq. (1)].

Rapid adaptation in the Westerman model is the result of the depletion of the synaptic material in the immediate store and is mainly limited by the diffusion permeability of synaptic material from the immediate store to the cleft. Short-term adaptation is the result of the depletion of the synaptic material in the local store, and is mainly limited by the diffusion permeability between the local and immediate stores.

The local store (V_L, C_L) in the Westerman model is similar to the reprocessing store (w) in the Meddis model, which provides synaptic material for short-term adaptation. The synaptic material (w) in the Meddis model comes from very fast reuptake of released synaptic vesicles in the cleft, whereas the synaptic material in the Westerman model for rapid adaptation is stored in local store (V_L, C_L). The steady-state response in both models is attributed to the existence of the global store. In the Meddis model, the synaptic material from the global store is released directly into the immediate store (in parallel with the reprocessing store, w), whereas in the Westerman model, synaptic material enters the immediate store through the local store (which is cascaded with the immediate store).

III. MATHEMATICAL ANALYSIS OF THE MEDDIS AND WESTERMAN MODELS

The instantaneous release probability of a vesicle from the immediate store, $k(t)$, in the Meddis model [or $P_I(t)$ in the Westerman model] is usually a function of intracellular IHC voltage (V_{IHC}), which in turn is determined by the input sound stimulus. For a high-frequency tone burst, the IHC receptor potential V_{IHC} is dominated by the "dc" component (Russell and Sellick, 1978; Cheatham and Dallos, 1993), and it is reasonable to assume that $k(t)$ is a constant after the onset (denoted as k_2; the value of $k(t)$ before the onset is denoted as k_1). For further analysis, Eqs. (3)–(5) can be transformed into the Laplace (complex frequency) domain as follows, for $t > 0$:

$$sQ(s) - q(0^-) = yM/s - yQ(s) + xW(s) - k_2 Q(s), \tag{9}$$

$$sC(s) - c(0^-) = k_2 Q(s) - (l+r)C(s), \tag{10}$$

$$sW(s) - w(0^-) = rC(s) - xW(s), \tag{11}$$

where $q(0^-)$, $c(0^-)$, and $w(0^-)$ are the reservoir concentrations before the onset.

After solving for $Q(s)$,

$$Q(s) = \frac{(sq(0^-) + yM)(s+x)(s+l+r) + c(0^-)rxs + w(0^-)xs(s+l+r)}{s(s+x)(s+y+k_2)(s+l+r) - k_2 rxs}, \tag{12}$$

the characteristic function of $q(t)$ can be represented by

$$q(t) = \Phi_0 + \Phi_1 e^{-t/\tau_1} + \Phi_2 e^{-t/\tau_2} + \Phi_3 e^{-t/\tau_3}, \tag{13}$$

where $-1/\tau_i$ are poles of $Q(s)$. The values of τ_1, τ_2, τ_3, and Φ_0, Φ_1, Φ_2, Φ_3 can be calculated from $Q(s)$ directly.

Based on the parameters given in Meddis (1986, 1988) and Sumner et al. (2002), we can assume that l and $r \to \infty$ (or $l, r \gg x, y, k$), and we will let $u = r/(l+r)$. Thus, the following equations describe a simplified version of the Meddis model:

$$\frac{dq}{dt} = y(M - q(t)) - kq(t) + xw(t), \tag{14}$$

$$\frac{dw}{dt} = kuq(t) - xw(t), \tag{15}$$

$$C(s) = \frac{k_2 Q(s) + c(0^-)}{s+l+r}, \tag{16}$$
FIG. 3. Comparison of synapse output for the original Meddis model (solid line) and the simplified model (dotted line) described in the current study. Both models used the parameter values given in the Meddis study (1988): $l=2500$, $r=6580$, $x=66.31$, $M=1$, $y=5.05$. The responses from two models are essentially identical, as illustrated by the overlapping curves. (a) The analytical solution of $k(t)q(t)$ for both models for a constant stimulus, with $k_1=40.49$ and $k_2=1660$. (b) Simulation results of $k(t)q(t)$ for both models with a time-varying input $k(t)$ (a half-wave rectified sinusoidal wave form at 1 kHz with amplitude of k_2: $k(t)=0.5k_2[\sin(2000\,\pi t)+|\sin(2000\,\pi t)|]$).

$$Q(s) = \frac{(sq(0^-) + yM)(s + x) + w(0^-)xs}{s(s + x)(s + y + k_2) - k_2uxs}, \quad (17)$$

$$q(t) = \Phi_0' + \Phi_1'e^{-t/\tau_1'} + \Phi_2'e^{-t/\tau_2'}, \quad (18)$$

where again, the primes are meant to distinguish the parameters in the simplified model from those in the original model.

Figure 3(a) shows the comparison of the analytical solution of $k(t)q(t)$ for both the original model [Eq. (13)] and the simplified model [Eq. (18)] using the parameters given in Meddis (1988). Figure 3(b) compares simulation results from both models with the same input $k(t)$, a sinusoid wave form at 1 kHz. Both plots show that solutions from the simplified equations and the original equations are essentially identical, and the accuracy of the prediction does not depend on the input stimulus (e.g., whether it is stationary or nonstationary). These results also hold for other parameter sets given in other studies (Meddis, 1986, 1988; Sumner *et al.*, 2002; not shown). Thus, the simplified equations provide a good description of the Meddis model, and the solution [Eq. (18)] has two components with different time constants that are the same as those used to describe the characteristics of onset adaptation in AN fibers [Eq. (1)].

The accuracy of the simplified equations describing the Meddis model across different values of the sum $l+r$ is illustrated in Fig. 4. Each component of $q(t)$ (t_i and Φ_i) is plotted as a function of $l+r$ for both models (Fig. 4). The values of these components are constant for the simplified model because u is the same for different values of $l+r$. The values of corresponding components in the original model reach the values in the simplified model as the value of $l+r$ increases, and the values are indistinguishable from each
FIG. 4. The difference of each individual component (t_i and Φ_i) of $q(t)$ between the Meddis (1986) model and the simplified model as a function of $l+r$. The values of these components are constant for the simplified model (dotted line) because $u=r/(l+r)$ is kept the same for different values of $l+r$. The amplitude of the component (Φ_i) is scaled by k so it can be interpreted as the instantaneous firing rate of the synapse output. The values of corresponding components in the original model (solid line) all converge quickly to the values in the simplified model as $l+r$ increases, and the values are indistinguishable from each other when $l+r>5000$. The amplitude (Φ_3) of the additional component does not exist for the simplified model; in the original model, this amplitude converges to zero as $l+r$ increases and it can be neglected when $l+r$ is large.

other when $(l+r)>5000$ (the values of $l+r$ used in the Meddis (1986, 1988) were usually greater than 15 000). The amplitude (Φ_3) of the additional component in the original model can be neglected compared to the other components when the value of $l+r$ is large. A detailed interpretation of the relationship between the simplified and original Meddis models is further explained in Sec. VI.

Because $k(t)$ and $P_I(t)$ are the only stimulus-dependent variables in the simplified Meddis and Westerman models, the two models can be compared more directly by substituting $k(t)$ with $P_I^M(t)$ and $q(t)$ with $C_I^M(t)$ in Eqs. (14) and (15). The constant yM in Eq. (14) can be removed by substituting $w(t)$ with $[(y+xu)/x][C_L^M(t) - yM/x - uC_I^M(t)]$. After making these changes, we have the following equations describing the simplified Meddis model:

$$\frac{dC_I^M}{dt} = -(y + xu)C_I^M(t) - P_I^M(t)C_I^M(t) + (y + xu)C_L^M(t), \quad (19)$$

$$\frac{dC_L^M}{dt} = \frac{xyM}{y + xu} + xu\left(\frac{x}{y + xu} - 1\right)C_I^M(t) - x(1 - u)C_L^M(t). \quad (20)$$

Since there is one free parameter in Westerman's model, we can always assume $V_I=1$ (that is, we can decrease V_I, V_L, P_I, P_L, P_G and increase C_I, C_L, C_G by the same scale, V_I, and the synapse output P_IC_I remains the same). It is obvious that the equations describing the two models [Eqs. (6), (7), (19), and (20)] are directly comparable. If we set the correspond-

X. Zhang and L. H. Carney: Analysis of auditory-nerve synapse

ing parameters to the same values (e.g., $P_L = y + xu$), then the synaptic response of the simplified Meddis model $[k(t)q(t)]$ and that of the Westerman model $[P_I(t)C_I(t)]$ to arbitrary inputs should be exactly the same.

IV. DERIVING MODEL PARAMETER VALUES FROM PERI-STIMULUS TIME HISTOGRAM PROPERTIES: THE RELATIONSHIP BETWEEN MODEL PARAMETERS AND ADAPTATION CHARACTERISTICS

The values of the parameters in the onset adaptation function [Eq. (1)] are usually determined by fitting this characteristic equation to the PST histogram of AN fiber responses. The refractoriness in the PST histograms can be removed before fitting (Westerman and Smith, 1988), so the IHC-AN synapse output (instantaneous firing rate) can be more accurately represented by the characteristic function.

With these adaptation parameters $(A_{sus}, A_r, A_{st}, \tau_R, \tau_{ST})$ and the spontaneous rate (A_{sp}) of the AN fibers, the values of parameters in both models can be derived. The analytical solution for the Westerman model is reported in previous studies (Westerman and Smith, 1988; Zhang et al., 2001). The derivation of the analytical solution for the values of the parameters in the simplified Meddis model from these characteristic parameters is given in the Appendix. Since any desired adaptation responses can be obtained from both models with appropriate parameters, comparing adaptation responses for different models with specific parameters will not give us any insight concerning these models.

It is important to note that the mapping from V_{IHC} to $k(t)$ in the Meddis model, or $P_I(t)$ in the Westerman model, should change with the fiber adaptation characteristics: each adaptation characteristic requires different sets of the model parameters (including the permeability at rest and the permeability at any other desired level); the spontaneous rate, rate threshold, and rate-level function curve differ among fiber types that require different V_{IHC}-k (V_{IHC}-P_I) relationships. An appropriate V_{IHC}-k (V_{IHC}-P_I) representation is critical for a composite model that successfully describes AN responses (Heinz et al., 2001; Sumner et al., 2002). The procedure for deriving the appropriate V_{IHC}-k (V_{IHC}-P_I) function combining the results in the present study and recent developments of these models are further discussed in Sec. VI.

Though the same desired adaptation responses can be obtained from both models, the dependence of the parameters in each model upon various adaptation characteristics differs. Also, because the models have different structures, these parameters have specific physical meanings in each model. A survey of how these parameters change with different model-AN fiber types will provide valuable information and further our understanding of both models.

Figures 5 and 6 show an example of how the parameters change systematically for different model-AN fiber types in the simplified Meddis model and Westerman models, respectively. Other possible ways to specify the adaptation across different model-AN fiber types are detailed in Sec. VI. Here, the fiber types are described by the peak-to-sustained ratio $[PTS = (A_r + A_{st} + A_{sus})/A_{sus}]$ of the onset adaptation, which changes with spontaneous rate, A_{sp} (Rhode and Smith, 1985), as described by the following equation:
FIG. 5. The relationship between parameter values (M, x, y, and u) and spontaneous rate for the Meddis model. Other adaptation parameters used to derive the model parameters are: $PTS = (A_r + A_{st} + A_{sus})/A_{sus} = 1 + 9A_{sp}/(9 + A_{sp})$, $\tau_R = 2$ ms, $\tau_{ST} = 60$ ms, $A_r/A_{st} = 6$, and $A_{sus} = 350$. The value of M in the Meddis model changes nonmonotonically with increasing spontaneous rate; all other parameters decrease as spontaneous rate increases.

$$PTS = 1 + 9 \times A_{sp}/(9 + A_{sp}). \tag{21}$$

The other adaptation parameters are held constant across model AN fibers ($\tau_R = 2$ ms, $\tau_{ST} = 60$ ms, $A_r/A_{st} = 6$, $A_{sus} = 350$). The parameter values from Fig. 5 for several specified spontaneous rates are given in Table I. Figure 5(a) shows that the value of M in the Meddis model changes nonmonotonically with increasing spontaneous rate; it drops initially and then increases from 3 to 10 as spontaneous rates increase from 1 to 100 spikes/s. All other parameters (x, y, and u) in the Meddis model decrease continuously as the model's spontaneous rate increases. The parameter changes in Westerman's model are plotted in Fig. 6. The global concentration (C_G) was always set to 1
FIG. 6. The relationship between parameters (P_L, P_G, V_L, V_I) and the spontaneous rate in the Westerman model. The other adaptation parameters are the same as in Fig. 5. The parameters were derived with global concentration (C_G) equal to 1.

TABLE I. Parameters in the simplified Meddis model for several fiber types, specified by the spontaneous rate in parentheses in the first column.

	x	y	M	u	$k1$	$k2$
HSR (60)	120.3	6.63	9.4	0.84	7.6	389.7
MSR (10)	149.6	9.48	5.8	0.87	1.78	357.6
LSR (0.1)	461.4	16.43	9.9	0.96	0.01	38.80

before determining the other parameter values. The trends in the value of the immediate volume, V_I [Fig. 6(d)], are similar to those of M observed in Fig. 5(a). Other parameters (P_G, P_L, and V_L) decrease initially and then are insensitive to the value of spontaneous rate above 5 spikes/s.

The A_{sus} defined in the adaptation parameters is the sustained rate at a certain stimulus level. The level is not specified here but is presumably a high level determined by the level-permeability function in the rest of the composite model for the AN response. The values of model parameters derived from these adaptation parameters are specified for this level (a medium or high level for high-spontaneous-rate model fibers, and a very high level for low-spontaneous-rate model fibers). The assumption of both models is that all of these parameters except one (P_I in Westerman model, and k in Meddis model) are constant across different levels. The adaptation characteristics of the models change as the value of the level-dependent parameter changes. When the level-dependent permeability (P_I, or k) increases, the sustained rate in both models saturates at a value:

$$A_{sus\_MAX} = \lim_{P_i \to \infty} P_I C_I = \frac{P_L P_G C_G}{P_L + P_G} = \lim_{k \to \infty} kq = \frac{yM}{1-u}. \quad (22)$$

The value of $A_{sus,\_MAX}$ also changes with the AN fiber's spontaneous rate (see Fig. 7): The value for high-spontaneous-rate model fibers is comparable to A_{sus},
FIG. 7. The maximum sustained rate [A_{sus_MAX}, solid line; see Eq. (22)] for both Meddis and Westerman models as a function of model spontaneous rate. The other adaptation parameters are set as in Fig. 5 (thus, A_{sus} has a constant value, as shown by the dotted line). The value of A_{sus_MAX} for high-spontaneous rate model fibers is comparable to A_{sus}, whereas the value increases rapidly as spontaneous rate decreases.

whereas A_{sus_MAX} increases rapidly as spontaneous rate decreases. The results above may suggest a fundamental difference between low- and high-spontaneous-rate AN fibers: The high-spontaneous rate fibers have a saturated response rate around A_{sus} with an input level higher than specified, and low-spontaneous-rate fibers will not have a saturated response at higher levels due to a much larger A_{sus_MAX} value than that of A_{sus}.

It is also possible to study analytically the effects of the model parameters on adaptation characteristics with the solution given above. For example, Eq. (17) is the analytical solution for the simplified Meddis model. The steady-state value of q is given by:

$$q_\infty = sQ(s)|_{s=0} = \frac{yM}{y + k_2(1-u)}. \quad (23)$$

If we denote k_L as the value of k at a specified sound stimulus level (L), the steady-state response rate, $R(L)$, can be derived:

$$R(L) = k_L q_\infty = \frac{k_L yM}{y + k_L(1-u)}. \quad (24)$$

With the values of the other model parameters fixed, the model's steady-state response $R(L)$ changes proportionally with the value of M. Sumner et al. [2002, Fig. 5(c)] reported the simulation results of rate-level functions with different values of M. Their results and comments are in fact a direct reflection of the relationship explained in Eq. (24).

Since P_I (or k in the Meddis model) is level dependent, changes of the model adaptation response as a function of the value of P_I after onset represent the effect of level on the model onset characteristics. If we set the value of P_I before onset (P_{I1}) to another value, we can also study the model adaptation responses to increments and decrements using the same paradigm (a comprehensive survey of adaptation in the Meddis model with specified parameters is provided by Sumner et al., 2003).

Figure 8 shows the change of components of the model onset adaptation as a function of the value of immediate permeability P_I after onset (or k in the Meddis model) for a model IHC-AN synapse with spontaneous rate of 50 spikes/s. The model has a spontaneous response with permeability of P_{I1} when there is no stimulus input. The sustained rate (A_{sus}) is roughly saturated at permeability P_{I2}, which generates the desired onset adaptation, while the contribution of short-term and rapid components continues to change as the permeability P_I increases [Fig. 8(a)]. Both the rapid decay time constant and short-term decay time constant decrease as P_I increases [Fig. 8(b); note that τ_R is multiplied by 10 in this plot]. For the simplified Meddis model, these two time constants are determined by the poles in Eq. (17), and values of $-1/\tau_R$ and $-1/\tau_{ST}$ are the roots of the polynomial function in the denominator. The values of τ_R and τ_{ST} can be approximated by $1/k$ and $1/(x-ux)$ when $k \gg x, y$ (i.e., at a medium or high stimulus level for this model fiber). For the model illustrated in Fig. 8, the short-term time constant is about 120 ms at rest and decreases to 50 ms at high levels, and the rapid time constant is 8 ms at rest and de-

X. Zhang and L. H. Carney: Analysis of auditory-nerve synapse
FIG. 8. Effects of the model parameter, P_I, (for the Westerman model) on onset adaptation characteristics. The model parameters were derived from adaptation properties specified in Fig. 5 with a spontaneous rate of 50 spikes/s. The values of P_{I1} and P_{I2} are the values of the immediate permeability before and after the stimulus onset. (a) The contribution of each PST onset component. The contribution of the rapid component (solid line) and short-term component (dotted line) are the integrals of their exponential functions (and thus have units of spikes). The contribution of the constant component (sustained rate–spontaneous rate; dashed line) saturates as P_I increases. (b) Both rapid and short-term time constants decrease as the permeability increases. The rapid time constant (τ_R, solid line) is multiplied by 10 to allow it to be plotted with the short-term time constant (τ_{ST}, dotted line).

creases continuously as the input sound level increases (the value we chose to derive the model parameters was $\tau_{ST} = 60$ ms, $\tau_R = 2$ ms). Since onset adaptation cannot be estimated accurately at low sound levels from physiological responses, these time constants in the model at rest are more related to other adaptation characteristics (e.g., offset adaptation, as discussed in next section, or recovery of onset adaptation).

V. MODIFYING THE SYNAPSE MODEL TO OBTAIN THE DESIRED OFFSET ADAPTATION RESPONSE

The above analysis shows that the model parameters can be determined on the basis of onset adaptation characteristics (at a certain stimulus level). When the model parameters are set, the other adaptation characteristics of the model synapse are automatically determined. If we set the level-dependent permeabilities P_{I1} and P_{I2} (k_1 and k_2 in the Meddis model) to the values before and after the stimulus offset, the analytical solution from Eq. (8) also provides a description of the responses of the model synapse after stimulus offset.

A direct conclusion is that the offset adaptation of the model synapse is also a sum of two exponential functions. The time constants of these two components are determined by P_I after offset and limited by the time constant at the onset. Since only P_{I2} affects the time constant [see Westerman and Smith, 1988, for Westerman's model and Eq. (17) for the Meddis model], Fig. 8(b) also shows how the time constant in the offset adaptation changes with the permeabil-

ity after offset. Physiological studies (Smith and Zwislocki, 1975; Smith, 1977; Westerman, 1985) suggest that AN fibers with medium- or high-spontaneous rate usually stop responding immediately after offset (which begins the deadtime period) and recover slowly with a time constant longer than that of short-term adaptation. However, the rapid component of the model recovery function causes the synapse to recover quickly after stimulus offset. Since $P_I(t)$ and $C_I(t)$ cannot be negative, the magnitude of these recovery components [ϕ'_1, ϕ'_2 in Eqs. (8) and (18); the sign of these components is negative at stimulus offset] is also limited by the value of ϕ'_0 (determined by the spontaneous rate). Because of these limitations, the offset adaptation of the model response is unrealistic as compared to the physiological responses specified in Eq. (2).

The function fitting offset adaptation responses has another general form (Harris and Dallos, 1979):

$$R_{off}(t) = (A_{sp} - A_{min})(1 - e^{-t/\tau_{sp}}) + A_{min} \quad \text{for } R(t) > 0$$
$$= 0 \quad \text{for } R(t) < 0, \quad (25)$$

where A_{min} is a negative value that accounts for the deadtime period of the offset response. Since an AN fiber has a very low probability of response during the deadtime period, the recovery process is not well studied, and there may be a rapid recovery component that corresponds to the onset rapid adaptation and becomes insignificant before the end of the deadtime period. The offset characteristic function can thus be described as:

$$R_{off}(t) = (A_{sp} - A_{min})(1 - e^{-t/\tau_{sp}}) + A_{min}$$
$$+ A_r^{off} e^{-t/\tau_r^{off}} \quad \text{for } R_{off}(t) > 0$$
$$= 0 \quad \text{for } R_{off}(t) < 0, \quad (26)$$

where A_r^{off} is the magnitude (with a negative value) and τ_r^{off} is the time constant of rapid recovery component. Since the model synapse output $P_I C_I$ in the Westerman model cannot be negative, we can assume that the measured synapse output is:

$$R_{off}(t) = P_I(t)C_I(t) - A_{shift} \quad \text{for } R_{off}(t) > 0$$
$$= 0 \quad \text{for } R_{off}(t) < 0, \quad (27)$$

where A_{shift} is a shift value to guarantee that $P_I C_I > 0$, for all t, and that $R_{off}(t)$ is the same offset adaptation function as in Eq. (26) (thus $A_{shift} > |A_r^{off}| + |A_{min}|$). The onset of the model synapse output now becomes

$$P_I(t)C_I(t) = R_{on}(t) + A_{shift}$$
$$= A_{shift} + A_{sus} + A_r e^{-t/\tau_r} + A_{st} e^{-t/\tau_{st}}. \quad (28)$$

Thus, by including this shift, the same equations can describe adaptation of both the onset and offset in the Westerman model. By substituting $P_I(t)C_I(t)$ with $k(t)q(t)$ in Eqs. (27) and (28), the same procedure can be applied to the Meddis model to obtain the desired onset and improved offset adaptation using the same equations.

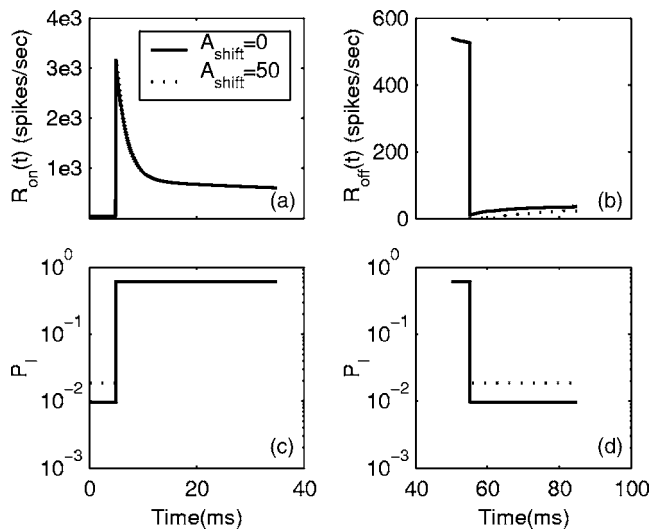
Figure 9 shows the onset and offset responses of the synapse model with or without the shift. The value of the model parameters was derived to have the same onset adap-


FIG. 9. Onset and offset responses of the Westerman model with (dotted line) or without (solid line) the shift value added. The shift value is set to 50 spikes/s. (a) The model onset responses are unchanged because the model parameters were derived to have the same onset adaptation. (b) The model offset response with the shift recovers more slowly than does the model offset response without the shift and has the desired deadtime period. (c), (d) The permeability $P_I(t)$ jumps from P_{I1} to P_{I2} at the onset (5 ms) and drops back to P_{I1} at the offset (55 ms). The model parameters (e.g., P_{I1}) were changed to maintain the same onset response.

FIG. 10. Effects of the parameter A_{shift} in Eq. (27) on the model offset components. The model parameters are derived so they have the same onset adaptation with different A_{shift} values [spontaneous rate $A_{sp}=50$, $A_{sus}=350$, PTS=$(A_r+A_{st}+A_{sus})/A_{sus}=9$, $\tau_R=2$ ms, $\tau_{ST}=60$ ms, $A_r/A_{st}=6.0$; see Eq. (1)]. The upper plots illustrate how the magnitude and time constant of the offset rapid component changes as a function of shift; the middle plots show changes of the offset short-term component. The time constants for both components decrease as shift increases and are larger than the corresponding onset time constants. The rapid component recovers quickly (usually during the deadtime period) and the recovery time constant is thus determined by the short-term component. The magnitude of this component is always negative and decreases (becomes more negative) as the shift increases. A_{min} [bottom right; see Eqs. (25) and (26)] changes from positive to the desired negative as the shift value increases; A_{min} and the time constant of the short-term component determine the duration of the deadtime period. The plot at the bottom left shows the most negative value (including the contribution of the rapid component, which recovers quickly) of the model response without rectification [$R_{off}(t=0)$ in Eq. (24)] as a function of the shift value.

tation. The permeability $P_I(t)$ jumps from P_{I1} to P_{I2} at 5 ms and drops back to P_{I1} at 55 ms. When the shift ($A_{shift}=50$) was added, the model parameters [e.g., P_{I1} in Figs. 9(c) and 9(d)] were changed to maintain the same onset response. Thus, the original model and modified model have the same onset responses [Fig. 9(a)] while the modified model has a greatly improved offset adaptation response [Fig. 9(b)].

The effect of A_{shift} on the offset components is illustrated in Fig. 10. Since the rapid component recovers quickly during the deadtime period, the offset adaptation process is dominated by the short-term component. The magnitude of the short-term component [$A_{min}-A_{sp}$ in Eq. (25)] determines the duration of the deadtime period, and the time constant (τ_{ST}) determines the value of the recovery time constant τ_{SP}. The recovery time constant is always greater than that of the onset short-term adaptation (60 ms), although the value decreases as the shift is increased. The value of A_{min} [Eq. (25)] becomes more negative with a larger shift, which produces the desired deadtime period.

The offset adaptation properties of the IHC-AN synapse could account for enhanced phase locking to the stimulus envelope in AN fibers. The AN fibers were less responsive during the dip of the envelope because of the offset adaptation, and thus the fibers were more synchronized to the peak of the envelope. Figure 11 illustrates the effects of offset adaptation on the modulation transfer function [(MTF), see Joris and Yin, 1992, for a comprehensive experimental study] for a model AN fiber (Zhang *et al.*, 2001) to a sinusoidally amplitude-modulated stimulus.[1] The IHC-AN synapse component of that model was replaced with the synapse model presented here (the onset adaptation parameters were the same as in previous study), and a different shift value was used to represent offset adaptation (i.e., a shift value of

0 means the synapse model was the same as the original model). The stimulus was always fully modulated (modulation index $m=1$) at 10 dB sound pressure level (SPL), with the carrier frequency set equal to the AN CF of 21 kHz. The model AN fibers with offset adaptation (e.g., with a larger shift value) had increased modulation gain and an enhanced MTF that was more consistent with the data from physiological experiments (Joris and Yin, 1992).

VI. DISCUSSION

In this section, we first discuss the differences and similarities between the different models under investigation. We then discuss how to use the analytical methods developed in the present study to further our understanding of adaptation in models and in the IHC-AN synapse. We consider different adaptation measures that can be used to describe a single AN fiber, as well as the fact that different adaptation properties may be observed for different AN fiber types. Finally, we discuss how to extend the analytical method to other models and identify the candidate model that represents the actual underlying physiological mechanism.
FIG. 11. Modulation transfer function for the model AN fibers. The stimulus was always fully modulated at 10 dB SPL with carrier frequency at AN CF of 21 kHz, gated with a 10-ms cosine-square function. The modulation gain was defined as $20 \log[(\text{modulation of responses})/(\text{modulation of stimulus})]$ (i.e., modulation gain $20 \log(2R/m)$, where R was the vector strength of the AN responses and m was the modulation depth; see Joris and Yin, 1992). The model AN fibers with larger shifts in the synapse had higher modulation gain and were more consistent with the data from physiological experiments (asterisks in the figure, from Joris and Yin, 1992).

A. Interpretation and justification of the simplified Meddis model

The loss rate, l, in the cleft of the original Meddis model, was represented in the simplified model by the fraction of synaptic material recycled, $u=r/(l+r)$, where r is the reuptake rate. The difference between the simplified and original model centers on the following questions: Is the recycling of synaptic material in the cleft a two-stage process, as in the original Meddis model, or a one-stage process, as in the simplified model (by assuming reuptake rate r is much larger than w and removing it)? Or, to put the question another way, is the phenomenological one-stage process of the simplified model sufficient to describe the recycling mechanism instead of the two-stage process in the original Meddis model?

With a value of r much larger than the values of x and k, the one-stage process in the simplified model definitely generates the same response as that of the two-stage process in the original Meddis model (see Fig. 4). Even when the value of r decreases to a value comparable to k (still much larger than x), the responses from the simplified model are still almost the same as those of the original model, since the recycling process contributes to the short-term adaptation, which is mainly determined by the value of x. For values of $l+r$ between 1000 and 5000 (Fig. 4), the amplitude and time constant of short-term adaptation does not change much, and the additional component (ϕ_3) which contributes to the rapid adaptation increases at the expense of another rapid component, ϕ_1. For a very small value of r, both reuptake (r) and reprocessing (x) will affect the short-term adaptation in a complex way for the original Meddis model.

It then becomes a question of whether the model with

small values of r and x could predict the adaptation of the IHC-AN synapse. It is not surprising that the exercise of finding model parameters to provide a satisfactory description of adaptation responses ended up with the large value of r in the original Meddis model (Meddis, 1986, 1988; Sumner et al., 2002). These findings justify our simplification of the original Meddis model.

When the value of k becomes extremely high (infinite) after the onset in the original Meddis model, all of the transmitter, $q(0^-)$, in the immediate pool is released into the cleft instantaneously right after the onset. The amount of transmitter in the cleft increases instantly and becomes $q(0^-)+c(0^-)$. Thereafter, all transmitter replenished from the reprocessing store (w) and the global factory into the immediate pool is released into the cleft instantaneously:

$$kq = yM + xw. \qquad (29)$$

The dynamics of the original Meddis model are now governed by Eqs. (4), (5), and (29). The solution of these equations in the Laplace domain is given by:

$$C(s) = \frac{(yM + c(0^-) + q(0^-))(s+x) + xw(0^-)s}{s(s+r/u)(s+x) - rxs}, \qquad (30)$$

where u is defined as the fraction of transmitters recycled, $u=r/(l+r)$.

If the synapse output is proportional to the amount of transmitter in the cleft $c(t)$, the responses in the original Meddis model can again be characterized by Eq. (18), based on Eq. (30). The steady-state response in the original Meddis model is also specified by Eq. (24), and is independent of the value of r. The rapid adaptation time constant (τ_R) can be approximated by u/r, or $1/(l+r)$, when $r/u \gg x$, and this value of τ_R is independent of k at high stimulus levels (k is very large). Thus, with an appropriate value of $l+r$, the original Meddis model is a better candidate than the simplified Meddis model in predicting the changes of the adaptation time constants at high stimulus levels (Westerman, 1985). In reality, the composite AN model with the original Meddis synapse model usually has k operating within a limited range, and thus the original Meddis model can be perfectly replaced by the simplified Meddis model.

B. Physiological assumptions underlying the Westerman and Meddis models

This study shows that two phenomenological IHC-AN synapse models that were designed to explain the onset adaptation characteristics of AN responses are essentially the same. It is impossible to differentiate these two models by evaluating their adaptation responses. There are many similarities between the Westerman and Meddis models. Rapid adaptation is modeled as a depletion of the synaptic material in the immediate store in both models, which is supported by recent physiological studies (Moser and Beutner, 2000).

The sustained response of the IHC-AN synapse in both models is attributed to the replenishment of synaptic material from the global store to the immediate store, either directly or indirectly. For model fibers with little adaptation but considerable sustained response rate (e.g., some low-

TABLE II. Adaptation characteristics derived from three model fibers specified in Sumner *et al.* (2002). The values of M, spontaneous rate, and sustained rate of fibers are specified in the first three columns. The sustained response rate of fibers is always 10 spikes less than the maximum response described in Eq. (22). The values of other model parameters are from Sumner *et al.* (2002): $y=10$, $x=66.3$, $l=2580$, $r=6580$. The values of $k1$ and $k2$ are then derived from Eq. (24), and the other adaptation characteristics are derived from the simplified Meddis model.

	M	A_{sp}	A_{sus}	$k1$	$k2$	τ_R (ms)	A_r (spikes/s)	τ_{ST}(ms)	A_{st} (spikes/s)
H1	10	60	345	7.2202	1225	0.78	9660	54.5	174.6
M1	13	10	451	0.7863	1603	0.60	19667	54.3	271.6
L1	8	0.1	274	0.0125	972.9	0.97	7340	54.7	167.0

spontaneous-rate fibers), the replenishment rate of synaptic material from the global pool into the immediate store must be comparable to the release rate of synaptic material from the immediate store into the cleft. For the Meddis model, either a small k or large y at high levels is needed for these model fibers (or both; see Table I and Fig. 5). To overcome this limitation, another global store that releases synaptic materials directly into the cleft can be included to generate the sustained response. This parallel global synaptic store separates the sustained response from adaptation, and adaptation across different fibers can be adjusted by changing the value of M (or C_G in the Westerman model) instead of the value of the replenishment rate of synaptic material into the immediate store.

The key difference between two models is that short-term adaptation is accounted for by the recycling of the synaptic material from the cleft in the Meddis model and by depletion in the Westerman model. Recent physiological studies (Moser and Beutner, 2000) show that the time constant of endocytosis is about 7.5 s in the IHC-AN synapse. However, in the Meddis model, the recycling rate of synaptic material in the cleft must be set to a time scale of approximately 10 ms to account for short-term adaptation. Thus, the model time constant is about 100 times faster than the value obtained in physiological studies.

In the Westerman model, it is assumed that short-term adaptation does not come from endocytosis, and the recycling process is not included in this model. Instead, short-term adaptation is modeled as the depletion of synaptic materials in the local store. Of course, it is entirely possible that the physiological assumptions in both models are wrong, but that the models work because they are sufficient models for representing actual physiological mechanisms that are unknown.

C. Different adaptation measures for single auditory-nerve fibers

Other than onset and offset adaptation, there are many other measures of adaptation: Recovery after offset (Harris and Dallos, 1979; Westerman, 1985), responses to increments (Smith and Zwilocki, 1975; Smith *et al.*, 1985), decrements (Smith *et al.*, 1985), and conservation (Westerman, 1985). Sumner *et al.* (2003) provided a comprehensive survey of these adaptation measures in a recently developed version of the Meddis model, with several sets of model parameters specified. These results can be applied to the Westerman model quite naturally since the two models are essentially the same, with the appropriate parameters specified. Our analytical results allow the adaptation characteristics to be derived directly from the specified model parameters (Table II).

Instead of evaluating whether specified model AN fibers can predict different measures of adaptation, our analytical results can provide insights for the limitations of these models, and explain the performance of these models for different adaptation measures. For example, Fig. 8 showed the changes of onset adaptation components with the stimulus-level-dependent variable k in the simplified Meddis model (or P_I in the Westerman model). The rapid and short-term adaptation time constants, τ_R and τ_{ST}, approach $1/k$ and $1/(x-ux)$, respectively, as the value of k increases. The value of τ_R is more affected by the value of k than that of τ_{ST}, especially when they are plotted on a log scale. These results explain the simulation results reported by Sumner *et al.* (2003), and provide insights into the failure of these models in predicting the changes of the rapid adaptation time constant at low sound levels.

For the Westerman model, recovery after stimulus offset of the onset rapid and short-term adaptation can be interpreted as the replenishment of the synaptic material in the immediate and local stores. The recovery time constant of rapid adaptation is thus determined by the permeability, P_L, between the local and immediate stores, which also determines the time constant of short-term adaptation (depletion of synaptic material in the local store) at onset. This explains why the recovery time constant of rapid adaptation is comparable to the short-term adaptation time constant instead of that of rapid adaptation, consistent with both physiological studies (Westerman, 1985; Moser and Beutner, 2000) and simulation studies (Sumner *et al.*, 2003).

The analytical results from these models show that different adaptation measures are highly correlated for a single model IHC-AN synapse. It is of great interest to see how these adaptation measures are correlated in the physiological responses of single AN fibers. The correlation studies of adaptation measures across AN fibers may be limited by the variation of physiological properties across AN fibers.

The values of model parameters can be derived from adaptation characteristics at different stimulus levels (Westerman and Smith, 1988). When more than one model parameter varies with level, the underlying assumptions of the method used here to generate the model parameters (e.g., allowing only P_I or k to change with level) is invalidated. In this situation, it is more mathematically challenging to estab-

lish the relationship between adaptation characteristics and model parameters. On the other hand, when this level-dependent relationship is established using more complex techniques, the model may provide more accurate predictions for different measures of IHC-AN adaptation, and it may also provide insights into the physiological properties specified by the model parameters.

D. Adaptation across different auditory-nerve fiber types and transmitter release functions in model auditory-nerve fibers

Our analytical approach makes it possible to link adaptation characteristics directly to the values of model parameters. Making models to predict adaptation across AN fiber types then becomes a question of how to determine different adaptation characteristics across AN fiber types. In the present study, we considered the example of a description of different fiber types based on the peak-to-sustained ratio $[PTS=(A_r+A_{st}+A_{sus})/A_{sus}]$ of the onset adaptation, which changes as a function of spontaneous rate, A_{sp} (Rhode and Smith, 1985) [Eq. (21)]; other parameters were fixed across different fiber types ($\tau_R=2$ ms, $\tau_{ST}=60$ ms, $A_r/A_{st}=6$, $A_{sus}=350$). For low-spontaneous-rate fibers with PTS close to a value of 1, values of A_r and A_{st} are very small. Since there is little contribution of these adaptation components to AN fiber responses, the values of other parameters (τ_R, τ_{ST}, and A_r/A_{st}) may not be determined with confidence based on a fit of the PST histograms, and models with a wide range of parameter values can provide equally good fits to the AN fiber responses.

It is possible to determine adaptation characteristics using the results of other experimental paradigms. Relkin and Doucet (1991) found that the recovery time constant for low-spontaneous-rate fibers is much larger than that of high-spontaneous-rate fibers, and the small peak-to-sustained ratio observed for low-spontaneous-rate fibers (Rhode and Smith, 1985) may have been partly determined by the short inter-stimulus intervals used to study them (105 ms for Rhode and Smith, 1985). The relationship between adaptation characteristics of different measures and model parameters can be created using our analytical approach, and values of model parameters can be derived accordingly.

When some characteristics of adaptation cannot be determined with confidence by fitting the PST histograms for certain AN fiber types (e.g., low-spontaneous-rate fiber), it is reasonable to fix some model parameters across all model fiber types (e.g., y for the Meddis model, or P_G for the Westerman model), and then derive the values of the other parameters in the model. The assumption underlying this method is that the corresponding physiological property specified by the model parameter does not change across different fiber types. It would be very interesting to see how these corresponding physiological properties varied across the IHC-AN synapse in physiological studies.

In addition to specifying the model parameters to explain adaptation, it is also critical to find an appropriate transmitter release function for the AN model fiber to generate desired rate-level responses. The relationship between IHC voltage (V_{IHC}, referenced to the IHC resting potential),

which is stimulus dependent, and release rate from the immediate store (k in the Meddis model, or P_I in the Westerman model) is highly simplified and usually specified by an *ad hoc* function in most modeling studies.

For the Meddis model, the relationship between the steady-state response rate and k is specified in Eq. (24), and the rate-level function is further determined by the V_{IHC}-k relationship. For a simple linear V_{IHC}-k relationship, the value of k at rest ($V_{IHC}=0$) determines the spontaneous response of the model fiber, and the slope of the V_{IHC}-k function determines how fast the response will approach saturation [A_{sus_MAX} in Eq. (22)] and whether or not the rate-level function will saturate. It is thus not surprising that equivalent parameters in these models varied across different model fiber types (Heinz *et al.*, 2001; Sumner *et al.*, 2002), and that the values of these parameters affected the shape of the rate-level functions in simulations [Figs. 5(a) and 5(b) in Sumner *et al.*, 2002, Fig. 1 in Sumner *et al.*, 2003].

Another useful conclusion from Eq. (22) is that the saturation of the synapse response is largely contributed by the synapse model itself, rather than by saturation of the value of k (or P_I). The fact that P_I does not saturate as V_{IHC} increases at high levels (Carney, 1993; Zhang *et al.*, 2001) is important for the model to predict AN fiber temporal response properties (e.g., synchronization index) across levels.

The V_{IHC}-k (or V_{IHC}-P_I) relationship for model AN fibers should also be characteristic frequency (CF) dependent. The voltage responses of the IHC at various basilar-membrane locations to a tone at CF have different ac/dc components (Cheatham and Dallos, 1993),[2] and attenuation of the AC component at high frequencies suggests that a steeper slope of V_{IHC}-k relationship (or V_{IHC}-P_I, see Zhang *et al.*, 2001) is required to generate similar rate-level functions.

Physiologically, the transmitter release at the IHC-AN synapse is controlled through V_{IHC}-dependent calcium dynamics, and is highly nonlinear and complex. Calcium dynamics have been considered in recent versions of these models. Sumner *et al.* (2002) included a specific calcium-controlled transmitter-release function in the Meddis model, and Zhang *et al.* (2001) used low-pass filters and an *ad hoc* control function to model the effects of calcium dynamics.

E. Understanding the relationship between offset and onset adaptation

The study shows that a simple shift can improve the model's offset adaptation without compromising the model's onset adaptation characteristics. Inclusion of offset adaptation in the model improves the model's prediction of the temporal aspects of the AN fiber responses and thus benefits other modeling studies based on the temporal responses of AN fibers (e.g., modulation studies). A negative adaptation was used in a previous study (Ross, 1996) to produce the deadtime period in the offset adaptation. This negative adaptation was limited to one of the parallel pathways and thus had a limited contribution to the temporal responses of AN fibers. The physiological meaning of the negative adaptation also needs further explanation.

The shift A_{shift} introduced in the present model can be

interpreted as a constant threshold (either concentration or number of neurotransmitter molecules) in the synaptic cleft before the transmitter reaches the postsynaptic site. When the transmitter concentration in the cleft is higher than A_{shift}, the firing probability in the postsynaptic neuron changes linearly as a function of concentration. The firing probability in the postsynaptic neuron approaches zero quickly when the transmitter concentration is less than A_{shift} (so zero in the model output could be interpreted as a very low firing probability). Since the offset adaptation of the AN fiber is related to the spontaneous rate (Harris and Dallos, 1979; Westerman, 1985), it is reasonable for the value of the shift to vary as a function of the spontaneous rate of the fiber as well. Further study of how the value of the shift is related to the other characteristics of the model fiber responses is needed.

Also, the results show that the offset adaptation time constant is closely related to the short-term constant of the onset adaptation for the model explored. In fact, if the model onset adaptation is measured from level L_0 to level L_1 (L_0 is the level before the onset and L_1 is the level after onset) and offset adaptation is measured from level L_2 to L_1 (L_2 is the level before the offset and L_1 is the level after the offset), the time constants for the onset short-term component and for the offset adaptation are the same, based on Eq. (17). Whether this is a limitation of the model or reflects some underlying mechanism of the synapse requires further examination.

Our modification to improve the model's offset adaptation is based on the assumed shape of offset adaptation from physiological studies: A period of deadtime (or period of low firing probability), followed by a single slow recovery function. Whether other characteristic functions can provide a better fit for the physiological data is an interesting topic for future studies. The modification of the model will be further justified if future studies suggest that this characteristic function provides a better fit to the physiological data than that of other models.

F. Extension of analytical approach to other models

The mathematical methods proposed in this study are also useful for analysis of models with other structures. Several models (Smith and Brachman, 1982; Ross, 1996) include parallel pathways of transmitter reservoirs to produce the additivity of responses to increments. These models could also be described by differential equations, and the relationship between adaptation characteristics and model parameters can be established for further understanding of these models.

The analytical approach provided in this study can help us to identify the candidate model that represents the actual underlying physiological mechanism. Values of model parameters can be derived from our analytical approach for different amounts of adaptation in the IHC-AN synapse, due to either different IHC-AN synapses (i.e., different AN fiber types) or to different stimulus levels. By studying the physiological changes of the synapse with different amounts of adaptation, and the correlation between changes of the model parameters and physiological properties, we can validate if the model can represent the actual physiological mechanism. For example, physiological studies (Moser and Beutner, 2000) support the idea that rapid adaptation is due to the depletion of the synapse material in the immediate store that is present in both models considered here.

Modeling the IHC-AN synapse is still a very challenging task because of the synapse structure (how the reservoirs are connected) and the processing dynamics (how the V_{IHC} affects model parameters such as permeabilities). While it is easy to complicate the IHC-AN synapse model with more physiologically realistic structures, the benefit of such complications in providing more accurate responses should be carefully studied. Modeling studies of other adaptation measures (Hewitt and Meddis, 1991; Sumner *et al.*, 2002, 2003), which focused on models with preset parameters, should also be extended. An analysis of the relationship of these adaptation measures and how they are affected by the model parameters will greatly improve our knowledge of both IHC-AN synapse models and of the underlying physical system.

APPENDIX: RELATIONSHIP BETWEEN ADAPTATION CHARACTERISTICS AND THE MEDDIS-MODEL PARAMETERS

The Meddis model with three neurotransmitter reservoirs (q, w, c) can be described by the simplified Eqs. (A1) and (A2) [rewritten from Eqs. (14) and (15)]:

$$\frac{dq}{dt} = y(M - q(t)) - kq(t) + xw(t), \tag{A1}$$

$$\frac{dw}{dt} = kuq(t) - xw(t). \tag{A2}$$

The model parameters M, y, x, u are constant, and k is the level-dependent permeability, which is denoted as k_1 before the onset and as k_2 after the onset.

The onset adaptation of the model synapse is characterized by:

$$R_{on}(t) = A_{sus} + A_r e^{-t/\tau_R} + A_{st} e^{-t/\tau_{ST}}, \tag{A3}$$

with a spontaneous rate of A_{sp}, where A_{sus}, A_r, and A_{st} represent the response amplitude (instantaneous firing rate) of the sustained component, rapid adaptation component, and short-term adaptation component, and τ_R and τ_{ST} represent the time constants of the rapid and short-term adaptation components.

If we assume that $kq(t)$ is the output of the model synapse, the relationship between the model parameters and adaptation characteristics can be described by the following equations [$-1/\tau_R$ and $-1/\tau_{ST}$ are the poles of $Q(s)$ in Eq. (17)]:

$$\frac{k_1}{k_2} = \frac{A_{sp}}{A_r + A_{st} + A_{sus}}, \tag{A4}$$

$$\frac{yMk_1}{y + k_1(1-u)} = A_{sp}, \tag{A5}$$

$$\frac{yMk_2}{y + k_2(1-u)} = A_{sus}, \tag{A6}$$

$$x + k_2 + y = 1/\tau_R + 1/\tau_{ST}, \tag{A7}$$

$$x(y + k_2(1-u)) = 1/(\tau_R \tau_{ST}), \tag{A8}$$

$$\frac{k_2}{k_1}(k_2 - k_1)A_{sp} = A_r/\tau_R + A_{sus}/\tau_{ST}. \tag{A9}$$

Several intermediate parameters are useful for the derivation of the model parameters:

$$A_{on} = A_{sus} + A_r + A_{st}, \tag{A10}$$

$$S_r = 1/\tau_R + 1/\tau_{ST} \tag{A11}$$

$$S_{r2} = A_r/\tau_R + A_{st}/\tau_{ST}, \tag{A12}$$

$$P_r = 1/(\tau_R \tau_{ST}). \tag{A13}$$

From Eqs. (A4) and (A9), k_1 and k_2 can be specified as:

$$k_2 = S_{r2}/(A_{on} - A_{sp}), \quad k_1 = A_{sp}/A_{on}k_2. \tag{A14}$$

Several other intermediate parameters are defined as:

$$\beta = (A_{sus} - A_{sp})k_1 k_2/(A_{sp}k_2 - A_{sus}k_1), \tag{A15}$$

$$a = (\beta + k_2)\beta, \quad b = -(S_r - k_2)(\beta + k_2), \quad c = P_r, \tag{A16}$$

$$z = -\frac{-b + \sqrt{b^2 - 4ac}}{2a}. \tag{A17}$$

The other model parameters then are set as follows:

$$u = 1 - z, \tag{A18}$$

$$y = \beta z, \tag{A19}$$

$$x = S_r - k_2 - y, \tag{A20}$$

$$M = \frac{A_{sp}(y + k_1 z)}{yk_1}. \tag{A21}$$

Computer code related to the material in this Appendix is available at the website http://web.syr.edu/~lacarney/.

[1]The model results presented here are illustrative. More extensive explorations have been conducted in another study (Nelson and Carney, 2004).

[2]We (and others) have assumed that there is no adaptation in the voltage responses of the IHC, but a recent study suggests that there may indeed be some adaptation at this level. It is important to explore the contribution of the IHC adaptation described by Zeddies and Siegel (2004) to AN responses, especially at the onset and offset of tone bursts and in response to AM stimuli.

Phase of neural excitation relative to basilar membrane motion in the organ of Corti: Theoretical considerations

Masayoshi Andoh, Chihiro Nakajima, and Hiroshi Wada[a)]
Department of Bioengineering and Robotics, Tohoku University, 6-6-01 Aoba-yama,
Sendai 980-8579, Japan

Although the auditory transduction process is dependent on neural excitation of the auditory nerve in relation to motion of the basilar membrane (BM) in the organ of Corti (OC), specifics of this process are unclear. In this study, therefore, an attempt was made to estimate the phase of the neural excitation relative to the BM motion using a finite-element model of the OC at the basal turn of the gerbil, including the fluid-structure interaction with the lymph fluid. It was found that neural excitation occurs when the BM exhibits a maximum velocity toward the scala vestibuli at 10 Hz and shows a phase delay relative to the BM motion with increasing frequency up to 800 Hz. It then shows a phase advance until the frequency reaches 2 kHz. From 2 kHz, neural excitation again shows a phase delay with increasing frequency. From 800 Hz up to 2 kHz, the phase advances because the dominant force exerted on the hair bundle shifts from a velocity-dependent Couette flow-induced force to a displacement-dependent force induced by the pressure difference. The phase delay that occurs from 2 kHz is caused by the resonance process of the hair bundle of the IHC. © 2005 Acoustical Society of America. [DOI: 10.1121/1.2000770]

I. INTRODUCTION

The mammalian cochlea consists of a fluid-filled duct that is coiled like a snail shell. Figure 1 shows a simplified sketch of the cross section of the gerbil cochlea. The cochlea is divided into three compartments, i.e., the scala vestibuli (SV), the scala media (SM), and the scala tympani (ST), by two longitudinal membranes, i.e., Reissner's membrane and the basilar membrane (BM). The vibration of the tympanic membrane and the ossicular chain, which is induced by sound, is transmitted to the BM through the cochlear fluid.

Figure 2 shows a schematic of a cross section of the organ of Corti (OC) of the gerbil. The OC, which sits on the BM, also vibrates in response to the vibration of the BM. When the OC undergoes vibration, it is conventionally thought that the hair bundles of the inner hair cell (IHC) and the outer hair cell (OHC) are deflected due to the shear motion between the tectorial membrane (TM) and the reticular lamina (RL), as shown in Fig. 2. The tip of the hair bundle of the IHC appears to be freestanding, while that of the OHC is embedded in the TM (Engströme and Engström, 1978). The deflection of the hair bundle induces a change of the membrane potential of these cells. As shown in Fig. 2, the deflection in the direction of the tallest hair induces depolarization and that in the direction of the shortest hair induces hyperpolarization. The IHC excites the auditory nerves when its membrane potential is depolarized (Katz and Miledi, 1967) and the OHC contracts and elongates in response to the depolarization and hyperpolarization (Brownell *et al.*, 1985; Kachar *et al.*, 1986; Zenner, 1986; Ashmore, 1987; Santos-Sacchi and Dilger, 1988), respectively. This motility of the OHC generates a force (Hallworth, 1995; Iwasa and Adachi,

1997; Frank *et al.*, 1999) which amplifies the OC vibration, especially at low stimulus intensity. The auditory transduction process is therefore dependent on specific factors of the neural excitation in response to the BM vibration. Knowledge of these factors is important in the investigation of the auditory mechanics and the development of speech processors for cochlear implants.

For an investigation of the phase of the neural excitation relative to the BM motion, considerable research has been conducted. The traditional view of the response of the hair bundle of the IHC to the BM vibration is that the hair bundle of the IHC responds to the velocity of the BM vibration (Pickles, 1988) because the shear force exerted on the hair bundle is thought to be due to the shear flow between the TM and the hair bundle, the so-called Couette flow, as indicated in Fig. 2, this force being proportional to the velocity of the shear flow. As a result, if the maximum velocity of the shear flow is assumed to occur when the velocity of the BM is maximum, the maximum displacement of the tip of the hair bundle of the IHC in the direction of the tallest hair, which induces depolarization, occurs when the velocity of the BM toward the SV is maximum, i.e., when the BM crosses its equilibrium position (zero displacement) from the ST to the SV. Although the phase of the neural excitation relative to the displacement of the hair bundle is influenced by low-pass filtering at the membrane of the IHC, this influence seems to be small if the stimulus frequency is sufficiently lower than the corner frequency of the filter [approximately 200 Hz (Cheatham and Dallos, 1999)]. Therefore, according to this traditional idea, at well below 200 Hz, neural excitation would occur when the velocity of the BM toward the SV is maximum.

Ruggero and Rich (1983) measured the relationship between the neural excitation and the simultaneous BM posi-

[a)]Electronic mail: wada@cc.mech.tohoku.ac.jp
FIG. 1. Schematic of the cross section of the cochlea of the gerbil.

tion, and concluded that neural excitation occurs when the displacement of the BM toward the ST is maximum at the basal turn of the chinchilla cochlea with the characteristic frequency (CF, the most effective stimulus frequency) of 16 kHz for low-frequency stimuli (30 to 100 Hz) at 100 dB SPL. Furthermore, Wada *et al.* (2002) measured the relationship between the neural excitation and the BM motion at the
FIG. 2. Structure and mechanoelectrical transduction of the OC of the gerbil. Large arrows on the TM and beside the BM indicate the direction of their displacement. When the BM undergoes oscillatory motion, the hair bundle of the OHC is deflected by the relative displacement between the TM and the RL because its tip is embedded in the TM. On the contrary, according to the traditional idea, the hair bundle of the IHC is assumed to be vibrated by the shear force due to the shear flow between the TM and the hair bundle, and this shear force in the excitatory direction (toward the tallest hair) is thought to become maximum when the velocity of the BM toward the SV is maximum, i.e., the BM crosses its equilibrium position (zero displacement) from the ST to the SV. The deflection of the hair bundle of the IHC causes the excitation of auditory nerves, while the deflection of the hair bundle of the OHC induces the OHC motility that generates the force.

basal turn of the guinea pig cochlea with high CFs (14–22 kHz) to low-frequency stimuli (50 to 2000 Hz) at 100 dB SPL, and demonstrated that neural excitation lags behind the maximum displacement of the BM toward the SV by 20° from 50 to 100 Hz and by 45° at 500 Hz, and leads it by 45° at 2 kHz. These experimental data are therefore different from each other, as well as differing from the above-mentioned conventional idea. Thus, the phase of the neural excitation in relation to the BM motion in the cochlea has remained unclear. Cai *et al.* (2004) constructed a model of the OC by which its dynamic behavior can be analyzed. Although such a micromechanical model is expected to make it possible to investigate the phase relationship between the displacement of the hair bundle of the IHC and that of the BM in detail, they did not conduct this kind of analysis. Steele and Puria (2003) numerically analyzed the force exerted on the hair bundle of the inner hair cell by using local lubrication theory. Their research was a pioneering work, and the three rows of cilia and tip links were taken into account. However, they analyzed the vibration of the OC until 300 Hz, although the CF of their model was higher than 10 kHz. In addition, the mechanism of the force generation was not discussed.

In this study, first, a finite-element model of the OC and finite-element models of the lymph fluid surrounding the OC and of such fluid in the sub-TM space, which is a narrow space between the TM and RL, were constructed. Using these models, the phase of the displacement of the hair bundle of the IHC relative to the BM motion was then calculated. Finally, by considering the phase delay due to the low-pass filtering at the membrane of the IHC, the phase of the neural excitation relative to the BM motion was estimated.

II. MODEL OF THE ORGAN OF CORTI

A. Modification of the previous model

In a previous study (Andoh and Wada, 2004), although the geometry of the OC at the basal turn of the gerbil cochlea, where the CF is approximately 16 kHz, was reproduced based on measurement in the hemicochlea of the gerbil (Edge *et al.*, 1998; Richter *et al.*, 2000), the shapes of the TM, Deiters' cells, Hensen's cells, pillar cells, and the inner sulcus were not realistic. In addition, the homogeneous layer, the so-called hyaline matrix, between the fibrous layers in the BM, was neglected. Furthermore, as the lymph fluid in the sub-TM space was omitted, the dynamic behavior of the hair bundle of the IHC could not be analyzed. Therefore, the following additional features were incorporated in the modified model.

(a) Realistic shapes of the TM, Deiters' cells, Hensen's cells, pillar cells, and the inner sulcus.
(b) Inclusion of the hyaline matrix in the BM.
(c) Modeling of the lymph fluid in the sub-TM space.

Figure 3(a) shows the previous model of the OC, and Fig. 3(b) shows the modified model of the OC. Shapes of the TM, Deiters' cells, Hensen's cells, pillar cells, and the inner sulcus were determined based on the measurement results of

(a)

(b)
FIG. 3. Model of the OC. (a) Previous model of the OC. (b) Modified model of the OC. Each shade of gray in the model indicates a portion with the same mechanical properties. Thick lines surrounding the model indicate the fluid-structure interface of the model.

FIG. 4. Model of the lymph fluid in the sub-TM space. The sub-TM space is a fluid-filled space below the TM. It was modeled from the inner sulcus to the narrow space between the hair bundle of the IHC and that of the first row of the OHC. The height of the hair bundle of the IHC is 4.3 μm, and its shape is sharply wedged. The number of nodes is 2128 and the number of elements is 1554.

the OC in the hemicochlea of the gerbil (Richter, 2003). Although the constituents of the hyaline matrix in the BM are unknown, its structure is similar to the gel-like structure of the TM. Young's modulus of the hyaline matrix was therefore assumed to be the same as that of the TM. Table I shows all mechanical properties assigned to the models.

The boundary conditions of the models of the OC and the lymph fluid are the same as those in the previous study. They were validated by comparing the experimental data, i.e., the pressure in the ST (Olson, 2001) and the frequency characteristics of the velocity of the BM (Ren and Nuttall,

TABLE I. Mechanical properties assigned to the models of the OC and lymph fluid. The stiffness of the hair bundle relative to the displacement of its tips is 2.5×10^{-3} N/m (Langer *et al.*, 2001). The density and viscosity of the lymph fluid are 1.0×10^3 kg/m^3 and 1.0×10^{-3} Pa·s, respectively, which are equal to those of water.

	Young's modulus (N/m^2)	Poisson's ratio
BM (fibrous layer)	1.0×10^7	0.3
BM (hyaline matrix)	3.0×10^4	0.49
Deiters' cell	1.0×10^7	0.3
Hair bundle	1.0×10^7	0.3
Hensen's cell	5.0×10^3	0.49
IHC	1.0×10^4	0.49
Kimura's membrane	1.0×10^6	0.3
Osseous spiral lamina	2.0×10^{10}	0.3
OHC	1.0×10^4	0.49
Phalanx	1.0×10^7	0.3
Pillar cell	1.0×10^9	0.3
RL	1.0×10^9	0.3
TM	3.0×10^4	0.49

2001), with the numerical results in the previous study (Andoh and Wada, 2004). As the force generated by the OHC motility is not taken into account, the simulation is limited to the passive cochlea, i.e., OHCs are dysfunctional, or to the active cochlea, i.e., OHCs are functional when the level of the input stimulation is greater than 100 dB SPL (Ren and Nuttall, 2001).

B. Lymph fluid in the sub-TM space

1. Model of the sub-TM space

To simulate the dynamic behavior of the hair bundle of the IHC, the pressure around the hair bundle must be analyzed. The model of the sub-TM space was therefore constructed as shown in Fig. 4. The width in the longitudinal direction (normal to the paper) and boundary conditions of the sub-TM model are the same as those of the SV and ST models (Andoh and Wada, 2004), i.e., the width in the longitudinal direction is 48 μm and free-flux boundary conditions are assigned to both longitudinal ends. The distribution of the velocity of the fluid around the hair bundle of the OHC was assumed to be the same as that of the hair bundle itself, due to the fact that its tip is embedded in the TM. In addition, as the hair bundle arranged in a W-shaped formation accounts for 80% of the diameter of the OHC, we assumed that the flow in the gap between the hair bundles of the OHCs in the same row was negligibly small. As a result, the sub-TM space was modeled up to the hair bundle of the first row of OHCs. These assumptions lead to the idea that the lymph fluid beyond the hair bundle of the first row of OHCs does not have an effect on the behavior of the lymph fluid around the hair bundle of the IHC. Although the tip of the hair bundle of the IHC is hemispherical, that of the model employed in this study is sharply wedged due to refinement of the mesh. The geometry of the space between the TM and the tip of the hair bundle of the IHC was determined based on a micrograph taken at the basal turn in the gerbil cochlea (Richter, 2003). The intervals of the mesh in the
FIG. 5. Force induced by the pressure difference and exerted on the hair bundle. The pressures in the fluid elements (light gray areas) adjacent to the structural elements of the hair bundle were converted to the force vector $\mathbf{f}_{\text{pres},n}$ at each node on the hair bundle. The force vectors at the attachment to the RL were omitted because they have no influence on the dynamic behavior of the hair bundle.

cross section are varied to avoid severe distortion of the cubic shape of the element, and result in 6×37 elements in one cross section, which make it possible to evaluate the pressure around the hair bundle of the IHC. The interval of the mesh in the longitudinal direction is 6 μm, which is the same as that in the SV and ST models.

2. Forces exerted on the hair bundle of the IHC

The pressure difference between the left and right sides of the hair bundle induces force that is exerted on the hair bundle of the IHC. In addition, as the pressure difference between the left and right sides and the relative velocity of the TM in relation to the hair bundle induce fluid flows in the narrow space, shear forces generated by these flows, i.e., Poiseuille flow and Couette flow, are considered to be exerted on the hair bundle. These three types of forces are therefore considered to be exerted on the hair bundle of the IHC.

a. Force induced by the pressure difference Figure 5 shows the force vectors induced by the pressure around the hair bundle and exerted on the hair bundle. The force vector $\mathbf{f}_{\text{pres},n}$ on each node of the structural element of the hair bundle caused by the pressure is obtained by

$$\mathbf{f}_{\text{pres},n} = \frac{1}{2} p_n A_n \mathbf{n}_n, \tag{1}$$

where p_n is the pressure in the fluid element adjacent to the structural element of the hair bundle, A_n is the area of contact between the fluid and structural element, and $\mathbf{n}_n$ is a unit normal vector of the fluid-structure interface. The sum of force vectors over nodes on the hair bundle is the force in-
(a)
(b)

FIG. 6. Shear forces exerted on the hair bundle. (a) Force induced by Poiseuille flow. Light gray areas indicate the places where the mean pressures were calculated. Poiseuille flow occurs in the gap between the TM and the hair bundle because of the difference between the mean pressure at the left side of the gap p_L and that at the right side of the gap p_R. The force vector induced by Poiseuille flow $\mathbf{f}_{\text{Poise}}$ is in equilibrium with the difference between the product of the pressure and the cross-sectional area at the left side of the gap between the TM and the hair bundle and that at the right side of the gap. (b) Force induced by Couette flow. Couette flow in the gap between the TM and the hair bundle results from the relative velocity V_{relative} of the TM in relation to the hair bundle. The force vector induced by Couette flow $\mathbf{f}_{\text{Couet}}$ is a product of the viscosity and the velocity gradient between the TM and the hair bundle.

duced by the pressure difference between the left and right sides of the hair bundle.

b. Analytical deviation of the shear forces Due to computer memory size limitation, the mesh intervals in the sub-TM model are insufficiently fine for an analysis of the distribution of the fluid velocity in the gap between the TM and the RL, which is the space bounded by the TM, RL, and light gray areas shown in Fig. 6(a). Therefore, the shear forces induced by the fluid flow and exerted on the hair bundle were derived analytically.

Figure 6(a) shows Poiseuille flow-induced shear force exerted on the hair bundle and the TM. The sum of Poiseuille flow-induced shear force exerted on the hair bundle and the

TM was assumed to be the same as the difference between the product of the pressure and the cross-sectional area at the left side of the gap between the TM and the hair bundle and that at the right side. As there are two structural element nodes on each surface facing the gap between the TM and the hair bundle, the force vector $\mathbf{f}_{\mathrm{Poise}}$ on each node of the structural element caused by Poiseuille flow is given by

$$\mathbf{f}_{\mathrm{Poise}} = \frac{1}{4}(p_{\mathrm{L}}A_{\mathrm{L}} - p_{\mathrm{R}}A_{\mathrm{R}})\mathbf{m}, \tag{2}$$

where p_{L} and p_{R} are the mean pressures in the fluid elements adjacent to the left and right sides of the gap between the TM and the hair bundle shown by light gray areas in Fig. 6(a), A_{L} and A_{R} are the cross-sectional areas at the left and right sides of the gap, respectively, and $\mathbf{m}$ is a unit normal vector of the constant pressure line. Figure 6(b) shows Couette flow-induced shear force exerted on the hair bundle and the TM. After Arnell *et al.* (1991), the force vector $\mathbf{f}_{\mathrm{Couet}}$ on each node of the structural element facing the gap between the TM and the hair bundle caused by Couette flow is given by

$$\mathbf{f}_{\mathrm{Couet}} = \frac{1}{2}\mu\frac{\mathbf{V}_{\mathrm{relative}}}{(H_{\mathrm{L}} - H_{\mathrm{R}})}A_{\mathrm{LR}}\ln\frac{H_{\mathrm{L}}}{H_{\mathrm{R}}}, \tag{3}$$

where $\mathbf{V}_{\mathrm{relative}}$ is the relative velocity vector of the TM in relation to the hair bundle, H_{L} and H_{R} are heights at the left and right sides of the gap between the TM and the hair bundle, respectively, A_{LR} is the area of the cross section between the left and right sides of the gap and parallel to $\mathbf{V}_{\mathrm{relative}}$, and μ is the viscosity of the lymph fluid.

   c. Numerical analysis of the shear forces To validate the analytically obtained shear forces exerted on the hair bundle represented by Eqs. (2) and (3), the shear forces were numerically analyzed by using the model of the gap between the TM and the hair bundle of the IHC, as shown in Fig. 7(a). The width in the longitudinal direction (normal to the paper) and boundary conditions of this model are the same as those of the other fluid models, i.e., the width in the longitudinal direction is 48 μm and free-flux boundary conditions are assigned to both longitudinal ends. In the case of Poiseuille flow, the pressures at the left and right sides of the gap between the TM and the hair bundle, i.e., p_{L} and p_{R}, are applied to the elements at the left and right sides of this model [light gray areas in Fig. 7(a)]. In the case of Couette flow, the relative velocity vector $\mathbf{V}_{\mathrm{relative}}$ of the TM in relation to the hair bundle is applied as the boundary condition at the top of this model. The distribution of the velocity vector between the TM and the hair bundle is obtained according to these inputs, and the shear force vector $\mathbf{f}_{\mathrm{shear}}$ induced by Poiseuille flow and Couette flow is then calculated as follows based on the parameters shown in Fig. 7(b):

$$\mathbf{f}_{\mathrm{shear}} = \frac{1}{2}\mu\sum_{n=1}^{16}\frac{\mathbf{v}_n + \mathbf{v}_{n+1}}{h_n + h_{n+1}}A_{\mathrm{top},n}, \tag{4}$$

where $\mathbf{v}_n$ is the velocity vector at nodes proximate to the hair bundle, h_n is the height of the fluid element adjacent to the hair bundle, and $A_{\mathrm{top},n}$ is the area of contact between the fluid element and the hair bundle. By comparing this nu-
FIG. 7. Numerical analysis of the shear forces exerted on the hair bundle of the IHC. (a) Model of the gap between the TM and the hair bundle of the IHC. The number of nodes is 2040 and the number of elements is 1568. p_{L} and p_{R} are mean pressures at the left and right sides of the gap (light gray areas), respectively, and $\mathbf{V}_{\mathrm{relative}}$ is the relative velocity of the TM in relation to the hair bundle. (b) Magnification of the model around the top of the hair bundle. Arrows indicate the velocity vectors $\mathbf{v}_n$ at nodes proximate to the hair bundle. h_n is the height of the fluid element adjacent to the hair bundle and $A_{\mathrm{top},n}$ is the area of contact between the fluid element and the hair bundle. Based on these velocity vectors, the shear force exerted on the hair bundle is obtained from Eq. (4) for validation of the analytically obtained shear forces represented by Eqs. (2) and (3).

merically obtained shear force with that given by Eqs. (2) and (3), the validity of the analytically obtained shear forces is examined.

3. Shear force exerted on the TM and RL

   In the narrow space between the TM and the RL, Couette flow is assumed to occur because of the shear motion between these two components, and the force caused by this shear motion is considered to be exerted on the TM and the RL. In this case, the force vector $\mathbf{f}_{\mathrm{TM,RL}}$ is given by

Andoh *et al.*: Neural excitation vs basilar membrane motion
FIG. 8. Electrical circuit model of the membrane of the IHC. R_m and C_m are the membrane resistance and membrane capacitance, respectively. I_m is the current across the membrane and V_m is the membrane potential. The membrane impedance consists of a parallel connection of R_m and C_m. The membrane behaves as a low-pass filter on the membrane potential as indicated by Eq. (6).

FIG. 9. A schematic of the model of the OC showing the stimulation of the model and the method of measurement. Hatching under the BM indicates the site where a sinusoidal pressure of 2 Pa is applied to the model of the OC as an initial pressure. The white circle on the BM indicates the point of displacement measurement. Positive displacement of the BM and that of the hair bundle were defined as that toward the ST and that in the excitatory direction (toward the tallest hair), respectively. A positive driving force exerted on the hair bundle was defined as that in the excitatory direction of the hair bundle.

D. Numerical procedure

Using the models mentioned above, the dynamic behavior of the OC, including the hair bundle of the IHC, was obtained from 10 Hz to 30 kHz when a sinusoidal pressure of 2 Pa was applied to the bottom of the OC, as shown in Fig. 9. The basic procedure for coupling the fluid and structure models is the same as that in the previous study (Andoh and Wada, 2004), but the forces exerted on the hair bundle of the IHC are newly taken into consideration. The revised procedure is as follows: First, the stimulus frequency is fixed to a specific frequency. As shown in Fig. 10, in time Step 1, initial pressure p_{INT}^1 is applied to the model of the OC and the velocity vector of the OC $\partial \mathbf{u}_s^1 / \partial t$ is obtained, where p_{INT} is the pressure initially applied to the model of the OC. Then, applying this obtained velocity vector $\partial \mathbf{u}_s^1 / \partial t$ to the SV, ST, and sub-TM models as a fluid velocity vector $\mathbf{v}_f^0$ over a fluid-structure interface, the pressure p_{OC}^1 in the SV, the ST and the sub-TM space caused by the movement of the OC is obtained. In time Step 2, the force vector $\mathbf{f}_{pres,n}^1$ induced by the pressure difference between the left and right sides of the hair bundle and Poiseuille flow-induced force vector $\mathbf{f}_{Poise}^1$ are given by substituting the pressure p_{OC}^1 into Eqs. (1) and (2), and Couette flow-induced force vector $\mathbf{f}_{Couet}^1$ is given by Eq. (3) by calculating the relative velocity vector $\mathbf{V}_{relative}^1$ of the TM in relation to the hair bundle of the IHC. The force vector $\mathbf{f}_{TM,RL}^1$ caused by the shear motion between the TM and the RL and exerted on them is given by substituting the relative velocity vector $\mathbf{V}_{RELATIVE}^1$ of the TM in relation to the RL into Eq. (5). The previously obtained pressure p_{OC}^1, the initial pressure p_{INT}^2 in time Step 2, the force vectors on the hair bundle, i.e., $\mathbf{f}_{pres,n}^1$, $\mathbf{f}_{Poise}^1$, and $\mathbf{f}_{Couet}^1$, and the force vector $\mathbf{f}_{TM,RL}^1$ exerted on the TM and the RL are applied to the model of the OC. By repeating the above procedure, the displacement of the OC, three types of forces exerted on the hair bundle and the displacement of the hair bundle at a

$$\mathbf{f}_{TM,RL} = \mu \frac{\mathbf{V}_{RELATIVE}}{h} A_{TM,RL}, \tag{5}$$

where $\mathbf{V}_{RELATIVE}$ is the relative velocity vector of the TM in relation to the RL, h is the height of the narrow space between the TM and the RL, and $A_{TM,RL}$ represents the area of the TM and that of the RL facing the lymph fluid.

C. Low-pass filtering at the membrane of the IHC

Although the phase of the neural excitation relative to the BM position has not been well understood, in this study, it is assumed to be as follows: the low-pass filtering at the membrane of the IHC is effective for the entire frequency and intensity range. As shown in Fig. 8, the electrical impedance of the membrane Z_m is represented as the resistance R_m and capacitance C_m in parallel (Russell and Sellick, 1983). In this case, the magnitude $|V_m|$ and the phase θ of the membrane potential relative to the current I_m across the membrane are given by

$$|V_m| = \frac{R_m}{\sqrt{1 + \left(\frac{\omega}{\omega_0}\right)^2}} |I_m|, \tag{6}$$

$$\theta = -\arctan\left(\frac{\omega}{\omega_0}\right), \tag{7}$$

where ω is the angular frequency of the stimulus and $\omega_0 = 1/R_m C_m$ represents the corner frequency, which is assumed to be 200 Hz (Cheatham and Dallos, 1999). Equation (6) represents the behavior of the membrane as a low-pass filter of the membrane potential.

FIG. 10. Scheme of the fluid-structure interaction using the staggered approach. In time Step 1, initial pressure p_{INT}^1 is applied to the model of the OC and the velocity vector of the OC $\partial \mathbf{u}_s^1 / \partial t$ is obtained, where p_{INT} is an applied sinusoidal pressure of 2 Pa at the bottom of the BM, as shown in Fig. 9. Then, applying this obtained velocity vector $\partial \mathbf{u}_s^1 / \partial t$ to the SV, ST, and sub-TM models as a fluid velocity vector $\mathbf{v}_f^0$ over a fluid-structure interface, the pressure p_{OC}^1 in each scala, and sub-TM space caused by the movement of the OC is obtained at the same time step. In time Step 2, this obtained pressure p_{OC}^1, the initial pressure p_{INT}^2 in time Step 2, the force vectors exerted on the hair bundle, i.e., the force vector $\mathbf{f}_{pres,n}^1$ induced by the pressure difference between the left and right sides of the hair bundle, Poiseuille flow-induced force vector $\mathbf{f}_{Poise}^1$ and Couette flow-induced force vector $\mathbf{f}_{Couet}^1$, and the force vector $\mathbf{f}_{TM,RL}^1$ exerted on the TM and the RL are applied to the model of the OC. By repeating the above procedure, the time history of the displacement of the OC and that of the hair bundle of the IHC are obtained.

specific frequency are obtained. This analysis is conducted for stimulus frequencies from 10 Hz to 30 kHz to obtain results for this frequency range.

A numerical analysis of the shear forces exerted on the hair bundle of the IHC is also conducted for each specific frequency. The relative velocity vector $\mathbf{V}_{relative}^1$ of the TM in relation to the hair bundle or the pressures at the left side p_L and right side p_R of the gap between the TM and the hair bundle are applied to the model shown in Fig. 7(a). A Navier-Stokes equation is used to analyze the dynamic behavior of the lymph fluid for these inputs, and it is solved by a Marker-and-Cell method (Harlow and Welch, 1965). The velocity vectors $\mathbf{v}_n^1$ in this space are then obtained. By substituting the obtained velocity vectors $\mathbf{v}_n^1$ into Eq. (4), the shear force $\mathbf{f}_{shear}^1$ induced by Couette flow or Poiseuille flow at a specific frequency is obtained. This analysis is also conducted for stimulus frequencies from 10 Hz to 30 kHz. Consequently, the shear force for this frequency range is obtained.

III. RESULTS

A. Validation of the analytically obtained shear forces exerted on the hair bundle

Analytically obtained shear forces from Eqs. (2) and (3) are compared with those obtained numerically by using the model shown in Fig. 7(a) and from Eq. (4). Figure 11 shows
FIG. 11. Degree of difference between the analytically obtained shear forces from Eqs. (2) and (3) and those obtained numerically from Eq. (4) when a pressure of 2 Pa was applied to the bottom of the BM. The analytically obtained shear forces are in the 10% range of those obtained numerically.

the degree of difference between the analytically obtained shear forces and those obtained numerically when a pressure of 2 Pa was applied to the bottom of the BM, as shown in Fig. 9. As the degree of difference is in the 10% range for the entire frequency range, the analytically obtained results are used hereafter.

B. Driving force exerted on the hair bundle and its displacement versus BM motion

Figure 12 shows the frequency characteristics of the displacement of the BM when a pressure of 2 Pa was applied to the bottom of the BM. The displacement of the BM increases with increasing frequency toward the CF (16 kHz), and then decreases. The frequency characteristics of the magnitude of the forces exerted on the hair bundle are shown in Fig. 13. The force induced by Couette flow is larger than the other forces below 1 kHz. This relationship changes around 1 kHz, and the force induced by the pressure difference between the left and right sides of the hair bundle is larger than those induced by Poiseuille flow and Couette flow above 1 kHz.
FIG. 12. Frequency characteristics of the displacement of the BM when a pressure of 2 Pa was applied to the bottom of the BM. The displacement of the BM was analyzed as the transversal displacement of the BM at the point indicated in Fig. 9 because the radial displacement of the BM was substantially small relative to the transversal one.
FIG. 13. Magnitudes of the three types of forces exerted on the hair bundle of the IHC versus frequency when a pressure of 2 Pa was applied to the bottom of the BM. (a) Forces plotted up to 10 kHz. (b) Forces for the entire frequency range. Below 1 kHz, the force induced by Couette flow is dominant over the forces exerted on the hair bundle. On the other hand, above 1 kHz, the force induced by the pressure difference between the left and right sides of the hair bundle is larger than the forces induced by Poiseuille flow and Couette flow.

FIG. 14. Frequency characteristics of the driving force exerted on the hair bundle of the IHC and the displacement of the hair bundle when a pressure of 2 Pa was applied to the bottom of the BM. (a) The amplitude of the driving force and the displacement of the hair bundle. (b) Phases of the driving force and the displacement of the hair bundle relative to the displacement of the BM. The zero phases of the driving force and the displacement of the hair bundle relative to the displacement of the BM mean that the driving force and the displacement of the hair bundle are maximum in the excitatory direction when the BM exhibits a maximum displacement toward the ST. The increase of these phases means that their responses lag behind the BM motion. The right ordinate shows positions of the BM when the driving force or the displacement of the hair bundle is maximum in the excitatory direction. ST and SV mean positions of the BM when the BM exhibits a maximum displacement toward the ST and the BM exhibits a maximum velocity toward the SV, i.e., the BM crosses its equilibrium position (zero displacement) from the ST to the SV, respectively. As shown in Fig. 9, the displacement of the hair bundle d was analyzed based on the relative displacement of the tip of hair bundle in the radial direction x and that in the transversal direction y to those of basal end of the hair bundle on the apical surface of the IHC, i.e., $d=\sqrt{x^2+y^2}$. The phase of the driving force according to the traditional idea is plotted for reference by the dotted line.

Figure 14(a) shows the frequency characteristics of the magnitude of the driving force exerted on the hair bundle (solid line), which is a sum of the three types of forces exerted on the hair bundle, as well as those of the displacement of the hair bundle (dashed line) when a pressure of 2 Pa was applied to the bottom of the BM. The increase of the driving force is approximately proportional to the second power of the stimulus frequency. By contrast, the displacement of the hair bundle reaches a maximum at 12 kHz and then decreases. The frequency characteristics of their phases relative to the displacement of the BM are shown in Fig. 14(b). The right ordinate shows positions of the BM when the driving force or the displacement of the hair bundle is maximum in the excitatory direction. The driving force in the excitatory direction (toward the tallest hair and to the right, as indicated in Fig. 9) takes a maximum when the BM exhibits a maximum velocity toward the SV below 1 kHz. It then shows a significant phase advance relative to the BM motion around 1 kHz and takes a maximum when the BM exhibits a maximum displacement toward the ST above 1 kHz. The maxi-

mum displacement of the hair bundle in the excitatory direction occurs when the BM exhibits a maximum velocity toward the SV at 10 Hz, and according to the phase shift of the driving force, it then shows a significant phase advance relative to the BM motion up to 2 kHz, where the maximum displacement of the hair bundle in the excitatory direction lags by 13° behind the maximum displacement of the BM toward the ST. From 2 kHz, unlike the driving force, it shows a phase delay relative to the BM motion with increasing frequency, and becomes 90° at 12 kHz.

C. Neural excitation versus BM motion

Figure 15 shows the phase of the membrane potential of the IHC relative to the current across the membrane versus the stimulus frequency derived from Eq. (7). Assuming that this phase is equivalent to that of the neural excitation relative to the displacement of the hair bundle, this result implies
FIG. 15. Phase of the membrane potential of the IHC relative to the current across the membrane versus stimulus frequency derived from Eq. (7). The corner frequency $\omega_0 = 1/R_m C_m$ was taken to be 200 Hz.

that the neural excitation has a slight phase delay relative to the displacement of the hair bundle until 50 Hz, e.g., 3° at 10 Hz and 14° at 50 Hz. This phase delay becomes 45° at the corner frequency of 200 Hz, and then gradually approaches 90° with increasing frequency.

Figure 16 shows the frequency characteristics of the phases of the displacement of the hair bundle [dashed line: the same as the dashed line in Fig. 14(b)] and the neural excitation (solid line) relative to the displacement of the BM. The phase of the neural excitation (solid line) was obtained by adding the phase delay of the membrane potential due to the low-pass filtering at the membrane of the IHC (shown in Fig. 15) to the phase of the displacement of the hair bundle (dashed line). The right ordinate shows positions of the BM when the displacement of the hair bundle is maximum in the excitatory direction or when neural excitation occurs. Neural excitation occurs when the BM exhibits a maximum velocity toward the SV at 10 Hz. It shows a phase delay relative to
FIG. 16. Frequency characteristics of the phases of the displacement of the hair bundle (dashed line) and the neural excitation (solid line) relative to the displacement of the BM. The dashed line is the same as that in Fig. 14(b). The right ordinate shows positions of the BM when the displacement of the hair bundle is maximum in the excitatory direction or when neural excitation occurs. ST, ṠT, ṠV, and SV mean positions of the BM when the BM exhibits a maximum velocity toward the ST, the BM exhibits a maximum displacement toward the ST, the BM exhibits a maximum velocity toward the SV, and the BM exhibits a maximum displacement toward the SV, respectively. The phase of the neural excitation (solid line) was obtained by adding the phase delay of the membrane potential due to the low-pass filtering at the membrane of the IHC (shown in Fig. 15) to the phase of the displacement of the hair bundle (dashed line). Other data were taken from the literature for purposes of comparison, and sources are indicated in the legend.

the BM motion with increasing frequency up to 800 Hz and then exhibits a phase advance until the frequency reaches 2 kHz, where the neural excitation lags by 7° behind the maximum velocity of the BM toward the SV. From 2 kHz, neural excitation again shows a phase delay with increasing frequency, and at the characteristic frequency of 16 kHz, neural excitation lags by 18° behind the maximum displacement of the BM toward the SV.

IV. DISCUSSION

A. Source of the driving force exerted on the hair bundle

The traditional idea regarding the mechanism of the hair bundle oscillation in relation to the OC vibration is shown in Fig. 2. When the OC undergoes vibration, shear motion occurs between the tectorial membrane (TM) and the reticular lamina (RL). This shear motion causes Couette flow in the sub-TM space. As indicated in Eq. (3), the driving force exerted on the hair bundle due to Couette flow becomes maximum when the relative velocity of the TM in relation to the hair bundle is maximum. As a result, if the maximum relative velocity is assumed to occur when the velocity of the BM is maximum, the maximum driving force exerted on the hair bundle in the excitatory direction occurs when the velocity of the BM is maximum toward the SV at any frequency, as shown by the dotted line in Fig. 14(b). However, the solid line in Fig. 14(b) shows that the driving force in the excitatory direction becomes maximum when the BM exhibits a maximum displacement toward the ST above 1 kHz, although the numerical result in this study shows the same tendency of the driving force as that in the traditional idea below 1 kHz. This result implies that the hair bundle is driven by a different mechanism from that posited by the traditional idea.

In this study, the forces induced by the pressure difference between the left and right sides of the hair bundle and by Poiseuille flow were considered in addition to that induced by Couette flow. As shown in Fig. 13, Couette flow-induced force, which is caused by the velocity difference between the TM and the hair bundle, is larger than the other forces exerted on the hair bundle below 1 kHz. Therefore, similar to the traditional idea, the maximum driving force in the excitatory direction occurs when the velocity of the BM is maximum toward the SV below 1 kHz. By contrast, above 1 kHz, the force induced by the pressure difference is larger than the forces induced by Poiseuille flow and Couette flow. To discuss the phase of the force induced by the pressure difference relative to the BM motion, these frequency characteristics should be considered.

The pressure in an incompressible viscous fluid flow is described by the Navier-Stokes equation as follows:

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \rho(\mathbf{v} \cdot \nabla)\mathbf{v} + \nabla p - \mu \Delta \mathbf{v} = 0, \tag{8}$$

where $\mathbf{v}$ is the velocity vector, p is the pressure, ρ is the density, μ is the viscosity, t is the time, and the gradient operator ∇ and the Laplacian operator Δ are defined in the following form:

$$\nabla = \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z} \right), \quad \Delta = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}. \tag{9}$$

Equation (8) means that the pressure gradient ∇p is determined by the product of the density and the acceleration (first term), the product of the density and the velocity gradient and velocity, i.e., the momentum change (second term), and the product of the viscosity and the Laplacian of the velocity, i.e., the shear stress (fourth term). Assuming that the vibration of the OC is sinusoidal, the acceleration is 180° out of phase with the displacement. Therefore, the first term in Eq. (8) is regarded as a displacement-dependent term, and in Eq. (8), it means that the pressure is proportional to the displacement. Substituting the value of the fluid velocity (17 μm/s) around the hair bundle at 1 kHz, which was obtained from FEM analysis, into Eq. (8), the pressures in the space between the TM and the RL at 1 kHz due to the first term (displacement), the second term (momentum), and the fourth term (viscosity) were determined to be 2.2 mPa, 0.33 μPa, and 3.4 mPa, respectively. If the amplitude of the fluid velocity is assumed to be constant for any frequency, only the first term in Eq. (8) increases with increasing frequency because only this term is differentiated by time. These facts mean that, above 1 kHz, the pressure around the hair bundle is dominated by the displacement of the fluid, and the driving force is therefore synchronized with the displacement of the fluid.

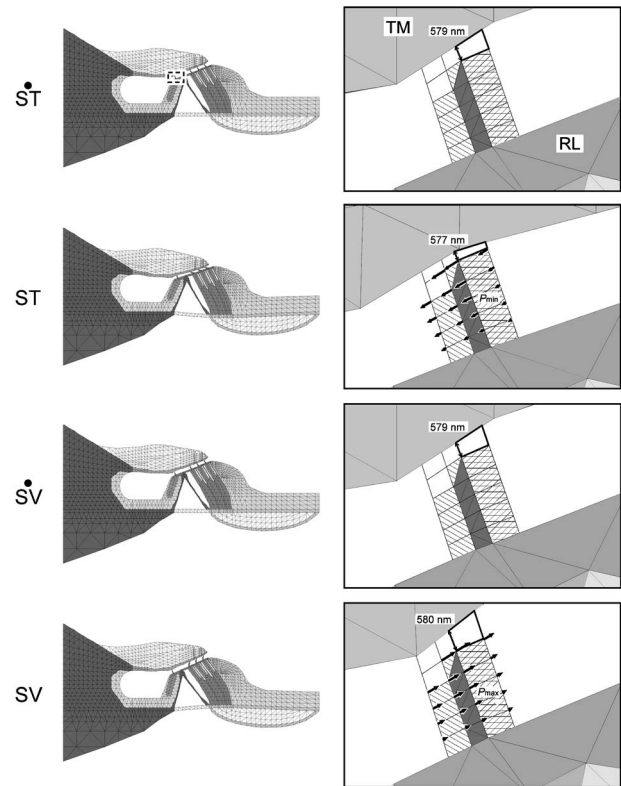
Figure 17 shows the motion of the structures around the hair bundle and displacements of the fluid in the space to the right (cross-hatched area) and that to the left (hatched area) of the hair bundle. In the space to the right of the hair bundle (cross-hatched area), differences were found between the inward and outward displacements of the fluid when the BM is displaced. As the inward displacement of the fluid is defined as being positive, the sum of the inward and outward displacements of the fluid in the cross-hatched area takes maximum positive and negative values when the displacements of the BM are maximum toward the SV and the ST, respectively. The cause of the difference between the inward and outward displacements of the fluid is the volume change of the fluid above the cross-hatched area, which is indicated by the thick line in Fig. 17, due to the change of the distance between the TM and the RL. The increase of this volume results in the positive value of the sum of the inward and outward displacements of the fluid in the cross-hatched area, and *vice versa*. As mentioned in the previous paragraph, the pressure is proportional to the displacement of the fluid above 1 kHz so that the maximum positive and negative pressures in the cross-hatched area occur when the displacements of the BM are maximum toward the SV and the ST, respectively. On the other hand, in the space to the left of the hair bundle (the hatched area in Fig. 17), the pressure exerted on the hair bundle does not have a profound effect on the behavior of the hair bundle because the sum of the inward and outward displacements of the fluid is less than 14% of that in the right space (cross-hatched area) when the displacement of the BM is maximum. Consequently, above 1 kHz, the maximum driving force exerted on the hair bundle in the excitatory direction occurs when the BM exhibits a


FIG. 17. Motion of the structures around the hair bundle and displacements of the fluid in the space to the right (cross-hatched area) and that to the left (hatched area) of the hair bundle when a pressure of 2 Pa was applied to the bottom of the BM at 1 kHz. ST, $\dot{\text{ST}}$, SV, and $\dot{\text{SV}}$ indicate positions of the BM as in Fig. 16. The images on the left are the overall appearance of the model of the OC at each position of the BM and are displayed for the sake of facilitating comprehension. Those on the right are enlarged images around the hair bundle of the IHC corresponding to the dashed square in the top image on the left. Arrows indicate displacements of the fluid. However, they are not displayed when the BM exhibits maximum velocities because they are negligibly small compared with those when the BM exhibits maximum displacements. The thick line surrounding the space above the cross-hatched area is drawn on the model for clarity of its volume change caused by the change of the vertical distance between the TM and the RL, i.e., the minimum and maximum value is 577 and 580 nm, respectively. P_{max} and P_{min} mean the averaged maximum positive and negative pressures at the space to the right of the hair bundle (cross-hatched area), respectively. Displacements of the left and right images are magnified 2000 and 1000 times, respectively.

maximum displacement toward the ST. For the above-mentioned reasons, the phase relationship between the driving force and the displacement of the BM significantly changes around 1 kHz.

The phase of the displacement of the hair bundle is shown by the dashed line in Fig. 14(b). In a frequency range below 1 kHz, the displacement of the hair bundle follows the driving force. However, from 1 kHz, the displacement of the hair bundle gradually lags behind the driving force with increasing frequency, and its phase delay becomes 90° at 12 kHz. Assuming that the hair bundle is a simple mass-spring system and by considering the added mass of fluid to the hair bundle, the resonance frequency of the hair bundle f_{res} is analytically given by

Andoh *et al.*: Neural excitation vs basilar membrane motion   1563

$$f_{\text{res}} = \frac{1}{2\pi}\sqrt{\frac{k_{\text{hair}}}{m_{\text{hair}} + m_{\text{fluid}}}}, \tag{10}$$

where k_{hair} and m_{hair} are the stiffness and mass of the hair bundle, respectively, and m_{fluid} is the added mass of the fluid. k_{hair} and m_{hair} assigned to the model of the OC are 2.5×10^{-3} N/m (Langer *et al.*, 2001) and 24 pg. If the hair bundle is assumed to be a simple cylindrical structure, the added mass of the fluid is a product of the volume of the hair bundle and the density of the fluid, and so is assumed to be 20 pg. In this case, the resonance frequency of the hair bundle obtained from Eq. (10) is 12.1 kHz. Therefore, the phase delay of the displacement of the hair bundle relative to the driving force appears to occur due to the resonance process of the hair bundle. As this phase shift directly changes the timing of the depolarization of the membrane potential of the IHC, the resonance frequency of the hair bundle, as well as the phase of the driving force, is highly important when investigating the phase of the neural excitation relative to the BM motion.

Cai *et al.* (2004) constructed a model of the OC by which its dynamic behavior could be analyzed. As they assumed that the height of the gap between the TM and the RL was constant, the pressure caused by the volume change in the sub-TM space was neglected. By contrast, Hu *et al.* (1999) measured the vibration trajectories of measured points on the TM and the top of the OHCs by applying an oscillatory force via a glass paddle to the OC and reported that the direction of the vibration at the TM is approximately vertical whereas that at the top of the OHCs is horizontal. As shown in Fig. 17, the geometrical configuration of the sub-TM space, which consists of the TM, the RL, and the hair bundle of the OHC, clearly demonstrates that the distance between the TM and the tip of the hair bundle of the IHC is 579 nm when the displacement of the BM is zero and that it varies from 577 to 580 nm depending on the displacement of the BM. This causes the volume change of the sub-TM space, which must be considered when analyzing the dynamic behavior of the hair bundle of the IHC.

B. Comparison with experimental data

As the motility of the OHC was not included in the present model, and as the OC at the basal turn of the cochlea was modeled, experiments conducted at a high stimulus level and at the basal turn are appropriate for purposes of comparison. A comparison of the phase of the neural excitation relative to the BM position is presented in Fig. 16. As the data shown in the figures (Ruggero and Rich, 1983; Ruggero *et al.*, 2000; Sellick *et al.*, 1982; Wada *et al.*, 2002) had already been corrected by subtracting synaptic delay and neural travel times, i.e., 1 ms delay, from the experimental data, our numerically obtained results were compared with their data without correction. Ruggero and Rich (1983) measured the relationship between the neural excitation and the BM position at the basal turn of the chinchilla cochlea with a CF of 16 kHz to low-frequency stimuli (30 to 100 Hz) at 100 dB SPL, and concluded that the neurons from IHCs may fire in response to the displacement of the BM toward the ST. Sel-

lick *et al.* (1982) measured the neural excitation at the basal turn of the guinea pig cochlea with CFs between 15 and 18 kHz to low-frequency stimuli (40 to 500 Hz) at 100 dB SPL, and demonstrated that the excitation of the IHC was synchronous with the maximum displacement of the BM toward the ST at 40 Hz and with the maximum velocity of the BM toward the SV at 500 Hz. Although these two experimental data show the phase delay of the neural excitation likely induced by the low-pass filtering at the membrane of the IHC as considered in the present study, they are different from our results by approximately 90°. Wada *et al.* (2002) measured the relationship between the neural excitation and the BM vibration at the basal turn of the guinea pig cochlea with high CFs (14–22 kHz) to low-frequency stimuli (50 to 2000 Hz) at 100 dB SPL and reported that neural excitation lags by 20° behind the maximum displacement of the BM toward the SV until 100 Hz and shows a phase delay relative to the BM motion with increasing frequency up to 500 Hz, where it lags by 45° behind the maximum displacement of the BM toward the SV. Neural excitation then shows a phase advance with increasing frequency and leads the maximum displacement of the BM toward the SV by 45° at 2 kHz. The phase advance with increasing frequency from 500 Hz in their data is similar to the present findings; however, the phase values are different from our results, especially at low frequencies. Although there is a hypothesis that at low frequencies the membrane potential of the IHC is modulated by the extra-cellular potential, which is the potential caused by the electrical activities of OHCs (Cheatham and Dallos, 1999), qualitative and quantitative influences of this extra-cellular potential on the membrane potential of the IHC are still unknown. A full understanding of the phase of the neural excitation relative to the BM vibration awaits further empirical investigations or refinement of our model in order to include an electrical field analysis.

V. CONCLUSIONS

In this study, first, a finite-element model of the OC and models of the lymph fluid surrounding the OC and in the sub-TM space were constructed. Using these models, the phase of the displacement of the hair bundle of the IHC relative to the BM motion was then calculated. Finally, by considering the phase delay due to the low-pass filtering at the membrane of the IHC, the phase of the neural excitation relative to the BM motion was estimated. Conclusions are as follows.

(1) Unlike the conventional idea, the phase of the driving force relative to the BM motion shows a significant phase shift around 1 kHz, i.e., although the maximum driving force in the excitatory direction occurs when the BM exhibits a maximum velocity toward the SV below 1 kHz, it also occurs when the BM exhibits a maximum displacement toward the ST above 1 kHz. This is because the dominant force exerted on the hair bundle changes from a velocity-dependent Couette flow-induced force to a displacement-dependent force induced by the pressure difference around 1 kHz.

(2) Neural excitation occurs when the BM exhibits a maximum velocity toward the SV at 10 Hz and shows a phase delay relative to the BM motion with increasing frequency up to 800 Hz. It then shows a phase advance until the frequency reaches 2 kHz, at which point the neural excitation lags by 7° behind the maximum velocity of the BM toward the SV. From 2 kHz, neural excitation again shows a phase delay with increasing frequency due to the resonance of the hair bundle, and at the characteristic frequency of 16 kHz, neural excitation lags by 18° behind the maximum displacement of the BM toward the SV.

Effects of aspirin on distortion product otoacoustic emission suppression in human adults: A comparison with neonatal data

Carolina Abdala[a)]

House Ear Institute, 2100 West Third Street, Children's Auditory Research and Evaluation Center, Los Angeles, California 90057

One of the distortion product otoacoustic emission (DPOAE) paradigms used to study cochlear function is DPOAE $(2f1-f2)$ ipsilateral suppression. Newborns do not have adultlike DPOAE suppression. At 6000 Hz, infants show excessively narrow DPOAE suppression tuning and shallow growth of suppression for low-frequency suppressor tones. The source of this immaturity is not known but the outer hair cell (OHC) is one possible locus. In the present study, DPOAE suppression was measured at $f2=1500$ and 6000 Hz from two groups with impaired OHC function in an attempt to model the observed immaturity in neonates: adults with aspirin-induced OHC dysfunction and subjects with sensorineural hearing loss (SNHL). Their DPOAE suppression results were compared to those obtained from a group of term newborns to address whether infant DPOAE suppression resembles suppression from individuals with known OHC dysfunction. Results indicate that aspirin systematically alters DPOAE suppression in adults at $f2=6000$ Hz, but not 1500 Hz. However, neither aspirin-induced OHC dysfunction nor naturally occurring SNHL produces "neonatal-like" DPOAE suppression at either test frequency. This finding does not support the hypothesis that non-adultlike DPOAE suppression characterizing newborns can be explained by minor impairments or alterations of OHC function. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1985043]

I. INTRODUCTION

Distortion product otoacoustic emissions (DPOAEs) are produced by the cochlea when the ear is presented with two simultaneous pure tones $(f1,f2)$ relatively close in frequency and level. Middle ear function and auditory thresholds must be normal or near normal and outer hair cells must be present and motile at the distortion generation site to detect a DPOAE in the ear canal (Dorn *et al.*, 1999). When outer hair cells are damaged, DPOAEs are reduced or eliminated (Brown *et al.*, 1989). The inner hair cell, in contrast, can be disabled or damaged with little or no impact on the generation of DPOAEs (Trautwein *et al.*, 1996). Clearly, distortion product otoacoustic emissions offer unique insight into outer hair cell function and integrity (Lonsbury-Martin and Martin, 2002; Ryan, 2002).

One of the DPOAE paradigms applied to study cochlear function and, more recently, cochlear maturation, is DPOAE $(2f1-f2)$ ipsilateral suppression. DPOAE suppression is not adult-like in human infants. Neonatal DPOAE suppression tuning curves are excessively narrow and have a steep low-frequency flank, particularly at $f2=6000$ Hz (Abdala *et al.*, 1996; Abdala, 2003; Abdala, 2004). Additionally, the rate of suppression growth is excessively shallow in newborns for suppressor tones lower in frequency than $f2$. These nonadult-like features of DPOAE suppression may indicate a cochlear immaturity in young infants, however, the source or locus of this immaturity within the cochlea is not known.

The outer hair cell (OHC) is one possible locus of functional immaturity in the newborn cochlea. Although anatomically mature, if the OHC is not *functioning* in an adult-like manner and does not exhibit normal motility at birth, the consequence may be apparent in measures of DPOAE suppression. Outer hair cells show a protracted developmental course in the human cochlea and changes in their pre- and postsynaptic specialization have been observed late into the third trimester of pregnancy in humans (Lavigne-Rebillard and Pujol, 1988). It is possible that human OHC maturation continues into the early post-term weeks and months. In laboratory animals, correlations have been found between the developmental sequence of changes in OHC subcellular organization and development of electromotile properties in vitro (He *et al.*, 1994). Comparable data on the development of OHC motility in humans are not available.

To test the hypothesis of OHC immaturity in newborns, naturally occurring OHC damage or benign manipulations of OHC function must be utilized as models. One such model is aspirin (acetylsalicylic acid). It has been safely used in humans to temporarily impair OHC function and simulate sensorineural hearing loss (SNHL) (McFadden *et al.*, 1984; Wier *et al.*, 1988). Aspirin's effect on the cochlea is well established; it typically causes temporary threshold elevation, tinnitus and a reduction, but not complete elimination of DPOAEs (Cazals, 2000; Long and Tubis, 1988; McFadden, 1982; McFadden *et al.*, 1984; Takahashi *et al.*, 1999; Wier *et al.*, 1988). Research with laboratory animals has clearly shown that aspirin produces these reversible effects by impairing OHC electromotility (Dieler *et al.*, 1991; Oliver *et al.*, 2001). Mild-moderate sensorineural hearing (SNHL) provides a second model. This degree and type of loss is associated with OHC dysfunction. DPOAE amplitude is re-

TABLE I. Hearing impaired subject summary.

	Subject	Age (Yr)	Sex	Ear	PTA (dB HL)	Threshold at f_2 (dB HL)
$f_2=1500$ Hz	HI01	12.5	F	R	35	20
	HI02	10.5	F	L	47	35
	HI03	15	M	L	43	25
	HI04	9	F	L	25	25
$f_2=6000$ Hz	HI05	7	M	L	48	15
	HI06	13	F	R	53	15
	HI07	7	M	L	30	20
	HI08	17	M	L	45	20

duced by even mild amounts of SNHL, presumably due to OHC damage (Abdala and Fitzgerald, 2003; Gorga *et al.*, 1997; Martin *et al.*, 1990).

In the present study, DPOAE suppression data from subjects with aspirin-induced OHC dysfunction and mild-moderate SNHL were compared to DPOAE suppression data from a group of healthy newborns to address the following research question: *Is the nonadult-like DPOAE suppression consistently observed in newborns similar to suppression measured from individuals with known impairment of OHC function?* If so, it may suggest that immature DPOAE suppression in newborns is due to OHC alterations (e.g., immaturities) similar to those produced by aspirin. Conversely, if neonatal DPOAE suppression remains different from adult suppression during aspirin, it would not support the hypothesis that the source of functional immaturity in the newborn cochlea is OHC motility.

II. METHODS

A. Subjects

A total of 41 subjects participated in this study: 10 normal hearing adults, 23 healthy term-born neonates, and 8 school-aged children with mild sensorineural hearing loss (SNHL). The ten adults (7 females and 3 males) had a mean age of 29.1 years (range=22–37 years) with no history of otologic disease or exposure to damaging noise. Four left ears and six right ears were tested. Prospective adult subjects filled out a medical questionnaire and received a medical examination at the House Ear Clinic.

All adult subjects had audiometric thresholds ⩽15 dB HL and normal middle ear function as measured by immittance audiometry. Their DPOAEs had signal to noise ratios (SNRs) ranging from 15 to 33 dB at the two test frequencies (mean=22.6 dB at 1500 Hz; 25.1 dB at 6000 Hz). Of the 24 interested adults who contacted the laboratory to participate, 10 met criteria and were included.

Twenty-three term-born neonates (14 males; 9 females) were tested on average within 2.5 days (59.8 h) of birth. Their mean 1 and 5 min APGAR scores were 8.75 and 9.5 (10=optimal). Fifteen left and eight right ears were tested. Average birth weight was 3216 g. All infant subjects passed a click-evoked ABR hearing screening (35 dB HL) and a screening DP-gram at birth to be included in the study. Neo-

nates who met subject inclusion criteria were randomly assigned to either the $f2=1500$ ($n=11$) or $f2=6000$ Hz ($n=12$) condition.

Eight children with mild SNHL were recruited from the Children's Auditory Research and Evaluation (CARE) Center of the House Ear Institute. Children rather than adults were selected as subjects because they have generally experienced less traumatic noise and/or ototoxic insult than adults, thus, increasing the likelihood of measurable DPOAEs despite mild hearing loss. Four girls and four boys (two right and six left ears) were tested. Each provided DPOAE data at either 1500 Hz ($n=4$) or 6000 Hz ($n=4$). The ear showing the greater DPOAE SNR at the test frequency was chosen as the test ear. Descriptions of the 8 HI subjects are shown in Table I.

B. Instrumentation and signal processing

An Ariel DSP16+ signal processing and acquisition board housed within a Compaq Prolinea 590 personal computer with Pentium processor was used to generate stimuli and acquire data. The Ariel board was connected to an Etymotic Research ER-10C probe system and to an analog high-pass filter (12 dB/oct; 710 Hz high-pass cut-off). The ER-10C probe contains two output transducers and a low-noise microphone. The two primary tones and the suppressor tone were generated by the DSP processor. The primary tone at $f1$ was generated by one D/A converter and delivered via one transducer. The primary tone at $f2$ and the suppressor tone (fs) were produced by the second D/A-converter and output through the second transducer. Twenty-five sweeps of the microphone signal were added and comprised one block at $f2=6000$ Hz. At $f2=1500$ Hz, fifty sweeps comprised one block.

C. Data acceptance criteria

Acceptance criteria were as follows: (1) noise measurements for three frequency bins (12.2 Hz wide) on either side of the $2f1-f2$ frequency had to be <0 dB SPL to assure appropriate subject state; and (2) the measured DPOAE level had to be at least 5 dB above the average noise measured in the same six bins around the distortion product frequency to be accepted into the grand average. In addition, sweeps were

accepted into a block of data only when the estimated rms level in that sweep did not exceed a user-controlled artifact rejection threshold.

D. Calibration

Intermodulation distortion produced by the recording system at $2f1-f2$ was measured with the probe in a Zwislocki coupler for all test conditions. The mean level of distortion was -21 dB SPL. The recording system noise floor was determined using a similar method with no tones present. The level of system noise floor ranged between -22 and -27 dB SPL.

An *in situ* calibration procedure was conducted on both output transducers before each subject was tested. Tones of fixed voltage were presented to the transducers at 250 Hz intervals from 500 to 10 000 Hz and the resulting SPL of these tones recorded in each ear canal. Based on this information, an equalization of output levels was performed for each subject to achieve target stimulus levels across test frequencies.

E. Procedure

1. Adults

Adult subjects were tested within an IAC sound-attenuated booth at the House Ear Institute in the Children's Auditory Research Laboratory while sitting comfortably in a padded easy chair, reading or watching a sub-titled video. The following procedures were performed during each session: (1) air and bone conduction audiogram, including interoctave frequencies, (2) DP-gram ($f2=1500–12\,500$ Hz), (3) immittance tympanometry (226 Hz probe tone), (4) spontaneous otoacoustic emissions, (5) DPOAE suppression tuning curves (STCs), and (6) DPOAE Input/output function at both $f2=1500$ Hz and 6000 Hz. An $f2/f1$ ratio of 1.21 and level separation of 10 dB ($L1>L2$) were used for all DPOAE testing. During suppression, primary tones were presented at 65/55 dB SPL.

To record DPOAE STCs at $f2=1500$ Hz, 12 different suppressor tones were presented ranging from 850 to 1890 Hz. At $f2=6000$ Hz, 15 suppressor tones were presented ranging from 3044 to 7232 Hz. Suppressor tones were presented at intervals of 25 to 150 cents (1 octave $=1200$ cents) with smaller intervals in the tip region. The suppressor tone was presented simultaneously with the primary tones and its level increased in 2 dB steps from 40 to 84 dB SPL. Unsuppressed DPOAE amplitude was measured at the start of data collection and again prior to the presentation of each new suppressor frequency.

Completion of this protocol yielded a series of suppression growth functions (DPOAE amplitude $\times$ suppressor level) for each of the two $f2$ conditions. To generate iso-suppression tuning curves (STCs), the suppressor level reducing DPOAE amplitude by 6 dB was determined from the suppression growth function using linear interpolation and was plotted as a function of suppressor frequency. Suppression growth slope was measured for each suppressor tone by fitting a regression line to this function. For DPOAE input/output (I/O) functions, stimuli ranged from 30 to 85 dB SPL and were decreased in 5 dB increments. A successful test session lasted approximately $1\frac{1}{2}–2$ h.

Following the baseline test, adult subjects were given a bottle of aspirin, verbal instructions about dosing and an information sheet with the same written instructions to take home. For any given subject, all aspirin was taken from the same bottle and all subjects took aspirin with an expiration date at least one year from their test date (±1 month). The dosage of aspirin was as follows: Three 325 mg tablets four times a day at 6 h intervals, for a total of 3.9 g daily. The schedule was maintained for four days (McFadden *et al.*, 1984).

The second test session (Session B) was conducted 72 h after initiating the aspirin regimen and the third test session (Session C) was conducted 96 h after initiation (and within 24 h of Session B) with an error range of ±1 h. A blood draw was scheduled either immediately before or after Session C, depending on availability of the phlebotomist. Serum salicylate levels were measured from the blood sample to ensure subject compliance with the drug regimen. Serum salicylate levels for all subjects were within the therapeutic range (11.92–31.87 mg/dl mean$=21.83$) indicating subject compliance with dosing. Only one subject did not complete Session C because of an illness unrelated to aspirin. A final DP-gram and audiogram were conducted within two weeks of completing the aspirin regimen to confirm a return to normal DPOAE amplitude and hearing thresholds.

2. Term neonates and hearing-impaired children

Following the acquisition of informed parental consent, term-born neonates were tested at Women and Children's Hospital Los Angeles County + USC Medical Center prior to discharge, in the Infant Auditory Research Laboratory. Newborns were swaddled and fed if necessary, then placed in a hospital isolette for testing. The DP-gram, DPOAE suppression data and I/O functions were collected in the same manner described for adult subjects with two exceptions: (1) 5 dB increments (not 2 dB) were used to increase suppressor levels during DPOAE ipsilateral suppression and (2) each infant provided data at one $f2$ frequency only. These procedural modifications were required because of time constraints intrinsic to newborn testing.

DPOAE testing with hearing-impaired (HI) subjects was conducted with the child seated comfortably in an easy chair inside a single-walled sound-attenuated booth. Subjects watched a silent video with subtitles during testing. The test procedure is as described for adults except that each of the eight subjects provided data at one test frequency only. Test sessions with HI subjects lasted approximately 2 h.

F. Data analysis

DPOAE suppression data were quantified in the following manner: (1) DPOAE suppression tuning curve width was quantified 10 dB above the tip by calculating a $Q10$; If the STC was so broad that a $Q10$ could not be measured, a low Q value was assigned to reflect this broadness: 1.0 for $f2=1500$ Hz and 1.4 for $f2=6000$ Hz; (2) *slope* of the low- and high-frequency flank of the STC was determined by fitting a

regression line from the tip of the curve to end points on the low and high-frequency flank; (3) *STC tip* frequency and tip level were measured; (4) *DPOAE suppression growth* was quantified by measuring slope of the DPOAE amplitude ×suppressor level function using a linear regression equation. Any initial amplitude plateau was eliminated in this calculation and only the linear portion of this function was included.

DPOAE I/O functions were quantified in the following manner: (1) *DPOAE threshold* was measured as the lowest stimulus level (L1) at which a valid DPOAE was detected, (2) *Saturation* was measured as the second point along a marked plateau in DPOAE amplitude. A plateau was defined as a sequence of three data points with <1 dB increase in amplitude or 4 points with <2 dB increase; (3) *slope* of the I/O function was measured by fitting a regression equation to the monotonically growing portion of the function.

There were two stages of data analysis: (1) Analyses were conducted within the adult group to compare pre-aspirin baseline data to data collected from whichever session (B or C) showed the greater shift in DPOAE values. This analysis was conducted at each $f2$ frequency separately (1500 and 6000 Hz) using paired t-tests; (2) the second stage of analysis compared DPOAE data recorded in the adult group during the maximum aspirin effect with DPOAE data collected from newborns. These comparisons were conducted using unpaired t-tests at 1500 and 6000 Hz separately. Data from HI subjects were included in the figures although not included in the statistical analyses due to small numbers at each frequency.

III. RESULTS

A. The effects of aspirin on adult DPOAEs

Spontaneous otoacoustic emissions (SOAEs) were measured in all adult subjects because a SOAE near the DPOAE frequency could influence DPOAE suppression characteristics, especially during aspirin use. Only 40% of adults had present SOAEs (1 per ear). None of these SOAEs were greater in frequency than 3076 Hz and none were within 300 Hz of either target DPOAE frequency (1000 or 4000 Hz).

Audiometric thresholds increased by a mean of 12.7 dB at 1500 Hz and by 14.3 dB at 6000 Hz when comparing adult data during the Baseline Session to Session C. DPOAE mean amplitude was reduced by 3.8 dB at 1500 Hz and 7.6 dB at 6000 Hz when comparing Baseline and Session C data. Figure 1 shows DPOAE suppression tuning curves from ten adult subjects at Baseline and during the two post-salicylate sessions (Sessions B and C). Additionally, the Appendix includes individual data from each adult subject at each test session.

1. f2=1500 Hz

At $f2=1500$ Hz, aspirin did not shift any DPOAE feature significantly. There was a trend for the STC to become broader (Baseline mean $Q=2.51$; Session C mean $Q=2.07$), but it did not reach significance. The only significant change noted at $f2=1500$ Hz, was a reduction in DPOAE amplitude from Baseline compared to Session C ($p=0.001$).
FIG. 1. Individual DPOAE suppression tuning curves for $f2=1500$ and 6000 Hz in 10 normal-hearing adult subjects during three test sessions: Baseline presalicylate, Session B (72 h after beginning a four-day salicylate regimen), Session C (96 h after beginning the salicylate regimen). STCs were generated using primary tones at 65/55 dB SPL and a 6 dB suppression criterion.

2. f2=6000 Hz

The effect of aspirin on DPOAE amplitude, suppression and I/O characteristics was systematic for $f2=6000$ Hz. During Session C, DPOAE unsuppressed amplitude was significantly decreased ($p=0.01$). As seen in Fig. 1, DPOAE STCs at $f2=6000$ Hz showed a general degradation of suppression tuning as the aspirin effect became stronger. Seven out of the 10 adults showed broadened STCs during Sessions B and C. Mean $Q10$ shifted from 2.38 during Baseline to 1.56 when measured after 4 days of aspirin. Paired t-tests comparing baseline DPOAE features to data collected during the maximum aspirin effect (either Session B or C) showed significantly smaller $Q10$ values ($p=0.05$), elevated tip level ($p=0.02$) and tip frequency shifted downward ($p=0.01$).

The slope of suppression growth showed aspirin-related changes restricted to low-frequency side suppressor tones. Figure 2 shows the mean slope of suppression growth, for

Carolina Abdala: Aspirin and distortion product suppression   1569
FIG. 2. Mean slope of suppression growth for $f2=6000$ Hz at each suppressor frequency. Results are shown for adult subjects during Baseline, Sessions B and C and for newborns during one test session. Data points that fall to the left of the vertical dashed line represent low-frequency side suppressor tones ($<f2$); those to the right are high-frequency side suppressor tones ($>f2$). Points above the horizontal line correspond to slopes of suppression growth >1 dB/dB and those below the line to slopes <1 dB/dB.

$f2=6000$ Hz, plotted as a function of suppressor frequency for adults (also shown, but discussed later, are newborn data). Adult data in Fig. 2 illustrate the typical pattern of steep suppression growth for low-frequency side ($<f2$) suppressors as they are increased in level, and shallow suppression growth for high-frequency side ($>f2$) suppressors. During Sessions B and C, suppression growth became steeper for three of the four lowest frequency suppressor tones.

The I/O function at $f2=6000$ Hz showed only one significant change during the drug regimen. Mean threshold values shifted from 50 to 57.8 dB SPL ($p=0.006$). Figure 3 shows an example of one adult subject with progressively more elevated DPOAE threshold during aspirin usage.

B. Newborn data

DPOAE suppression tuning curves recorded from 23 term-born neonates are shown in Fig. 4 (See Abdala, 1998 for detailed report of DPOAE suppression in newborns). There was a trend for newborn DPOAE STCs to be slightly narrower at 1500 Hz (Adult $Q=2.5$; Newborn $Q=3.0$) although this effect did not reach statistical significance. Otherwise, at 1500 Hz, DPOAE suppression appears to be gen-
FIG. 3. DPOAE input/output functions at $f2=6000$ Hz for one adult subject during Baseline, Session B, and Session C.
FIG. 4. Individual DPOAE suppression tuning curves for $f2=1500$ (11 ears) and 6000 Hz (12 ears) in term-born neonates. STCs were generated using primary tones at 65/55 dB SPL and a 6 dB suppression criterion.

erally adult-like by term birth. At $f2=6000$ Hz, consistent with previous reports, newborn DPOAE STCs were narrower and steeper than adult STCs collected during baseline (Adult $Q=2.3$; Newborn $Q=3.3$: $p=0.02$). Additionally, suppression growth slope was characteristically shallow in newborns for low-frequency suppressor tones only (see Fig. 2: "x" symbols only).

C. Comparison of aspirin-altered DPOAEs with neonatal DPOAEs

To address the primary question of interest, analyses were conducted to determine whether DPOAE suppression during Sessions B and C (while altered by aspirin) was similar to DPOAE suppression measured from neonates. In all cases, the adult value showing the greater shift from baseline was used in analyses. As previously reported, adult DPOAE data at $f2=1500$ Hz did not shift significantly during the aspirin regimen.

Figure 5 shows mean 6000 Hz DPOAE features measured from adults during their three test sessions and from term neonates tested during one session. Newborn data are plotted under "Session C" (also shown, but discussed later, are HI data). Unpaired t-tests were conducted between adult data from Sessions B/C and neonatal data. Results indicate that newborns and adults tested during aspirin use were significantly different with respect to: Q10 ($p=0.0001$), low and high-frequency STC slope ($p=0.0004$ and 0.0001, respectively), tip level ($p=0.027$), tip frequency ($p=0.017$), and DPOAE amplitude ($p=0.0001$). Tuning curves from neonates were narrower, with steeper flanks, showed a lower tip level, higher tip frequency and a larger amplitude unsuppressed DPOAE relative to adult DPOAEs recorded during the aspirin effect. From Fig. 5 it is also apparent that the shift produced by aspirin did not move adult DPOAE data toward neonatal values; rather, adult tuning curves became less, not more "neonatal-like," during aspirin-induced alterations in OHC function.

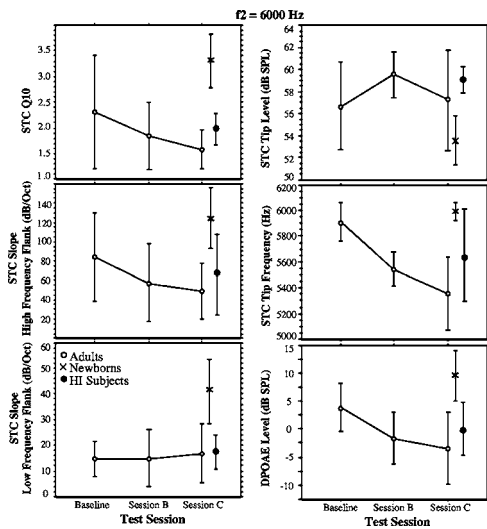
Mean adult and newborn DPOAE suppression growth at $f2=6000$ Hz is shown in Fig. 2. Clear neonatal and adult differences are present at baseline, as expected, but more important, these differences are preserved during test ses-


FIG. 5. Mean DPOAE features at $f2=6000$ Hz for adults, term neonates, and a group of hearing impaired subjects. Adult data are plotted during three sessions: pre-salicylate Baseline, Session B (72 h later) and Session C (96 h after beginning the salicylate regimen). Newborn and hearing-impaired data are plotted under Session C for comparison. Error bars represent ± one standard deviation.

sions B and C. Neonates have significantly more shallow suppression growth slope than adults for the four lowest suppressor frequencies. Aspirin did not shift adult suppression growth toward neonatal values, nor minimize differences between these two groups.

DPOAE threshold increased by a mean of 7.8 dB (shifted from 50 to 57.8 dB SPL) during aspirin. Given this shift, adult DPOAE threshold measured during Session C, appears to have become more similar to newborn threshold (55 dB SPL). However, similarity between adult and infant thresholds seen here cannot be attributed to aspirin, because these thresholds were similar both before and after the drug regimen.

D. Comparison of newborn DPOAEs with DPOAEs from hearing-impaired subjects

For a detailed account of how SNHL affects DPOAE suppression, please see Abdala and Fitzgerald, 2003. Although DPOAE STCs recorded from HI subjects showed variability in shape and width, a general degradation or disruption of DPOAE suppression tuning was apparent at both frequencies, but particularly at $f2=6000$ Hz (Fig. 6). At $f2=1500$ Hz, STC width was in the normal range for the HI group; however, at 6000 Hz, their suppression tuning was broadened ($Q=1.98$ vs 2.36 for normal hearing). Tip frequencies were shifted downward at both $f2$ frequencies and STC tip was elevated, only at 6000 Hz.

There does not appear to be any systematic similarity between DPOAE suppression data from these individuals with SNHL and newborn data. The broader suppression tuning at 6000 Hz for HI subjects is in contrast to the excessively narrow STCs observed in newborns (HI $Q10=1.98$ vs 3.3 in newborns). One of the most notable differences between individuals with SNHL and newborns, is STC tip
FIG. 6. Individual DPOAE suppression tuning curves for $f2=1500$ and 6000 Hz in eight children with mild-moderate SNHL. STCs were generated using primary tones at 65/55 dB SPL and a 6 dB suppression criterion.

level. At $f2=6000$ Hz, the tip was markedly elevated in the HI group, as is clearly evident by comparing 6000 Hz STCs in Fig. 6 (HI) to those in Fig. 4 (Newborn).

Newborns and HI subjects also show dissimilar DPOAE suppression growth at $f2=6000$ Hz (Fig. 7). In the HI group, the pattern of suppression growth slope is more erratic and shows large fluctuations across suppressor frequency. Additionally, for the lowest three suppressor frequencies, newborns show more shallow suppression growth than HI subjects. These observations suggest that newborn DPOAE suppression does not approximate suppression data from individuals with hearing loss.

The DPOAE I/O functions generated from HI subjects were normal in slope and saturation characteristics but showed elevated DPOAE thresholds (50 dB SPL at 1500 Hz; 55 dB SPL at 6000 Hz). An elevated DPOAE threshold is an expected result when SNHL is present and has been described in the literature previously (Stover *et al.*, 1996). At $f2=1500$ Hz, neonates also had an elevated mean DPOAE threshold of 52 dB SPL. Newborns and these four subjects with hearing impairment were similar with respect to this DPOAE feature at $f2=1500$ Hz.
FIG. 7. Mean slope of suppression growth for $f2=6000$ Hz at each suppressor frequency. Data are shown for hearing-impaired subjects and newborns. Data points to the left of the vertical dashed line represent low-frequency side suppressor tones ($<f2$); those to the right are high-frequency side suppressor tones ($>f2$). Points above the horizontal line correspond to slopes of suppression growth >1 dB/dB and those below the line to slopes <1 dB/dB.

E. Serum salicylate levels

Pearson Product Moment Correlations were conducted between the serum salicylate blood level measured following the last adult test session and changes in: (1) audiometric threshold, (2) DPOAE amplitude, and (3) STC Q10 values. This analysis was conducted to examine whether variability in serum salicylate levels among subjects influenced the DPOAE results in a systematic fashion. Only one correlation was significant. At 1500 Hz, there was a significant correlation between serum salicylate blood levels and the decrease in audiometric threshold ($r=0.75$; $p=0.019$). The higher the salicylate level, the greater the shift in audiometric threshold. The lack of correlation between serum salicylate blood level and changes in the DPOAE suggests that it did not influence the results in a systematic fashion.

IV. DISCUSSION

This is the first investigation of the effects of aspirin on DPOAE ipsilateral suppression in humans. Direct studies of the effects of aspirin on the OHC have shown a reduction in cell motility and turgor (Shehata *et al.*, 1991). OHC membrane characteristics are altered when exposed to salicylate, showing increased permeability to K+ on the basolateral membrane, which causes an increased flow of resting current through the cell (Tunstall *et al.*, 1995).

The present study found that salicylate-induced OHC dysfunction in human adults produced significant and systematic effects on DPOAE suppression only for high-frequency primary tones. It has also been show that aspirin-induced hearing loss is more pronounced in high, rather than low frequencies (Cazals, 2000). At $f2=6000$ Hz, aspirin produced broadened DPOAE STCs with elevated tips shifted toward lower frequencies. This frequency effect is consistent with findings that OHC-related phenomenon, such as cochlear nonlinearity and cochlear signal amplification, are strongest in the basal region of the cochlea (Cooper and Rhode, 1995; Rhode and Cooper, 1996).

Aspirin-induced degradation of frequency tuning has been documented previously. Frequency selectivity measured psychoacoustically becomes poorer in human subjects after aspirin usage (Carlyon and Butt, 1993; Beveridge and Carlyon, 1996). Interestingly, Carlyon and Butt (1993) reported that the largest shifts in hearing threshold did not correlate well with the largest degradations in tuning. This was observed in the present study as well. The mean audiometric threshold shifts induced by aspirin at 1500 and 6000 Hz are not greatly different from one another (6000 Hz=14.5 dB; 1500 Hz=12.5 dB) yet DPOAE suppression tuning was only disrupted at $f2=6000$ Hz. It appears that a shift in hearing threshold does not accurately predict the degree or level of disruption in DPOAE suppression tuning. In addition to the effects of aspirin on DPOAE suppression tuning at 6000 Hz, the DPOAE threshold at this frequency was also elevated during the aspirin effect. Combined, these changes in DPOAE suppression tuning and DPOAE threshold suggest that electromotility of OHCs was temporarily disrupted in adult subjects and that the DPOAE suppression paradigm was able to measure or reflect this induced dysfunction.

A. Does OHC dysfunction provide a good model for neonatal cochlear immaturity?

Infants through 3 months of age do not have mature DPOAE suppression at $f2=6000$ Hz, although the locus of this immaturity is not known (Abdala, 2004). The research question in the present study was whether aspirin-induced or naturally occurring OHC dysfunction produces DPOAE suppression that mimics neonatal suppression. Do aspirin-induced alterations in the OHC produce suppression tuning that becomes more narrow and steep on the low-frequency flank with more compressive rates of suppression growth for low-frequency side suppressor tones? If observed, this result would indicate that cochlear function in newborns is like cochlear function in individuals with minor impairments of OHC function. However, adult DPOAE suppression tuning *did not* become more sharp and neonatal-like during the aspirin effect. Adult DPOAE STCs generally became broader and less steep, producing DPOAE data that not only remained significantly different from newborn data but *became more different* during the aspirin effect. It is difficult to argue that dysfunction (or immaturity) of a common cochlear source, such as the OHC, could produce two completely different and opposite patterns of DPOAE suppression.

Neonates do not have DPOAE STCS like those recorded from individuals with OHC dysfunction due to mild-moderate sensorineural hearing loss either. Instead, the disruption of DPOAE suppression in both groups with altered OHC function is consistent with degradation of tuning and cochlear non-linearity observed at many levels of the auditory system when OHCs are damaged or destroyed (Liberman and Dodds, 1984; Evans and Harrison, 1976; Hicks and Bacon, 1999). Hearing-impaired subjects and adults with aspirin-induced OHC dysfunction demonstrate many shared DPOAE characteristics but neither group produces data mimicking the unique patterns of DPOAE suppression consistently observed in neonates.

The dissimilarity between neonatal data and data from either subject group with OHC dysfunction, suggests that an immaturity in OHC motility is not an adequate or likely explanation for nonadult-like DPOAE suppression in newborns. We cannot unequivocally rule out that other aspects of the OHC, not directly related to motility, might be immature and contribute to the DPOAE suppression results seen in infants.

B. DPOAE threshold elevation at 1500 Hz

At 1500 Hz, subjects with SNHL and newborns had comparably elevated DPOAE thresholds (50 and 52.2 dB SPL respectively; normal hearing=38 dB SPL). DPOAE threshold elevation in HI subjects is related to elevated audiometric thresholds produced by hearing loss (Stover *et al.*, 1996). Likewise, DPOAE threshold elevation in newborns may suggest elevated hearing thresholds in the low-frequency audiometric range, possibly due to immaturity of middle ear function. The inefficient transfer of energy through the neonatal middle ear may attenuate stimulus tones entering the cochlea (Keefe *et al.*, 1993, 1994). Elevation of DPOAE threshold at $f2=1500$ Hz could also be unrelated to

auditory phenomena and associated only with the generally high infant noise floor recorded in the low-frequency range. These possibilities should be further explored. It is likely that this threshold immaturity at 1500 Hz comes from a different source than the nonadult-like DPOAE suppression consistently observed in neonates for high-frequency primary tones.

V. CONCLUSION

Numerous studies have documented nonadult-like DPOAE suppression in infants for high-frequency primary tones (Abdala *et al.*, 1996; Abdala, 1998; Abdala and Chatterjee, 2003). This immaturity has been hypothesized to arise from various sources: the outer hair cell, the medial efferent system, the middle ear or from passive vibratory characteristics of basilar membrane. The present study tested one of these hypotheses by investigating whether newborn DPOAE suppression was similar to suppression recorded from two groups with known OHC dysfunction. The findings do not support the hypothesis that nonadult-like DPOAE suppression results that characterize this age group may be explained by minor alterations of OHC function. Neither aspirin-induced changes in OHC function or OHC dysfunction associated with SNHL provide a good model for neonatal immaturity, as measured by DPOAE suppression.

Although a functionally immature middle ear produces attenuation of sound that could influence DPOAE suppression results to some extent, simple modeling of this effect cannot easily account for neonatal immaturities in DPOAE suppression (Abdala, 2004). It may explain the elevation of DPOAE threshold in the low frequencies however. An experiment is currently under way in our laboratory to more directly examine the relationship between middle ear function and DPOAE suppression/threshold during the first months of postnatal life.

Finally, evidence suggests that nonadult-like cochlear function in neonatal gerbils may be due to constraints imposed by immature mass and stiffness of the basilar membrane (Mills and Rubel, 1996). If the physical properties of the basilar membrane cannot sustain or support sound-initiated vibration in a normal way, it may limit effectiveness of the "cochlear amplifier," even if the amplifier is fully developed and functional. The hypothesis that passive vibratory characteristics of the basilar membrane may be immature in human newborns and may contribute to nonadult-like DPOAE suppression results, warrants further investigation.

Transient evoked otoacoustic emissions of a large population of neonates (466 ears) are analyzed, with the aim of establishing if a significant latency difference can be observed between "pass" (333) and "fail" (133) ears, discriminated with a screening protocol based on band and global reproducibility. The ears that did not pass the test in at least one frequency band are named "fail," for simplicity, but they should be more appropriately defined as "partial pass." In a previous study, significantly different average latencies had been observed in adult subjects, comparing normal hearing and hearing impaired ears [J. Acoust. Soc. Am. **111**, 297–308 (2002)], but no similar study has been conducted on neonates yet. An improved wavelet technique was applied to transient evoked otoacoustic emission data, to get accurate experimental measurements of the otoacoustic emission latency. The results show statistically significant differences between the latency distributions of the "pass" and "fail" populations, with the "fail" latencies longer. However, non-Gaussianity of the distributions and systematic errors associated with low reproducibility levels suggested using a conservative approach in the data analysis and interpretation. New otoacoustic estimates of cochlear tuning in neonates are also provided. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000769]

I. INTRODUCTION

Otoacoustic emissions (OAEs) provide important information about cochlear physiology (Probst *et al.*, 1991). The transient evoked OAE (TEOAE) latency is defined as the delay between the onset of the click and the maximum of the evoked OAE amplitude. For each frequency within the stimulus bandwidth, latency essentially consists of the traveling time along the cochlear membrane from the base to its tonotopic site and back (cochlear round trip delay). A much smaller contribution, of order 0.5 ms (Sisto and Moleti, 2002) comes from the transmission through the outer and middle ear. As tonotopic sites are distributed along the cochlea according to the Greenwood frequency map (Greenwood, 1990), latency is intrinsically frequency dependent. In particular, the relation between latency and frequency is dependent on the quality factor of the cochlear filter through the dependence of the traveling wave velocity on the sharpness of the resonance. Thus, measurements of the transient evoked otoacoustic emission (TEOAE) latency provide an indirect estimate of the tuning curve, which is important for subjects that, like neonates, cannot be studied with psychoacoustical techniques. More generally, as with other OAE measurable parameters (DPOAE phase-gradient delays, TEOAE stimulus-response curves, TEOAE decay time, etc.), TEOAE latency provides important information about the cochlear transmission and amplification mechanisms. Cochlear transmission and amplification are related, because both the amplifier gain and the traveling wave velocity are dependent on the sharpness of the cochlear resonances.

Clinical dichotomic "pass-fail" criteria discriminate between presumed normal-hearing and presumed sensorineural hearing loss ears on the basis of the TEOAE reproducibility (Vohr and Maxon, 1996), which is equivalent to the signal to noise ratio or to the absolute response level, given a typical instrumental noise level. Latency and tuning curves could also be used, in principle, to test the cochlear functionality, with the advantage of using differential measurements, insensitive to absolute calibration uncertainties.

Time-frequency analysis techniques are now available (Wit *et al.*, 1994; Tognola *et al.*, 1997; Tognola *et al.*, 1998; Sisto and Moleti, 2002; Jedrzejczak *et al.*, 2004), which are capable of providing reliable estimates of the OAE spectral latency.

[a]Electronic mail: arturo.moleti@roma2.infn.it
[b]Electronic mail: r.sisto@dil.ispesl.it
[c]Electronic mail: gabriella.tognola@polimi.it

Previous time-frequency estimates of the OAE latency in adults found a clear frequency dependence, in good agreement with a simple power law:

$$\tau(f) = af^b, \tag{1}$$

with f in kHz. The experimental estimates were consistent with a value of a of order 10 ms and b in the range -0.4 to -0.7 (Tognola *et al.*, 1997; Sisto and Moleti, 2002). As the Greenwood map $x(f)$ is a logarithmic function of the frequency, this power law is approximately equivalent to the exponential function of the cochlear distance that has been proposed to fit the spectral latency versus cochlear distance relationship in studies of the derived band acoustic brainstem response (ABR) latency (Donaldson and Ruth, 1993). A recent study (Jedrzejczak *et al.*, 2004) confirmed earlier OAE observations, and demonstrated that very good time-frequency resolution may be achieved using Matching Pursuit (MP) iterative algorithms.

Cochlear latency is also related to the $2f_1-f_2$ distortion product OAE (DPOAE) group delay (more correctly named the phase-gradient delay) (Moulin and Kemp, 1996; Prijs *et al.*, 2000; Schoonoven *et al.*, 2001). The DPOAE phase-gradient delay is a characteristic time associated with the slope of the functional relation between the DPOAE phase and the DPOAE frequency $f_{DP}=2f_1-f_2$. This measure can be performed by either sweeping f_2 (fixed-f_1 paradigm, yielding the characteristic delay τ_1) or f_1 (fixed-f_2 paradigm, yielding a conceptually different delay, τ_2). The DPOAE group delays are related to the round trip delay introduced by the forward transmission along the cochlear membrane of the primary tones from the source to the DPOAE generation place and the backward transmission of the DPOAE to the microphone.

The interpretation of the DPOAE phase-gradient delay data in terms of cochlear tuning is rather difficult (Shera *et al.*, 2000), mainly because the forward and backward transmitted signals are of different frequency, and because the DPAOE signal itself comes from minimally two sources at two different cochlear positions, the tonotopic place $x(f_{DP})$ and the region between $x(f_1)$ and $x(f_2)$. For the same reason, phase-gradient delays cannot be directly compared to TEOAE latencies.

Shera *et al.* (2002) measured stimulus-frequency OAE (SFOAE) group delays, in humans and small mammals, also providing an interpretation of the results in terms of cochlear tuning. Human cochlear tuning resulted sharper than previously assumed, and in agreement with recent behavioral measurements (Oxenham and Shera, 2003). More recently, Shera and Guinan (2003) applied these results to successfully test the predictions of the theory of coherent reflection filtering (Zweig and Shera, 1995; Talmadge *et al.*, 1998).

We have remarked that the measure of the cochlear characteristic times is important because they are related to the quality factor (tuning) of the cochlear filter. We also note that the cochlear filter parameters are, in turn, responsible for the sensitivity and frequency selectivity of the cochlear amplifier, and they are very sensitive to outer hair cell (OHC) damage. Thus OAE characteristic times are expected to be sensitive, as OAE amplitudes are, to mild cochlear damage,

with the advantage of being estimated with differential measurements, so avoiding the systematic errors associated with the measurement of absolute amplitudes.

From a clinical point of view, many authors reported a correlation between hearing loss and the degradation of many OAE parameters (Attias *et al.*, 1995; Kowalska and Sulkowski, 1997; Hussain *et al.*, 1998; Hall and Lutman, 1999; Tognola *et al.*, 1999; Lucertini *et al.*, 2002).

With regard to OAE latency, Sisto and Moleti (2002) and Lucertini *et al.* (2002) showed a significant correlation between anomalously long OAE spectral latency and hearing impairment in adults exposed to impulsive noise. A significant latency difference was also found between healthy neonates and healthy adults (Moleti and Sisto, 2003). As high-level click stimuli had been used in both studies (80 dB peak SPL), the response of the cochlear amplifier is strongly nonlinearly saturated. Thus, a possible interpretation of these results is that the longer latencies observed in damaged ears and in neonate ears, which would imply a higher quality factor, if a resonant transmission line cochlear model is assumed, are due to reduced nonlinear saturation of the cochlear amplifier. In the case of neonates a similar effect on DPOAE suppression tuning curves has been attributed indeed to immaturity of the efferent feedback system (Abdala, 2001). In impaired ears, this could be due to some compensative modification of the nonlinear characteristics of the cochlear amplifier, whose interpretation could provide important clinical information. Hence, the interest of comparing the latency measured in populations of neonates discriminated according to their score in standard hearing screening tests.

Our aim in this work is indeed to establish if a statistically significant difference can be observed between OAE latency and cochlear tuning in populations of neonate ears discriminated with a standard screening protocol based on TEOAE reproducibility. We will carefully discuss the possible sources of systematic errors, associated with the proposed latency estimate methods, which could bias the comparison between different populations.

These accurate measurements of the latency-frequency relationship on a large dataset of neonates, may also serve as a reference for future clinical studies using the same acquisition and analysis techniques.

II. METHOD

TEOAEs were obtained from 466 ears of full-term babies on the third day after delivery during a universal hearing screening program at the Service of Neurophysiopathology of the Mangiagalli Clinic, (Milan, Italy). Responses were recorded using an ILO88 system (Otodynamics, Ltd.), digitized at a rate of 25 000 samples/s. A standard neonatal probe was used. For each ear, two sets of replicate responses (A and B replicates recordings in ILO equipment) to 260 repetitions of the click-train (4 clicks per train) were averaged, according to the "nonlinear" mode of operation (Bray and Kemp, 1987; Kemp *et al.*, 1986). The averaged data were windowed and digitally filtered using the default ILO window (2.5–20 ms, cosine tapered from 2.5 to 5 ms) and

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Moleti *et al.*: Otoacoustic emission latency in neonates   1577

filter (second-order digital bandpass set at 600–6000 Hz). All the responses included in the examined dataset were checked to have a stimulus stability greater than 75% and a stimulus level ranging from 77 to 83 dB peak SPL.

Hearing functionality was assessed accordingly to the following criteria (Vohr and Maxon, 1996): an emission was defined as "pass" when the overall reproducibility (i.e., the zero-lag cross-correlation coefficient between the A and B replicates in the 2.5–20 ms window) was ⩾0.7 and the reproducibility in 0.8 kHz wide frequency bands was ⩾0.5 at 1.6 kHz, ⩾0.7 at 2.4, 3.2, and 4.0 kHz; "partial pass" when not all the five values met the criterion; "refer" when all values did not meet it. The criterion for the first frequency band is lower than the others to take into account the effects of the residual noise, which mostly affects the low-frequency region of TEOAEs. In the following we will call "fail" these "partial pass" emissions, for brevity, but one has to remember that they mostly include relatively high reproducibility OAEs, which have not passed the test in only one or two frequency bands. In fact, all these subjects passed an ABR test, so they are all "normal hearing," with different degrees of TEOAE reproducibility. We are just assuming that a systematically lower reproducibility (i.e., SNR) is likely to be statistically associated with a lower effectiveness of the cochlear active mechanisms.

The 20 ms TEOAE waveforms were analyzed by a time-frequency wavelet transform (WT) technique (for more details, see Tognola *et al.*, 1997; Tognola *et al.*, 1998). The WT at the generic time t and frequency f of signal $x(t)$ is defined as (Mallat, 1989)

$$\mathrm{WT}(\tau,f) = \int_t x(t)\left(\frac{f}{f_0}\right)^{-2}\sqrt{\frac{f}{f_0}}\psi^*\left(\frac{f}{f_0}(t-\tau)\right)dt, \qquad (1')$$

where * denotes complex conjugation. Basically, the WT decomposes a signal $x(t)$ into elementary components by means of a bank of bandpass filters—$\sqrt{f/f_0}\cdot\psi[f/f_0(t)]$—that are iteratively derived from a unique prototype function $\psi(t)$, called the mother wavelet. The mother wavelet $\psi(t)$ is a function with finite energy and centered on time $t = 0$; its Fourier transform is a bandpass function centered on frequency f_0. The bandwidth of the bandpass filters derived from the mother wavelet is proportional to the central frequency of the filter, whereas the duration of their impulse response in the time domain is inversely proportional to the central frequency of the filter [for a more detailed mathematical treatment, see Tognola *et al.* (1997, 1998)]. Roughly speaking, this type of analysis provides a decomposition of a signal into subbands with a bandwidth linearly increasing with frequency. In this form, the WT can be viewed as a special case of a spectral analyzer.

The original signal $x(t)$ can be synthesized by adding all the contributions $\mathrm{WT}(\tau,f)$ as follows (Mallat, 1989):

$$x(t) = c\iint \mathrm{WT}(\tau,f)\sqrt{\frac{f}{f_0}}\psi\left(\frac{f}{f_0}(t-\tau)\right)\left(\frac{f}{f_0}\right)^2 d\tau\,df, \qquad (2)$$

where c is a constant that depends on the mother wavelet, and the frequency integration is extended over the whole frequency range. By integration of the coefficients $\mathrm{WT}(\tau,f)$ over 500 Hz-wide frequency bands we get the wavelet band coefficients $W(f_k,t)$, which represent the time evolution of the evoked signal in seven frequency bands, centered at the frequency $f_k(k=1,\ldots,7)$ equal to 1, 1.5, 2, 2.5, 3, 3.5, and 4 kHz. Each function $W(f_k,t)$ is normalized to its maximum value, and describes the time evolution of the signal belonging to a given spectral band.

As in Sisto and Moleti (2002), two alternative definitions of latency were considered. For each ear j, the time at which the function $W_j(f_k,t)$ reaches its maximum value is defined as the latency $\tau_j(f_k)$ of the jth ear at frequency f_k. By doing so, one gets a statistical distribution of the latency for each frequency, for the two populations (in this study, the "pass" and "fail" ears). An average of the $\tau_j(f_k)$ is performed over the ears, yielding

$$\langle\tau^*(f_k)\rangle = \frac{1}{N_{\mathrm{ears}}}\sum_{j=1}^{N_{\mathrm{ears}}}\tau_j(f_k), \qquad (3)$$

which is an estimate of the average spectral latency of each population in the kth frequency band.

The alternative average latency estimate was obtained by computing the average of the band coefficients over the ears of each population:

$$\langle W(f_k,t)\rangle = \frac{1}{N_{\mathrm{ears}}}\sum_{j=1}^{N_{\mathrm{ears}}}W_j(f_k,t), \qquad (4)$$

and defining the average latency $\langle\tau(f_k)\rangle$ as the time for which the averaged band coefficient $\langle W(f_k,t)\rangle$ reaches its maximum value. This method has the advantage of being less sensitive to the fact that high-frequency wavelet band coefficients sometimes have large amplitudes at very long delays, but does not give an estimate of individual latencies; thus a quantitative evaluation of the significance of the difference between the two populations is more difficult. In the next section we will show the results obtained with both methods.

For approximately Gaussian distributions, the two methods tend to give coincident results, as shown in Sisto and Moleti (2002), and the student's t-test procedure applied to the distributions of individual latencies would give a reasonable estimate of the statistical significance of a difference between distributions of the two populations. Unfortunately, the statistical distributions turned out to be non-Gaussian and, in particular, the high-frequency latency distributions of the "fail" population showed long tails corresponding to unreasonably long latency values. This turned out to be due to a systematic error, which required the introduction of a data selection criterion, as will be discussed in Sec. III.

The average latencies were best fitted to a power law of the form

$$\tau(f) = \tau_{\mathrm{nc}} + af^b, \qquad (5)$$

with f in kHz and $\tau_{\mathrm{nc}}=0.5$ ms. This estimate was first obtained by Sisto and Moleti (2002), by analyzing the TEOAE wavelet band coefficients as functions of time, in ears showing intense individual resonances in their TEOAE spectrum. In such cases, a quasiperiodic time behavior was observed, which was attributed to subsequent

reflections of the same wave packet between the tonotopic place and the base. The noncochlear contribution was roughly estimated as the difference between the absolute delay of the first echo and the differential delay between subsequent echoes. This procedure had also been applied to the neonate data analyzed in Moleti and Sisto (2003), finding again $\tau_{nc}=0.5$ ms.

We recall that the measured latency $\tau(f)$ at a given frequency f is made up of a cochlear contribution, $\tau_c(f)$, due to the round-trip delay associated with the transmission of the acoustic signal along the cochlear membrane, and of a much smaller contribution from the outer and middle ear, τ_{nc}. The previously described technique had been successfully used to show significant differences between the latencies of normal-hearing and impaired ears (Sisto and Moleti, 2002), and also between those of normal-hearing ears of subjects exposed to impulsive firearm noise and of nonexposed subjects (Lucertini *et al.*, 2002).

In a previous study (Sisto and Moleti, 2002), it was noted that the use of octave bands, which was a consequence of the filterbank cascade algorithm used to perform the wavelet transform, could lead to systematic errors in the estimate of the slope of the latency-frequency relation, depending on the typical frequency of the main TEOAE lines in each octave band. This source of systematic error is reduced, in the present study, by performing the analysis with better frequency resolution.

The method described in Moleti and Sisto (2003) was applied to the average latency data, to get an estimate of the neonatal tuning curve. This method is based on a simple transmission line cochlear model, in which the round trip cochlear delay is computed as twice the integral of the inverse traveling wave velocity (TWV) from the base to the tonotopic place:

$$\tau_c(\omega) = 2\int_0^{x(\omega)} dx\, \mathrm{TWV}^{-1} = 2\int_0^{x(\omega)} dx\, \frac{\partial k}{\partial \omega}. \quad (6)$$

The TWV is a function of the relation between the wavenumber k, angular frequency $\omega=2\pi f$, and cochlear position x, and drops to a minimum near the resonant place. As this slowing down is a function of the resonance quality factor Q, it is possible to get an estimate of the tuning curve from the measured latency:

$$Q(\omega) \approx \left(\frac{\omega k_\omega}{\alpha k_0}[\tau(\omega) - \tau_{nc}] - \frac{\sqrt{2}}{\alpha} \right)^2, \quad (7)$$

where $\tau(\omega)$ is the experimental average latency value, $k_\omega = 1.382$ cm^{-1} is the scale parameter of the Greenwood map, $k_0=31$ cm^{-1} is a constant associated with the geometry and density of the basilar membrane and of the cochlear cavity (Talmadge *et al.*, 1998), and $\alpha \approx 0.9$.

III. RESULTS

The wavelet analysis method was applied to all the data collected in this experiment. The two definitions of average latency described in the previous section failed to give coincident results. In Fig. 1 we show the average latency values obtained for the two populations using the two methods. Two
FIG. 1. A comparison between the average latency of the 333 "pass" (black triangles) and of the 133 "fail" (white circles) neonate ears, using the two alternative definitions of average latency $\tau^*(f)$ (top), defined as the average of the individual latencies, and $\tau(f)$ (bottom), defined as the time of the maximum of the average wavelet band coefficients.

main facts are evident: (1) in both cases the average latencies of the "fail" population are longer than those of the "pass" population; (2) the difference is much larger using the first definition of the average latency $\langle \tau^*(f) \rangle$ [see Eq. (3)], which is the average of the individual latencies. The large discrepancy between the two results in the high-frequency range can be explained by looking more carefully at the distributions of the individual latency data. As an example, in the bottom panel of Fig. 2 the histogram of the 3 kHz individual latency data is shown for the "fail" population. Long tails extending up to unreasonably long latencies are clearly visible, which give a significant contribution to the average latency. The histograms of the "pass" population latency do not show such abnormal tails, as shown in the top panel of Fig. 2. The same individual data of the bottom panel of Fig. 2 are plotted in Fig. 3 (top panel) as a function of the individual band reproducibility. This plot shows that the abnormally long latencies are typically associated with low reproducibility in the same 500 Hz wide band. The same pattern may be observed in all mid-high-frequency bands, as shown in Fig. 3 (bottom panel) for the 2.5 kHz band. The seven average wavelet band coefficients are plotted in Fig. 4, showing a plateau on the long latency side of the high-frequency band coefficients, including a large contribution from the ears

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

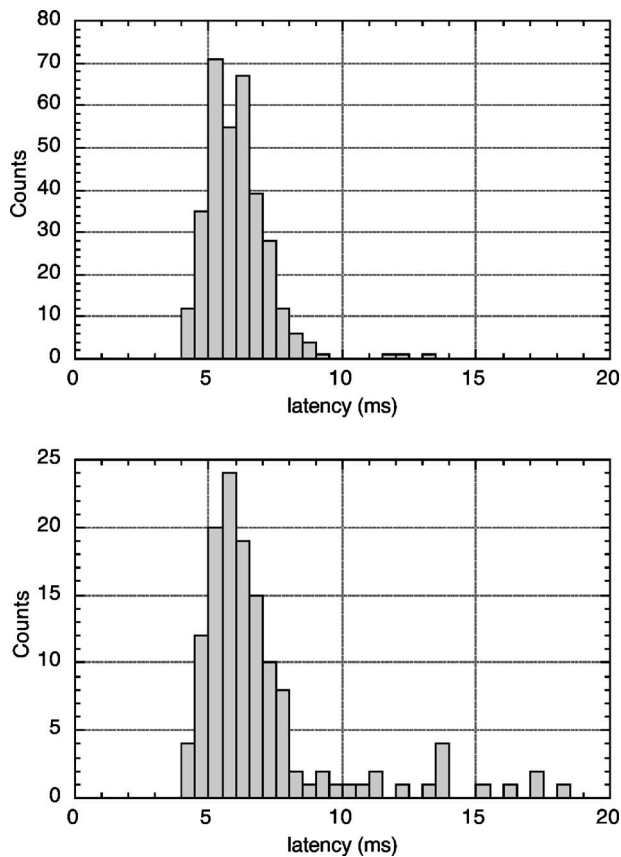
Moleti *et al.*: Otoacoustic emission latency in neonates   1579


FIG. 2. Experimental histograms of the 3 kHz latency for the "pass" population (top) and for the "fail" population (bottom). The "fail" histogram shows a significant tail extending to unreasonably long latency values.

FIG. 3. Individual latency at 3 kHz (top) of the "fail" population as a function of reproducibility in the same 500 Hz band. Latency data are the same, as shown in previous Fig. 2, bottom panel. Abnormally long latency values are systematically associated with low reproducibility. The same pattern is shown for the 2.5 kHz band (bottom).

whose individual latency is unreasonably long, which does not affect the position of the maximum of the function. In other words, there is evidence for a systematic error associated with the determination of high-frequency individual latencies, more frequent for low reproducibility data, which seriously affects the average latency defined as the average of the individual latency distribution, leaving almost unchanged the peak time of the corresponding average wavelet band coefficient. On the other hand, if we could recover quasi-Gaussian distributions for the individual latencies of the "fail" population, we would get a meaningful statistical comparison of the two populations. These abnormal individual latency values are mainly due to the fact that the individual high-frequency wavelet coefficients often show a periodic structure associated with subsequent reflections in the cochlea (Sisto and Moleti, 2002), and the first peak may sometimes be lower than the following ones, due to the combined effect of acquisition window and noise. Very low reproducibility data are most sensitive to these effects, thus we have filtered the individual latency data, cutting out the lowest reproducibility data of the "fail" population. By doing so, we have restricted our data analysis to the comparison of two populations discriminated by a much smaller, yet significant, difference in band reproducibility. After having computed the time at which each wavelet band coefficient reaches its maximum value for each ear, which is our definition of individual spectral latency, we have discarded the latency values relative to bands with poor reproducibility in that band. This

selection has not significantly affected the "pass" data, whose reproducibility is very high in all bands by definition, but turned out to be important to get meaningful results for the "fail" population, as we will discuss in detail in the next section. The band reproducibility threshold was fixed at 0 at 1 kHz, at 0.35 in the frequency range 1.5–3 kHz, and at 0.7 for the 3.5 and 4 kHz bands. This particular choice is motivated by the spectral shape of the band reproducibility, whose median is plotted in Fig. 5 for the two populations of ears, with and without the selection, and by the particularly high sensitivity of the high-frequency data to the above mentioned systematic error. From Fig. 5, one can see that, after this selection, the reproducibility difference between the two populations is very small in the two highest frequency bands.

This selection rule was sufficient to eliminate most of the unreasonably long latency values, producing quasisymmetrical histograms also for the selected "fail" population, named "fail sel," as shown in Fig. 6. In this way meaningful statistical evaluations have become possible. Average latency data $\langle \tau^*(f) \rangle$ are shown in Fig. 7, for the two populations, computed with the above mentioned selection criterion. The application of the selection criterion has significantly modified the average latency of the "fail" population, by cutting out roughly one-third of the latency data, and the latency estimates are consistent with those obtained with the alternative definition of latency, shown in Fig. 1.

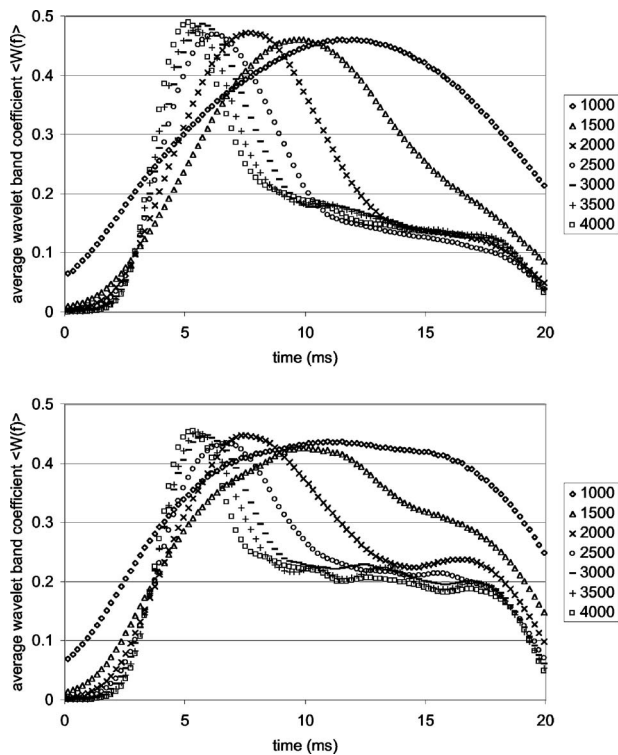
As shown in Table I, the average latency difference between the two populations becomes very small after the selection, with a significant difference in the 1.5 and 2.5 kHz


FIG. 4. Average wavelet band coefficients of the "pass" (top) and "fail" (bottom) population. The plateau on the long latency side of high-frequency components is associated with the systematic error in the determination of the average latency τ^*, but does not affect the latency τ, given by the time of the peak of these curves.

bands only. A systematic latency excess is, however, observed in the "fail sel" population over the whole frequency range. We would like to stress that the large number of ears makes the standard errors very small, as shown in Table I and Fig. 7, and that our conservative data selection choice ensures that the statistical distributions can be meaningfully compared, as shown by the shape of the selected data histograms (Fig. 6).

The selected latency data were best fitted to a power law of the frequency, Eq. (5). We recall that τ_{nc} was assumed to
FIG. 5. A Comparison between the median of the band reproducibility distributions of the "pass" and "fail" populations, and of the "pass sel" and "fail sel" subsamples obtained with the selection criterion based on band reproducibility, as described in the text.
FIG. 6. Experimental histograms of the 3 kHz latency for the "fail" population, before and after the data selection. The dark region of the histogram represents the selected latency subset, "fail sel," surviving the selection procedure based on band reproducibility. A quasi-Gaussian shape is recovered.

be 0.5 ms, according to Sisto and Moleti (2002) and Moleti and Sisto (2003). With this assumption, the power law best fit computed on the average selected latency data $\langle \tau^*(f) \rangle$, yielded $a = 11.2$ ms, $b = -0.61$ for the "pass" ears and $a = 11.5$ ms, $b = -0.59$ for the "fail sel" ears. Using the alternative estimate of the average latency $\langle \tau(f) \rangle$, one gets, respectively, $a = 11.4$ ms, $b = -0.68$ for the "pass" ears and $a = 11.5$ ms, $b = -0.64$ for the "fail" ears.

The estimate of the tuning curve $Q(f)$ obtained by applying Eq. (7) to the experimental latency data is shown in Fig. 8 for the two populations of ears. In the case of $Q(\tau^*(f))$, standard errors are also plotted to show that the difference between the two populations is marginally significant over the whole frequency range. In the same figure are also shown the values of $Q(f)$ obtained from the alternative definition of average latency $\langle \tau(f) \rangle$, which are slightly lower, and follow the same trend.

IV. DISCUSSION

The large number of ears examined in this study provides a rather precise estimate of the average spectral latency
FIG. 7. A comparison between the average latency $\langle \tau^*(f) \rangle$ of the "pass sel" (triangles) and of the "fail sel" (circles) neonate ears, selected according to the procedure based on band reproducibility.

TABLE I. Average latencies $\tau^*(f)$ [see Eq. (3)] of the "pass sel" and "fail sel" populations and p values associated with the difference between them. The latency values obtained without data selection (τ^*_{pass} and τ^*_{fail}) and using the alternative definition of average latency (τ_{pass} and τ_{fail}) [see Eq. (4)] are also shown for comparison. The threshold value $p<0.05$ has been used as a conventional criterion for statistical significance.

f(Hz)	1000	1500	2000	2500	3000	3500	4000

τ_{fail}	11.6	10.22	7.68	6.68	5.9	5.58	5.3

of normal hearing neonates, with a very small experimental uncertainty, in regard to random errors. Unfortunately, the latency estimate is subject to systematic errors, which have been discussed in the previous sections. These systematic errors tend to affect the latency distributions, producing a significant number of unreasonably long latency values at high frequencies.

As described in the previous sections, two alternative definitions of average latency were used, which, in previous studies (Sisto and Moleti, 2002; Lucertini *et al.*, 2002) on the OAE latency of normal-hearing and impaired adults, had given almost coincident results. The large difference observed in the present work between the results obtained for the "fail" population with the two alternative definitions of average latency is a clear indication of the mentioned systematic error, which seems to be characteristic of the neonate OAEs. Indeed, the observed large latency difference between "pass" and "fail" ears using no data selection criterion turned out to be mostly due to a small set of these unreasonably long high-frequency latency values in the "fail" population. This systematic error source was eliminated by restricting the analysis to the bands in which the "fail" ears showed a relatively high reproducibility. This conservative choice made the difference between the average band reproducibility of the two populations very small, thus it is not surprising that the residual difference between the average latency of the two populations has become correspondingly small. In

FIG. 8. An OAE-based estimate of the average cochlear tuning curves $Q(f)$ of the two populations, based on the two definitions of average latency $\langle\tau^*(f)\rangle$ (computed on the selected subsample) and $\langle\tau(f)\rangle$.

Sisto and Moleti (2002), a much larger latency difference was observed, but in that study the two adult populations were discriminated by actual audiometric tests, with an average hearing threshold difference between 10 and 40 dB between the two populations. In this work, the discrimination is based on a screening parameter (reproducibility), which is only statistically correlated to cochlear functionality, so the neonates of our "fail" population, are actually "normal hearing" subjects with a slightly lower cochlear response. Moreover, the "fail sel" data have a relatively good reproducibility (see Fig. 5). Yet a significant difference has still been observed, between two neonate populations that were not very different from each other.

We remark that we are discussing the relation between two observable quantities: the TEOAE reproducibility, correlated to response level, which is what discriminates between our two populations, and the latency. They are dependent, respectively, on the gain and on the quality factor of the nonlinear cochlear amplifier, which are not trivially related to each other. Our finding that the latency slightly increases in "fail" ears is due to the correlation between these two cochlear amplifier parameters. According to transmission line cochlear models (e.g., Moleti and Sisto, 2003, and references therein), this effect is associated with a difference in cochlear tuning between the two samples. Any further interpretation depends on the particular nonlinear model assumed for describing the cochlear response. Most nonlinear oscillator models (e.g., Tubis and Talmadge, 1998; Sisto and Moleti, 1999) involve a nonlinear damping term, which implies that Q (at sound levels well above the hearing threshold) is higher when the excitation level is lower. At a given stimulus level, this means higher Q for lower gain, in agreement with the present results. In the case of substantial hearing loss, as in Sisto and Moleti (2002) and in Lucertini *et al.* (2002), other less trivial mechanisms could be involved: the reduction of saturation of the response associated with the nonlinear damping term could also be due to a reaction of the auditory system to the threshold increase, which modifies the parameters of the feedback mechanisms to try to compensate for hearing loss. These rather speculative hypotheses should be tested by further more complex experiments on hearing impaired subjects, also involving other OAE techniques, and variable stimulus levels.

From a clinical diagnostic point of view, this study shows that the application of latency measurements to the
early detection of cochlear damage in neonates is a difficult task, partly because the interpretation is not straightforward, partly because the measured difference is rather small, and becomes significant only after averaging over a large population, and partly because neonatal OAEs seem to be intrinsically more sensitive to the systematic errors described in this work, leading to unreasonably long latency estimates at high frequency. This may also be a consequence of the larger high-frequency content and SOAE prevalence in the neonatal OAE waveforms and of the generally higher quality factor of neonatal cochlear response, which makes it more probable the occurrence of high-frequency multiply reflected OAE signals.

The observed dependence of latency on frequency is in agreement with a power law with a negative exponent, significantly smaller than unity (−0.61 and −0.59 for "pass" and "fail sel" ears, respectively). This slope, which is a clear indication of cochlear scale-invariance symmetry breaking (Sisto and Moleti, 2002; Moleti and Sisto, 2003), is in agreement with experimental latency estimates coming from previous TEOAE, DPOAE, SFOAE, and ABR studies.

From a normative point of view, it should be stressed that the estimate of the "pass" average latency was obtained on a large and homogeneous sample of full-term neonates. Thus it could be used as a reference, e.g., for comparing the spectral latency of premature neonates, using the same data analysis technique.

From a technical point of view, we have evidenced that, particularly in the case of neonates, much care must be given to the detection of possible systematic errors associated with the individual latency estimate. These errors partly arise from the necessity of using an acquisition window to cut off the linear ringing artifact. The use of the nonlinear acquisition paradigm strongly limits the linear ringing artifact, yet its residual fraction requires the use of data windowing. This limits the applicability of the method to 4 kHz, because the higher-frequency (and shorter latency) cochlear response is significantly affected by the window onset. In the case of long-lasting emissions, which are quite common in neonates, the reduction of the early high-frequency response due to the window can make the second peak of the wavelet coefficient, associated with double reflection along the cochlea, higher than the first one. This leads to mistakenly attributing the peak time (our definition of latency) to the second peak, whose delay is roughly double the correct one. The presence of strong spontaneous emissions, which is quite common in neonates, should also be considered, in a dedicated study, as a possible source of systematic error.

In this work we have controlled the rate of systematic errors in the determination of individual latencies by selecting relatively high reproducibility data, but it would be interesting to check if the application of different acquisition or stimulation paradigms could limit the effect of the linear ringing perturbation. This would permit anticipation of the window start time, extending the latency measurements to a higher-frequency range. This possibility would be very important, because the neonate OAE spectrum has a large high-frequency component, and, more generally, because sensorineural hearing loss is typically first observed at frequencies of 4 kHz and above. An improvement in the acquisition techniques would allow more reliable comparisons between populations with greater different average values of reproducibility, in order to confirm or disclaim the present results.

The estimates of the cochlear tuning curve shown in Fig. 8 imply an increase of tuning with frequency in the 1–4 kHz range. This result is similar to that obtained by Moleti and Sisto (2003), using a much smaller independent TEOAE dataset, and confirms the increase of the quality factor $Q(f)$ with frequency that had been observed in other studies, based on DPOAE suppression tuning curve data (Kummer *et al.*, 1995; Gorga *et al.*, 2003) and on Stimulus Frequency OAE measurements (Shera *et al.*, 2002; Shera and Guinan, 2003).

V. CONCLUSIONS

TEOAE latency data of a large statistical sample of "pass" (333) and "fail" (133) neonate ears are presented in this study. Latency was measured with an optimized time-frequency wavelet analysis of TEOAE nonlinear data, with a frequency resolution of 500 Hz, between 1 and 4 kHz. Despite the fact that the two populations did not differ very much in their average reproducibility, a small yet significant difference between the average latencies of the two populations has been found, which could be associated with better tuning at high stimulus levels in ears with poorer cochlear response. The results of this study resemble the TEOAE latency increase observed in hearing impaired adults (Sisto and Moleti, 2002), and also in audiometrically "normal" ears of subjects exposed to noise (Lucertini *et al.*, 2002), but the interpretation of all these findings is not model independent, and needs more complex experiments to be clarified. In particular, experiments using different stimulus levels would be very useful to test the predictions of any given nonlinear cochlear model. An improved data acquisition and/or analysis technique would also be needed to get reliable latency information in the high-frequency range (>4 kHz). The latency values of the "pass" population are in agreement with previous estimates of the neonatal OAE latency (Moleti and Sisto, 2003), and may be effectively used for statistical comparisons in future studies involving different populations (infants, adults, impaired neonates, etc.). In this study we also provide new estimates of the cochlear tuning curve in neonates.

Measurements of motion of an *in vitro* preparation of the alligator lizard basilar papilla in response to sound demonstrate elliptical trajectories. These trajectories are consistent with the presence of both a translational and rotational mode of motion. The translational mode is independent of frequency, and the rotational mode has a displacement peak near 5 kHz. These measurements can be explained by a simple mechanical system in which the basilar papilla is supported asymmetrically on the basilar membrane. In a quantitative model, the translational admittance is compliant while the rotational admittance is second order. Best-fit model parameters are consistent with estimates based on anatomy and predict that fluid flow across hair bundles is a primary source of viscous damping. The model predicts that the rotational mode contributes to the high-frequency slopes of auditory nerve fiber tuning curves, providing a physical explanation for a low-pass filter required in models of this cochlea. The combination of modes makes the sensitivity of hair bundles more uniform with radial position than that which would result from pure rotation. A mechanical analogy with the organ of Corti suggests that these two modes of motion may also be present in the mammalian cochlea. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1993147]

I. INTRODUCTION

The transformation from transverse motion of the basilar membrane (BM) to shearing displacement of the reticular lamina is one of the largest unresolved issues in cochlear mechanics. Most cochlear models assume that the cochlea has multiple modes of motion, where each mode represents a natural vibration of the system. Recent experiments show evidence of multiple modes of motion at the BM (Nilsen and Russell 1999, but see Cooper 2000), reticular lamina (Ulfendahl *et al.* 1995), tectorial membrane (Hemmert *et al.* 2000), outer hair cells (Karavitaki and Mountain 1997), inner hair cells (Mountain and Cody 1999), and organ of Corti (Richter and Dallos 2003; Scherer and Gummer 2004), as well as in neural responses (Lin and Guinan 2000, 2004), and otoacoustic emissions (Lukashkin and Russell 2003) of mammalian cochleae. The complexity of the mammalian cochlea and the major contribution of active nonlinear processes to cochlear mechanics allow for a potentially rich set of modes, making modal analysis difficult. However, we can gain some insight into cochlear modes by analyzing the motion of a simpler cochlea.

In contrast to the mammalian cochlea, the alligator lizard basilar papilla is relatively simple (Mulroy 1974). In response to sound, the BM moves in phase along its entire length, with tuning similar to that of the stapes (Peake and Ling 1980; Manley *et al.* 1988). A mechanical model of the alligator lizard cochlea assumes that the basilar membrane drives rotation of the basilar papilla (Weiss and Leong 1985). Two experimental studies qualitatively confirmed this assumption (Frishkopf and DeRosier 1983; Holton and Hudspeth 1983). However, both of those studies noted an increase in the motion of the basal end of the papilla above 3 kHz, suggesting that the motion of the papilla is more complex than pure rotation.

The present studies were undertaken to characterize the number and nature of modes of motion of the alligator lizard basilar papilla. These modes were characterized by measuring the motion of this structure in response to sound stimulation. The measurements demonstrate that the basilar papilla undergoes both a translational and a rotational mode of motion simultaneously, and that both modes can contribute to cochlear sensitivity. An analogy with the organ of Corti suggests that similar modes may be present in the mammalian cochlea as well.

II. METHODS

The methods used to collect and analyze data have been described in a previous publication (Aranyosi and Freeman

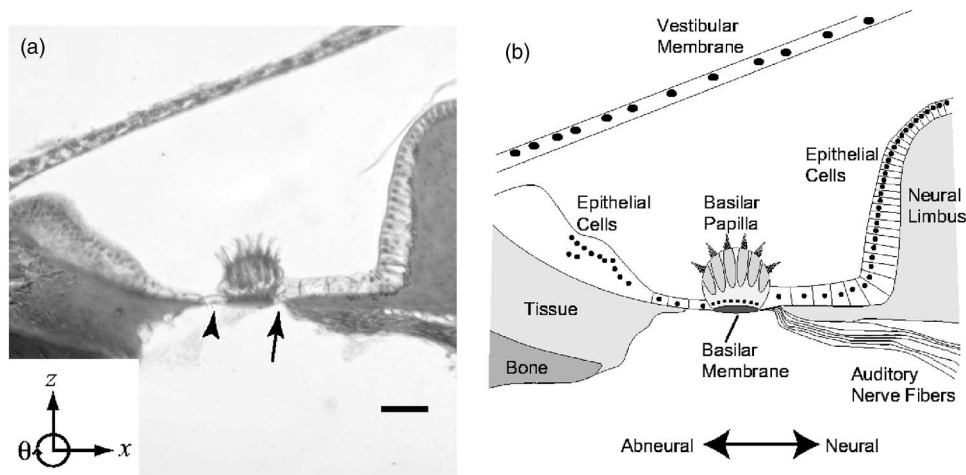
[a]Electronic mail: freeman@mit.edu


FIG. 1. Histological cross-section (**a**) and labeled drawing (**b**) of the alligator lizard basilar papilla. The basilar papilla is circular in cross section and rests on a stiff basilar membrane, which appears dark in the figure and is coupled to surrounding tissue by epithelial cells. The attachment is marked with an arrow on the neural side, and with an arrowhead on the abneural side. The methylene blue stain highlights the difference between the basilar membrane and the epithelial cells. The entire basilar papilla is about 400 μm long in the direction orthogonal to this image, so that the flat area surrounding the basilar papilla is oval-shaped when viewed in the z direction. The footplate of the columella is located above the vestibular membrane, is parallel to the BM, and moves in the z direction. The axis in the lower left defines the directions of x, z, and Θ which are used throughout this paper. The x axis is positive in the neural direction, and the z axis is positive in the direction pointing from scala tympani to scala media. Scale bar=50 μm.

2004). We present a brief summary here. The alligator lizard cochlea was carefully excised and placed in an experiment chamber. This chamber clamped the cochlea over a hole separating an endolymphlike apical fluid from a perilymph-like basolateral fluid. The experiment chamber was designed to allow high-resolution imaging of the clamped cochlea. A piezoelectric disk coupled to the basal fluid generated pressure differences across the BM to drive cochlear motion. Sound stimuli were delivered at 120 dB sound pressure level (SPL) in fluid, corresponding to 85–100 dB SPL at the tympanic membrane, depending on frequency (Rosowski *et al.* 1985). All animal procedures were approved by the Massachusetts Institute of Technology Committee on Animal Care.

To image cochlear motions, a green light-emitting diode was strobed with a 1/8 duty cycle at the frequency of the sound stimulus. The resulting image, which shows the position of the cochlea at a chosen phase of the sound stimulus, was captured with a charge coupled device camera. Eight such images were taken at eight evenly spaced stimulus phases. This process was repeated at 60–100 focal planes separated by 1 μm. The resulting data set at each stimulus frequency was a sequence of three-dimensional images taken at different stimulus phases, where each voxel in the images has dimensions of $0.19 \times 0.19 \times 1.0$ μm^3. Computer vision algorithms (Horn and Weldon 1988; Davis and Freeman 1998; Timoner and Freeman 2001) were used to measure the three-dimensional motion of structures from the images. Noise in the measurements was due to ambient vibrations, drift of the tissue, and noise inherent in the imaging system. This noise was aliased by the measurement process to the stimulus frequency and its harmonics. Most measurements showed primarily sinusoidal motion. In addition, when the light source was strobed to alias motion to 2–3 Hz, the motions seen by eye in the microscope were primarily sinusoidal. Consequently, to eliminate noisy measurements, we included measurements only when higher harmonics of mo-

tion were at least 10 dB smaller than the fundamental component. Papilla motion was examined qualitatively in twelve preparations, and quantitatively in five of these.

III. MEASUREMENTS OF BASILAR PAPILLA MOTION

A. Anatomy of the basilar papilla

Although in many ways similar to the mammalian cochlea, the basilar papilla of the alligator lizard has a relatively simple structure. Figure 1 shows a cross-sectional view of the basilar papilla, with several structures labeled. The basilar papilla itself is roughly cylindrical, and contains hair cells and supporting cells. The hair bundles of hair cells project into scala media, with their sensitive axis parallel to the curved apical surface of the basilar papilla (Shotwell *et al.* 1981). The BM contains a rigid plate at the base of the basilar papilla, but this plate does not extend across the entire BM. Instead, epithelial cells attach the basilar papilla to surrounding tissue on both sides. The footplate of the columella, analogous to the mammalian stapes, sits above the plane of the image in Fig. 1 and lies parallel to the basilar membrane (Mulroy 1974). Thus unlike in the mammalian cochlea, motions of the footplate and basilar membrane are oriented in the same direction. Figure 1 illustrates the convention for directions used in this paper.

B. Displacement versus lateral position

Figure 2 shows trajectories of displacement for four locations on the body of the basilar papilla in one preparation. The image in the background shows a radial (xz) cross section of the papilla, with the neural side on the right. The circles show displacement at each location at each of eight phases of the 5 kHz sound stimulus; the filled circles indicate the displacement at the peak of the electrical stimulus driving the piezoelectric disk. At each location, the papilla moves in
FIG. 2. (Color online) Two-dimensional trajectories of displacement of the basilar papilla. The background of this plot shows a cross-sectional view of the basal end of the basilar papilla, with the neural side to the right. The BM is just below the bottom of this image. Circles show the displacement of four points on the papilla as a function of stimulus phase in response to a 5 kHz tone. The displacements are plotted at the location at which they were measured, but the motions are magnified by a factor of 5 to improve visibility. The filled circle indicates the measured position at the peak of the electrical drive to the piezoelectric bimorph. Lines represent the least-squares fit of two-mode motion to the data as described in Sec. IV. The fit had 0.79 μm z translation, 0.85 μm x translation, and 1.1° rotation about the center of the papilla. Rotation and x translation were in phase with each other, and lagged z translation by 58°. The rms error of the fit was 0.130 μm.

an elliptical pattern. Displacements in each direction are nearly sinusoidal; higher harmonics are more than 40 dB below the fundamental component. The solid lines in the figure denote the best fit of a rigid-body model of papilla displacement to the measurements. This fit is discussed further in Sec. IV.

Figure 3 shows displacement trajectories of the basal end of the papilla from a total of 142 nonoverlapping $5 \times 5 \times 5 \ \mu m^3$ regions in five preparations at frequencies between 3 and 4 kHz. In each preparation, motion at each point is elliptical, although the shapes of these ellipses vary across preparations. For a given preparation, the shapes of the elliptical motions vary with position in a systematic manner. The major axes of the ellipses are largely in the z direction near the abneural edge of the papilla, with an x component that becomes larger toward the neural edge. In addition, the ellipses are more circular near the neural edge than near the abneural edge. When viewed with the neural side of the papilla on the right, the elliptical motion is typically in a clockwise direction; that is, x displacement lags z displacement. Motion in the y direction, which corresponds to the longitudinal axis of the cochlea, was typically near the noise floor of the measurement system.

C. Phase of x relative to z displacement

The measurements of Fig. 3 can be described as the sum of sinusoidal displacement in the x and z directions. Similar measurements were made for about 1000 nonoverlapping regions with volumes of $(5 \ \mu m)^3$ throughout each basilar papilla at each frequency studied. A total of 72 such data sets were analyzed across the five papillae studied, yielding 75 594 total measurements. Figure 4 shows the phase lag of x relative to z displacement for each of the 72 data sets used in this study, as well as a combined average of all measurements. For 75.4% of the measurements, x displacement lags z displacement. For only 4.6% of the measurements, x displacement leads z displacement by more than 22.5°. There is a trend for the phase lag of x displacement to increase with frequency.
FIG. 3. (Color online) Elliptical motion of the basilar papilla in five preparations. These plots show the measured displacement of multiple locations at the basal end of the basilar papilla. In each plot, the neural edge of the papilla is to the right. The motion at each location is primarily elliptical. The tallest ellipses are typically near the abneural edge, and the widest are typically near the top center of the papilla. Symbols are as in Fig. 2. Dark gray (red) dots are the position at the peak of the electrical drive to the piezoelectric bimorph; light gray (cyan) dots are the position at the next measured phase. Motions are magnified by a factor of 10 relative to positions, except in **d**, for which the magnification is a factor of 5. Stimulus frequencies are 3000 Hz (**a**), 3464 Hz (**b**), 3746 Hz (**c**), 3834 Hz (**d**), and 3981 Hz (**e**). Solid lines show the best fit of a rigid-body model, described in Sec. IV, to the entire set of measurements for each papilla. The light gray (cyan) portion of the line connects the first two phases. Measurements at some locations were omitted for clarity.
FIG. 4. Phase of *x* relative to *z* displacement as a function of frequency. For each papilla at each frequency measured, displacements in the *x* and *z* directions were measured for many (roughly 1000) nonoverlapping regions, and the phase of *x* relative to *z* displacement was determined. The median, interquartile range, and full range of these phase values are plotted for 72 such data sets obtained at frequencies from 500 Hz to 10 kHz from five papillae. The horizontal bar for each histogram indicates the median value, the vertical bar indicates the interquartile range, and the dots represent the full range of measurements. Phases above 90° or below −270° are wrapped into that range. The median values and interquartile ranges are almost all at or below 0°, indicating that *x* displacement typically lags *z* displacement. The bar to the right of the plot pools measurements across all papillae and frequencies. A total of 75 594 phase measurements are included in this bar, of which 56 976 have a relative phase less than zero.

IV. MODAL DECOMPOSITION OF BASILAR PAPILLA MOTION

In Fig. 3, the motion at any location can be approximated by sinusoidal motion in the *x* and *z* directions. However, these motions vary systematically with position, suggesting that the motion of the entire papilla can be described as the sum of a translational and a rotational mode. To perform this modal decomposition, the measured displacements at all locations in a single longitudinal cross section were fit in a least-squares sense by rigid-body motion of the basilar papilla. This rigid-body fit had three degrees of freedom: translation in the *x* and *z* directions and rotation in the Θ direction, where the center of rotation was chosen arbitrarily to be the center of the basilar papilla. These fits were computed separately for each frequency at which measurements were made. These three degrees of freedom were reduced to two by shifting the center of rotation for all frequencies based on two criteria. First, since translation in the *x* direction was typically in phase with rotation, it was assumed that these two components of motion represented a single mode. Accordingly, the center of rotation was shifted in the *z* direction to minimize the sum-squared magnitude of the *x* translational component across frequency. Second, since measurements of basilar membrane motion *in vivo* show little frequency dependence (Peake and Ling 1980), the center of rotation was shifted in the *x* direction to minimize the variance in magnitude of the *z* component across frequency.

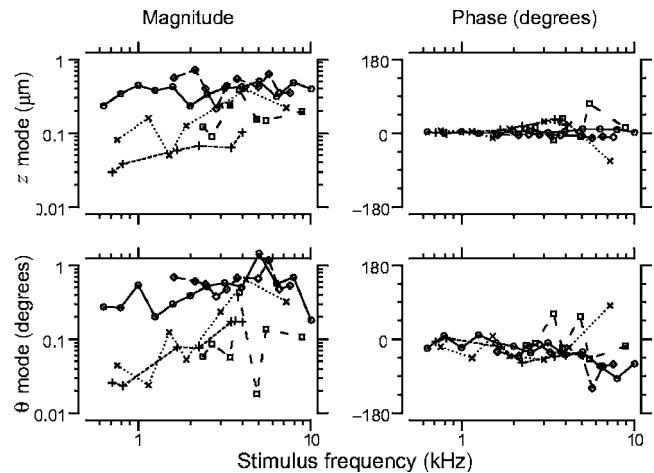
Figure 5 shows the result of this modal decomposition process for the five preparations of Fig. 3. Although there is considerable variability across preparations, this variability consists largely of vertical offsets in the magnitude; that is, some preparations moved more than others. Aside from these changes in magnitude, no systematic differences between


FIG. 5. Modal decomposition of basilar papilla motion. These plots show the magnitude (left) and phase (right) of the *z* (top) and Θ (bottom) modes of motion of five preparations as a function of frequency. The *z* mode magnitude is largely independent of frequency, and the phase is near 0°. The Θ mode magnitude peaks between 4 and 5 kHz, and the phase increasingly lags with frequency. All phases for each papilla are plotted relative to the phase of the *z* mode at the lowest frequency measured.

preparations were seen. The origin of these magnitude differences is unknown. For this reason, with the exception of Secs. V B and VI C, the remainder of this paper is focused on the relative contribution of each mode as a function of frequency rather than the absolute motions.

The magnitude of the *z* translational mode is largely independent of frequency for most papillae. The phase of the *z* translational mode is near 0° at all frequencies for all preparations, relative to the phase of *z* translation at the lowest frequency measured. The magnitude of the Θ mode consistently has a local maximum near 4–5 kHz. In addition, Θ is in phase with *z* at low frequencies and increasingly lags with increasing frequency. The center of rotation is typically on the medial side of the basilar papilla, above the level of the BM. The differing frequency dependence of the *z* and Θ components of motion indicates that these motions constitute two separate modes rather than a single complex mode.

V. A MECHANICAL MODEL OF THE BASILAR PAPILLA

A. Deriving the model from anatomy and measurements

The anatomy of the alligator lizard basilar papilla suggests a simple mechanical model which is consistent with the results shown in Secs. III and IV. The attachment of the BM and basilar papilla to the surrounding tissue is asymmetric; the neural side is about half as wide and twice as thick as the abneural side (see Fig. 1). Consequently, pressure across the BM can induce both translation and rotation of the basilar papilla. Figure 6 shows a simplified mechanical representation of the basilar papilla which demonstrates how two modes of motion can arise. The stiffness of the attachment on the neural side of the basilar papilla is larger than that on the abneural side. The applied pressure is equal on both sides, causing the abneural side to move more than the neural side. Consequently, the basilar papilla undergoes both translation
FIG. 6. Mechanical representation of basilar papilla attachment. The basilar papilla and basilar membrane are attached to surrounding tissue in an asymmetric fashion (Fig. 1). The tissue on the neural side is thicker and shorter than on the abneural side. In this figure, each side is represented by a spring that can pivot at both attachments. The spring on the neural side is stiffer and shorter than on the abneural side, as represented by the thicker line. Force exerted on the basilar membrane will cause the two springs to be stretched by different amounts, allowing the basilar papilla to both translate and rotate. Although the cochlear fluids are expected to contribute viscous and inertial impedance, such contributions are not shown in this drawing.

and rotation. According to this model, both translation and rotation are second-order resonant systems, but the frequency dependence of the two modes may differ.

The frequency dependence of the two modes of motion can be represented by an electrical circuit as shown in Fig. 7. In this representation, the translational and rotational modes have been explicitly separated. Both the current measurements and those of previous studies (Peake and Ling 1980; Rosowski et al. 1985) suggest that the translational impedance of the BM is compliant, so the contributions of mass and damping to impedance in the translational domain have been ignored. The compliance C_m of the BM in the translational domain is the proportionality constant relating the applied force $F = PA$ at the basilar membrane to the resulting velocity V_{BM}; that is, C_m represents the net compliance of the BM. The applied pressure also acts in the rotational domain to exert a torque $\tau = PAL$ on the basilar papilla, where the transformer ratio L is an effective lever arm that determines the scaling from force to torque. Because the rotational mode is mechanically resonant, this portion of the circuit includes a moment of inertia J_r, a rotational compliance C_r, and a rotational damping R_r.

B. Estimating model parameter values from measurements

The model in Fig. 7 has six parameters: C_m, C_r, J_r, R_r, A, and L. By estimating the two transformer ratios A and L,
FIG. 7. Circuit model of the basilar papilla. The circuit model contains three domains. In the acoustic domain, sound pressure P generates a volume velocity U. U acts on the BM area A to generate a velocity V_{BM} across the BM compliance C_m in the translational domain. Because of the asymmetry of the BM attachments, represented by an effective lever arm L, the pressure P also acts in the rotational domain to generate a rotational velocity $\dot{\theta}$. This rotational velocity acts on a moment of inertia J_r, a rotational compliance C_r, and a rotational damping R_r.

the other parameter values can be determined from measurements. Because of the variability in motion magnitude across preparations, a range of parameter values is estimated here. The area A of the BM has been measured to be 0.03 mm^2 (Rosowski et al. 1985). The effective lever arm L can be estimated by representing the applied pressure P with an equivalent force at the center of the basilar membrane, and measuring the distance from this center to the center of rotation of the basilar papilla. Based on the center of rotation determined by the modal fits, $L \approx 30~\mu$m.

Given the input pressure $P = 120$ dB SPL, the compliance $C_m = |z|/P \cdot A$ can be estimated from the average magnitude of the z component of motion, which is between 0.1 and 0.4 μm for most preparations. The resulting compliance is $0.12 \leq C_m \leq 0.48$ m/N. Similarly, $C_r = |\Theta_{LF}|/P \cdot A \cdot L$. The low-frequency asymptote of rotation $|\Theta_{LF}|$ is between 0.05° and 0.5°, so $3.5 \times 10^7 \leq C_r \leq 3.5 \times 10^8$ rad/N m. Assuming a second-order resonance, $J_r = 1/C_r(2\pi f_p)^2$, which for a resonant frequency of 5 kHz yields $4 \times 10^{-18} \leq J_r \leq 4 \times 10^{-17}$ kg m^2. At f_p, the net impedance of C_r and J_r is zero, so $R_r = P \cdot A \cdot L/2\pi f_p |\Theta_p|$. With $0.1° < \Theta_p < 1°$, the resulting estimates of R_r range from 5×10^{-14} to 5×10^{-13} N m s/rad. The damping R_r can also be estimated from the quality of tuning $Q \approx 1/C_r R_r \omega$. The shallow peak in magnitude of Θ and slow rolloff of phase with frequency seen in Fig. 5 suggest that $Q < 2$. Using $C_r = 10^8$ rad/N m, $R_r > 10^{-13}$ N m s/rad.

VI. DISCUSSION

A. Gross motions are comparable to those measured *in vivo*

Peake and Ling (1980) measured the velocity of the BM in the transverse (z) direction using the Mössbauer technique and found it to be a linear function of sound pressure. In response to a 75 dB SPL tone at 1.4 kHz, they measured a velocity of −25 dB re 1 cm/s, which corresponds to a peak displacement of 90 nm. With an estimated middle-ear pressure gain of 35 dB at this frequency (Rosowski et al. 1985), we expect our stimuli to correspond to 85 dB SPL at the eardrum, which would result in a peak BM z displacement of 280 nm based on the Peake and Ling (1980) data. Figure 3 shows peak z displacements of 250–600 nm near the abneural edge of the basilar papilla. These measurements were made near 5 kHz, where the rotational mode contributes significantly to z displacement, so the displacements are expected to be smaller near 1.4 kHz. Thus the z motions measured in this study are roughly comparable to those measured *in vivo* using a different technique. However, there are many caveats to comparing these studies directly: Our comparison uses a rough estimate of the middle ear pressure gain; in some preparations, displacements in the transverse direction were considerably smaller than in others (Fig. 3); the efficiency of coupling sound pressure to the papilla in our experiment chamber may differ from that *in vivo*; Peake and Ling (1980) measured motion on the perilymphatic surface of the BM, but we measured motion on the endolymphatic surface of the basilar papilla; The Mössbauer source used by Peake and Ling (1980) was $\sim 40 \times 40~\mu$m, much larger than
FIG. 8. Relative sensitivity of hair bundles to sound as a function of position. The plot shows the shearing displacement of the basilar papilla (r axis) as a function of position along the surface of the basilar papilla (θ axis), normalized by the maximum value of each curve. The dashed line shows the predicted shearing displacement if the basilar papilla underwent pure rotation about a point near the neural edge of the BM. The solid line shows the normalized shearing displacement predicted from the two-mode motion used to fit the measurements of Fig. 1. Except near the neural edge, where there are no hair bundles, the shearing displacement due to the sum of translation and rotation is more uniform with position than that due to rotation alone.

our measurement regions—the motion of the $(5 \ \mu\text{m})^3$ regions measured here may differ from the average motion of a larger region. Nonetheless, the reasonable agreement between the magnitude of motion measured *in vivo* and *in vitro* supports the idea that the mechanical properties measured here are relevant to normal hearing.

B. The relative sensitivity of different hair bundles is made more uniform by two-mode motion

Hair bundle deflection in this cochlea is believed to be driven by shearing motion at the reticular lamina (Freeman and Weiss 1990) in the direction of maximum sensitivity of hair bundles (Shotwell *et al.* 1981). Because of the circular shape of the papilla in cross section, the direction of shearing displacement at the surface of the papilla changes with lateral position on the papilla (Mulroy 1974). Thus, the drive for hair bundle deflection depends not only on the magnitudes and phases of the two modes of papilla motion, but on the lateral position of each hair bundle.

Rotation of the basilar papilla generates a shearing displacement that is a strong function of lateral position. Since the center of rotation is on the neural side of the basilar papilla, in response to a given rotation the motion of the abneural side is larger. In addition, this motion is parallel to the surface of the reticular lamina on the abneural side, but perpendicular to the surface near the neural side. As a result, the sensitivity of hair cells to the rotational mode of motion of the basilar papilla varies dramatically with radial position (Fig. 8). When both modes of motion are included, the sensitivity of hair cells is less dependent on position. The translational mode generates shearing forces for hair bundles not excited by the rotational mode and vice versa. Consequently, at nearly all locations which have hair bundles, the relative shearing displacement is more uniform with position for two-mode motion than for pure rotation. Thus, the combination of two modes causes the hair bundles to have a more uniform sensitivity to sound across the width of the basilar papilla.

C. Model parameters are physiologically reasonable

Rosowski *et al.* (1985) describe measurements of the acoustic impedance at the tympanic membrane before and after destroying the cochlear partition. Those measurements assign the BM an acoustic compliance of $5.7 \times 10^{-16} \ \text{m}^3/\text{Pa}$. When reflected into the mechanical domain using their measured $A=0.03 \ \text{mm}^2$, the mechanical compliance is $0.63 \ \text{m/N}$; using their "effective BM area" of $0.07 \ \text{mm}^2$ gives a mechanical compliance of $0.12 \ \text{m/N}$. When the rotational compliance C_r is reflected into the mechanical domain and added to the translational compliance C_m, the net compliance ranges from 0.15 to 0.80 m/N. Thus, the range of compliances estimated in the current study is roughly consistent with those seen in measurements at the tympanic membrane.

Since the basilar papilla is roughly cylindrical, the moment of inertia J_r can be compared to that of a rotating cylinder, where the center of rotation is a distance L from the center of mass; namely, $J_r = \rho l[(\pi r^4/2) + \pi r^2 L^2]$, where ρ is the mass density of the cylinder, l is the length, and r is the radius. Assuming that the basilar papilla length is about $400 \ \mu\text{m}$, the density is that of water ($\rho=1000 \ \text{kg/m}^3$), and the center of rotation is near the neural edge ($L=30 \ \mu\text{m}$), our estimate of J_r yields an effective basilar papilla radius of $35 \leq r \leq 60 \ \mu\text{m}$. This effective radius is somewhat larger than the anatomical radius of the basilar papilla, which is roughly $30-35 \ \mu\text{m}$. This difference is most likely due largely to the entrained motion of fluid. Since the center of rotation is not the center of the papilla, rotation of the papilla induces bulk displacement of fluid. The hair bundles that project from the basilar papilla also entrain fluid. Moreover, at 5 kHz (the frequency at which J_r was estimated), fluid viscosity creates a boundary layer about $8 \ \mu\text{m}$ thick that moves with the papilla (Freeman and Weiss 1988). This entrained fluid increases both the effective radius r and the effective distance L from the center of rotation to the center of mass; both effects would cause an increase in our estimate of r.

The damping of the rotational mode, however, is larger than the damping expected for a cylinder moving through fluid. The fluid force on a cylinder oscillating in fluid is a function of the cylinder diameter and length and the oscillation frequency (Freeman and Weiss 1985). For a cylinder of $30 \ \mu\text{m}$ diameter with a length of $400 \ \mu\text{m}$ oscillating at 5 kHz, the fluid impedance is roughly $\mu \times 4 \times 10^{-2} \ \text{N s/m}$, where μ is the dynamic viscosity of the fluid, assumed to be that of water. However, more than half of this impedance is inertial and contributes to the effective mass of the cylinder, as described above. The viscous component of this impedance, about 40% of the total, is $1.8 \times 10^{-5} \ \text{N s/m}$. The minimum estimate of the rotational damping of the basilar papilla was $5 \times 10^{-14} \ \text{N m s/rad}$; reflecting this value into the translational domain gives $5.5 \times 10^{-5} \ \text{N s/m}$. Thus the total damping of basilar papilla rotation is at least three times larger than that predicted from the motion of a cylinder. This difference suggests that fluid drag due to motion of the basilar papilla is not the primary contributor to viscous damping in this cochlea.

A. Aranyosi and D. M. Freeman: Two modes of lizard cochlear motion

One additional source of viscous damping is in the motion of hair bundles relative to cochlear fluids. Based on a hydrodynamic model of such motion (Freeman and Weiss 1990), which predicts the sharpness of mechanical tuning of hair bundles in this cochlea (Aranyosi and Freeman 2003), the viscous impedance to hair bundle rotation is $4.56 \times 10^{-3} \, h^2/w$ N s/m, where h is the height of the hair bundle and w is its width. The free-standing region of the basilar papilla contains about 150 hair bundles with heights ranging from about 12 to more than 30 μm and widths of about 8 μm (Mulroy 1974). The net viscous impedance of these hair bundles as predicted by the hydrodynamic model is on the order of $4-8 \times 10^{-5}$ N s/m. This value suggests that much of the damping seen in the rotational mode of motion in the current study results from the rotation of hair bundles through a viscous fluid. This finding is significant, since the motion of hair bundles relative to cochlear fluids determines the sensitivity and frequency selectivity of hearing in much of this cochlea (Aranyosi and Freeman 2004). If a principal source of energy loss in this cochlea is viscous damping at the level of hair bundles, then the force generated by hair bundle motility (Martin and Hudspeth 1999; Ricci *et al.* 2000) is ideally situated to counteract this viscous damping and sharpen tuning in this cochlea (Manley *et al.* 2001; Aranyosi and Freeman 2005). Additionally, although the reduction in viscous damping due to hair bundle motility is likely to cause only a small change in the impedance seen at the basilar membrane, such a change may be large enough to explain the presence of otoacoustic emissions in lizard species (Manley 1997; Manley *et al.* 2001).

D. Phase lag between translational and rotational modes—the "missing low-pass filter"

The resonant frequency of the rotational mode of basilar papilla motion is typically near 4–5 kHz and is largest at the basal end of the papilla. Hair cells in this region have best frequencies between 3 and 4 kHz. Thus, the papilla resonance at the basal end is just beyond the range of frequencies to which hair cells in this cochlea are most sensitive. At 5 kHz, hair cells with best frequencies of 3–4 kHz are 20–40 dB less sensitive than at the best frequency (Weiss *et al.* 1976). Thus, the mechanical resonance of the papilla is ideally positioned to increase the high-frequency slopes of neural tuning curves without altering frequency selectivity in the range of best frequencies.

Previous models of the alligator lizard cochlea required a first-order mechanical low-pass filter to explain the high-frequency slopes of tuning curves from neurons innervating the free-standing region (Weiss and Leong 1985; Freeman and Weiss 1990; Shatz 2000). However, these models did not specify the physical basis of this filter. The measurements and model reported here show that at high frequencies, the rotational mode of motion is attenuated relative to the translational mode. This attenuation provides a physical explanation for the required low-pass filter. However, since at least some hair bundles are sensitive to the translational mode of motion, variations of as much as 6 dB/octave should be present in the high-frequency slopes of tuning curves of au-

ditory nerve fibers. Such variations have been seen in auditory nerve fiber recordings (Weiss *et al.* 1976).

E. Implications for mammalian cochlear mechanics

Although more complex than that of the alligator lizard, the mammalian BM also has two regions of differing stiffnesses, separated by the base of the outer pillar cell—the arcuate zone under the tunnel of Corti and the pectinate zone which extends from the outer pillar cell to the spiral ligament. However, the nature of the difference between zones is not entirely clear. Stiffness measurements made in the basal region of the guinea pig cochlea showed that the arcuate zone was about five times stiffer than the pectinate zone (Miller 1985). Measurements in the gerbil cochlea showed the opposite trend (Olson and Mountain 1994; Naidu and Mountain 1998). In the gerbil hemicochlea, the arcuate zone is less stiff in the basal turn, but stiffer in the middle turn (Emadi *et al.* 2004). Measurements of basilar membrane motion in the guinea pig show that these two zones can move in antiphase (Nilsen and Russell 1999, 2000). Other measurements in guinea pigs and gerbils do not show antiphase motion, but do show an asymmetric vibration pattern (Cooper 1999, 2000; Rhode and Recio 2000; Ren 2002). Such a pattern is roughly consistent with the motion of a beam that is clamped at the outer spiral lamina and simply supported at the inner spiral lamina (Cooper 1999; Homer *et al.* 2004). The fit is improved if the beam is made less stiff in the arcuate zone. Thus although many details of the differences have not yet been clearly established, it is clear that both the stiffness and attachment of the basilar membrane differ in the two zones. These differences suggest that the organ of Corti is likely to undergo both translation and rotation. Such an interaction of multiple modes of motion appears to be necessary to explain responses of auditory nerve fibers (Lin and Guinan 2004). In addition, force generation by outer hair cells may preferentially excite one mode. For these reasons, characterizing these modes more precisely is critical to understanding cochlear function.

Contribution of harmonicity and location to auditory object formation in free field: Evidence from event-related brain potentials

The contribution of location and harmonicity cues in sound segregation was investigated using behavioral reports and source waveforms derived from the scalp-recorded evoked potentials. Participants were presented with sounds composed of multiple harmonics in a free-field environment. The third harmonic was either tuned or mistuned and could be presented from the same or different location from the remaining harmonics. Presenting the third harmonic at a different location than the remaining harmonics increased the likelihood of hearing the tuned or slightly (i.e., 2%) mistuned harmonic as a separate object. Partials mistuned by 16% of their original value "pop out" of the complex and were paralleled by an object-related negativity (ORN) that superimposed the N1 and P2 components. For the 2% mistuned stimuli, the ORN was present only when the mistuned harmonic was presented at a different location than the remaining harmonics. Presenting the tuned harmonic at a different location also yielded changes in neural activity between 150 and 250 ms after sound onset. The behavioral and electrophysiological results indicate that listeners can segregate sounds based on harmonicity or location alone. The results also indicate that a conjunction of harmonicity and location cues contribute to sound segregation primarily when harmonicity is ambiguous. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2000747]

I. INTRODUCTION

One of the primary functions of the auditory system is to assign incoming acoustic elements from different physical sound sources into perceptual auditory objects. This process, known as auditory scene analysis, requires parsing sounds that originate from different physical objects and grouping together sounds that emanate from the same physical sound source. Bregman (1990) proposed two classes of mechanisms that aid in determining which components belong to a particular sound source. "Primitive grouping mechanisms" use basic stimulus properties to segregate the incoming sounds. Listeners may be innately tuned to these properties and thus they do not depend on specific experiences. These grouping mechanisms most likely utilize general properties of sound sources, such as frequency, intensity, phase, harmonicity, and temporal coherence. "Schema-based mechanisms" use knowledge from past experience to group the acoustic input into meaningful mental representations. These schemata are thought to be learned and therefore are dependent on a listener's specific experiences.

The general problem of auditory scene analysis, and the more specific task of revealing those acoustic cues that are critical for the perception of distinct auditory objects, has received considerable attention over the last two decades (for reviews, see Alain and Arnott, 2000; Bregman, 1990; Car-lyon, 2004; Kubovy and Van Valkenburg, 2001). For example, complex sounds consisting of multiple tonal elements can be grouped and segregated on the basis of frequency periodicity (i.e., the harmonic series). Previous research has shown that the likelihood of hearing more than one concurrent auditory object increases as the amount of mistuning increases for lower tonal components of a harmonic series, resulting in the "pop out" of the lower mistuned partials from the complex (e.g., Chalikia and Bregman, 1989; Hartmann *et al.*, 1990; Lin and Hartmann, 1998; Moore *et al.*, 1986). Another factor that may contribute to concurrent sound segregation is the spatial distance between the two sound sources. For example, performance in identifying speech sounds improves with increasing spatial separation of concurrent streams of sounds (e.g., Arbogast *et al.*, 2002; Bronkhorst and Plomp, 1988, 1992; Drennan *et al.*, 2003). The perceived azimuth of a particular source is influenced by either interaural time differences (ITDs) or interaural level differences (ILDs). The former plays an important role for localizing lower frequency sounds whereas the latter appears to be more important in localizing high frequency sounds.

Few studies have examined the contribution of both harmonicity and location cues in parsing concurrent sounds and the findings that have been reported provide conflicting evidence about the relative importance of these two cues in segregating simultaneously present auditory events. For example, Gockel and Carlyon (1998) showed that the ability to detect mistuning was better when both the target harmonic

[a]Electronic mail: calain@rotman-baycrest.on.ca

and the remaining components were presented to the same ear than when they were presented to opposite ears (see also, Lee and Green, 1994). Interestingly, performance in detecting mistuning was comparable in a dichotic situation in which the perceived location of the remaining harmonics was contralateral to the target harmonic. However, using a short sound duration (i.e., 110 ms), Lee and Green (1994) reported similar thresholds in detecting mistuning for lower harmonics when the mistuned harmonic was presented ipsilateral or contralateral to the remaining harmonics. Buell and Hafter (1991) also found that the segregation of inharmonic components was little affected by ITD and that listeners were unable to segregate harmonic components even when the components were presented with different ITD. They concluded that tones that are harmonically related are combined into a single auditory object regardless of their spatial location and that harmonicity is a more compelling cue for object perception than common spatial location (for different results and conclusion see Stellmack and Dye, 1993). The listeners' task, however, was to identify the stimulus containing an ITD and participants were not asked to detect the number of sound sources that had been presented.

The current study aims to further investigate the relative contribution of harmonicity and location cues in parsing concurrent sounds using event-related brain potentials (ERPs). Recording ERPs is a powerful measure for examining the time course and level of processing at which concurrent sound segregation takes place. This technique allows for the examination of neural activity within hundreds of milliseconds following sounds. Because ERPs can be recorded to the same stimuli when they are either task-relevant or task-irrelevant, they provide a means to evaluate the effects of variables such as selective attention on concurrent sound segregation. Recent studies have identified a new ERP component referred to as the object-related negativity (ORN), whose amplitude correlates with listeners' likelihood of reporting two simultaneous auditory objects (Alain *et al.*, 2001a, 2002; Alain and Izenberg, 2003). The ORN is thought to index a mismatch process between the perceived frequency of the mistuned harmonic, and the frequency expected on the basis of a harmonic template extrapolated from the components of the incoming stimulus. The perception of the mistuned harmonic as a separate event is also associated with a late positive wave (P400). Like the ORN, its amplitude was correlated with perceptual judgment, being larger when participants perceived the mistuned harmonic as a separate tone. However, in contrast with the ORN, this component was present only when participants were required to respond whether they heard one or two auditory stimuli. Thus, whereas the ORN appears to be more associated with automatic processing, the P400 seems to be more related to controlled processes.

In the present study, ERPs were recorded during both active and passive listening conditions to investigate the degree to which harmonicity and location cues were processed automatically. Based on previous studies of concurrent sound segregation (Alain *et al.*, 2001a, 2002, 2003; Alain and Izenberg, 2003), it is expected that an ORN will be present in both the active and passive listening conditions and that the

P400 will be elicited only when participants are involved in the active detection of more than one simultaneous auditory event. Furthermore, it is expected that coincident harmonicity and location cues will increase the amplitude of both components as well as improve accuracy and reaction time in detecting concurrent sounds.

II. EXPERIMENT 1

A. Methods

1. Participants

Twelve right-handed adults (between 22 and 36 years of age, mean age$=28.58\pm4.14$ years; 6 males) participated in the experiment. All participants had pure-tone thresholds less than or equal to 30 dB HL at frequencies in the range 250–8000 Hz in both ears. Each participant gave informed consent in accordance with the University of Toronto and Baycrest Centre for Geriatric Care guidelines. Participants included volunteers from the University of Toronto and laboratory staff. All individuals were paid for their participation.

2. Stimuli and task

The stimuli consisted of complex sounds comprised of 10 pure tones of equal intensity. The fundamental frequency (f_0) was 200 Hz and stimulus duration was 400 ms, including a 10 ms rise-fall time. Stimuli were digitally generated at a sampling rate of 25 kHz using a System 3 Real-Time Processor from Tucker Davis Technology and presented over two EMI loudspeakers via a GSI 61 Clinical Audiometer. The loudspeakers were placed at a 45° angle from listeners' heads and the distance from each loudspeaker to the estimated center of participants' heads was 1.58 m while the distance between loudspeakers was 2.23 m. Stimuli were either "harmonic," where all of the harmonics were integer multiples of the f_0, or "mistuned," in which the third harmonic was shifted upwards or downwards by either 2% or 16% of its original value. It was expected that the harmonic with 16% mistuning would be easily segregated from the remaining complex while the 2% mistuning would represent a more ambiguous cue (Alain *et al.*, 2001b; Moore *et al.*, 1986). The third harmonic was played from either the same loudspeaker or a different loudspeaker than the other nine harmonics. The location of the target harmonic changed from trial to trial, eliminating the opportunity for participants to focus on the output of one loudspeaker to make their judgments. The output of each speaker was matched for intensity and the stimuli were presented at 65 dB SPL. Sound calibration measurements were made using a free-field microphone placed at the estimated center of a participant's head (Damilar SPL meter model 824).

Participants were tested individually in a double-walled sound attenuated chamber (IAC model 1204A). Each participant completed an active and passive listening session, which took place on two separate days (within a two week period). In the active listening session, a single complex tone was presented on each trial. Participants indicated whether they heard one sound (i.e., a buzz) or two sounds (i.e., a buzz plus another sound with a pure tone quality) following the presentation of each stimulus. Participants were instructed to

respond as quickly and accurately as possible by pressing one of two buttons on a response box using the index and middle fingers of their right hand. Participants did not receive any feedback on their performance. Within a block of trials, six different and equiprobable stimuli were played at random (three possible levels of mistuning −0%, ±2%, and ±16%; third harmonic presented from either the same or different loudspeaker as the remaining harmonics). A chin rest was used throughout the experiment to ensure that participants' heads remained in a constant position relative to the loudspeakers. The intertrial interval, i.e., the length of time between a participant's response and the next trial, was 1500 ms. Participants were presented with a small sample of trials prior to data collection to familiarize them with the task and response box. A total of 864 trials were presented to each participant (144 per stimulus type; 2 locations × 3 levels of mistuning).

In the passive listening session, the same stimuli were presented but participants were asked to ignore the stimuli and watch a subtitled movie of their choice. The interstimulus interval varied randomly between 800 and 1200 ms. A total of 1560 trials were presented to each participant (260 per stimulus type).[1]

The order of presentation of the active and passive listening sessions was counter-balanced across participants, with six participants completing the active listening condition first and the other six completing the passive session first.

3. Electrophysiological recording

Electrophysiological signals were digitized continuously (bandpass: 0.05–100 Hz; 500 Hz sampling rate) from an array of 64 electrodes, including those from the standard 10–20 placement, using NeuroScan Synamps and stored for offline analysis. During the recording, all electrodes were referenced to the Cz electrode; for data analysis they were re-referenced to an average reference. Electrodes placed at the outer canthi and at the superior and inferior orbit monitored vertical and horizontal eye movements.

The analysis epoch included 200 ms of prestimulus activity and 800 ms of poststimulus activity. Trials contaminated by excessive peak-to-peak deflection (±150 μV), excluding those channels adjacent to the eyes, were automatically rejected before averaging. ERPs were then averaged separately for each electrode site, stimulus type, and listening condition before being digitally low-pass filtered to attenuate frequencies above 15 Hz. For each individual average, ocular artifacts, such as blinks, saccades, and lateral movements, were corrected by ocular source components using Brain Electrical Source Analysis (BESA) software (Picton et al., 2000). ERPs to stimuli presented from the left loudspeaker (either all components of the stimulus or all harmonics except the third) were averaged separately from ERPs elicited by stimuli presented from the right loudspeaker. To improve the signal-to-noise ratio and to reduce the number of comparisons, the electrophysiological data were averaged over side of presentation of the harmonic series with electrode positions transposed for harmonic series presented from the right loudspeaker so that electrodes over the right

hemisphere were contralateral to the location of the harmonic series (e.g., electrode F4 was renamed electrode F3).[2] Then, trials in which the harmonic series were presented from the left and right loudspeakers were averaged together. For each participant, we used a weighted average procedure, which takes into account the number of trials in each individual average. Additionally, in order to facilitate the comparison between the active and passive listening conditions, the ERPs were averaged irrespective of the participant's responses in the active listening condition.

4. Data analysis

For the behavioral data, an analysis of variance (ANOVA) for repeated measures was performed on the proportion of trials where participants reported hearing two concurrent auditory objects with percentage mistuning (0%, 2%, and 16%) and location (same or different from the remaining harmonics) as factors. A similar analysis was performed on the response time data.

In most electrophysiological research, ERP analyses are performed on a subset of electrodes where the components of interest show the maximum amplitude. Although these analyses are acceptable, they do not take into account information available from the whole montage. This is particularly evident in situations where large arrays of electrodes are used to measure brain activity (e.g., 64 or 128 electrodes). Furthermore, it implies either an *a priori* decision regarding the electrodes that are entered in the analyses or an *a posteriori* decision based on visual inspection of the data. In the present study, we minimized such problems by comparing the source waveforms obtained for each participant and stimulus condition. Such a strategy has been used extensively to analyze data from neuromagnetic recordings of auditory stimuli and has the advantage of reducing a large number of channels to a smaller and more manageable number of sources (e.g., 2 dipole sources, one in the left and one in the right hemisphere).

The spatio-temporal source analyses were performed with the BESA 5.1 software package (MEGIS Software, GmbH, Munich). To enhance the signal-to-noise ratio, the fit procedure was based on the group mean ERPs collapsed across stimulus type. The analysis assumed a four-shell ellipsoidal head model with relative conductivities of 0.33, 0.33, 0.0042, and 1 for the head, scalp, bone, and cerebrospinal fluid, respectively, and sizes of 85 mm (radius), 6 mm (thickness), 7 mm (thickness), and 1 mm (thickness). As an initial step, two regional sources were seeded in left and right Heschl's gyrus (Talairach coordinates: X-Loc = ±47, Y-Loc = −26, Z-Loc = 11) to account for the neural activity between 0 and 260 ms after sound onset. Each source contained three orthogonal dipoles to account for all directions of current flow at the source location (tangential, radial, and anterior/posterior). Maintaining the symmetrical and orthogonal constraints, the orientations of the tangential sources were then aligned with the maximum direction of activity and the three sources were converted to single dipoles. Two additional regional sources were seeded in the left and right inferior parietal lobule (IPL) to account for the sustained potential between 300 and 800 ms post-stimulus. This area was chosen

TABLE I. Group mean responses (and standard error of the mean) as a function of harmonicity and location.

Percentage mistuning	Location	Percentage of stimuli heard as two sounds	Confidence intervals lower–upper bound	Response time (ms)	Confidence intervals lower–upper bound
0%	Same	20.31 (4.46)		737.88 (36.32)	
	Different	32.81 (4.57)		752.39 (39.26)	
	Difference	12.50 (4.18)	3.30–21.70	14.52 (14.86)	−18.19–47.22
2%	Same	69.44 (8.06)		752.85 (52.77)	
	Different	79.80 (7.04)		714.24 (56.70)	
	Difference	10.36 (3.76)	2.08–18.64	−38.62 (11.84)	−64.69−−12.55
16%	Same	96.01 (1.80)		607.72 (43.93)	
	Different	96.41 (1.70)		601.80 (40.49)	
	Difference	0.41 (0.50)	−0.70–1.51	−5.92 (7.20)	−21.77−9.94

because it has been found to be active during auditory localization tasks (Arnott *et al.*, 2004). The regional sources were then converted to single dipoles and the anterior-posterior component of the regional source in Heschl's gyrus was removed since it accounted for less than 1% of the total variance. As a final step, the orientation of the tangential and radial sources in Heschl's gyrus and the IPL sources were allowed to change. For the optimization of the radial and tangential sources in Heschl's gyrus, the IPL sources were turned off. The resulting model was held fixed and used as a spatial filter to derive the source waveforms (three in each hemisphere) in each participant and for all stimulus types and listening conditions, separately. The ANOVAs were performed on mean amplitude (nAm) over selected latency regions based on previous studies using similar stimuli (Alain *et al.*, 2001a; Alain and Izenberg, 2003; Alain *et al.*, 2002). The factors included in the ANOVA were percentage of mistuning (0%, 2%, 16%), location (same, different), and hemisphere (ipsi- or contralateral to the harmonic series).

B. Results

1. Behavioral data

Participants were more likely to report hearing two concurrent sounds when the third harmonic was mistuned, $F(2,22)=102.48$, $p<0.001$, all pairwise comparisons $p<0.01$ (Table I). Participants were also more likely to report hearing two separate auditory objects when the third and remaining harmonics were presented from different loudspeakers $F(1,11)=15.06$, $p<0.01$. There was a significant interaction between both harmonicity and location, $F(2,22)=4.19$, $p<0.05$. When the third harmonic was in tune or mistuned by only 2%, participants were more likely to indicate hearing two sounds when it was presented at a different location than the remaining harmonics, $F(1,11)>7.58$, $p<0.05$ in both cases. In comparison, the likelihood of reporting hearing two concurrent sounds was little affected by the location of the third harmonic when it was mistuned by 16% of its original value, $F(1,11)=0.65$, $p=0.44$. This is unsurprising given the proficiency of the participants at identifying two sounds when the third harmonic was mistuned by 16%.

We also examined the effects of location and harmonicity on response time for trials in which harmonic and inharmonic stimuli were identified as one or two objects, respec-

tively. Trials that were identified as two sounds when there was no mistuning and trials identified as one sound when mistuning was present were excluded from the analysis. A significant main effect of harmonicity was found for participants' mean response times, $F(2,22)=11.58$, $p<0.001$. Planned comparisons revealed that participants responded more quickly to the 16% mistuned stimuli than the 2% mistuned or tuned stimuli, $p<0.01$ for both. There was no significant difference in response times between tuned and 2% mistuned stimuli. Response times were also significantly faster when the third harmonic was presented at a different location than the remaining harmonics, $F(1,11)=11.76$, $p<0.01$. There was only a trend towards an interaction between harmonicity and location cues, $F(2,22)=3.71$, $p<0.06$. When the third harmonic was presented at a different location than the remaining harmonics, participants tended to respond more quickly when the third harmonic was mistuned but more slowly when it was in tune.

2. Electrophysiological data

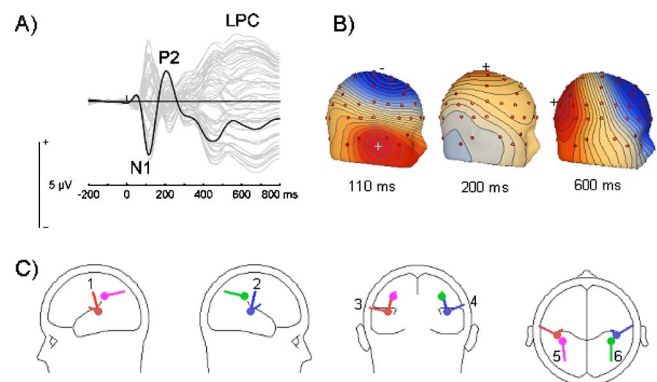
a. Active listening. Figure 1(A) shows the grand average ERPs for 65 channels. The ERPs were comprised of N1 and P2 waves peaking at about 110 and 200 ms after sound onset, respectively. The N1-P2 was maximal over the fronto-


FIG. 1. (Color online) (A) Group mean auditory evoked potentials (for 65 channels) elicited by complex sounds averaged over stimulus type during active listening. The Cz electrode is shown in black whereas the other channels are shown in gray. (B) Iso contour maps are shown for the N1, P2, and LPC (late positive complex). The contour spacing was set at 0.30 μV. (C) Dipole source model of the grand average ERPs recorded during listening conditions.

B) Active Listening: 16%
FIG. 2. Active listening. Source waveforms of the group mean ERPs recorded during active listening. (A) Source waveforms for the tuned and the 2% mistuned harmonic presented either at the same or at a different location than the remaining harmonics. (B) Source waveforms for the tuned and the 16% mistuned harmonic presented either at the same or at a different location than the remaining harmonics.

central scalp region and was followed by a sustained potential that was positive and maximal over the parietal regions [Fig. 1(B)]. This neural event is referred to as the late positive complex (LPC). The dipole model for the scalp-recorded data is illustrated in Fig. 1(C). The residual variance for the whole epoch was 4.08% for ERPs recorded during active listening and 3.70% for those obtained during passive listening, suggesting that this model provides a good fit to the scalp-recorded data.

Figure 2 shows group mean source waveforms when the mistuned harmonic was presented from the same or at a different location than the remaining harmonics during active listening. The N1 and P2 waves of the scalp-recorded data were best represented on the tangential sources whereas the N1c was expressed as radial sources. The LPC was accounted for by sources in IPL.

The N1 wave peaked earlier and its amplitude was larger in the hemisphere contra- (119 ms; -36.19 nA m) than ipsi-lateral (124 ms; -31.43 nA m) to the harmonic series [$F(1,11)=13.69$ and 15.57, respectively, $p<0.005$ in both cases]. The N1 peak latency and amplitude increased with

mistuning, $F(2,22)=4.36$ and 8.57, $p<0.05$ in both cases. This effect of mistuning on N1 latency and amplitude may be caused by the superimposition of the N1 and P2 wave by the ORN (see the following). A similar analysis on the N1c revealed a longer latency but larger amplitude in the hemisphere contra- (152 ms; -13.94 nA m) than ipsi-lateral to the harmonic series (146 ms; -10.47 nA m), $F(1,11)=5.62$ and 40.36, $p<0.05$ in both cases. There was also a tendency, of borderline significance, for the N1c to be earlier when the third harmonic was presented at a different location than the remaining harmonics [147 ms vs 150 ms for same location; $F(1,11)=4.24$, $p=0.06$]. The effect of mistuning on the N1c latency was not significant, but its amplitude increased with mistuning, $F(2,22)=4.57$, $p<0.05$. The effects of location on the N1 and N1c amplitude or latency were not significant.

The P2 peak latency and amplitude measured at the tangential source was quantified between 140 and 280 ms after sound onset. The main effect of mistuning or location was not significant. However, there was a significant interaction between mistuning and location on the P2 latency, $F(1,11)=9.53$, $p<0.01$. For the tuned stimuli, the P2 latency was earlier when the third harmonic was presented at a different location than the remaining harmonics (207 vs 222 ms, $t(10)=3.31$, $p<0.007$). For the 2% mistuned stimuli, the P2 latency was not affected by location whereas for the 16% mistuned stimuli the P2 was delayed when the third harmonic was presented at a different location than the remaining harmonics [228 vs 217 ms, $t(11)=2.30$, $p<0.05$]. For the P2 amplitude, the main effect of mistuning or location was not significant nor was the interaction between these variables.

The neural activity associated with distinguishing concurrent auditory objects is best illustrated by subtracting source waveforms to harmonic stimuli originating from the same location from those obtained for mistuned stimuli presented either at the same or different location than the remaining harmonics (Fig. 3). In the active listening condition, the difference wave revealed a biphasic response similar in latency with the scalp-recorded ORN and P400 waves.

The ORN and P400 latency and amplitude varied with the amount of mistuning and therefore the effect of location on these neural events was quantified over different latency windows. For the 2% mistuned stimuli, the first reliable difference in neural activity was noticed between 200 and 300 ms post-stimulus. An ANOVA on the mean amplitude from the tangential sources yielded a significant interaction between mistuning and location, $F(2,22)=5.68$, $p<0.02$. That is, the conjunction of harmonicity and location lead to significant enhancement in negativity but only for the 2% mistuned harmonic stimuli, $p<0.001$. There was no significant effect of location on the tuned or the 16% mistuned harmonic.

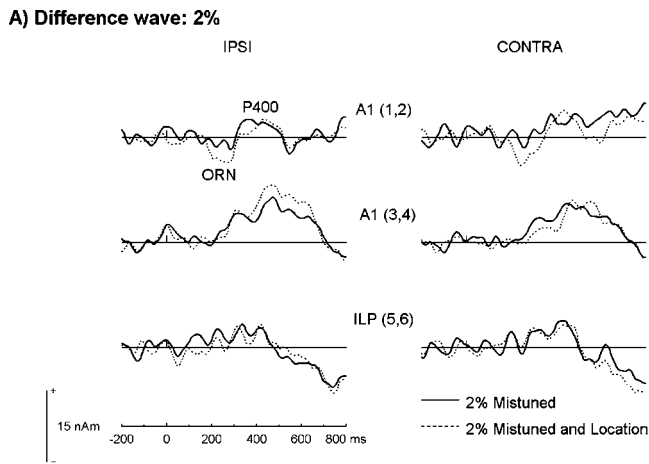
For the 16% mistuned stimuli, the first reliable difference in neural activity was noticed between 100 and 200 ms post-stimulus. An ANOVA on the mean amplitude from the tangential sources yielded a main effect of mistuning, $F(2,22)=12.56$, $p<0.001$. Planned comparisons revealed a significant ORN only when the third harmonic was mistuned by 16%, $p<0.001$. There was no significant difference in the


FIG. 3. Active listening. Object-related negativity isolated by subtracting source waveforms from the tuned harmonic presented at the same location from those obtained for mistuned stimuli presented either at the same or different location as the harmonic series. (A) ORN for the 2% mistuned harmonic. (B) ORN for the 16% mistuned harmonic.

source waveforms for the tuned and 2% mistuned stimuli. The main effect of location was not significant nor did location interact with other factors.

The ORN was followed by a P400 response peaking at about 450 ms after sound onset. An ANOVA on mean amplitude between 400 and 500 ms yielded a main effect of mistuning, $F(2,22)=15.54$, $p<0.001$. The P400 was larger for the 16% mistuned stimuli, intermediate for the 2% and smallest for the tuned stimuli, all pairwise comparisons significant at $p<0.02$. The main effect of location was not significant nor was the interaction between location and harmonicity. However, the interaction between location and hemisphere tended toward significance, $F(1,11)=3.66$, $p=0.08$.

b. Passive listening. Figure 4 shows group mean source waveforms when the mistuned harmonic was presented from the same or at a different location than the remaining harmonics during passive listening. As for the active listening condition, the N1 and P2 waves recorded during passive listening were best represented at the tangential sources. However, the N1c and the late positive complex were smaller and more difficult to identify than during active listening. Consequently, the analyses of the source waveforms were limited to the tangential component.
FIG. 4. Passive listening. Source waveforms of the group mean ERPs during passive listening. (A) Source waveforms for the tuned and the 2% mistuned harmonic presented either at the same or at a different location than the remaining harmonics. (B) Source waveforms for the tuned and the 16% mistuned harmonic presented either at the same or at a different location than the remaining harmonics.

As in active listening, the N1 wave peaked earlier and its amplitude was larger in the hemisphere contra- (117 ms; -14.94 nA m) than ipsi-lateral (122 ms; -11.72 nA m) to the harmonic series [$F(1,11)=31.37$ and 11.70, respectively, $p<0.006$ in both cases]. The N1 peak latency and amplitude increased with mistuning, $F(2,22)=5.44$ and 12.07, $p<0.05$ in both cases. The main effect of location was not significant nor did location interact with any other factors. The P2 peak latency and amplitude measured at the tangential source was quantified between 140 and 280 ms after sound onset. The main effect of mistuning, location or hemisphere on P2 latency and amplitude was not significant nor was the interaction between mistuning and location.

Figure 5 shows ORN elicited by mistuned stimuli presented at either the same or different location than the remaining harmonics. An ANOVA on the mean amplitude for the 100–200 ms interval from the tangential sources yielded a main effect of mistuning, $F(2,22)=18.47$, $p<0.001$, all pairwise comparisons at $p<0.05$. The main effect of location was not significant nor was the interaction between location and any other factor.

C. Discussion

Participants were more likely to report hearing two distinct sounds when the stimulus contained a mistuned har-

monic. The greater the degree of inharmonicity within the stimulus, the more quickly and reliably participants reported the presence of two sounds. This is consistent with previous research (e.g., Alain *et al.*, 2001a, 2002; Hartmann *et al.*, 1990; Moore *et al.*, 1986) and provides further confirmation that frequency periodicity provides an important cue in distinguishing co-occurring auditory objects.

Presenting the third harmonic at a different location than the remaining harmonics also modulated participants' responses, increasing the likelihood of reporting that two sounds were present when the stimulus contained a tuned or a mistuned harmonic at near-threshold levels, and decreasing the response time needed to indicate this. The fact that participants reported hearing two concurrent objects significantly more often when the third harmonic was presented from a separate loudspeaker than when it came from the same speaker even when the third harmonic was in tune with the rest of the partials, indicates that sounds can be segregated based on location alone. When the third harmonic was mistuned by 16%, however, the additional location cue did not further influence listeners' responses. This is not surprising given that the likelihood of reporting hearing two con-

current sounds was already at 96% when the third harmonic was presented at the same location as the remaining harmonics.

The effects of harmonicity and location on perception were associated with distinct patterns of neural activity. As in previous studies, the 16% mistuned harmonic "popped out" of the complex sound and was accompanied by an ORN and P400 (Alain *et al.*, 2001a, 2002; Alain and Izenberg, 2003). The latter was present only when listeners were asked to make a response whereas the ORN was observed in both active and passive listening conditions, consistent with the proposal that concurrent sound segregation based on inharmonicity occurs automatically (Alain and Izenberg, 2003; Dyson and Alain, 2004). Although the two listening conditions differed in terms of stimulation rate, it is unlikely that this factor played an important role since the ORN recorded during passive listening is not affected by stimulus onset asynchrony (Alain *et al.*, 2002).

Like participants' phenomenological experience, the source waveforms for the 16% mistuned stimuli were little affected by presenting the third harmonic at a different location than the remaining harmonics. A different pattern of results emerged for the tuned and near threshold-mistuned stimuli. For the tuned stimuli, the P2 wave peaked earlier when the third harmonic was presented at a different location, providing further evidence that sound can be segregated based on location alone. In the present study, the location-based segregation of the tuned harmonic appears to be indexed by a different neural event than mistuning. It is possible that the simultaneous activity of harmonically related, yet spatially distinct physical sources, may have contributed to a "wider" acoustic image with a perceived location somewhere between the two loudspeakers. The sum of acoustic energy from both speakers could also account in part for the early P2 wave. Although the effect of location on the P2 latency was reversed with increasing mistuning, this could be due to the superimposition of the ORN on the N1 and P2 wave.

Paralleling the behavioral data for the 2% mistuned stimuli, there was a late negative potential that resembled the ORN, which was greater in amplitude when the mistuned harmonic was presented at a different location than the remaining harmonics. However, this effect of location appeared relatively late in comparison to the ORN elicited by 16% mistuning and was present only when the stimuli were attended. Thus, it is possible that the P2 amplitude decrement was caused by the superimposition of the P2 wave by attention-related negativity waves or a late ORN. This late negativity associated with the conjunction of mistuning and location could be related to the N2b wave, which reflects stimulus classification and decision processes that control behavioral responses in discrimination tasks (Ritter *et al.*, 1979, 1982). For instance, participants may have adopted a strategy in which they equally divided their attention between the two speakers thereby facilitating the detection of the third harmonic when it was presented at a different location than the remaining harmonics. This would seem a reasonable strategy given that the probability of sounds emanating from the left or right speaker was equiprobable.

When all of the harmonics were in tune and presented from one location, participants indicated the presence of two sounds on 20% of the trials. This may reflect some response bias in responding that two objects were present. It is also possible that participants heard the third harmonic as a separate object because it was the only harmonic that was ever mistuned. For example, participants may have realized that the changes in the frequency component were always in the same frequency region and therefore listened more carefully for sounds at that particular frequency. It has been shown that individuals are able to identify a single harmonic in a complex sound if they have previously listened to that harmonic presented alone (Plomp, 1964; Plomp and Mimpen, 1968). This directed attention might have been facilitated by those trials in which the third harmonic was presented from a different location because it may have increased the participants' focus on this frequency region and further primed them to hear the frequency of the third harmonic.

In this first experiment, participants were never asked to indicate where they perceived the sound with a pure tone quality as coming from, making it difficult to determine whether participants could localize the third harmonic when they reported hearing it as a separate object. This is particularly important for trials in which the third harmonic was tuned or slightly mistuned since they were likely to benefit the most from the addition of a location cue. In Experiment 2, listeners were asked to indicate the location of the sound with the pure tone quality. This experimental design allowed us to assess whether participants could segregate and localize the third harmonic. In addition, the f_0 varied randomly to decrease the likelihood that participants would focus on one frequency region to complete the task and a larger spatial separation was used to promote segregation based on location alone.

III. EXPERIMENT 2

A. Methods

1. Participants

Ten right-handed adults (between 20 and 38 years of age, mean age=27.9 ± 5.65 years; 4 males) participated in the experiment. All participants had pure-tone thresholds less than or equal to 30 dB HL at frequencies in the range 250–8000 Hz in both ears. Each participant gave informed consent in accordance with the University of Toronto and Baycrest Centre for Geriatric Care guidelines. Participants were volunteers from the University of Toronto and laboratory staff, and were paid for their participation.

2. Stimuli and task

Stimuli were complex sounds comprised of 10 harmonics of equal intensity with an f_0 of 175, 200, or 225 Hz. Three different f_0's were chosen to decrease the likelihood that participants would focus on one frequency region to complete the task. For the mistuned stimuli, the third harmonic was shifted upwards or downwards by 4% of its original value. This magnitude of mistuning was chosen because it is above threshold (Alain *et al.*, 2001b) and therefore should be detected by most listeners, but not so overwhelm-

ing a frequency cue as the 16% mistuning used in the first experiment. We also used only one level of mistuning to increase the number of observations per stimulus and to reduce response bias since 50% of stimuli did not include a mistuned harmonic as opposed to only 33% in the first experiment. As in the first experiment, the third harmonic was played from either the same loudspeaker or a different loudspeaker than the other nine harmonics.

On each trial, participants first indicated whether they heard one sound or two sounds following the presentation of each stimulus. If they indicated that two sounds were present, then participants specified the location (left or right of center) of the sound with the pure tone quality (i.e., the mistuned harmonic). Participants did not receive any feedback on their performance. Within a block of trials, twelve different and equiprobable stimuli were played at random (three levels of f_0; two possible levels of mistuning −0% and ±4%; third harmonic presented at either the same or different loudspeaker as the remaining harmonics). A chin rest was used throughout the experiment to ensure that participants' heads remained in a constant position relative to the loudspeakers (at an angle of 60° to each speaker). The angle was increased from the first experiment to emphasize the location cue. The distance from each loudspeaker to the estimated center of participants' heads was 1.32 m while the distance between loudspeakers was 2.23 m. A total of 960 trials were presented to each participant (80 per stimulus type).

3. Electrophysiological recording and data analysis

Recording and analysis of ERPs were similar to that of Experiment 1. ERPs were averaged across the three different f_0 to increase the signal-to-noise ratio. As in Experiment 1, two regional sources were seeded in left and right Heschl's gyrus to account for the neural activity between 0 and 260 ms after sound onset. Maintaining the symmetrical and orthogonal constraints, the orientations of the tangential sources were then aligned with the maximum direction of activity and the three sources were converted to single dipoles. Two dipoles were seeded in the left and right IPL to account for the sustained potential between 300 and 800 ms post-stimulus. The anterior-posterior component of the regional source in primary auditory cortex was removed since it accounted for less than 1% of the total variance and the orientation of the tangential, radial, and parietal sources was allowed to change. The resulting model was held fixed and used as a spatial filter to derive the source waveforms (three in each hemisphere) in each participant and for all stimulus types, separately. The residual variance was 4.84%.

B. Results

1. Behavioral data

Participants were more likely to report hearing two concurrent sounds when the third harmonic was mistuned, $F(1,9)=267.78$, $p<0.001$, and when the third and remaining harmonics were presented from different loudspeakers, $F(1,9)=30.05$, $p<0.001$ (Table II). There was also a significant interaction between harmonicity and location, $F(1,9) =16.83$, $p<0.005$. When the third harmonic was in tune,

Percentage mistuning	Location	Percentage of stimuli heard as two sounds	Confidence intervals lower–upper bound	Response time (ms)	Confidence intervals lower–upper bound
0%	Same	18.81 (4.35)		546.04 (42.86)	
	Different	32.12 (5.29)		522.17 (32.23)	
	Difference	13.32 (2.50)	7.67–18.96	−23.87 (16.64)	−61.52–13.78
4%	Same	87.88 (2.56)		622.82 (49.36)	
	Different	91.29 (1.86)		620.33 (53.75)	
	Difference	3.42 (1.16)	0.80–6.04	−2.50 (20.66)	−49.24–44.25

participants reported hearing two sounds more often when it was presented at a different location than the remaining harmonics, $t(9)=7.58$, $p<0.05$, whereas listeners' perception was little affected by differences in spatial location when the third harmonic was mistuned by 4%, $t(9)=0.65$, $p=0.44$. It is possible that participants were responding at ceiling before the location cue was introduced. There was also no significant difference in response time among the various stimulus types.

The overall proportion of trials in which participants indicated hearing two concurrent auditory events was 58%, and participants could accurately identify the location of the third harmonic on 34% of those trials. Performance was comparable for tuned and mistuned stimuli. A close examination of the individual data revealed a bimodal distribution, with five participants almost always reporting hearing the third harmonic at the same location as the remaining harmonics (mean=99%). Thus, although participants reported hearing two auditory events on many occasions, they were unable to accurately indicate the location of the target signal (i.e., the third harmonic) on these trials. Four of the remaining five participants were able to accurately localize the third harmonic more than 50% of the time (mean=70%) in which they reported hearing two concurrent sounds. The last participant was able to accurately localize the third harmonic on only 35% of trials previously identified as containing two sounds.

2. Electrophysiological data

Figure 6 shows group mean source waveforms when the mistuned harmonic was presented from the same or at a different location than the remaining harmonics. As in the first experiment, the N1 wave peaked earlier and its amplitude
was larger in the hemisphere contra- (111 ms; −40.56 nA m) than ipsi-lateral (114 ms; −37.29 nA m) to the harmonic series $[F(1,11)=11.84$ and 14.07, respectively, $p<0.01$ in both cases]. The effects of mistuning or location on N1 peak latency and amplitude were not significant. The N1c peaked at about 144 ms after sound onset and tended to be larger in the hemisphere contralateral to the harmonic series, $F(1,9)=4.70$, $p=0.058$. The effects of mistuning and location on the N1c peak latency and amplitude were not significant.

For the P2 wave, the main effect of mistuning or location was not significant. However, there was a main effect of hemisphere $[F(1,9)=8.38$, $p<0.02]$, and a significant interaction between hemisphere and location on the P2 peak amplitude, $F(1,11)=6.12$, $p<0.05$. There was a greater P2 amplitude decrement in the hemisphere ipsi- than contra-lateral to the harmonic series when the third harmonic was presented at a different location than the remaining harmonics. There was also a main effect of mistuning on the tangential component during the 130–230 ms interval, $F(1,9)=5.61$, $p<0.05$. This is best illustrated in the difference wave between source waveforms elicited by tuned and mistuned stimuli presented either at the same or different location than the remaining harmonics (Fig. 7). The ORN was little affected by the conjunction of location and harmonicity. However, there was a significant interaction between mistuning and location for the P400 (400–500 ms), $F(1,9)=10.56$, $p<0.01$. For the tuned stimuli, the P400 showed larger amplitude when the third harmonic was presented at a different location whereas for the mistuned stimuli, adding a location cue generated smaller amplitude relative to the mistuned stimuli presented at the same location as the remaining harmonics.

Half of our participants could localize the third harmonic when they reported hearing two concurrent auditory events. The other half was unable to localize the third har-

monic regardless of mistuning and/or location. We further examined the effect of mistuning and location on those listeners ($N=5$) that could localize the third harmonic when reported as standing out of the complex sound (Fig. 8). In this subset of participants, we found a significant interaction among mistuning, location, and hemisphere, $F(1,4)=16.43$, $p<0.02$. There was a significant ORN when the tuned harmonic was presented from a different location than the remaining harmonics and the amplitude was larger in the hemisphere contra-lateral to the location of the single harmonic.[3] This ORN for location only was comparable to the one recorded to a mistuned harmonic presented at either the same or different location than the remaining harmonics. In the subset of participants that could not localize the third harmonic, there was also a significant interaction among mistuning, location, and hemisphere, $F(1,4)=8.36$, $p<0.05$. However, the ORN was significant only when mistuning was present and was larger in the hemisphere contra-lateral to the harmonic series. Lastly, an ANOVA with group as an additional between-subject factor yielded a significant group $\times$ mistuning $\times$ location $\times$ hemisphere interaction, $F(1,8)=21.32$, $p<0.002$, indicating that location effects on brain activity were different in individuals that could accurately localize the third harmonic presented at a different location than the remaining harmonics.

C. Discussion

The likelihood of hearing two concurrent sounds was greater for mistuned than tuned stimuli and for tuned stimuli when the third harmonic was presented at a different location than the remaining harmonics. The participants' likelihood of hearing the mistuned harmonic as a separate object was little affected by differences in spatial location. Although 4% mistuning may be less salient than 16%, it appears that it was sufficient in itself to guide listeners' responses.

As in the first experiment, the perception of concurrent auditory objects was paralleled by an ORN. The ORN was present for both location- and harmonicity-based segrega-

tion. Coupled with the behavioral data, the ORN for segregation based on location alone is consistent with recent studies showing an ORN to ITD leading to the perceptual segregation of a dichotically embedded pitch (Hautus and Johnson, 2005; Johnson *et al.*, 2003). The fact that a significant ORN was recorded in cases where sounds were segregated based on location alone indicates that this component is more related to the perception of concurrent events than the level of mistuning per se.

When the third harmonic was mistuned by 4%, participants reported hearing two concurrent objects on almost 90% of the trials. This is higher than in previous studies (Alain *et al.*, 2001a; Moore *et al.*, 1986) and may indicate a tendency for participants to report hearing two sounds when they perceive mistuning, even if they did not clearly hear the third harmonic as a separate entity. The fact that half of the participants could not accurately locate the position of the spatially or harmonically segregated sound when they reported hearing two auditory objects is consistent with a bias toward responding hearing two simultaneous auditory events.

As mentioned earlier, some participants who reported hearing two concurrent auditory objects could not localize the source of the third harmonic on those trials. There are several possible explanations for such findings. One possibility is that sound object segregation based on spatial cues and sound localization do not rely on the same mechanisms. For example, Thiran and Clarke (2003) report a case study in which a patient with a right temporo-parieto-frontal ischemic lesion was able to segregate sounds on the basis of a location cue but was unable to accurately localize auditory events. Another possibility is that those individuals that were not able to localize the third harmonic did not hear it as a separate object but rather reported hearing two sounds on those trials in which they perceived the mistuning. The level of mistuning could have been ambiguous for less experienced listeners. It is interesting to note that those five individuals that had difficulty localizing the third harmonic also had less experience with the sort of task used in the current study than those that could accurately localize the third harmonic when it was heard as a separate object.

As in the first experiment, participants often reported hearing two concurrent sounds when the third harmonic was in tune and presented at the same location as the remaining harmonics. The level of performance for the tuned stimuli cannot easily be accounted for by attention to a particular frequency because the f_0 varied randomly from trial to trial. However, it remains possible that schema-guided processes may have played a role in the perception of the tuned harmonic as a separate sound. For instance, listeners may have learned to quickly shift their attention to a particular frequency region according to the f_0 of the incoming stimulus.

IV. GENERAL DISCUSSION

The aim of the present study was to evaluate the relative contribution of harmonicity and location cues during auditory scene analysis. More specifically, we were interested in assessing the role of location cues in concurrent sound seg-

regation. In both experiments, we found comparable effects of spatial separation on listeners' likelihood of reporting two simultaneous auditory objects.

The perception of concurrent auditory objects was paralleled by an ORN that superimposed the N1 and P2 waves. A clear ORN was recorded when the sounds were segregated based on harmonicity. In Experiment 1, the location cues modulated ERPs approximately 250 ms after sound onset whereas in Experiment 2 location cues modulated ERPs as early as 150 ms after sound onset. Differences between the two experiments may be related to the greater spatial separation in Experiment 2.

The harmonic sieve has often been proposed to account for the perception of the mistuned harmonic as a separate event. That is, a template would be formed on the basis of the fundamental frequency and then the harmonics would "pass" through some sort of filter (i.e., sieve). When a harmonic is sufficiently mistuned, it can no longer "pass" through the sieve and therefore would generate a mismatch signal indicating that there is likely more than one sound source active. Such detection of inharmonicity based on a harmonic sieve could occur as early as 30 ms after sound onset (Dyson and Alain, 2004). Although a harmonic sieve or template could account for the effects of mistuning, such a model has difficulty explaining the effects of location as well as the interactions between inharmonicity and location cues on electrophysiological and behavioral data. One alternative possibility to the harmonic sieve would be a model in which the template extrapolated from the incoming stimulus includes both harmonicity and location information.

A secondary question was whether a difference in spatial location would impair listeners' ability to perceptually fuse the stimuli containing exclusively harmonic components. When the harmonic stimuli were presented from two locations, the harmonicity and location cues were working in direct opposition to one another. Previous studies have found that a discrepancy in location may be ignored when other cues favor the fusion of components (Deutsch, 1975). The likelihood of indicating the perception of two sounds significantly increased when the location cue was introduced, suggesting that a contradictory location cue can influence listeners' perception of a harmonic stimulus. A previous study investigating perceptual grouping of sequential sounds found that increasing the spatial separation between a target tone and background tones by 32° reduced the perceptual capture of the target tone (O'Connor and Sutter, 2000). It is possible that the same thing occurred here—the perceptual capture of the third harmonic was impeded by its spatial separation from the remaining harmonics. The loudspeakers in the current studies were separated by angles of 90° and 120° relative to the center of participants' heads (each loudspeaker was 45° or 60° left/right of center), well past the 32° used in the study of sequential grouping. Evidence from previous research suggests that our auditory space may be divided into two broadly tuned perceptual channels, occupying the left and right auditory hemifields, respectively, each extending 30° across the midline (Boehnke and Phillips, 1999; Phillips,

1999). From this perspective, the spatial separation used in both experiments falls well outside these perceptual channels.

In the present study, both ITD and ILD may have contributed to segregation based on spatial location. Given the frequency of the third harmonic ($\sim$600 Hz), it is likely that segregation was based primarily on ITD, which plays an important role in localizing low frequency sounds. This interpretation differs from that of previous work showing that ITD provides little help in parsing concurrent vowels whereas ILD does help the listener somewhat (Darwin and Hukin, 1999). This discrepancy may be related to the fact that our stimuli were presented in free field as opposed to over headphones. The effects of spatial separation between the target harmonic and the remaining harmonics on both behavioral and electrophysiological data were relatively small, albeit significant. Previous works have shown that reverberation reduces the advantage of spatial separation between sound sources (Culling *et al.*, 1994; Plomp, 1976). Hence, in the present study room reverberation could have contributed to the small effects of spatial separation on ERPs.

In summary, the behavioral and electrophysiological results indicated that sounds are segregated based on harmonicity and/or location. In particular, when harmonicity provides a somewhat ambiguous cue, a difference in the spatial location of one sound can aid the listener in segregating it from other sounds. The effects of mistuning on brain activity were present during both active and passive listening, consistent with the proposal that processing harmonicity occurs automatically. In comparison, the effects of location on brain activity were observed only during active listening. This suggests that sound segregation based on sound location may rely on top-down attentional processes to a greater extent than segregation based on frequency periodicity. Additional studies are needed to confirm this hypothesis as well as to further assess where in the brain these effects may be mediated.

[1]We recorded more trials in the passive listening condition because the ISI was shorter and thus allowed us to record more observations within the same amount of recording time.
[2]Note that the midline electrodes remained unchanged during the transposition.
[3]An ANOVA based on a subset of four subjects (excluding the one that could only occasionally localize the third harmonic) generated the same pattern, although the three-way interaction failed to reach significance, $F(1,3)=9.45$, $p=0.054$.

Informational masking release in children and adults

Joseph W. Hall III,[a] Emily Buss, and John H. Grose
Department of Otolaryngology/Head and Neck Surgery, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27599

This study assessed informational masking and utilization of cues to reduce that masking in children aged 4–9 years and in adults. The signal was a train of eight consecutive tone bursts, each at 1 kHz and 60 ms in duration. Maskers were comprised of a pair of synchronous tone-burst trains, with randomly chosen frequencies spanning 200–5000 Hz, with a protected region 851–1175 Hz. In the reference condition, maskers were eight bursts in duration, with a fixed frequency within intervals. Experiment 1 tested two monotic masking release conditions: within-interval randomization of masker burst frequency and the introduction of leading masker bursts. Experiment 2 examined masking release in which the signal was presented to one ear and masking components were presented to both ears (masker components in the contralateral ear were 10 dB higher than those in the ipsilateral ear). Both adults and children demonstrated a significant informational masking effect, with children showing a larger effect on average. Both groups also showed significant release from masking in the two monotic conditions, although children received somewhat less benefit from the masking release cues. The binaural condition supported a moderate release from informational masking in adults, but resulted in *increased* informational masking in children. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1992675]

I. INTRODUCTION

Previous investigations have shown that stimulus components well separated in frequency from a sinusoidal target signal can cause large masking effects when the spectral composition of the remote masker varies randomly on a trial-by-trial basis (e.g., Neff and Callaghan, 1987; Neff and Green, 1987; e.g., Watson, 1987; Neff and Callaghan, 1988; Lutfi, 1990; Leek *et al.*, 1991; Kidd *et al.*, 1994; 2002; Richards *et al.*, 2002; Kidd *et al.*, 2003). Such effects are usually referred to as informational rather than energetic masking because they do not appear to depend upon the excitation of peripheral sensori-neural elements associated with the signal frequency. Informational masking is of particular interest because of its potential to provide insights about auditory processing of complex and variable sounds that occur in natural settings.

There is a small body of research suggesting that informational masking is particularly large in young listeners. For example, Werner and Bargones (1991) showed that infants experienced appreciable masking arising from spectral components two octaves above the signal frequency. This result was interpreted in terms of nonsensory masking in the infants. Informational masking is also relatively large in young children. When tested using maskers having trial-by-trial frequency variability, preschool and school-aged children often showed more informational masking than adults (Allen and Wightman, 1995; Oh *et al.*, 2001; Wightman *et al.*, 2003).

The present study is concerned primarily with release from informational masking. Studies by Neff (1995) and by Kidd and colleagues (Kidd *et al.*, 1994; Arbogast *et al.*,

2002) have shown that informational masking in adults can be reduced substantially by the introduction of stimulus cues thought to promote the perceptual segregation of the signal from the masking stimulus. For example, informational masking can be reduced by providing cues that influence perceptual segregation via auditory streaming, spectro-temporal coherence, and binaural spatial separation (Kidd *et al.*, 1994; Arbogast *et al.*, 2002). In general, informational masking can be reduced by the introduction of stimulus features that make the signal sound different or separate from the masker (Durlach *et al.*, 2003a; 2003b). The study of release from informational masking is important because it may provide clues about auditory processes that enable listeners to separate attended signals from complex, dynamic acoustical maskers.

Whereas psychoacoustical experiments indicate that children are especially prone to informational masking, the ramifications that this may have for hearing are not clear. One reason for this is that little is currently known about the extent to which children experience release from informational masking with the introduction of segregation cues. If such release is robust in children, then informational masking effects in real environments, where multiple sound source segregation cues often exist (e.g., Bregman, 1990; e.g., Yost, 1991), may not be of particular significance. There is some evidence that release from informational masking in children may not be particularly robust. A recent study by Wightman *et al.* (2003) indicated that children in the age range of approximately 4–13 years showed less release from masking than adults when the masker was presented to the nonsignal ear; in this case, the segregation cue was presentation of the signal and masker to opposite earphones, a manipulation that could result in masking release via differential

lateralization of the signal and masker. Whereas this stimulus manipulation resulted in essentially total release from masking in adult listeners, it resulted in essentially no release for the younger children and only partial release for many of the older children.

The purpose of the present investigation was to study the development of release from informational masking further. Experiment 1 explored developmental effects for release from informational masking using monaural sound segregation cues related to onset asynchrony and spectro-temporal coherence. Previous studies on adult listeners (Kidd *et al.*, 1994) have shown that such manipulations can result in significant release from informational masking. At the outset, it was hypothesized that children would show relatively poor benefit from monotic cues to informational masking. This hypothesis is consistent with the findings of reduced efficacy of binaural cues to masking release reported by Wightman *et al.* (2003).

II. EXPERIMENT 1

A. Methods

1. Stimuli

The conditions used here were based on the multiburst paradigm of Kidd *et al.* (1994). In this paradigm, the signal was a train of eight bursts of a 1000-Hz pure tone, each burst 60 ms in duration including 10-ms $\cos^2$ ramps. These bursts were concatenated, with no interburst gaps, resulting in a total signal duration of 480 ms. The condition associated with the largest informational masking in this paradigm is referred to as a *multiburst-same* (MBS) stimulus. Here, the masker was comprised of two trains of eight, 60-ms tone bursts that were synchronous with the signal bursts. For each observation interval, the frequency for the bursts in each of the trains was randomly selected from a range 200–5000 Hz. Within this range, there was a "protected" frequency region, extending from 851–1175 Hz, from which random masker picks were excluded. The purpose of the protected region was to limit the influence of energetic masking. Once selected, the frequency of each masker train remained constant over the observation interval. An example of a signal-present stimulus in the MBS condition is illustrated in Fig. 1 [panel (A)], with the tone bursts represented by dashed lines and gray regions indicating the range of possible masker frequencies.

There were also two masking conditions incorporating cues for perceptual segregation of the signal and masker components. After Kidd *et al.* (1994), one of these employed a perceptual segregation cue related to spectro-temporal coherence, and is referred to as the *multiburst-different* (MBD) condition. Here, the masker was again composed of two trains of stimuli, each comprised of eight 60-ms bursts. However, in this MBD stimulus, the frequency within each of the two trains varied randomly from burst to burst (over the ranges 200–851 and 1175–5000 Hz). Thus, as illustrated in Fig. 1 [panel (B)], the frequency components within each of the two masker trains varied randomly over the course of the eight bursts, while the frequency of the signal remained fixed over the course of the eight bursts. Kidd *et al.* (1994) specu-
FIG. 1. Stimulus schematic for experiment 1.

lated that masking release in the MBD condition resulted from a perceptual process in which the spectro-temporal constancy of the signal allowed its segregation from the set of randomly varying masker components.

The second masking release condition employed a temporal onset asynchrony cue. Here, the signal and masker were the same as for the MBS masker except that the masker began two bursts prior to the signal onset. In this case, the masker was comprised of ten 60-ms bursts, with the frequency within each train remaining constant across the ten bursts. An example of a signal-present stimulus in the *fringed*-MBS condition is shown in Fig. 1 [panel (C)]. The assumption was that, if spectral components possess temporal asynchrony, they should be easier to separate perceptually (Bregman and Pinker, 1978; Dannenbring and Bregman, 1978; Darwin, 1984). Note that, when the signal bursts were present, they were synchronous with the masker bursts, and that the asynchrony in this paradigm was with respect to the masker burst train beginning earlier than the stimulus burst train. This stimulus bears some resemblance to a masking release condition used by Kidd *et al.* (1994), where signal bursts were presented synchronously with alternate masker bursts. It also shares similarities with the "masker first" technique used by Richards *et al.* (2004), where a pretrial cue of masker alone resulted in release from informational masking.

Sound generation was performed digitally, in the time domain, using an array processor (TDT, APOS), with the signal and masker played out via separate channels of a

digital-to-analog converters (TDT, DD1) at a rate of 20 kHz. The level of each channel was adjusted via a programmable attenuator (TDT, PA4). Each channel was antialias filtered at 7 kHz (Kemo, VBF8), summed (TDT, SM3), and played to the left channel of a Sony MDR V6 earphone.

2. Procedures

Stimuli were presented in blocks of three-alternative, forced-choice trials, and responses were tracked adaptively using a 3-up, 1-down paradigm (Levitt, 1971). An initial step size of 8 dB was reduced to 4 dB after the first reversal, and to 2 dB after the second reversal. The adaptive track included six total reversals, with the track result estimated as the average level at the final four reversals. An adaptive track typically consisted of 25–30 trials. Three such track estimates were obtained, and a fourth was performed if the first three estimates varied by more than 3 dB. Data reported below were the average of all track estimates obtained for a particular condition. Thresholds were obtained first for the eight-burst signal presented in quiet. This threshold in quiet was then used to set the signal level for the remaining conditions of the experiment. In the masking conditions, the signal level was maintained at 30 dB SL (with regard to the threshold in quiet), and the level of the masker was changed adaptively to estimate the masked threshold. The maximum masker level allowed by the software was 83 dB SPL, but very few tracks reached this maximum, so this constraint had minimal impact on the results presented here. Each listener first completed the MBS condition and then completed one of the two masking release conditions.

There were two versions of experimental procedure. In the version used with the younger children (under 7.5 years of age), pictures on a video monitor signaled the listening intervals, and the children responded by pointing to the picture associated with the signal. The experimenter entered the response and visual feedback was provided via the action of an animated figure, for example, a frog turning into a prince (e.g., Veloso *et al.*, 1990). In a second version, older children and adults received visual cues of listening intervals, entered responses, and received visual feedback via a handheld response box. Whereas it is possible that use of different methods with the younger children could have introduced differences into the data, our own pilot work using a wide range of experimental paradigms has suggested that these two methods most effectively maintain attention of these very different populations.

3. Listeners

All listeners had pure-tone detection thresholds of 20 dB HL or better at octave frequencies from 250 to 8000 Hz (ANSI, 1996). None had a history of chronic ear disease, and none had a known history of otitis media within a 3-year period preceding testing. There were 30 child listeners (11 females and 19 males), ranging in age from 4.5 to 9.0 years, with a mean age of 6.6 years. Because previous research suggested a developmental effect in the preschool years, effort was made to recruit children in this age range. The 12 children under 6.0 years of age will be re-

ferred to as the *preschool* group. There were 20 adult listeners (13 females and 7 males), ranging in age from 19 to 33 years, with a mean age of 24.5 years. All listeners were paid for participation and provided data in 1–2 sessions lasting no more than 1 h each.

Each listener was assigned to one of the two masking release conditions. In the conditions examining masking release for the MBD manipulation, there were 11 adults and 13 children. In the conditions examining the temporal fringe manipulation, there were 9 adults and 17 children. The reason for restricting each listener to only one of the masking release conditions was to limit the possibility that susceptibility to informational masking in one set of conditions might become unstable due to exposure to other condition sets. Pilot data on a small number of adult listeners suggested that such instability was a possibility. Although we wished to reduce the possibility of such instability in performance, we wanted to be able to measure any instability in susceptibility to informational masking that might occur within the conditions completed. For that reason, each listener completed a final set of thresholds in which the MBS condition was repeated. This allowed us to determine whether, during the course of testing, the listener might have learned strategies that reduced informational masking in the baseline condition.

B. Results and discussion

Thresholds for detection in quiet were significantly lower for the adults than for the children by 5.3 dB ($t_{46.6}=5.3; p<0.001$). For the children, the threshold in quiet ranged from 1.8 to 22.8 dB SPL, and for adults the threshold in quiet ranged from −1.0 to 8.3 dB SPL. Because the signal level at threshold in quiet varied, the signal level used in the masking conditions, set at 30 dB *re*: detection in quiet, also varied.

The top two panels of Fig. 2 plot results for experiment 1, with listeners in the MBD group shown in the top panel and listeners in the fringed-MBS group shown in the middle panel. The bottom panel shows results for experiment 2 (see below). In each panel, the masker levels at threshold for the initial MBS condition and the masking release condition are plotted in dB SPL as a function of age. In examining the masked thresholds, bear in mind that, because the signal level was fixed at 30 dB SL and the masker level was varied, a relatively lower masker level at threshold reflects relatively greater masking. A low masker level at threshold is expected in the MBS condition, consistent with a large informational masking effect, and higher masker level at threshold is expected in the MBD and fringed-MBS conditions, consistent with a release from masking. One striking feature of the present data is the enormous range of individual differences. Such variance is often noted in studies of informational masking (Neff and Dethlefs, 1995). In the MBS condition of the present study, the masker level at threshold spanned approximately 45 dB within the adult group, whereas the variation in this condition was less among the children (approximately 28 dB). In contrast, variability was very high among the children in the MBD and fringed-MBS conditions, whereas variability was relatively low for the adults in these
FIG. 2. Masker level at threshold is plotted in dB SPL as a function of age for individual listeners. The dashed line indicates the (approximate) maximum sensitivity achieved by child listeners in the *multiburst-same* (MBS) condition. The top, middle, and bottom panels are associated with the MBD (13 children, 11 adults), fringed-MBS (17 children, 9 adults), and binaural (10 children, 10 adults) conditions, respectively.

TABLE I. Masker levels at threshold (dB SPL) and masking release (dB) for experiments 1 and 2. Standard deviations are in parentheses. The "matched adult" data are for the subset of adults who obtained a masker level at threshold of 40 dB or lower in the initial MBS condition (comparable to children). Values connected by dashed lines are instances where child performance was significantly worse than for adults (comparisons are between children and all adults for the masker levels at threshold and between children and matched adults for masking release). A single asterisk denotes masking release that was statistically significant. The double asterisk denotes significant *increase* in masking.

conditions. Because of the gross differences in variability between groups, nonparametric methods were used to examine group differences and some within-group differences in the statistical tests reported below. Nonparametric tests were used in cases where the Levene's test of equality of variances (Levene, 1960) indicated unequal variances.

1. Developmental results for informational masking

Among the children, the masker levels at threshold in the MBS condition were uniformly low, with most points falling between 10–40 dB SPL, indicating appreciable informational masking. This is somewhat in contrast to the adults, where some listeners showed low masker levels at threshold (10–40 dB SPL), but others tolerated considerably higher masker levels (up to 72 dB SPL). Thus, compared to adults, children showed informational masking that was larger and more consistent (see Fig. 2). Masker levels at threshold in the initial MBS baseline condition were significantly better for adults than children (see Table I). In the MBD group, the adult MBS threshold was 19 dB better (Mann-Whitney U =20.0; p=0.002), and in the fringed-MBS group, the adult MBS threshold was 16.5 dB better (Mann-Whitney U=38.0; p=0.03). This developmental effect is consistent with previ-

ous work showing more informational masking in pre-school and young school-aged children than adults (Allen and Wightman, 1995; Oh *et al.*, 2001; Wightman *et al.*, 2003). The fact that this difference is modest when contrasted with the individual variability within listener group, which was on the order of 50 dB for adults and 30 dB for the children, should be taken as evidence that the children were only somewhat more susceptible to informational masking than adults.

The wide range of adult results in the MBS conditions allows identification of adults with baseline informational masking comparable to the child listeners: a subset of 70% of the adults had masker levels at threshold below 40 dB SPL in the initial MBS condition, comparable to those of the typical child listener (8 of 11 adult listeners in the MBD group and 6 of 9 adult listeners in the fringed-MBS group). This division is indicated by the dashed horizontal lines in Fig. 2, and will be referred to again below in the statistical analyses assessing amount of masking release.

2. Developmental results for release from informational masking

In the adults, both monaural release conditions consistently improved performance in all listeners who had appreciable informational masking in the MBS baseline condition. Adults showing very little informational masking release were presumably already performing near ceiling in the baseline condition. Children, on the other hand, did not benefit uniformly from the release manipulations. In one extreme case, performance of an 8-year-old child deteriorated substantially in the fringed-MBS condition (see Fig. 2), a result that replicated with additional data collection several days after the first session. Despite this nonuniformity, the performance of most children tended to improve in both of the release conditions.

Of primary interest here was whether children differed from adults in terms of the amount of release from informational masking. One coarse way in which this was assessed was simply in terms of the masker level at threshold in the masking release conditions. The Mann-Whitney U nonparametric test indicated that children had significantly lower (poorer) masker levels at threshold than adults in both of the monaural informational masking release conditions. In the MBD condition, this difference was 28.6 dB ($U=22; p=0.03$), and in the fringed-MBS condition it was 17.4 dB ($U=31; p=0.02$) (see Table I). Note that in this comparison, all of the adults (even those who showed very little informational masking in the baseline condition) were included. The comparison of informational masking release between adults and children is complicated somewhat by this fact, as the adults who did not show much informational masking in the baseline condition could not show much release from masking (ceiling effect). One general observation is that, for the adult listeners who did demonstrate low masker levels at threshold in the baseline condition, the masker levels at threshold increased substantially for the release condition in every case. In contrast, there were some cases among the children where the masker levels at threshold remained low in the release condition. We therefore performed statistical assessment of group differences in release from informational masking comparing children and the subset of 70% of adults who showed comparable baseline informational masking. Masking release was defined as the difference in the masker level at threshold between the first block of MBS and the monaural release condition, either MBD or fringed-MBS. Mean masking release is shown in Table I. In the MBD condition, the average masking release was 17.1 dB greater for the adults than for the children. This difference was significant ($U=22; p=0.03$). In the fringed-MBS condition, the average masking release was 12.4 dB greater for the adults than for the children. This difference was not significant ($U=31; p=0.18$). In order to confirm that children actually showed a significant masking release in both masking release conditions, Wilcoxon signed ranks tests were performed in which the initial masker level at threshold in the MBS condition was compared to the masker level at threshold in the masking release condition (either MBD or fringed-MBS).

These tests indicated significant masking release for the children in both the MBD condition ($z=2.5; p=0.01$) and the fringed-MBS condition ($z=3.2; p=0.001$).

Three brief comments regarding the above statistical outcomes are in order. For each, recall that the statistical outcomes pertain to the subset of adults who showed substantial informational masking in the initial MBS baseline. The first comment pertains to the fact that the children achieved a masking release that was not statistically different from that of the adults in the MBS/fringed-MBS comparison, but achieved significantly less masking release than the adults in the MBS/MBD comparison. A feature of the data that is in line with this outcome is that, whereas many children performed like the adults in the fringed-MBS condition, fewer did so in the MBD condition (cf. Fig. 2). For example, in the fringed-MBS condition, the worst adult masker level at threshold was approximately 60 dB SPL, and over half of the children achieved a masker level at threshold that was as good or better than this value. In the MBD condition, the worst adult masker level at threshold was approximately 70 dB SPL, and only 3 of 13 children achieved a masker level at threshold that was as good or better than this value. Overall, these results support a tentative interpretation that children in the age range investigated here are more likely to show adult-like levels of masking release for cues related to temporal asynchrony than for cues related to spectro-temporal coherence. The second comment pertains to the finding that adults and children did not differ significantly in terms of masking release in the MBS/fringed-MBS comparison. It is nevertheless clear that, whereas all adults showed masking release here, some of the children did not. The third comment pertains to the finding that children showed a significant release from masking for both of the monaural cues investigated here. Examination of Fig. 2 reveals that this result must be interpreted with care, as there were instances, for both cues, where individual children showed little or no masking release.

Comparisons of *preschool* and *young school-aged* children yielded mixed evidence regarding a difference in informational masking release between these groups. For the children who listened to the MBD release condition, 3 of 6 *preschool* children had the smallest masking release obtained in this condition (just 1–2-dB improvement), but 2 of 6 had a masking release above the mean for the child group (36- and 43-dB improvement). For the children who listened to the fringed-MBS release condition, 5 of 6 of the *preschool* children had masking release above the mean for the child group, and the remaining child had a release just 1 dB less than the mean. These results, while inconclusive, suggest that any difference between *preschool* and *young school-aged* children in ability to make use of the MBD and fringed-MBS cues for informational masking release is highly listener dependent, and may be more pronounced in, or restricted to, the MBD manipulation.

3. Developmental results related to learning

Because the MBS baseline condition was run both before and after the masking release condition, these data can be used to estimate changes in performance with listening

J. Acoust. Soc. Am., Vol. 118, No. 3, Pt. 1, September 2005

Hall, Buss, and Grose: Informational masking release   1609
FIG. 3. Individual (narrow, filled bars) and average (wide, unfilled bars) results for the change in the masker level at threshold between the first and second estimates for the MBS condition. The data are from the listeners in the fringed-MBS group of experiment 1. The error bars show plus and minus 1 standard error of the mean.

experience. Such a change could result from exposure to the masking release condition, additional exposure to the baseline condition itself, or central factors unrelated to the particular stimuli encountered (e.g., fatigue or general familiarity with testing procedures). The mean MBS results and standard deviations appear in Table I. In statistical tests of change in the MBS result for the adults, only those listeners with a masker level at threshold below 40 dB for the first estimate were included. Children showed relatively consistent intersubject variability across the estimates for the first and second MBS conditions, so change in masker level at threshold was assessed using a t-test. In contrast, adults showed high intersubject variability in the second MBS condition, so the nonparametric Wilcoxon test was used to assess change in performance here. For the MBD release group, there was no significant change in performance over the two MBS conditions for either group ($t_{11}=0.2$; $p=0.84$ for children and $Z=1.4$; $p=0.16$ for adults). For the fringed-MBS group, both groups showed significant change. The adults improved in the second MBS estimate ($Z=2.0$; $p=0.04$), while the children showed a small but significant decrease in performance ($t_{16}=3.3$; $p=0.005$). These differences are shown in Fig. 3, with individual data in filled, narrow bars (ordered by age) and mean data in unfilled, wide bars. As with the initial MBS condition, adults had better thresholds than children for the second MBS condition (see Table I) both in the MBD group (Mann-Whitney $U=20.0$; $p=0.004$), and in the fringed-MBS group (Mann-Whitney $U=5.5$; $p<0.001$).

There is no evidence that sensitivity of the children in the baseline condition improved over the course of testing. For adults, however, exposure to the fringed-MBS release condition improved thresholds. It is not obvious why the performance in the MBS condition improved for the adults in the context of the fringed-MBS condition but not in the context of the MBD condition. It is possible that the improvement within the fringed-MBS context is related to the fact that stimuli are quite similar between the MBS and the fringed-MBS conditions. These conditions are identical (except for the leading masker bursts in the fringed-MBS condition), and it is possible that this facilitated the transfer of strategies learned in the fringed-MBS condition to the final

MBS condition. A very different strategy may be utilized in the MBD condition, perhaps involving spectral variations that are absent from the MBS condition. A caveat to this interpretation is that the observed differences may have arisen from individual differences between the randomly assigned listener samples comprising the two groups of adults.

III. EXPERIMENT 2

Whereas experiment 1 examined the ability of children to make use of monaural cues to reduce informational masking, Wightman *et al.* (2003) studied the ability of children to make use of binaural cues related to sound lateralization. In that study, the informational masking condition involved signal and masker presentation to a single ear, and the informational masking release condition involved signal presentation to one ear and masker presentation to the opposite ear. This manipulation eliminated informational masking in adults, reduced or eliminated informational masking in some school-age children, but had little or no effect on performance of the preschool children. In some contrast, the present experiment 1 indicated little evidence of a consistent difference between the preschool and school-aged children. Overall, experiment 1 (where monaural cues for masking release were employed) showed more evidence for release from informational masking in younger children than in the study of Wightman *et al.* (2003) (where cues for masking release were binaural in nature). Several aspects of the methods of the Wightman *et al.* study differed substantially from those of experiment 1, making comparisons across the monaural and binaural conditions problematic. The most obvious was that there was no masking energy in the signal ear in the masking release condition of the Wightman *et al.* study. Furthermore, stimuli in the Wightman *et al.* study were presented at a steady level for the 360-ms presentation interval, rather than bursting on and off, and the signal level was adjusted to obtained threshold, rather than the masker level adjustment used here. Finally, each listening interval was preceded by a signal cue in the Wightman *et al.* study. Because of the large differences in method between studies, we decided to run a binaural condition that shared features with both the current experiment 1 and the study of Wightman *et al.* The intent was to examine whether developmental effects for release from informational masking may be relatively pronounced for binaural spatial hearing cues related to interaural intensity differences.

A. Methods

1. Stimuli

In an initial implementation of this experiment, stimuli were identical to those in the MBS condition of experiment 1, with the exception that, whereas the signal was presented to the left ear only, masker components were presented diotically. This was similar to a previous approach by Kidd *et al.* (1994), where a release from informational masking was presumably due to the fact that the signal was lateralized to one ear, and the masker was lateralized to the midline. Our initial data using this method showed masking release that was relatively unreliable, so we modified the approach such that the masker components in the contralateral ear were pre-

sented at a level 10 dB higher than the masker components presented in the ipsilateral ear (masker frequencies and phases were identical). The rationale for this modification was to enhance the difference between the lateralized images of the signal versus the masker. This will be referred to as the *binaural* condition. As pointed out above, this masking release condition was like the MBS condition of experiment 1, except that masker components were presented to both ears. The condition was intended to be akin to the release condition in the Wightman *et al.* (2003) study, in that the masker stimuli were manipulated in such a way as to promote lateralization of the masker to the ear contralateral to the signal.

2. Procedures

The procedures for experiment 2 were identical to those of experiment 1, with the exception that the maximum level of the ipsilateral masker was reduced from 83 dB SPL (experiment 1) to 73 dB SPL.

3. Listeners

Listeners participating in this experiment were demographically quite similar to those participating in experiment 1. All had pure-tone detection thresholds of 20 dB HL or better at octave frequencies from 250 to 8000 Hz (ANSI, 1996), and none had a history of chronic ear disease. There were ten child listeners, ranging in age from 6.1 to 10.2 years, with a mean age of 8.2 years. There were ten adult listeners, ranging in age from 18 to 28 years, with a mean age of 22.3 years. All listeners were paid for their participation and provided data in 1–2 sessions lasting no more than 1 h each. None of the listeners in experiment 2 had previously participated in any psychophysical studies of informational masking, including those performed in experiment 1.

B. Results and discussion

Thresholds for detection in quiet were significantly lower for the adults than for the children by 5.5 dB (t_{18} =2.3; p=0.03). The bottom panel of Fig. 2 plots the masker level at threshold (ipsilateral ear) for the first block of MBS and the binaural block as a function of listener age.

1. Developmental results for informational masking

As in experiment 1, the initial MBS condition was associated with uniformly poor performance for the children (large informational masking), and a range of results among the adult listeners. Masker levels at threshold in the initial MBS baseline condition (see Table I) were higher (better) for the adults than for the children, but the probability value (U=25.5; p=0.06) did not reach statistical significance (α =0.05). As in experiment 1, there was a wide range of adult performance in the MBS condition, allowing identification of adults with baseline informational masking comparable to the child listeners: a subset of 80% of the adults had masker levels at threshold below 40 dB SPL, comparable to those of the typical child listener.

2. Developmental results for release from informational masking

Among the adults, the binaural manipulation improved performance in some of the listeners who had appreciable informational masking in the MBS baseline condition (see the bottom panel of Fig. 2). Children, on the other hand, showed a consistent lack of masking release, with most even showing additional masking in the binaural condition. Overall, the adults showed significantly higher (better) masker levels at threshold in the binaural condition than did the children (see Table I). The Mann-Whitney U nonparametric test indicated that children had significantly lower (poorer) masker levels at threshold than adults in the binaural condition (U=2.0; p<0.001). Paired t-tests were performed to compare the initial MBS and binaural conditions. For the adults, this was performed on the 80% of the listeners who showed baseline informational masking comparable to that for the children (see Fig. 2). The tests showed a significant improvement in performance for the adults (t_7=4.7; p =0.002) and a significant decline in performance for the children (t_9=4.3; p=0.002). We note that, if some of the children had demonstrated a masking release in the binaural condition, we would have tested younger children to explore differential effects of age (the youngest child in this experiment was 6.1 years of age). Among the children tested, there was no significant correlation between age and the amount of increased masking in the binaural condition (r=0.03; df =8; p=0.93).

The present results, where children actually showed a masking increase in the condition designed to result in masking release, contrast with the results of experiment 1 where children typically showed a decrease in masking in the masking release condition. This indicates that the ability of children to take advantage of masking release cues depends strongly upon the type of cue available. The present results indicate that a lateralization cue based upon interaural intensity differences was not utilized well by the children tested here.

In comparing the present binaural results to those of Wightman *et al.* (2003), it might seem incongruous that, whereas some of the children showed masking release in the Wightman *et al.* study, none of the children did so in the present study. It is possible that this difference is related to the overall salience of the cue for masking release in the different paradigms. In the Wightman *et al.* study, it is clear that the masking release cue in the binaural condition was highly salient among the adults, as there was essentially no informational masking among adults in that condition. In the present study, it can be inferred that the masking release cue in the binaural condition was less salient, as some of the adults continued to show substantial masking here. Thus, the failure of any of the children in the present study to show masking release in the binaural condition may be related to the relatively modest salience of the cue for masking release. The results of the present study are in general agreement with the conclusions of Wightman *et al.*, in that children were relatively poor in achieving benefit from the spatial hearing cue.

3. Developmental results related to learning

As in experiment 1, the change in performance in the MBS condition was quantified as the difference in the masker level at threshold between the first and second estimates for MBS condition, and only the subset of adults with thresholds below 40 dB for the first estimate was included. The mean results appear in Table I. Although the change in the MBS threshold was greater for the adults than for the children, the change was not significant for either group ($t_7 = 0.99$; $p = 0.35$ for the children and $Z = -1.54$; $p = 0.12$ for the adults). As with the initial MBS condition, adults had better thresholds than children for the second MBS condition (see Table I), but the difference was not statistically significant (Mann-Whitney $U = 25.0$; $p = 0.06$).

4. Relation between informational masking and threshold in quiet, assessed across experiments 1 and 2

In both of the experiments of this study, it was found that the children had higher thresholds in quiet than the adults. Although not directly related to the main aims of the study, a question of interest is whether there was a relationship between the threshold in quiet and the masker level at threshold in the MBS condition. A *negative* relationship (high threshold in quiet associated with a low masker level at threshold) might be expected on the grounds that a high threshold in quiet will occur for poor listeners, and poor listeners may not be able to tolerate high masker levels in the MBS condition. On the other hand, a *positive* relationship (high threshold in quiet associated with a high masker level at threshold) might be expected on the grounds that a high threshold in quiet will result in the signal being presented at a relatively high SPL in the MBS condition (30 dB SL), therefore requiring a relatively high SPL masker level to mask it. A correlation performed on the data of the children of both experiments (40 children total) supported the latter expectation ($r = 0.61$; df $= 38$; $p < 0.001$). Because children had higher thresholds in quiet than adults, this correlation would suggest a bias toward lower informational masking in the MBS condition for children than adults (the higher thresholds in quiet for the children being associated with higher masker levels at threshold in the MBS condition). Nevertheless, the results of this study showed significantly *more* informational masking in the children than the adults in the MBS condition. This is likely due to the fact that, among adults, interlistener variability in informational masking overshadowed factors related to the threshold in quiet. This is supported by the observation that the correlation between threshold in quiet and the masker level at threshold in the MBS condition was not significant ($r = 0.24$; df $= 28$; $p = 0.20$) among the 30 adults tested in experiments 1 and 2.

IV. GENERAL DISCUSSION

A key strength of the present approach was that we were able to identify subsets of adults who showed informational masking that was comparable to that demonstrated by the children, thereby allowing reasonable tests of potential developmental differences in release from informational mask-

ing. The present results indicated no significant difference between adults and children for informational masking release related to temporal asynchrony (although there were several individual cases in which children did not show masking release here), and indicated significantly smaller masking release in children for cues related to spectro-temporal coherence (although most children achieved substantial masking release here). In general, there were remarkable individual differences in the ability of children to achieve masking release in the monaural conditions examined. These individual differences appeared to be related only poorly to age across the children tested here. The results of the present study indicate that the ability to achieve informational masking release from lateralization cues related to interaural intensity differences may develop relatively late. This result is consistent with previous results from Wightman *et al.* (2003), where children often continued to show considerable informational masking even when the masker was moved to the ear contralateral to the signal. Overall, these results suggest that children have a relatively poor ability to benefit from informational masking release cues that hinge upon the differential lateralizations of the signal and masker. In experiment 2, the binaural cue did not result in release from informational masking in any of the children, but instead resulted in a significant increase in masking in this group. Although the methodologies differed between experiment 2 and the Wightman *et al.* study, both studies used manipulations that would tend to isolate the percepts of the signal and maskers to opposite ears. The manipulation in the present study was less radical than in Wightman *et al.*, where the masker was physically absent from the signal ear in the masking release condition. Taken as a whole, the available results suggest that the development of the use of cues related to informational masking release is highly dependent upon the type of cue under investigation.

As Wightman *et al.* (2003) noted, caution should be used in generalizing results obtained in highly constrained laboratory conditions to more natural listening situations. For example, even though the results obtained to date show poor performance by children on masking release tasks that are associated with sound lateralization (listening via earphones), it is possible that such deficits would not occur in tasks involving sound localization in real environments, where the available cues are more natural than those occurring in highly controlled but unnatural earphone studies. In this regard, it should be kept in mind that a developmental effect associated with a particular type of cue might be related to a multitude factors, one of which is the context in which the cue (monaural or binaural) is presented. For example, in segregating sound sources in real environments, children might be adept in using spatial hearing cues in combination with the other cues that often occur in concert (e.g., cues related to harmonicity and/or onset asynchrony), but may be less efficient than adults when required to use isolated cues for sound segregation in less natural listening conditions.

It should also be cautioned that results indicating late development of the ability to use binaural cues in release from informational masking do not mean that children are

Hall, Buss, and Grose: Informational masking release

generally poor in using binaural cues for masking release, even in the context of highly controlled laboratory experiments. For example, the results of several experiments indicate that children have adult-like masking-level differences (MLDs) (Hirsh, 1948) in a relatively broadband masking noise by age 5–6 years (Hall and Grose, 1990; Grose *et al.*, 1997).

V. CONCLUSIONS

Results of experiment 1 suggest that children aged 4–9 years can make use of monaural cues associated with informational masking release, though at a somewhat reduced level when compared to adults with similar amounts of baseline informational masking. There was some suggestion that the ability to achieve masking release may develop earlier for the cue of temporal asynchrony than for the cue of spectro-temporal coherence. Results from experiment 2 showed that children approximately 6–10 years of age failed to show a masking release (and actually showed increased masking) when interaural level differences were provided that would tend to lateralize the signal and masker to opposite ears. Development of the ability to achieve masking release from informational masking under highly controlled conditions depends strongly upon the kind of cue under study.

Binaural release from informational masking in a speech identification task[a)]

Frederick J. Gallun,[b)] Christine R. Mason, and Gerald Kidd, Jr.
Communication Disorders and Hearing Research Center, Sargent College, Boston University,
635 Commonwealth Avenue, Boston, Massachusetts, 02215

Binaural release from informational masking (IM) was examined in a speech identification task. Target and masker sentences were processed into mutually exclusive frequency bands, thus limiting energetic masking (EM), and presented over headphones. In a baseline condition, both were presented monotically to the same ear (T_mM_m). Despite minimal frequency overlap between target and masker, the presence of the masker resulted in reduced performance, or IM. Presenting the target monotically and the masker diotically (T_mM_0) resulted in a release from IM. Release was also obtained by imposing interaural differences in level (ILDs) and in time (ITDs) on the maskers (T_mM_{ILD}, T_mM_{ITD}). Any masker with a perceived lateral position that differed from that of a truly monaural stimulus resulted in a similar amount of release from IM relative to T_mM_m. For binaural targets and maskers (T_0M_{ILD}, T_0M_{ITD}), release was seen whenever ITDs or ILDs differed between target and masker. These results suggest that binaural cues can be very effective in reducing IM. Because mechanisms based on differences in perceived location make predictions that are similar to those of nonlocation-based binaural mechanisms, a variant of the equalization-cancellation model is also considered. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.1984876]

I. INTRODUCTION

Kidd *et al.* (2005) reported that with stimuli in which the spectral overlap of target and masker was minimized and the binaural parameters fluctuated randomly, a monaural target was identified more easily with a binaural than a monaural masker. This study attempted to systematically examine if perceived location, which was uncontrolled in that study, could have allowed listeners to distinguish between the auditory stimuli. Situations in which performance is governed by the presence of masker energy in the frequency regions occupied by the target (i.e., "energetic masking" or EM) make it difficult to differentiate the role of perceived location from the effects of nonlocation-based mechanisms that result in binaural release from masking (Colburn and Durlach, 1978, pp. 498–501). Using stimuli that fall into distinct auditory filters reduces the likelihood that observed effects can be explained by mechanisms that improve signal-to-noise ratio within a filter. Stimuli that meet these criteria include the spectrally processed speech described in Arbogast *et al.* (2002) and used in Kidd *et al.* (2005). In those studies, the target and masker were sentences comprised of sets of very narrow, mutually exclusive frequency bands, with which target identification performance was substantially reduced relative to the performance obtained with a noise-masker processed to have the same long-term spectrum as the speech. This additional masking has been attributed to "informational" masking (IM).

For the stimuli used in Arbogast *et al.* (2002) and Kidd *et al.* (2005), IM was due largely to listener uncertainty about which sentence was the target. Unlike with a noise masker, the listener was confronted with two very similar sentences, only one of which was the target. Although the talkers speaking the sentences were always different for masker and target, the narrowband processing disrupted fundamental frequency and intonation information. Both of these factors are known to provide important cues that listeners use to segregate natural competing speech (Darwin and Hukin, 2004). The result of the processing, then, was that listeners were forced to rely upon the temporal correlations between bands and timbral differences to group the bands successfully. Faced with this difficulty, listeners were motivated to make use of any additional information available—such as perceived location—to determine which bands corresponded to the target and which to the masker.

In Kidd *et al.* (2005), listeners were asked to report the keywords associated with a target sentence in the presence of a masker sentence processed into mutually exclusive frequency bands (called "different-band speech" or DBS). When both sentences were presented to the same ear, performance declined significantly relative to when no masker was present. The surprising result that motivated the experiments described here occurred when a second noise masker occupying the same bands as the speech masker (but different bands from the target) was added in the opposite (contralateral) ear. The addition of this "different-band noise" (DBN) masker in the contralateral ear *reduced* the amount of observed masking significantly by *increasing* identification performance. This result was unexpected because it is at odds with the assumption that noise in one ear does not energeti-

---

cally mask information in the opposite ear. Nonetheless, these results resembled those obtained when the noise was added to the same ear as the masking speech. Thus the noise "masked the masker" even though it was in the opposite ear. The reason for this is almost certainly that the two maskers, speech in the target ear and noise in the nontarget ear, shared the same narrow frequency bands. This resulted in binaural cues that were fluctuating randomly within each masker band and were uncorrelated between bands. It seems likely that some aspect of this situation resulted in either decreased intelligibility or—the possibility examined in this study—increased separation for the masking speech.

In general, it has been found that adding noise to the contralateral ear has very little effect on speech recognition performance in the ipsilateral ear. Brungart and Simpson (2002), for example, reported that performance was not changed for an ipsilateral speech identification task when a broadband noise was added to the opposite ear. Similarly, Brungart *et al.* (2005) found that when no speech masker was present, adding different-band noise to the contralateral ear produced performance statistically identical to that obtained when no masker was present. In the cases where adding a contralateral masker does have an impact, the finding is that adding a speech masker to the contralateral ear *increases* the amount of masking caused by an ipsilateral speech masker (e.g., Brungart and Simpson, 2002; Brungart *et al.*, 2005). The main difference between broadband and narrowband maskers is that a broadband masker has the same effect on both target and masker, but a narrowband masker has the ability to affect only one. This may explain why a release from masking has not been seen previously when broadband maskers have been added to the contralateral ear.

Kidd *et al.* (2005) suggested that the interaction of the narrowband DBS and DBN stimuli presented to opposite ears may have created a binaural image that allowed listeners to distinguish monaural-only target bands from masker bands on the basis of differences in perceived location. In addition, the combination of DBS and DBN maskers across ears may have reduced the intelligibility of the speech masker by some form of binaural interaction (for example, binaural summation) thus reducing its ability to compete with the target. The purpose of the experiments described in this paper is to examine whether perceived lateralization derived from narrowband binaural interactions is capable of explaining the finding reported by Kidd *et al.* (2005). Two main difficulties with evaluating the role of lateralization in the original study were that (1) the DBN masker may have been interfering with the intelligibility of the speech masker (second possible explanation above) and (2) it is not clear exactly what perceived lateralizations were associated with those stimuli. Because the DBN and DBS maskers were uncorrelated, the interaural differences that were created would have differed among the bands. Furthermore, the main finding occurred for cases where the target was monaural and the masker was either monaural or was binaural, leaving open the possible complication of a monaural versus binaural effect regardless of any differences that occurred in lateral position. The current experiments were intended to evaluate the above-offered lateral

position explanation for the Kidd *et al.* findings while minimizing or controlling for these potentially confounding variables.

II. GENERAL METHODS

The experiments described in this paper were carried out largely simultaneously with the data collected for the experiments described in Kidd *et al.* (2005). The perceived lateralization study (presented as experiment 1) was conducted several months later. The three listeners were the same and the design of the experiments was influenced by the fact that these conditions were introduced as part of a larger group of conditions already in progress.

A. Listeners

Three females, aged 22–25 years, participated in 2 h sessions three to four times each week. All were very familiar with the stimuli through several thousand trials of listening experience prior to the introduction of these conditions. All had audiometric thresholds of 20 dB HL or better in each ear for octave frequencies from 250 to 8000 Hz.

B. Stimuli

The stimuli resembled those of Arbogast *et al.* (2002). Sentences spoken by four male talkers from the coordinate response measure (CRM) corpus of Bolia *et al.* (2000) were used. Each sentence has the structure: "Ready [callsign] go to [color] [number] now." There are eight callsigns, four colors ("white," "red," "green," and "blue") and eight numbers (1–8). Each sentence wave form was digitally preprocessed to restrict the frequency content. Down-sampling from 40 to 20 kHz was followed by a high-frequency emphasis using a first-order high-pass butterworth filter with a cut-off of 1200 Hz. Each wave form was then passed through a bank of fifteen, approximately one-third octave, fourth-order butterworth filters. The filters were evenly spaced on a logarithmic scale from 215 to 4891 Hz with successive center frequencies spaced at a ratio of 1.25, making them approximately one-third of an octave apart as well. Half-wave rectification and low-pass filtering at 50 Hz by a fourth-order butterworth filter extracted the amplitude envelope within each band.

Thus, each wave form was reduced to a set of amplitude envelopes, each corresponding to one of the fifteen frequency bands. Processed sentences were generated by randomly choosing a subset of the fifteen envelopes and using that subset to modulate pure tones with frequencies equal to the center frequencies of the bands, amplitudes of one, and starting phases of zero. Digitally adding the envelope-modulated tones resulted in a sentence with restricted frequency energy and reduced harmonic structure but with temporal content that reflected the original sentence. The processed sentences (when composed of at least six bands and presented at an adequate level) were perfectly intelligible to listeners (see also Brungart *et al.*, 2005) with only a few minutes of exposure—although this is probably due in part to the closed-set nature of the task. After preprocessing, the sentences were up-sampled to 50 kHz, scaled to equal rms amplitude, and saved to disk for later presentation.

Processed sentences were presented via a Tucker-Davis Technologies (TDT) System II hardware array. The digital to analog conversion was at 50 kHz with 16 bits amplitude quantization and all signals were low-pass filtered at 7.5 kHz. The attenuation and signal routing as well as the relative timing of the signals were varied across conditions and are discussed in the following. Stimuli were presented to the listener over TDH-50 headphones in a double-walled sound-attenuating (IAC) booth.

III. EXPERIMENT 1: PERCEIVED LATERAL POSITION

In order to examine whether increasing masker lateralization can cause release from informational masking, it was first important to show that variations in interaural parameters resulted in changes in perceived lateralization for these listeners with these stimuli. Consequently, an experiment was conducted in which listeners were not required to identify the sentences, but simply to rate their lateral positions.

A. Methods

On all trials, the stimulus was a sentence from the CRM corpus processed into six narrow frequency bands using the method described earlier (Sec. II B). In the first experiment, the sentence was presented to the right ear at 50, 60, or 70 dB SPL and the sentence in the left ear was either (1) not present (monaural presentation), (2) presented at a different level from the sentence at the right ear [interaural differences in level (ILD) condition], or (3) presented at the same level as the sentence at the right ear but either advanced or delayed in time relative to the onset of the sentence in the right ear [interaural differences in time (ITD) condition].

For the ILD trials, the left-ear sentence was presented at levels that varied in 10 dB steps from 30 to 70 dB SPL. To calculate the ILD created for a given combination, the level at the left ear (L_L) is subtracted from the level at the right ear (L_R). A positive ILD denotes a situation in which the ILD favors the right ear (L_R exceeds L_L), while a "negative" ILD indicates that L_L exceeds L_R.

For the ITD trials, onset and ongoing ITDs were created by delaying the onset of one of the sentences (left or right) by either 300 or 600 μs. To calculate ITD, the onset time for the left-ear sentence (T_L) is subtracted from the masker onset time for the right-ear sentence (T_R). In cases where the right-ear sentence was delayed, T_L exceeded T_R and the ITD was negative. The ITD values used were 600, 300, 0, −300, and −600 μs.

On 80% of the trials, the speech was binaural. On the remaining trials, the speech was monaural at the right ear. Listeners reported the perceived lateralization of a sound source on a rating scale—a method similar to that of Sayers and Toole (1964). After listening to each sentence, listeners rated the location on a nine-point scale. A midline location was to be indicated with a rating of five, all the way to the left with a rating of one and all the way to the right with nine. No feedback was given and listeners were not informed of the relative likelihoods of monaural and binaural sentences. The precise distribution was random and each listener completed 15 blocks of 50 trials each. Due to the truly ran-
FIG. 1. Average ratings associated with the perceived interaural locations of the stimuli presented in experiment 1. The top panel indicates the ratings associated with ILDs and the bottom those associated with ITDs. Error bars indicate ± one standard deviation around the mean rating.

dom design, the actual numbers of each sentence type were not equal, but this method did result in at least 15 ratings of each combination of interaural parameters for each listener. The monaural signals were rated at least 75 times by each listener.

B. Results

The top panel of Fig. 1 shows the average ILD ratings and the bottom panel the average ITD ratings. The bars on the far right of each panel show the ratings for monaural stimuli. Both data sets show a monotonic increase in ratings that occurs for all subjects for both ILDs and ITDs. The effect of ILD on listener ratings was examined by a two-way ANOVA on masker level at the right and left ears. The effect of level at the right ear was significant [$F_{(2,4)}=51.097$, $p=0.001$] as was level at the left [$F_{(4,8)}=85.939$, $p<0.001$]. The lack of a significant interaction [$F_{(8,16)}=1.929$, $p=0.125$] shows that as the level at one ear increased, the effect of the relative level was not changed. This confirms the use of ILD as a measure of lateralization independent of level at either ear. A two-way ANOVA on masker level and ITD showed no significant effect of level [$F_{(2,4)}=0.544$, $p=0.588$], but a significant effect of ITD [$F_{(4,8)}=27.414$, $p<0.001$]. This confirms that although the range of ratings was smaller than for ILD, the various ITDs were in fact perceived as different.

Regardless of level at the left ear, ILDs between −20 and 20 dB were rated in a manner significantly different from monaural ($p<0.05$) but 30 and 40 dB were not ($p>0.10$). All of the mean ratings at the various ITDs were statistically different ($p<0.01$) from the monaural ratings. Thus, listen-

ers rated all of the ITDs as producing perceptions that differ in laterality from a monaural stimulus, but only stimuli with ILDs of greater than 20 dB are rated as occupying a lateral position similar to that of a monaural stimulus. These results are in accordance with those of Hafter and Kimball (1980), who found that the ability to discriminate a large ILD from a truly monaural signal declines to chance once the ILD exceeds 45 dB. The second set of comparisons involving the ILDs and ITDs used in experiment 3 found that 10 and 20 dB ILDs were rated as different from 0 dB ($p < 0.05$), but that while 600 μs was different from 0 μs ($p < 0.05$), 300 μs was not ($p = 0.07$).

C. Trading ratios

One method of calculating the amount of ILD needed to produce the same lateralization as a given ITD (and vice versa) is by presenting a signal lateralized with one cue (ITD or ILD) and asking listeners to point to the location of the signal with an acoustic pointer that is moved by varying the other cue. The values found with this method tend to fall between 20 and 50 μs/dB [reviewed, along with methods that give divergent results, in Hafter and Jeffress (1968)]. The rating responses from the first experiment can also be used to establish a rough estimate of the "trading ratio" between interaural differences in level and in time. Since ratings of lateral position were assigned to all of the ITDs and ILDs using the same scale, the trading ratio was calculated by performing three linear regressions: first on the ratings of ILD and the ILDs presented, second on the ITD ratings and the ITDs presented, and third, between the predictions generated by the first two functions. This allowed an estimate of which ILD and ITD values result in the same rating of lateral position. For these listeners and these stimuli and equipment, the rating data produced a fairly large tradeoff between ITD and ILD: 47.6, 32.1, and 36 μs/dB for L1, L2 and L3, respectively. The mean was 38.6 μs/dB. In addition, the values associated with a rating of five (midline) were displaced from zero for the three listeners by 103.2, −67.3, and −139.7 μs, respectively. This corresponds to values of 2 to 4 dB in ILD, according to the trading ratios. While large, these values are not outside the expected range, especially given the fact that no ITDs were presented between 0 and 300 μs and no ILDs were presented between 0 and 10 dB. Given this very coarse sampling of interaural differences, the trading ratios obtained seem quite reasonable. Most significantly for interpreting the data from experiments 2 and 3, it can be seen from these values that the maximum ITDs employed, −600 and 600 μs, cover a range of roughly −20 to 20 dB in ILD.

IV. EXPERIMENT 2: IDENTIFICATION, TARGET MONAURAL

The second experiment was designed to examine the ways in which listeners make use of interaural differences in the masker to improve performance on an IM task where the target is monaural. In particular, the goal was to examine whether release from IM can be predicted from the ratings of lateral position obtained in experiment 1.
FIG. 2. Example of the magnitude spectra of target (grey) and masker (black).

A. Methods

The task was single-interval forced-choice closed-set speech identification using processed versions of the coordinate response measure (CRM) corpus of spoken sentences (Bolia *et al.*, 2000). Each trial involved presentation of two sentences: a "target" (identified by the presence of the callsign "Baron") and a "masker." Each unprocessed target sentence was first paired with a random masker sentence seven times, resulting in a total of 896 target-masker pairs. Target-masker pairs were constrained to differ on talker, callsign, color, and number. Each sentence was then processed into a collection of randomly chosen narrowband signals using the method described in Sec. II B. In order to ensure that the frequency bands comprising the target and the masker were mutually exclusive, eight target bands were randomly chosen and then six of the remaining seven bands were assigned to the masker. Target and masker-sentence lengths were not equalized. An example of the frequency content of a target and masker pair appears in Fig. 2. It can be seen that the target sentence (grey) and the masker sentence (black) each contain mutually exclusive bands and that the peaks are well separated. For most combinations of bands, the masker was at least 40 dB lower than the target at the center frequency of the target band and was always at least 20 dB lower.

On each trial, the listener was presented with a single target-masker pair and was instructed to report the color and number keywords associated with the target, designated by the presence of the callsign "Baron." In the masker sentence, any of the other callsigns could appear. The four talkers, four colors, and eight numbers resulted in 128 unique target sentences. After stimulus presentation, the listener made two responses, one indicating the color and the other the number associated with the target sentence. The first response (color) had four alternatives and the second response (number) had eight. Response was via a keyboard with the numbers and color names labeled on the keys. Feedback was given via an LCD screen.

Three conditions were tested. In the first condition, the monaural 60 dB SPL target was added to a monaural masker that could be at one of three levels: 50, 60, or 70 dB SPL. This resulted in three T/M ratios at the target ear ("ipsilateral" T/M values): 10, 0, and −10 dB, respectively. Adapting terminology from the binaural masking literature, this condi-

tion is referred to as T_mM_m: target monotic, masker monotic. The second condition, T_mM_α, consisted of presenting the masker sentence to both the right (target or ipsilateral) and left (contralateral) ears with an interaural level difference (ILD). The target sentence was always presented monaurally at 60 dB SPL to the right ear and the masker at the ipsilateral ear was set to 50, 60, or 70 dB SPL. The ILDs were constructed in the same manner as for experiment 1. The range of ILDs was from −20 to 40 dB, although the range was smaller for each ipsilateral T/M due to the constraint that the masker in the contralateral ear would take on the same set of values (30–70 dB SPL) regardless of masker level at the target ear. In the third experimental condition, T_mM_τ, masker ITD was investigated. A target was presented to the right ear at 60 dB SPL while the masker was presented to both ears with no ILD (the masker was presented to the two ears at 50, 60, or 70 dB for any given trial). ITDs were created in the same manner as for experiment 1. Again, the ITD values used were 600, 300, 0, −300, and −600 μs. The levels for each condition were presented randomly within a block of 50 trials. Blocks were generally repeated until a minimum of 100 trials had been obtained at every combination of levels for each listener.

B. Results

The condition in which target and masker were both monaural, T_mM_m, was the same as that reported in Kidd *et al.* (2005), but additional data were collected in order to ensure that improvements were not due to learning effects. A comparison of the first half of the data with the second showed no significant effects. The data were combined to improve the estimates of baseline performance. This led to a greater number of trials for the monaural conditions (∼400 points per listener). For each masker level in each condition, proportion correct was calculated for each listener by dividing the number of trials on which a listener was correct (correctly reported both the color and number of the target sentence) by the total number of trials at that masker level for that condition. ANOVAs were conducted on these "proportion correct" data.[1] The data presented as T_mM_m are the same as those reported in Kidd *et al.* (2005). The individual data for all three listeners for the ILD condition (T_mM_α) are plotted in the successive panels of Fig. 3. Each listener occupies one row of panels and the columns of panels indicate the level of the ipsilateral masker (50, 60, or 70 dB). The solid horizontal line in each panel indicates performance in the baseline condition T_mM_m. By comparing the solid lines across rows in Fig. 3 it can be seen that decreases in T/M in the target ear are associated with decreases in performance, despite the nonoverlapping target/masker bands. The solid lines are included in this and later figures as a monaural masker baseline reference: Any points that are higher than this baseline indicate release from masking due to the presence of a contralateral masker.

The first dichotic condition, T_mM_α, involved a monaural target sentence and a binaural masker sentence. Figure 3 summarizes the effect of changing ILD, the level of which is shown in decibels (dB) along the abscissa for each panel. A
FIG. 3. Proportion correct in the masker ILD condition of experiment 2. Each row of panels contains the results for a single listener and each column contains those for a given T/M. The solid lines represent performance when the masker was presented only at the target ear and the symbols represent performance when the same masking sentence was also presented at the contralateral ear. The range of ILDs varies for the three T/M values because ILD was dependent upon the relationship between the masker levels at the two ears and the range of masker levels at the contralateral ear was always 30–70 dB (see the text).

two-way repeated-measures ANOVA found significant main effects of both ipsilateral masker level [$F_{(2,4)}=19.10$, $p<0.01$] and contralateral masker level [$F_{(4,8)}=24.27$, $p<0.01$]. The interaction was also significant [$F_{(8,16)}=5.50$, $p<0.01$]. These results show that for a monaural target, it is the ILD that matters, and not just the T/M in the target ear. As can be seen in Fig. 3, both increasing ipsilateral masker level and decreasing contralateral masker level (expressed as increasing ILD) were associated with decreasing performance. The interaction occurred because higher ipsilateral masker levels caused increasing ILD to have a larger impact on performance. Correlations were calculated between the performance values obtained with a 70 dB SPL ipsilateral masker and the mean ratings associated with ILD from experiment 1. The correlations were negative, indicating that for increasing ILDs, ratings increased and performance decreased. The values were −0.753, −0.946, and −0.962 for the listeners L1, L2, and L3. The variation in mean ratings accounted for 79% of the variance in performance (R^2 averaged across the three listeners).

The second dichotic condition, T_mM_τ, explored the effect of masker ITD in the presence of a monaural target. The individual data for all three listeners are plotted in the successive panels of Fig. 4. As in Fig. 3, each listener occupies one row of panels and the columns indicate the level of the dichotic masker (50, 60, or 70 dB in both ears). Again, the solid line in each panel indicates the effect of a monaural masker at that level and points that fall above the line indicate an improvement relative to baseline. The symbols in this case indicate what occurs when the masker is binaural, with

Gallun *et al.*: Binaural release from informational masking
FIG. 4. Proportion correct for the masker ITD condition in experiment 2. Each row of panels contains the results for a single listener and each column contains those for a given T/M. Solid lines indicate performance when only the masker at the target ear was presented and symbols when a masker was presented at both ears at the same level. The ITD values indicate the interaural delay (in microseconds) for the masker. Positive ITDs indicate that the ipsilateral masker led.

the ITD values plotted along the abscissa. Each panel in Fig. 4 indicates that there was substantial release from masking for all of the ITD values used in the study and that, unlike with ILD, changes in masker ITD had essentially no systematic effect. For all three listeners at all three masker levels, the function is somewhat irregular and essentially independent of ITD. Although increasing ITD led to a shift in perceived masker location towards that of the monaural target (see Fig. 2), and the effect of ITD on perceived lateralization was significant in experiment 1, identification performance was largely unaffected. A two-way repeated-measures ANOVA conducted on T/M at the target ear and ITD found a reliable effect of T/M [$F_{(2,4)}=61.93$, $p<0.01$], but no effect of ITD [$F_{(4,8)}=0.78$, $p=0.569$]. Unlike T_mM_α, ceiling performance at a masker level of 50 dB SPL did not cause an interaction because performance was essentially independent of ITD at all levels. Another difference from T_mM_α is that correlations between performance and mean lateral position rating from experiment 1 were very small, accounting for only 4% of the variance in performance for the 70 dB SPL masker (average R^2 across listeners). To summarize, these results indicate that *all* ITDs produced a release from masking and that shifts toward and away from the location of the target (as shown by the results of experiment 1) were not enough to reliably change the amount of release.

By combining the results of the trading ratio analysis (described in Sec. III C) with the results from experiment 2, it can be seen that the amount of release from masking is dependent largely on the lateral position of the masker. Since the lateral positions associated with the ITD manipulations were restricted to values between −20 and 20 dB, it is not surprising that all the amount of release was quite large across all ITD conditions—release was also quite large for ILDs between −20 and 20 dB.

C. Masking release in dB

To compare our result more directly with those of other researchers, the averaged performance data from experiment 2 were used to plot three-point psychometric functions for each ITD and for a subset of the ILDs (0, 10, and 20 dB). These functions relate performance in the various conditions to the T/M at the target ear. The difficulty is that the slopes of the psychometric functions were much steeper for the monaural masking condition than for the binaural conditions. Unequal slopes result in T/M differences that depend heavily on which performance value is used for the comparison. The performance value associated with 2-down, 1-up adaptive tracking (70.7%) results in extremely large estimates of masking release (20–50 dB for the ILDs and 50–120 dB for the ITDs), suggesting that 70.7% would be an inappropriate value. A more reasonable value is 90%, because it requires little or no extrapolation of the functions—each data set contains a value near 90% correct. In order for a function to be included in this analysis, the correlation between predicted and actual performance values was required to exceed 0.85. "Release from masking" expressed in dB was calculated by subtracting the T/M that was associated with 90% performance in the monaural masker condition from the T/M associated with 90% correct in each binaural condition. When this analysis was performed for the ILD functions, 5.2 dB of release was estimated for the 0 dB ILD, 9.6 dB for the 10 dB ILD, and 10.9 for the 20 dB ILD. The other ILD functions (−10, −20, 30, and 40 dB ILDs) had fewer than three points and so accurate psychometric functions could not be estimated. For the ITD functions, the 300 μs ITD function only correlated 0.79 with the actual data and the 0 μs ITD function was nonmonotonic and so only correlated 0.10. Consequently, neither was included. The remaining functions (600, −300, and −600 μs ITDs) resulted in release estimates of 16.1, 21.7, and 24.4 dB, respectively. While large, these are the most conservative estimates possible given this data set.

D. Summary

Experiment 2 found that: (1) with monaural targets, the introduction of binaural maskers resulted in substantial release from masking relative to the monaural maskers (note the large number of points that fall above the horizontal lines in Figs. 3 and 4); (2) the correlations between ratings of lateral position and performance accounted for a large percentage of the variation in performance for the ILD manipulation (when the masker was at 70 dB SPL) but almost none of the variance for the ITD manipulation.

There are two conflicting explanations for these data. The first is that differences in lateral position *do* increase the ability of listeners to distinguish between target and masker bands, but that the lateral position associated with the monaural target was substantially different from the positions associated with all of the ITD values and the majority of the ILD values. This is supported by the finding that all of the

lateral position ratings obtained for the ITDs in experiment 1 were statistically different from the monaural ratings. This was also true for many of the ILD values and the few that had similar location ratings to the monaural stimulus accounted for the only reduced performance found in experiment 2.

The second explanation is that differences in lateral position are not useful *per se*, but rather that the ILD values that caused reductions in performance resulted in percepts that were not perceived as binaural. This argument asserts that the majority of the maskers were perceived as binaural and that the very salient difference between a binaural masker and a monaural target was responsible for the improved performance at all of the ITD and the majority of the ILD values. Experiment 3 was designed to gather evidence on the specific question of whether a binaural/monaural difference is required to obtain the high levels of performance seen in experiment 2.

V. EXPERIMENT 3: IDENTIFICATION, TARGET DIOTIC

It is possible that the results from the second experiment depend heavily on the fact that the target was monaural and the maskers binaural. In this experiment, the target and masker were both binaural, allowing a test of whether differences in T/M, ITD, and ILD are all effective at causing a release from masking. This situation is much more similar to real-world listening conditions in which all targets and maskers are usually binaural. Experiment 3 serves as a test of the hypothesis that while a perceptible monaural/binaural difference is sufficient to produce maximal release from masking, it may not be necessary

A. Methods

The target and masker sentences were drawn from the same pool of processed sentences as were used in experiment 2. The task and response method were also identical. The primary difference in experiment 3 was that the target was no longer presented monaurally. In the first condition, T_0M_α, the target was presented diotically (same level at both ears with no interaural delay) at 60 dB and the masker was presented to both ears with an average level of 50, 60, or 70 dB across the two ears. There was no ITD on target or masker in the ILD condition, T_0M_α. Three ILDs were created at each nominal masker level: 0, 10, and 20 dB. For the 0 dB ILD, the masker sentence was at the same level in both ears. When a 10 or 20 dB ILD was imposed, however, the masker level at the left ear was raised and the level at the right ear was lowered. Thus, for an average masker level of 60 dB and a 20 dB ILD, the left ear would receive the masker sentence at 70 dB and the right ear would receive the same sentence at 50 dB. Hence the T/M was different at the two ears. All three average masker levels and all three ILDs were presented in random order on every block of ILD trials. Each listener participated in an average of 100 trials at each combination of average masker level and ILD.

For experiment 3, the target was presented to both ears, so ILDs had to be constructed in order to minimize the mismatch between the T/M at the two ears. To produce average

T/M's of -10, 0, and 10 dB and ILDs of 0, 10, and 20 dB, on successive trials the masker at the left ear was presented at levels ranging between 45 and 70 dB (in 5 dB steps) and the masker at the right ear at levels between 55 and 80 dB, also in 5 dB steps. Thus, an average T/M of -10 dB and an ILD of 20 dB was created by presenting the left masker at 60 dB and the right masker at 80 dB. This also created a subset of conditions that allow ILDs to be examined with T/M held constant at one ear.

For the second condition, T_0M_τ, varying ITD, the target was presented as described earlier and the masker was presented to both ears with no ILD (both maskers were presented at 50, 60, or 70 dB SPL for any given trial), hence the same T/M of -10, 0, or 10 dB was present at both ears. The difference between the maskers was created by adding a delay of 300 or 600 μs to the beginning of the masker presented to the right ear. This meant that the masker sentence in the left ear started playing before the one in the right, producing both an onset and an ongoing ITD (as well as an offset ITD). The ITD values tested were 600, 300, and 0 μs relative to the target sentence. All three masker levels and all three ITDs were presented in random order on every block of ITD trials. Each listener participated in an average of 100 trials at each combination of masker level and ITD.

The results of experiment 1 suggested that maskers with these ILDs and ITDs were experienced at a variety of interaural locations and that maskers with ILDs of 10 and 20 dB were rated in a manner statistically different from those with 0 dB ILDs. Ratings of maskers with 600 μs ITDs were statistically different from ratings of those with 0 μs ITDs, but those with 300 μs ITDs were not. This difference seems to have been due to the increased variability of the ratings of masker with ITDs relative to those with ILDs and could perhaps have been overcome with the collection of more data.

B. Results

The masking data will be described as in the second experiment. "Proportion correct" refers to the proportion of the total trials at any one combination of parameters for which both the color and number of the target sentence were correctly reported by a given listener. Figure 5, the results of the T_0M_α condition, shows the effect on performance of introducing a difference in level in the speech masker presented to the two ears when the target sentence was presented diotically. The individual data for all three listeners are plotted in successive panels along each row and the columns of panels indicate the level of the masker. Masker ILD is plotted along the abscissa of each panel, with the 0 dB value corresponding to the case in which there was no interaural difference in masker level (T_0M_0). Performance in T_0M_0 (indicated by the dashed line as well as the leftmost point in each panel) serves as a baseline for the other two ILD values. It also serves as a comparison with T_mM_m (indicated by the solid line in each panel), both of which, it seems reasonable to assume, would lead to identical performance. As can be seen, this was generally the case. The exceptions are discussed in Sec. V C. The question that motivated this portion of the experiment was whether or not masker ILD
FIG. 5. Proportion correct as a function of masker ILD for the diotic targets in experiment 3. Each row of panels contains the results for a single listener and each column contains those for a given T/M. The solid lines show performance when both target and masker were monaural. The symbol at a masker ILD of 0 (as well as the dashed line) indicates that both target and masker were diotic. The remaining symbols indicate the result of lowering the level at one ear and raising it at the other to produce ILDs of 10 or 20 dB.

FIG. 6. Proportion correct for the ITD condition in experiment 3. Each row of panels contains the results for a single listener and each column contains those for a given T/M. The solid lines show performance when both target and masker were monaural. The symbol at a masker ITD of 0 (as well as the dashed line) indicates that both target and masker were diotic. The remaining symbols indicate the result of delaying the onset of the masker at one ear in order to produce onset and ongoing masker ITDs of 300 or 600 μs.

supports a release from masking when the target is also binaural. Focusing again on the condition where performance is least influenced by ceiling effects (average T/M of -10 dB) shows that average proportion correct performance in T_0M_0 was 0.73. Creating a 10 dB ILD in the masker increased performance to 0.92 and a 20 dB ILD increased it to 0.95. A repeated measures two-way ANOVA confirmed the effects of T/M [$F_{(2,4)}=15.14$, $p<0.05$] and ILD ($F_{(2,4)}=19.32$, $p<0.01$). The interaction of the two factors was also reliable [$F_{(4,8)}=22.66$, $p<0.01$]. As in experiment 2, the interaction was due to the near ceiling performance found at large T/M values. Correlations between lateral position ratings and performance for the -10 dB T/M data were 0.998, 0.994, and 0.836 for L1, L2, and L3, respectively. Thus lateral position can account for 90% of the variance in performance (average R^2 across listeners).

Figure 6 shows the performance values obtained for each of the three listeners in the T_0M_τ condition, in which the target was diotic and various ITDs were imposed upon the masker. Each listener's data are confined to a single row and the columns contain all of the data associated with a given masker level (50, 60, or 70 dB). As with the 0 dB masker ILD, the 0 μs masker ITD, T_0M_0 (indicated by the dashed line as well as the leftmost point in each panel) serves as a baseline for the other two ITD values. A comparison between T_mM_m (indicated by the solid line in each panel) and T_0M_0 shows that, as in the ILD conditions, there are a number of panels in which diotic performance is better than monaural, primarily for the T/M of -10 dB (see the discussion in Sec. V C for more on this point). As with ILD, there was substantial release associated with the imposition of masker ITD, indicated by points that fall above the horizontal lines.

In the majority of panels, the improvement for a 300 or 600 μs ITD is obvious relative to the 0 μs condition. Those not showing improvement typically have near ceiling performance in T_0M_0. A repeated-measures two-way ANOVA confirmed the effect of T/M [$F_{(2,4)}=15.81$, $p<0.05$] and ITD [$F_{(2,4)}=9.53$, $p<0.05$]. The interaction of the two factors was not reliable in this condition [$F_{(4,8)}=2.06$, $p=0.178$]. Correlations calculated between lateral position ratings and performance in the -10 dB T/M condition were 0.671, 0.654, and 0.954 for L1, L2, and L3, respectively, thus accounting for 60% of the variance in performance (average R^2 across listeners).

C. Masking release in dB

Using the same method as in experiment 2, an estimate of the amount of masking release in dB was obtained by fitting curves to the psychometric functions for the T_0M_0 conditions and then subtracting the T/M associated with 90% correct on those functions from the T/M associated with 90% correct on the functions associated with the dichotic conditions. For these functions, the correlations were required to exceed 0.85. Only the correlation for the 300 μs ITD function, which was nonmonotonic, failed this test. The amount of release estimated from this difference was 27.7 dB for the 10 dB ILD and 73.5 dB for the 20 dB ILD condition. The estimate of release associated with the 600 μs ITD condition was 21.6 dB. Clearly, these estimates are made unreliable by the large differences in the slope of the functions associated with diotic and dichotic maskers. Nonetheless, it is also the case that these values are no less than the values found by Arbogast et al. (2002) and they give an approximate idea of the size of the effects expressed in dB. For a

more precise assessment, performance should be held constant while masker level is varied or, equivalently, complete psychometric functions should be obtained for all conditions.

D. Better-ear advantage

In comparing binaural to monaural masking, it is important to consider the "better-ear advantage" (Bronkhorst and Plomp, 1988). If a binaural masking situation is such that the T/M at one ear becomes better than it was in the monaural case, improvements in performance could be a simple result of this improvement in T/M rather than a result of binaural processing or a difference in perceived location. For experiment 2, this was not an issue because the T/M at the target ear was independent of binaural manipulations. For the ILD condition in experiment 3, however, the actual T/M at one of the ears was equal to the diotic T/M for that condition plus half of the ILD imposed. Thus, a 20 dB ILD created both an interaural difference and a change in T/M at one ear by 10 dB relative to the T/M in that ear for T_0M_0. In order to help separate the effect of binaural interactions from the effects of an improved T/M at the better ear, there are several relevant performance values that can be compared. If the T/M at the better ear was the sole determining factor, performance would be unaffected by changing the T/M at the contralateral ear. The average performance across listeners for the case where ILD was 0 dB and T/M at both ears was 0 dB was 0.78. When the better ear T/M was kept at 0 dB and the worse ear was lowered to −20 dB, performance increased to 0.95. This improvement of 0.17 cannot be due to a better-ear advantage because the T/M at the better ear remained the same. It cannot be due to a binaural effect based on a time difference because the ITD was 0 μs in both cases. Consequently, it is concluded that, at least for the stimuli used in this experiment, an ILD alone is capable of improving performance substantially and the effect is not mediated by the T/M at the better ear.

E. Summary

The performance obtained when target and masker were diotic was compared to that obtained when masker ILD and ITD were systematically varied. Substantial improvement was found for all listeners at nearly every combination of masker level and interaural difference. In general, less improvement was obtained when the masker level was 50 dB, probably due to ceiling effects. These results suggest that the release from masking found in experiment 2 was not due entirely to the monaural/binaural comparison between target and masker. Rather, it seems that interaural differences *can* support substantial release from IM. As with the first experiment, there was little difference between the release observed for a 10 and a 20 dB ILD or a 300 and a 600 μs ITD. This is in accordance with the trading ratios obtained in Sec. III C, which suggested that these listeners found these values of ILDs and ITDs to be roughly equivalent in terms of the lateral positions they produce.

VI. DISCUSSION

A. Lateral position and release from masking

The primary question driving these experiments was whether or not listeners can use differences in the perceived lateralization of target and masker to improve their performance on a speech identification task. The use of spectrally nonoverlapping stimuli allowed this question to be addressed in a configuration that substantially reduced the amount of energetic masking. This was important because, as discussed by Durlach and Colburn (1978), if the target and masker fall in the same auditory filters then performance that correlates with differences in perceived location is also the performance predicted by nonlocation-based binaural mechanisms. Despite the lack of EM, the amount of binaural release in this study was anticipated to be high based on similar work by Arbogast *et al.* (2002). That study showed that stimuli processed in this way resulted in substantial release from masking when target and masker each were presented from spatially separated loudspeakers compared to both from the same loudspeaker. In that study the stimuli were presented in a mildly reverberant chamber rather than over headphones, meaning that the ITD and ILD information occurred together naturally and the effect of better-ear T/M could not be ascertained. This study had the advantage that it could examine the effects of ITD and ILD in isolation while controlling for better-ear advantage.

The first experiment showed that ILD and ITD manipulations with these stimuli were sufficient to produce a wide range of lateral position ratings. Statistical tests showed that there were significant effects of ILD and ITD on the lateralization ratings obtained from the listeners. A trading ratio between ITD and ILD was estimated for these stimuli and the average value was 38.6 μs/dB. This suggests that the largest ITD values presented (±600 μs) were equivalent to ILD values of only 20 dB.

The results of experiment 2 showed that listener performance was related to whether or not the masker had a binaural configuration that had been reliably rated as different from the monaural target. The correlations between lateral position ratings and performance were high for the ILD conditions in experiment 2, but not for the ITD conditions (all of which supported good performance). The ambiguity of the relationship between release and perceived location raised the possibility that release might be based on the difference between a monaural target and a binaural masker. The results of the third experiment did not support this interpretation, however. When the target was diotic, the introduction of ILDs and ITDs still produced release from masking and the correlations between performance and lateral position accounted for at least 60% of the variance across all listeners and both manipulations.

B. Mechanisms based on perceived location

These results are concordant with those of Carhart *et al.* (1969), who showed that masker ITDs of 800 μs produced release from speech-on-speech masking with wideband stimuli. In that study, four wideband maskers, two of speech and two of modulated noise, were presented at opposing time

delays with a diotic target. The introduction of these time delays produced release from masking similar to that obtained when all of the maskers had the same (parallel) time delays. This similarity of release poses problems for any mechanism that relies upon a single compensatory time delay for each frequency channel. Since a single delay would only compensate for one of the two sets of maskers, the authors argue that such a mechanism cannot completely explain the results. Instead, they suggest that release from masking based on signal location acts in parallel with binaural unmasking based on interaural compensation.

There is conflict between our results and those of Culling and Summerfield (1995), however. The stimuli in that study were four noise bursts with narrow bandwidths and different center frequencies that listeners were taught to identify based on their similarity to vowel spectra. If only two were presented, a recognizable vowel was perceived, but if all four were presented at the same level, vowel identification was at chance. Introducing a 390 μs ITD into one pair did not improve performance, but presenting one pair monaurally did cause improvement. This result is in conflict with those of experiment 3 in which a 300 μs ITD was effective in changing the amount of masking obtained relative to the T_0M_0 condition.

Darwin and Hukin (1999) proposed a solution to this apparent contradiction, based on a difference they had observed between segregating one time-varying signal from another (target-word identification) and segregating the steady portions of a complex stimulus (segregating a harmonic from a vowel). While the identification task showed an effect of ITD, the task of segregating a harmonic did not. They suggested that the harmonic was grouped with the other vowel components on the basis of grouping factors such as harmonicity and common-onset and that the ITD of the grouped object was assigned later by a weighted averaging of ITD across its frequency components. The target word, on the other hand, was grouped as a separate object from the remainder of the sentence and thus a difference in ITD between the target and the sentence was able to serve as a cue for tracking one object among others.

The arguments of Darwin and Hukin (1999) could be applied to this study if we assume that listeners used interaural differences to focus attention on the target instead of the masker. This would imply that both sentences were available for processing (consistent with reports of typical error patterns; e.g., Brungart and Simpson, 2002; Arbogast et al., 2002), but that the listeners used interaural differences to track the information in the target and ignore the masker. Evidence that a successful grouping of the frequency components is possible when the target and masker are both presented monaurally is supported by the fact that listeners performed the task at above-chance levels in the T_mM_m condition. Cues that listeners could have been using monaurally included correlations between component envelopes (of which common-onset is an example) as well as "goodness-of-fit" tests on various band combinations, perhaps based on the fact that the target bands were constrained to produce the callsign "Baron" as the second word of the sentence. Once the bands have been successfully grouped, the main diffi-

culty facing the listener is to track the proper sentence. For the monaural case, the only cue that identifies the target sentence is the set of bands that were associated with the word "Baron." Once the callsigns have been uttered, the listener must combat uncertainty about which sentence to track by focusing attention only on the target bands. When there is an interaural difference between target and masker, however, an additional cue is available for tracking the target sentence, an operation that Darwin and Hukin (1999) describe as selective attention.

C. Mechanisms based on cancellation

An alternative argument is that performance is improved by a binaural cancellation operation conceptually similar to the equalization-cancellation (E-C) mechanism (Durlach, 1963; also discussion of "Listener-Min" in Durlach et al., 2003) that acts on the masker bands only, leaving the target bands unaffected. According to this explanation, initial grouping still occurs on the basis of monaural cues as described earlier, but once the masker bands are identified they are cancelled and thus removed. For the stimuli in experiment 2, all masker combinations were binaural and all targets were monaural, so if all the binaural bands could be equalized and cancelled the resulting stimulus would—ideally—contain only the target. While this usage of the E-C model is different from how it has been traditionally considered, it is in accordance with the basic "nulling" analogy from radar operations that was referenced from the earliest discussions of the model (e.g., Durlach, 1963). In most cases, the E-C model has been used to explain how binaural manipulations could lead to reductions in the effectiveness of a masker overlapping the frequencies of the target, a situation in which the sizes of differences between the interaural parameters of the target and masker correlate with the reduction in effectiveness. For these stimuli, neither the predictions nor the results follow this pattern. As long as the binaural masker bands can be successfully identified (and the mechanism can select the equalization parameters for just the masker bands), the masker may be "cancelled." This could explain why changes in the interaural parameters had so little effect on the amount of release obtained.

The only case where there seemed to be a relationship between ILD and binaural release was when the target was monaural and the ILD was so great that the ratings of lateral position were not significantly different from monaural. In this case, the system was unable to generate a release from masking. This limit is actually in agreement with data on release from masking with broadband binaural noise maskers and monaural tonal targets (reviewed in Durlach and Colburn, 1978). In that case, it has been found that although release does occur based on the noise ILD, the amount of release declines with increasing ILD. The limit seems to be similar to that seen in experiment 2—roughly 30 dB. If, as this suggests, the level-equalization simply has a limited range, then it is perhaps the case that the masker can only be completely equalized when the difference between the ears falls within that range. In fact, Breebaart et al. (2001) have modeled these data and suggest that, with noise maskers,

large ILDs lead to a decorrelation at the two ears. The mechanism is based on peripheral nonlinearities and the suggestion is that the level adjustment alone is no longer sufficient to match the noise at the two ears.[2] If such a mechanism were to operate for stimuli such as those employed in this study, this would allow an E-C approach to explain the ILD data from experiment 2 as well.

Recent work by Akeroyd (2004) examined the central question of whether or not the band parameters can be selected independently, allowing (in our case) cancellation of only the masker. The stimuli were multiple-component signals in wideband noise that was interaurally 180° out of phase from each signal component. In the baseline condition, the noise had no interaural-phase difference (IPD) applied to it (and thus ITD was constant across frequency), while the signal components were each 180° out of phase at the two ears. Applying a constant equalization parameter to these signals would result in optimal cancellation of the noise. The test conditions involved noise that also had a constant IPD, still 180° out of phase from the signal components. In those cases, a single equalization parameter would not permit optimal cancellation of the noise. Nonetheless, the test conditions had thresholds indistinguishable from baseline performance, supporting a version of the E-C model in which the equalization and cancellation process selects equalization parameters independently in each band. This is also the conclusion reached by Edmonds and Culling (2005).

D. The diotic advantage

One aspect of the data that is not captured by either an E-C mechanism or an attentional explanation is the consistent finding that presenting target and masker to both ears results in better performance than presenting them to only one ear. Improvement due to diotic presentation is not the usual pattern of results, but it does occur (Langhans and Kohlrausch, 1992). Several of the factors that tend to result in a diotic improvement were present in this study: a cross-frequency analysis was required and the target had limited spectral overlap with the masker. It is possible that the two ears allow two independent samples to be taken of the stimuli, thus reducing the variability of the estimated signal parameter (as suggested by Zwicker and Henning, 1985 and by Schooneveldt and Moore, 1989). Additionally, as suggested by Langhans and Kohlrausch, interactions between the left and right hearing pathways could be responsible for an increased sensitivity in binaural but not monaural conditions. Another of their suggestions, that the headphones were not actually equivalent, was eliminated by a series of acoustical measurements. None of this explains why a difference should occur primarily for the −10 dB T/M (see Figs. 5 and 6).

E. Better-ear listening

These conditions allowed us to test the hypothesis, initially proposed by Bronkhorst and Plomp (1988), that the effects of interaural level differences can be completely described as better-ear listening. While this describes their data quite well (and that of Hawley *et al.*, 2004), if the only effect of ILD is to change the T/M at the better ear, then for the ILD conditions in experiment 2 of this study there should have been no effect of ILD. This is because T/M at the better ear was held constant as ILD was manipulated. As is clear in Fig. 3, however, ILDs clearly lead to improvements despite the constant T/M at the "better" ear. Further support comes from Shinn-Cunningham *et al.* (2005), who showed that, with stimuli very similar to those used in this study, the improvements in performance obtained by separating the source locations of target and masker contained a large component related to differences in perceived location. In addition, these differences could be obtained by introducing variations in just ILD or just ITD. In fact, combining ILD and ITD information produced no greater release from masking.

The conclusion from the Shinn-Cunningham *et al.* (2005) study as well as from this one is that, for IM, the traditional models of spatial unmasking may encourage researchers to focus on the wrong mechanisms. Since there is relatively little masker energy in the target bands for these stimuli, the decorrelation caused by introducing a target and the effect of improved T/M at one ear may be fairly unimportant compared to traditional binaural conditions in which target and masker occupy the same frequency regions. This parallels the conclusion of Carhart *et al.* (1969) that binaural mechanisms that ignore perceived location may be missing an important part of the explanation for why interaural differences improve performance. It is important to also consider the differences in perceived location that serve to enhance the segregation of two very similar sentences, one of which is the target and the other of which is the masker.

F. Summary

This study found that for a monaural target masker ILDs and ITDs that favored the target ear were just as effective as cues that favored the opposite ear—so long as the lateral positions were rated as significantly different. This is in accord with the data that directly inspired this study, in which a binaural interaction with no long-term correlation between the ears still supported substantial release from IM. The results of experiment 2 can be summarized by the statement that when a sufficiently intense masker is perceived as occupying a lateral position different from that of a monaural stimulus, listeners somehow exploit the pairing of a monaural target with a binaural masker to overcome IM. The third experiment showed that the result is not entirely dependent on distinguishing a binaural masker from a monaural target, however. Substantial release due to the presence of ILDs and ITDs was obtained when the target and masker were both binaural. Two mechanisms were proposed to explain the data. According to the first mechanism, listeners use the perceptual differences arising from the binaural/monaural comparison and/or the differences in perceived location to maintain their attention on the target sentence and thus report the correct words. In the second mechanism, listeners actively suppress the activity caused by the masker by relying on an equalization-cancellation mechanism similar to that suggested by Durlach (1963).

[1]It has been argued that a rationalized arcsine transform should be applied to proportion correct data prior to statistical analyses in order to normalize the data (see Studebaker, 1985). For this experiment and for the data in experiment 3, this transformation was performed and the statistical analyses were repeated. There were no differences in the results. In particular, the differences between conditions at T/M values of 10 dB, where performance approached ceiling values, were still not statistically reliable. As the results did not vary from those for the untransformed data, proportion correct is reported throughout for ease of interpretation.

[2]The applicability of the Breebaart *et al.* (2001) model to our data was suggested by Dr. Armin Kohlrausch, to whom we are grateful.

Measures of extents of laterality for high-frequency "transposed" stimuli under conditions of binaural interference

Leslie R. Bernstein and Constantine Trahiotis
Department of Neuroscience and Department of Surgery (Otolaryngology),
University of Connecticut Health Center, Farmington, Connecticut 06030

Our purpose in this study was to determine whether across-frequency binaural interference would occur if ITD-based extents of laterality were measured using high-frequency transposed stimuli as targets. The results of an earlier study [L. R. Bernstein and C. Trahiotis, J. Acoust. Soc. Am. **116**, 3062–3069 (2004)], which focused on threshold-ITDs, rather than extents of laterality, suggested that high-frequency transposed stimuli might be "immune" to binaural interference effects resulting from the addition of a spectrally remote, low-frequency interferer. In contrast to the earlier findings, the data from this study indicate that high-frequency transposed targets are susceptible to binaural interference. Nevertheless, high-frequency transposed targets, even when presented along with an interferer, yielded greater extents of ITD-based laterality than did high-frequency Gaussian noise targets presented in isolation. That is, the "enhanced potency" of ITDs conveyed by transposed stimuli persisted, even in the presence of a low-frequency interferer. Predictions made using an extension of the model of Heller and Trahiotis [L. M. Heller and C. Trahiotis, J. Acoust. Soc. Am. **99**, 3632–3637 (1996)] accounted well for across-frequency binaural interference obtained with conventional Gaussian noise targets but, in all but one case, overpredicted the amounts of interference found with the transposed targets. © *2005 Acoustical Society of America.*

I. INTRODUCTION

Several experiments concerning binaural hearing have demonstrated that sensitivity to an ongoing interaural temporal disparity (ITD) conveyed by a high-frequency "target" can be degraded by presenting a simultaneously gated, diotic, low-frequency "interferer." This general outcome is termed binaural interference in order to differentiate it from other deleterious effects, such as masking. Binaural interference has been demonstrated both in experiments concerning the detection of ITDs and in experiments concerning extents of the laterality produced by ITDs. (e.g., McFadden and Pasanen, 1976; Davis, 1985; Zurek, 1985; Dye, 1990; Trahiotis and Bernstein, 1990; Bernstein, 1991; Buell and Hafter, 1991; Woods and Colburn, 1992; Buell and Trahiotis, 1993; Stellmack and Dye, 1993; Bernstein and Trahiotis, 1992; 1995; Heller and Trahiotis, 1995a, 1996; Bernstein and Trahiotis, 2004).

One explanation offered to account for binaural interference is that it stems from a "nonoptimal" combination of ITD information conveyed by the target and the interferer, respectively (e.g., Buell and Hafter, 1991; Heller and Trahiotis, 1995a, 1996; Bernstein and Trahiotis, 2004). Within that view, the ITD value of zero carried by the low-frequency diotic interferer is combined with the ITD carried by the high-frequency target. As a consequence, the "internal" effective magnitude of the ITD conveyed by the target is diminished, as compared to what it would be in the absence of the interferer. For that reason, ITDs imposed on the high-frequency target must be increased: (1) in order to reach threshold, and (2) in order to produce an extent of laterality comparable to that obtained in the absence of the interferer.

Bernstein and Trahiotis (2004) have recently shown that across-frequency binaural interference effects as measured via ITD thresholds were, for all practical purposes, absent when certain "transposed" stimuli served as high-frequency targets. Transposed stimuli are specially constructed in order to provide high-frequency auditory channels with envelope-based temporal information that mimics waveform-based temporal information normally available only in low-frequency channels (see van de Par and Kohlrausch, 1997; Bernstein and Trahiotis, 2002; 2003; 2004).

Our purpose in this study was to determine to what degree binaural interference would occur if extents of laterality, rather than the resolution of ITD, were measured using high-frequency transposed stimuli as targets. It has long been recognized, using conventional stimuli, that one cannot predict extents of laterality solely from measurements of threshold ITDs made with the same stimuli (e.g., Stern and Colburn, 1978; Bernstein and Trahiotis, 1985; Trahiotis *et al.*, 2001). Therefore, it seemed important to determine whether interference effects would be revealed when extents of laterality, a type of the "suprathreshold" measure of the potency of ITD, were the focus.

II. EXPERIMENT

A. Procedure

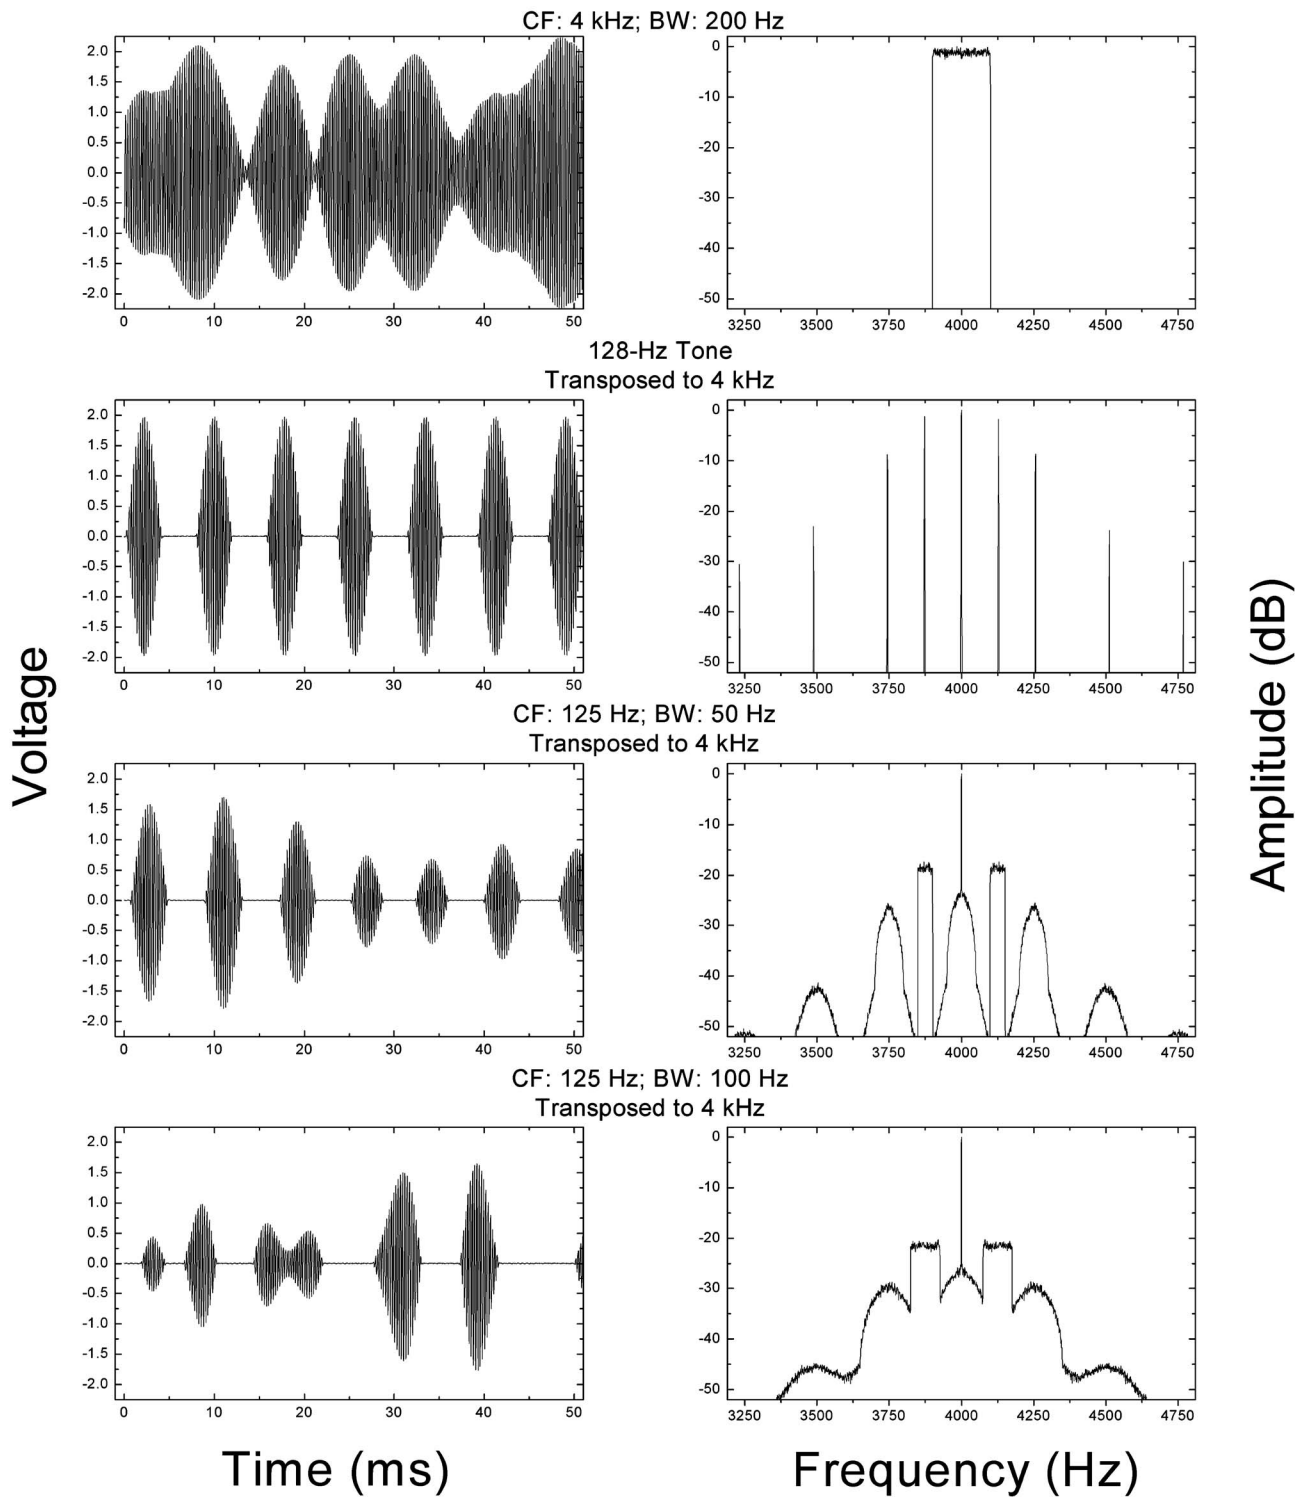
Two sets of four high-frequency stimuli served as targets and each set of four will be described and justified in turn. The first set of four consisted of (1) a 200-Hz-wide band of Gaussian noise centered at 4 kHz; (2) a 128-Hz tone transposed to 4 kHz; (3) a 50-Hz-wide band of Gaussian noise


FIG. 1. Left-hand panels: Randomly chosen 50-ms epochs of the four types of targets employed in the main experiment. Right-hand panels: The long-term power spectra of each of the four types of targets.

centered at 125 Hz transposed to 4 kHz; (4) a 100-Hz-wide band of Gaussian noise centered at 125 Hz transposed to 4 kHz.[1]

Examples of each of the four types of high-frequency target stimuli composing this first set are depicted in Fig. 1. The left-hand panels show randomly chosen 50-ms epochs of each type of target; the right-hand panels show their (long-term) power spectra calculated over tens of seconds. Begin-

ning with the left-hand panels, note that six or seven envelope maxima occur for each type of target during the 50-ms epochs. That is so because the number of envelope-maxima per second for each type of target is about 125. This corresponds to the rate of the low-frequency stimuli that were transposed to 4 kHz and is the expected number of envelope maxima per second for a 200-Hz-wide band of Gaussian noise (see Rice, 1954).

The primary reason for choosing a rate of envelope fluctuation near 125 Hz was that transposed stimuli having a similar rate of envelope fluctuation have been shown to produce the greatest enhancements (relative to their conventional counterparts) of ITD processing at high frequencies (e.g., van de Par and Kohlrausch, 1997; Bernstein and Trahiotis, 2002; 2003). Therefore, using such a rate would help to maximize observed differences in the extents of laterality between the transposed and conventional stimuli. Furthermore, using such a rate causes more than 99% of the energy of the transposed stimuli to fall between the sidebands centered at 3750 Hz and 4250 Hz (see the right-hand panels of Fig. 1). As a result, only minimal amounts of energy associated with each transposed target would fall outside the approximately 500-Hz-wide auditory filter centered at 4 kHz (see Moore, 1997). It was judged that having all stimuli satisfy this latter constraint would enhance the validity of comparisons among the data obtained with the various targets and, perhaps, simplify interpretations of the results.

The second set of four targets consisted of (1) a 400-Hz-wide band of Gaussian noise centered at 4 kHz; (2) a 256-Hz tone transposed to 4 kHz; (3) a 50-Hz-wide band of Gaussian noise centered at 250 Hz transposed to 4 kHz; (4) a 100-Hz-wide band of Gaussian noise centered at 250 Hz transposed to 4 kHz. Note that the rates of envelope fluctuation of these four targets are twice those of their counterparts in the first set of targets. Despite this difference, 90% of the energy associated with each of the transposed targets in the second set also fell within the sidebands centered at 3750 and 4250 Hz.

The major reason for employing the second set of targets was that increasing the rate of fluctuation of transposed noises from 125 to 250 Hz has been shown to result in *somewhat smaller* extents of laterality (Bernstein and Trahiotis, 2003). In contrast, for conventional bands of Gaussian noise, increasing the rate of envelope fluctuation from about 125 Hz to about 250 Hz by increasing bandwidth from 200 to 400 Hz has been shown to result in *somewhat greater* extents of laterality across values of ITD (e.g., Bernstein and Trahiotis, 2003). Mindful of these results, it seemed prudent to assess the degree to which amounts of interference measured with the second set of stimuli would be commensurate with those measured with the first set of stimuli. Of special interest was whether transposed noises in the second set, which have been shown to yield relatively less enhancement of ITD processing in terms of the extent of laterality, would be relatively more susceptible to across-frequency binaural interference. Posed differently, would the "less-robust" processing of ITD supported by the transposed noises in the second set of targets result in more binaural interference?

The transposed stimuli were generated in the manner described by Bernstein and Trahiotis (2002; 2003; 2004). Briefly, the time-domain representation of a narrow band of low-frequency Gaussian noise or a low-frequency tone was (linearly) half-wave rectified. This was accomplished by setting all negative values to zero. Then, the rectified waveforms were transformed to the frequency domain and all spectral components above 2 kHz were removed by setting their magnitudes to zero [see pp. 1027–1028 of Bernstein

and Trahiotis (2002) for a justification of the choice of this type of rectification and filtering]. Following this, each rectified and filtered waveform was transformed back to the time domain and multiplied by a 4-kHz sinusoidal "carrier." This procedure resulted in transposed stimuli, each having an envelope with a time signature that mimicked that of the rectified and filtered low-frequency narrow band of noise (or low-frequency tone) used to generate it.

The stimulus that served as the interferer was a diotic 400-Hz-wide band of Gaussian noise centered at 500 Hz. That stimulus has been shown to produce substantial amounts of binaural interference, as indexed by threshold ITDs, for conventional stimuli centered at 4 kHz (e.g., Bernstein and Trahiotis, 1995; 2004).

All stimuli were generated digitally as seconds-long buffers using a sampling rate of 20 kHz (TDT AP2), were low-pass filtered at 8.5 kHz (TDT FLT2), and were presented via Etymotic ER-2 insert earphones. Targets and interferers were each presented at a level matching 72 dB SPL, as produced by TDH-39 earphones in a 6-cm^3 coupler.[2] For all stimuli that served as targets, ongoing ITDs (0, 200, 400, 600 μs, left ear leading) were imposed by applying linear phase-shifts to the representation of the signals in the frequency domain and then gating the signals destined for the left and right ears coincidentally after transformation to the time domain.

Four normal-hearing young adults (one male and three female) who had each participated in previous binaural experiments served as listeners. Extents of laterality were measured via an acoustic pointing task in which the listeners varied the interaural intensitive difference (IID) of a 200-Hz-wide band of noise centered at 500 Hz (the pointer) so that it matched the intracranial position of a second, experimenter-controlled, stimulus (the target). This procedure has been used previously in several studies (e.g., Trahiotis and Stern, 1989; Buell *et al.*, 1991; Heller and Trahiotis, 1996) and is described fully in Bernstein and Trahiotis (1985). The overall level of the pointer, when presented diotically (IID=0 dB), was 65 dB SPL. Listeners adjusted the intracranial position of the pointer by rotating a knob. Rotation of the knob produced symmetric changes of the IID (in dB) of the pointer (i.e., increases in level at one ear and decreases in level at the other ear). The IID adjusted by the listener served as a metric of the intracranial position of the target. A value of IID was chosen randomly from the range±4 dB (in 0.5 dB steps) and was inserted in the pointer prior to each match. This served to randomize the initial position of the pointer with respect to the absolute position of the knob. Each sequence of stimuli consisted of three presentations of the target (each separated by 50 ms), a pause of 300 ms, three presentations of the pointer (each separated by 200 ms) and a pause of 650 ms. The duration of target and pointer stimuli was 100 ms, including 20 ms cos^2 rise/decay, and each was extracted from the appropriate longer buffer.

Targets and pointers were repeated until the listeners indicated that they had matched the intracranial positions of the target and pointer. Prior to completing a match, listeners

had the option of halting, and then restarting, the sequence in order to "check" their adjustments after a period of silence.

Testing began by measuring extents of laterality in the absence of the interferer. All of the aforementioned targets were visited in pseudorandom order. Having chosen a particular stimulus condition as the target, a random process was used to select a value of ITD from the set to be tested until the listeners had completed three independent matches for each value of ITD. The mean IID inserted by the listener to match the diotic targets (ITD=0) served as a "correction factor." That is, it was subtracted from the IIDs resulting from all the matches in the run. Any series of matches that yielded a correction factor with a magnitude greater than 5 dB was discarded and rerun until a "valid" series was obtained with a correction factor less than that value. After matches were made in all of the "without-interferer" conditions, the same stimulus conditions were re-visited in reverse order. Finally, the entire process was repeated for targets presented in the presence of the simultaneously-gated low-frequency interferer. The data reported in the figures represent the mean "corrected" value of IID of the pointer across the six valid matches made by each listener for a particular combination of target and ITD.

B. Results and discussion

In all of the plots of the data that follow (Figs. 2–4), filled squares represent data obtained in the absence of the interferer and open triangles represent data obtained in the presence of the interferer. Only the data averaged across the four listeners will be presented because between-listener differences were small, as indicated by the error bars that represent ± one standard error of the mean. Table I contains information regarding the within-listener precision with which the matches were made. The average standard deviation was computed for each value of ITD tested. This was done separately for the no-interference and interference conditions. Each entry in the table represents the mean of the 32 (eight targets × four listeners) measures of standard deviation computed across the six matches made by each listener for each experimental condition. Note that the average, within-listener standard deviation increases with ITD, being only slightly larger than 1 dB when the targets were presented diotically and increasing to about 2.5±0.25 dB when the ITD was 600 μs. This indicates that the precision of binaural processing is greater for stimuli perceived near midline than for stimuli that are perceived to be lateralized well toward the ear. This is in accord with the findings of previous studies (e.g., Mills, 1958; Hafter and DeMaio, 1975; Domnitz and Colburn, 1977). The standard errors of the means indicated in the figures, taken together with the standard deviations appearing in Table I, indicate that both the within- and between-listener variance was small in comparison to, and need not constrain interpretations of, the magnitude of the differences found between conditions.

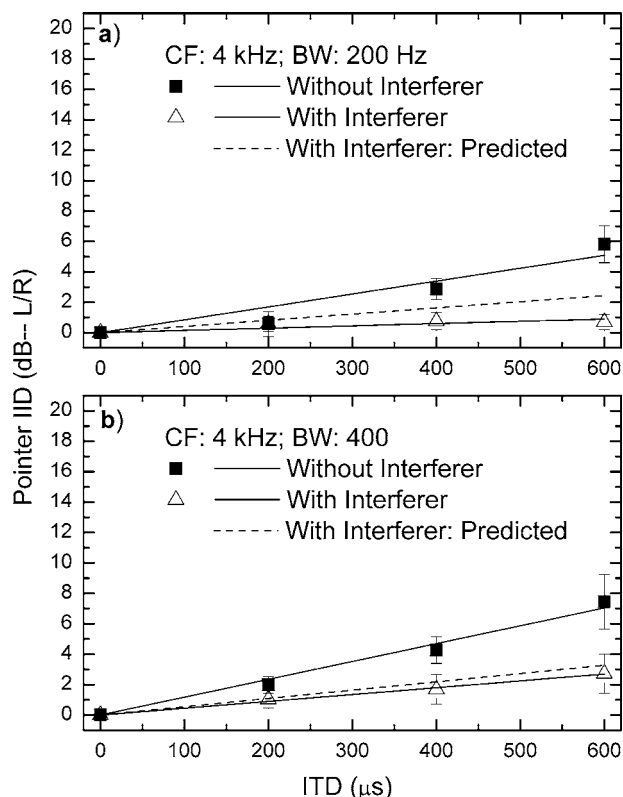
The solid lines within the figures are the best linear-regression fits to the data with the intercept forced to be zero. An intercept of zero is consistent with our use of "correction factors" for matches made with diotic targets. Using the cor-


FIG. 2. IID of the pointer (in dB) required to match the intracranial position of the target as a function of the ongoing ITD (left ear leading) imposed on a 200-Hz-wide [panel (a)] or 400 Hz wide [panel (b)] band of Gaussian noise. The data points represent the mean values computed across the four listeners. The error bars represent ±1 standard error of the mean. Squares represent data obtained when the target was presented in isolation; triangles represent data obtained when the target was presented along with the low-frequency interferer. Solid lines represent the best linear-regression fits to the data with the intercept forced to be zero. Dashed lines represent quantitative predictions of the extents of laterality in the presence of the interferer. Predictions were derived from an extension of the Heller and Trahiotis (1996) model described in Sec. III C of the text.

rection factors forces the empirical match to an ITD of 0 μs to be 0 dB of IID of the pointer. The dashed lines within the figures represent quantitative predictions of extents of laterality in the presence of the interferer. Those predictions are discussed in Sec. II C.

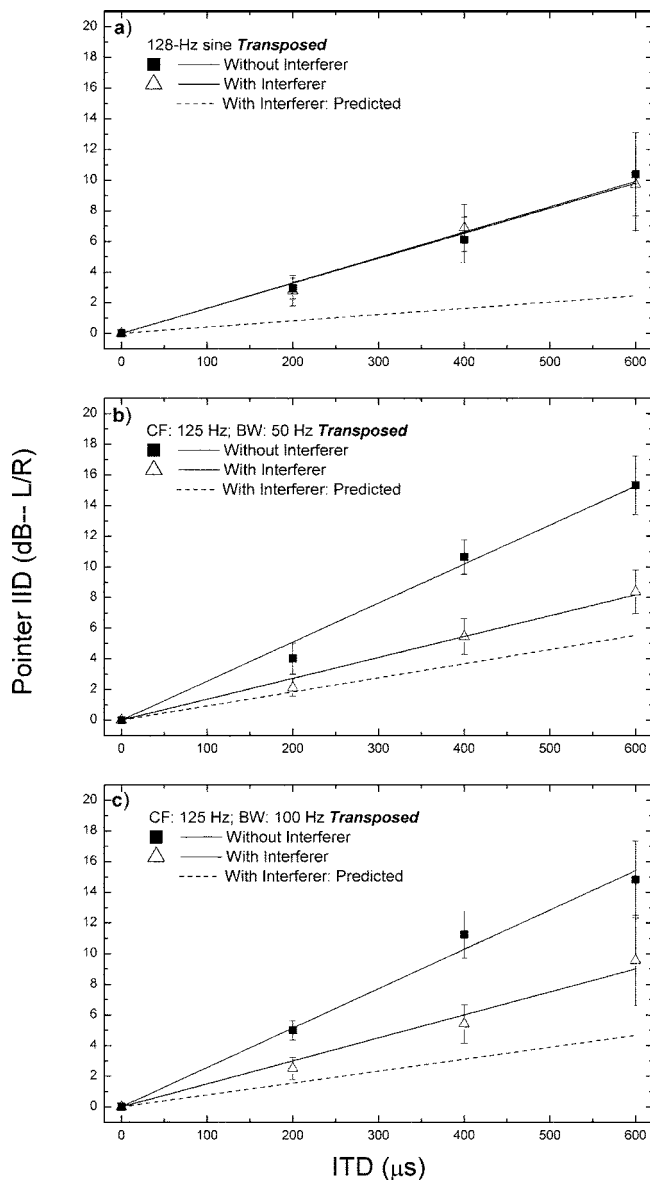
A summary of the statistical analyses that will be used to help interpret the data is presented in Table II. The first column of the table indicates the type of target. The second column of the table contains the slopes of the best-fitting lines to the data for each target when it was presented in the absence of the interferer. The third column indicates the amount of variance accounted for by the fitted line forced through the origin.[3] The fourth and fifth columns contain the same types of information for the conditions in which the interferer was presented along with the target. The sixth column contains the ratio of the "without-interferer" slope to the "with-interferer" slope for each target. Because, as will be discussed, the data are well-fit by straight lines passing through the origin, the ratio of the value of the pointer-IID obtained in the without-interferer condition to the value obtained in the with-interferer condition can be taken to be constant for all values of ITD of the target. Therefore, the


FIG. 3. Similar to Fig. 2, but for the "125 Hz" transposed stimuli.
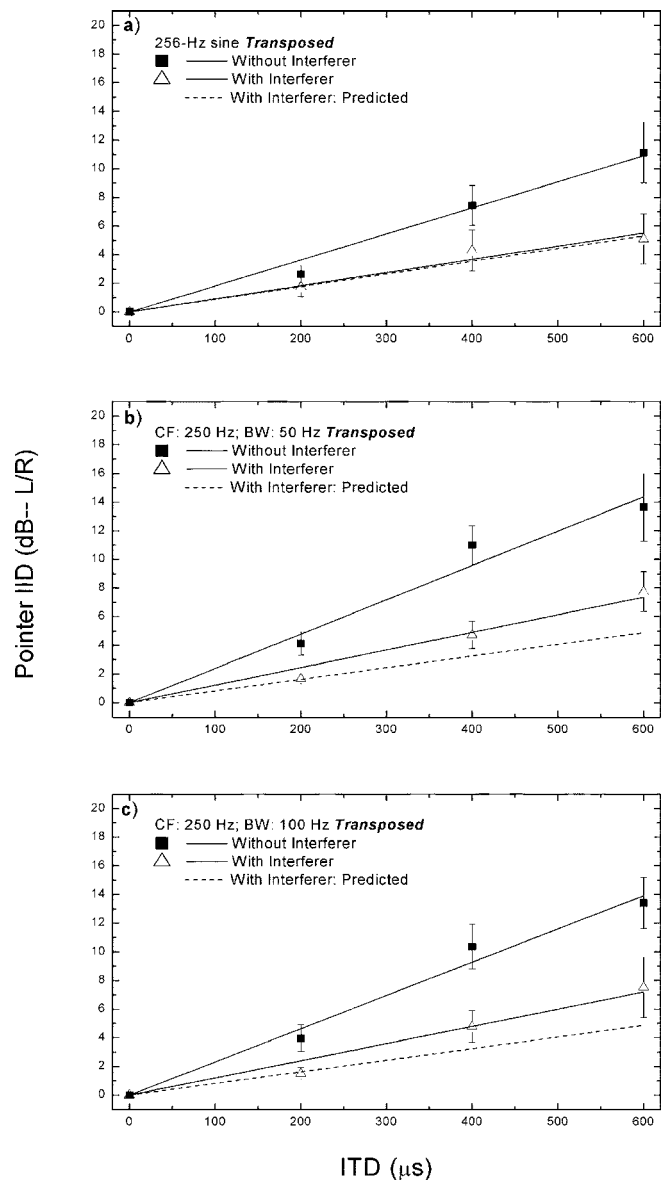

FIG. 4. The same as Fig. 3, but for the "250 Hz" transposed stimuli.

ratio of the slopes provides a consistent measure of binaural interference independent of the perceived intracranial loci of the targets. Bernstein and Trahiotis (1995) used similar types of ratios to quantify binaural interference in an experiment measuring threshold ITD, threshold IID, and thresholds for the detection of a signal in noise.

The seventh and eighth columns show the F-ratios and their associated probabilities derived from a statistical analysis (Edwards, 1964) that yields the significance of the differences of the regression slopes (calculated using the mean data) obtained for the targets presented in isolation versus when they were presented along with the interferer. This type of statistical analysis was deemed appropriate because it is the amount of the disparity between the two slopes that directly (i.e., independently of the magnitude of ITD) reflects the amount of binaural interference that occurred.

Asterisks indicate significance using an alpha level of $p < 0.05$. The percentages of variance accounted for by the linear fits (columns 3 and 5), being, in the great majority of

cases between 97% and 99%, indicate that the data are well fit by straight lines having an intercept of zero. Given the quality of the linear fits, the ratio of the slopes obtained for "without-interference" and for "with-interference" conditions can be taken as valid descriptors of the amounts of interference produced for each target.

TABLE I. The average standard deviation (in dB) obtained for each ITD in the "no-interference" and "interference" conditions. Each entry in the table represents the mean of the 32 (eight targets × four listeners) measures of standard deviation computed across the six matches made by each listener for each experimental condition.

ITD	No Interference	Interference
0	1.31	1.19
200	1.94	1.54
400	2.66	2.06
600	2.78	2.25

Bernstein and Trahiotis: Binaural interference and transposed stimuli

TABLE II. The second through fifth columns report the slopes (dB/μs) and variance accounted for by the best-fitting lines to the data obtained in each experimental condition. The sixth column contains the ratios of the "without-interferer" to "with interferer" slopes. The two rightmost columns of the table show the results of the statistical analysis (Edwards, 1964) yielding the significance of the differences of the regression slopes obtained when the targets were presented in isolation versus when they were presented along with the interferer. Asterisks indicate significance using an alpha level of $p < 0.05$.

Target	Without-interferer slope	% var. acc.	With-interferer slope	% var. acc.	Slope ratio	F	p

Panels (a) and (b) of Fig. 2 display the results obtained when 200-Hz-wide and 400-Hz-wide bands of Gaussian noise, respectively, served as targets. Note that only modest extents of laterality were obtained when the high-frequency Gaussian-noise targets were presented in isolation (filled squares), the largest values of the IID of the pointer being only 6–7.5 dB when the ITD was as large as 600 μs. Such values of IID are substantially less than the 10–12 dB or so that have been commonly found to indicate intracranial images lateralized near the leading ear (see Watson and Mittler, 1965; Yost, 1981; Trahiotis and Bernstein, 1986). Comparison of the data in panel (b) to those displayed in panel (a) reveals that slightly greater extents of laterality were obtained when the bandwidth of the target was increased from 200 to 400 Hz.

Most important for our purposes, for both of the Gaussian-noise targets, extents of laterality were diminished with the addition of the simultaneously gated low-frequency noise (open triangles), thereby indicating binaural interference. The degree of across-frequency binaural interference is quantified by the ratios of the without-interferer to with-interferer slopes that can be found in the fifth column of Table II. For the data obtained with the two Gaussian noise targets, the ratios of the slopes were 5.65 (200-Hz-wide noise) and 2.61 (400-Hz-wide noise). As indicated by the rightmost column of the table, the underlying pairs of slopes for these two targets were significantly different. Note that the slope ratios for these Gaussian-noise targets are the largest in the table. This indicates that the largest interference effects occurred with these two conventional Gaussian-noise targets. In fact, the relatively small values of the IID of the pointer required to make matches in the presence of the interferer for those two targets indicates intracranial positions of the targets quite close to or at the midline. The only seemingly poor linear fit to the data occurred when the 200-Hz-wide Gaussian-noise target was presented along with the interferer. As indicated in Table II, the linear fit to these data accounted for only 60% of the variance. This outcome should be interpreted with caution for two reasons. First, as shown in Fig. 2(a), in the presence of the interferer, there was virtually no ITD-based lateralization and, therefore, virtually no variance above and beyond the noise of measurement for which to account. Second, the best fitting line deviates, at most, by about 0.5 dB from the data. Overall, the

extents of laterality and the amounts of interference obtained with the Gaussian-noise targets are entirely consistent with and essentially replicate patterns of data reported in our earlier studies (Bernstein and Trahiotis, 1995; 2003; Heller and Trahiotis, 1996).

We now turn to the data of most interest, those obtained with high-frequency, transposed stimuli. Panel (a) of Fig. 3 displays data obtained when the target was a 128-Hz pure tone transposed to 4 kHz. Two effects are apparent. First, ITDs conveyed by the transposed target presented in isolation resulted in larger extents of laterality as compared to the Gaussian-noise targets when they were presented in isolation. For example, an IID of the pointer of 10 dB was required to match the intracranial position of the target when the ITD was 600 μs. This indicates an intracranial image near the leading ear and is typical of the extent of laterality produced by a 600-μs ITD conveyed by a *low-frequency* stimulus. Second, the addition of the interferer had no effect. This is confirmed quantitatively in Table II in that the ratio of the without-interferer to with-interferer slopes is 1.01 for this target. Furthermore, as also indicated in the table, the 128-Hz transposed target is the *only* one for which the difference between the two underlying slopes is not significant.

This set of observations, taken together, supports the conclusion that adding the diotic low-frequency interferer had *no effect* on ITD-based lateralization for this target. A similar apparent "immunity" to across-frequency binaural interference was found with the same stimulus when threshold ITD, rather than the extent of laterality, was the dependent variable (Bernstein and Trahiotis, 2004).

Panels (b) and (c) of Fig. 3 display data obtained when the target was either a 50-Hz-wide or a 100-Hz-wide band of noise centered at 125 Hz and transposed to 4 kHz. Note that these two transposed-noise targets consistently produced larger extents of laterality than did the transposed tone [panel (a)] in the absence of the interferer (filled squares). For example, for the transposed noises, the listeners required about 11 dB of IID in the pointer, indicating an image just at the leading ear when the ITD was only 400 μs. Furthermore, an IID of about 15 dB was required to match an image when the ITD was 600 μs. These extents of laterality are very similar to those reported with the same stimuli by Bernstein and Trahiotis (2003). At this time, we cannot account for the finding that the transposed noises produced slightly greater

extents of laterality than did the transposed tone. Perhaps this outcome is related to an earlier finding with conventional stimuli, namely that high-frequency Gaussian noises produce greater extents of ITD-based laterality than do high-frequency SAM tones having the same "bandwidth" (Trahiotis and Bernstein, 1986).

Unlike what was found with the transposed tone [panel (a)], the addition of the low-frequency, diotic noise to the transposed *noises* resulted in interference, in that extents of laterality were reduced. As indicated in Table II, the ratios of the lateralization slopes for the two bandwidths were 1.87 and 1.71, respectively, indicating substantial (and statistically significant) binaural interference.

Interestingly, as can be seen by visual inspection of Fig. 3 and by referring to the lateralization slopes in Table II, the extents of laterality measured in the presence of the interferer when the targets were transposed noises were very much like those measured with the 128-Hz transposed-tonal target. In all four cases, the slopes are near 0.015. Thus, the increments in lateralization measured when the ITDs were conveyed by the transposed noises, rather than by a transposed tone, were essentially "neutralized" in the presence of the interferer. That is, in the presence of the interferer, the extents of laterality measured with the transposed tone and the two transposed noises are virtually identical. Note that, even under interference conditions, these transposed stimuli yielded greater (i.e., enhanced) extents of laterality than did conventional high-frequency Gaussian-noise targets *presented in isolation* [compare Fig. 3(b) with Figs. 2(a) and 2(b)].

The data obtained when the low-frequency stimuli to be transposed were centered near 250 Hz are displayed in Fig. 4. Once again, panel (a) contains data obtained for targets generated by transposing a pure tone, in this case 256 Hz, to 4 kHz. Panels (b) and (c) contain data obtained when 50-Hz-wide [panel (b)] or 100-Hz-wide [panel (c)] Gaussian noise centered at 250 Hz and transposed to 4 kHz served as targets.

The comparisons to be made among the data displayed in the panels of Fig. 4 directly parallel those made among the data presented in Fig. 3. The reader is reminded that the primary reason for employing this second set of transposed stimuli was that low-frequency noises centered on 250 Hz and transposed to 4 kHz have been shown to yield smaller extents of laterality than low-frequency noises centered on 125 Hz (Bernstein and Trahiotis, 2003). The question of interest here was whether such "less-robust" processing of ITD would result in more binaural interference.

For ease of exposition, we begin with the data in panels (b) and (c) of Fig. 4. The data show that these transposed targets, when presented in isolation, result in extents of laterality that are substantially *greater* than those obtained with conventional Gaussian-noise targets (compare to Fig. 2) but only slightly *smaller* than extents of laterality measured with their counterparts derived from bands of noises centered on 125 [compare to panels (b) and (c) of Fig. 3]. These differences are consistent with those reported by Bernstein and Trahiotis (2003). The *amounts of interference*, as quantified by the ratio of the slopes obtained with these targets (1.95 and 1.93, respectively), were slightly greater than those ob-

tained with transposed noise targets derived from noises centered at 125 Hz (1.87 and 1.71, respectively).

Finally, we turn to the data obtained with a 256-Hz pure tone transposed to 4 kHz [Fig. 4, panel (a)]. Note that the extents of laterality measured in the absence of the interferer are virtually the same as those obtained with the 128-Hz pure tone transposed to 4 kHz when it was also presented alone [see panel (a) of Fig. 3]. As seen by considering their respective lateralization slopes of 0.0165 and 0.0182, those two stimuli, when presented in isolation, were lateralized essentially identically. Nevertheless, for the 256-Hz pure tone transposed target, the addition of the low-frequency diotic noise produced *substantial* interference, as evidenced by the ratio of the without-interferer to with-interferer slope-ratio of 1.98. This clearly indicates that this target, unlike its 128 Hz transposed counterpart [Fig. 3(a)] was, indeed, "susceptible" to across-frequency binaural interference.

The comparisons among the data discussed above do not appear to yield insights regarding (1) which features of transposed targets affect their ITD-based extents of laterality and (2) which features of the transposed targets render them more or less susceptible to across-frequency binaural interference. For example, as can be seen in Fig. 1, the difference between a transposed tone and a transposed noise is manifest as both a change from a deterministic to a stochastic envelope and a change from a discrete "line spectrum" to one having sidebands characterized by spectral extent or "breadth." In future experiments, we plan to investigate whether and to what degree various temporal and/or spectral aspects of high-frequency complex waveforms affect their susceptibility to across-frequency binaural interference.

All of these issues notwithstanding, the main findings of the study are quite clear: high-frequency transposed stimuli not only produce greater ITD-based extents of laterality than do high-frequency Gaussian noises, but they are, generally speaking, less susceptible to across-frequency binaural interference.

C. Extending and testing a laterality-based quantitative model of binaural interference

In this section, we describe the application to the data described above of an extension of the quantitative model of across-frequency binaural interference described by Heller and Trahiotis (1996). To date, the model has been found to account quantitatively for binaural interference measured via threshold-ITDs when the targets and interferers were sinusoidally amplitude-modulated tones (Heller and Trahiotis, 1996) and when the targets and interferers were narrow bands of Gaussian noise (Bernstein and Trahiotis, 1994). A fundamental underlying assumption of that model is that binaural interference arises from an obligatory, nonoptimal, across-frequency-channel, combination of binaural cues. The combining of information is nonoptimal because the low-frequency diotic interferers, which convey no information useful for detecting or lateralizing on the basis of ITDs within high-frequency targets, are not ignored. A second important assumption of the model is that it is *the extent of laterality* produced at threshold-ITD that is the crucial variable, and not the magnitude of the threshold ITD itself. The

extent of laterality at threshold (in terms of IID of the pointer) is estimated by multiplying the threshold ITD (in μs) by the lateralization slope (in IID of the pointer/μs). That extent of laterality is, in turn, used to compute the salience or "weight" of the ITD-based information carried by the target or interferer when each is presented in isolation [see pp. 3066–3068 of Bernstein and Trahiotis (2004) for a more formal and much more detailed discussion]. Computing the weights via empirical measures obtained with targets and interferers presented in isolation allows the model to *predict* the expected amounts of interference when targets and interferers are presented simultaneously. This approach should be differentiated from others in the general literature that compute "weights" derived in a post-hoc manner that are then used as *descriptors* of the relative potencies of the elements in compound stimuli.

In order to compute the predicted lateralization slope for each target in the presence of the interferer, the Heller and Trahiotis (1996) model had to be extended. This was done by assuming that

$$effs_{t+i} = \frac{a * effs_t + b * effs_i}{a + b}, \qquad (1)$$

where a and b represent the weights applied to the ITD-based information conveyed by the target and interferer, respectively. The term $effs_{t+i}$ represents the *effective* lateralization slope of the target in the presence of the interferer, $effs_t$ and $effs_i$ represent the *effective* lateralization slopes for the target and interferer, respectively. The effective lateralization slope for the target, $effs_t$, is simply the lateralization slope measured when the target is presented in isolation. The effective lateralization slope for the interferer, $effs_i$, however, is *not* the lateralization slope measured when the extent of laterality of the interferer is measured in isolation because, in the experimental conditions, the interferer carried an ITD of zero *regardless of the value of the ITD of the target*.

The *effective* slope of either the target or the interferer is obtained by multiplying that particular stimulus' lateralization slope (i.e., the one obtained in isolation) by the ratio relating the ITD actually imposed on that particular stimulus to the ITD of the target. In our case, the ITD actually imposed on the target was, of course, the ITD of the target itself and, therefore, that ratio is one. This means, as stated above, that the effective slope of the target, $effs_t$, is the same as its lateralization slope measured in isolation. Formally,

$$effs_t = s_t * 1, \qquad (2)$$

where s_t is the lateralization slope of the target measured in isolation.

Now, in the interference conditions for which predictions are to be made, the ITD actually imposed on the interferer was always zero. Therefore, the ratio relating the ITD actually imposed on the interferer to the ITD imposed on the target was always zero and, therefore, the effective lateralization slope of the interferer was zero. Formally,

$$effs_i = s_i * 0, \qquad (3)$$

where s_i is the lateralization slope of the interferer measured in isolation.

It should be understood that this form of the model takes into account the fact that the targets had ITDs ranging up to 600 μs while the interferers always carried an ITD of zero, independent of the ITD imposed on the target. On an intuitive level, the model can be seen as attempting to capture the combination of the positive lateralization slope of the target with the effective "zero" lateralization slope of the diotic interferer.

Because only lateralization slopes, and not threshold ITDs, were measured in the current study, the weights (a and b) were derived from measures obtained in an earlier study that employed stimuli that were essentially identical to those employed here. In the earlier study, both threshold ITDs and lateralization slopes were measured (Bernstein and Trahiotis, 2004). Three of the four listeners in the current study also participated in that earlier study. The lateralization slopes obtained in the prior and current study for common stimulus conditions were functionally identical. In order to arrive at a prediction for the lateralization slopes measured with targets in the presence of the interferer, the weights, a and b, were entered into Eq. (1) along with the effective lateralization slopes estimated, as described above.

Inspection of Fig. 2 reveals that the predictions of the model (dashed lines) are fairly accurate (within less than 1 dB or so of the obtained data) when the targets were conventional high-frequency bands of Gaussian noise. The model slightly, but consistently, *underpredicts* effects resulting from the addition of the interferer. That is, the model predicts slightly greater extents of laterality in the presence of the interferer than were obtained.

In contrast, inspection of Fig. 3 reveals that, for the "125 Hz" transposed targets, the model consistently and, in many instances substantially, *overpredicts* the effects of adding the interferer. Especially noteworthy is the failure of the model for the data depicted in panel a, when the target was a 128-Hz tone transposed to 4 kHz. In this condition, no interference was observed and the model predicted as much as 5–7 dB of interference depending on the ITD imposed was 400 or 600 μs.

The finding that the model accounts fairly well for interference effects obtained with conventional high-frequency targets, but overpredicts the degradation produced by the interferer for high-frequency *transposed* stimuli, is consistent with the results of our earlier study, which focused on threshold ITDs (Bernstein and Trahiotis, 2004). Inspection of Fig. 4 reveals that the model accurately predicts the effects of adding the interferer to the 256 tone transposed to 4 kHz and moderately overpredicts the effects of adding the interferer to the two transposed targets derived from Gaussian bands of noise centered at 250 Hz. Overall, the success and failure of predictions of across-frequency interference effects via the Heller and Trahiotis (1996) model in this study parallel those of Bernstein and Trahiotis (2004).

III. GENERAL DISCUSSION AND SUMMARY

As a follow-up to Bernstein and Trahiotis (2004), the purpose of this study was to determine whether across-frequency binaural interference would occur if ITD-based extents of laterality were measured using high-frequency transposed stimuli as targets. In the earlier study, which focused on threshold ITDs rather than the extents of laterality, no binaural interference was observed when the targets were high-frequency transposed stimuli. That outcome suggested that transposed high-frequency stimuli might, somehow, be "immune" to across-frequency interference effects commonly found with conventional high-frequency targets.

The data from the current study indicate that high-frequency transposed targets can, indeed, be susceptible to binaural interference when extents of laterality, rather than threshold ITDs, are measured. That is, it appears that whether one observes binaural interference with high-frequency transposed targets depends upon whether threshold ITDs or ITD-based extents of laterality are measured. It should be emphasized, however, that even when interference occurred, high-frequency transposed targets yielded greater extents of ITD-based laterality than did Gaussian noise targets presented in isolation. That is, enhancements of ITD-based lateralization obtained with high-frequency transposed stimuli, as compared to their conventional counterparts presented in isolation, were found even under conditions of across-frequency binaural interference. Predictions made using an extension of the model of Heller and Trahiotis (1996) accounted quite well for binaural interference obtained with conventional Gaussian noise targets but, in all but one case, overpredicted the amounts of interference found with the transposed targets.

One broad implication of the findings in this study, taken together with those of Bernstein and Trahiotis (2004), is that across-frequency binaural interference effects cannot, in general, be accounted for solely by assessing the relative potency and/or salience of ITDs conveyed by targets and interferers when each is presented in isolation. It appears that the types of "blackbox" models that have been used to account for across-frequency binaural interference with conventional stimuli (e.g., Buell and Hafter, 1991; Heller and Trahiotis, 1995a, 1996) will have to be augmented or superceded by a more sophisticated, and probably more mechanistic, approach. The success of such models will depend upon their ability to capture how the stimuli, as processed, determine the "strength" of across-frequency interactions that appear to occur within the binaural system. Based on previous studies, (e.g., Trahiotis and Bernstein, 1990; Heller and Trahiotis, 1995a) across-frequency binaural interference appears, in the main, to be central, rather than peripheral, in origin.

ACKNOWLEDGMENTS

[1]The frequency of the tone that was transposed to 4 kHz was chosen to be 128 Hz in order to match the frequency that was employed in our earlier studies (Bernstein and Trahiotis, 2002; 2004). The center frequency of the low-frequency bands of noise that were transposed to 4 kHz was chosen to be 125 Hz in order to match the center frequency employed in our earlier study of extents of laterality using transposed noises. The same considerations dictated the choice of 256 and 250 Hz for the transposed tone and noises, respectively, which composed the second set of targets described later in the text. These very small disparities within each set of targets between the frequencies of the tones and the center frequencies of the noises that were transposed to 4 kHz are, for all practical purposes, inconsequential.

[2]Stimulus levels produced according to the calibration supplied with the Etymotic ER-2 earphones sounded less loud than stimuli presented at nominally the same level via TDH-39 earphones, according to their calibration. Dr. Mead Killion, of Etymotic Research, validated our listening experience and agreed with us that the two respective methods of calibration would be expected to produce levels of stimulation differing by about 10 dB. We chose to "calibrate" the outputs of the Etymotic earphones to the nominal levels produced by the TDH-39s so that listeners in this study would receive levels of stimulation directly comparable to those utilized by us and others in prior psychophysical experiments employing TDH-39s. We verified that the levels from the Etymotic earphones were appropriate by presenting a high-frequency, stimulus to one ear via an Etymotic ER-2 earphone and simultaneously to the other ear via a TDH-39 earphone. We then adjusted the relative levels between the two ears to produce a "centered" intracranial image, as is produced by diotic stimuli in normal-hearing listeners. In order to produce a centered image, it was necessary to impose a 10 dB larger voltage on the Etymotic ER-2 than would be expected on the basis of its calibration. Incidentally, the same type of ear-to-ear comparison allows one to compare and to cross-calibrate any earphone to any other one, notwithstanding local variations in the frequency response of the earphones.

[3]The formula used to compute the percentage of the variance for which our predicted values of pointer IID (in dB) accounted was $100 \times (1 - [\Sigma (O_i - P_i)^2]/[\Sigma (O_i - \bar{O})^2])$, where O_i represents the average observed values and P_i represents the predicted values. $\bar{O}$ represents the grand mean of the observed values of IID.

This study explores the effects of hearing status and bite blocks on vowel production. Normal-hearing controls and postlingually deaf adults read elicitation lists of /hVd/ syllables with and without bite blocks and auditory feedback. Deaf participants' auditory feedback was provided by a cochlear prosthesis and interrupted by switching off their implant microphones. Recording sessions were held before prosthesis was provided and one month and one year after. Long-term absence of auditory feedback was associated with heightened dispersion of vowel tokens, which was inflated further by inserting bite blocks. The restoration of some hearing with prosthesis reduced dispersion. Deaf speakers' vowel spaces were reduced in size compared to controls. Insertion of bite blocks reduced them further because of the speakers' incomplete compensation. A year of prosthesis use increased vowel contrast with feedback during elicitation. These findings support the inference that models of speech production must assign a role to auditory feedback in error-based correction of feedforward commands for subsequent articulatory gestures. © *2005 Acoustical Society of America.* [DOI: 10.1121/1.2001527]

I. INTRODUCTION

As part of a broader inquiry into speech production, our laboratory has had a longstanding interest in determining the role of auditory feedback in that performance (Perkell *et al.*, 1992; Guenther and Perkell, 2004). To that end, our research has investigated speech production in late-deafened adults who have had no auditory feedback for many years. When those adults have some hearing restored with cochlear implants, we measure acoustic parameters of their speech again, as well as their phoneme perception. In some studies such as the present one, we also switch off implant microphones in order to block auditory feedback for short periods of time. Finally, we make measures of speech perception and production in participants with normal hearing, in order to have some normative benchmarks.

One method of investigating the role of auditory feedback in speakers with normal hearing that has attracted wide interest is to measure speech parameters while the subject clenches a bite block between the teeth and produces a set of utterances. It turns out that such speakers' vowel formants are only slightly altered from their unperturbed state. Moreover, evidence for this compensation can be found in measures of the first glottal pulse, indicating that most of the needed reorganization was not accomplished with the aid of closed loop auditory feedback (Lindblom and Sundberg, 1971; Lindblom *et al.*, 1978; Lubker, 1979; Flege *et al.*, 1988; Baum *et al.*, 1996). McFarland and Baum (1995) found that compensation to bite blocks was neither immediate nor complete and, at least for vowels, compensation strategies may develop over time. Flege *et al.* (1988) measured linguapalatal contact patterns in /s/ and /t/ and found that ten minutes' conversation with bite block led to normal acoustic parameter values; they suggest that sensory feedback may have provided error based correction of articulatory gestures. Hoole (1987) gave bite blocks to a German-speaking patient who had suffered loss of oral sensation due to head trauma. Neutralization of vowels was particularly marked in the bite block plus masking condition and there was no evidence of learning. Hoole concludes that afferent information is required to "establish a frame of reference for motor commands" (p. 19).

The combined interventions of bite block and changes in hearing status present an opportunity to test several hypotheses concerning dispersion and vowel contrast. The present experiment employs postlingually deaf adults to test these hypotheses since prelingually deaf participants may not have mastered the phonemic system or the motor commands and feedback mechanisms required for speech. Remarkably, there appears to be only a single published study in which bite blocks were used with postlingually deaf adults (Tye *et al.*, 1983).

Should we expect that late-deafened adults, asked to speak while clenching a bite block between their teeth, will compensate as accurately as their normal-hearing counterparts? On the one hand, yes, for late-deafened adults had the normal opportunity to master speech production and to monitor their own speech aurally (as well as somesthetically). If speakers with normal hearing do not require closed-loop auditory feedback for accurate compensation, then late-deafened adults who have little or no auditory feedback may have no disadvantage in this regard. On the other hand, no, for late deafened adults have been for some time without sufficiently acute hearing to "update" their model of the relations between the configuration of the vocal tract and its auditory consequences. Speakers with normal hearing are able to update their model when there is drift, when oral morphology has changed, or indeed, when speaking with something in their mouths (Jones and Munhall, 2003).

A. Theoretical background

In thinking about such issues and in formulating experimental hypotheses, our theoretical framework has been guided by the DIVA model of speech motor planning (Guenther and Perkell, 2004). When controlling a model of the vocal tract, DIVA accounts qualitatively for a wide range of observations on speech production, including speech sound acquisition, articulatory variability, motor equivalence, coarticulation and rate effects (Guenther, 1994; Guenther, 1995; Guenther *et al.*, 1998).

Figure 1 presents a schematic of how feedforward and feedback mechanisms are hypothesized to interact in speech motor planning according to our framework. Representations of speech sounds, syllables, and words are stored in long-
FIG. 1. Schematic diagram of the functionality of the DIVA model. Cells in premotor, motor, and sensory cortical areas are indicated by boxes. Dashed lines: projections from premotor to sensory cortex that encode expected sensory consequences. Dotted lines: projections from sensory periphery to sensory cortex. Solid lines: projections that encode motor commands.

term memory (box 1). (These representations are acquired as the developing child generates vocal-tract movements and begins to form associations among the motor commands, the resulting sounds, and their linguistic significance.) The production of an utterance consisting of a sequence of sounds involves the activation of two sets of projections from the stored representations: (1) projections in the feedback subsystem of *expected auditory consequences* of the movements to be produced. These projections, called *auditory goals*, correspond to regions in multidimensional auditory-temporal space. (2) *Feedforward* projections that result in motor commands to the articulators. As the movements evolve and sound is generated, auditory feedback about the movements' actual consequences is compared with the auditory goals, and if there is a mismatch, an auditory error signal (box 3 in Fig. 1) arises and leads to auditory feedback-based corrective motor commands. These corrective motor commands are also used to help refine feedforward commands for subsequent movement attempts. Eventually, as feedforward commands become well tuned, the control becomes almost entirely feedforward.[1] As the child is learning to produce speech sounds, patterns of somatosensory feedback are also generated. These patterns become incorporated into somatosensory goals, which are used in comparison with somatosensory feedback for error correction as part of the feedback control subsystem.

B. Vowel dispersion hypotheses

Hypothesis (1): A bite block will increase *deaf speakers' dispersion* of vowel tokens around their target means in the formant-1 $\times$ formant-2 plane.

When late-deafened adults have had little or no hearing available for a long time, the bite block is expected to disrupt

their speech production extensively since such speakers' feedforward commands (box 1 to box 2, Fig. 1) were established many years earlier. With a bite block inserted, that mapping is likely to be invalid in some degree but speakers have no way without being able to discriminate the changes in their speech to update such mappings in order to achieve the desired auditory phonemic goals.

Hypothesis (2): The effects of the bite block on *implant users' vowel dispersion* will be less after a year of prosthesis use compared to a month of such use.

When the deaf participant has been using a cochlear implant for an extended period, he or she is better able to retune the articulatory-to-acoustic mappings that will be used to compensate for the subsequent introduction of the bite block.

Hypothesis (3): Speakers with *normal hearing* will respond to the introduction of a bite block with lesser increases in *dispersion* of vowel tokens than implant users.

Speakers with normal hearing are expected to have more accurate articulatory to auditory mappings in the first place since they have had the possibility of updating those mappings continually. Further, their auditory error signal may be more accurate since their hearing does not have the reduced bandwidth and distortion arising from the use of a cochlear implant. Consequently, when movement trajectories for achieving a given vowel target are modified after a bite block has been introduced, the range of those trajectories is more constrained in normal-hearing speakers.

Hypothesis (4): Implant users and speakers with normal hearing, speaking with *bite blocks* inserted, will increase vowel token *dispersion* during short-term interruptions in auditory feedback.

In the presence of the bite block perturbation, movement trajectories are more consistent across trials when an auditory error signal is available to correct subsequent feedforward commands; when that signal is interrupted, dispersion increases.

C. Vowel separation hypotheses

The preceding hypotheses regarding the effects of bite block and hearing status on dispersion are linked to hypotheses concerning their effects on vowel contrasts, for high dispersion leads to low contrast (and conversely) according to the theoretical framework we have sketched. To see the reason for this connection, consider Fig. 2, a schematic of two trajectories that pass through a sequence of goal regions, C1, V1, C2, and V2. It will be seen that the larger goal regions (closed squares) give rise to reduced vowel contrast (closed double-headed arrow). That is because the trajectory, guided by least effort (Lindblom, 1980; 1990), passes through the most proximal parts of the goal regions, thereby reducing its travel and hence vowel separation. Therefore:

Hypotheses (5): Insertion of a *bite block* will decrease vowel *separation*, (6) less so for hearing speakers than for implant users; (7) vowel *separation* will increase after extended *implant use*, and (8) it will diminish with *short-term interruptions* of auditory feedback.
FIG. 2. According to the DIVA model, during speech production an auditory trajectory is planned to pass through the sequence of auditory goals that correspond to the input phoneme string. When the dispersion of the goal region is reduced (dotted squares), the contrast distance between the goals increases (dotted double-headed arrow).

II. METHOD

A. Participants

The experimental group was comprised of six male and two female postlingually deaf, adult, paid volunteers, speakers of Standard American English. Table I shows that the group was heterogeneous in several respects, as is characteristic of this population. Age at onset of hearing loss ranged from birth to 60 years; age at onset of profound loss from 26 to 72. Duration of profound loss varied from less than a year to ten years; the average age of receiving an implant ranged from 28 to 78. Subjects' consonant recognition scores measured before activation of their implants ranged from 21% to 49% correct, and their vowel recognition scores from 25% to 64%. For a description of the phoneme recognition test, see Lane *et al.* (2005) The implant was either the Clarion (Advanced Bionics), cf. Wilson *et al.* (1995); or the Nucleus 24, (Cochlear Corp.), cf. Blamey *et al.* (1987) and McKay and McDermott (1993).

A control group was comprised initially of four male and six female participants, speakers of Standard American English, who reported no speech or hearing anomalies. A screening test was administered to speakers in this group over age 40, in order to determine approximate thresholds at 0.5, 1, 2, and 4 kHz. After a practice tone at 50 dB HL, sound pressure was increased in 5 dB increments from 0 to 25 dB HL or until the subject reported hearing a tone. The series was presented twice at each of the four frequencies to each ear. Subjects who failed to report hearing the tone in any of the 16 series were excluded; this resulted in excluding two male participants, leaving eight subjects in the group. Cochlear implant users participated in four recording sessions, two pre-implant, one approximately a month after activation of their implant speech processors, the other approximately a year after activation. The normal-hearing controls served only once.

B. Procedure

The elicitation set consisted of five /hVd/ words. Before each utterance in a bite block condition, a bite block made of plastic (the kind used in football mouth guards) was inserted between the participant's upper and lower left first bicuspid. The thickness of the bite blocks varied inversely with typical jaw opening for each vowel, as follows: *heed* 2.5 cm; *hid* 2.0 cm, *head* 1.5 cm, *had* 1.0 cm, *hot* 0.5 cm. These sizes were chosen to significantly disrupt the vertical displacement of the jaw relative to its normal position (informally observed) for the particular vowel, e.g., a large bite block was used to force an unnaturally large opening during the high vowel in "heed," whereas a small bite block was used to force an unnaturally small opening for the low vowel in "hot."

Implant users were tested in two sessions prior to activation of the speech processors of their cochlear implants, at one month postactivation and at one year postactivation. For the control group, only a single time sample was recorded. For all subjects, twenty repetitions of each of the five hVd words, uttered in isolation with emphasis on the vowel, were elicited in random order in each of four experimental conditions—the four possible combinations of auditory feedback available or not and bite block inserted or not: (1) No bite block, auditory feedback; (2) No bite block, no feedback; (3) Bite block, no feedback; (4) Bite block, auditory feedback. Since a vowel-specific bite block was inserted for each trial and the vowel order was randomized, the bite block was changed between trials in the bite block conditions. The four experimental conditions were always presented in the order just given with one exception: Feedback was not varied with the deaf participants in the recording

TABLE I. Characteristics of participants with cochlear implants.

Speakers	FI	FJ	MJ	MK	ML	MM	MO	MP
Consonant perception (% correct)	26	25	21	24	21	32	49	21
Vowel perception (% correct)	29	26	35	25	64	32	51	27
Etiology	Autoimmune response	Infection	Hereditary	Unknown	Infection	Noise (WWII)	Blood clot	Hereditary
Age at onset of change in hearing	19	5	Early 30s	18	10	20	60	Birth
Age at onset of profound loss	54	45	43	28	48	72	67	26

session prior to activation of their implants. They received only the no-bite-block followed by the bite-block conditions. To simulate to a limited degree the implant users' lack of auditory feedback in the processor-off condition, the speakers with normal hearing had their auditory feedback masked by speech-shaped noise presented at 95 dB (SPL).

C. Equipment

Speakers were seated in a sound-attenuating room in a comfortable office chair. A head-mounted electret microphone (Audio-Technica, model AT803B) was placed at a fixed distance of 20 cm from the speaker's lips. Elicitation utterances were presented on a monitor. For the feedback-off condition, participants with normal hearing wore calibrated TDH-39 headphones with ear cushions. The headphones were supplied with noise from a custom-built device (Technical Collaborative, Lexington, MA). The noise was approximately speech-shaped, with a spectral envelope that rolls off at 6 dB per octave. Participants with cochlear prostheses used the normal settings of their speech processors for the feedback-on conditions. For the feedback off conditions, the input to their processors was turned off.

For calibration of sound pressure level, a sound generator (electrolarynx) was placed in front of the speaker's lips while an experimenter observed the sound pressure level on a sound level meter (C scale) placed next to the microphone. The calibration signal and participants' speech were low-pass filtered at 7.2 kHz and digitized in real-time with a 16 kHz sampling rate.

D. Data extraction

The start and end of each token (/hVd/) were labeled automatically based on smoothed rms thresholding exceeding 20% of the peak value for the utterance. The first and second formants were extracted algorithmically from an LPC spectrum around mid-vowel (half the interval from onset to offset) using a 40 ms analysis window for F0 and a 25 ms window for the formants. The algorithm displayed, for each vowel token, (a) LPC-derived formant estimates computed initially at mid-vowel; (b) a broadband spectrogram on which was superimposed the formant trajectories that were detected; and (c) the spectral cross section at the measurement time. In a preliminary pass through the data, the experimenter set the formant bandwidth and LPC filter order to optimize formant identification in each subject's vowel tokens. In the data collection pass, if three formants were detected unambiguously in the regions expected for that vowel target, the experimenter accepted that token with those values as complete and moved on to the next. If the algorithm did not succeed in detecting a formant, the experimenter shifted the time of spectral analysis between one and three pitch periods.

To measure dispersion, we determined for each utterance of a phoneme the Euclidean distance of that single token in the $F1 \times F2$ plane from the average position of all the tokens of that phoneme. Then, those deviations were converted to logarithms (to render the distributions more normal) and averaged across repetitions and subjects to obtain
FIG. 3. Mean token dispersion in the formant plane for the five vowels elicited. For the implant users (left pane), dispersion is plotted as a function of the time sample, and presence ("ON") or absence of auditory feedback during elicitation, with bite block insertion (triangles) as a parameter. For the speakers with normal hearing, the treatments were presence or absence of auditory feedback and of bite block (triangles). (For the cochlear implant users, each point is the mean of 800 determinations, 20 repetitions of each of 5 vowels produced by 8 speakers. For the hearing controls, each point is the mean of 700 determinations, 20 repetitions of 5 vowels produced by 7 speakers.) Error bars are one standard error of the mean.

the mean dispersion for that phoneme under the given experimental condition. To measure acoustic contrast distance, Mahalanobis distances were calculated for the ten possible pairs of five vowels, on each of twenty repetitions. Each repetition of a particular vowel on the ith trial is given a Mahalanobis distance to the distribution of each of the other vowels. The square roots of the distances were averaged for each group and listening condition.[2]

III. RESULTS

A. Dispersion

The average dispersion of vowel phones around their mean in the formant plane is plotted in Fig. 3, for implant users and hearing controls separately. For the implant users (left pane), dispersion is plotted as a function of the time sample, and presence ("ON") or absence of auditory feedback during elicitation, with bite block insertion (triangles) as a parameter. For the hearing speakers, the treatments were presence or absence of auditory feedback and of bite block.

Hypothesis (1) states that the bite block will increase implant users' vowel dispersion. As the figure shows, it did so under all conditions of the experiment and especially before speakers had some hearing restored by cochlear prosthesis. Hypothesis (2), which states that the effect of the bite block will decline over time as the implant user gains experience with auditory feedback, is not supported: the effect of time sample (one month or one year after processor activation) and the time $\times$ bite block interaction are not significant. (The results of an ANOVA are reported in Table II). Hypothesis (3) states that vowel dispersion measured on speakers with normal hearing will increase less as a result of introducing the bite blocks than dispersion measured on implant users. These outcomes must be compared cautiously as the groups are small and differ in several respects, including gender and age. Contrary to the hypothesis, as Fig. 3 shows, the smaller increase in dispersion for the hearing controls, 10 Hz, was as large or larger than all the implant users' in-

dence that this enlarged dispersion declined after greater experience hearing with the implant. Interrupting feedback did increase implant users' vowel dispersion but only in the one-year sample. It also increased the controls' dispersion but only without the bite blocks. The bite blocks were approximately equally disruptive for implant users and hearing controls.

B. Vowel contrast

Figure 4 presents a measure of speakers' compensations for the bite blocks. The vertical axes plot the average effect on F1 of inserting the bite block, compared to measures

creases in dispersion except for the preimplant condition. The mean increases were 13.7 Hz for the hearing subjects and 9.9 Hz for the implant users. The very high dispersion in the preimplant condition with no auditory feedback and bite blocks may be due to the elevated dispersion found without bite blocks in that condition. The increase in dispersion in that condition due to bite block, 26%, is comparable to the parallel increase obtained from the controls, 24%.

Hypothesis (4) states that dispersion of vowel tokens will be greater without auditory feedback than with it. It is supported by the findings with the implant users who yielded a significant effect of feedback condition (Table II), due primarily to their vowel dispersion measured one year after their implant speech processors had been activated. For the hearing speakers (Table III), the effects of interrupting auditory feedback on vowel dispersion depended on whether the bite blocks were present or not. Without bite blocks, dispersion was greater in the absence of feedback, consistent with hypothesis (4) ($F=3.8, df=7, 130, p<0.01$). However, with bite blocks, dispersion was higher in the presence of feedback than in its absence ($F=5.8, df=7, 130, p<0.01$), as was the case with the implant users in the one month sample.

To summarize: the bite blocks did indeed increase the dispersion of implant users' vowel phones, especially prior to their receiving their prostheses. However, there was no evi-

FIG. 5. The average size of the vowel space (AVS) is expressed as the mean of (the square root of) the Mahalanobis distances between the members of all ten possible pairs of the five vowels. For the implant users (left pane), AVS is plotted as a function of the time sample, and presence ("ON") or absence of auditory feedback during elicitation, with bite block insertion (triangles) as a parameter. For the controls, the treatments were presence or absence of auditory feedback and of bite block (triangles). (For the cochlear implant users, each point is the mean of 800 determinations of average vowel spacing. The 4 distances from each vowel token to the other tokens in each repetition set were averaged, and a grand mean obtained for the 20 repetitions of each of the 5 vowels produced by 8 speakers. For the hearing controls, each point is the mean of 700 determinations, 20 repetitions of 5 vowels produced by 7 speakers.) Error bars are one standard error of the mean.

without a bite block, and normalized by the latter (in percent) ("re: normal"). The horizontal axis plots the comparable measure for F2. Closed circles represent measures made with auditory feedback available; open, no feedback. The finding that most points lie within a few percent of the dotted lines at F1 % change=0 and F2 % change=0 indicates that our speakers, both implant users and controls, compensated for the bite block in a way that allowed them nearly to restore their formant frequencies in the unperturbed state. Nevertheless, the mean percent changes in F1 and F2, pooling across subjects and vowels (N=approximately 750 values) were significantly different from zero in every case but one (viz., F2 at one year without feedback). Those changes were, on average, almost identical comparing feedback and no feedback conditions. Not surprisingly, /i/ is one of the vowels most resistant to compensation as it is the vowel with the highest place of articulation in this study and thus particularly hindered by its 2.5 cm bite block.

The effects of the experimental interventions on the vowel space will be seen in Fig. 5 and Table IV. Findings for implant users and controls are shown separately. The average size of the vowel space (AVS) is expressed as the average Mahalanobis distance between the members of all ten possible pairs of the five vowels. For the implant users (left pane), AVS is plotted as a function of the time sample, and

presence ("ON") or absence of auditory feedback during elicitation, with bite block insertion (triangles) as a parameter. For the controls, the treatments were the presence or absence of auditory feedback and of bite block (Table V).

Hypothesis (5) states that the insertion of a bite block will reduce the distances in the formant plane separating vowels. It is supported by visual inspection of Fig. 5, where the triangles fall below the circles in both panes, and by ANOVAs for both groups of speakers. Hypothesis (6) states that the reduction in size of the vowel space due to the bite block will be less for the controls than for the implant users. This expectation is clearly not borne out, whether one measures the decrease in AVS in absolute terms (4.3 units for controls, 2.5 for implant users, averaging across all values) or relative terms (31% for controls, 22% for implant users). The reduction in the controls' vowel space with a bite block appears to be so large, compared to the implant users, at least in part because they had a larger vowel space in the first place (14.0 vs 11.2 units). This view is supported by the observation that AVS for the controls with a bite block is higher than the AVS for implant users with a bite block (9.7 units vs 9.0), despite the bigger percent reduction in AVS for normal-hearing speakers ($t=4.2, df=199, p<0.01$).

Hypothesis (7) states that vowel contrast will improve after extended implant use. Figure 5 shows that with auditory feedback (indicated by "on"), the size of the implant users' vowel space increased from one month to one year (both with and without bite block). However, without feedback no such improvement appeared: the vowel space was unchanged in size (no bite blocks, $t=1.2, df=784, p=0.25$) or became a half unit smaller (bite blocks, $t=5.7, df=783, p<0.01$). Examining normal-hearing speakers' productions of /s/ with and without masking while they wore a dental prosthesis, Jones and Munhall (2003) report a parallel result: There was improvement in compensating for the prosthesis but only when speakers could hear their speech.

Hypothesis (8) states that the size of the vowel space will be greater with auditory feedback than without it. This was confirmed by measures taken, both with and without bite blocks, at implant users' one year session but was not observed at the one month session where, on the contrary, AVS with bite blocks inserted was larger in the absence of feedback ($t=15.3, df=787, p<0.01$). Likewise, the controls showed significantly larger vowel spaces without auditory feedback across bite block condition (Table V).

To summarize: the implant users and hearing controls in this experiment did not compensate fully for the shift in formant values caused by insertion of the bite blocks. Consequently there were net changes to the size of the vowel space and those changes varied with the samples of time since implantation and the presence or absence of auditory feedback. The insertion of the bite blocks did indeed reduce the distances separating vowels for both groups. However, the hearing controls did not appear to be better compensators; on the contrary, they had greater compression of the vowel space in both relative and absolute terms, though their AVS with the bite block was still higher than that for the implant users with the bite block. The implant users' vowel spaces had grown by the one-year session but not in the first month. Finally, interrupting implant users' auditory feedback at one year led to a reduction in their vowel spaces, consistent with the hypothesis, but interruption produced the opposite effect in the controls.

IV. DISCUSSION

A. Dispersion

The dispersion of vowel tokens around their means (Fig. 3) was substantially increased by insertion of the bite blocks, confirming hypothesis (1). For the implant users, dispersion of vowel productions was highest before they received prosthetic hearing; at this time most of the speakers had too little audition to distinguish among vowels and that had been the case for some years. Then the bite blocks were introduced exacerbating the already elevated vowel dispersion. In terms

of the model in Fig. 1, the deaf speakers' poor discriminative capacity deprived them of accurate auditory error signals (box 3) that would otherwise modify future feedforward commands (setting aside for now the issue of closed-loop error correction within a syllable). The lack of an auditory error signal caused the deaf speakers to produce a greater range of trajectories (Fig. 2) passing through the phonemic goal regions, and that greater range was reflected in the mid-vowel formant measures and thus in the measured dispersion. Despite this variability, the late-deafened speakers compensated astonishingly well to bite blocks after decades with degraded or no auditory feedback (cf., Fig. 4). This may be a reflection of goal regions that are highly stable over time and over feedback conditions, while the changes in dispersion due to bite block and changes in feedback may be attributable to changes in trajectories passing through the outskirts of those goal regions. The DIVA model postulates that goal regions and feedforward commands degrade very slowly over time with extensive hearing loss. [On the stability of the goal regions, see Perkell *et al.* (1992).]

Consistent with our findings, the sole study of the effects of bite block on late-deafened adults that has come to our attention (Tye *et al.*, 1983) reports that two deaf speakers showed more variable tongue shapes and positions, both with and without bite blocks, than did three hearing controls. The dramatic drop in implant users' vowel dispersion in the present study that occurred a month after they had some hearing restored, and the long-term decrease of their dispersion into the normal range, confirm that auditory feedback reduces production variability (Harris *et al.*, 1985; McGarr and Campbell, 1995), possibly by making trajectories smoother and more accurate.

One month of auditory experience with the implant markedly reduced dispersion both with and without the bite blocks. The enlarged vowel dispersion due to the bite blocks did not diminish significantly as the implant users gained auditory experience from one month to one year (Fig. 3), disconfirming hypothesis (2). (If auditory feedback were a guarantor of reduced variability, the speakers with normal hearing would not have increased dispersion as much as they did with the introduction of the bite block.) At one year after activation of their speech processors, however, implant users' dispersion reached a minimum without the bite blocks, indicating a greater role for auditory feedback after longer experience with the implant.

The controls were also more variable in their vowel productions with introduction of the bite blocks. The increase in their dispersion compared to their vowel productions without bite blocks was not less than that of implant users, contrary to hypothesis (3).

Finally, do short-term interruptions of auditory feedback increase vowel token dispersion, as hypothesis (4) posits? The answer is a qualified "yes." For the implant users, dispersion was greater without auditory feedback in the sample at one year but not that at one month. Auditory feedback may not have reduced dispersion at one month because prosthetic feedback is quite different from the speaker's former auditory feedback. Thus it takes some time before the auditory system reorganizes to the point where it can make use of the

new auditory information for guiding speech. For the control speakers, dispersion without bite blocks was also greater without auditory feedback. However, with the bite blocks in place, the controls' vowel dispersion was unexpectedly less without feedback than with it, possibly because speakers had adopted a "clear speech" strategy in the face of bite blocks and no feedback (Lane and Tranel, 1971; Picheny *et al.*, 1986).

B. Vowel contrast

Tye *et al.* (1983) found that two deaf speakers (one congenitally deaf, the other postlingually deaf), exhibited articulatory compensation for a bite block. Campbell (1999) reported that a group of six congenitally, profoundly deaf speakers not only compensated but in fact overcompensated for a bite block in production of high vowels. In the present study, the implant users' compensation for the bite blocks was excellent (Fig. 4), with most vowel means falling within 5% of perfect compensation. It is questionable whether the implant users, given the limited fidelity of their prosthetic hearing, were able to detect that they had undercompensated. With speakers having normal hearing, Baum *et al.* (1996) found no effect of bite block on the speaker's vowel intelligibility and rated vowel quality (except for /i/). Fowler and Turvey (1980) found that bite block vowels were slightly less identifiable than unperturbed vowels for three of their four speakers, but the bite block had a substantial effect on vowel identification with only one speaker.

The significant shortfall in bite block compensation that remained after our speakers' compensatory movements is reflected in the average vowel spacing as a reduction (Fig. 5), as predicted by hypothesis (5). Turning to the control speakers, Fig. 5 shows that with bite blocks in place they also reduced their vowel spaces but to a much greater degree than the implant users thus disconfirming hypothesis (6) that their vowel contrast would be less affected than that of the implant users.

There is evidence, confirming hypothesis (7), that vowel contrast improved with extended use of the auditory prosthesis: with auditory feedback, the average vowel space grew from the one-month to the one-year sample (Fig. 5) both with and without bite blocks. With sustained auditory feedback and hearing speakers, Baum *et al.* (1996) found that 15 min of conversation with bite blocks in place enhanced compensation. Flege *et al.* (1988) obtained a similar result. We examined our data for a short-term practice effect by comparing percent bite block compensation on the first and last (twentieth) trial in the one-month and one-year samples; however, we found none. Most likely, it was the extended experience with their prostheses that led implant users to increase contrast distance by the time of the one-year sample. Economou *et al.* (1992) reported on a postlingually deaf preadolescent who had a failed single-channel implant replaced by a multichannel device. Eighteen days after the failure of the single-channel implant, his vowel space was reduced and after a year's experience with the multichannel implant, it was significantly expanded.
