The First Joint Meeting of the Acoustical Societies of America and Japan—How it happened

John C. Burgess[a]
Department of Mechanical Engineering, University of Hawaii, 2540 Dole Street, Honolulu, Hawaii 96822

To the editor:

The First Joint Meeting of the Acoustical Societies of America and Japan was a major milestone in the history of both societies. It opened the doors for much productive research collaboration and many personal associations. Neither Society has been the same since. This is the story of how it happened.

It was a cold 1973 winter day in Ottawa, at the National Research Council of Canada. I was an Invited Researcher in the Acoustics Section of the Physics Department, on Sabbatical leave from the University of Hawaii. During one of the Section's coffee hours, Edgar Shaw, out of the blue, asked me, "When are we going to have a meeting in Hawaii?" It was an amusing thought, since Ottawa was then a frozen wonderland. It would have been easy to forget—except that it came from the President of the Acoustical Society of America.

Edgar's question gave birth to what became the First Joint Meeting of the Acoustical Society of America (ASA) and the Acoustical Society of Japan (ASJ), held at the Sheraton-Waikiki in Honolulu, Hawaii, 27 November–1 December 1978, with James L. Flanagan as ASA President and T. Nimura as ASJ President.

Edgar's thought germinated until my return to Hawaii. With "Why not?" in mind, I sent an offer to Betty Goodfriend. Betty's response was "the Executive Council will never approve it." To her surprise, the Council did, and appointed me the Meeting Chairman (MC).

At that time, a MC was responsible for everything that happened—or could happen—or should have happened—at the meeting location. There was no Executive Director or Meetings Committee. The MC reported directly to the Executive Council. It was a recognized but unwritten rule that the MC had authority to make all final decisions, even to over-rule a Society officer. In effect, the MC was the meeting CEO. Of course, the MC had to face the music if the decisions ruffled feathers.

A worrying thought gradually surfaced. Would company managers in the United States regard a Hawaii meeting as a boondoggle? The potential effect of this bias was all too clear. How could we marginalize it? If the meeting were a joint meeting with the ASJ, managers would be faced with missing out on what their Japanese competitors were doing.

It worked! Later, a Bell Labs colleague told me that one of the Lab managers had gone around saying, "They have *no right* to hold a meeting in Hawaii!" But Bell Labs acousticians were there.

A joint meeting required the agreement of the ASJ. But we were handicapped. As a Society, we knew almost nothing about the ASJ. The ASA office had only an address in Tokyo. ASA President Bob Gales wrote to the ASJ president with the suggestion. The ASJ agreed, and appointed Professor Juichi Igarashi as the ASJ Co-chairman for the meeting. Professor Hiroya Fujisaki became what amounted to the ASJ Foreign Minister.

Professor Fujisaki and I worked out the details of procedure, responsibility, and funding during one of his visits to Hawaii. The ASA and ASJ approved them. They were successful, and they became the basis for other joint meetings.

Technical Program Organizing Committee (TPOM) arrangements had a hidden surprise. George Sutton, our original Technical Program Chairman, was also an active oceanographer. A scheduled ocean trip was delayed—and delayed—until it coincided with the scheduled time for the TPOM.

We were lucky. Tony Embleton and Eileen were planning to stop in Hawaii on return from Australia—at exactly the time scheduled for the TPOM! Tony graciously agreed, on two-week's notice, to extend his visit and take on the job as Technical Program Chairman. The rest is history. Tony's ability to organize and coordinate made this one of the best technical programs ever.

The TPOM was held at the University of Hawaii. We used a new system for allocating session space. We set five 4 ft×8 ft "Canec" boards against a wall, one for each meeting day. Each had spaces for each meeting room down a side, and major time periods along the top. We preallocated all space and times and pinned small, multicolor identifying cards on the boards. These included committee meetings and social functions. The objective was to replace the race to be first to claim time and space with negotiation among Technical Committee (TC) representatives for exchange. It worked! Tony made some changes, and the procedure has been adopted by others. I've been told that our Japanese colleagues thought we had always done it this way.

To allow members to enjoy Hawaii during the best part of the day without missing important papers, I asked the TC representatives to keep the time period 12 noon to 2 p.m. clear of sessions. But a "work" mentality governed. The ending times for morning sessions and the starting times for afternoon sessions crept toward each other until little was left. After the TPOM was over, acting as the MC, I shortened the time allowed for both morning and afternoon papers until the morning sessions ended at noon, and the afternoon sessions did not start until 2 p.m. I don't recall any later complaints.

I arranged for the two presidents to have side-by-side suites. These were premier ocean-view, two-room suites. At that time, Presidents' Receptions were held in their suites. The idea was that the two presidents could create the environments they wanted, and that ASA and ASJ visitors could easily move from one to the other. It was crowded, but it worked! Japanese hospitality was exquisite, and American hospitality was superb. Everyone enjoyed it—except, possibly, the presidents' wives.

The Accompanying Persons Program was a great success. Frances Burgess and Milly Darby arranged genuine Hawaiian activities for each morning, including history, crafts, food preparation, singers, and dancers. These were not the usual tourist tinsel. Milly also provided the large number of leis that we used lavishly throughout the meeting. For many years afterwards, ladies would tell me at ASA meetings how much they enjoyed what Frances and Milly had done for them.

For this special occasion, I decided to depart from the standard ASA procedure of having two socials, and to replace one with an old-time, traditional banquet. The banquet was so popular that several people actually tried to crash it. The major features were a grand, multicourse Chinese dinner,

[a]Home address: 1269 Mokulua Dr., Kailua, HI 96734. Electronic mail: jcb@hawaii.edu

and Hawaiian entertainment. When attendees reached their tables, they were greeted with bottles of cooled champagne. The loud popping of corks set a great tone!

A pleasant surprise followed the ASA awards ceremony when ASJ President Nimura presented unique awards (with silver medals!) to ASA President James Flanagan and Meeting Chairman John Burgess.

The ASJ created a special "preparation committee" for this meeting. I was greatly surprised at how few of its ASA members were not Fellows. Professor Igarashi agreed to coordinate nominations. A special feature of the banquet was honoring seven new Japanese ASA Fellows.

This history would not be complete without recognizing George Curtis as the Facilities and Equipment Chairman and Ron Darby as the Registration Chairman. George hired university students as projection equipment operators, giving them first-hand experience with a major international technical meeting. Ron's innovative and efficient registration process had the important effect of giving attendees a pleasant first impression.

A final anecdote concerns Bob Beyer, the ASA Treasurer. During the meeting, in the lobby of the hotel, the ASJ casually handed him a large stack of $100 bills. With his attention thoroughly concentrated, he carried this cash across busy Kalakaua Avenue to the Bank of Hawaii—and has never fully recovered from the experience.

The First Joint Meeting was almost the largest ASA meeting and had the largest number of papers presented to that date. It was so popular that it was followed ten years later by a Second Joint Meeting, then after eight years by a Third, and now by a Fourth. Our two Societies were changed.

Anomalous negative dispersion in bone can result from the interference of fast and slow waves

Karen R. Marutyan, Mark R. Holland, and James G. Miller
Laboratory for Ultrasonics, Department of Physics, Washington University in St. Louis,
One Brookings Drive, St. Louis, Missouri 63130
james.g.miller@wustl.edu

Abstract: The goal of this work was to show that the apparent negative dispersion of ultrasonic waves propagating in bone can arise from interference between fast and slow longitudinal modes, each exhibiting positive dispersion. Simulations were carried out using two approaches: one based on the Biot-Johnson model and one independent of that model. Results of the simulations are mutually consistent and appear to account for measurements from many laboratories that report that the phase velocity of ultrasonic waves propagating in cancellous bone decreases with increasing frequency (negative dispersion) in about 90% of specimens but increases with frequency in about 10%.

1. Introduction

Ultrasound studies of bone are often motivated by the goal of developing ultrasonic markers for clinical diagnosis, e.g., for diagnosis of osteoporosis. Cancellous or trabecular bone is a porous material consisting of a solid matrix (trabeculae) and pores filled with fluidlike bone marrow. The mechanical architecture of cancellous bone is anisotropic—bone trabeculae are aligned along the specific directions resulting from stresses placed on bone during its development. Ultrasound propagation in bone has been modeled using Biot theory (Biot, 1955a; 1955b) that was originally introduced in the geophysics literature for application to fluid-saturated porous rocks. Biot theory presents numerous challenges, in part because of the need for values of many parameters of bone that are not readily available in the published literature, even for isotropic media. More recently, Schoenberg theory for stratified media has been applied to model bone as alternating layers of solid and fluid layers (Hughes *et al.*, 1999; Padilla and Laugier, 2000; Wear, 2001). Both the Biot and the stratified model predict the existence of two compressional wave modes, a fast and a slow mode.

Both models enjoy some success in accounting for experimental data. Measurements of the ultrasonic characteristics of bone include the attenuation coefficient, speed of sound, and phase velocity, and their respective frequency dependences. Bone attenuates ultrasound in a manner that is approximately linear with frequency (Chaffai *et al.*, 2000; Wear *et al.*, 2000). The attenuation characteristics are frequently reported as a rate of change with frequency, Broadband Ultrasound Attenuation (BUA) or, if normalized with the propagation distance, normalized Broadband Ultrasound Attenuation (nBUA). Although there is a general consensus on the linear or quasilinear with frequency dependence of attenuation, there is considerable variation in the behavior of the frequency dependence of phase velocity (dispersion) among bone samples. Indeed, measurements from many laboratories indicate that, on average, the phase velocity of ultrasonic waves propagating in cancellous bone decreases with increasing frequency (negative dispersion). However, positive dispersion is observed in approximately 10%–20% of sites measured (Droin *et al.*, 1998; Nicholson *et al.*, 1996; Strelitzki and Evans, 1996; Waters and Hoffmeister, 2005; Wear, 2000). Furthermore, the confusion is aggravated by the fact that the velocity of both the fast and the slow wave varies with the porosity level and

insonation direction relative to the orientation of the trabecular network (the insonation angle). As a consequence, in some experiments both the slow and fast waves are detected and are clearly delineated. However, in a significant number of experiments the time difference between arrivals of the waveforms associated with both waves is small compared to the temporal extent of the ultrasonic pulse. This results in an overlap in the recorded data and makes it impossible to separate fast and slow modes for quantitative assessment.

One goal of the present work is to examine these apparent inconsistencies in measured ultrasonic indices based on causality considerations. For media with an attenuation coefficient that can be approximated as increasing linearly with frequency, such as bone, the nearly local approximations to the Kramers-Kronig relations with one subtraction (Waters *et al.*, 2000) suggest that an increase of velocity with frequency would be expected, which is in sharp contrast with the decrease with frequency that is often reported. If the attenuation coefficient were strictly proportional to frequency, the dispersion would increase logarithmically with frequency. It is on this basis that we refer to the negative dispersion in bone as anomalous. We note that the term "anomalous dispersion" has a different meaning in optics. In this work we propose an alternative explanation for the observed negative dispersion in cancellous bone. Our hypothesis is that the apparent negative dispersion can result from the interference between the fast wave and the slow wave modes that characterize the composite structure of bone.

2. Methods and computer simulations

Computer simulations were carried out using two different models. An input waveform was constructed with the power spectrum peaking at 550 kHz, with the −6-dB spectrum spanning the frequency range of 250 to 850 kHz and the −20-dB spectrum spanning the frequency range of 100 to 1100 kHz, typical of that used for measurements in bone. The temporal extent of the input signal was approximately 3.8 μs. For both simulations, the input signal was propagated through the specimen or through a nonattenuating and nondispersive water path with velocity of 1500 m/s over the identical travel distance to generate sample and reference radio frequency (rf) traces, respectively. Linear plane-wave propagation was assumed. The thickness of bone specimen served as a variable parameter to adjust the overlap of the fast and slow waveforms. The resulting mixed-mode rf traces that correspond to the interference field were analyzed with a phase spectroscopy algorithm previously validated with experimental data (Marutyan *et al.*, 2006; Trousil *et al.*, 2001) to assess the apparent ultrasonic properties of the resulting rf trace.

For one set of simulations, the acoustic propagation was modeled using the modified Biot-Johnson approach following the formalism by Fellah *et al.* (2004) in which the complex Biot coefficients (or "mass" coefficients) were modified in accordance with the dynamic complex tortuosity introduced by Johnson *et al.* (1987). The propagated waveform was obtained by evaluating a complex transmission coefficient $T(\omega, l)$ that depends on frequency ω and specimen thickness l, as well as on bone structural parameters, which were taken to be identical to

TABLE I. Input data for simulations of Biot-Johnson and stratified models.

Parameter	Value
Porosity	0.83
Viscous characteristics length	5 μm
Tortuosity	1.05
Bulk modulus of pore fluid	2.28 GPa
Bulk modulus of elastic solid	20 GPa
Bulk modulus of the bone skeletal frame	3.3 GPa
Shear modulus of the bone skeletal frame	2.6 GPa
Solid bone density	1960 kg/m^3
Fluid density	1000 kg/m^3
Fluid viscosity	10^{-3} kg/(ms)

those for the specimen evaluated in Fellah *et al.* (Table 1). The mathematical expression for the transmission coefficient is defined in Eqs. (24)–(28) of Fellah *et al.* and derived in the appendix of that work.

In a second set of simulations, bone was modeled by independently propagating two modes that correspond to fast and slow waves, both of which were characterized by attenuation and dispersion that were causally linked. The values for nBUA were assigned to be 7 and 20 dB/MHz/cm for the slow and the fast wave, respectively, identical to the values reported in literature (Waters and Hoffmeister, 2005). The corresponding dispersion curves were then calculated from the nearly local Kramers-Kronig approximation. Because the Kramers-Kronig relations are ambiguous to a constant offset, the values of the phase velocity were arbitrarily set to 2100 and 1500 m/s at 300 kHz for the fast and the slow velocity, respectively. Other choices for phase velocities were explored and were shown not to alter significantly the outcome of the simulations, suggesting that the results obtained would be valid for a range of anatomical locations and degrees of porosity. Once the ultrasonic parameters for sound propagation in bone were established, the frequency domain representation of the output waveform was obtained in the following manner:

$$\text{Output}(\omega) = w \cdot \text{Input}(\omega) \cdot H_{\text{fast}}(\omega, l) + (1 - w) \cdot \text{Input}(\omega) \cdot H_{\text{slow}}(\omega, l), \tag{1}$$

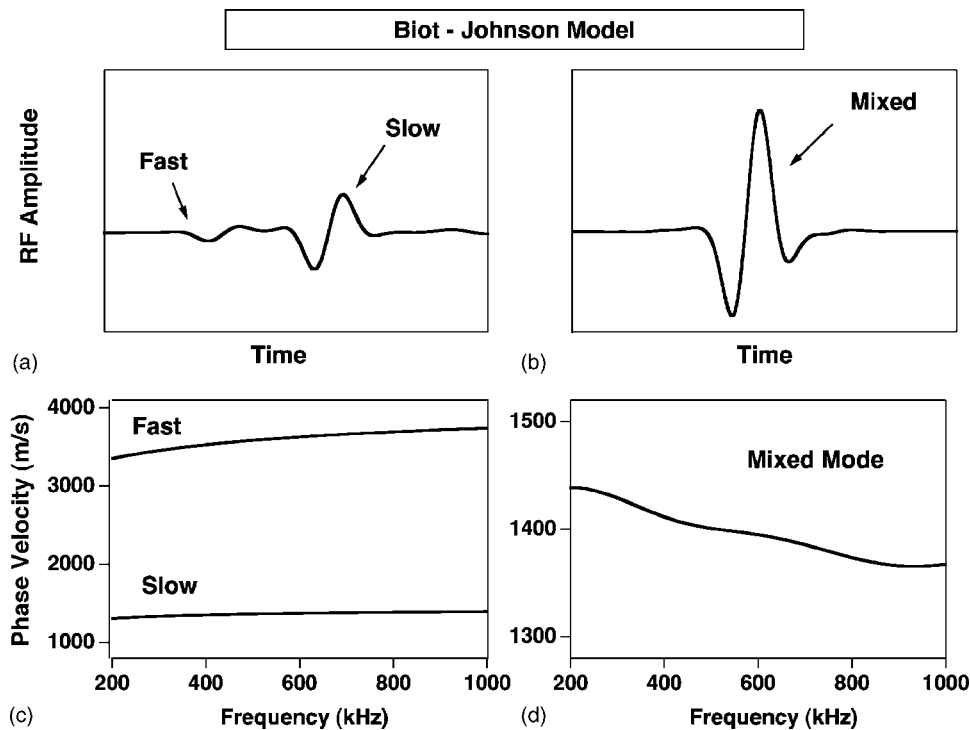
where w represents a weighting parameter that varies from 0 to l, $\text{Input}(\omega)$ is the frequency spectrum of the input waveform. The transfer functions $H_{\text{fast}}(\omega, l)$ and $H_{\text{slow}}(\omega, l)$ for the fast and slow modes are given by


FIG. 1. Simulations for the Biot-Johnson model. Bone parameters used in the simulations are listed in Table I. (a) Radio frequency signal that contains distinctly separable fast and slow waves; (b) radio frequency signal of the mixed mode; (c) theoretical values for phase velocity of the fast and slow wave; (d) phase velocity for the mixed mode ($\Delta t = 0.7 \ \mu s$).
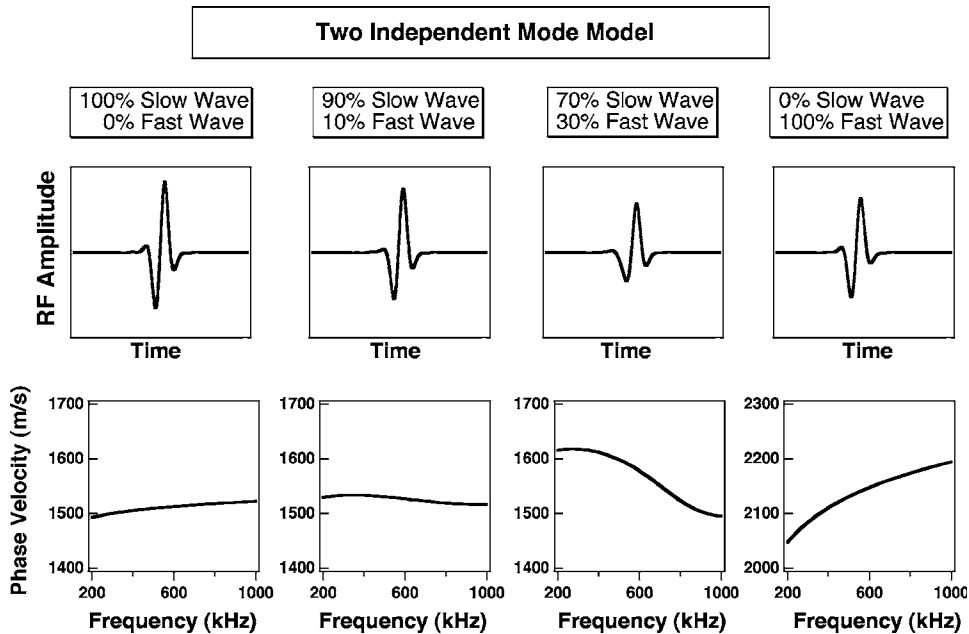

Fig. 2. Results for the two independent mode simulations with the weighting parameter, *w*, of values of 0.0, 0.1, 0.3, and 1.0 from the leftmost to rightmost column, respectively. For all cases Δt is set to 0.6 μs.

$$H_{\text{fast/slow}}(\omega, l) = \exp(- \alpha_{\text{fast/slow}}(\omega) \cdot l) \cdot \exp(i\omega l / c_{\text{fast/slow}}(\omega)), \tag{2}$$

where $\alpha_{\text{fast/slow}}(\omega)$ denotes the (linear with frequency) attenuation coefficient and $c_{\text{fast/slow}}(\omega)$ denotes the (logarithmically increasing) phase velocity for the fast and the slow wave, respectively.

3. Results and discussion

Results from the simulations based on the Biot-Johnson model are shown in Fig. 1. For the given sets of parameters, the phase velocity of the fast and the slow wave was characterized with a theoretical dispersion that is positive and logarithmiclike as seen in panel (c). The midband value of phase velocity for the fast wave lay in the range of 3000 to 4000 m/s, whereas the phase velocities of the slow wave were about 1400 m/s. To characterize the temporal overlap of the two modes, we introduced the parameter Δt, representing the time difference in the arrival times of the fast and slow waves. As the value of Δt decreases, significantly overlapped composite waveforms are produced. For a representative case with $\Delta t \approx 0.7$ μs, a *negative* dispersion was predicted in accordance with the proposed hypothesis [panels (b) and (d) of Fig. 1]. However, the appearance of the composite rf waveform reveals very little, if any, interference effects. Nevertheless, the interference overlap resulted in an apparent negative dispersion, which is substantial (about −70 m/s from 200 kHz to 1 MHz) and could be approximated as quasilinear. This value for the magnitude of dispersion is comparable to values measured experimentally (Droin *et al.*, 1998).

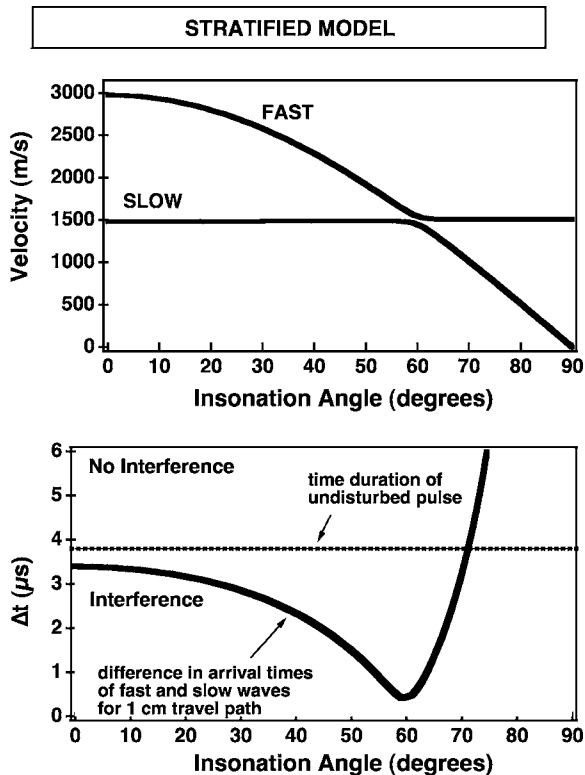
      Results of the second set of simulations are illustrated in Fig. 2, in which composite rf waveforms obtained by superposition of the fast and slow waves are plotted along with the estimated dispersion. The content of the mixed waveform was varied to produce fields ranging from 100% slow wave to 100% fast wave (the leftmost and rightmost columns of Fig. 2, respectively). The second and third columns represent signals that correspond to propagation of the ultrasonic pulse with weighting factor *w* equal to 0.1 and 0.3 (10% and 30% contribution of fast wave), respectively. The overall velocity level of the vertical axes for the dispersion plots is


FIG. 3. Predictions from the stratified model of bone: (top panel) anisotropy in velocity of fast and slow waves; (bottom panel) the time difference between arrival time of the fast and slow wave Δt (normalized per propagation distance in cm) plotted vs insonation angle relative to trabecular alignment. The region below the dashed line, which is defined by the pulse length (3.8 μs for current work), is where the interference of fast and slow wave modes occurs.

varied, but the relative scale is preserved so that the phase velocity axis spans a range of 300 m/s in each plot. As expected, for the cases with the existence of only one of the modes (100% slow or 100% fast waves) the ultrasonic parameters (i.e., a logarithmically increasing dispersion and linear attenuation) that served as input for simulations were recovered. For the mixed-mode cases, however, the simulations resulted in an apparent negative dispersion (second and third columns in Fig. 2). Once again a superficial examination of the rf traces reveals no visual indications of the effects due to the mode mixing. For this simulation the temporal overlap was characterized using values of $\Delta t \approx 0.6$ μs. Further investigation revealed that dispersion for the most part remained negative as Δt was varied from 0.4 to 1.0 μs. These values are similar to those used in simulations based on the Biot-Johnson model. In addition, simulations were performed by incrementally increasing the overall level of the velocity of the fast wave $V_{\text{Fast at 300 kHz}}$ from 1900 to 2500 m/s. These simulations (not shown here) similarly revealed mostly negative dispersion for the cases in which $\Delta t < 1$ μs.

In the laboratory setting, the interference of fast and slow waves has been observed in a number of studies. In an early study of bone anisotropy Hosokawa and Otani (1998) observed that "fast and slow waveforms widely overlap in time at incident angles $\theta_I = 20°$ and 30°" and higher. More recently, Lee *et al.* (2003) stated that "since the fast and slow waves were completely overlapped, only one longitudinal wave was observed for propagation in the ML directions." Padilla and Laugier (2000) independently proposed mode mixing to explain the disappearance of "slow wave at high angle of the trabecular alignment." They invoked a stratified model to estimate the arrival time for both modes, and showed that fast and slow waves are

strongly overlapped. In that theoretical work, a study with varying oblique incidence angle θ_I was assumed, and arrival times for slow and fast waves were evaluated as the function of the refraction angle θ_r. For the identical incident angle θ_I, slow and fast waves propagate at *different* refraction angles. Therefore, in our studies, we have chosen to evaluate the difference in arrival time Δt as a function of insonation angle, as illustrated in Fig. 3. The top panel of this figure depicts velocity of the fast and slow waves, and the bottom panel shows the difference in arrival time Δt for a 1-cm ultrasonic path plotted from parallel (0°) to perpendicular (90°) insonation relative to trabecular alignment. Of course, the curve of Δt would scale with the distance, whereas the pulse length would not. The order of Δt at which interference occurs is in the same range at which negative dispersion was shown to occur in our simulations, especially in the range of angles from 50° to 70°. The large values of Δt near perpendicular insonation result from stratified model predictions of nearly zero velocity for the slow wave at that angle. The calculations are based on the bone parameters given in Table 1.

Only phase distortions due to interference effects in the ultrasonic field are considered in the current study. In practice, there are additional complexities, such as phase cancellation effects at the face of a phase-sensitive (piezoelectric) receiver or receiving array, diffraction effects, and potential frequency-dependent reflection and transmission coefficients at the bone boundaries. These effects are usually specific to the experimental setup.

4. Conclusion

Results presented suggest that an interference effect between fast and slow wave modes can be a source for the measurement of an apparent negative dispersion in bone. These simulations using two independent approaches indicate that an apparent negative dispersion can arise even though the individual dispersions for the both fast and slow waves are positive. The degree of interference between fast and slow waves was consistent between both types of simulations and appeared to be comparable to that seen in representative experimental studies.

Report of the 27th F. V. Hunt Postdoctoral Fellow (2005-2006)

Catherine Berchok, Marine Physical Laboratory/Scripps Institution of Oceanography, University of California, San Diego, California 92106

I was fortunate to spend my year as the 2005–2006 F.V. Hunt Post-doctoral Fellow under the guidance of two mentors: Dr. Gerald D'Spain and Dr. John Hildebrand. Because their current research focuses on acoustic localization and bioacoustics, I was able to work on my research topic, studying the Lombard effect in fin whales, from a well-balanced perspective. I thank them, the Hunt family, and the Acoustical Society of America for this amazing learning experience.

The Lombard effect is a subconscious reflex in which an individual adjusts its vocal amplitude in response to perceived changes in the signal-to-noise ratio. Anyone who has ever tried to carry on a conversation in a crowded room has experienced this effect, but it has also been shown to exist in a variety of other animals including birds, primates, frogs, cats, and odontocete whales. Despite this diversity, there are several common trends found across all species: the Lombard effect shows high inter-individual variability, it is highly context dependent, the strongest response is seen for noise sources that fall within the frequency range of the vocalizations, and the increase in signal level for a given change in noise level is relatively small.

It was this last trend that guided much of my efforts over the past year. Because the Lombard effect is fairly small, accurate source localizations are vital to obtaining source levels with small enough error bounds that the actual Lombard effect is not obscured. To this end I developed a method to visualize and quantify the impact of measurement uncertainties on source

localization errors. I then used this method to examine the effects of array design as well as measurement of different properties of the received acoustic field (including time-of-arrival differences, amplitude ratios, and vector sensor bearings) on the reduction of these source location error bounds. I will be presenting these results at the upcoming Acoustical Society meeting this fall and will be submitting a paper for peer review in the near future. Improvements were made in my analysis routines (signal detector, cross correlator, and localizer) based on the findings of this study. For example, I added the relative-relocation cross-correlation technique (an approach developed in the seismic signal processing community and suggested by Dr. Mark McDonald and Dr. John Hildebrand) to improve time-of-arrival difference measurement uncertainty.

It is clear that when using an array of widely separated acoustic sensors to measure the Lombard effect, the optimal situation exists when the calling animal is within the perimeter of the array, and the noise source is either homogeneous (like wind-generated noise) or at a range significantly greater than the dimensions of the array (in the case of a point source such as a transiting ship). In this case the localization errors are minimized and the noise field received by the animal can be determined fairly easily. For this reason a widely spaced acoustic sensor array that can be redeployed frequently as the animals move about is the ideal solution. As a first stage in the design of this array, I collaborated with Richard Sears (Mingan Island Cetacean Study, Québec, Canada) to design and build a single autonomous recording buoy which is currently being used to record whales in the field. I am also working under the guidance of Bertel Møhl and his colleagues at Aarhus University in Denmark to incorporate their GPS-based time synchronization module into the buoy, which will greatly improve the localization accuracy of the array.

The high inter-individual variation was another aspect of the Lombard effect that caught our interest over the past year. Working with Dr. Ann Bowles at the Hubbs-SeaWorld Research Institute and with Dr. Pat Moore, Dr. Jim Finneran, and Dr. Dorian Houser at the SPAWAR Systems Center in San Diego, we developed an experimental protocol for measuring the extent of and possible reasons for this variability between individuals in a controlled environment. Presently, it is in review by the Hubbs-SeaWorld Research Institute's Institutional Animal Care and Use Committee.

I would once again like to extend my deepest thanks to the Hunt family for providing me with this opportunity. The questions raised during the research funded by this fellowship have led me into many new interesting areas of research that I had not been familiar with before this year, and I am fortunate to have met so many knowledgeable and helpful researchers in these areas. We hope to continue this work in the future and have submitted a detailed, multi-faceted proposal to the Office of Naval Research to further pursue various aspects of the Lombard effect in marine animals.

List of Publications from the past year:

Berchok, C. L., D'Spain, G. L., and Hildebrand, J. A. (**2006**) "Reducing source localization errors: a visualization method to help guide the design, calibration and use of widely separated acoustic sensor arrays," *152nd Meeting of the Acoustical Society of America Joint Meeting With* the Acoustical Society of Japan, Honolulu, Hawaii, 28 Nov. 2 Dec.

Berchok, C. L., D'Spain, G. L., and Hildebrand, J. A., "Comments on marine mammal localization errors using an array of widely separated sensors" (*submission pending*).

USA Meetings Calendar

Listed below is a summary of meetings related to acoustics to be held in the U.S. in the near future. The month/year notation refers to the issue in which a complete meeting announcement appeared.

2006

28 Nov. 2 Dec.	152nd Meeting of the Acoustical Society of America joint with the Acoustical Society of Japan, Honolulu, Hawaii [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; www: http://asa.aip.org]. Deadline for receipt of abstracts: 30 June 2006.

2007

4–8 June	153rd Meeting of the Acoustical Society of America, Salt Lake City, Utah [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; www: http://asa.aip.org].
22–24 Oct.	NoiseCon 2007, Reno, NV [Website is: www.inceusa.org/nc07]
27 Nov.– 2 Dec.	154th Meeting of the Acoustical Society of America, New Orleans, Louisiana (note Tuesday through Saturday) [Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2360; Fax: 516-576-2377; E-mail: asa@aip.org; www: http://asa.aip.org].

2008

28 July–1 Aug.	9th International Congress on Noise as a Public Health Problem (Quintennial meeting of ICBEN, the International Commission on Biological Effects of Noise). Foxwoods Resort, Mashantucket, CT [Jerry V. Tobias, ICBEN 9, Post Office Box 1609, Groton, CT 06340-1609, Tel. 860-572-0680; Web: www.icben.org. E-mail icben2008@att.net].

Cumulative Indexes to the Journal of the Acoustical Society of America

Ordering information: Orders must be paid by check or money order in U.S. funds drawn on a U.S. bank or by Mastercard, Visa, or American Express credit cards. Send orders to Circulation and Fulfillment Division, American Institute of Physics, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502; Tel.: 516-576-2270. Non-U.S. orders add $11 per index.

Some indexes are out of print as noted below.

Volumes 1–10, 1929–1938: JASA, and Contemporary Literature, 1937–1939. Classified by subject and indexed by author. Pp. 131. Price: ASA members $5; Nonmembers $10.
Volumes 11–20, 1939–1948: JASA, Contemporary Literature and Patents. Classified by subject and indexed by author and inventor. Pp. 395. Out of Print.
Volumes 21–30, 1949–1958: JASA, Contemporary Literature and Patents. Classified by subject and indexed by author and inventor. Pp. 952. Price: ASA members $20; Nonmembers $75.
Volumes 31–35, 1959–1963: JASA, Contemporary Literature and Patents. Classified by subject and indexed by author and inventor. Pp. 1140. Price: ASA members $20; Nonmembers $90.
Volumes 36–44, 1964–1968: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 485. Out of Print.
Volumes 36–44, 1964–1968: Contemporary Literature. Classified by subject and indexed by author. Pp. 1060. Out of Print.
Volumes 45–54, 1969–1973: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 540. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).
Volumes 55–64, 1974–1978: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 816. Price: $20 (paperbound); ASA members $25 (clothbound); Nonmembers $60 (clothbound).
Volumes 65–74, 1979–1983: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 624. Price: ASA members $25 (paperbound); Nonmembers $75 (clothbound).
Volumes 75–84, 1984–1988: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 625. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).
Volumes 85–94, 1989–1993: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 736. Price: ASA members $30 (paperbound); Nonmembers $80 (clothbound).
Volumes 95–104, 1994–1998: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 632, Price: ASA members $40 (paperbound); Nonmembers $90 (clothbound).
Volumes 105–114, 1999–2003: JASA and Patents. Classified by subject and indexed by author and inventor. Pp. 616, Price: ASA members $50; Nonmembers $90 (paperbound).

ACOUSTICAL STANDARDS NEWS

Susan B. Blaeser, Standards Manager

ASA Standards Secretariat, Acoustical Society of America, 35 Pinelawn Rd., Suite 114E, Melville, NY 11747 [Tel.: (631) 390-0215; Fax: (631) 390-0217; e-mail: asastds@aip.org]

George S. K. Wong

Acoustical Standards, Institute for National Measurement Standards, National Research Council, Ottawa, Ontario K1A 0R6, Canada [Tel.: (613) 993-6159; Fax: (613) 990-8765; e-mail: george.wong@nrc.ca]

American National Standards (ANSI Standards) developed by Accredited Standards Committees S1, S2, S3, and S12 in the areas of acoustics, mechanical vibration and shock, bioacoustics, and noise, respectively, are published by the Acoustical Society of America (ASA). In addition to these standards, ASA publishes Catalogs of Acoustical Standards, both National and International. To receive copies of the latest Standards Catalogs, please, contact Susan B. Blaeser.

Comments are welcomed on all material in Acoustical Standards News.

This Acoustical Standards News section in JASA, as well as the National and International Catalogs of Acoustical Standards, and other information on the Standards Program of the Acoustical Society of America, are available via the ASA home page: http://asa.aip.org

Standards Available for Use in the Classroom

In many technical areas it is essential that students become familiar with standards while they are still in school. Until recently, however, the high cost of standards was a barrier to using them in the classroom. Under a special ASA program, teachers who are ASA members can obtain a site license to reproduce standards needed in the classroom at a low cost.

Nearly 120 American National Standards developed by Accredited Standards Committee S1 Acoustics, S2 Mechanical Vibration and Shock, S3 Bioacoustics, and S12 Noise, are available under this program.

For more information contact the ASA Standards Secretariat at 631 390-0215. The complete list of American National Standards developed by these committees can be seen at the ASA Standards Store at http://asastore.aip.org/ or request a catalog from the Secretariat.

New Working Groups in S12

Accredited Standards Committee S12, Noise, recently approved the formation of two new working groups. S12/WG 45 "Measurement of Occupational Noise Exposure from Telephone Equipment" is chaired by A. K. Woo. The scope of S12/WG45 is: "Development of standard method(s) for measuring occupational noise exposure from telephone handsets, headsets, and headphones. This work may result in either the revision of ANSI S12.19-1996 or the development of a new standard."

S12/WG 46 "Acoustical Performance Criteria for Relocatable Classrooms" is co-chaired by T. Hardiman and P. D. Schomer. The scope of S12/WG 46 is: "To develop a standard that focuses on the challenges and unique circumstances surrounding the use and relocation of relocatable classrooms with a focus on labeling and methods to quantify acoustical performance."

WG membership is open to all interested experts and there is no fee to participate in a working group. If you are interested in more information about these or other standards working groups, please contact the Secretariat.

Standards Meetings Calendar National

The 152nd ASA Meeting, Honolulu, Hawaii, at the Sheraton Waikiki Hotel, 28 November–2 December 2006, the ASA Committee on Standards (ASACOS) and ASACOS STEERING Committees will meet as below:

•*Tuesday, 28 November 2006*

ASACOS Steering Committee

•*Wednesday, 29 November 2006*

ASA Committee on Standards (ASACOS). Meeting of the Committee that directs the Standards Program of the Acoustical Society.

International Standards Committee Meetings

•*16–20 April 2007*

Meeting of **ISO/TC 108/SC 5, Condition monitoring and diagnostics of machines**, Prague, Czech Republic

SC 5 and all of its working groups will be joined by the following additional working groups:

TC 108/WG 31 Balancing

TC 108/SC 2/WG 1 Vibration of machines

TC 108/SC 2/WG 7 Vibration of machines with active magnetic bearings

TC 108/SC 2/WG 10 Basic techniques for vibration diagnostics

•*23–27 April 2007*

Meetings of **ISO/TC 108, TC/108 SC 2, TC 108/SC 3 and TC 108/SC 6**, joined by their working groups (except those listed above), will meet in Berlin, Germany.

Recent International Standards Meetings

September and October 2006 were busy months for meetings of the International Standards Committees for which ASA administers the U.S. Technical Advisory Groups, as well as other international committees that are of interest to ASA's standards committees. The meetings began in September in Barcelona Spain, where **IEC/TC29 Electroacoustics** and its working groups met.

During the following week Madrid hosted the meetings of **ISO/TC 43 Acoustics; TC 43/SC 1 Noise**; and **TC 43/SC 2 Building Acoustics**, and their working groups.

During the same week, the **Consultative Committee on Acoustics, Ultrasound and Vibration** (CCAUV) met in Sèvres, France.

Members of **ISO/TC 108/SC 4, Human exposure to mechanical vibration and shock** and its European counterpart, **CEN/TC 231**, and their working groups met in Bratislava, Slovakia in October.

Results from these meetings were not available by press time. Items of

particular interest will appear in future issues. For information about these Committees or any other aspects of the ASA Standards Program, please contact the Secretariat.

Standards News from the United States

(Partially derived from *ANSI Reporter* and *ANSI Standards Action*, with appreciation)

American National Standards Call for Comment on Proposals Listed

This section solicits comments on proposed new American National Standards and on proposals to revise, reaffirm, or withdraw approval of existing standards. The dates listed in parenthesis are for information only.

ASA (ASC S1) (Acoustical Society of America)
Revisions

BSR S1.40-200x, Specification and Verification Procedures for Sound Calibrators [revision of ANSI S1.40-1984 (R2001)]

The standard specifies performance requirements for the sound pressure level, frequency, and total distortion generated by a sound calibrator. It also provides requirements for the influence of environmental conditions, for electromagnetic compatibility, and for instrument marking and documentation. It gives details of the tests necessary to verify that a model of sound calibrator conforms to all the requirements, as well as details of the method for periodic testing of a sound calibrator. (28 August 2006)

ASTM (ASTM International)

BSR/ASTM Z2340Z (F2544)-200x, Test Method for Determining a Weighted Sound Power Level of Central Vacuum Power Units (new standard) (3 September 2006)

CEA (Consumer Electronics Association)
New Standards

BSR/CEA 2031-200x, Testing and Measurement Methods for Mobile Loudspeaker Systems (new standard)

Defines test procedures for rating the performance and physical size of mobile loudspeakers, and requirements for reporting these characteristics. CEA 2031, when used in conjunction with CEA 2006-A, Testing & Measurement Methods for Mobile Audio Amplifiers, enables consumers to select mobile loudspeakers with power handling capabilities that are appropriate for the power output characteristics of their mobile amplifiers. (11 September 2006)

SCTE (Society of Cable Telecommunications Engineers)
New Standards

BSR/SCTE 24-21-200x, BV16 Speech Codec Specification for Voice Over IP Applications in Cable Telephony (new standard)

This document contains the description of the BV16 speech codec. BV16 compresses 8-kHz sampled narrowband speech to a bit rate of 16 kb/s by employing a speech coding algorithm called two-stage noise feedback coding (TSNFC).

ATIS (Alliance for Telecommunications Industry Solutions)

BSR T1.421-2001 (R200x), In-Line Filter for Use with Voiceband Terminal Equipment Operating on the Same Wire Pair with High Frequency (up to 12 MHz) Devices (reaffirmation of ANSI T1.421-2001)

This standard addresses the steady-state operation of both plain old telephone service (POTS) and digital subscriber line (DSL) services. Various tests and requirements are described to minimize mutual interactions in terms of continuous noise or signal degradation. Transient events such as impulsive noise and large current spikes introduced by POTS signaling or DSL state changes have not been considered and are left for further study.

Project Initiation Notification System (PINS)

ANSI Procedures require notification of ANSI by ANSI-accredited standards developers of the initiation and scope of activities expected to result in new or revised American National Standards. This information is a key element in planning and coordinating American National Standards. The following is a list of proposed new American National Standards or revisions to existing American National Standards that have been received from ANSI-accredited standards developers that utilize the periodic maintenance option in connection with their standards. Directly and materially affected interests wishing to receive more information should contact the standards developer directly.

EIA (Electronic Industries Alliance)

BSR/EIA 364-45A-2000 (R200x), Firewall Flame Test Procedure for Electrical Connectors (reaffirmation of ANSI/EIA 364-45A-2000)

Establishes test methods to determine the ability of a mated electrical firewall connector to resist specified flame and vibration during a 20-minute exposure. (26 September 2006)

ARI (Air-Conditioning and Refrigeration Institute)
New Standards

BSR/ARI 370-200x, Sound Rating of Large Outdoor Refrigerating and Air-Conditioning Equipment (new standard)

This standard applies to the outdoor portions of factory-made commercial and industrial large outdoor refrigerating and air-conditioning equipment, including heat pumps, used for refrigerating or air-conditioning of spaces. (24 October 2006)

Final Actions on American National Standards
The standards actions listed below have been approved by the ANSI Board of Standards Review (BSR) or by an ANSI-Audited Designator, as applicable.

ASA (ASC S2)
Withdrawals

ANSI S2.47-1990, Vibration of Buildings—Guidelines for the Measurement of Vibrations and Evaluation of Their Effects on Buildings [withdrawal of ANSI S2.47-1990 (R2001)] (19 May 2006)

IEEE (Institute of Electrical and Electronics Engineers)

BSR/IEEE C37.082-1982 (R200x), Standard Methods for the Measurement of Sound Pressure Levels of AC Power Circuit Breakers [reaffirmation of ANSI/IEEE C37.082-1982 (R2000)]

Establishes uniform guidelines for measurement and reporting of sound produced by AC power circuit breakers. Intended for use in measurement of the sound produced by outdoor circuit breakers in a free-field environment. Methods may be used indoors or in a restricted field, provided that precautions are observed in measurement and interpretation of results. Three types of tests are described: design tests, conformance tests, and field tests.

New National Adoptions

AMCA (Air Movement and Control Association)
New Standards

ANSI/AMCA 301-2006, Methods for Calculating Fan Sound Ratings from Laboratory Test Data (new standard): 8/3/2006

UL (Underwriters Laboratories, Inc.)
Revisions

BSR/UL 299 CAN/ULC-S504-200x, Standard for Safety for Dry Chemical Fire Extinguishers (revision of ANSI/UL 299/ULC-S504-2002) This proposal bulletin includes revisions to: correct a reference; operation test requirements; vibration test requirements; and temperature and humidity test requirements for the nameplate exposure and adhesion tests. (25 September 2006)

Information Concerning:
U.S. National Committee of the IEC

USNC TAG to IEC/TC 113—Nanotechnology Standardization for Electrical and Electronic Products and Systems

Call for Participants

The Technical Management Committee (TMC) of the U.S. National Committee for IEC has assigned the National Electrical Manufacturers' Association (NEMA) as the TAG Administrator for the newly established IEC/TC 113—Nanotechnology standardization for electrical and electronic products and systems. The interim scope of the TC is as follows:

Scope:

Standardization in the field of nanotechnology relevant to electricity and related technologies within the area of the IEC. These are especially electronics, magnetics and electromagnetics, electroacoustics, multimedia, telecommunication, and energy production. Specific topics are terminology and symbols, measurement and performance, reliability, design and development, electromagnetic compatibility, safety and environment. NOTE: Liaison will be ensured with other technical committees inside the IEC; relevant national, regional and international standardization bodies and organizations; as well as with other interested organizations and networks world-wide. Special attention will be given to the Liaison with the ISO TC 229 "Nanotechnology" to ensure coordination and to prevent duplication of work. Ken Gettman of NEMA is now in the process of organizing this TAG and anyone interested in participating is invited to contact him as follows: Kenneth E. Gettman, NEMA, 1300 North 17th Street, Suite 1752, Rosslyn, VA 22209; PHONE: (703) 841-3254; FAX: (703) 841-3354; e-mail: ken_gettman@nema.org.

Newly Published ISO and IEC Standards
Listed here are new and revised standards recently approved and promulgated by ISO—the International Organization for Standardization.

ISO Standards

ACOUSTICS (TC 43)

ISO 140-16:2006, Acoustics—Measurement of sound insulation in buildings and of building elements—Part 16: Laboratory measurement of the sound reduction index improvement by additional lining

ISO 717-1/Amd1:2006, Acoustics—Rating of sound insulation in buildings and of building elements—Part 1: Airborne sound insulation in buildings and of interior building elements—Amendment 1: Rounding rules related to single number ratings and single number quantities

ISO 717-2/Amd1:2006, Acoustics—Rating of sound insulation in buildings and of building elements—Part 2: Impact sound insulation—Amendment 1

ISO 17201-2:2006, Acoustics—Noise from shooting ranges—Part 2: Estimation of muzzle blast and projectile sound by calculation

ISO 16832:2006, Acoustics—Loudness scaling by means of categories

MECHANICAL VIBRATION AND SHOCK (TC 108)

ISO 16063-15:2006, Methods for the calibration of vibration and shock transducers—Part 15: Primary angular vibration calibration by laser interferometry

TRACTORS AND MACHINERY FOR AGRICULTURE AND FORESTRY (TC 23)

ISO 22867/Cor1:2006, Forestry machinery—Vibration test code for portable hand-held machines with internal combustion engine—Vibration at the handles—Corrigendum

SIEVES, SIEVING AND OTHER SIZING METHODS (TC 24)

ISO 20998-1:2006, Measurement and characterization of particles by acoustic methods—Part 1: Concepts and procedures in ultrasonic attenuation spectroscopy

IEC Standards

SEMICONDUCTOR DEVICES (TC 47)

IEC 60749-35 Ed. 1.0 b:2006, Semiconductor devices—Mechanical and climatic test methods—Part 35: Acoustic microscopy for plastic encapsulated electronic components

ISO Draft Standard

ACOUSTICS (TC 43)

ISO/DIS 13473-5, Characterization of pavement texture by use of surface profiles—Part 5: Determination of megatexture (2 November 2006)

IEC Draft Standard

77/319/FDIS, IEC 61000-4-1 Ed.3: Electromagnetic compatibility (EMC)—Part 4-1: Testing and measurement techniques—Overview of IEC 61000-4 series (1 September 2006)

29/604/FDIS, IEC 60118-4 Ed.2: Electroacoustics—Hearing aids—Part 4: Induction loop systems for hearing aid purposes—Magnetic field strength (1 September 2006)

87/357/FDIS, IEC 60565 Ed.2: Underwater acoustics-Hydrophones—Calibration in the frequency range 0,01 Hz to 1 MHz (6 October 2006)

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Acoustical Standards News 2391

29/607/FDIS, IEC 61672-3 Ed.1: Electroacoustics—Sound level meters—Part 3: Periodic tests (8 September 2006)

International documents submitted to the U.S. for vote and/or comment

Some of the documents processed recently by the ASA Standards Secretariat. Dates in parentheses are deadlines for submission of comments and recommendation for vote, and they are for information only.

U.S. TAG	ISO and IEC documents
S1	**IEC/FDIS 60118-4 Ed. 2 (29/604/FDIS)** "Electroacoustics—Hearing aids —Part 4: Induction loop system for hearing aid purposes—Magnetic field strength" (14 August 2006)
S12	**Second ISO/CD 9612** "Acoustics—Measurements and calculation of occupational noise exposure—Engineering method" (Revision of ISO 9612:1997) (10 August 2006)
	ISO NWIP 13742-2 and ISO/CD 13742-2 "Acoustics—Measurement of sound absorption properties of road surfaces in situ—Part 2: Spot method for low absorption surfaces" (18 August 2006)
	ISO/CD 1683 "Acoustics—Preferred reference quantities for acoustical levels"

BOOK REVIEWS

P. L. Marston

Physics Department, Washington State University, Pullman, Washington 99164

These reviews of books and other forms of information express the opinions of the individual reviewers and are not necessarily endorsed by the Editorial Board of this Journal.

Editorial Policy: *If there is a negative review, the author of the book will be given a chance to respond to the review in this section of the Journal and the reviewer will be allowed to respond to the author's comments. [See "Book Reviews Editor's note," J. Acoust. Soc. Am.* **81***, 1651 (May 1987).]*

Handbook of Underwater Acoustic Engineering

Heinz G. Urban

The purpose of the book, quoting the author "is to present the principles of underwater engineering in as simple and concise a form as possible." The book was first published in German in 2000 and, as a result of the wide use both in Germany and outside, was rewritten in English, based on an updated German version. It was published by the Naval Systems Division of STN ATLAS Elektronic GmbH. To obtain a copy of the book, the request is sent to the following address: ATLAS Elektronik GmbH, Naval Systems Division, Attn: Prof. Manfred Siegel, Sebaldsbrucker Heerstr. 235, D-28305 Bremen, Germany. The policy of the publisher is not to sell it, but to request a donation (70 Euros or approximately $100.00 US) to a charity organization (German Maritime Rescue Service).

To put the book in context, it is between Urick's *Principles of Underwater Sound (3rd Edition)*, which has an extensive reference base and presents physical data as collected at sea and in laboratory measurements, organized around the terms of the sonar equation and Jensen, Kuperman, Porter, and Schmidt's *Computational Ocean Acoustics*, which is an analytic treatise, necessarily focused on a subset of sonar equation subjects, and provides detail that allows a reader to write computer codes to calculate, e.g., acoustic pressure amplitude as a function of depth and range, leading to transmission loss, a sonar equation parameter.

The text has 11 chapters and six appendices. This reviewer found that it naturally divided into three parts: an introduction to basic units and fundamental acoustic concepts, application of those concepts in the ocean environment or to acoustic devices used in the ocean and discussion of sonar equation terms, use, and assumptions necessary that allow the sonar equation to be used as a design tool. Following the discussion of basic acoustic concepts, reflection and scattering from ocean boundaries are addressed and next propagation. Transduction, transducers, and array directivity are discussed, and then underwater noise. A chapter is devoted to signal processing and introduces signal-to-noise ratios, detection concepts and the book concludes with a chapter that discusses the sonar equation terms, their use in system design, and some specific problems (examples of sonar equation calculations).

It is written in a very "reader friendly" style, near to conversational, and clearly benefits from the author's extensive background in a very complex subject. The value of the text lies in its clear, easy-to-grasp statements of equations, limitations, approximations, most commonly used techniques, etc., that provide a reader with an understanding and capability to work in the world of underwater acoustics. The techniques, formulas, and concepts that have stood "the test of time" are the focus of this text. With the two books noted above, it is a member of a "triad" that should be on the bookshelf of those working in this field.

The bibliography following each chapter could be more complete, but is sufficient to provide the reader with a good start toward the exploring the literature base behind each topic.

DAVID BRADLEY
Applied Research Laboratory
Pennsylvania State University
State College, Pennsylvania 16804-0030

REVIEWS OF ACOUSTICAL PATENTS

Lloyd Rice
11222 Flatiron Drive, Lafayette, Colorado 80026

The purpose of these acoustical patent reviews is to provide enough information for a Journal reader to decide whether to seek more information from the patent itself. Any opinions expressed here are those of reviewers as individuals and are not legal opinions. Printed copies of United States Patents may be ordered at $3.00 each from the Commissioner of Patents and Trademarks, Washington, DC 20231. Patents are available via the Internet at http://www.uspto.gov.

6,968,740

43.20.Hq SYSTEMS AND METHODS FOR DETERMINING AN ACOUSTIC AND/OR THERMAL CHARACTERISTIC OF A TARGET MATERIAL

Brandon Dillan Tinianov, assignor to Johns Manville International Incorporated
29 November 2005 (Class 73/645); filed 26 January 2004

A number of material-property detectors transmit sound waves through the substance to be tested and measure the resulting spectrum in various ways. The method described in this very short patent would simply measure the resulting signal amplitude, but would also measure the density of the material under test. The intended application is testing insulation material for building construction.—DLR

7,035,166

43.30.Pc 3-D FORWARD LOOKING SONAR WITH FIXED FRAME OF REFERENCE FOR NAVIGATION

Matthew Jason Zimmerman and James Henry Miller, assignors to FarSounder, Incorporated
25 April 2006 (Class 367/88); filed 17 October 2003

A forward-looking (or side-looking, or bottom-looking) sonar system incorporates a transmit transducer for projecting a signal into the water ahead of the vessel and a phased array of receivers to provide return signals to a computer, which then determines azimuthal and elevation angles and times of arrival of the return signals. The system is equipped with roll and tilt sensors, GPS receiver, and compass. The acoustic information plus the roll and tilt information is processed to create a 3-D image of the space ahead of the vessel relative to a fixed frame of reference, i.e., the earth.

Advanced signal processing techniques allow the computer to extract targets from the raw data and other features of the system enable the suppression of multipath targets.—WT

7,049,730

43.35.Ei ACOUSTIC DRIVER ASSEMBLY FOR A SPHERICAL CAVITATION CHAMBER

Ross Alan Tessien et al., assignors to Impulse Devices, Incorporated
23 May 2006 (Class 310/323.12); filed 11 March 2005

Sonoluminescence is an interesting phenomenon that has been studied since the 1930s. Most experimental setups use high-intensity sound waves to stimulate a liquid in a cavitation chamber. This patent (the third in a series of

continuations) describes a balanced, piezoelectric inertia transducer bonded to the surface of a spherical chamber. The arrangement is said to provide more efficient coupling of energy than prior art.—GLA

7,053,529

43.35.Pt TORSIONAL ACOUSTIC WAVE SENSOR

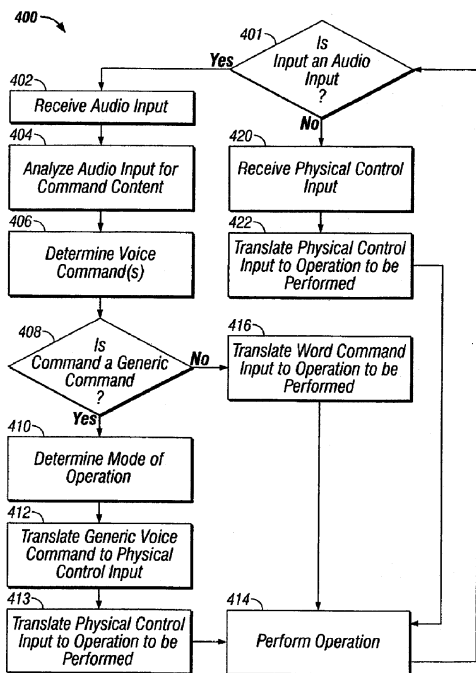
Terence J. Knowles, assignor to TexZec, Incorporated
30 May 2006 (Class 310/333); filed 1 July 2003

This patent discloses the use of torsional waves in a thin substrate to create a touch-activated switch suitable for hazardous environments and other high-value specialty application. It is said that positioning transducer **12** at an appropriate radius and orientation will result in a circulating shear
wave traveling around the center of the raised feature **15**. This wave will be strongly damped if the raised area is touched by a finger. This device seems rather complicated and trouble-prone for the task of simply switching something. The patent gives no performance details or detection criteria by which a contact closure might be judged.—JAH

7,052,459

43.35.Yb METHOD AND APPARATUS FOR CONTROLLING ULTRASOUND SYSTEMS

Michael Joseph Washburn et al., assignors to General Electric Company
30 May 2006 (Class 600/437); filed 10 September 2003

In one embodiment, a user interface for controlling an ultrasound system is provided. The user interface includes multiple selectable elements for controlling the ultrasound system and multiple identifiers. Each identifier corresponds to one of the selectable elements and associates control


commands with that element. In a second embodiment, the method includes associating a set of identifiers with multiple operations for controlling the ultrasound system, receiving control commands, and performing operations on the basis of receiving control commands corresponding to one or more sets of identifiers.—DRR

7,024,935

43.35.Zc ELECTROMAGNETIC ACOUSTIC TRANSDUCERS

David Paige and Robert Andrew Mercel, assignors to Pii Limited
11 April 2006 (Class 73/643); filed in the United Kingdom 5 February 2002

Assembly **4** is mounted in a "pig" that is sent through an operating gas pipeline **2**. Magnet **30** magnetizes the steel pipeline wall **6**. Ultrasound is generated in the steel pipeline wall by eddy-current excitation via an ac magnetic field **8** produced by an ac current passed through coil **36**. This device is termed as an electromagnetic acoustic transducer (EMAT). Coil **36**
is then switched to a receiver to detect the subsequent ultrasound so generated. The strength of the ultrasound so detected is modulated by nonuniformities in the steel wall. This transducer is asserted to operate over a wider range of operating environments than heretofore. Other magnet and coil arrangements are shown.—AJC

7,040,557

43.35.Zc SYSTEM AND METHOD FOR PULVERIZING AND EXTRACTING MOISTURE

William Graham et al., assignors to Power Technologies Investment Limited
9 May 2006 (Class 241/1); filed 1 April 2004

Sensor **108**, which might be an acoustic sensor in material crusher-dryer **800**, monitors the flow rate of material from blender **102** into inlet tube **12**. An acoustical emission sensor **702** monitors 50–950-kHz ultrasound generated by material flowing through inlet tube **12**, venturi **18**, airflow generator **32**, and housing **35**. The resonant frequency sound
received by **702** indicates the volumetric flow rate. Controller **703** communicates with processor **110** to control that flow rate through flow valves **111** or a diverter (not shown). Sensor **702** also receives sounds that may indicate improper balance or dislodged blades on fan **32**.—AJC

7,044,163

43.35.Zc DRAG REDUCTION IN PIPE FLOW USING MICROBUBBLES AND ACOUSTIC ENERGY

Joline Fan and Zhe Cui, assignors to The Ohio State University
16 May 2006 (Class 137/828); filed 10 February 2005

Gas microbubbles and ultrasound are injected into flowing fluid to reduce the drag of liquid flow in pipes. The author claims a microbubble gas injector **10** comprising a length of pipe **12** with 50- to 400-μm-diam gas injector orifices **14** and a flow restrictor **18**, causing negative pressure to draw the gas into the liquid stream inside the pipe. Drag reductions of up to 30% are cited. Also claimed is the application of acoustic energy into the
fluid via transducer **22** to cause the microbubbles to move away from the pipe wall. With microbubbles of average diameter of 300 μm, but without acoustic energy, a 125 ml/s flow rate occurred, accompanied by some pressure head fluctuations due to chaotic flow. When up to 600 W (sic) of acoustic energy at 16–20 kHz was applied, the flow rate increased to 130 ml/s, and the pressure fluctuations decreased, indicating organized liquid flow.—AJC

7,053,319

43.35.Zc ELECTRONIC WEIGHING APPARATUS UTILIZING SURFACE ACOUSTIC WAVES USING SENSORS OPERATING AT DIFFERENT FREQUENCIES, HAVING TEMPERATURE COMPENSATION, AND A PUSH OSCILLATOR

Vyacheslav D. Kats and Arnold S. Gordon, assignors to Circuits and Systems, Incorporated
30 May 2006 (Class 177/210 FP); filed 1 February 2002

Weighing apparatus **10** has adjacent surface acoustic wave (SAW) devices **20** and **22** installed on supports **17** and **19** in a cutout **15** within the aluminum weighing beam **14**, whose end will deflect as much as 200 μm downward when a load is placed in pan **16**. SAW devices **20** and **22** are separated by a 20 μm gap **g**, which allows acoustical coupling between said devices. The surface wave induced in **22** from **20** is amplified and fed back to **20**, causing system self-oscillation of a frequency determined by the phase shift of the wave coupled from **20** to **22**. As weight is added, the phase shift is increased, and the frequency reduced accordingly. Several modal
frequencies are possible. The modal frequency found to have a minimal or zero temperature coefficient is assured by driving the system briefly with a "push" oscillator, then measuring the subsequent free oscillating frequency as the weight-indicating value. The claims include the coupling means, the push oscillator application, a second oscillator SAW pair with a weight-dependent self-oscillation frequency, and other arrangements more repeatable under large beam displacements.—AJC

7,053,522

43.35.Zc SURFACE ACOUSTIC WAVE SENSOR

Mauricio Pereira da Cunha, assignor to University of Maine System Board of Trustees
30 May 2006 (Class 310/313 A); filed 26 February 2003

A surface acoustic wave (SAW) delay line **10** is claimed with sensitivity to the properties of liquid **23**, apart from those of pure water. Interdigital transducer (IDT) **16**, **18** on piezoelectric substrate **14** of the lanthanum gallium oxide family (LGX) is cut at selected Euler angles. For a minimum temperature coefficient, Euler angles of ϕ being 0°, θ being about
14°, and ψ being about 90° are claimed, along with there being a minimum sensitivity to water, while retaining sensitivity to chemical or biological agents. Changes in a SAW "parameter" (loss? phase?) are said to occur in the presence of any of those agents.—AJC

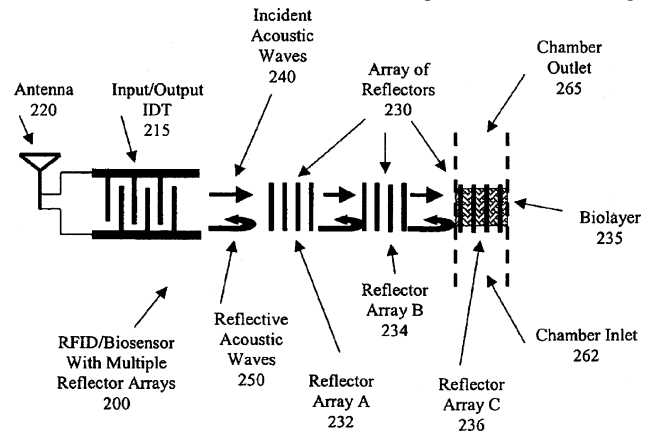
7,053,524

43.35.Zc SURFACE ACOUSTIC WAVE SENSOR OR IDENTIFICATION DEVICE WITH BIOSENSING CAPABILITY

Peter J. Edmonson *et al.*, assignors to P.J. Edmonson Limited
30 May 2006 (Class 310/313 D); filed 31 May 2005

A radio-frequency identification biosensor **200**, all on a piezoelectric substrate, sends surface waves **240** on that substrate toward reflectors **232**, **234**, and **236**, the last of which, **236**, is coated with a biolayer **235** under a fluid chamber **262–265**. When a biomaterial is present in (flows through)

2397   J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Reviews of Acoustical Patents   2397


that chamber, biolayer **235** is changed, and the acoustic velocity of the surface wave in reflector **236** is also changed, altering the delay, or phase, or amplitude of the wave reflected by **236**. Detection algorithms for the phase shift of the reflected wave and a "reference modulation code" are claimed.—AJC

7,042,138

43.38.Ar PIEZOELECTRIC ACOUSTIC TRANSDUCER

Yuko Yokoi *et al.*, assignors to Murata Manufacturing Company, Limited
9 May 2006 (Class 310/324); filed in Japan 10 April 2003

This patent describes a shrink-curved piezoelectric laminate consisting of plastic film adhered to a thin piezo sheet. It is argued here that by using upper and lower films of plastics having different hardening temperatures, a curvature may be developed in the parts as they cool and that the curved parts will have a higher radiation efficiency for sound production.—JAH

7,043,035

43.38.Ar MINIATURE MICROPHONE

Zacharias M. Rittersma *et al.*, assignors to SonionMicrotronic Nederland B.V.
9 May 2006 (Class 381/173); filed 7 December 2000

The patent discusses improvements in miniature microphones for
hearing aid applications. A cylindrical form allows the most effective use of available space.—JME

7,045,768

43.38.Ar DISPLACEMENT/QUANTITY OF LIGHT CONVERTER

Toru Shinzou and Yoshio Sakamoto, assignors to Kabushiki Kaisha Kenwood
16 May 2006 (Class 250/229); filed in Japan 20 February 2001

The patent describes a geometric arrangement whereby light **2** impinging on a curved surface can be reflected selectively to a receiver **3**, allowing
the conversion of "small mechanical displacement into a significant variation of light quantity." The idea has much in common with an optical microphone developed by Sennheiser Electronics some years ago.—JME

7,048,699

43.38.Ar NON-CYLINDRICAL ACOUSTIC WAVE DEVICE

Moshe Ein-Gal, Ramat Hasharon, Israel
23 May 2006 (Class 601/2); filed 12 September 2001

Shapes of lithotripter **10**, transducer **12**, and reflector **16** are claimed. The preferred shape for transducer **12** is noncylindrical, but conical or curved conical sections. The preferred reflector shape is also not cylindrical,
but curved conic sections. The transducer types claimed are impinging mass, explosive, electrical discharge, piezoelectric, or pneumatic.—AJC

2398   J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Reviews of Acoustical Patents   2398

7,049,732

43.38.Ar ELECTROACTIVE POLYMERS

Qibing Pei *et al.*, assignors to SRI International
23 May 2006 (Class 310/800); filed 16 July 2004

This patent describes many different configurations of an "electroactive polymer" transducer having a built-in prestress. The configurations shown are sometimes novel, sometimes pedestrian. The discussion is very superficial; it glosses over the relative merits of the different configurations, merely cataloging individual applications. It seems that most of these were conceived previously elsewhere.—JAH

7,050,597

43.38.Ar DIRECTIONAL CAPACITOR MICROPHONE

Hiroshi Akino, assignor to Kabushiki Kaisha Audio-Technica
23 May 2006 (Class 381/356); filed in Japan 19 September 2003

The patent relates to manufacturing methods in miniature directional capacitor microphones, specifically in the area of controlling the acoustical
impedance of the back opening in the microphone to ensure the integrity of pattern control.—JME

7,053,523

43.38.Bs LATERAL FIELD EXCITATION OF BULK ACOUSTIC WAVES FROM AN IC-COMPLIANT LOW VOLTAGE SOURCE

Arthur Ballato *et al.*, assignors to The United States of America as represented by the Secretary of the Army
30 May 2006 (Class 310/313 B); filed 2 February 2004

This patent discloses the use of dielectric coatings over interdigital transducers (IDTs) to reduce the likelihood of electrical breakdown at the edges of the IDT fingers. There are a few other tricks that are disclosed in the patent, such as mentioned here, but this all seems like well-trodden turf.—JAH

7,053,531

43.38.Bs COMPOSITE PIEZOELECTRIC VIBRATOR

Makoto Chisaka and Osamu Kobayashi, assignors to Tayca Corporation
30 May 2006 (Class 310/334); filed in Japan 26 April 2002

The patent discloses a relatively straightforward approach to making a 3-1 composite piezoceramic from a slab of piezoceramic and epoxy filled with plastic micro-balloons. If all of this sounds familiar, it is. Only the materials have been changed.—JAH

7,024,014

43.38.Dv MULTIPLE VOICE-COIL CONE-DRIVER

Michael Noll, assignor to Harman International Industries, Incorporated
4 April 2006 (Class 381/401); filed 4 June 2003

By using separate voice coils wound on a single voice-coil former, an increase in the high-end response of an electrodynamic loudspeaker is achieved. The patent states that a third voice coil connected in parallel to the first and second voice coils, also connected in parallel, can increase the high-end response by 500 to 1000 Hz. Adding a fourth voice coil can yield
a similar increase in performance. The voice coils can be wound using bifilar, trifilar, and quadfilar techniques. The impedance of the coils is varied so that, as coils are added, the overall impedance remains the same. Some manufacturers may wish to examine claim 5, of 20, which deals with the simultaneous winding of at least two voice coils.—NAS

7,042,312

43.38.Hz LADDER-TYPE BULK ACOUSTIC WAVE FILTER WITH COMMON GROUND INDUCTOR

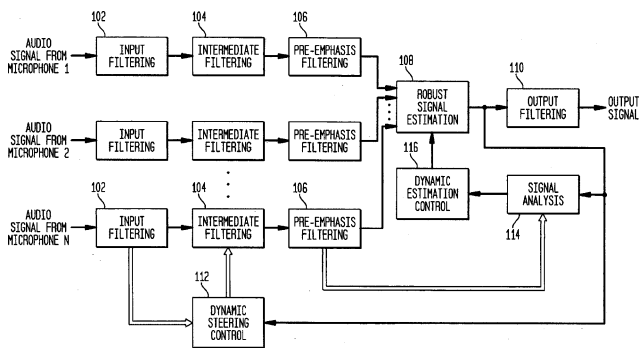
Sang Chul Sul and Jea Shik Shin, assignors to Samsung Electro-Mechanics Company, Limited
9 May 2006 (Class 333/187); filed in the Republic of Korea 7 October 2003

This patent describes a ladder-type filter constructed of multiple resonators in series and in parallel having a common-ground inductor. The filters are mostly band pass in the 1.8–2.0-GHz range. There is nothing novel in this class of filters.—JAH

7,046,812

43.38.Hz ACOUSTIC BEAM FORMING WITH ROBUST SIGNAL ESTIMATION

Gregory P. Kochanski and Man M. Sondhi, assignors to Lucent Technologies Incorporated
16 May 2006 (Class 381/92); filed 23 May 2000

This relatively concise patent deals with adaptive beam forming. As stated in the abstract: "Audio signals from any array of microphones are individually filtered, delayed, and scaled in order to form an acoustic beam


that focuses the array on a particular region. Nonlinear robust signal estimation processing is applied to the resulting set of audio signals to generate an output signal for the array. ... The nonlinear robust signal estimation processing effectively discriminates against noise originating at an unknown location outside of the focal region of the acoustic beam."—JME

7,046,816

43.38.Ja COINCIDENT SOURCE STEREO SPEAKER

Richard J. Vandersteen, Hanford, California
16 May 2006 (Class 381/182); filed 31 January 2002

The explanatory text of this patent includes numerous misleading statements and false assertions. Since the inventor is a respected loudspeaker designer, these may have originated as part of the effort to obtain a patent. Fortunately, the invention is easy to describe. Most home theater systems do not use a perforated projection screen, thus requiring the center speaker to be located above or below the screen. To achieve the desired wide, thin
proportions, speaker manufacturers often resort to a horizontal array, consisting of a high-frequency transducer flanked by a pair of small woofers. Such an array can be designed to exhibit the same on-axis response as the left and right speakers, but off-axis response suffers. By placing woofers **66a** and **66b** as shown, their effective spacing can be reduced by half or more, at the expense of new waveguide resonances. Skeptics may argue that this arrangement simply trades one irksome problem for another.—GLA

7,050,601

43.38.Ja VOICE COIL OF SPEAKER

Takashi Suzuki et al., assignors to Matsushita Electric Industrial Company, Limited
23 May 2006 (Class 381/409); filed in Japan 19 July 2002

A loudspeaker voice coil **70** is usually wound of solid copper or aluminum wire that is connected to separate flexible leads **12** joined to fixed terminals **90**. The flexible leads may consist of several strands of fine wire
surrounding a core thread made of cotton or other fiber. This patent suggests that a simpler assembly can be realized if the voice coil itself is wound of such flexible stranded wire. "Thus, reliability is ensured and a superb sound quality is achieved."—GLA

7,016,509

43.38.Lc SYSTEM AND METHOD FOR VARYING LOW AUDIO FREQUENCIES INVERSELY WITH AUDIO SIGNAL LEVEL

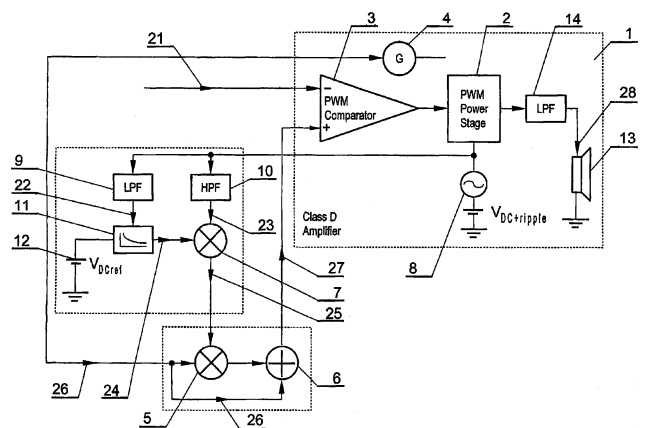
Sunil Bharitkar and Timothy Shuttleworth, assignors to Harman International Industries, Incorporated
21 March 2006 (Class 381/98); filed 8 September 2000

A means is disclosed of adjusting a loudness-compensation filter based on the signal level and the inverse of the Fletcher-Munson curves. The technique can be implemented in both the analog and digital domains. The patent is well written and easy to follow, although better proofreading would have caught the problems with the labeling of the curves in Fig. 2 that renders it almost useless, as well as some nomenclature discrepancies in the text.—NAS

7,038,534

43.38.Lc CLASS D AUDIO AMPLIFIER AND METHOD FOR COMPENSATION OF POWER SUPPLY VOLTAGE INFLUENCE ON OUTPUT AUDIO SIGNAL IN CLASS D AUDIO AMPLIFIER

Tomasz Hanzlik, assignor to Advanced Digital Broadcast Polska Sp. z o.o.
2 May 2006 (Class 330/10); filed in Poland 21 January 2002

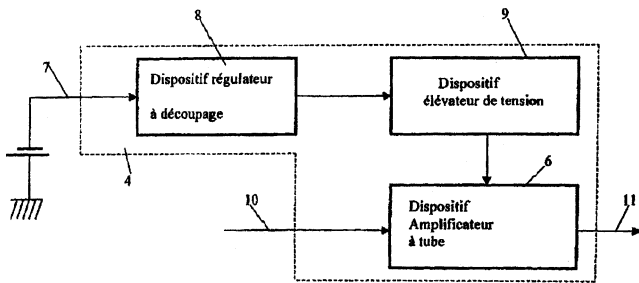
At the present time, there is considerable interest in developing high-quality class D audio amplifiers because very high conversion efficiency is possible. However, the interface between the amplifier output and the loudspeaker is finicky, and it is difficult to utilize conventional negative feedback


for distortion reduction. Yet without some form of negative feedback, any ripple in the power supply modulates the signal. Alternative schemes have been patented that attempt to correct the PWM signal in reaction to power supply voltage fluctuations. This short patent discloses such a scheme. Generator **4** produces sawtooth or triangular waves. The power-supply voltage, including ripple **8**, is fed to separate filters, lowpass **9** and highpass **10**, deriving a rapidly fluctuating signal and a slowly fluctuating signal. These are combined with the generator output through multiplier **5** and adder **6** to create a predistorted carrier signal **27**. The patent is well written and the invention is clearly disclosed in both the specifications and the claims sections.—GLA

7,046,814

43.38.Lc IMPEDANCE ADAPTER PREAMPLIFIER DEVICE FOR ELECTRONIC TUBE AUDIO FREQUENCIES ABLE TO BE INSERTED ON LINE ON THE PATH OF THE LOW FREQUENCY SIGNAL

Nicolas Girard, Paris, France
16 May 2006 (Class 381/120); filed in France 15 September 1999

A simple vacuum-tube line amplifier might consist of a cathode follower driven by a triode gain stage, providing very high input impedance and low output impedance. Variations of this well-known configuration have been in use for more than 50 years, including portable devices utilizing


small "A" and "B" batteries. If a switching-type power supply were used, the "B" battery could be eliminated, and that appears to be the sole novel feature of this invention.—GLA

7,038,575

43.38.Md SOUND GENERATING APPARATUS FOR USE WITH GLOVES AND SIMILAR ARTICLES

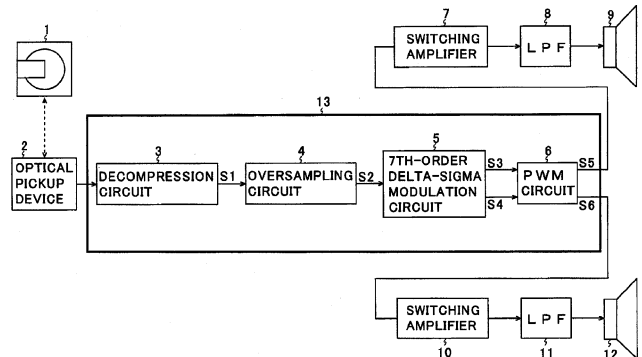
Jan A. Frohman and James L. Jorgensen, assignors to The Board of Regents of the University of Nebraska
2 May 2006 (Class 340/384.7); filed 31 May 2001

Simply, the inventors propose adding the ubiquitous sound chip to a pair of gloves for use at a (cold) sporting event. Mechanical actuators (i.e., switches) will turn on the "sound generation apparatus" (speaker **24**). What
seems to have been forgotten is the audio power required in a crowd and the size of the accompanying battery.—MK

7,038,606

43.38.Md DIGITAL SIGNAL PROCESSING DEVICE AND AUDIO SIGNAL REPRODUCTION DEVICE

Tsunehiko Hongoh and Hirotoshi Yamamoto, assignors to Sharp Kabushiki Kaisha
2 May 2006 (Class 341/143); filed in Japan 29 October 2002

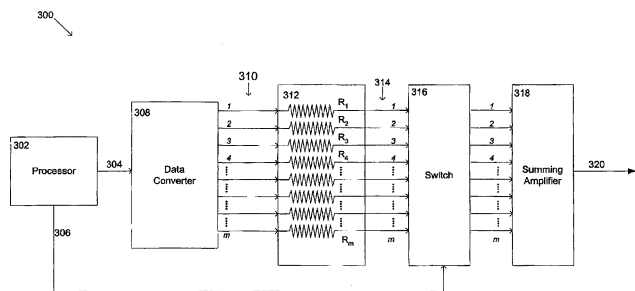
Like the DASD scheme, the inventors propose using an oversampled one-bit stream with a seventh-order delta-sigma modulator **5**. The output


of the modulator is amplified by a PWM (class D) amp of unspecified design. After (passive) lowpass filtering, the output is suitable for loudspeakers.—MK

7,043,027

43.38.Md SYSTEM FOR DETECTING FAILURES IN A LOUDSPEAKER ASSEMBLY

Bradley C. Wood, assignor to Harman International Industries, Incorporated
9 May 2006 (Class 381/58); filed 1 October 2001

It is usual for surround sound decoders and computer sound cards to provide a diagnostic check in which a test signal is sent sequentially to all channels—left, center, right, left surround, etc. But suppose that the sound


card itself is defective? This patent describes a similar but very specific method for sending a test signal sequentially to all loudspeakers in a multimedia system. Since the associated circuitry is to be included as part of the speaker kit, any problems can be isolated from other components.—GLA

7,030,539

43.38.Rh SURFACE ACOUSTIC WAVE DEVICE AND ELECTRONIC COMPONENT COMPRISING IT

Mitsuhiro Furukawa *et al.*, assignors to Matsushita Electric Industrial Company, Limited
18 April 2006 (Class 310/313 D); filed in Japan 3 October 2001

Metal film can be cut to SAW pattern **2**, **3** by an ion beam that also leaves a charge that bends said beam while cutting the deeper metal. Carbonized photoresist is deposited in the cut region that reduces the acoustic
energy produced in use. To prevent this anomaly, a portion **5** of the reflector electrode set **3** is cut off.—AJC

7,034,433

43.38.Rh SURFACE ACOUSTIC WAVE DEVICE

Michio Kadota *et al.*, assignors to Murata Manufacturing Company, Limited
25 April 2006 (Class 310/313 A); filed in Japan 12 October 2001

The author claims a surface acoustic wave device **11** that has high electromechanical and reflection coefficients. The chosen material **12** is
25°–50° Y-plate lithium tantalate with preferred Euler angles, having aluminum interdigital transducer (IDT) fingers **13** and **14**, with optimized aluminum thickness and with silicon oxide film **15** covering at least one IDT.—AJC

7,034,434

43.38.Rh SURFACE ACOUSTIC WAVE DEVICE

Koji Yamamoto *et al.*, assignors to Murata Manufacturing Company, Limited
25 April 2006 (Class 310/313 R); filed in Japan 3 June 2002

SAW chip **2** and substrate **3** are held separate by gold bump **4** so that vibration space **7** is assured. Resin seal material **5** is prevented from flowing
into space **7** by barrier bump **9**. The authors claim various groove and bump geometries.—AJC

7,038,353

43.38.Rh SURFACE ACOUSTIC WAVE DEVICE AND METHOD OF MANUFACTURING THE SAME

Yoshio Maeda *et al.*, assignors to Seiko Epson Corporation
2 May 2006 (Class 310/313 D); filed in Japan 10 January 2001

For low-frequency (viz. 100 MHz) SAW operation, Rayleigh wave reflection must occur in order that the device be efficient and also small. Rayleigh waves created between IDT electrodes **14a** and **14b** flow to the
right and are reflected by end face **15** placed at the favored distance **B**, where δ is an allowance determined from the number of IDT reflector strips.—AJC

7,038,560

43.38.Rh SURFACE ACOUSTIC WAVE FILTER AND SURFACE ACOUSTIC WAVE RESONATOR HAVING BENT ELECTRODE FINGERS

Katsuro Yoneya, assignor to Seiko Epson Corporation
2 May 2006 (Class 333/195); filed in Japan 19 June 2003

A surface acoustic wave filter with bent fingers is claimed that suppresses spurious higher frequency modes, or moves their frequency outside of the useful pass band of the filter. Fingers **121**, **122**, **131**, **132**, **141**, and **142**
are shaped into three or more segments **a**, **b**, and **c**. Segment **c** is as short as possible and arranged to produce a specific side shift **L**, shown here, for instance, as $\frac{1}{2}$ surface wave wavelength. "[R]esonance in the first-order transverse mode...becomes primary response (sic) ... ." Resonant energy in the second-order mode cancels, and resonant energy in the third-order mode becomes the main spurious response, but at a frequency sufficiently changed as to be outside the normal pass band of the filter. The claims include multiple segments (zig-zag) and different shifting distance **L**.—AJC

7,042,056

43.38.Rh CHIP-SIZE PACKAGE PIEZOELECTRIC COMPONENT

Yoshihiro Koshido, assignor to Murata Manufacturing Company, Limited
9 May 2006 (Class 257/414); filed in Japan 31 July 2002

Surface acoustic wave (SAW) resonator **204-205** is protected from deterioration in use by providing a closed operating space between bonding substrate **223** and piezoelectric substrate **1**. External terminals **226** and **227** are provided by solder **226a** and **227b** through bonding substrate **223a** to
wiring lines **210** and **211**. A recess **223b** assures a clear and corrosion-free space over the SAW IDT fingers **207** and **208**. The claims include fabrication sequences and solder alloys. The fifth of eight embodiments is shown.—AJC

7,042,131

43.38.Rh SURFACE ACOUSTIC WAVE DEVICE

Yuichi Takamine, assignor to Murata Manufacturing Company, Limited
9 May 2006 (Class 310/313 R); filed in Japan 6 June 2001

A 36° Y-cut, X-propagating lithium tantalate substrate **2** has tandem pass-band SAW filter elements **3** and **4**. Silicon dioxide film **7** is deposited over at least one SAW terminal pair, with film thickness optimized for the
(aluminum) finger thickness and to present a minimal temperature coefficient of the frequency of the band-pass edges.—AJC

7,042,133

43.38.Rh SURFACE ACOUSTIC WAVE DEVICE AND METHOD OF ADJUSTING A TEMPERATURE CHARACTERISTIC OF THE SAME

Shigeo Kanna, assignor to Seiko Epson Corporation
9 May 2006 (Class 310/313 A); filed in Japan 4 October 2002

Two surface acoustic wave devices **M1** and **M2** on quartz piezoelectric substrate **3**, cut at specific Euler angles, propagate Rayleigh surface waves in two slightly different directions $\psi 1$ and $\psi 2$, whose wave velocities have
temperature coefficients that differ slightly. A calculation method is provided to select the optimum propagation directions $\psi 1$ and $\psi 2$, especially selecting the turnover temperatures with respect to the operating temperature range.—AJC

7,046,102

43.38.Rh SURFACE ACOUSTIC WAVE FILTER, BALANCED TYPE CIRCUIT, AND COMMUNICATION APPARATUS

Hiroyuki Nakamura *et al.*, assignors to Matsushita Electric Industrial Company, Limited
16 May 2006 (Class 333/133); filed in Japan 6 March 2002

The uniformity (flatness) of the passband of a rf surface acoustic wave filter **A-A′** is said to be improved by adding a thin layer of lower dielectric-constant film **201′** (e.g., silicon nitride having a dielectric constant of 10)
over the piezoelectric substrate **200′** (e.g., lithium tantalate of dielectric constant 40) before the fingers **240-210′-250** are applied.—AJC

7,039,179

43.38.Si ECHO REDUCTION FOR A HEADSET OR HANDSET

John F. Gerhardt *et al.*, assignors to Plantronics, Incorporated
2 May 2006 (Class 379/390.02); filed 27 September 2002

There must be more than 100 U.S. patents dealing with ways to reduce echo in telephone communications, yet this patent cites only one reference and that was supplied by the examiner. Although this reviewer is not an expert in the field, the patent claims suggest that the core of the invention is
not a new echo cancelling circuit, but rather a practical method of achieving useful echo cancellation when communicating over packet-switched networks. A variety of handsets and headsets can be accomodated, allowing the user to enjoy improved echo reduction without replacing every piece of communications equipment.—GLA

7,043,279

43.38.Si HANDSFREE STRUCTURE WITH ANTIBACKGROUND NOISE FUNCTION

Ching-Chuan Lee, Taipei, Taiwan
9 May 2006 (Class 455/569.1); filed in China 3 December 2002

A variety of small, plug-in headsets are available to cellular phone users, allowing hands-free operation. The headset patented here adds a

separate vibration pickup (throat microphone) that can be used in a high-noise environment.—GLA

7,043,286

43.38.Si EXTRINSIC SIGNAL TO SHUNT AN ACOUSTIC DRIVER IN A CELLULAR TELEPHONE, PAGER OR THE LIKE

David Leason, assignor to Leason Holding Company, LLC
9 May 2006 (Class 455/701); filed 13 June 2001

Wouldn't it be nice if cellular phone ring signals could be automatically disabled inside a concert hall or movie theater? This patent describes a method of achieving this goal, assuming that all cellular telephones include

the required circuitry. Since cell phones are known to be used by terrorist groups, perhaps a mandate could be enforced by the Department of Homeland Security.—GLA

7,046,082

43.38.Si ELECTRONIC DEVICE HAVING SOUND OUTPUT MODULE

Kunihiro Komiya and Tadayuki Sakamoto, assignors to Rohm Company, Limited
16 May 2006 (Class 330/51); filed in Japan 27 December 2002

The title of this fairly long patent is misleading; it actually describes transient suppression circuitry for use in audio amplifiers. When a quiescent output circuit is energized by switching on its bias voltage, an audible pop results. If a simple R-C filter is used to control charging time, it may not provide sufficient power-supply rejection. The invention adds a fairly complicated "bias adjustment circuit" to provide optimum voltage rise characteristics.—GLA

2404   J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Reviews of Acoustical Patents   2404

43.38.Si CELLULAR PHONE TERMINAL

Hiroshi Akai *et al.*, assignors to Hitachi, Limited
16 May 2006 (Class 455/575.1); filed in Japan 19 July 2002

Laptop DVD players include loudspeakers for stereo sound, so why can't we enjoy stereo music downloads on our cell phones? In fact, suitable technology has already been patented. Well, if a cell phone has a video

screen and stereo speakers, then the next logical step is video teleconferencing with stereophonic audio pickup and reproduction. That is the challenge taken up by this patent. A cellular phone is described that houses a "plurality of speakers" and a "plurality of microphones." It may also include a proximity sensor to automatically switch between normal and stereo pickup.—GLA

7,050,796

43.38.Si METHOD OF CONTROLLING THE AUDITORY RESPONSE OF WIRELESS DEVICES

Thomas Ward Humphrey and Larry Dean Moore, assignors to
International Business Machines Corporation
23 May 2006 (Class 455/420); filed 25 January 2002

IBM seems to be interested in what might be called semi-intelligent local networks. With such a network, if your daily schedule is entered into your desktop computer, it automatically becomes available through your

palmtop computer, cell phone, etc. Moreover, the behavior of individual devices can be modified by their location or, as this patent suggests, by the ambient sound field. For example, if the environment is quiet and other wireless devices are present, the network may decide that you are in conference and disable your cell phone except for emergency messages.—GLA
7,013,012

43.38.Tj METHOD FOR PROCESSING SOUND EFFECTS IN A NOTEBOOK COMPUTER

Li-Chun Lo, assignor to Quanta Computer Incorporated
14 March 2006 (Class 381/307); filed in Taiwan
20 September 2002

This patent describes a scenario wherein a determination is made as to whether an audio signal is a stereo signal or a 4/5.1-channel signal. For stereo signals, the internal speakers of the notebook computer are used. For four-channel signals, the left and right signals are presented for use via the
mic-in jack and the surround channels via the line-out jack. For 5.1 signals, the mic-in jack is used for the subwoofer (or woof as it is called in the patent) and the center channel with the line-in jack signals as before. Sounds like a lot of jack switching and outboard equipment may be needed in addition to the "laptop" computer.—NAS

43.38.Tj PORTABLE INFORMATION PROCESSING APPARATUS

Dai Ueda *et al.*, assignors to Matsushita Electric Industrial Company, Limited
21 March 2006 (Class 361/683); filed in Japan 28 March 2003

A means of mounting piezoelectric audio transducers **5** in the top cover **9** of a notebook computer **1** is described. The goal is to save space and protect the speakers from rain or dust. Protection of the keyboard and
display from these contaminants is not discussed, although the invention may be destined for use in the assignee's line of Panasonic "ruggedized" notebook computers.—NAS

43.38.Tj SHARING DEVICE FOR MULTIPLE AUDIO SOURCES

Ying-Cou Wang, Taipei, Taiwan
21 March 2006 (Class 369/2); filed 26 November 2002

Many new homes (and older ones so fitted) now have in-house audio and video systems that take multiple sources and allow for their distribution to multiple outputs (rooms). The patent describes a way of doing this that
many may recognize as being a good description of the prior art perhaps installed in their own home or easily available as an option in homes now offered for sale by some of this nation's home-building conglomerates.—NAS

43.38.Tj VARIABLE DISPOSITION WIDE BAND MULTI-WAY LOUDSPEAKERS

Guido Noselli, assignor to Outline S.n.c. di Noselli G. & C.
21 March 2006 (Class 381/386); filed in Italy 2 March 2000

The main point of the patent is that the internal volume of subwoofer and woofer loudspeaker systems can be used to nest the smaller components of a large system while transporting same, so as to use what would be wasted space. For example, the mid-hi enclosure **11** can fit inside the subwoofer enclosure **10** when traveling. Various combinations and permutations
of the nesting (nestee?) box and nestor box, as well as means for actuating the deployment of the inner box, are described and illustrated. Questions about resealing the bigger box when the rear cover is replaced, as well as how stiff the enclosure can be without interfering with the nesting capability, are not discussed.—NAS

43.38.Vk ACOUSTIC CORRECTION APPARATUS

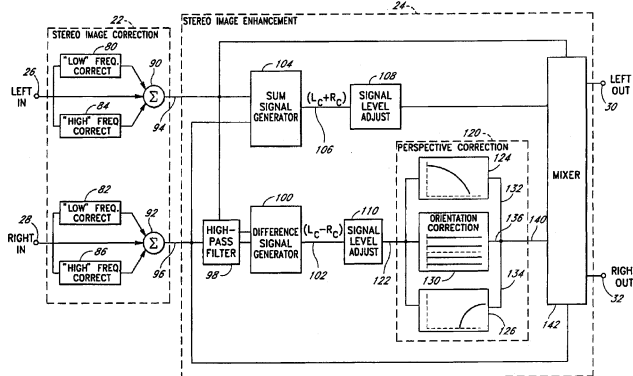
Arnold I. Klayman and Alan D. Kraemer, assignors to SRS Labs, Incorporated
9 May 2006 (Class 381/98); filed 22 January 2004

The patent assignee has long been at the forefront of two-channel matrix enhancement techniques for a variety of consumer applications,
principally television sound transmission and playback in the home. The patent covers ongoing improvements in image definition and stability.—JME

7,043,036

43.38.Vk AUDIO REPRODUCING APPARATUS

Yuji Yamada and Koyuru Okimoto, assignors to Sony Corporation
9 May 2006 (Class 381/309); filed in Japan 18 March 2002

This patent describes a number of signal processing techniques for converting one or more audio signals for playback over headphones. The problems of "in-the-head" localization are addressed through multiple


delays and proper equalization, presumably resulting in multiple images that can be positioned around the listener. The figure shows how a single input channel may be processed for this purpose.—JME

7,050,849

43.40.Ng VIBRATIONAL THERAPY DEVICE USED FOR RESYNCHRONIZATION PACING IN A TREATMENT FOR HEART FAILURE

Debra S. Echt et al., assignors to EBR Systems, Incorporated
23 May 2006 (Class 607/3); filed 15 June 2004

This system for pacing the heart includes a vibrational transducer that directs energy to the heart, usually aimed at a ventricle, to pace the heart and to promote synchronized contraction of the ventricles. Also, additional
vibratory and/or electrical stimulation may be provided. These vibrational transducers are usually implanted near the vicinity of the heart.—DRR

7,038,357

43.40.Sk STRETCHED ROLLED ELECTROACTIVE POLYMER TRANSDUCERS AND METHOD OF PRODUCING SAME

Andrew A. Goldenberg et al., assignors to Engineering Services Incorporated
2 May 2006 (Class 310/328); filed 21 August 2003

This actuator transducer is a cylindrical tube (axis **114**) comprising stretched rolled electroactive polymers. The wall **102** is laminated **132–138**. Thin electrostriction film **132** and conducting film **134** are wrapped in the
circumferential direction on substrate **138**. The tube interior can house electronics within and mechanical connections and terminals on its ends. Variations include patterned regions of electrostriction and strain feedback. Unfortunately, specific forces and possible actions are not detailed in the text.—AJC

7,048,473

43.40.Tm VIBRATION-PROOF CONSTRUCTION METHOD

Hirokazu Takemiya, assignor to Hirokazu Takemiya
23 May 2006 (Class 405/302.5); filed in Japan 5 November 2002

This patent describes means for attenuating vibration transmission through the ground—for example, from railways to nearby buildings. The idea in essence involves the introduction of alternate stiff and resilient layers along a portion of the propagation path. A preferred embodiment makes use of arrays of closely spaced or contiguous concrete piles surrounded by rubber from pulverized scrap tires. Other embodiments employ concrete plates with rubber along their surfaces.—EEU

7,025,342

43.40.Vn ACTUATOR DRIVE CONTROL DEVICE FOR ACTIVE VIBRATION ISOLATION SUPPORT SYSTEM, AND METHOD OF USING SAME

Hirotomi Nemoto et al., assignors to Honda Motor Company, Limited
11 April 2006 (Class 267/140.14); filed in Japan 13 June 2003

This is related to United States Patent 7,010,889 by Atsusi Abe. Here, the angular acceleration of the crankshaft is also computed and applied as a correction to the control signal to this actuator.—AJC

43.40.Vn APPARATUS AND METHOD FOR DETECTING AND COMPENSATING FOR RESONANCE FREQUENCY IN DATA STORAGE SYSTEM

Da-woon Chung, assignor to Samsung Electronics Company, Limited

18 April 2006 (Class 360/75); filed in the Republic of Korea 10 November 2003

The resonant frequency and response of a hard-disk, read-head-servo drive system is determined in two steps: First, a gain increase of the position-error-signal (PES) amplification is made in boosting filter **203** driving the voice-coil-motor (VCM) actuator **206** so that resonant oscillation
occurs. Resonant frequency detector **207** detects that frequency. Second, the VCM is fed a signal having the detected resonant frequency, and the PES is analyzed for a possible second resonant frequency. Information on these frequencies is analyzed by **210** and the results stored in **213** for subsequent use in **211** and **212**.—AJC

7,046,478

43.40.Vn METHOD AND APPARATUS FOR REDUCING VIBRATION IN A DYNAMIC SYSTEM

Tao Zhang et al., assignors to Seagate Technology LLC
16 May 2006 (Class 360/77.08); filed 11 April 2003

In order to control the displacement of a dynamic system, such as a disk drive, primary position-control signals are generated at a position-measurement sampling frequency. Position-control performance is improved by the use of additional position-control signals that occur between the primary ones and whose characteristics are determined on the basis of the primary signals.—EEU

7,047,109

43.40.Vn MACHINERY FOR IMPROVING PERFORMANCE IRREGULARITIES ARISING FROM VIBRATIONS

Katsuyuki Ogura and Hirotada Anzai, assignors to Mitutoyo Corporation
16 May 2006 (Class 700/280); filed in Japan 13 May 2003

Apparatuses like coordinate measuring machines include moving platforms that are subject to performance-degrading vibrations. In order to suppress the vibrations of such a platform that moves in a given direction, an inertial actuator is attached to the platform, with the actuator's motion controlled in response to appropriately processed signals from a vibration sensor. The actuator described in this patent consists of two similar counter-rotating unbalanced flywheels that are driven by a motor that is controlled so that the net inertia force resulting from any rotating imbalance acts at the same frequency as the offending vibrations and counteracts these.—EEU

43.50.Gf SILENCER FOR VENTILATION SYSTEM AND METHODS

Leon Robert Cuvelier et al., assignors to Donaldson Company, Incorporated
23 May 2006 (Class 415/119); filed 1 March 2004

This silencer for a ventilation system (which could be the intake of a gas turbine) functions by directing flow through two body sections spaced apart from each other to define a gas flow path in between. The first body section consists of a base, a sidewall, and an upper wall. The upper wall has a center region with a concave wall smoothly sloping downward, terminating at the sidewall. The base, sidewall, and upper wall together form a
sectional interior volume that is preferably filled with a packing material. The second body section has a base, inner and outer sidewalls, and an upper wall. The base and walls together define an interior volume that is also filled with packing material. The second body section also has a center aperture, wherein the inner sidewall lines the center aperture.—DRR

7,042,218

43.50.Ki SYSTEM AND METHOD FOR REDUCING AUDITORY PERCEPTION OF NOISE ASSOCIATED WITH A MEDICAL IMAGING PROCESS

Michael B. Sellers, assignor to General Electric Company
9 May 2006 (Class 324/309); filed 6 May 2004

A noise-cancellation method is described for reducing the perception of noise generated as a byproduct of a medical imaging process. The imaging scanner is configured to scan a subject within an imaging area that emits system noise during the course of operation. An ultrasonic emitter system is incorporated to emit an inaudible signal having properties to reduce perception of the system over at least a portion of the imaging area. It is apparent

from the patent description that the noise cancellation applies to the upper frequencies, with questionable results for the audio range.—DRR

7,035,414

43.50.Lj ACTIVE NOISE ATTENUATION SYSTEM

Paul D. Daly, assignor to Siemens VDO Automotive Incorporated
25 April 2006 (Class 381/71.4); filed 28 February 2001

Vehicle-engine air intake **18** with opening **16** is fitted with a cone-shaped insert **20** faced with loudspeaker **46**. Microphone **42** on arm **54** senses emitted sound, providing a signal to electronics center **38**, which
reverses its phase and feeds it back to speaker **46** to attenuate the emission of engine air-induction-system noise. Engine firing signals **52** are also fed to **38**. The author also claims the preferred forward microphone position at **42** and the use of flexible connectors **48** and **56**.—AJC

7,016,503

43.58.Vb ADAPTIVE EQUALIZER FOR VARIABLE LENGTH SOUND TUBES UTILIZING AN ACOUSTIC PRESSURE RESPONSE MEASUREMENT

Richard Lance Willis, assignor to Motorola, Incorporated
21 March 2006 (Class 381/58); filed 30 December 2002

By using the acoustic response technique (as in the figure), the electrical impedance response method, or the time of flight technique, the equalization needed to compensate for the length of tubing used in an earpiece
can be determined and then automatically implemented. The measurement can be used for hearing aids as well as for the plethora of blue-tooth and wired earpieces now used with cell phones and other personal entertainment devices.—NAS

7,027,921

43.60.Qv SURFACE ACOUSTIC WAVE SENSOR

Kourosh Kalantar-Zadeh and Wojtek Wlodarski, assignors to Microtechnology Centre Management Limited
11 April 2006 (Class 702/2); filed in Australia 21 May 2001

Substrate **1** supports a SAW source **3** and detector **4**. A shear wave is transmitted through a layer **5** coated with a sensing layer **6**. The sound velocity and attenuation of **5** and **6** combined will change when exposed to
a specified gas or liquid. Frequency counter **11** and computer **12** (algorithms not specified) are used to correlate the received level with concentration.—AJC

7,028,548

43.60.Qv VIBRATION TYPE ANGULAR VELOCITY SENSOR

Hirofumi Higuchi and Takeshi Ito, assignors to Denso Corporation
18 April 2006 (Class 73/514.12); filed in Japan 31 March 2003

This device senses the vehicle turn rate (angular velocity) in the presence of random vibration and noise. Bodies **4a** and **4b** oscillate in the x direction, but with opposite phase. The vehicle turning rotates enclosure **10** to produce a coriolis force in the y direction, which in turn causes complementary signals to be generated via capacitor plates **5a** and **5b**. Linear
vibrations of enclosure **10** via random vehicle motions causes capacitor-plate **5a** and **5b** signals that are the same in amplitude and phase, thereby cancelling. The claims include laser trimming of gain setting resistors **31t** and **32t**.—AJC

7,038,780

43.60.Rw METHOD FOR SENSING ACOUSTIC ENERGY

Joseph Lawrence Chovan *et al.*, assignors to Lockheed Martin Corporation
2 May 2006 (Class 356/432); filed 20 June 2002

A source **S1** emits sound energy **31** into dense medium **10**, such as water. Part of that sound energy **33** continues into less dense medium **20**. The radius of curvature of wave front **33** is increased so as to be essentially parallel to the interface **25**. A laser beam source and detector **100-100** transmits a beam **110** through **20** parallel to the interface **25**. Subsequent pressure modulation by **33** of medium **20** produces a corresponding variation in
phase of the transmitted laser beam **110**, causing a phase-shift modulation of the laser energy received by detector **100**. Intermediate frequency (IF) modulation of the laser beam source serves to distinguish laser light from other light received by **100**. Sound modulation of **S1** is presented as a corresponding phase-shift modulation found by laser beam receiver **100**. The claims include a 1014-Hz laser frequency and a 108-Hz IF beam modulation.—AJC

7,039,208

43.66.Ts BEHIND-THE-EAR HOUSING FUNCTIONING AS A SWITCH

Josef Wagner and Daniel Oertli, assignors to Phonak AG
2 May 2006 (Class 381/322); filed 5 August 2002

To make manual switch activation easier for persons with limited dexterity, a pressure-sensitive, elastic, or bendable section in the center or end of a behind-the-ear hearing aid case is connected to an internal switching
circuit element. Bending motion, compression, or deformation of the pressure-sensitive section triggers the switching operation.—DAP

7,039,209

43.66.Ts COVER DEVICE FOR HEARING AIDS

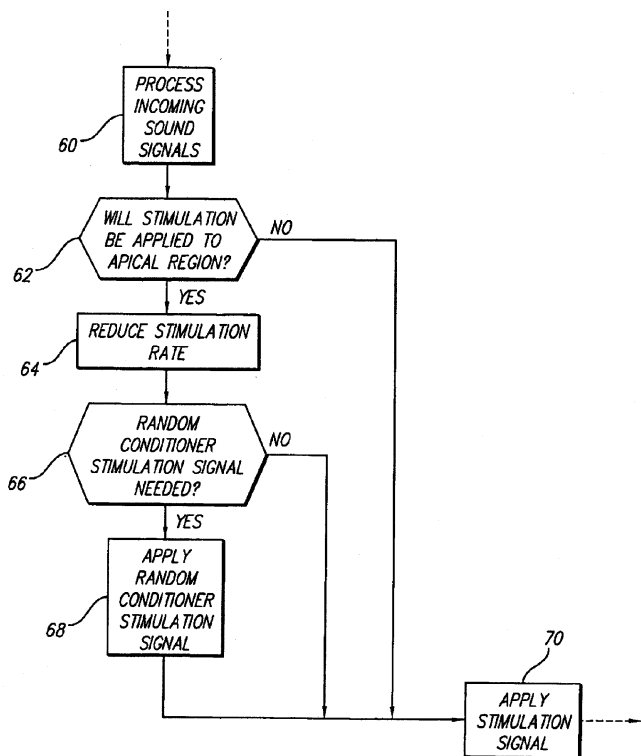
Christian Schmitt, assignor to Siemens Audiologische Technik GmbH
2 May 2006 (Class 381/322); filed in Germany 27 March 2002

The space required for a electronics/battery module is reduced (1) by using an Ω-shaped wire-spring-like element as an elastic hinge pin to pivot the battery drawer and (2) by removing the electronics portion from the
housing through the same opening used by the battery compartment after the battery compartment and wire spring are removed.—DAP

7,039,466

43.66.Ts SPATIAL DECIMATION STIMULATION IN AN IMPLANTABLE NEURAL STIMULATOR, SUCH AS A COCHLEAR IMPLANT

William Vanbrooks Harrison and Michael A. Faltys, assignors to Advanced Bionics Corporation
2 May 2006 (Class 607/56); filed 28 April 2004

Spontaneous neural activity is restored by inducing stochastic resonance via high-rate electrical stimulation. Power required from the battery is kept low via reducing the stimulus rate tonotopically by determining


whether synchronous neural firings occur in the low-frequency region, for which high-rate pulses produce little benefit.—DAP

7,043,037

43.66.Ts HEARING AID HAVING ACOUSTICAL FEEDBACK PROTECTION

George Jay Lichtblau, Ridgefield, Connecticut
9 May 2006 (Class 381/317); filed 16 January 2004

Undesirable signals created internal to the hearing aid via acoustical or mechanical feedback are distinguished from desirable ambient signals and
attenuated by taking the difference between two microphones' output signals. Both microphones are attached to the hearing aid housing, but only one microphone is positioned to pick up the desired ambient signals.—DAP

7,043,038

43.66.Ts IN-THE-EAR HEARING DEVICE

Herbert Bächler _et al._, assignors to Phonak AG
9 May 2006 (Class 381/322); filed 24 July 2002

An elastic textile material covers the rigid outer surface of an ITE hearing aid module and is adaptable to changes in the shape of the ear canal
of the wearer during talking or chewing. Fitting comfort relative to that of an ITE hearing aid with a hard outer shell is said to be improved.—DAP

7,043,039

43.66.Ts HOUSING FOR A HEARING AID OR HEARING DEVICE RESPECTIVELY

Bruno Gabathuler, assignor to Phonak AG
9 May 2006 (Class 381/322); filed in the European Patent Office 21 November 2003

To prevent damaging force from being transferred to wires and components in an electronics module of a modular hearing device, the module has a battery compartment to hold the battery with a cap pivotable over a
hinge pin. A bushing on each end of the hinge pin slips into receptacles in the faceplate of the modular device.—DAP

7,043,040

43.66.Ts HEARING AID APPARATUS

Patrick Westerkull, assignor to P&B Research AB
9 May 2006 (Class 381/326); filed in Sweden 21 June 2001

For hearing impaired persons with unilateral hearing loss, a bone-anchored hearing aid is implanted in the skull on the deaf side of the patient,

2411   J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Reviews of Acoustical Patents   2411
forming a "CROS" hearing aid device. High-frequency vibrations, in particular, are conducted through the skull bone to the inner ear of the better ear.—DAP

7,043,041

43.66.Ts INTEGRATED TELECOIL AMPLIFIER WITH SIGNAL PROCESSING

Miroslav hacek over (S)vajda and Alwin Fransen, assignors to SonionMicrotronic Nederland B.V.
9 May 2006 (Class 381/331); filed 3 October 2001

The frequency response of an integrated hearing-aid telecoil amplifier may be shaped with internal filtering for various input sources. The frequency shaping is independent of telecoil properties and may be used with
two signal paths for both audio frequency and radio frequency inputs. Radio frequency applications include programming and controlling the hearing aid.—DAP

7,043,303

43.66.Ts ENHANCED METHODS FOR DETERMINING ISO-LOUDNESS CONTOURS FOR FITTING COCHLEAR IMPLANT SOUND PROCESSORS

Edward H. Overstreet, assignor to Advanced Bionics Corporation
9 May 2006 (Class 607/57); filed 25 August 2003

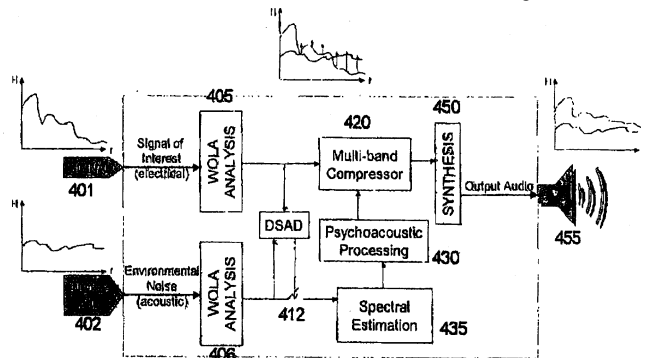
Automatic self-programming for cochlear implant patients is made possible by predicting iso-loudness contours from iso-neural response contours. That is, minimum threshold level contours are predicted from measured moderately loud (M) level contours, which eliminates the need for patient responses. M contours are determined by setting a volume adjust-

ment of the signal in one channel until it is judged equal in loudness to that of a signal in a second channel and repeating this procedure for all channels.—DAP

7,050,966

43.66.Ts SOUND INTELLIGIBILITY ENHANCEMENT USING A PSYCHOACOUSTIC MODEL AND AN OVERSAMPLED FILTERBANK

Todd Schneider et al., assignors to AMI Semiconductor, Incorporated
23 May 2006 (Class 704/200.1); filed in Canada 7 August 2001

A desired signal is made audible over an undesired signal in high-noise environments as follows: the level of the undesired signal is measured either outside of the headset in the ambient environment, or under the headset, or in the ear canal of the wearer. After noise estimation and signal detection,


the level of the estimated desired signal is adaptively adjusted relative to the estimated level of the undesired signal. The dynamic range of the desired signal is mapped over the frequency range into the available dynamic range of the wearer to prevent excessively loud levels.—DAP

7,039,195

43.66.Vt EAR TERMINAL

Jarle Svean et al., assignors to Nacre AS
2 May 2006 (Class 381/71.6); filed 1 September 2000

A self-contained, idealized, in-the-ear noise protection/communication/dosimeter device contains both ear canal and environmental microphones, a speaker, and a ventilation channel with a pressure-release valve and a bypass path. Active noise cancellation is performed on the residual ear
canal signal. The output of the device is transmitted via wireless means to a similar device in the opposite ear of the wearer. No mention is made about how to fit and power all of this into an in-the-ear device.—DAP

43.66.Yw HEARING TEST APPARATUS AND METHOD HAVING AUTOMATIC STARTING FUNCTIONALITY

Steven J. Iseberg *et al.*, assignors to Etymotic Research, Incorporated
23 May 2006 (Class 381/60); filed 2 March 2000

This is a device to analyze the distortion product otoacoustic emissions (DPOAEs) generated by the ear in order to determine middle ear function. In general a DPOAE test device generates and emits two audible tones (i.e., test signals) at different frequencies into a subject's ear canal. A healthy ear will produce, in response to the two audible tones, a response signal having a frequency that is a combination of the frequencies of the two audible tones. In this version of the DPOAE test device, the device analyzes the responses to determine whether the testing probe has been properly placed in the ear canal. The device may determine, e.g., whether the probe is stable, whether it is properly sealed in the ear canal, whether the resulting volume of the ear is acceptable, and/or whether the stimulus delivery is blocked in any way. If the device indicates that the testing probe has been properly placed in the ear canal, the device automatically starts a DPOAE test without requiring any operator input.—DRR

6,971,993

43.70.Dn METHOD FOR UTILIZING ORAL MOVEMENT AND RELATED EVENTS

Samuel G. Fletcher, assignor to Logometrix Corporation
6 December 2005 (Class 600/587); filed 14 November 2001

Described as a device to help a speaker improve the articulation of speech, this is a computer station with one or two attached palatography sensor plates. When in use, the speaker's areas of tongue contact with the palate sensor are displayed, together with an optional second display of
either a second speaker or a computer-generated reference palate-contact model. The patent includes a brief discussion of the patterns of palatal contact that might be expected during normal speech.—DLR

7,043,424

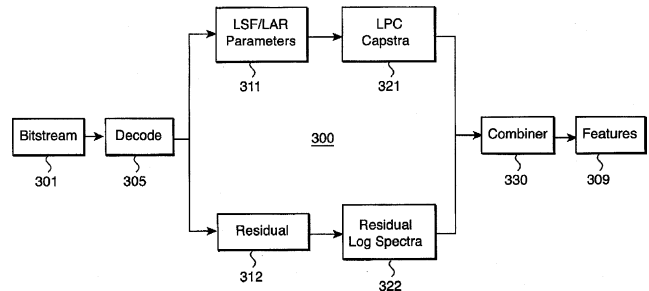
43.72.Ar PITCH MARK DETERMINATION USING A FUNDAMENTAL FREQUENCY BASED ADAPTABLE FILTER

Jau-Hung Chen and Yung-An Kao, assignors to Industrial Technology Research Institute
9 May 2006 (Class 704/207); filed in Taiwan 14 December 2001

This patent proposes to pinpoint the fundamental period of voiced speech by means of filtered waveform zero-crossing points. The signal must first go through a tight adaptive bandpass filter that closely tracks the fundamental frequency, so that all harmonics are filtered out. Of course, this necessitates actually tracking the fundamental frequency by some unmentioned means, and the whole approach seems a tad circular—one senses some labor is being needlessly repeated somewhere by a scheme that tracks pitch in order to tightly filter so that the pitch can be tracked.—SAF

43.72.Bs DISTRIBUTED SPEECH RECOGNITION WITH CODEC PARAMETERS

Bhiksha Raj *et al.*, assignors to Mitsubishi Electric Research Laboratories, Incorporated
23 May 2006 (Class 704/219); filed 27 November 2001

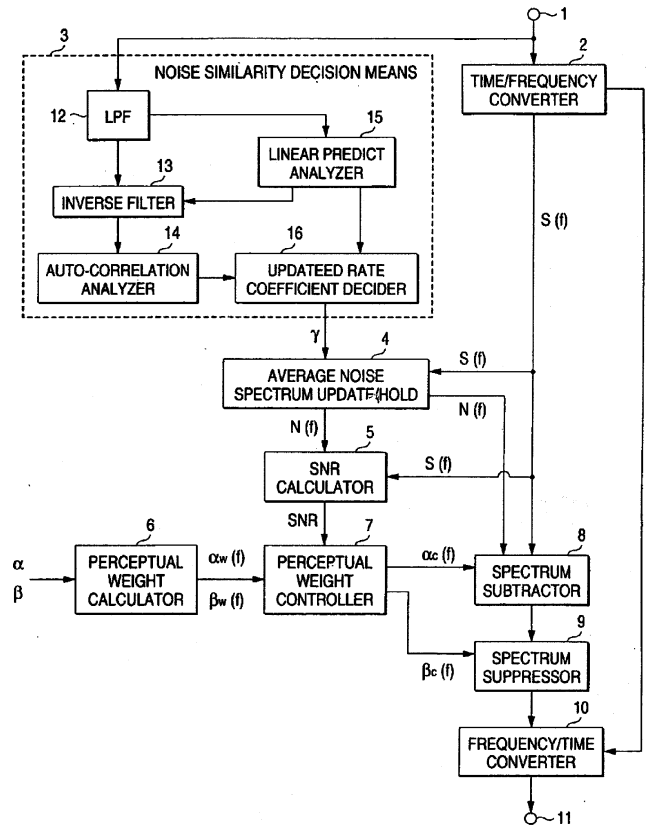
An encoded bitstream is first decoded to produce linear predictive coding (LPC) filter parameters and a residual signal, which are then combined using linear discrimination analysis to form speech recognition


features. The LPC parameters represent the important short-term spectral characteristics and the residual signal models the long-term information such as pitch and perceptual quality. The method may be applied to various coding methods including LPC, GSM, and CELP.—DAP

7,043,030

43.72.Dv NOISE SUPPRESSION DEVICE

Satoru Furuta, assignor to Mitsubishi Denki Kabushiki Kaisha
9 May 2006 (Class 381/94.1); filed in Japan 9 June 1999

This extensive patent includes 15 embodiments and 48 claims, all surrounding a noise filtration scheme that is supposedly able to clean noise from a signal in a way that avoids numerous typical problems, including


introduction of musical noise and excessive reduction of signal amplitude. The central idea seems to be the use of two or three ''perceptual weights'' that adapt to signal/noise ratio in a complicated spectral subtraction algorithm. How it works is presented in detail; why it works is still mysterious.—SAF

6,970,819

43.72.Ja SPEECH SYNTHESIS DEVICE

Yukio Tabei, assignor to Oki Electric Industry Company, Limited
29 November 2005 (Class 704/256); filed in Japan 17 March 2000

The patent describes a strategy to be used for assigning durations to vowels and consonant closures for use by a parametric speech synthesizer. Consonants are divided into classes, applying duration parameters to continuant portions and/or closure portions as appropriate. The actual method used to determine the durations is not described other than by reference in the patent text to two Japanese patent applications. However, these publications are not listed as references on the front page.—DLR

6,970,820

43.72.Ja VOICE PERSONALIZATION OF SPEECH SYNTHESIZER

Jean-Claude Junqua et al., assignors to Matsushita Electric Industrial Company, Limited
29 November 2005 (Class 704/258); filed 26 February 2001

A system is described for generating controls for a parametric speech synthesizer, with the intent that the synthesized output would closely approach the speech characteristics of a particular human speaker. This would be done by constructing the control parameters from two separate influences, those due to the speech content and those due to speaker characteristics. The novel element here is the construction of a speaker eigenspace based on a fairly short sample of representative speech. The eigenspace model can then be consulted to determine values for parameters not explicitly present in the speech sample. Construction of the eigenspace is covered in some detail in the patent text, but without mathematics.—DLR

6,975,987

43.72.Ja DEVICE AND METHOD FOR SYNTHESIZING SPEECH

Seiichi Tenpaku and Toshio Hirai, assignors to Arcadia, Incorporated
13 December 2005 (Class 704/258); filed in Japan 6 October 1999

This patent presents a technique for improving the quality of speech synthesized by concatenation of stored waveform segments. In such a system, the stored segments will typically need to be modified in order for the synthesized speech pitch to have the proper contours. The patent presents a
method of modeling the speech waveform so that a cut may be made for the purpose of pitch and/or duration modification while minimizing the effects of distortion of the speech spectral qualities.—DLR

6,975,988

43.72.Ja ELECTRONIC MAIL METHOD AND SYSTEM USING ASSOCIATED AUDIO AND VISUAL TECHNIQUES

Adam Roth, New York, New York et al.
13 December 2005 (Class 704/260); filed 10 November 2000

A technique is presented here for delivering an email message, in a multimedia form that may involve text and/or voice, as well as a facial image that appears to be voicing the words. The original message may have been in the form of either text or speech. At the receiving end, the facial image may be the actual speaker's image, the image of another person, or perhaps a cartoon image. A central aspect of the patented system is the ability to include emotional content into the message, which would not be conveyed by text alone. The patent describes different ways this goal may be achieved under the various combinations of modalities on the sending and receiving ends. What is still missing here is the yet unanswered but vital question of eye contact.—DLR

6,970,185

43.72.Ne METHOD AND APPARATUS FOR ENHANCING DIGITAL IMAGES WITH TEXTUAL EXPLANATIONS

Paul Steven Halverson, assignor to International Business Machines Corporation
29 November 2005 (Class 348/207.1); filed 31 January 2001

The basic scheme patented here is that a digital camera would provide a speech recognition service, allowing the photographer to speak a phrase to be digitally attached to the photo. Since a reasonably thorough and accurate recognition system would exceed the camera's ''on board'' resources, the
first step would involve a simpler version of audio analysis, producing a sort of phonetic script. Later, when the photo is downloaded to a computer, a more complete recognition system would finish the conversion of the phonetic script to a phrase in proper English text.—DLR

6,975,983

43.72.Ne NATURAL LANGUAGE INPUT METHOD AND APPARATUS

Nicholas David Fortescue and Robert Alexander Keiller, assignors to Canon Kabushiki Kaisha
13 December 2005 (Class 704/9); filed in the United Kingdom 29 October 1999

This patent covers the use of a natural language grammar as the language reference needed in a speech recognition system and, in particular, it describes how the natural language grammar may be modified so as to specify points in time where the speaker might pause, thus improving the recognition accuracy. The application involves the entry of speech data into a computer while the user also operates a mouse or keyboard. This might often involve the overlapping of speech with computer events, i.e., clicks or keystrokes, using these as a way of pointing to an item that is also mentioned verbally. The recognition grammar would use this dual-mode information to correctly identify the referent item.—DLR

7,039,589

43.72.Ne INTERACTIVE MULTIMEDIA BOOK

Charles Lamont Whitham, Reston, Virginia
2 May 2006 (Class 704/270); filed 1 December 2003

A computer-based book, containing both audio/video and text, provides hands-on multimedia instruction in response to voiced commands. The material is presented in a manner that is suitable for use in a variety of environments such as do-it-yourself repair. A word used as a hyperlink to other related topics changes its visual attributes when spoken and takes effect with a minimum of user interaction required, just as if a cursor had been placed on it.—DAP

7,043,425

43.72.Ne MODEL ADAPTIVE APPARATUS AND MODEL ADAPTIVE METHOD, RECORDING MEDIUM, AND PATTERN RECOGNITION APPARATUS

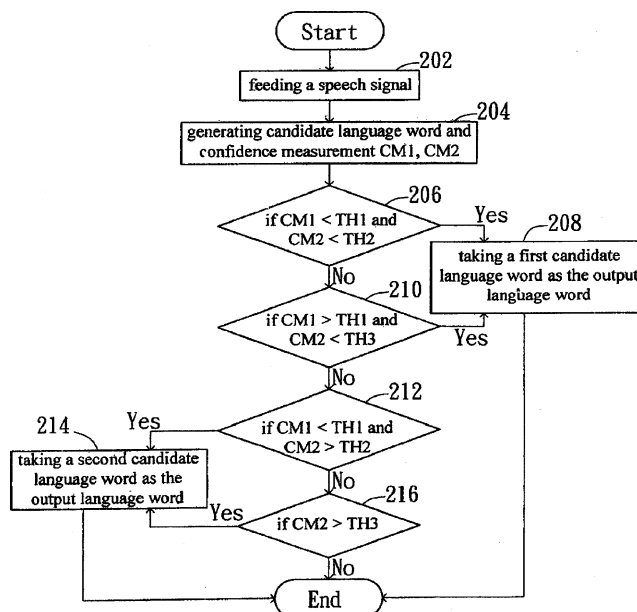
Hongchang Pao, assignor to Sony Corporation
9 May 2006 (Class 704/211); filed in Japan 28 December 1999

This patent introduces an adaptive method for adaptation of nonspeech models in speech recognition tools. The inventors believe that fresh nonspeech models can dynamically model noise characteristics, which may increase performance of speech recognition systems. To adapt nonspeech models with environmental noise, the invention has employed linear and nonlinear weighted functions. The model's parameters are altered based on the spectrum of the nonspeech signal.—AAD

7,043,429

43.72.Ne SPEECH RECOGNITION WITH PLURAL CONFIDENCE MEASURES

Sen-Chia Chang et al., assignors to Industrial Technology Research Institute
9 May 2006 (Class 704/236); filed in Taiwan, Province of China 24 August 2001

A speech recognition system for multiple languages avoids the need to formulate a complete set of speech data banks and acoustic models for each language. Two speech recognizers and three preset thresholds are used with


two confidence measures to determine whether a first or second candidate language word is best for the output language word.—DAP

7,043,430

43.72.Ne SYSTEM AND METHOD FOR SPEECH RECOGNITION USING TONAL MODELING

Grace Chung et al., assignors to Infotalk Corporation Limited
9 May 2006 (Class 704/251); filed 22 November 2000

A two-stage speech recognition methodology is proposed for application to tone languages such as Chinese. Stage one is, in essence, a standard speech recognition setup as would be applied to nontonal languages, but in which an effort is made to decode the speech syllabically. Stage two brings in the tone recognition scheme that concentrates on deciding which tone (pitch pattern) each syllable has been spoken with, and then the recognition scores from the two stages are combined to yield the predicted utterance.—SAF

7,047,192

43.72.Ne SIMULTANEOUS MULTI-USER REAL-TIME SPEECH RECOGNITION SYSTEM

Darrell A. Poirier, Quinebaug, Connecticut
16 May 2006 (Class 704/235); filed 27 June 2001

A speech recognition system creates a textual representation of a discussion by multiple speakers—a conference-to-text system. The system may include real-time language translation if multiple languages are used.—DAP

7,050,973

43.72.Ne SPEAKER RECOGNITION USING DYNAMIC TIME WARP TEMPLATE SPOTTING

Hagai Aronowitz, assignor to Intel Corporation
23 May 2006 (Class 704/246); filed 22 April 2002

Dynamic time warping involves aligning corresponding parts of an utterance against those of a target utterance. Spectral distances between coefficients are compared for spoken utterances against those for several

43.72.Ne ENVIRONMENT ADAPTATION FOR SPEECH RECOGNITION IN A SPEECH COMMUNICATION SYSTEM

Yasuhiro Komori and Masayuki Yamada, assignors to Canon Kabushiki Kaisha
23 May 2006 (Class 704/256); filed in Japan 14 September 1999

This patent is mainly related to a remote speech recognition system. The system sends speech information to a remote host server through a communication network where recognition is performed. Environmental factors such as room acoustics, noise level, and communication-channel noise are calculated at the input terminal and sent to the server. In order to improve the performance of recognition, the speech models may be updated in the server upon noticing significant changes in the environmental factors.—AAD

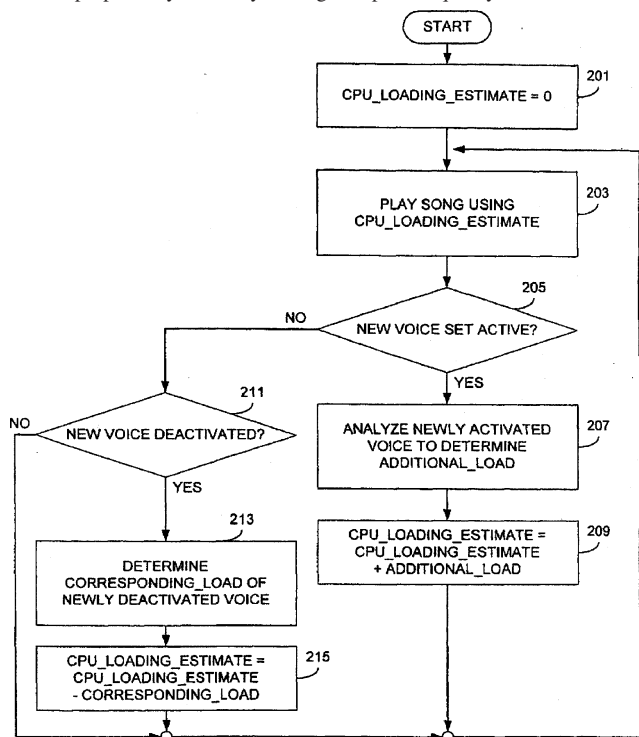
43.75.Wx DYNAMIC CONTROL OF PROCESSING LOAD IN A WAVETABLE SYNTHESIZER

Andrej Petef, assignor to Telefonaktiebolaget L M Ericsson (publ)
2 May 2006 (Class 84/604); filed 18 July 2003

It is well known that the fixed sampling rate will impact the maximum number of voices in a synthesizer. A significant part of the computational load is devoted to the interpolation of ASDR (attack, sustain, decay, release) parameters. Naturally, the better the interpolation, the better the fidelity. This inventor proposes dynamically trading interpolator quality for the number of


voices. Of course the distortion will increase as the number of voices in-ceases due to the decrease in interpolator quality. The inventor argues that the added voices will introduce additional masking effects, thereby reducing the audibility of the interpolator artifacts.—MK

7,039,478

43.75.Wx METHOD AND SYSTEM FOR AUTHORING A SOUNDSCAPE FOR A MEDIA APPLICATION

Eric Ledoux *et al.*, assignors to Microsoft Corporation
2 May 2006 (Class 700/94); filed 16 June 2004

As shown, this software can be divided into four stages: In stage 1, a flow graph is created. Stage 2 creates a graphic "control panel" as a graphi-cal user interface (GUI) while stage 3 assigns actions. All of this can be previewed before use (stage 4). Given this disclosure, you would think that
GUIs for sound did not exist before 1993. But is not this just a virtual sound scripting language? Where are references to Puckette's Max? Where is Tcl/Tk in all this?—MK

7,041,059

43.80.Qf 3D ULTRASOUND-BASED INSTRUMENT FOR NON-INVASIVE MEASUREMENT OF AMNIOTIC FLUID VOLUME

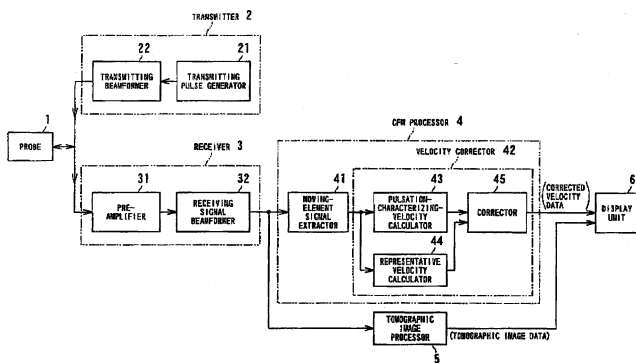
Vikram Chalana *et al.*, assignors to Diagnostic Ultrasound Corporation
9 May 2006 (Class 600/437); filed 20 May 2003

Disclosure is made of a hand-held 3-D ultrasound instrument for au-tomatically and noninvasively measuring amniotic fluid volume in the
uterus. Through the use of a 2-D image-processing algorithm, this instrument provides the medical specialist with automatic feedback information as to where to acquire the 3-D image set. The user obtains one or more 3-D data sets covering all of the amniotic volume in the uterus, and this data is then processed using an optional 3-D algorithm to yield the total amniotic fluid volume corrected for any contributions from the fetal head volume.—DRR

7,044,913

43.80.Qf ULTRASONIC DIAGNOSIS APPARATUS

Eiichi Shiki, assignor to Kabushiki Kaisha Toshiba
16 May 2006 (Class 600/454); filed in Japan 15 June 2001

The goal of this ultrasonic apparatus is to effectively display dynamic blood-flow states in a patient being examined, and, in particular, to display pulsation of the blood flow, and to provide a 3-D view of pulsatile flows of blood. The apparatus consists of an ultrasound probe, a transmitter (that includes a transmitting pulse generator and a transmitting beamformer), a receiver (that includes a preamplifier and a receiving beamformer), a color-flow mapping processor, which incorporates a moving-element signal


extractor, and a velocity corrector, a tomographic image processor, and a display unit. The device scans an area of interest by transmitting and receiving an ultrasound pulse to and from the patient. The velocity corrector calculates a pulsation-characterizing velocity, a representative (i.e., a reference) velocity, and corrects the velocities of the moving element on the basis of the standard velocity. The corrected velocity data are visualized on the display unit.—DRR

7,048,690

43.80.Qf PRECISION ULTRASOUND MEASUREMENT FOR INTRAOCULAR LENS PLACEMENT

Jackson D. Coleman *et al.*, assignors to Cornell Research Foundation, Incorporated
23 May 2006 (Class 600/452); filed 19 March 2002

The patent relates to a method of collecting, processing, and displaying data that are generated during scanning of the eye utilizing high-frequency ultrasound apparatus and associated devices. The geometry and/or topography of the relevant portions of the eye are depicted in preparation for lens
implantation and/or lens replacement in the case of cataract removal. Visual displays of the eye geometry and/or topography are obtained from data generated during a number of angularly spaced ultrasound scans taken across a meridional coronal section or a marginal section of the anterior surface of the eye.—DRR

7,052,462

43.80.Qf ULTRASONIC PROBE AND ULTRASONIC DIAGNOSTIC EQUIPMENT

Hiroshi Fukuda and Masayoshi Omura, assignors to Olympus Corporation
30 May 2006 (Class 600/445); filed 24 October 2002

The object of this device is to provide an ultrasonic probe in which ultrasonic attenuation at high frequencies is small and the decrease of the capacity of an acoustic medium, due to volatilization, can be reduced. A flexible shaft is inserted through a sheath constituting an insertion portion of an ultrasonic probe connected to an ultrasonic observation platform. An ultrasonic transducer, driven to rotate, is attached at the distal end. The attenuation at high frequencies can be reduced through the use of a hydrocarbon-based oil having a kinematic viscosity of 20 mm^2/s as an acoustic medium surrounding the ultrasonic probe in the acoustic window. The decrease in the capacity of the acoustic medium due to volatilization is also minimized.—DRR

7,052,467

43.80.Qf STETHOSCOPIC SYSTEMS AND METHODS

Shawn C. D. Johnson, Winchester and David S. Geller, Lexington, both of Massachusetts
30 May 2006 (Class 600/528); filed 4 October 2002

This is a device for communicating stethoscope sounds over a telephone system. The device consists of a chest piece, an amplifier, and a mixer compatible with a conventional voice-quality telephone system. Electrical signals are generated that are representative of the physiological sounds, such as breathing sounds, heart sounds, and bowel sounds. The electrical signals can be combined with voice communications at the remote site and
transmitted over the telephone system. A system and method is also provided for diagnosis by a trained health-care professional with the patient being located at a remote site. In a second embodiment, a system and method are also provided for training students to interpret stethoscope sounds.—DRR

7,044,737

43.80.Sh ULTRASOUND ORAL HYGIENE AND THERAPEUTIC DEVICE

Liang Fu, Potomac, Maryland
16 May 2006 (Class 433/119); filed 5 March 2004

An ultrasound therapeutic device uses a combination of ultrasonic transducer array and a filling means to control the ultrasound radiation to each part of the oral cavity that is being treated for cleaning and therapy. Every surface of the oral cavity, including the interdental and gingival areas, is cleaned and treated for therapy simultaneously, uniformly, and with
optimal amount of ultrasound radiation. It is also asserted that every part of the oral cavity is protected from an overdose of ultrasound radiation through limited ultrasound action zones for specific exposure times. The soft, resilient filling element sits snugly into a patient's oral cavity and it serves to confine the cleaning solution and the ultrasound action.—DRR

7,044,960

43.80.Sh METHOD AND APPARATUS FOR PROVIDING NON-INVASIVE ULTRASOUND HEATING OF THE PREOPTIC ANTERIOR HYPOTHALAMUS

Marc E. Voorhees and Gary A. Carson, assignors to Medivance Incorporated
16 May 2006 (Class 607/96); filed 17 September 2003

Among neuroprotectant approaches to treating strokes is the induction of mild hypothermia, which has been shown to inhibit the chemical cascade that causes secondary cellular death after an ischemic event and to provide broad neuroprotection. The patent covers a method and system to induce mild hypothermia in a patient through controlled heating of the preoptic anterior hypothalamus (POAH) in conjunction with cooling of the patient's body. An ultrasound transducer is positioned extracorporeally to the patient's skull in order to transmit ultrasound energy to the POAH. This heats the POAH to inhibit thermoregulatory responses so that the patient's core
body temperature may more effectively be cooled. Feedback sensors may be strategically placed at various locations on the patient in order to monitor the core temperature. A control subsystem controls the amount of heat the POAH receives and the amount of cooling the body receives on the basis of feedback signals from the sensors.—DRR

7,052,506

43.80.Sh ULTRASONIC SURGICAL TOOL

Michael John Radley Young and Stephen Michael Radley Young, both of South Devon, the United Kingdom
30 May 2006 (Class 606/169); filed in the United Kingdom 17 September 1999

The goal of this surgical device is to provide a surgical tool with a disposable shroud system that can be quickly and easily detached from the apparatus and replaced by a replacement shroud. The tool consists of an ultrasonic vibration generator with a waveguide at one end. The distal end of the waveguide is provided with cutting and/or coagulating means. A shroud
is adapted to surround and isolate the waveguide and an actuating rod surrounds the rod or vice versa. The shroud and actuating rod are detachably connected at the proximal ends to the generator.—DRR

Stuart Cunningham
Department of Human Communication Sciences, University of Sheffield, Sheffield, S1 4DP United Kingdom

Xu Shao
Department of Computer Science, University of Sheffield, Regent Court, 211 Portobello Street, Sheffield, S1 4DP United Kingdom

An audio-visual corpus has been collected to support the use of common material in speech perception and automatic speech recognition studies. The corpus consists of high-quality audio and video recordings of 1000 sentences spoken by each of 34 talkers. Sentences are simple, syntactically identical phrases such as "place green at B 4 now." Intelligibility tests using the audio signals suggest that the material is easily identifiable in quiet and low levels of stationary noise. The annotated corpus is available on the web for research use. © 2006 Acoustical Society of America. [DOI: 10.1121/1.2229005]

I. INTRODUCTION

Understanding how humans process and interpret speech in adverse conditions is a major scientific challenge. Two distinct methods for modeling speech perception have been studied. The traditional approach has been to construct "macroscopic" models, which predict overall speech intelligibility in conditions of masking and reverberation. Models such as the articulation index (French and Steinberg, 1947), the speech transmission index (Steeneken and Houtgast, 1980), and the speech intelligibility index (ANSI S3.5, 1997) fall into this category. A more recent idea is to apply automatic speech recognition (ASR) technology to construct what might be called "microscopic" models of speech perception, which differ from macroscopic approaches in their additional capability to predict listeners' responses to individual tokens. Examples of microscopic models include Ghitza (1993), Ainsworth and Meyer (1994), Holube and Kollmeier (1996), and Cooke (2006).

Although microscopic modeling results have been promising, a serious barrier to further development of these models has been the lack of suitable speech material. Unlike speech perception studies, microscopic models require a large volume of speech material for training purposes. Many corpora for ASR exist, but the use of such corpora in speech perception testing is problematic. Speech material tends to be uncontrolled, phonetically unbalanced, or consists of tokens whose durations make them unsuitable for behavioral studies. By contrast, corpora used in perceptual studies tend to be too small or insufficiently varied for microscopic models of speech perception.

Previous models have attempted to explain the *auditory* perception of speech signals. However, speech production results in both acoustic and optical signals. It has become increasingly clear that the visual modality has a fundamental role in speech perception, and any full perceptual account needs to explain the complicated interactions between modalities (Rosenblum, 2002). Acoustically confusable phoneme pairs such as /m/ and /n/ can be disambiguated using visual cues. Automatic speech recognition systems can exploit these cues to improve audio-only recognition performance in both clean and noisy conditions (Potamianos *et al.*, 2003). Visual cues can also be used to separate speech from competing noise sources. One particularly interesting area of study in this respect is the audio-visual separation of simultaneous cochannel speech. Despite the clear importance of visual speech information, until now there have been no eas-

a)Electronic mail: m.cooke@dcs.shef.ac.uk

ily accessible corpora suitable for building multimodal models. However, recent advances in video compression technology, the rapidly falling cost of hard disk storage, the increasing capacity of optical storage media, and the increasing bandwidth of typical Internet connections, mean that storage and distribution are no longer a barrier.

These factors motivated the collection of an audio-visual corpus designed for both ASR-based and perceptual studies of speech processing. The form of the corpus was heavily influenced by the coordinate response measure (CRM) task (Moore, 1981; Bolia *et al.*, 2000), which consists of simple sentences of the form "READY <call sign> GO TO <color> <digit> NOW." CRM used 8 call signs, 4 colors, and 8 digits and each combination was spoken once by 8 talkers for a total of 2048 sentences. CRM is useful for studies of early processes in speech perception since it contains sentence length material, yet is devoid of high-level linguistic cues. The design of CRM makes it valuable in multitalker tasks (e.g., Brungart *et al.*, 2001) where listeners are asked to identify the color-digit combination spoken by the talker who provided a given call sign.

The new collection, which we call the Grid corpus, consists of sentences such as "place blue at F 9 now" of the form <command:4> <color:4> <preposition:4> <letter:25 > <digit:10> <adverb:4>," where the number of choices for each component is indicated. Grid extends CRM in a number of ways. The set of talkers is larger (34 rather than 8) and the number of sentences per talker is 1000 rather than 256, giving a total corpus size of 34 000 as opposed to 2048 sentences. Consequently, Grid contains greater variety and is large enough to meet the training requirements of ASR systems. Grid has an improved phonetic balance due to the use of alphabetic letters, which also presents listeners with a more difficult task than the four color options of CRM. Grid is more varied than CRM since the "filler" items (command, preposition, and adverb) are no longer static. This also prevents echo-like artifacts arising when two or more sentences with identical fillers are summed in, for example, experiments involving multiple simultaneous talkers. Finally, Grid provides speech video as well as audio, allowing the development of multimodal perceptual models.

While the primary motivation for the Grid corpus was to support the construction of microscopic, multimodal models of speech perception, it can also be used for conventional behavioral studies of audio and audio-visual speech perception. Similarly, Grid is valuable for ASR studies of speech in noise, the separation of speech from multitalker backgrounds, and audio-visual speech recognition and separation.

II. CORPUS

A. Sentence design

Each sentence consisted of a six word sequence of the form indicated in Table I. Of the six components, three—color, letter, and digit—were designated as "keywords". In the letter position, "w" was excluded since it is the only multisyllabic English alphabetic letter. "Zero" was used rather than "oh" or "nought" to avoid multiple pronunciation alternatives for orthographic "0." Each talker produced all combinations of the three keywords, leading to a total of

TABLE I. Sentence structure for the Grid corpus. Keywords are identified with asterisks.

command	color*	preposition	letter*	digit*	adverb
bin	blue	at	A–Z	1–9, zero	again
lay	green	by	excluding W		now
place	red	in			please
set	white	with			soon

1000 sentences per talker. The remaining components—command, preposition, and adverb—were "fillers." Four alternatives were available in each filler position. Filler words were chosen to create some variation in contexts for the neighboring key words. Different gross phonetic classes (nasal, vowel, fricative, plosive, liquid) were used as the initial or final sounds of filler words in each position.

B. Speaker population

The aim of speaker selection was to provide a sufficiently large number of speakers to allow users of the corpus to select subsets based on criteria such as intelligibility, homogeneity, and variety. Sixteen female and 18 male talkers contributed to the corpus. Participants were staff and students in the Departments of Computer Science and Human Communication Science at the University of Sheffield. Student participants were paid for their contribution. All spoke English as their first language. All but three participants had spent most of their lives in England and together encompassed a range of English accents. Two participants grew up in Scotland and one was born in Jamaica. Ages ranged from 18 to 49 years (mean: 27.4 years).

C. Collection

Audio-visual recordings were made in an IAC single-walled acoustically isolated booth. Speech material was collected from a single Bruel & Kjaer (B & K) type 4190 $\frac{1}{2}$ -in. microphone placed 30 cm in front of the talker. The signal was preamplified by a B & K Nexus model 2690 conditioning amplifier prior to digitization at 50 kHz by a Tucker-Davis Technologies System 3 RP2.1 processor. Collection of speech material was under computer control. Sentences were presented on a computer screen located outside the booth, and talkers had 3 s to produce each sentence. Talkers were instructed to speak in a natural style. To avoid overly careful and drawn-out utterances, they were asked to speak sufficiently quickly to fit into the 3-s time window. Talkers were allowed to repeat the sentence if they felt it necessary, either because of a mistake during production or if part of the utterance fell outside the 3-s window. As an aid, the captured waveform was displayed on the screen. In addition, talkers were asked to repeat the utterance if the captured waveform was judged by the software to be too quiet or too loud. Prior to saving, signals were scaled so that the maximum absolute value was unity, in order to optimize the use of the quantized amplitude range. Scale factors were stored to allow the normalization process to be reversed.

A simultaneous continuous video recording was made on to MiniDV tape using a Canon XM2 video camcorder. The camera was set up to capture full frames at 25 frames/s.

To avoid both noise and distraction from the video apparatus, the camera was placed at eye level outside the booth, abutting the booth window. Light sources were arranged to produce uniform illumination across the face, and the subject was seated in front of a plain blue background. To ease temporal alignment of the audio and visual signals, the camera took its audio input from the high-quality audio signal provided by the microphone in the booth.

Although talkers were allowed to repeat an utterance if they misread the prompt, they occasionally made errors without realizing they had done so. A semi-automatic screening procedure was employed to locate errors in the corpus. The screening process used an ASR system based on talker-dependent, whole-word hidden Markov models (HMM), trained separately for each talker. A "jack-knife" training procedure was used in which 80% of the talker's utterances were used for training and the remaining 20% recognized. This procedure was performed five times with a different subset of utterances so that the subset recognized was independent of the training set on each occasion. The ASR system produced word-level transcripts for each utterance, and errors were flagged if the recognition output differed from the sentence the talker was meant to have read. On average, 57 out of 1000 utterances were flagged per talker. Flagged utterances were checked by a listener and any sentences with errors were marked for re-recording. Talkers were recalled to perform the re-recording session, during which time their utterances were monitored over headphones. Talkers were asked to repeat any incorrectly produced utterances. In all, 640 utterances (an average of 19 per talker or 1.9% of the corpus) were re-recorded.

While the screening process guaranteed that many of the errors in the corpus were corrected, it is possible that some errors were not detected. For a spoken sentence containing an error to appear correct, the recognition system must have made a complementary error (i.e., an error which corrects the error made by the talker). However, since the error rates of both the talkers and recognizer are very low, the conjunction of complementary errors is extremely unlikely. Informal human screening of a subset of utterances led to an estimate of an error rate of not more than 0.1% (i.e., one error per 1000 utterances). Most of the errors detected involved misproduced filler items, so the number of sentences containing misproduced keywords is smaller still.

D. Postprocessing
1. Audio

Prior to further processing, audio signals were down-sampled to 25 kHz using the MATLAB *resample* routine. A subset of 136 utterances (four randomly chosen from each talker) was used to estimate the peak S/N according to the ITU P.56 standard (ITU-T, 1993). The peak S/N varied across talkers from 44 to 58 dB (mean=51 dB, s.d.=3.6 dB).

The talker-dependent HMM-based ASR systems used in the screening of speaker errors were employed to estimate the alignment between the word-level transcription and the utterance. In addition, phone-level transcriptions of each utterance were produced by forced alignment using the HVITE program in the HTK hidden Markov model toolkit (Young *et*

al., 1999). Pronunciations were taken from the British English Example Pronunciation dictionary (BEEP[1]). To bootstrap the initial set of HMMs, 60 sentences from one of the speakers were manually transcribed at the phone level.

2. Video

Unlike the audio collection, which was computer-controlled, the video data were collected continuously throughout the recording session, and thus contained both genuine Grid utterances as well as false starts, incorrect utterances, and other material. Consequently, it was necessary to extract video segments corresponding to the final end-pointed audio recordings. Utterance segments were first located approximately using a timestamp recorded by the software controlling the audio recording session. A precise location was then found by searching in this region for the 3-s period of the video file that best correlated with the 3 s of high-quality audio captured by the TDT processor. Correlations were performed using the smoothed energy envelope of the signals. Once the audio was precisely located, the corresponding 75-frame (i.e., 3-s) segment of video was extracted. The high-quality 50-kHz audio captured by the TDT processor was resampled to 44.1 kHz and used to replace the audio track of the video segment.

The DV format video was converted to MPEG-1 format using FFMPEG.[2] Two compression rates were used to produce both high and moderate quality versions of the video data. The high-quality video employed a bandwidth of 6 Mbits per s (comparable to DVD quality), while the moderate quality version used a bandwidth of 600 Kbits per s (a quality intermediate between a typical business-oriented videoconferencing system and VHS video). In both cases, the audio bit rate was set to 256 kbits per s.

III. AUDIO INTELLIGIBILITY TESTS

Twenty listeners with normal hearing heard independent sets of 100 sentences drawn at random from the corpus. All speech material had initial and trailing silence removed prior to presentation using utterance endpoints derived from the word alignments. Utterances were scaled to produce a presentation level of approximately 68 dB SPL and were presented diotically over Sennheiser HD250 headphones in the IAC booth. Listeners were asked to identify the color, letter, and digit spoken and entered their results using a conventional computer keyboard in which four of the nonletter/digit keys were marked with colored stickers. Those keys representing colors were activated immediately following the onset of each utterance. As soon as a color key was pressed, the 25 relevant letter keys were enabled, followed by the 10 digit keys. This approach allowed for rapid and accurate data entry: most listeners were able to identify a block of 100 utterances in 5–7 min. Listeners were familiarized with the stimuli and the task by identifying an independent practice set of 100 sentences prior to the main set.

Figure 1 (triangles) shows the mean scores and their standard errors across listeners. Unsurprisingly, fewer errors were made for colors (0.25% of the 2000 sentences) than for digits (0.7%) or letters (0.95%). At least one error occurred
FIG. 1. Mean error rates across listeners for sentences, colors, digits, and letters. A sentence contained an error if one or more keywords were incorrectly identified. Triangles: clean sentence material; circles: sentences in speech-shaped noise. Error bars denote $+/-1$ standard errors.

FIG. 2. Error rates for colors, digits, letters, and per talker for the noise conditions. Horizontal lines indicate mean error rates in each category. Talker error rates are measured as percentages of utterances in which at least one keyword was misidentified.

in 1.85% (37 out of 2000) of sentences. These low error rates suggest that the speech material collected was of high intelligibility overall.

Insufficient errors were reported using clean speech material to allow a more detailed inspection of the intelligibility of individual keywords or talkers. To support such an analysis, the same 20 listeners heard three further independent sets of 100 utterances mixed with speech-shaped noise whose spectrum matched the long-term spectrum of the Grid corpus at three signal-to-noise ratios: 6, 4, and 2 dB, producing a total of 6000 responses. Figure 1 (circles) shows error rates for colors (0.7%), digits (1.6%), letters (5.2%), and wholly correct sentences (7.1%). Figure 2 depicts the distribution of errors by keyword and across talkers. While the color and number distributions are reasonably flat, certain letters are recognized significantly less well than others. Inspection of letter confusion matrices revealed that most of the /v/ errors were caused by misidentification as /b/, while /m/ and /n/ tokens were confused with each other.

A range of identification rates (defined as the percentage of utterances in which at least one keyword was misidentified) across the 34 contributing talkers was observed. In particular, listeners misidentified keywords in utterances by talkers 1 (19.8%), 20 (16.2%), and 33 (15.6%), while fewer than 2% of sentences spoken by talker 7 were misidentified by this listener group. However, most talkers produced errors rates of around 5%.

IV. SUMMARY

Grid, a large multitalker audio-visual sentence corpus, has been collected to support joint computational-behavioral studies in speech perception. Audio-only intelligibility tests suggest that the speech material is easily identified in quiet and low-noise conditions. Further tests of visual and audio-visual intelligibility are planned. The complete corpus and transcriptions are freely available for research use at the website <http://www.dcs.shef.ac.uk/spandh/gridcorpus>.

This paper studies the reflection and transmission of plane elastic waves at interfaces in fluid-saturated poroviscoelastic media in which the solid matrix is composed of two weakly coupled solids. The analysis of this problem, not formally performed before, is based on a theory recently developed by some of the authors, which allows us to derive expressions for the reflection and transmission coefficients at a plane interface within this kind of media and their relationship with the energy flux (Umov-Poynting) vector. The results of the present derivation were applied to study the energy splitting that takes place when a plane fast compressional wave strikes obliquely an interface defined by a change in ice content within a sample of water saturated partially frozen sandstone. The numerical results show wave mode conversions from fast to slow compressional and shear waves, with maximum energy conversion on the order of 20% from fast to slow wave modes near the critical angle. This phenomenon was observed at frequencies lying from the seismic to the ultrasonic range, showing that the role of the slow waves must be taken into account when considering wave propagation in this type of media. © *2006 Acoustical Society of America.*

I. INTRODUCTION

It is well known that variations of reflection coefficients with angle of incidence at the interface between two different media is a useful tool for their characterization. This is very important in the context of exploration geophysics for the study of reservoir rocks saturated by hydrocarbon fluids. There is a vast literature about reflection and transmission coefficients in fluid-saturated porous media (see, Deresiewicz and Rice,[1] Dutta and Odé,[2] Santos *et al.*,[3] Denneman *et al.*,[4] among others). In these works, the medium is assumed to be composed by a porous solid fully saturated by a fluid. The mechanical behavior of the rock matrix, which is generally composed by many different minerals, is represented by a single-phase equivalent elastic or dissipative solid. The same kind of simplification is commonly applied for the description of the pore fluids.

However, there are situations in which it is important to describe independently the behavior of the main components. This requires more detailed formulations involving *multiphase models*. Some important applications are related to the study of seismic and acoustic wave propagation in shaley sandstones, permafrost environments, oceanic or continental sediments containing gas-hydrates, and ultrasonic testing of frozen foods.

A Biot-type three-phase theory describing wave propagation in partially frozen porous media was first derived by Leclaire *et al.*[5] for the case of uniform porosity. The formulation involves two solid phases which are assumed to have no direct contact and one single-phase fluid (water). This model predicts the existence of three compressional waves, referred to as p_I, p_{II}, and p_{III} compressional waves, and two shear waves, referred to as s_I and s_{II}, respectively. Later, Carcione and Tinivella[6] included in that model the interaction between the solid phases and grain cementation with decreasing temperature. More recently, Carcione *et al.*[7] and Santos *et al.*[8] extended and applied that theory to the case of variable porosity.

These models are based on the assumptions of *phase connectivity* for solids and fluids, the validity of the continuous medium description, and *weak coupling* between the solid phases. This means that both solids are nonwelded and consequently they can suffer different displacements and deformations under an applied stress. This assumption also implies that there exists an interchange of strain and kinetic energies between the different constituents.

The computation of the reflection and transmission coefficients of elastic waves in these kinds of media was first presented by Carcione and Tinivella.[6] However, the coefficients were computed using an effective single-phase vis-

---

[a]Electronic mail:grubino@fcaglp.unlp.edu.ar

coelastic model, which ignores the presence of slow waves and neglects the energy conversions among the different wave modes.

This encouraged us to obtain the amplitude and energy reflection and transmission coefficients for waves striking with an arbitrary angle at a plane boundary within an isotropic composite porous saturated solid, using the model developed by Santos *et al.*[8] generalizing the ideas given elsewhere.[2,3] This also led us to define an appropriate energy flux (Umov-Poynting) vector for this model and to analyze its relationship with the energy coefficients.

The application of the procedure is illustrated by considering the case of a plane p_I compressional wave arriving at a plane interface defined by a change in ice content in the pores within a sample of water saturated partially frozen Berea sandstone. The results show that a significant part of the incident energy is partitioned at the interface by mode conversion, generating either reflected or transmitted slow waves. Consequently, the role of these types of waves must be taken into account when considering wave propagation in fluid-saturated composite poroviscoelastic materials, even for frequencies lying in the seismic range.

II. REVIEW OF THE MODEL

Let Q be an elementary cube of porous material composed of two solid phases, referred to by the subscripts or superscripts 1 and 3, saturated by a fluid phase indicated by the subscript or superscript 2, so that $Q = Q_1 \cup Q_2 \cup Q_3$. From now on, such type of material will be referred to as a *composite Biot medium*. Let V_i denote the volume of the phase Q_i and V_b and V_{sm} the bulk volume of Q and the solid matrix $Q_{sm} = Q_1 \cup Q_3$, so that

$$V_{sm} = V_1 + V_3, \quad V_b = V_1 + V_2 + V_3.$$

Let $S_1 = V_1 / V_{sm}$ and $S_3 = V_3 / V_{sm}$ denote the two solid fractions of the composite matrix and define $\phi = V_2 / V_b$, $\phi_1 = V_1 / V_b$, and $\phi_3 = V_3 / V_b$.

Following Santos *et al.*,[8] denoting by ω the angular frequency and $\mathbf{x} = (x, y, z)$ the position of the particle, let $u^{(1)} = u^{(1)}(\mathbf{x}, \omega), \tilde{u}^{(2)} = \tilde{u}^{(2)}(\mathbf{x}, \omega)$, and $u^{(3)} = u^{(3)}(\mathbf{x}, \omega)$ be the time-Fourier transforms of the averaged solid and fluid displacements over the bulk material and the relative fluid flow vector $u^{(2)}$, given by

$$u^{(2)} = u^{(2)}(\mathbf{x}, \omega) = \phi(\tilde{u}^{(2)} - S_1 u^{(1)} - S_3 u^{(3)}), \quad (2.1)$$

with $\zeta = -\nabla \cdot u^{(2)}$ representing the change in fluid content. Also set $u = (u^{(1)}, u^{(2)}, u^{(3)})^T$ and $v = (v^{(1)}, v^{(2)}, v^{(3)})^T$ with $v^{(j)} = i\omega u^{(j)}$ being the corresponding particle velocities.

A. Isotropic stress-strain relations

Next, denote by $\tilde{\sigma}_{jk}^{(1)}$ and $\tilde{\sigma}_{jk}^{(3)}$ the time-Fourier transform of the stress tensors in Q_1 and Q_3 averaged over the bulk material Q, respectively, and let p_f denote the time-Fourier transform of the fluid pressure. Assuming statistical isotropy, let us also introduce the tensors

$$\sigma_{jk}^{(1)} = \tilde{\sigma}_{jk}^{(1)} - S_1 \phi p_f \delta_{jk}, \quad \sigma_{jk}^{(3)} = \tilde{\sigma}_{jk}^{(3)} - S_3 \phi p_f \delta_{jk}, \quad (2.2)$$

associated with the total stresses in Q_1 and Q_3, respectively, taking into account that for the isotropic case the volume fractions S_1, S_3 are equivalent to surface fractions. The linear isotropic stress-strain relations stated in the space-frequency domain are given by[8]

$$\sigma_{jk}^{(1)}(u) = [K_{G1}\theta_1 - B_1 \zeta + B_3 \theta_3]\delta_{jk} + 2\mu_1 d_{jk}^{(1)} + \mu_{13} d_{jk}^{(3)},$$

$$\sigma_{jk}^{(3)}(u) = [K_{G3}\theta_3 - B_2 \zeta + B_3 \theta_1]\delta_{jk} + 2\mu_3 d_{jk}^{(3)} + \mu_{13} d_{jk}^{(1)},$$

$$p_f(u) = -B_1 \theta_1 - B_2 \theta_3 + K_{av}\zeta, \quad (2.3)$$

where $d_{jk}^{(m)} = \epsilon_{jk}(u^{(m)}) - \frac{1}{3}\theta_m \delta_{jk}$, $m = 1, 3$, is the deviatoric strain tensor in Q_{sm}, and $\epsilon_{jk}(u^{(m)})$ denotes linear strain tensor in Q_m, with linear invariant $\theta_m = \epsilon_{jj}(u^{(m)})$.

Santos *et al.*[8] have stated the constitutive relations (2.3) in the space-time domain with real elastic moduli, which were computed in terms of the properties of the individual solid and fluid phases. In this work, some of these moduli will be assumed to be complex and frequency dependent in order to include linear viscoelasticity in the formulation, as described in Appendix A. It must be emphasized that under the weak coupling assumption between the two solids, two different stress tensors are needed to describe the stress states in the solid phases. This constitutes a generalization of the classic Biot's theory, in which the different rock minerals are treated as a single phase solid.

B. The equations of motion

Let the positive definite mass matrix $\mathcal{P} = \mathcal{P}(\omega)$ and the non-negative dissipation matrix $\mathcal{B} = \mathcal{B}(\omega)$ be defined by

$$\mathcal{P} = \begin{bmatrix} p_{11}I & p_{12}I & p_{13}I \\ p_{12}I & p_{22}I & p_{23}I \\ p_{13}I & p_{23}I & p_{33}I \end{bmatrix}, \quad \mathcal{B} = \begin{bmatrix} f_{11}I & -f_{12}I & -f_{11}I \\ -f_{12}I & f_{22}I & f_{12}I \\ -f_{11}I & f_{12}I & f_{11}I \end{bmatrix},$$

where I denotes the identity matrix in $\mathbb{R}^{3\times3}$. The non-negative coefficients $p_{ij} = p_{ij}(\omega)$, $f_{ij} = f_{ij}(\omega)$, can be computed as explained in Appendix B. Next, let $\mathcal{L}(u)$ be the second-order differential operator defined by

$$\mathcal{L}(u) = (\nabla \cdot \sigma^{(1)}(u), -\nabla p_f(u), \nabla \cdot \sigma^{(3)}(u))^T.$$

Then, the equations of motion of a composite Biot medium, stated in the space-frequency domain, can be written in the form[8]

$$-\omega^2 \mathcal{P}u(\mathbf{x}, \omega) + i\omega \mathcal{B}u(\mathbf{x}, \omega) = \mathcal{L}(u(\mathbf{x}, \omega)), \quad (2.4)$$

which is equivalent to considering an oscillatory time dependence of the form $e^{i\omega t}$. Finally, introducing the matrix $\mathcal{R} = \mathcal{P} - (i/\omega)\mathcal{B}$, we can write

$$-\omega^2 \mathcal{R}u(\mathbf{x}, \omega) = \mathcal{L}(u(\mathbf{x}, \omega)). \quad (2.5)$$

C. Plane wave analysis

Let us consider a monochromatic plane compressional wave of frequency ω in the (x,y) plane. The displacements $u^{(m)}$, $m=1,2,3$, can be written in terms of scalar potentials in the form:

$$u^{(1)} = \nabla \varphi^{(1)} = \nabla(A_P e^{-i\mathbf{K_P} \cdot \mathbf{x}}),$$

$$u^{(2)} = \nabla \varphi^{(2)} = \nabla(B_P e^{-i\mathbf{K_P} \cdot \mathbf{x}}),$$

$$u^{(3)} = \nabla \varphi^{(3)} = \nabla(C_P e^{-i\mathbf{K_P} \cdot \mathbf{x}}), \tag{2.6}$$

where $\mathbf{K_P}=(n_P, l_P)$ is a complex wave vector and $\mathbf{x}=(x,y)$ is the position vector in $\mathbb{R}^2$. Introducing Eq. (2.3) in Eq. (2.4), assuming spatially constant coefficients and using Eq. (2.6) the following 3×3 linear system of equations is obtained:

$$\mathcal{M}^P \cdot c^P = \bar{0}, \tag{2.7}$$

where $c^P = (A_P, B_P, C_P)^T \in \mathbb{C}^{3 \times 1}$ and $\mathcal{M}^P = (\mathcal{M}^P)_{lm} \in \mathbb{C}^{3 \times 3}$ is a symmetric matrix given by

$$(\mathcal{M}^P)_{11} = p_{11} i\omega^2 + f_{11}\omega - K_{G1} i K_P^2 - \tfrac{4}{3}\mu_1 i K_P^2,$$

$$(\mathcal{M}^P)_{12} = p_{12} i\omega^2 - f_{12}\omega - B_1 K_P^2 i,$$

$$(\mathcal{M}^P)_{13} = p_{13}\omega^2 i - f_{11}\omega - B_3 K_P^2 i - \tfrac{2}{3}\mu_{13} i K_P^2,$$

$$(\mathcal{M}^P)_{22} = p_{22}\omega^2 i + f_{22}\omega - K_{av} K_P^2 i,$$

$$(\mathcal{M}^P)_{23} = p_{23}\omega^2 i + f_{12}\omega - B_2 K_P^2 i,$$

$$(\mathcal{M}^P)_{33} = p_{33}\omega^2 i + f_{11}\omega - K_{G3} K_P^2 i - \tfrac{4}{3}\mu_3 i K_P^2, \tag{2.8}$$

with $K_P^2 = n_P^2 + l_P^2$. To obtain nontrivial solutions A_P, B_P, C_P of Eq. (2.7) the determinant of $\mathcal{M}^P$ must be zero, i.e.,

$$\det(\mathcal{M}^P) = P_3(Z) = 0, \tag{2.9}$$

where $Z = K_P^2$ and $P_3(Z)$ is a cubic polynomial in Z. For any given frequency ω, the displacement amplitude of any phase must decay with the distance, which implies that there are only three physically meaningful solutions for the modulus of the wave vector $K_P = \pm\sqrt{Z}$, having negative imaginary parts, corresponding to the p_I, p_{II}, and p_{III} compressional waves,[8] in agreement with Leclaire et al.[5]

For shear (rotational) waves, if $\mathbf{K_S}=(n_S, l_S)$ denotes the corresponding complex wave vector and $\breve{e}_1$, $\breve{e}_2$, $\breve{e}_3$ denote the unit vectors along the x, y, z Cartesian axis, respectively, then

$$u^{(1)} = -\nabla \times \psi^{(1)} = -\nabla \times (A_S e^{-i\mathbf{K_S} \cdot \mathbf{x}} \breve{e}_3),$$

$$u^{(2)} = -\nabla \times \psi^{(2)} = -\nabla \times (B_S e^{-i\mathbf{K_S} \cdot \mathbf{x}} \breve{e}_3),$$

$$u^{(3)} = -\nabla \times \psi^{(3)} = -\nabla \times (C_S e^{-i\mathbf{K_S} \cdot \mathbf{x}} \breve{e}_3), \tag{2.10}$$

and proceeding in a similar fashion, the following linear system is obtained:

$$\mathcal{M}^S \cdot c^S = \bar{0}, \tag{2.11}$$

where $\mathcal{M}^S \in \mathbb{C}^{3 \times 3}$ is a symmetric matrix with entries

$$(\mathcal{M}^S)_{11} = -p_{11} i\omega^2 - f_{11}\omega + \mu_1 i K_S^2,$$

$$(\mathcal{M}^S)_{12} = -p_{12} i\omega^2 + f_{12}\omega,$$

$$(\mathcal{M}^S)_{13} = -p_{13} i\omega^2 + f_{11}\omega + \tfrac{1}{2}\mu_{13} i K_S^2,$$

$$(\mathcal{M}^S)_{22} = -p_{22} i\omega^2 - f_{22}\omega,$$

$$(\mathcal{M}^S)_{23} = -p_{23} i\omega^2 - f_{12}\omega,$$

$$(\mathcal{M}^S)_{33} = -p_{33} i\omega^2 - f_{11}\omega + \mu_3 i K_S^2, \tag{2.12}$$

and $c^S = (A_S, B_S, C_S)^T \in \mathbb{C}^{3 \times 1}$. As before, to obtain nontrivial solutions of Eq. (2.11),

$$P_2(Z) = \det(\mathcal{M}^S) = 0 \tag{2.13}$$

must be solved, with $P_2(Z)$ being a quadratic polynomial in $Z = K_S^2 = n_S^2 + l_S^2$. Equation (2.13) yields only two physically meaningful square roots of Z, with negative imaginary parts, associated with the s_I and s_{II} shear waves.[8]

The p_I and s_I waves correspond to the classical fast longitudinal and transversal waves propagating in elastic or viscoelastic isotropic solids. The additional slow modes are waves strongly attenuated in the low frequency range, related to motions out of phase of the different components. The experimental observation of some of these slow waves was reported by Leclaire et al.[9]

Both for compressional and shear waves, the corresponding phase velocities c_i and attenuation α_i (measured in dB/Hz s) are given by

$$\alpha_i = 2\pi \cdot 8.685\,889 |\text{Im}(K_i)| / |\text{Re}(K_i)|,$$

$$c_i = \omega / |\text{Re}(K_i)|, \quad i = p_I, p_{II}, p_{III}, s_I, s_{II}. \tag{2.14}$$

III. REFLECTION AND TRANSMISSION COEFFICIENTS AT A PLANE INTERFACE

Let us consider an infinitely large plane interface Γ defined by the equation $y=0$ (i.e., normal to $\breve{e}_2$) between two composite Biot half-spaces denoted as Ω_u, Ω_d, where Ω_d is located below Ω_u. A plane p_I compressional wave (of frequency ω) propagating in the plane (x,y) arrives at Γ from Ω_u with an angle θ_{i,p_I} with respect to the normal. Such a perturbation will generate three compressional waves and two shear waves in both Ω_u and Ω_d. The incident, reflected, and transmitted waves will be represented using potentials. For the incident wave p_I, let

$$\varphi_i^1 = A_{i,p_I} e^{-i\mathbf{K_{i,p_I}} \cdot \mathbf{x}},$$

$$\varphi_i^2 = B_{i,p_I} e^{-i\mathbf{K_{i,p_I}} \cdot \mathbf{x}},$$

$$\varphi_i^3 = C_{i,p_I} e^{-i\mathbf{K_{i,p_I}} \cdot \mathbf{x}} \tag{3.1}$$

be the scalar potentials for the solid 1, the fluid, and the solid 3, respectively. Also, let φ_q^j and ψ_q^j be the compressional and shear potentials for the solids 1 and 3 ($j=1$ and $j=3$, respectively) and for the fluid displacement ($j=2$), with $q=r$ for the

reflected waves and $q=t$ for the transmitted waves. They are given by

$$\varphi_q^1 = A_{q,p_I}e^{-i\mathbf{K_{q,p_I} \cdot x}} + A_{q,p_{II}}e^{-i\mathbf{K_{q,p_{II}} \cdot x}} + A_{q,p_{III}}e^{-i\mathbf{K_{q,p_{III}} \cdot x}},$$

$$\psi_q^1 = [A_{q,s_I}e^{-i\mathbf{K_{q,s_I} \cdot x}} + A_{q,s_{II}}e^{-i\mathbf{K_{q,s_{II}} \cdot x}}]\breve{e}_3,$$

$$\varphi_q^2 = B_{q,p_I}e^{-i\mathbf{K_{q,p_I} \cdot x}} + B_{q,p_{II}}e^{-i\mathbf{K_{q,p_{II}} \cdot x}} + B_{q,p_{III}}e^{-i\mathbf{K_{q,p_{III}} \cdot x}},$$

$$\psi_q^2 = [B_{q,s_I}e^{-i\mathbf{K_{q,s_I} \cdot x}} + B_{q,s_{II}}e^{-i\mathbf{K_{q,s_{II}} \cdot x}}]\breve{e}_3,$$

$$\varphi_q^3 = C_{q,p_I}e^{-i\mathbf{K_{q,p_I} \cdot x}} + C_{q,p_{II}}e^{-i\mathbf{K_{q,p_{II}} \cdot x}} + C_{q,p_{III}}e^{-i\mathbf{K_{q,p_{III}} \cdot x}},$$

$$\psi_q^3 = [C_{q,s_I}e^{-i\mathbf{K_{q,s_I} \cdot x}} + C_{q,s_{II}}e^{-i\mathbf{K_{q,s_{II}} \cdot x}}]\breve{e}_3. \quad (3.2)$$

In Eqs. (3.1) and (3.2),

$$\mathbf{K_{q,j}} = (n_{q,j}, l_{q,j}) = K_{q,j}(\sin\theta_{q,j}, \cos\theta_{q,j}),$$

$$q = i, r, t, \quad j = p_I, p_{II}, p_{III}, s_I, s_{II},$$

are the complex wave vectors for each type of wave, with $K_{q,j}$ satisfying equations of the form (2.9) or (2.13) in Ω_u for $q=i,r$ and in Ω_d for $q=t$. Also, $\theta_{q,j}$ denotes the incidence, reflection, or transmission angle for the corresponding wave.

The displacement vectors in the three phases in Ω_u and Ω_d, denoted $u^{(m,u)}, u^{(m,d)}$, are given by

$$u^{(m,u)} = (u_x^{(m,u)}, u_y^{(m,u)}) = \nabla\varphi_i^m + \nabla\varphi_r^m - \nabla \times \psi_r^m$$

$$= u_{(i,p_I)}^{(m)} + u_{(r,p_I)}^{(m)} + u_{(r,p_{II})}^{(m)} + u_{(r,p_{III})}^{(m)} + u_{(r,s_I)}^{(m)} + u_{(r,s_{II})}^{(m)},$$

$$u^{(m,d)} = (u_x^{(m,d)}, u_y^{(m,d)}) = \nabla\varphi_t^m - \nabla \times \psi_t^m$$

$$= u_{(t,p_I)}^{(m)} + u_{(t,p_{II})}^{(m)} + u_{(t,p_{III})}^{(m)} + u_{(t,s_I)}^{(m)} + u_{(t,s_{II})}^{(m)}, \quad m = 1, 2, 3. \quad (3.3)$$

Here, $u_{(q,j)}^{(m,u)}, u_{(q,j)}^{(m,d)}$ $(q=i,r,t, j=p_I, p_{II}, p_{III}, s_I, s_{II})$ denote the parts of the displacement vectors $(u^{(m,u)}$ and $u^{(m,d)})$ associated with the incident, reflected, or transmitted j wave.

The natural boundary conditions at the interface Γ (i.e., at $y=0$) are the continuity of displacements and generalized forces, as an extension of those given by Dutta and Odé:[2]

$$u_x^{(1,u)} = u_x^{(1,d)}, \quad (3.4a)$$

$$u_y^{(1,u)} = u_y^{(1,d)}, \quad (3.4b)$$

$$u_x^{(3,u)} = u_x^{(3,d)}, \quad (3.4c)$$

$$u_y^{(3,u)} = u_y^{(3,d)}, \quad (3.4d)$$

$$u_y^{(2,u)} = u_y^{(2,d)}, \quad (3.4e)$$

$$p_f^{(u)} = p_f^{(d)}, \quad (3.4f)$$

$$\sigma_{21}^{(1,u)} = \sigma_{21}^{(1,d)}, \quad (3.4g)$$

$$\sigma_{22}^{(1,u)} = \sigma_{22}^{(1,d)}, \quad (3.4h)$$

$$\sigma_{21}^{(3,u)} = \sigma_{21}^{(3,d)}, \quad (3.4i)$$

$$\sigma_{22}^{(3,u)} = \sigma_{22}^{(3,d)}, \quad (3.4j)$$

where, from now on, the superscripts (u) and (d) denote, respectively, the values of any variable in Ω_u and Ω_d.

The reflection and transmission coefficients R_j and T_j, $j=p_I, p_{II}, p_{III}, s_I, s_{II}$, can be defined for each wave as the ratio of the corresponding displacement amplitude of the solid 1 and that of the incident wave, i.e.,

$$R_j = A_{r,j}K_{r,j}/A_{i,p_I}K_{i,p_I},$$

$$T_j = A_{t,j}K_{t,j}/A_{i,p_I}K_{i,p_I}. \quad (3.5)$$

Since the amplitude A_{i,p_I} as well as the incidence angle θ_{i,p_I}, or equivalently the incident complex wave vector, are assumed to be known, to compute the reflection and transmission coefficients (3.5) the amplitudes $A_{r,j}, A_{t,j}$ must be obtained. For this purpose, first note that each triplet $(u_{(q,j)}^{(1)}, u_{(q,j)}^{(2)}, u_{(q,j)}^{(3)})$ in Eq. (3.3) must individually satisfy either Eq. (2.7) or Eq. (2.11). Thus, taking into account that $\mathcal{M}^{\mathcal{P}}$ and $\mathcal{M}^{\mathcal{S}}$ are singular matrices, the amplitudes of the different types of waves in the fluid phase and solid 3 phase can be written in terms of that of the solid 1 phase by means of the following relations:

$$\gamma_i^B = \frac{B_{i,p_I}}{A_{i,p_I}}, \quad \gamma_i^C = \frac{C_{i,p_I}}{A_{i,p_I}},$$

$$\gamma_{q,j}^B = \frac{B_{q,j}}{A_{q,j}}, \quad \gamma_{q,j}^C = \frac{C_{q,j}}{A_{q,j}}, \quad q = r, t, \quad j = p_I, p_{II}, p_{III}, s_I, s_{II}. \quad (3.6)$$

Next, using the boundary conditions (3.4) and the relations (3.6) the desired amplitudes $A_{q,j}$ are computed. First, from Eqs. (3.3) and (3.4a), it is easy to see that

$$n_{i,p_I} = n_{r,p_I} = n_{r,p_{II}} = n_{r,p_{III}} = n_{r,s_I} = n_{r,s_{II}} = n_{t,p_I} = n_{t,p_{II}}$$

$$= n_{t,p_{III}} = n_{t,s_I} = n_{t,s_{II}}, \quad (3.7)$$

which is a generalization of Snell's law for this model, and it allows us to obtain the reflection and transmission angles $\theta_{q,j}$ for each type of wave as functions of the incidence angle.

Now, using Eqs. (3.3), (3.4), (3.6), and (3.7), the following 10×10 linear system of equations for the unknowns $A_{m,j}$ is obtained, with right-hand side Y_m, $m=1, \ldots, 10$:

$$-\sum_{j=p_I, p_{II}, p_{III}} n_{i,p_I}(A_{r,j} - A_{t,j}) + \sum_{\alpha=s_I, s_{II}} (l_{r,\alpha}A_{r,\alpha} - l_{t,\alpha}A_{t,\alpha})$$

$$= Y_1,$$

$$\sum_{j=p_I, p_{II}, p_{III}} (-l_{r,j}A_{r,j} + l_{t,j}A_{t,j}) - \sum_{\alpha=s_I, s_{II}} n_{i,p_I}(A_{r,\alpha} - A_{t,\alpha}) = Y_2,$$

$$\sum_{j=p_I, p_{II}, p_{III}} n_{i,p_I}(-\gamma_{r,j}^C A_{r,j} + \gamma_{t,j}^C A_{t,j}) + \sum_{\alpha=s_I, s_{II}} (\gamma_{r,\alpha}^C l_{r\alpha}A_{r,\alpha}$$

$$- \gamma_{t,\alpha}^C l_{t,\alpha}A_{t,\alpha}) = Y_3,$$

$$\sum_{j=p_I,p_{II},p_{III}} (-\gamma_{r,j}^C l_{r,j} A_{r,j} + \gamma_{t,j}^C l_{t,j} A_{t,j}) + \sum_{\alpha=s_I,s_{II}} n_{i,p_I}(-\gamma_{r,\alpha}^C A_{r,\alpha}$$
$$+ \gamma_{t,\alpha}^C A_{t,\alpha}) = Y_4,$$

$$\sum_{j=p_I,p_{II},p_{III}} (-\gamma_{r,j}^B l_{r,j} A_{r,j} + \gamma_{t,j}^B l_{t,j} A_{t,j}) + \sum_{\alpha=s_I,s_{II}} n_{i,p_I}(-\gamma_{r,\alpha}^B A_{r,\alpha}$$
$$+ \gamma_{t,\alpha}^B A_{t,\alpha}) = Y_5,$$

$$\sum_{j=p_I,p_{II},p_{III}} [K_{r,j}^2[B_1^u + \gamma_{r,j}^C B_2^u + K_{av}^u \gamma_{r,j}^B]A_{r,j} - K_{t,j}^2[B_1^d + \gamma_{t,j}^C B_2^d$$
$$+ K_{av}^d \gamma_{t,j}^B]A_{t,j}] = Y_6,$$

$$\sum_{j=p_I,p_{II},p_{III}} n_{i,p_I}[l_{r,j}[-2\mu_1^u - \mu_{13}^u \gamma_{r,j}^C]A_{r,j} + l_{t,j}[2\mu_1^d$$
$$+ \mu_{13}^d \gamma_{t,j}^C]A_{t,j}]$$

$$+ \sum_{\alpha=s_I,s_{II}} \left[(l_{r,\alpha}^2 - n_{i,p_I}^2)\left[\mu_1^u + \frac{1}{2}\mu_{13}^u \gamma_{r,\alpha}^C\right]A_{r,\alpha} + (n_{i,p_I}^2 - l_{t,\alpha}^2)\right.$$
$$\left. \times \left[\mu_1^d + \frac{1}{2}\mu_{13}^d \gamma_{t,\alpha}^C\right]A_{t,\alpha}\right] = Y_7,$$

$$\sum_{j=p_I,p_{II},p_{III}} \left[\left[K_{r,j}^2\left(\frac{2}{3}\mu_1^u - K_{G1}^u - B_1^u \gamma_{r,j}^B + \gamma_{r,j}^C\left(\frac{1}{3}\mu_{13}^u - B_3^u\right)\right)\right.\right.$$
$$\left. - l_{r,j}^2\left(2\mu_1^u + \mu_{13}^u \gamma_{r,j}^C\right)\right]A_{r,j}$$

$$+ \left[K_{t,j}^2\left(K_{G1}^d - \frac{2}{3}\mu_1^d + B_1^d \gamma_{t,j}^B + \gamma_{t,j}^C\left(B_3^d - \frac{1}{3}\mu_{13}^d\right)\right)\right.$$
$$\left.\left. + l_{t,j}^2\left(2\mu_1^d + \mu_{13}^d \gamma_{t,j}^C\right)\right]A_{t,j}\right]$$

$$+ \sum_{\alpha=s_I,s_{II}} [n_{i,p_I}l_{r,\alpha}[-2\mu_1^u - \mu_{13}^u \gamma_{r,\alpha}^C]A_{r,\alpha} + n_{i,p_I}l_{t,\alpha}[2\mu_1^d$$
$$+ \mu_{13}^d \gamma_{t,\alpha}^C]A_{t,\alpha}] = Y_8,$$

$$\sum_{j=p_I,p_{II},p_{III}} n_{i,p_I}[l_{r,j}(-2\mu_3^u \gamma_{r,j}^C - \mu_{13}^u)A_{r,j} + l_{t,j}(2\mu_3^d \gamma_{t,j}^C$$
$$+ \mu_{13}^d)A_{t,j}]$$

$$+ \sum_{\alpha=s_I,s_{II}} \left[(l_{r,\alpha}^2 - n_{i,p_I}^2)\left(\mu_3^u \gamma_{r,\alpha}^C + \frac{1}{2}\mu_{13}^u\right)A_{r,\alpha} - (l_{t,\alpha}^2 - n_{i,p_I}^2)\right.$$
$$\left. \times \left(\mu_3^d \gamma_{t,\alpha}^C + \frac{1}{2}\mu_{13}^d\right)A_{t,\alpha}\right] = Y_9,$$

$$\sum_{j=p_I,p_{II},p_{III}} \left[\left[K_{r,j}^2\left(\frac{1}{3}\mu_{13}^u - B_3^u - B_2^u \gamma_{r,j}^B + \gamma_{r,j}^C\left(\frac{2}{3}\mu_3^u - K_{G3}^u\right)\right)\right.\right.$$
$$\left. - l_{r,j}^2(\mu_{13}^u + 2\mu_3^u \gamma_{r,j}^C)\right]A_{r,j}$$

$$+ \left[K_{t,j}^2\left(B_3^d - \frac{1}{3}\mu_{13}^d + B_2^d \gamma_{t,j}^B + \left(K_{G3}^d - \frac{2}{3}\mu_3^d\right)\gamma_{t,j}^C\right)\right.$$
$$\left.\left. + l_{t,j}^2\left(\mu_{13}^d + 2\mu_3^d \gamma_{t,j}^C\right)\right]A_{t,j}\right]$$

$$+ \sum_{\alpha=s_I,s_{II}} [n_{i,p_I}l_{r,\alpha}(-2\mu_3^u \gamma_{r,\alpha}^C - \mu_{13}^u)A_{r,\alpha} + n_{i,p_I}l_{t,\alpha}(2\mu_3^d \gamma_{t,\alpha}^C$$
$$+ \mu_{13}^d)A_{t,\alpha}] = Y_{10}, \quad (3.8)$$

where using Snell's law (3.7)

$$l_{r,j} = (K_{r,j}^2 - n_{i,p_I}^2)^{1/2}, \quad l_{t,j} = -(K_{t,j}^2 - n_{i,p_I}^2)^{1/2}, \quad (3.9)$$

$$j = p_I, p_{II}, p_{III}, s_I, s_{II},$$

and

$$Y_1 = n_{i,p_I}A_{i,p_I}, \quad Y_2 = l_{i,p_I}A_{i,p_I}, \quad Y_3 = \gamma_i^C n_{i,p_I}A_{i,p_I},$$

$$Y_4 = \gamma_i^C l_{i,p_I}A_{i,p_I},$$

$$Y_5 = \gamma_i^B A_{i,p_I}l_{i,p_I}, \quad Y_6 = A_{i,p_I}K_{i,p_I}^2[-B_1^u - B_2^u \gamma_i^C - K_{av}^u \gamma_i^B],$$

$$Y_7 = (2\mu_1^u + \mu_{13}^u \gamma_i^C)n_{i,p_I}l_{i,p_I}A_{i,p_I},$$

$$Y_8 = A_{i,p_I}\left[K_{i,p_I}^2\left(K_{G1}^u - \frac{2}{3}\mu_1^u + B_1^u \gamma_i^B + \left(B_3^u - \frac{1}{3}\mu_{13}^u\right)\gamma_i^C\right)\right.$$
$$\left. + l_{i,p_I}^2(2\mu_1^u + \mu_{13}^u \gamma_i^C)\right],$$

$$Y_9 = n_{i,p_I}l_{i,p_I}(2\mu_3^u \gamma_i^C + \mu_{13}^u)A_{i,p_I},$$

$$Y_{10} = A_{i,p_I}\left[K_{i,p_I}^2\left(B_3^u - \frac{1}{3}\mu_{13}^u + B_2^u \gamma_i^B + \gamma_i^C\left(K_{G3}^u - \frac{2}{3}\mu_3^u\right)\right)\right.$$
$$\left. + l_{i,p_I}^2(\mu_{13}^u + 2\mu_3^u \gamma_i^C)\right].$$

The signs in Eq. (3.9) are chosen according to the propagating direction (upgoing or downgoing) of the different waves. Once the linear system (3.8) is solved, the amplitude reflection and transmission coefficients R_j and T_j at the interface Γ can be computed from Eq. (3.5).

IV. ENERGY CONSIDERATIONS IN THE COMPOSITE MEDIUM

It is also useful and physically important to compute the reflection and transmission coefficients in terms of the energy flux across the interface. Since our formulation is stated in the space-frequency domain, and the model coefficients are frequency dependent, it is necessary to derive an expression for the *energy flux vector* for the composite medium in the frequency domain.

A. Definition of the Umov-Poynting vector

Following the usual procedure, take the dot product of Eq. (2.5) with v^{*T} (where the superscript * denotes the complex conjugate) and integrate over a volume V. Using integration by parts in the $\mathcal{L}(u)$ term and the symmetry properties of the tensors $\sigma_{ij}^{(1)}(u), \sigma_{ij}^{(3)}(u)$, the following equation is obtained:

$$i\omega \int_V v^{*T}\mathcal{R}v\,dV - \int_V \left(\frac{\partial \sigma_{ij}^{(1)}(u)}{\partial x_i}v_j^{(1)*} \right.$$

$$\left. - \frac{\partial p_f(u)}{\partial x_i}v_i^{(2)*} + \frac{\partial \sigma_{ij}^{(3)}(u)}{\partial x_i}v_j^{(3)*} \right)dV$$

$$= i\omega \int_V v^{*T}\mathcal{R}v\,dV + \int_V (\sigma_{ij}^{(1)}(u)\epsilon_{ij}(v^{(1)*}))$$

$$- p_f(u)\,\nabla \cdot v^{(2)*} + \sigma_{ij}^{(3)}(u)\epsilon_{ij}(v^{(3)*}))dV$$

$$- \int_{\partial V} [(\sigma_{ij}^{(1)}(u)v_j^{(1)*} - p_f(u)v_i^{(2)*} + \sigma_{ij}^{(3)}(u)v_j^{(3)*})\nu_i]dS$$

$$= 0, \tag{4.1}$$

where $\nu=(\nu_i)$ denotes the unit outer normal to ∂V.

Let $\mathcal{S}\in\mathbb{C}^{13\times13}$ be the complex symmetric frequency-dependent stiffness matrix, having as entries the viscoelastic moduli of the medium. Then the stress-strain relations (2.3) can be written in the form

$$\sigma = \mathcal{S}\epsilon, \tag{4.2}$$

where $\sigma=[\sigma_{ij}^{(1)}(u),\sigma_{ij}^{(3)}(u),p_f(u)]^T\in\mathbb{C}^{13\times1}$ and $\epsilon=[\epsilon_{ij}(u^{(1)}),\epsilon_{ij}(u^{(3)}),\zeta]^T\in\mathbb{C}^{13\times1}$, $1\le i\le j\le3$, are the stress and strain arrays, respectively.

Next, use Eq. (4.2) in Eq. (4.1), to derive the relation

$$i\omega \int_V v^{*T}\mathcal{R}v\,dV - i\omega \int_V \epsilon^{*T}\mathcal{S}\epsilon\,dV = \int_{\partial V} [(\sigma_{ij}^{(1)}(u)v_j^{(1)*}$$

$$- p_f(u)v_i^{(2)*} + \sigma_{ij}^{(3)}(u)v_j^{(3)*})\nu_i]dS. \tag{4.3}$$

Splitting the terms in Eq. (4.3) into their real and imaginary parts leads to

$$i\omega \int_V 2(\mathcal{W} - \mathcal{T})dV - \int_V (\hat{\mathcal{D}}_\mathcal{T} + \hat{\mathcal{D}}_\mathcal{W})dV = \int_{\partial V} \mathbf{P}\cdot\nu\,dS$$

$$= \int_V \nabla\cdot\mathbf{P}\,dV, \tag{4.4}$$

where

$$\mathcal{T} = \frac{1}{4}\,\text{Re}(v^{*T}\mathcal{R}v), \quad \mathcal{W} = \frac{1}{4}\,\text{Re}(\epsilon^{*T}\mathcal{S}\epsilon),$$

$$\hat{\mathcal{D}}_\mathcal{T} = -\frac{\omega}{2}\,\text{Im}(v^{*T}\mathcal{R}v), \quad \hat{\mathcal{D}}_\mathcal{W} = \frac{\omega}{2}\,\text{Im}(\epsilon^{*T}\mathcal{S}\epsilon). \tag{4.5}$$

For any complex scalar or tensor A, $\text{Re}(A)$ and $\text{Im}(A)$ denote the real and imaginary parts of A, respectively. The vector $\mathbf{P}=P_k\breve{e}_k$, with components

$$P_k(u,v) = -\frac{1}{2}(\sigma_{kj}^{(1)}(u)v_j^{(1)*} - p_f(u)v_k^{(2)*} + \sigma_{kj}^{(3)}(u)v_j^{(3)*}), \tag{4.6}$$

is the *complex Umov-Poynting vector* for this model, analogous to that given by Carcione[10] for poroviscoelastic media, and can be considered as its formal generalization.

To understand the physical significance of the different terms in Eqs. (4.4) and (4.5), recall that if A is a complex time-harmonic vector having entries of the form $a = a_0 e^{i(\omega t-\beta)}$, and D is a complex symmetric matrix, then, denoting by

$$\langle a \rangle = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} a(t)dt$$

the time average over a cycle, the following relations can be verified:[10]

$$\langle \text{Re}(A^T)\text{Re}(D)\text{Re}(A) \rangle = \frac{1}{2}\,\text{Re}(A^T D A^*),$$

$$\langle \text{Re}(A^T)\text{Im}(D)\text{Re}(A) \rangle = \frac{1}{2}\,\text{Im}(A^T D A^*). \tag{4.7}$$

Since by hypothesis all variables on the right-hand side of Eq. (4.5) are periodic with temporal dependency of the form $e^{i\omega t}$, it is straightforward to see that

$$\mathcal{T} = \frac{1}{2}\langle \text{Re}(v^T)\text{Re}(\mathcal{R})\text{Re}(v) \rangle, \tag{4.8a}$$

$$\mathcal{W} = \frac{1}{2}\langle \text{Re}(\epsilon^T)\text{Re}(\mathcal{S})\text{Re}(\epsilon) \rangle, \tag{4.8b}$$

$$\hat{\mathcal{D}}_\mathcal{T} = -\omega\langle \text{Re}(v^T)\text{Im}(\mathcal{R})\text{Re}(v) \rangle, \tag{4.8c}$$

$$\hat{\mathcal{D}}_\mathcal{W} = \omega\langle \text{Re}(\epsilon^T)\text{Im}(\mathcal{S})\,\text{Re}(\epsilon) \rangle. \tag{4.8d}$$

Taking into account that (4.8a) and (4.8c) can be written as

$$\mathcal{T} = \frac{1}{2}\langle \text{Re}(v^T)\mathcal{P}\,\text{Re}(v) \rangle, \quad \hat{\mathcal{D}}_\mathcal{T} = \langle \text{Re}(v^T)\mathcal{B}\,\text{Re}(v) \rangle,$$

it can be concluded that $\mathcal{T}$ is the kinetic energy density and $\hat{\mathcal{D}}_\mathcal{T}$ is the rate of dissipated kinetic energy density. With regards to the stress-strain terms, note that (4.8b) is analogous to the strain energy density for this model,[8] while the term (4.8d) represents the rate of dissipated strain energy density. Thus, Eq. (4.4) represents an energy-balance equation relating the complex Umov-Poynting vector with the energy densities $\mathcal{T}$, $\mathcal{W}$ and their rates of dissipation $\hat{\mathcal{D}}_\mathcal{T}$ and $\hat{\mathcal{D}}_\mathcal{W}$.

Also using Eq. (4.7), the real Umov-Poynting vector $\mathbf{P_R}=P_{Rk}\breve{e}_k$, defined by

$$P_{Rk} = -(\text{Re}(\sigma_{kj}^{(1)}(u))\text{Re}(v_j^{(1)}) - \text{Re}(p_f(u))\text{Re}(v_k^{(2)})$$

$$+ \text{Re}(\sigma_{kj}^{(3)}(u))\text{Re}(v_j^{(3)})) \tag{4.9}$$

satisfies $\langle \mathbf{P_R} \rangle = \text{Re}(\mathbf{P})$, in agreement with other works,[10,11] and this time-average represents the magnitude and direction of the time-averaged power flow. As a consequence of the boundary conditions (3.4), the normal component of the real Umov-Poynting vector (4.9) is continuous at the interface.

Note that the analysis performed in this section (Sec. IV A) was not restricted to the particular case of plane wave propagation.

B. Energy reflection and transmission coefficients

Using the previous results, let us go back to the reflection-transmission problem at a plane interface. The time-average of the normal component of the energy flux, either in Ω_u or in Ω_d, is given by

$$F = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} \mathbf{P_R} \cdot \breve{e}_2 dt = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} P_{R2}(u,v) dt. \quad (4.10)$$

Applying the superposition principle stated in Eq. (3.3) to the particle velocities $v^{(m,u)}, v^{(m,d)}$, the generalized stress components and the fluid pressure, F can be splitted into different components associated with the different wave modes. In this sense, following Dutta and Odé[2] (except for a sign), the *partial orthodox fluxes* $F_{k,k}$ are defined as

$$F_{k,k} = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} (-1)(\mathrm{Re}(\sigma_{2j,k}^{(1)}(u))\mathrm{Re}(v_{j,k}^{(1)})$$
$$+ \mathrm{Re}(\sigma_{2j,k}^{(3)}(u))\mathrm{Re}(v_{j,k}^{(3)}) - \mathrm{Re}(p_{f,k}(u))\mathrm{Re}(v_{2,k}^{(2)}))dt,$$
$$j = 1,2, \quad (4.11)$$

and the *interference fluxes* $F_{k,q}$ are given by

$$F_{k,q} = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} (-1)(\mathrm{Re}(\sigma_{2j,k}^{(1)}(u))\mathrm{Re}(v_{j,q}^{(1)})$$
$$+ \mathrm{Re}(\sigma_{2j,k}^{(3)}(u))\mathrm{Re}(v_{j,q}^{(3)}) - \mathrm{Re}(p_{f,k}(u))\mathrm{Re}(v_{2,q}^{(2)})$$
$$+ \mathrm{Re}(\sigma_{2j,q}^{(1)}(u))\mathrm{Re}(v_{j,k}^{(1)}) + \mathrm{Re}(\sigma_{2j,q}^{(3)}(u))\mathrm{Re}(v_{j,k}^{(3)})$$
$$- \mathrm{Re}(p_{f,q}(u))\mathrm{Re}(v_{2,k}^{(2)}))dt, \quad j = 1,2, \quad (4.12)$$

where $k,q = ip_\mathrm{I}, rp_\mathrm{I}, rp_\mathrm{II}, rp_\mathrm{III}, rs_\mathrm{I}, rs_\mathrm{II}$ in Ω_u and $k,q = tp_\mathrm{I}, tp_\mathrm{II}, tp_\mathrm{III}, ts_\mathrm{I}, ts_\mathrm{II}$ in Ω_d denotes the wave associated with the variable and the sum convention is applied on the index j.

In this way, the energy reflection and transmission coefficients are defined as follows:

$$ER_j = \frac{|F_{rj,rj}|}{|F_{ip_\mathrm{I}}|},$$

$$ET_j = \frac{|F_{tj,tj}|}{|F_{ip_\mathrm{I}}|}, \quad j = p_\mathrm{I}, p_\mathrm{II}, p_\mathrm{III}, s_\mathrm{I}, s_\mathrm{II}, \quad (4.13)$$

where

$$F_{ip_\mathrm{I}} = F_{ip_\mathrm{I},ip_\mathrm{I}} + F_{ip_\mathrm{I},rp_\mathrm{I}} + F_{ip_\mathrm{I},rp_\mathrm{II}} + F_{ip_\mathrm{I},rp_\mathrm{III}} + F_{ip_\mathrm{I},rs_\mathrm{I}} + F_{i,rs_\mathrm{II}}. \quad (4.14)$$

The total reflected and transmitted energy fluxes F_r and F_t are defined as

$$F_j = F_{jp_\mathrm{I},jp_\mathrm{I}} + F_{jp_\mathrm{II},jp_\mathrm{II}} + F_{jp_\mathrm{III},jp_\mathrm{III}} + F_{js_\mathrm{I},js_\mathrm{I}} + F_{js_\mathrm{II},js_\mathrm{II}}$$
$$+ F_{jp_\mathrm{I},jp_\mathrm{II}} + F_{jp_\mathrm{I},jp_\mathrm{III}} + F_{jp_\mathrm{I},js_\mathrm{I}} + F_{jp_\mathrm{I},js_\mathrm{II}} + F_{jp_\mathrm{II},jp_\mathrm{III}}$$
$$+ F_{jp_\mathrm{II},js_\mathrm{I}} + F_{jp_\mathrm{II},js_\mathrm{II}} + F_{jp_\mathrm{III},js_\mathrm{I}} + F_{jp_\mathrm{III},js_\mathrm{II}} + F_{js_\mathrm{I},js_\mathrm{II}}, \quad (4.15)$$

where $j = r, t$. Thus, the continuity of the normal component of the real Umov-Poynting vector implies the energy balance at the interface, which can be stated as

$$F_{ip_\mathrm{I}} + F_r = F_t. \quad (4.16)$$

TABLE I. Material properties of the frozen sandstone model.

Solid grain	Bulk modulus, K_{s1}	38.7 GPa
	Shear modulus, μ_{s1}	39.6 GPa
	Density, ρ_1	2650 kg/m³
	Permeability $\kappa_{1,0}$	1.07×10^{-13} m²

	Shear modulus, μ_a	0 GPa

V. NUMERICAL EXAMPLE

Here the formulas derived in Sec. IV are used to compute the energy reflection and transmission coefficients for an incident plane p_I compressional wave striking a plane interface defined by a change in ice content in the pores within a sample of water saturated partially frozen Berea sandstone. The material properties of the system are given in Table I.[6,7] The absolute porosity of the sandstone, defined as the ratio of the volume of the interconnected pores of the rock (V_p) and the total volume of the sample, i.e., $\phi_a = V_p/V_b$, is taken to be equal to 0.18. The bulk water content ϕ was chosen such that the ice content in the pores $\phi_i = V_3/V_p = \phi_3/(1-\phi_1)$ varies from 0.1 in the upper layer to 0.9 in the lower layer.

The calculation of the elastic coefficients requires values for the bulk and shear moduli of the two solid (dry) frames, denoted by $K_{s1,m}, K_{s3,m}, \mu_{s1,m}$, and $\mu_{s3,m}$, respectively (see Appendix A 1). It is assumed that $K_{s1,m} = 14.4$ GPa and that $\mu_{s1,m}$, $\mu_{s3,m}$, and $K_{s3,m}$ can be obtained using a percolation-type model in the form[5,6,8]

$$\mu_{sj,m} = [\mu_{sj,m}^{(\mathrm{max})} - \mu_{sj,m}^0]\left[\frac{\phi_3}{1-\phi_1}\right]^{3.8} + \mu_{sj,m}^0, \quad j = 1,3,$$

$$K_{s3,m} = [K_{s3,m}^{(\mathrm{max})} - K_{s3,m}^0]\left[\frac{\phi_3}{1-\phi_1}\right]^{3.8} + K_{s3,m}^0, \quad (5.1)$$

where $\mu_{s1,m}^{(\mathrm{max})}$, $\mu_{s3,m}^{(\mathrm{max})}$, and $K_{s3,m}^{(\mathrm{max})}$ are computed employing a Kuster and Toksöz model,[8,12] using known values of $K_{s1}, \mu_{s1}, K_{s3}, \mu_{s3}$ for the background medium with inclusions of air, with properties K_a, μ_a (see Table I). The moduli $\mu_{s1,m}^0$, $\mu_{s3,m}^0$, and $K_{s3,m}^0$ are reference values taken to be

$$\mu_{s1,m}^0 = 13.1 \text{ GPa}, \quad K_{s3,m}^0 = \mu_{s3,m}^0 = 0. \quad (5.2)$$

The viscoelastic parameters describing the dissipative behavior of the saturated sandstone are (see Appendix A 2) $T_{1,M} = (2\pi 10^{-5})^{-1}$ ms, $T_{2,M} = (2\pi 10^6)^{-1}$ ms, for $M = K_{G1}, K_{G3}, \mu_1, \mu_3$. For the mean quality factors, we take $\hat{Q}_{K_{G1}} = \hat{Q}_{\mu_1} = 100$ and $\hat{Q}_{K_{G3}} = \hat{Q}_{\mu_3} = 80$. The value of the Kozeny-Carman constant was taken to be 5.[13] For these rock and fluid properties, the phase velocities for the different wave modes given by Eq. (2.14) are presented in Table II for

20 Hz and 1 MHz, corresponding to frequencies used in seismic exploration and laboratory testing, respectively.

Figures 1–4 show the magnitude of the energy coefficients computed using Eq. (4.13) as functions of the incidence angle. Since the energy coefficients related to the p_{III} compressional waves are negligible, for brevity the corresponding curves are not presented. Due to the dissipative behavior of the medium and the inhomogeneous nature of the different wave modes, the analysis of the existence of critical angles requires a rigorous definition. For each transmitted wave mode the critical angle(s) is computed as the angle(s) of incidence beyond which the *corresponding* time-averaged energy flux vector (i.e., the time-average of the real Umov-Poynting vector $\mathbf{P_R}$) becomes parallel to the interface.[10,14] In our case, neglecting the interference fluxes,

this is approximately equivalent to the condition that the orthodox flux $F_{tj,tj}$ vanishes (i.e., ET_j=0). Figure 3(a) shows the presence of a critical angle associated to the p_{I} wave at about 55° for both frequencies. This value is very close to the approximate value 54° obtained from the classic Snell's law for two elastic media using the fast velocities $c_{p_{\mathrm{I}}}$ in Table II. As expected, beyond the critical angle, Figs. 1(a) and 3(a) show an important increase in the reflected energy of the p_{I} wave, with a consequent decrease in the transmitted energy for the same kind of wave.

The other wave modes have peaks near the critical angle, which is particularly interesting in the case of the transmission of the p_{II} compressional wave in Fig. 3(b), showing that near this angle of incidence almost a fifth of the incident energy is being converted into this slow wave. As
FIG. 1. Magnitude of the energy reflection coefficients at low and high frequencies for (a) p_{I} and (b) p_{II} compressional waves.

FIG. 2. Magnitude of the energy reflection coefficients at low and high frequencies for (a) s_{I} and (b) s_{II} shear waves.

Rubino *et al.*: Reflection and transmission in composite media
FIG. 3. Magnitude of the energy transmission coefficients at low and high frequencies for (a) p_I and (b) p_{II} compressional waves.
FIG. 4. Magnitude of the energy transmission coefficients at low and high frequencies for (a) s_I and (b) s_{II} shear waves.

observed in Figs. 1(b) and 2(b), the energy of the reflected slow waves is not significant for the present experiment.

In Figs. 2(a) and 4(a) it can be observed that for angles of incidence around the critical angle there is a significant conversion of incident energy into reflected and transmitted fast shear waves. For these angles of incidence, the energy converted into transmitted s_{II} shear wave is more than 1%, as observed in Fig. 4(b).

Tables III and IV present numerical results for the energy fluxes computed as described in Eqs. (4.11) and (4.12) for 20 Hz and 1 MHz, for a fixed angle of incidence equal to 45°. Note that in this case the interference fluxes are negligible with respect to the incident flux. Also, according to Eq. (4.16), the value $(F_t - F_r)$ at the bottom of Table IV is equal to F_{ip_I} (at the bottom of Table III), as expected.

VI. CONCLUSIONS

In this work the reflection and transmission coefficients for plane elastic waves arriving at a plane interface separating two porous composite half-spaces were defined and analyzed. The medium was assumed to be composed by two weakly coupled solids saturated by a single-phase fluid, according to the model proposed by Santos *et al.*[8] The energy flux Umov-Poynting vector appropriate for this kind of me-

dia was defined aiming to obtain the energy reflection and transmission coefficients and to check the corresponding amplitude coefficients as well.
These calculations were applied to study the energy splitting at a plane interface defined by a change in ice content in the pores within a sample of water saturated partially frozen Berea sandstone. The same procedure can be applied to study similar problems in shaley-sandstones, gas-hydrate bearing sediments, or other composite porous media, which will be the subject of forthcoming publications.

The numerical example showed that, in some cases, an important part of the incident energy may be converted into slow waves energy. This fact allowed us to conclude that

disregarding the presence of slow waves may produce significant errors in the computation and analysis of reflection and transmission coefficients for frequencies lying between the seismic and ultrasonic ranges.

APPENDIX A: COMPUTATION OF THE COEFFICIENTS IN THE STRESS-STRAIN RELATIONS

1. The elastic coefficients

Let $K_{s1,m}, K_{s3,m}, \mu_{s1,m}$, and $\mu_{s3,m}$ denote the bulk and shear moduli of the two solid (dry) frames, respectively. Also, let $K_{s1}, \mu_{s1}, K_{s3}, \mu_{s3}$ denote the bulk and shear moduli of the grains in the two solid phases, respectively, and K_f, η the bulk modulus and viscosity of the fluid phase. Then, the elastic coefficients are given by[6,8]

$$\mu_j = [(1-g_j)\phi_j]^2 \mu_{av} + \mu_{sj,m}, \quad g_j = \frac{\mu_{sj,m}}{\phi_j \mu_{sj}}, \quad j=1,3,$$

$$\mu_{13} = (1-g_1)(1-g_3)\phi_1 \phi_3 \mu_{av},$$

$$\mu_{av} = \left[\frac{(1-g_1)\phi_1}{\mu_{s1}} + \frac{\phi}{2\omega\eta} + \frac{(1-g_3)\phi_3}{\mu_{s3}} \right]^{-1},$$

$$K_{av} = \left[(1-c_1)\frac{\phi_1}{K_{s1}} + \frac{\phi}{K_f} + (1-c_3)\frac{\phi_3}{K_{s3}} \right]^{-1},$$

$$c_j = \frac{K_{sj,m}}{\phi_j K_{sj}}, \quad j=1,3,$$

$$K_{Gj} = K_{sj,m} + (\alpha_j)^2 K_{av}, \quad \alpha_j = S_j - \frac{K_{sj,m}}{K_{sj}},$$

$$B_1 = \frac{S_1 \phi^2 K_{av} + C_{12}}{\phi}, \quad B_2 = \frac{S_3 \phi^2 K_{av} + C_{23}}{\phi},$$

$$B_3 = (C_{13} + S_3 C_{12} + S_1 C_{23} + S_1 S_3 \phi^2 K_{av}),$$

where

$$C_{12} = \phi K_{av}(\alpha_1 - S_1 \phi), \quad C_{23} = \phi K_{av}(\alpha_3 - S_3 \phi),$$

$$C_{13} = K_{av}(\alpha_1 - S_1 \phi)(\alpha_3 - S_3 \phi).$$

The moduli K_{G1} and K_{G3} are the analogues of Gassmann's moduli,[15] while the coefficients α_1 and α_3 correspond to the effective stress coefficients in the classic Biot theory.[10,16]

2. Viscoelastic moduli

Viscoelastic dissipation was introduced by using the correspondence principle stated by Biot,[16,17] in which the real poroelastic coefficients in the constitutive relations are replaced by complex frequency dependent poroviscoelastic moduli satisfying the same relations as in the elastic case. Among the different existing models, the linear viscoelastic model presented in Liu et al.[18] was chosen to make the moduli $K_{G1}, K_{G3}, \mu_1, \mu_3$ in Eq. (2.3) complex and frequency dependent. The set of poroviscoelastic moduli is computed using

$$M(\omega) = \frac{M_{re}}{R_M(\omega) - iT_M(\omega)},$$

where $M = K_{G1}, K_{G3}, \mu_1, \mu_3$ and the coefficient M_{re} is the relaxed elastic modulus associated with M.[19] The frequency dependent functions R_M and T_M, associated with a continuous spectrum of relaxation times, characterize the viscoelastic behavior and are given by[18]

$$R_M(\omega) = 1 - \frac{1}{\pi \hat{Q}_M} \ln \frac{1 + \omega^2 T_{1,M}^2}{1 + \omega^2 T_{2,M}^2},$$

$$T_M(\omega) = \frac{2}{\pi \hat{Q}_M} \tan^{-1} \frac{\omega(T_{1,M} - T_{2,M})}{1 + \omega^2 T_{1,M} T_{2,M}}.$$

The model parameters $\hat{Q}_M$, $T_{1,M}$, and $T_{2,M}$ are taken such that the quality factors $Q_M(\omega) = T_M/R_M$ are approximately equal to the constant $\hat{Q}_M$ within a wide frequency band, ranging from the low frequencies used in seismic exploration to the very high values used in ultrasonic testing. Values of $\hat{Q}_M$ range from $\hat{Q}_M = 20$ for highly dissipative materials to about $\hat{Q}_M = 1000$ for almost elastic ones.

APPENDIX B: MASS AND FRICTION COEFFICIENTS

Let ρ_m, $m = 1, 2, 3$, denote the mass density of each solid and fluid constituent in Q. Santos et al.[8] have taken the mass coupling coefficients to be real and frequency independent with $p_{jk} = m_{jk}$ and the m_{jk}-entries defined by

$$m_{11} = \rho_2 \phi (1 + (S_1)^2 a_{32} + (S_3)^2 a_{12} - 2S_3 - (S_1)^2)$$

$$+ a_{13} \rho_1 \phi_1 + (a_{31} - 1) \rho_3 \phi_3,$$

$$m_{12} = \rho_2 (S_3(1 - a_{12}) + S_1 a_{32}),$$

$$m_{13} = \rho_2 \phi (1 - (S_1)^2 a_{32} - (S_3)^2 a_{12} - S_1 S_3)$$

$$+ \rho_1 \phi_1 (1 - a_{13}) + \rho_3 \phi_3 (1 - a_{31}),$$

$$m_{22} = \frac{\rho_2}{\phi}(a_{12} + a_{32} - 1),$$

$$m_{23} = \rho_2 (S_1(1 - a_{32}) + S_3 a_{12}),$$

$$m_{33} = \rho_2 \phi (1 + (S_1)^2 a_{32} + (S_3)^2 a_{12} - 2S_1 - (S_3)^2)$$

$$+ a_{31} \rho_3 \phi_3 + (a_{13} - 1) \rho_1 \phi_1.$$

Here,

$$a_{12} = \frac{\phi_1 \rho}{\phi \rho_2} r_{12} + 1, \quad a_{32} = \frac{\phi_3 \rho'}{\phi \rho_2} r_{32} + 1,$$

with the r_{jk}'s being the geometrical aspects of the boundaries separating the phases j and k (equal to $1/2$ for spheres). It is assumed that[7] $a_{13} = a_{31} = 1$, $r_{12} = r_{32} = 1/2$, and

$$\rho = \frac{\phi \rho_2 + \phi_3 \rho_3}{\phi + \phi_3}, \quad \rho' = \frac{\phi \rho_2 + \phi_1 \rho_1}{\phi + \phi_1}.$$

Next, the coefficients f_{ij}'s were computed as follows.[8] For the case of frozen porous media, let

$$d_{12} = \frac{\phi^2}{\kappa_1}, \quad d_{23} = \frac{\phi^2}{\kappa_3},$$

where the permeability coefficients κ_1 and κ_3 are defined in terms of the absolute permeabilities $\kappa_{1,0}$ and $\kappa_{3,0}$ of the two solid frames by (see also the works of Leclaire et al.[5,9])

$$\kappa_1 = \kappa_{1,0} \frac{\phi^3}{(1 - \phi_1)^3}, \quad \kappa_3 = \kappa_{3,0} \frac{(1 - \phi_1)^2}{(\phi_3)^2} \left(\frac{\phi}{\phi_1}\right)^3.$$

Then the frequency independent friction coefficients f_{11}, f_{12}, and f_{22} are determined from

$$g_{11} = d_{12}(S_3)^2 + d_{23}(S_1)^2, \quad g_{12} = \frac{d_{12}S_3 - d_{23}S_1}{\phi},$$

$$g_{22} = \frac{d_{12} + d_{23}}{\phi^2},$$

$$f_{11} = \eta g_{11} + g_{13}, \quad f_{12} = \eta g_{12}, \quad f_{22} = \eta g_{22}. \quad (B1)$$

Since the coefficient g_{13} takes into account friction between the two solid frames, a proper model based, for example, in a Coulomb-type friction theory may be used, but for simplicity in all the numerical examples presented in this article the coefficient g_{13} was set to be zero.[6,8] This is consistent with the thermodynamical condition stated by Santos et al.[8] [Eq. (B9)] about the non-negative character of the dissipation function.

In the high frequency range the set of inertial and friction coefficients m_{jk}, $1 \le j, k \le 3$, and f_{11}, f_{12}, and f_{22} need to be modified to include the departure of the relative flow from laminar type above a certain critical frequency depending on the pore radius as explained by Biot.[17] For that purpose, the dissipative terms f_{11}, f_{12}, and f_{22} are modified by multiplying the fluid viscosity η by the frequency correction factor $F_R(\theta)$, where the complex valued frequency dependent function $F(\theta) = F_R(\theta) + iF_I(\theta)$ is the frequency correction function defined by Biot:[17]

$$F(\theta) = \frac{1}{4} \frac{\theta T(\theta)}{1 - \frac{2}{i\theta} T(\theta)}, \quad T(\theta) = \frac{\text{ber}'(\theta) + i \, \text{bei}'(\theta)}{\text{ber}(\theta) + i \, \text{bei}(\theta)},$$

with $\text{ber}(\theta)$ and $\text{bei}(\theta)$ being the Kelvin functions of the first kind and zero order. The frequency dependent argument $\theta = \theta(\omega)$ is given in terms of the pore size parameter a_p by

$$\theta = a_p \sqrt{\omega \rho_2 / \eta}, \quad a_p = 2\sqrt{\kappa A_0 / \phi},$$

where $1/\kappa = 1/\kappa_1 + 1/\kappa_3$ and A_0 is the Kozeny-Carman constant.[20,13]

Consequently the frequency dependent mass and viscous coupling coefficients are defined in the following fashion:

$$p_{11}(\omega) = m_{11} + \frac{\eta F_I(\theta) g_{11}}{\omega}, \quad p_{12}(\omega) = m_{12} - \frac{\eta F_I(\theta) g_{12}}{\omega},$$
$$(B2)$$

$$p_{13}(\omega) = m_{13} - \frac{\eta F_I(\theta) g_{11}}{\omega}, \quad p_{22}(\omega) = m_{22} + \frac{\eta F_I(\theta) g_{22}}{\omega},$$
$$(B3)$$

$$p_{23}(\omega) = m_{23} + \frac{\eta F_I(\theta) g_{12}}{\omega}, \quad p_{33}(\omega) = m_{33} + \frac{\eta F_I(\theta) g_{11}}{\omega},$$
$$(B4)$$

$$f_{11}(\omega) = \eta F_R(\theta)g_{11} + g_{13}, \tag{B5}$$

$$f_{12}(\omega) = \eta F_R(\theta)g_{12}, \quad f_{22}(\omega) = \eta F_R(\theta)g_{22}.$$

Marcia J. Isakson[b)]
Applied Research Laboratories, The University of Texas at Austin, Austin, Texas

This work compared three plane wave reflection coefficient models to laboratory sediment reflection measurements collected using a spherical source and receiver. Plane wave decomposition was used to modify the reflection coefficient models to include the inherent spherical effects such as lateral wave interference for direct comparison with the data. Sets of data at two transducer separation distances (1.27 and 0.25 m) were collected to compare the range dependence of the spherical effects. Bandpass filtered linear frequency-modulated chirps from 30 to 160 kHz were used to measure frequency dependence. Grazing angles from 5° to 75° were measured to compare angle dependence. Each set of data was collected along approximately 3 m of smoothed sediment for spatial averaging. Unavoidable experimental effects including transducer response, beam pattern, and spherical spreading were accounted for in order to compare the reflection coefficient measurements with the modified models. Significant spherical wave effects were measured in the data. Three reflection coefficient models were considered: the viscoelastic model, the grain shearing model [M. Buckingham, J. Acoust. Soc. Am. **108**, 1796–2815 (2000)] and the effective density fluid model [K. Williams, J. Acoust. Soc. Am. **110**, 2276–2281 (2001)]. The viscoelastic and grain shearing models predicted values for the reflection coefficient that were not within the 95% confidence interval for low frequencies. The data exhibited high variance which was frequency and angle dependent. This variance is not likely to be caused by variations in bulk properties as defined by the fluid or viscoelastic models. The cause of the variance will be considered in subsequent publications. © *2006 Acoustical Society of America.*

I. INTRODUCTION

There is an increasing need in ocean acoustics to fully understand acoustic wave interaction with sediments. As more and more applications are focusing on shallow water environments, the importance of accurate sediment models is ever increasing. The plane wave reflection coefficient is particularly important in underwater acoustics. Once the reflection coefficient is known, realistic propagation modeling can assist in communication, detection, and classification in littoral environments. Several plane wave models exist that are used to calculate the reflection coefficient given the sediment material parameters. These plane wave models are effective in the majority of situations encountered in real-world activities.

Spherical wave sources present a unique challenge as the plane wave models cannot properly account for the effects of a very broad beam pattern. Using spherical sources in long range applications is often a nonissue since a spherical wave eventually becomes locally planar. Close range applications, on the other hand, are affected greatly by the spherical wave effects. This is particularly important in a laboratory environment, where longer ranges are not feasible.

Measuring acoustic observables in a laboratory environment has many benefits, though. Laboratory measurements can be used to discern which models are most accurate; and assuming an accurate model, they can be inverted to determine well characterized sediment properties. Ideally, the laboratory is a carefully controlled environment where experimental parameters like incident angle, surface roughness and location are all precisely regulated. *In situ* measurements have increased variability that makes comparisons to theoretical models often difficult. In order to compare laboratory measurements made with spherical sources to the plane wave models, the models must first be modified to include the spherical wave effects.

It is a misnomer to call measurements of the bistatic response at the specular angle reflection coefficient measurements when the data are modified by spherical wave effects. However, these measurements will be called, "reflection coefficient measurements" throughout the text for clarity. When spherical wave effects are included in the reflection coefficient, the nomenclature, "spherical wave reflection coefficient" will be explicitly used.

The work presented here compares experimental spherical wave reflection coefficient measurements to three common plane wave reflection coefficient models that have been modified to include the spherical wave effects. A wide range of frequencies and grazing angles (30–160 kHz, 5°–75°) were tested at two ranges (1.27 and 0.25 m) to accurately compare experimental measurements to predicted model values. The three models that are compared are the viscoelastic model,[1] Buckingham's grain shearing model,[2] and Williams effective density fluid model (EDFM).[3] The elastic model assumes the sediment has a homogeneous composition and the averaged or bulk parameters for the wet sediment are used. The grain shearing and effective density models are poroelastic models that assume the individual sediment grains interact separately from the surrounding fluid.

The three models were used in plane wave decomposition (PWD) analysis[1] to include the spherical wave effects. PWD represents the spherical wave as a summation of plane waves which are individually modified by the respective plane wave reflection coefficients. The resulting summation which inherently takes into account all spherical wave effects can be directly compared to the measured data. The models and the PWD method will be further discussed in Sec. II.

The experiments were conducted during the summer of 2004 at the Applied Research Laboratories, The University of Texas at Austin. The experimental setup is discussed in Sec. III. Data analysis procedures are presented in Sec. IV. Experimental effects are discussed in Sec. V and results including the comparison of the data to models are shown in Sec. V. Finally, in Sec. VI, conclusions are drawn from the data/model comparisons.

II. THEORY

A. Viscoelastic model

The viscoelastic reflection coefficient model is a function of the incident angle and the characteristic acoustic impedances of the two mediums. The model includes an additional impedance for the shear wave motion. For the viscoelastic case[4]

$$R = \frac{Z_{tot} - Z_1}{Z_{tot} + Z_1},$$
(1)

where

$$Z_1 = \frac{\rho_1 c_1}{\cos \theta_i},$$
(2)

$$Z_{tot} = Z_c \cos^2 2\gamma_s + Z_s \sin^2 2\gamma_s,$$
(3)

$$Z_c = \frac{\rho_2 \omega}{(k_c^2 - k_1^2 \sin^2 \theta_i)^{\frac{1}{2}}},$$
(4)

$$Z_s = \frac{\rho_2 \omega}{(k_s^2 - k_1^2 \sin^2 \theta_i)^{\frac{1}{2}}}.$$
(5)

In the above equations, R is the reflection coefficient and Z_1 is the impedance of the water column. Z_{tot} is the total impedance of the sediment and Z_c is the impedance of the com-

pressional wave while k_c is the complex compressional wave number. Z_s is the impedance of the shear wave while k_s is the complex shear wave number and ω is the radial frequency. The viscoelastic model is completely defined by seven parameters and the incident angle, θ_i: the sound speed and density of the water column, c_1 and ρ_1, the sound speed of the compressional and shear waves, c_p and c_s, the density of the second medium, ρ_2, and the compressional and shear attenuations. The transmission angle of the shear wave, γ_s can be determined using Snell's law.

Equation (1) predicts a critical angle based on the ratio of the sound speeds both compressional and shear. However, if the shear wave speed in the sediment is much lower than the sound speed in the upper fluid, there will not be a second critical angle. Additionally, the Z_s term would then be negligible compared to the other impedances. In this case, the elastic reflection coefficient reduces to the fluid reflection coefficient.

B. Effective density fluid model

The sediment can also be considered as a poroelastic medium in which the displacement of the fluid and the displacement of the sand grains are considered independently. In a poroelastic model, there are three possible waves: a compressional wave in which the fluid and sand grain frame are moving in phase with each other, a compressional wave in which the fluid and sand grain frame are out of phase and a shear wave. The out-of-phase compressional wave is referred to colloquially as the "slow" wave. One formulation of a poro-elastic model is the Biot/Stoll model.[5–7] The Biot/Stoll model has 13 independent parameters, several of which are difficult to measure directly. The parameters are classed into three groups: bulk parameters, fluid motion parameters, and frame parameters. The bulk parameters are porosity β, pore size parameter α, grain density ρ_g, fluid density ρ_f, grain bulk modulus K_g, and fluid bulk modulus K_f. The fluid motion parameters include viscosity η, permeability κ and tortuosity τ. Last, in Biot/Stoll theory the sand grains are assumed to form a frame with its own complex bulk and shear moduli. The frame moduli are very difficult to measure, and they are generally assumed to be much smaller than the bulk moduli. If the frame parameters are assumed to zero, the Biot/Stoll equations can be reformulated into fluid-like equations.[3] The poroelastic effects are contained in the "effective density" term and a complex sound speed. The effective density is given by

$$\rho_{eff} = \rho_f \frac{\alpha(1-\beta)\rho_g + \beta(\alpha-1)\rho_f + \frac{i\beta\rho F\eta}{\rho_f \omega \kappa}}{\beta(1-\beta)\rho_g + (\alpha - 2\beta + \beta^2)\rho_f + \frac{i\beta F\eta}{\omega \kappa}},$$
(6)

where ρ is the sediment density given by $\beta\rho_f + (1-\beta)\rho_g$ and F is a function derived by Biot to account for the deviation from Poisuille flow at higher frequencies.[7] The complex sound speed is represented by

Camin and Isakson: Comparison of spherical wave reflection measurements

$$c = \sqrt{\frac{\left(\frac{1-\beta}{K_g} + \frac{\beta}{K_f} \right)^{-1}}{\rho_{\text{eff}}}}. \tag{7}$$

The resulting complex density from Eq. (6), compressional sound speed from Eq. (7) and attenuation which given by the imaginary part of ω/c from Eq. (7) are used in the fluid model described above.

C. Grain shearing model

Recently, Buckingham has suggested that acoustic reflection phenomena can also be modeled by considering the physics of the grain contact.[2] Translational and rotational shearing of the individual grains against one another amounts to a "random stick-slip" motion statistically combined to produce a relaxation mechanism. Using the average density, the grain shearing model yields the shear and compressional sound speeds and the shear and compressional attenuations, which are input into the elastic model detailed above. According to Buckingham, the equation for the bulk density of the saturated sediment is based on the porosity β and fluid and grain densities ρ_f, ρ_s:

$$\rho_2 = \beta \rho_f + (1-\beta)\rho_s. \tag{8}$$

The equations for the compressional and shear sound speeds c_p, c_s and attenuations α_p, α_s are given by

$$\frac{1}{c_p} = \frac{1}{c_0}\text{Re}\left[\left(1 + \frac{3\gamma_p + 4\gamma_s}{3\rho c_0^2}(i\omega)^n \right)^{-1/2} \right], \tag{9}$$

$$\alpha_p = -\frac{\omega}{c_0}\text{Im}\left[\left(1 + \frac{3\gamma_p + 4\gamma_s}{3\rho c_0^2}(i\omega)^n \right)^{-1/2} \right], \tag{10}$$

$$\frac{1}{c_s} = \frac{1}{c_0}\sqrt{\frac{\rho c_0^2}{\gamma_s}}|\omega|^{-n/2}\cos\left(\frac{n\pi}{4} \right), \quad \text{and} \tag{11}$$

$$\alpha_s = \frac{|\omega|}{c_0}\sqrt{\frac{\rho c_0^2}{\gamma_s}}|\omega|^{-n/2}\sin\left(\frac{n\pi}{4} \right). \tag{12}$$

Here ρ is the sediment density defined in Eq. (8). The compressional wave speed in an equivalent suspension, c_0, is determined by Wood's equations.[8] The radial stress-relaxation exponent, n, is computed from initial empirical measurements. The compressional and shear rigidity coefficients, γ_p and γ_s, are solved simultaneously from empirical measurements as well.

D. Plane wave decomposition

Since sediments have an angular dependent reflection coefficient which varies in amplitude and phase, the reflection from a flat sediment surface will not produce a perfectly spherical reflection, but a distorted semispherical wave. Furthermore, if the sediment has a higher sound speed than the fluid above, there is a critical angle past which there is total internal reflection. At this critical angle, the acoustic wave propagates along the fluid/sediment interface at the speed of sound in the sediment and reradiates back into the fluid at the same critical angle. This phenomenon is called the head
FIG. 1. Ray paths of the direct wave, specular reflection, and lateral wave.

wave or lateral wave since it travels ahead of the reflected acoustic wave in the water. Figure 1 shows the various ray paths between a source and a receiver that are possible with spherical waves. The interested reader can find color pictorials of lateral waves in Ref. 9.

From the figure, the direct path (DP) is the shortest distance between a source and a receiver. The specular reflection path (RP) is incident on the sediment at a grazing angle dependent on the position of the source and receiver. The lateral wave path represents an additional ray that may cause interference with specular reflection. It is simplistic to consider only the ray theory approximation of the lateral wave when addressing spherical effects since, around the critical angle, ray theory will produce infinite intensity at caustics, points in space where rays cross. In order to calculate the spherical wave reflection coefficient, the evaluation of the entire field integral is necessary.[10] Also, it is important to note that spherical wave effects will only be prevalent for source receiver ranges of less than 100–200 wavelengths and only for small grazing angles. For example, at 140 kHz in seawater, spherical effects are negligible after about 2 m, but at 40 kHz, spherical effects are prevalent up to about 5–7 m subcritically. This is due to attenuation and spreading of the lateral wave.

Section 26 in Brekhovskikh[1] details the development of a method to represent a spherical wave as an infinite summation of plane waves. The plane wave reflection coefficients computed from various models can be linearly multiplied by the individual plane waves inside the integral. The resulting integration yields the spherical wave reflection coefficient. The first step in PWD is to assume the incoming wave has the form of a spherical wave in three dimensions where the time dependence ($e^{-i\omega t}$) has been suppressed and only relative pressures are considered

$$P_i = \frac{p_0 e^{ikr}}{r}, \tag{13}$$

where

$$r = \sqrt{x^2 + y^2 + z^2}. \tag{14}$$

The received pressure, P_r, is a function of the initial pressure, p_0, the wave number, k, and the linear distance between the source and receiver, r. The distance between the two is a function of the coordinate displacements, x, y, and z from the source. As shown in Eq. (15), the expansion into the Fourier space, or the Helmholtz equation, reduces to

$$P_r = p_0 \frac{i}{2\pi} \int \int_{-\infty}^{\infty} e^{i(k_x x + k_y y \pm k_z z)} \frac{dk_x dk_y}{k_z}. \qquad (15)$$

Brekhovskikh shows that by converting to polar coordinates and making use of several identities and substitutions the spherical wave reflection coefficient (R_{SW}) can be written in the form of

$$R_{SW} = \frac{p_0 i k}{P_i} \int_0^{\pi/2 - i\infty} R(\theta) J_0(kr \sin\theta) e^{i2kh\cos\theta} \sin\theta d\theta. \qquad (16)$$

Here h is the height above bottom for the transducer array, θ is the grazing angle, and P_i is the incident spherical wave. Equation (16) is the PWD integral that is used to modify the plane wave reflection models for comparison with spherical wave data. It yields the reflected pressure for a given geometry based on the height above the sediment and the range between the transducers. In order to modify a given plane wave reflection coefficient model, the plane wave reflection coefficient, $R(f, \theta_g)$, computed from the model of interest is linearly multiplied by the kernel of the PWD integration.

Although traditional analysis involves many simplifications of Eq. (16) and typically various forms of saddle point integration, current computer processing power facilitates the direct numerical integration in this work. This greatly simplifies the conceptual procedure.

In the past, numerical integration has successfully been used to verify Brekhovskikh's work.[11] Until recently, however, the computational requirements were too high to make this approach a feasible means of solving repeated integrals.

Numerically integrating Eq. (16) near normal incidence and near zero degrees grazing angle is difficult. The frequency of oscillation of the function is much higher at normal incidence than at other angles. In this region, a sufficiently fine grid size results in large computation time. As the glazing angle decreases, the exponential decay in the imaginary portion of the PWD kernel decreases and a sinusoidal component becomes dominant. The limit occurs at exactly zero degrees where the imaginary portion is a varying sinusoid to minus infinity. However, with the transducer geometry used in this experiment, it was impractical to measure data at grazing angles of more than about 70° grazing or less than about 7° grazing. Therefore, it was unnecessary to numerically calculate the spherical wave reflection coefficient at the limits.

Figure 2 shows the comparison of the numerical integration of PWD integral with the plane wave reflection coefficient for a fluid model. The results were computed at two different separation distances and frequencies to show the general trends. As suspected, lower frequencies and closer distances cause greater spherical effects. Note that even at 1.27 m apart and at 112 kHz, there is some indication of spherical wave effects.

III. EXPERIMENTAL SETUP

Reflection coefficient measurements were taken in the ARL:UT Sonar Modal Calibration Tank 1. The tank is
FIG. 2. PWD results (dark) compared with the plane wave reflection coefficient for the fluid model (light). The spherical waves cause significant changes in the apparent critical angle particularly at low frequencies and separation distances.

18.3 m long, 4.5 m wide, and 3.6 m deep. At the bottom there is 1 m of unwashed river sand that was collected from the lower Colorado River in the 1970s. It has remained generally undisturbed for over 30 years. Biological activity is kept to a minimum through periodic chlorination. The tank has a slight temperature gradient of 0.45 °C/m extending approximately 0.3 m below the air/water interface. Below 0.3 m depth, the temperature is constant. Situated above the tank are two moving platforms, each equipped with a vertical shaft capable of positioning 150 lb of equipment at any depth in the water column. It provides an ideal location to precisely measure the reflection coefficient of sediments as a function of grazing angle.

The sediment in the tank includes various in homogeneities commonly found in river sand. Though it is generally fine sand, there are numerous rocks, and chunks of clay. A 2002 study characterizing the sediment found the sound speed to be 1740 ± 20 m/s at 30 kHz.

The average total density was measured to be 1.99 g/cm³. A detailed grain analysis was performed in 1992. A visual analysis at that time revealed a majority of quartz crystals with some silt and feldspar. The majority of the grains were poorly sorted and angular to subangular in shape. The porosity was measured to be 0.40. The average grain size diameter is 0.25 mm based on sieve measurements.

Figure 3 shows an elevation schematic of Calibration Tank 1. The moving platform can horizontally traverse the entire length of the tank. Attached to the vertical column is a two transducer acoustic test frame. The frame itself is narrow in depth and can easily be reversed to take data both from the sediment/water interface or the air/water interface. The frame was engineered so that it had less than a 1 mm deflection in either configuration. For the sediment/water interface data collection at the larger range, a cork reflector was mounted at a 45 deg angle above the sending transducer to exclude the air/water surface reflection for the sediment data. (See Fig. 4.)
FIG. 3. ARL Sonar Model Tank with experiment frame (to scale). Inset shows air/water configuration.

FIG. 5. Schematic of experiment and signal processing layout.

Each transducer was a spherical ITC 1089 transducer positioned so that the *XY* planes of the transducers were aligned. The z axis points along the transducer pigtail. The beam patterns of the two spherical transducers are nominally constant to 1 dB about the *XY* plane.

The reflection coefficient as a function of angle was measured by changing the height of the transducer array to sample different angles. Figure 1 shows that a change in height above the interface directly corresponds to a change in the grazing angle, θ_g, assuming the range, r, is held constant. The individual rays indicate the arrivals via the direct path and reflected path. The direct path will experience normal spherical spreading and will decrease in amplitude at a rate of $1/r$. The reflected path will experience a similar spreading loss due to the added distance, $\cos \theta_g / r$ where θ_g is the grazing angle.

To insure spatial stability, approximately 30 different locations on the sand were sampled. At each location, 75 angle measurements were made by coherently averaging 300–500 individual pings together. A 1 ms linear frequency modulated chirp, from 30 to 160 kHz, was used to sample a range of frequencies with each ping. Bandpass filtering allowed 10 subbands to be analyzed in each ping. This method uses one measurement to take the place of ten measurements at indi-

FIG. 4. Underwater view of the experiment apparatus and smoothed sediment. A reflector was added above the sending transducer to deflect rays from interacting with the air/water interface.

vidual frequencies. The above procedure was conducted at two different ranges between the transducers to compare the spherical effects as a function of range. The collected data represent one of the most comprehensive acoustic analysis of the sediment in ARL:UTs calibration tank to date.

Rough interface scattering effects were minimized by smoothing the sand with a 4 in. PVC pipe filled with scrap steel. The weighted pipe was gently dragged across the bottom several times. The laser line scan method developed at ARL:UT could not detect any surface roughness. This method has millimeter accuracy for spatial wavelengths from 0.1 to 1 m.[12]

The average root-mean-square roughness of smoothed, dry sand taken from the calibration tank was measured to be approximately 0.5 mm. This is about twice the average grain size, but is not unexpected. Various effects can increase the apparent roughness such as imperfections in the smoothing process, adhesion between sand grains and grain size distribution. Roughly 62% of the grains by mass are larger than the average grain size diameter.[*] The packing order of the individual grain sizes may also affect the apparent roughness.

An experiment test frame was designed and built in order to provide a stable platform that accommodated both air/water interface and sediment/water interface measurements. The sediment reflection measurements were normalized by the air/water data in order to correct for beam pattern and transducer response effects. This method improves the accuracy of the transducer response to nominally 0.25 dB.

The entire experiment, broken down into transfer functions, is shown in Fig. 5. The analog to digital (ADC) and digital to analog (DAC) converters on a National Instruments™ PCI-6115 data acquisition card were configured to trigger off of the same 4 MHz clock. A linearly amplified

signal from the DAC is applied directly to the 1TC 1089 transmit transducer, T_x. This produces relatively low amplitude, frequency dependent sound pressure levels of 155–170 dB in the water column. Because the transducers deviated from an ideal spherical source, slight beam pattern effects, B, contributed to the overall signal. The received signal also includes effects from spherical spreading, S_p, and the spherical reflection from the interface, $R(f, \theta_g)$. The received signal (X_t), including both the direct path pressure (X_{DP}) and reflected pressure (X_{RP}), is modified by the receiving transducer response including amplification.

IV. SIGNAL PROCESSING

Measuring the spherical wave reflection coefficient required accounting for several additional effects, in addition to the spherical wave effects, that were inherent in the experiment.

Each of the physical steps in the experiment, as outlined in Sec. III, can be reduced to transfer functions for signal processing. These transfer functions operate on the Fourier transform of the pressure amplitude

$$\eta_{DP}(f, \theta_0) = \text{TR}(f)B(f, \theta_0)Sp(\theta_0), \tag{17}$$

$$\eta_{RP}(f, \theta_g) = \text{TR}(f)B(f, \theta_g)Sp(\theta_g)R(f, \theta_g). \tag{18}$$

In general, two signals can be isolated in the data, the direct path pressure amplitude and the received path pressure amplitude. The amplitude of the direct path (η_{DP}) includes the transducer response TR, the beam pattern B, and spreading S_p effects the direct path angle θ_0 which was zero degrees grazing. The transducer response includes all effects from the amplifiers and DA/AD conversions. The beam pattern effects include both source and receiver beam patterns. The amplitude of the reflected path (η_{RP}) includes the same effects as the direct path, but are dependent on the particular grazing angle of each measurement. In addition, the reflected path includes the reflection R effects associated with interaction with the sediment or the air/water interface. These simplifications allow the different received pressure amplitudes to be described as

$$X_i(f) = I(f) + N(f), \tag{19}$$

$$X_{DP}(f, \theta_0) = X_i(f)\eta_{DP}(f, \theta_0) + N_{DP}(f), \tag{20}$$

$$X_{RP}(f, \theta_g) = X_i(f)\eta_{RP}(f, \theta_g) + N_{RP}(f). \tag{21}$$

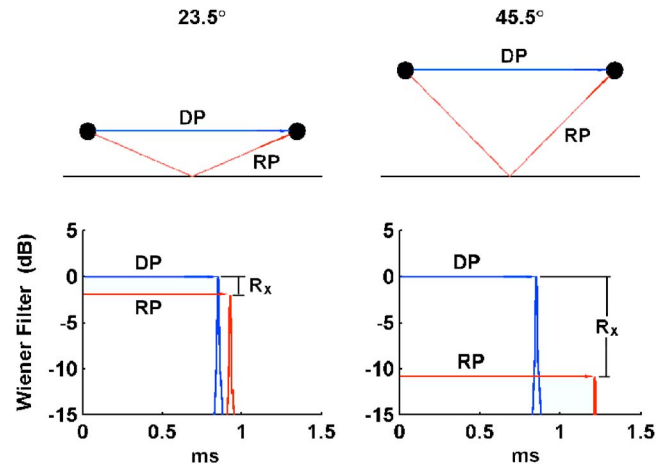
The input signal X_i includes only the initial wave form I with some small added electronic random noise $N(f)$. Both the direct path amplitude X_{DP} shown in Eq. (20) and the reflected path amplitude X_{RP} shown in Eq. (21) include the input signal, but have the additional effects associated with each. The respective noise terms in each equation represent the contribution of the noise in Eq. (19) as well as added random noise $N(f)$ associated with each path. For the direct path the noise is associated with local temperature variations in the water column and is expected to be small. Some possible noise contributions for the reflected path are discussed in Sec. V E. The sum of the direct and reflected paths was


FIG. 6. Illustration of experiment and signal processing. The direct path time is set to zero before computing the grazing angle.

recorded. However, since the distance between the transducers is constant, the direct path contribution for any measurement is the same. Therefore, the direct and reflected paths can be separated by subtracting a temporally isolated direct path that was recorded in the middle of the water column before each set of measurements.

The process for calculating the reflection coefficient from a measured time series is as follows. First, the direct and reflected path arrival times were determined using a time domain correlation with a calculated replica based on the input signal. Next, the grazing angle was determined from the delay between the direct path arrival and reflected path arrival. A temporally isolated direct path signal was subtracted from the recorded time series leaving only the reflected path signal and associated noise. Then, a second correlation was preformed using a temporally isolated direct path signal as the replica. The signal was then bandpass filtered on the data to isolate each frequency band. The initial specular bistatic amplitude and phase were determined by comparing the reflected path amplitude and phase at the peak of the correlation to the direct path amplitude and phase. Last, the data were corrected for transducer response, beam pattern, and spherical spreading by normalizing with the air/water interface response determined in the same manner.

A. Replica correlation and time compression

For this work, the replica correlation and associated time compression were accomplished using a Wiener filter based on the expected signal, x_{DP},

$$F_{RP,DP}(f, \theta_0) = \frac{X^*_{DP}(f, \theta_0)}{|X_{DP}(f, \theta_0)|^2 + \varepsilon^2}X_{RP,DP}(f, \theta_g)\text{BP}(f). \tag{22}$$

Here $F_{RP,DP}$ is the Fourier transform of the filtered signal. X_{DP} is the Fourier transform of the expected signal. $X_{RP,DP}$ is the Fourier transform of the raw data and BP (f) is the pass band. ε is the noise floor.

A sample Wiener filtered time series is shown in Fig. 6. The Wiener filter is constructed so that the time delay of the direct and reflected paths are absolute.

Frequency resolution is established by band pass filtering the direct and reflected paths. The pass bands were spaced every 12 kHz. Chebyshev windows in the frequency domain were used to enhance the time compressed peaks and suppress side lobes in the time domain.

The disadvantage to using the Wiener filter method is the limited frequency resolution. The peak width is inversely proportional to the bandwidth of the signal. If the bandwidth is decreased, then the peak width in the time domain will increase. If the bandwidth is too small, the time series width becomes too large to distinguish the reflected path arrival from scattered arrivals from the walls of the tank. The bandwidth of the band pass filters was optimized so that the direct and reflected peaks were resolvable.

B. Determining the grazing angle

The grazing angle is calculated by taking the arc-cosine of the direct path length over the reflected path length. Since the sound speed in the water column is relatively constant, distance and time are proportional. Therefore, taking the ratio of the direct and reflected path length is equivalent to taking the ratio of the direct and reflected arrival times, t_{DP} and t_{RP}, respectively,

$$\theta_g = \cos^{-1}\left(\frac{t_{DP}}{t_{RP}}\right). \tag{23}$$

Figure 6 shows how Wiener filtering over the entire frequency range (30–160 kHz) was used to precisely locate the arrival times of the direct and reflected paths. The figure also illustrates how the change in height above the bottom increases the grazing angle and how the reflection coefficient (R_x) may be determined by the ratio of the peaks height of the correlated signal. In this figure, the initial reflection coefficient for $23.5°$ is -2 dB and for $45.5°$ it is -11 dB.

For the determination of the grazing angle, the expected signal used in the Wiener filter was the input signal modified by the amplitude of the direct path. Since the DAC and ADC clocks are synchronized, the transmitted input signal starts simultaneously with the actual recorded measurements. This absolute reference was critical to accurately determining the proper arrival time.

C. Determining the reflection coefficient

The initial reflection coefficient $[R(f, \theta_g)]$ is determined by the ratio of the peak of the reflected path correlation and the direct path correlation. This has the added benefit of accounting for transducer response.

The beam pattern and spreading losses were accounted for by normalization with the data taken from the air/water interface. Assuming that the noise is negligible, the ratio of the reflection coefficient measurement from the air/water interface η_a and that of the water/sediment interface η_s is

$$\frac{\eta_s}{\eta_a} = \frac{B(f, \theta_g)}{B(f, \theta_g)} \frac{S_p(\theta_g)}{S_p(\theta_g)} \frac{R_a(f, \theta_g)}{R_s(f, \theta_g)}. \tag{24}$$

Since the complex reflection coefficient for the air/water R_a interface is known, normalizing the sediment initial reflection coefficient by the air/water initial reflection coeffi-
FIG. 7. Magnitude and phase of the 1.27 m air/water interface at 54 kHz, which includes only spreading and beam pattern effects.

cient removes both the frequency and angular dependent beam pattern and the spherical spreading. For normalization, all initial reflection coefficients are first interpolated to a standard angle and frequency set. Then both the air/water interface and sediment/water interface data are averaged over all spatial locations.

D. Phase determination and normalization

For the phase measurement, the Hilbert transform of the time series was taken prior to filtering. This created a complex time series. The phase angle was determined at the peak of the correlation with the Wiener filter in the time domain. The absolute phase was determined by subtracting the phase of the direct path from the reflected path. As with the magnitude, the phase was corrected for beam pattern effects by normalizing by the air/water interface data.

V. RESULTS

A. Normalization measurements

Ten normalization measurements were taken over the entire angle range at each range by inverting the experimental frame and measuring the specular bistatic response from the air/water interface. These data were averaged and used to verify that the grazing angle calculations were valid and to remove beam pattern effects from the sediment measurements. Figure 7 shows the phase and magnitude for the 1.27 m data for the air/water interface at 54 kHz uncorrected for spreading losses. The data were averaged over nine sets. The dashed lines represent the 95% confidence bounds. The overall trend of the data matches well with theoretical spherical spreading ($1/r$). This indicates that the algorithms used to calculate the grazing angle are reliable. The variations can be attributed to the beam pattern. It is evident that the effects of
FIG. 8. Magnitude and phase of the 1.27 m air/water interface at 125 kHz compared with theoretical spreading. Deviations are indicative of beam pattern effects.

the beam pattern are small compared to the effects of the spreading. The beam pattern exhibits 0.1 dB oscillations especially in the 25–30 angle range at 54 kHz as evident in Fig. 7. These oscillations are not apparent at larger frequencies as seen in Fig. 8.

The frequency dependent beam pattern of the two phones was calculated by subtracting the theoretical spreading from the measured air/water interface reflection data. For the phase, the beam pattern effects is determined by subtracting 180° from the phase. The 1.27 m data set has slight variations of approximately ±1 dB for a 95% confidence interval over the entire frequency range. The phase difference can be as much as 50° depending on the frequency and angle. The error is generally around 10° when averaged over the broadband. The 0.25 m data set has similar characteristics up to approximately 80 kHz. At the higher frequencies, the 0.25 m data becomes unstable. This is shown in Fig. 9 for 125 kHz. The 0.25 m data may be more heavily influenced by volume properties due to a higher influence of the sediment born lateral wave and steeper ray angles which may penetrate further into the sediment. Therefore, only the 1.27 m data will be considered quantitatively.

B. Spherical wave effects

The normalized reflection coefficient results for the 1.27 m case and the 0.25 m case are shown in Figs. 10 and 11 for 54 kHz band with a 95% confidence interval. These are spatial averages of 30 1.27 m measurements and 35 0.25 m measurements along the sediment floor in the calibration tank. Although the critical angle should be located at approximately 30°, both data sets are heavily influenced by spherical wave effects which shifts the critical angle value. This inward shift of the critical angle, especially at lower
FIG. 9. A comparison of the variability of the 1.27 m range data with the 0.25 m range data at 125 kHz. The spatial instability of the 0.25 m may imply a stronger dependence on volume heterogeneities due to steeper, more penetrating rays and an increased influence of the sediment born lateral wave.

frequencies, as well as the interference pattern in the subcritical region of the 1.27 m data are indicative of lateral wave interference.[10]

To demonstrate these effects, the plane wave elastic reflection coefficient and the spherical wave elastic reflection coefficient are calculated using plane wave decomposition and the visco-elastic model and plotted with the data (see Figs. 10 and 11). It is clear that predicting the data with only the plane wave model would lead to large errors especially in the critical region. The plane wave model overpredicts the location of the critical angle by 5° for the 1.27 m data and 12° for the 0.25 m data. The spherical wave model correctly
FIG. 10. Plane wave models compared to actual measurements at 1.27 m, 54 kHz. The dashed light line indicates the plane wave model while the solid line indicates the model as calculated using plane wave decomposition. The spherical wave model (solid line) is a better predictor of the data.
FIG. 11. Plane wave models compared to laboratory measurements at 0.25 m, 54 kHz. The dashed light line indicates the plane wave model while the solid line indicates the model as calculated using plane wave decomposition. The spherical wave model (solid line) is a better predictor of the data.

predicts the decrease in critical angle as well as the presence of an interference pattern subcritically. Additionally, the spherical wave model correctly predicts the dependence of spherical wave effects on transducer spacing although the 0.25 m data is higher than either model as the grazing angle approaches normal. The spherical wave effect is not present at angles larger than critical. The change in phase due to spherical wave effects is small and is not measured in this experiment. For the 1.27 m data both the plane wave model and spherical wave model correctly predict the phase. For the 0.25 m data, the phase is not predicted by either model in the critical region.

In all other model comparisons in this work, only the spherical wave reflection coefficients as calculated using plane wave decomposition will be considered. As stated above for the air/water data, the 0.25 m data were found to be unstable and will not considered quantitatively.

C. Calculation of the models for data comparison

A standard set of parameters were used to calculate all of the reflection coefficients based on the three models described above. The parameters were determined based on sand measurements made in the calibration tank and similar sand collected in the SAX'99 experiment, inversion results of the reflection data collected in the calibration tank, and values found in common reference tables. The attenuation in the water column is assumed to be zero. No attempts were made to adjust the parameters to reflect experimental results.

Table I shows the parameters used in the fluid and viscoelastic models. The fluid density was found in common reference tables. The fluid sound speed, measured as part of this study, was 1476 ± 7 m/s. This value corroborates well with common reference tables. The average wet sediment density was calculated based on porosity and the density of

the sand grains and water.[13] The sediment sound speed in the calibration tank was measured[14] and inversion results[15] verified this result. The value for the compressional attenuation was taken from the SAX'99 measurements since the sediments at that site and that of the calibration tank are similar in composition and size distribution.[16] The shear speed was obtained by inversion results[15] and corroborated with measurements at 312 Hz.[17] The shear attenuation, which will be shown to have little effect on the data, was extrapolated from measurements on unsorted sand at lower frequencies.[18]

Table II shows the poroelastic parameters used in the grain shearing model and the effective density fluid model. The frame shear and bulk moduli are assumed to be zero as described in Sec. II. The porosity was obtained by inversion[15] and is consistent with, values measured in the tank[13] and recorded at SAX'99.[16] The fluid bulk modulus was also determined by inversion[15] and substantiated by common reference tables. Viscosity was determined from common reference tables. The grain density was based on a grain analysis in the tank which revealed that the sand consisted of 85% quartz and 15% feldspar*. Grain bulk modulus was obtained by inversion of this data set[15] and is in the 95% confidence interval measured for similar sediment.[20] The value for tortuosity was taken from the SAX 99 measurements[16] although the same value was determined by inversion.[15] The pore size parameter was calculated using the Kozeny-Carmen equation[19] and the permeability was assumed to be similar to the SAX'99 valued.[16]

Table III shows the empirical values used in Buckingham's model. The frequency at which the sediment compres-

sional sound speed in the calibration tank was measured was 30 kHz.[14] The frequency of the shear sound speed measurement is 312 kHz.[17] The remaining values are from Table II. The plane wave reflection coefficient (PWRC) models calculated with the common parameters were modified with PWD to include spherical wave effects and then compared to the measured spherical wave reflection coefficient.

D. Data/model comparison

In order to compare the data with the predictive models, three frequency bands were chosen of the ten measured. These bands were centered at 54, 102, and 125 kHz. These data were indicative of the quality of the entire data set. The model predictions compared with the data are shown in Figs. 12–14. The data are shown with a 95% confidence interval.

Qualitatively, at 54 kHz, (Fig. 12), the elastic and grain shearing models are all underpredicting the bottom loss by almost 1 dB from the mean although these models do fit within the error. The EDFM, however, overpredicts the losses above the critical angle. However, this model is also

FIG. 13. Spherical wave models compared to measurements at 1.27 m, 102 kHz. All models lie within the 95% confidence interval.

within the 95% confidence interval. All three models predict the critical angle within about 3° and correctly predict the phase behavior.

For the higher frequencies, the elastic and grain shearing models under predict the value of the reflection coefficient at high grazing angles while the EDFM model predicts the mean value. In fact, both the fluid and grain shearing models predict values that are not within the 95% confidence interval of the data. EDFM model predicts a lower than measured

FIG. 12. Spherical wave models compared to measurements at 1.27 m, 5 Hz. All models lie within the 95% confidence interval.
FIG. 14. Spherical wave models compared to measurements at 1.27 m spacing, 125 kHz. Only the poroelastic, EDFM lies within the 95% confidence interval.

FIG. 15. Sensitivity analysis of three parameters for the poroelastic model. Shown in the figure are all of the combinations of the parameter ranges from Table V compared to the measured data and the elastic model predictions. In (a) are shown the angle dependent measurements and predictions at 125 kHz. In (b) are shown the frequency dependent predictions at 50 deg. There is still significant difference between the poroelastic model predictions and the elastic model at high frequencies and grazing angles.

value for of the reflection coefficient at the critical angle, however, the prediction is still within the 95% confidence interval. All three models correctly predict the phase behavior at 54 kHz although the phase measurement becomes more unstable at higher frequencies. At 125 kHz none of the models predict the phase behavior subcritically.

The three models were quantitatively compared by taking the mean absolute relative error averaged over the angle range at 54, 102, and 125 kHz. The mean relative error was also considered averaged over frequency at three angles, 15°, 30°, and 45°. The results are shown in Table IV.

The elastic model performs slightly better at low angles, while the poroelastic model is significantly more accurate at higher angles and high frequencies. This is in agreement to the results from Williams who found that at lower frequencies, the water is locked to the frame and the total mass density is in closer agreement with the effective density.[3]

A sensitivity analysis was performed on the EDFM model for three parameters: the fluid bulk modulus, the grain bulk modulus, and the tortuosity. The analysis was performed since the fluid bulk modulus and the grain bulk modulus were determined from an inversion of the same data set and the tortuosity was measured within a range at SAX 99.[16] The range of parameters tested are given in Table V. The fluid bulk modulus range is determined to be a proportional range as determined at SAX 99 for seawater. The range of the grain bulk modulus is taken from the 95% confidence interval of the measurements in Ref. 19. The tortuosity range is given by the measurement at SAX 99.[16] All possible combinations of these parameters were calculated and the range of solutions is shown in Fig. 15 compared with the measured data and the elastic solution for all angles at 125 kHz [Fig. 15(a)] and for all frequencies at an angle of 50 deg. [Fig. 15(b)]. As shown in the figure, the poroelastic model at all range combinations is significantly different

TABLE V. Ranges for the three underdetermined parameters from the poroelastic model. The fluid bulk modulus has the same proportional range as that measured at SAX 99 (see. Ref. 16). The grain bulk modulus range was measured in 1998 by Briggs et al. (see Ref. 20). The range for the tortuosity was measured at SAX 99 (see Ref. 16).

from the elastic model at high grazing angles and a better fit for the data at high grazing angles and frequencies.

E. Data variance

The standard deviation at high grazing angles and high frequencies in the data is typically 2 dB or more. The variation of the data as measured with the scintillation index is highly dependent on both frequency and angle as shown in Fig. 16.

There are several effects that may contribute to the variation. These include interface scattering, volume scattering, layering, and gradients and variation of bulk sediment properties. Additional sources of error associated with the experimental technique or data analysis are not suspected
FIG. 16. Scintillation index of the data at 20 and 50 deg grazing as a function of frequency. The variability has a strong dependence on the frequency and grazing angle.
FIG. 17. A comparison of two methods of determining the reflection coefficient: (1) computing the ratio of the reflected path peak height of the Weiner filtered response to that or the direct path and (2) computing the ratio of the reflected path peak area of the Weiner filtered response to that of the direct path. The second method, energy average, is considered the upper bound of the reflection coefficient as it may include effects of volume scattering and multiple layers. The peak height method represents the lower bound of the reflection coefficient.

because of the extremely consistent measurements of the air/water interface. As shown in Fig. 7, the standard deviation of the air/water interface is less than 0.1 dB for the 1.2 m data.

If the interface roughness is small compared to the acoustic wave length, scattering can be considered a stationary random process and the mean value of the reflection coefficient should not be affected.[21] However, for this experiment, the Rayleigh parameter was not much less than 1 for all frequencies. An estimate of the contribution of the interface scattering can be obtained by comparing the peak height measurement of the reflection coefficient with the energy average value. The peak height measurement, which is used throughout this study, is determined by calculating the ratio of the reflected path peak height of the intensity of the replica correlation to that of the direct path. The energy average value is made by computing the ratio of the area under the reflected path peak of the intensity of the replica correlation to that of the direct path. The energy average measurement will include contributions of the scattered energy which will arrive at slightly different times than the energy that is directly reflected. However, the energy average may also include contributions from multiple layers and is considered the upper bound for the value of the reflection coefficient. In contrast, the peak height measurement will only include energy that is reflected along the shortest path and is considered the lower bound for the reflection coefficient. Shown in Fig. 17 are the energy average measurement in light gray compared with the peak height measurement in black at 50 deg grazing. The 95% confidence interval is indicated by the dashed lines. As shown in the figure, the energy average reflection coefficient is about 1–2 dB higher than the peak height reflection coefficient. It is unknown whether this effect is caused by interface scattering, multiple layers, or volume scattering. This issue will be considered in subsequent publications.

Bulk variations as defined by the fluid or viscoelastic models are not suspected to account for the high degree of variation in the data. In fact, if these variations were due to spatially dependent bulk sediment properties, there would be roughly a 230% difference in the local sediment impedances along the tested area. This equates to sound speed and density changes on the order of 1200–3200 m/s and 0.9–5.4 g/cm^3, respectively. These limits are significantly outside the realm of independent measurements.

The analysis of the effects which are causing the high variation in the data is outside the scope of this paper and will be considered in subsequent publications.

VI. CONCLUSION

PWD was used to modify three plane wave reflection coefficient models to include spherical wave effects. The resulting spherical wave reflection coefficients were compared to experimental measurements. The measurements were taken from unwashed river sediment from 5° to 75° grazing at frequencies from 30 to 160 kHz. Two different transducer ranges were used, 1.27 and 0.25 m. Thirty different locations were tested to insure statistical significance.

The data were shown to have significant contributions from spherical wave effects that were dependent on frequency and range. The plane wave models overpredicted the location of the critical angle by 5° and 12° for the 1.27 and 0.25 m data, respectively. The spherical wave model as calculated by plane wave decomposition correctly predicted the location of the critical angle. Plane wave decomposition did not significantly alter the phase prediction.

The 1.27 m data were compared with three current models for acoustic interaction with sandy sediments. Each model was calculated using plane wave decomposition to correct for spherical wave effects. It was found that the viscoelastic model and grain shearing model predictions were not within the 95% confidence interval at high frequencies and angles.

The data exhibited high variance which was frequency and angle dependent. This variance is not likely to be caused by variations in bulk properties as defined by the fluid or viscoelastic models. The cause of the variance will be considered in subsequent publications.

In conclusion, these reflection coefficient measurements suggest that plane wave decomposition is a viable method for computing the effects of spherical waves. Furthermore, the data suggest that the poroelastic model is the best predictor for the reflection coefficient from sandy sediments.

A fast near-field method for calculations of time-harmonic and transient pressures produced by triangular pistons

Duo Chen, James F. Kelly, and Robert J. McGough[a)]

Department of Electrical and Computer Engineering, Michigan State University,
East Lansing, Michigan 48824

Analytical expressions are demonstrated for fast calculations of time-harmonic and transient near-field pressures generated by triangular pistons. These fast expressions remove singularities from the impulse response, thereby reducing the computation time and the peak numerical error with a general formula that describes the near-field pressure produced by any triangular piston geometry. The time-domain expressions are further accelerated by a time-space decomposition approach that analytically separates the spatial and temporal components of the numerically computed transient pressure. Applied to a Hanning-weighted input pulse, time-space decomposition converts each spatio-temporal integral into six spatial integral evaluations at each field point. Time-harmonic and transient calculations are evaluated for an equilateral triangle with sides equal to four wavelengths, and the resulting errors are compared to pressures obtained with exact and approximate implementations of the impulse response method. The results show that the fast near-field method achieves smaller maximum errors and is consistently faster than the impulse response and methods that approximate the impulse response. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2356839]

I. INTRODUCTION

As increasingly complex transducer geometries are adopted for emerging applications of ultrasound imaging and therapy, new methods are needed for rapid calculations of pressure fields produced by these transducers. Fast numerical calculations are especially important for simulations of phased array structures containing hundreds or thousands of transducers that generate pressures in large computational domains. Simulation methods that either directly evaluate the impulse response[1–4] or subdivide each transducer into smaller subelements and then superpose the pressure[5,6] provide a convenient model for these calculations, but in the near-field region, the convergence of these methods is relatively slow.[7] Furthermore, numerical implementations of the impulse response for flat unfocused transducers encounter some difficulties throughout the paraxial region.[8–10]

The numerical problems with the impulse response are eliminated with the fast near-field method (FNM) defined previously for circular[9] and rectangular[10] sources. The FNM also reduces the numerical error and the computation time relative to calculations that employ the impulse response. Further reductions in the computation time with FNM expressions are achieved through a time-space decomposition approach that separates the temporal and spatial components for transient pressure calculations.[7] The resulting expressions contain a small number of spatial integrals that are evaluated numerically and then multiplied by analytical temporal terms. The time-space decomposition approach applied to a circular piston accelerates transient pressure calculations by exploiting the structure of the FNM integral, achieving the same numerical error as the impulse response in much less time.

The substantial reduction in computation time demonstrated by the FNM for calculations of near-field pressures generated by circular and rectangular pistons motivates the derivation of similar integral expressions for triangular sources. After the impulse response is obtained for right, acute, and obtuse triangular sources, general FNM expressions for time-harmonic and transient inputs are then demonstrated for a triangular source, and the time-space decomposition of the FNM integral is presented for a transient excitation. Based on these expressions for the near-field pressure generated by a triangular source, computation times are evaluated for the same peak numerical errors. For time-harmonic inputs applied to a triangular source, results show that FNM calculations are several times faster than both exact and approximate impulse response calculations, and for pulsed excitations, results demonstrate that FNM calculations performed with time-space decomposition are also much faster than exact and approximate impulse response calculations for triangular piston geometries.

II. TIME-HARMONIC AND TRANSIENT NEAR-FIELD PRESSURE CALCULATIONS FOR TRIANGULAR SOURCES

A. Impulse response calculations for a triangular source

The geometry for a right triangular source with a *right angle* $\angle BCA$ at vertex C is depicted in Fig. 1(a). For this right triangle and the triangles in Figs. 1(b) and 1(c), the impulse response is evaluated at a point directly over the

---

[a)]Electronic mail: mcgough@egr.msu.edu

(a) Triangular source with right angle at $\angle BCA$.

(b) Triangular source with acute $\angle BCA$.

(c) Triangular source with obtuse $\angle BCA$.
FIG. 1. Triangular source geometries defined for near-field pressure calculations. The near-field pressure is evaluated above the vertex A (indicated in bold), and the shape of the triangle (right, acute, or obtuse) is defined by the angle $\angle BCA$. The height of each triangle is indicated by l, and the bases of the individual right triangles are indicated by s, s_1, and s_2. The acute triangle in (b) is represented by the sum of two right triangles, and the obtuse triangle in (c) is defined as the difference between two right triangles.

vertex A (indicated in bold in Fig. 1), where the orthogonal projection of the observation point onto the source plane is exactly coincident with the vertex A, and the distance from the observation point to the source plane along this orthogonal projection is represented by the variable z. In Fig. 1(a), the acute angle $\angle CAB = \tan^{-1}(s/l)$ defines the angular extent of sector EAB with radius $\sqrt{l^2+s^2}$, which has an impulse response of $c/(2\pi)\tan^{-1}(s/l)$ for $(z/c) \leqslant t \leqslant \sqrt{z^2+l^2+s^2}/c$. The impulse response for the right triangle $\triangle ABC$ contained

within the sector EAB is obtained by subtracting the impulse response of the region ECB between the curved outer edge of the sector and the near edge of the right triangle so that only the contribution from the right triangle $\triangle ABC$ remains. The impulse response of the region ECB is $c/(2\pi)\cos^{-1}(l/\sqrt{c^2t^2-z^2})$ for $\sqrt{z^2+l^2}/c \leqslant t \leqslant \sqrt{z^2+l^2+s^2}/c$, and therefore the impulse response at an orthogonal distance z above the vertex A is

$$
h_{\text{right}}(z;t) = \begin{cases} c/(2\pi)\tan^{-1}(s/l) & \text{for } \dfrac{z}{c} \leqslant t \leqslant \dfrac{\sqrt{z^2+l^2}}{c} \\[2ex] c/(2\pi)\left\{\tan^{-1}(s/l) - \cos^{-1}\dfrac{l}{\sqrt{c^2t^2-z^2}}\right\} & \text{for } \dfrac{\sqrt{z^2+l^2}}{c} \leqslant t \leqslant \dfrac{\sqrt{z^2+l^2+s^2}}{c}. \\[2ex] 0 & \text{otherwise} \end{cases}
\tag{1}
$$

For other triangular sources, the impulse response is readily constructed from the sum or difference between two right triangles. Figure 1(b) contains an example of a triangular source with an *acute angle* $\angle BCA$ at vertex C. The expression for the impulse response evaluated at a point directly over the vertex A is obtained by evaluating the *sum* of the contributions from the right triangles $\angle CDA$ and $\angle BDA$, each with a right angle at vertex D. The resulting impulse response above the vertex A in Fig. 1(b) is represented by

$$
h_{\text{sum}}(z;t) = \begin{cases} c/(2\pi)\{\tan^{-1}(s_1/l) + \tan^{-1}(s_2/l)\} & \text{for } \dfrac{z}{c} \leqslant t \leqslant \dfrac{\sqrt{z^2+l^2}}{c} \\[2ex] \dfrac{c}{2\pi}\{\tan^{-1}(s_1/l) + \tan^{-1}(s_2/l) - 2\cos^{-1}(l/\sqrt{c^2t^2-z^2})\} & \text{for } \dfrac{\sqrt{z^2+l^2}}{c} \leqslant t \leqslant \dfrac{\sqrt{z^2+l^2+s_2^2}}{c} \\[2ex] c/(2\pi)\{\tan^{-1}(s_1/l) - \cos^{-1}(l/\sqrt{c^2t^2-z^2})\} & \text{for } \dfrac{\sqrt{z^2+l^2+s_2^2}}{c} \leqslant t \leqslant \dfrac{\sqrt{z^2+l^2+s_1^2}}{c}, \\[2ex] 0 & \text{otherwise} \end{cases}
\tag{2}
$$

where the values of s_1 and s_2 are selected such that $s_1 \geqslant s_2$.

Similarly, Fig. 1(c) contains an example of a triangular source with an *obtuse angle* $\angle BCA$ at vertex C, where the impulse response is again evaluated at a point directly over the vertex A, but the impulse response is instead evaluated for the *difference* between two right triangles. The impulse response for the triangle in Fig. 1(c) is

$$
h_{\mathrm{diff}}(z;t) = \begin{cases} c/(2\pi)\{\tan^{-1}(s_1/l) - \tan^{-1}(s_2/l)\} & \text{for } \dfrac{z}{c} \leqslant t \leqslant \dfrac{\sqrt{z^2+l^2+s_2^2}}{c} \\[2ex] c/(2\pi)\{\tan^{-1}(s_1/l) - \cos^{-1}(l/\sqrt{c^2t^2-z^2})\} & \text{for } \dfrac{\sqrt{z^2+l^2+s_2^2}}{c} \leqslant t \leqslant \dfrac{\sqrt{z^2+l^2+s_1^2}}{c}, \\[2ex] 0 & \text{otherwise} \end{cases}
\tag{3}
$$

where the values of s_1 and s_2 are selected such that $s_1 > s_2$.

1. Time-harmonic impulse response calcuations

The time-harmonic pressure generated by these triangular source geometries is proportional to the Fourier transform of the impulse response. Therefore, the formula for the time-harmonic pressure generated by the right triangle in Fig. 1(a) is

$$
P_{\mathrm{right}}(z;k) = \frac{\omega\rho_0 v e^{j\omega t}}{2\pi}\left\{\frac{j}{k}\tan^{-1}\frac{s}{l}e^{-jkz}\right.
$$
$$
-\frac{j}{k}\tan^{-1}\frac{s}{l}e^{-jk\sqrt{z^2+l^2+s^2}}
$$
$$
\left.+\int_{\sqrt{z^2+l^2}}^{\sqrt{z^2+l^2+s^2}} e^{-jk\beta}\cos^{-1}\frac{l}{\sqrt{\beta^2-z^2}}d\beta\right\}.
\tag{4}
$$

The time-harmonic pressures that are produced by the remaining triangles depicted in Figs. 1(b) and 1(c) are obtained by adding and subtracting the contributions of two right triangles, as for calculations of the impulse response in Eqs. (2) and (3), respectively.

2. Transient impulse response calculations

Transient near-field pressures are computed with the impulse response through the convolution

$$
p(z;t) = \rho_0 \dot{v}(t) \otimes h(z;t),
\tag{5}
$$

where the time derivative of the particle velocity $\dot{v}(t)$ is evaluated analytically from the excitation pulse $v(t)$, and the convolution $\otimes$ is evaluated with the fast Fourier transform (FFT). In particular, the discrete Fourier transforms of $\dot{v}(t)$ and $h(z,t)$ are computed with the FFT, the results are multiplied, and the inverse FFT is applied to the product. The forward and inverse FFT routines are computed with the Fastest Fourier Transform in the West (FFTW) library.[11]

3. FIELD II

FIELD II is a software package[12] that computes the impulse response either by superposing far-field contributions from small rectangles or by evaluating expressions similar to Eqs. (1)–(3). With both approaches, FIELD II modifies the impulse response according to the area under the impulse

response curve.[13] This modification allows FIELD II to reduce the temporal sampling for impulse response calculations, which are directly applicable to transient and steady-state near-field pressure computations.

4. Smoothed impulse response

The Fourier transform of Eq. (5) is

$$
P(z;\omega) = j\omega\rho_0 V(\omega)H(z,\omega).
\tag{6}
$$

Normally, the excitation $V(\omega)$ is bandlimited, so the high-frequency components in the Fourier transform $H(z;\omega)$ of the impulse response are negligible. To exploit the bandlimited characteristics of the excitation $v(t)$, the formula for a smoothed impulse response is given by[14]

$$
h_{\mathrm{smooth}}(z;t) = \frac{O(c(t+\Delta t/2)) - O(c(t-\Delta t/2))}{2\pi tc\Delta t},
\tag{7}
$$

where $O(ct)$ is the area that formed by the intersection of the transducer and the sphere with radius ct centered at the observation point, and Δt is the length of the rectangular pulse that smooths the analytical impulse response. The constraint

$$
f_{E\,\max} < \frac{1}{\Delta t}
\tag{8}
$$

insures proper smoothing, where $f_{E\max}$ is the highest-frequency component of the excitation pulse, and $\Delta t = 0.02\ \mu s$ in the simulations that follow. The result obtained from Eq. (7) is then directly applied to calculations of the near-field pressure for time-harmonic and transient inputs.

B. The fast near-field method for a triangular source

Integral expressions that describe the fast near-field method (FNM) for a triangular source excited by a time-harmonic input are obtained by replacing the inverse cosine term with the integral form of the inverse tangent and then exchanging the order of integration in the impulse response expressions for right, acute, and obtuse triangles. After defining a new variable of integration and subtracting the singularity at $z=0$ from each integrand, the resulting FNM expression for a *right* triangle [Fig. 1(a)], the *sum* of two right triangles [Fig. 1(b)] that share a common side of length l, and

the *difference* between two right triangles [Fig. 1(c)] that share a common side of length l is

$$P(z;k) = -\frac{\rho c v e^{j\omega t}}{2\pi} \int_{x_C}^{x_B} \frac{l}{\sigma^2 + l^2}$$
$$\times (e^{-jk\sqrt{\sigma^2 + z^2 + l^2}} - e^{-jkz}) d\sigma, \qquad (9)$$

where l represents the height of the triangle, and x_B and x_C represent the x coordinates of B and C, respectively. In Figs. 1(a)–1(c), the values of (x_B, x_C) are $(s, 0)$, $(s_1, -s_2)$, and (s_1, s_2), respectively. Thus, a single FNM expression represents all three triangle geometries in Fig. 1, whereas the impulse response requires a separate expression for each triangle in Fig. 1.

1. Transient FNM calculations

The inverse Fourier transform of Eq. (9) generates the FNM expression for the transient response. The transient pressure generated by a triangular source above the vertex A is represented by

$$p(z;t) = -\frac{\rho c}{2\pi} \int_{x_C}^{x_B} \frac{l}{l^2 + \sigma^2}$$
$$\times \left[v\left(t - \frac{1}{c}\sqrt{z^2 + \sigma^2 + l^2}\right) - v(t - z/c) \right] d\sigma, \quad (10)$$

where the transient excitation is represented by $v(t)$. By retaining the $v(t-z/c)$ term within the integral and subtracting the singularity, Eq. (10) maintains the rapid rate of convergence achieved for time-harmonic calculations with Eq. (9).

2. Time-space decomposition

Transient FNM computations are accelerated by decoupling the temporal and spatial dependence of Eq. (10). The time-space decomposition approach, demonstrated previously for a circular source,[7] expands the delayed input pulse $v(t-\tau)$ in terms of temporal weighting functions $g_n(t)$ and spatially dependent terms $f_n(\tau)$ that depend only on the coordinates of the observation point and the variable of integration σ through $\tau = (1/c)\sqrt{z^2 + \sigma^2 + l^2}$. The decoupled input pulse is thus represented by

$$v(t-\tau) = \text{rect}\left(\frac{t-\tau}{W}\right) \sum_{n=1}^{N} f_n(\tau) g_n(t), \qquad (11)$$

where the time duration of the pulse is indicated by the parameter W. The decomposed pulse in Eq. (11) is then inserted into Eq. (10), and then time-dependent terms are factored out of the integral. The result consists of N edge wave terms specified by

$$E_n = -\frac{\rho c}{2\pi} l \int_{x_C}^{x_B} \frac{f_n(\tau)}{\sigma^2 + l^2} \text{rect}\left(\frac{t-\tau}{W}\right) d\sigma \qquad (12)$$

and a direct wave term given by

$$D = -\frac{\rho c}{2\pi} v(t - z/c) l \int_{x_C}^{x_B} \frac{1}{\sigma^2 + l^2} d\sigma. \qquad (13)$$

The temporal dependence of the edge wave integrand in Eq. (12) is eliminated when the effect of the rect function is instead shifted to the limits of integration. This operation, which restricts the edge wave contributions by only considering those that have reached the observation point without completely passing the observation point, completely removes all temporal variables from the integrand. As a result, calculations of transient pressure fields are converted into the numerical evaluation and subsequent superposition of N spatial integrals that are weighted by analytical time-dependent terms. Further reduction in the computation time is achieved by storing redundant edge wave calculations from Eq. (12) in the matrix

$$K_n(i,j) = \sum_{m=i}^{j} w_m \frac{f_n(\tau[\sigma_m])}{\sigma_m^2 + l^2}. \qquad (14)$$

In Eq. (14), w_m represents the weights and σ_m represents the abscissas computed for Gauss quadrature, the value of $\tau[\sigma_m]$ is obtained from the relation $\tau[\sigma_m] = (1/c)\sqrt{z^2 + \sigma_m^2 + l^2}$, and the indices i and j indicate the shortest and longest times that correspond to the limits of integration. The values in the $K_n(i,j)$ are initialized within the computation procedure only for the points that are needed, and then the time-space decomposition calculations superpose the numerically computed results of the spatial integrals with analytical time-dependent weighting factors to achieve a significant reduction in computation time for transient pressure calculations in the near-field region.

C. Superposition calculations with impulse response and FNM expressions

At observation points away from the normal that passes through a vertex of the triangular source, impulse response and FNM calculations project the observation point onto the source plane and then superpose the contributions from two or three triangles as in Fig. 2. The contributions from three triangles are either added, as shown in Fig. 2(a) for an observation point within the lateral extent of the source triangle $\triangle ABC$, or added and subtracted as demonstrated in Fig. 2(b) for an observation point outside of the lateral extent of the source triangle. Whether a contribution is added or subtracted depends on the location of the projected observation point in the source plane relative to each side of the triangular source.

The FNM admits some additional simplifications for near-field calculations of pressures generated by the triangle $\triangle ABC$ in Fig. 2. If the three lines that are coincident with the three sides of the source triangle $\triangle ABC$ are defined in the general form $E_i x + F_i y + G_i = 0$, then the distances from the projected observation point to each of the three sides are represented by $l_i = |E_i x + F_i y + G_i| / \sqrt{E_i^2 + F_i^2}$. Likewise, the sign of each contribution is defined as $S_i = (E_i x + F_i y + G_i) / |E_i x + F_i y + G_i|$ for coefficients E_i, F_i, and G_i chosen such that S_i is positive within the lateral extent of the source $\triangle ABC$. Furthermore, the lower and upper limits of integra-

Chen *et al.*: Fast near-field method for triangular pistons   2453
FIG. 2. Superposition operations that calculate near-field pressures generated by the equilateral triangular source ABC, where each side is 4 wavelengths long. The vertex D (indicated in bold) is the projection of the observation point onto the source plane, which partitions the radiating source into three triangles with sides (a_i, b_i, c_i). (a) The field point is located inside of the equilateral triangular source, and the total field is obtained by adding the contributions from the three triangles that share a vertex at D. (b) The field point is located outside of the equilateral triangular source, and the total pressure is obtained by adding and subtracting the contributions from the three triangles that share a vertex at D.

tion are defined as $(a_i^2 - b_i^2 - c_i^2)/(2c_i)$ and $(a_i^2 + c_i^2 - b_i^2)/(2c_i)$, respectively. The resulting near-field pressure generated by $\triangle ABC$ in Fig. 2 is therefore represented by

$$
P(x,y,z;k) = -\frac{\rho c v e^{j\omega t}}{2\pi} \sum_{i=1}^{3} \left(\frac{E_i x + F_i y + G_i}{\sqrt{E_i^2 + F_i^2}} \right.
$$
$$
\left. \times \int_{\frac{a_i^2 - b_i^2 - c_i^2}{2c_i}}^{\frac{a_i^2 + c_i^2 - b_i^2}{2c_i}} \frac{e^{-jk\sqrt{\sigma^2 + z^2 + l_i^2}} - e^{-jkz}}{\sigma^2 + l_i^2} d\sigma \right). \quad (15)
$$

Calculations with Eq. (15) compute the values of c_i, E_i, F_i, and G_i only once for each edge of $\triangle ABC$, whereas the values of a_i and b_i are calculated once for each (x,y) pair. Unlike the expressions for the impulse response that change depending on the spatial coordinate, Eq. (15) is a general formula that computes the near-field pressure with a single expression that is valid at all points in space.

D. Transient input waveform

Evaluations of the impulse response and the FNM with time-space decomposition are performed for the Hanning-weighted pulse specified by

$$
v(t) = \frac{1}{2}[1 - \cos(2\pi t/W)]\sin(2\pi f_0 t)\mathrm{rect}(t/W), \quad (16)
$$

where $\mathrm{rect}(t) = 1$ if $t \in [0,1]$ and $\mathrm{rect}(t) = 0$ otherwise. In the simulations that follow, the input is a Hanning-weighted pulse with a center frequency $f_0 = 2$ MHz and a pulse duration $W = 1.5$ μs. Time-space decomposition performed on this pulse with $N = 6$ yields the entries in Table I, where the spatial edge wave integral in Eq. (12) is evaluated once for each row entry applied to each edge of the source triangle $\triangle ABC$ in Fig. 2, and then the results are weighted by the temporal basis functions in Table I.

E. Error calculations

For time-harmonic near-field pressure calculations, the numerical error $\eta(x,y,z)$ is defined as the normalized difference between the reference field and the computed field according to

$$
\eta(x,y,z) = \frac{|P(x,y,z) - P_{\mathrm{ref}}(x,y,z)|}{\max|P_{\mathrm{ref}}(x,y,z)|}, \quad (17)
$$

where $P_{\mathrm{ref}}(x,y,z)$ is the reference time-harmonic near-field pressure. For transient near-field pressure calculations, the numerical error $\eta(x,y,z)$ between the computed transient field and the reference transient field is defined by

$$
\eta(x,y,z) = \frac{\|p(x,y,z;t) - p_{\mathrm{ref}}(x,y,z;t)\|}{\max_{x,y,z}\|p_{\mathrm{ref}}(x,y,z;t)\|}, \quad (18)
$$

where $\|\cdot\|$ denotes the energy norm used with respect to time, and $p_{\mathrm{ref}}(x,y,z;t)$ is the reference transient pressure field as a function of time. The maximum error is defined as $\eta_{\max} = \max_{x,y,z}\eta(x,y,z)$, and this value is computed for both time-harmonic and transient excitations.

III. RESULTS

All simulation programs are written in C, then compiled and executed within a MATLAB-C language MEX interface. The simulations are performed on an eMachines T3958 per-

sonal computer with a 2.93-MHz Celeron D processor. The operating system on this computer is Fedora Core 3 Linux. All simulations are run sequentially under similar operating conditions.

A. Time-harmonic near-field pressure calculations

1. Reference pressure distribution

The reference pressure field is computed in Fig. 3 for an equilateral triangular source with sides equal to 4 wavelengths. In Fig. 3, the acoustic field is evaluated in the $x=0$ plane defined in Fig. 2. The reference near-field pressure distributions in Fig. 3 are obtained when the impulse response is calculated for all triangles with 100 000-point Gauss quadrature. This pressure distribution is selected as the reference because near-field pressures computed with 100 000 abscissas produce normalized errors that converge to 15 significant digits throughout the near-field region, which represents the smallest error achievable with double-precision arithmetic.

2. FNM and impulse response calculations

The numerical errors and computation times for the fast near-field method and the impulse response method are shown in Fig. 4. For the FNM, the exact impulse response, and FIELD II with "use_triangles," near-field pressures are evaluated in an 81×101-point grid in the $x=0$ plane as shown in Fig. 3. FIELD II with "use_rectangles" and the

smoothed impulse response require an offset due to a singularity on the piston face and are therefore evaluated on a smaller 81×86-point grid. The FNM and the exact impulse response are evaluated with Gauss quadrature, and all three integrals corresponding to the three sides of the source triangles are evaluated with the same number of abscissas. The remaining methods that approximate the uniformly sampled impulse response (i.e., FIELD II and the smoothed impulse response) are evaluated with the midpoint rule as described in the user's guide on the FIELD II website (http://www.es.oersted.dtu.dk/staff/jaj/field/). Figure 4 shows that the error for a given computation time is consistently smaller with the FNM, where smaller errors are located nearer to the horizontal axis on the bottom of this log-log plot. Likewise, the time required to achieve a given error is consistently smaller with the FNM, since the FNM plot is consistently located to the left of the impulse response plot.

Comparisons between the impulse response and the FNM evaluated for the same peak error are summarized in Table II. For a 10% peak error, the FNM is 4.39 times faster than the impulse response, and for a 1% peak error, the FNM is 3.44 times faster than the impulse response for this grid and piston geometry. Even greater improvements are observed for smaller peak error values due to the rapid convergence of the FNM. Although these values change somewhat for different source and grid geometries, the FNM is consis-

TABLE II. Number of Gauss abscissas, computation times, and time ratios that describe the reduction in the computation time achieved with the fast near-field method relative to the impulse response and methods that approximate the impulse response for peak errors of 10% and 1%. The FNM and exact impulse response results are evaluated for time-harmonic calculations on a 81×101-point grid located in the $x=0$ plane, and the FIELD II and smoothed impulse response results are evaluated on an 81×86-point grid in the $x=0$ plane that is slightly offset from the transducer face.

	Time-harmonic Near-field computations							
	10% peak error				1% peak error			
	FNM	Impulse response	FIELD II use_triangles	Smoothed impulse response	FNM	Impulse response	FIELD II use_triangles	Smoothed impulse response
Parameters	$N=8$	$N=11$	$f_s=16$ MHz	$f_s=32$ MHz	$N=11$	$N=12$	$f_s=32$ MHz	$f_s=128$ MHz
Time	0.0938 s	0.4112 s	2.7212 s	1.0051 s	0.1286 s	0.4419 s	3.3993 s	4.0130 s

tently faster than the exact and the approximate impulse response for near-field calculations of time-harmonic pressures.

3. FIELD II calculations

The FIELD II simulation program[12] includes the "use _triangles'" option for calculations that model rectangular and triangular pistons as the superposition of triangular sources. For calculations of time-harmonic pressures with the "use_triangles" option applied to the source geometry in Fig. 2, FIELD II requires a temporal sampling frequency of $f_s = 16$ MHz to achieve a peak error of 10%. The computation time for FIELD II with "use_triangles" is 29.02 times slower than the FNM evaluated on the same grid. For time-harmonic calculations, FIELD II with the "use_triangles" option requires a temporal sampling frequency of $f_s = 32$ MHz to achieve a peak error of 1%. This results in a computation time that is 26.43 times longer than that required for the FNM evaluated on the same grid.

FIELD II also provides a "use_rectangles" option that introduces a numerical singularity on the piston surface, so the pressure is evaluated on a smaller 81×86-point spatial grid that is offset from the piston face. FIELD II with "use _rectangles" evaluated on this reduced grid produces a 10% peak error in 0.8908 s, which is 9.5 times slower than the FNM on the full 81×101-point grid. For a 1% peak error, FIELD II with "use_rectangles" computes the result on the restricted grid in 218.2492 s, which is 1697 times slower than the FNM on the full grid. Only the four fastest methods (on average) are tabulated, so the FIELD II "use_rectangles" calculation results are plotted in Fig. 4 but not included in Table II.

4. Smoothed impulse response calculations

Time-harmonic calculations with the smoothed impulse response[14] evaluate the pressure on a smaller 81×86-point spatial grid that is offset from the piston face. The offset is required for smoothed impulse response calculations so that the singularity in Eq. (7) on the piston face is avoided. For calculations of the time-harmonic pressure generated by the triangular source depicted in Fig. 2 and evaluated within an 81×86-point subset of the grid shown in Fig. 3, the smoothed impulse calculation converges to a peak error of 10% with a temporal sampling rate of $f_s = 32$ MHz. This computation is completed in 1.0105 s, which is 10.74 times longer than the time required for the corresponding FNM calculation evaluated on a larger 81×101-point spatial grid. Time-harmonic calculations with the smoothed impulse response achieve a peak error of 1% for a temporal sampling rate of $f_s = 128$ MHz. This computation is completed in 3.9983 s, which is 31.26 times longer than time required to obtain the FNM result with 1% peak error in Table II.

B. Transient near-field pressure calculations

1. Reference pressure distribution

The reference near-field pressure distribution for transient excitations is calculated with impulse response waveforms that are sampled at $f_s = 524.288$ GHz, zero padded, and
FIG. 5. Simulated transient pressure field in the $x = 0$ plane for a equilateral triangular source with sides equal to 4 wavelengths. For this calculation, the excitation is the Hanning-weighted pulse in Eq. (16), and the transient pressure is evaluated at 85 time points in an 81×101-point grid. The result is plotted at 1.8125 μs after the initiation of the input pulse.

convolved with FFTs. The resulting temporal variations in the near-field pressure, which are evaluated for an equilateral triangular piston with 4 wavelengths on each side, are then downsampled and stored at $f_s = 16$ MHz. The reference field is calculated for a sound speed of $c = 1.5$ mm/μs on an 81 $\times 101$-point spatial grid evaluated at 85 time points, and the result at time $t = 1.8125$ μs is shown in Fig. 5. This error reference is accurate to five significant digits for calculations in the $x = 0$ plane.

2. FNM and impulse response calculations

Figure 6 plots the numerical error as a function of the computation time for the FNM with time-space decomposition and calculations based on the impulse response method. All methods, except for FIELD II with "use_rectangles" and the smoothed impulse response, are evaluated relative to an 81×101-spatial point reference transient pressure distribution computed at 85 time points. FIELD II with "use _rectangles" and the smoothed impulse response are singular at the piston face, so a smaller 81×86-point spatial grid that incorporates an offset from the piston face is again required for transient field computations. The input for the reference
FIG. 6. The peak normalized error plotted as a function of the computation time for the FNM/time-space decomposition method, the impulse response method, and methods that approximate the impulse response. These errors and times are evaluated for transient near-field calculations of an equilateral triangular source with sides equal to 4 wavelengths. The excitation for these calculations is a Hanning-weighted pulse with a center frequency of 2 MHz.

TABLE III. Comparisons of computation times, input parameters, and time ratios that describe the reduction in the computation time achieved with the FNM and time-space decomposition relative to the exact and approximate impulse response for specified maximum errors of 10% and 1%. For FNM, impulse response, and FIELD II calculations with "use_triangles," these transient results are evaluated in an 81×101-spatial point computed at 85 time points, and for the smoothed impulse response, the results are valued at the same temporal points in a restricted 81×86-point spatial grid.

	Transient near-field computations							
	10% peak error				1% peak error			
	FNM	Impulse response	FIELD II use_triangles	Smoothed impulse response	FNM	Impulse response	FIELD II use_triangles	Smoothed impulse response
Parameters	$N=5$	$f_s=128$ MHz	$f_s=16$ MHz	$f_s=32$ MHz	$N=9$	$f_s=1$ GHz	$f_s=64$ MHz	$f_s=128$ MHz
Time	0.4867 s	1.8911 s	5.3317 s	1.0122 s	0.6160 s	23.5241 s	6.8078 s	4.1261 s

is generated by a Hanning-weighted pulse with a center frequency of $f_0=2$ MHz. The transient near-field pressures are compared for $f_s=16$ MHz, which is the original sampling rate for the FNM calculations and the resulting rate after downsampling for impulse response calculations. Figure 6 shows that the FNM with time-space decomposition is consistently faster than the impulse response and the methods that approximate the impulse response. Similarly, Fig. 6 indicates that the FNM with time-space decomposition achieves much smaller numerical errors than the impulse response and approximations to the impulse response.

Table III shows that the FNM with time-space decomposition achieves a 10% peak error with five Gauss abscissas in 0.4867 s. To achieve a 1% peak error, the FNM with time-space decomposition needs nine Gauss abscissas and the computation time is 0.6160 s. In contrast, the impulse response method achieves a peak error of 10% with a sampling frequency of $f_s=128$ MHz in 1.8911 s. To achieve a peak error of 1%, the impulse response method requires a sampling frequency of $f_s=1$ GHz and a computation time of 23.5241 s. Thus, the reduction in the computation time with time-space decomposition applied to the FNM relative to the impulse response is a factor of 3.89 for a peak error of 10% and a factor of 38.19 for a peak error of 1%.

3. FIELD II calculations

The FIELD II result obtained with the "use_triangles" option for the transient excitation in Eq. (16) requires a sampling frequency of $f_s=16$ MHz to achieve a peak error of 10%, and the computation time for this combination of parameters is 5.3317 s. For a peak error of 1%, FIELD II with the "use_triangles" option requires a sampling frequency of $f_s=64$ MHz, and the computation time is 6.8078 s. Therefore, the FNM with time-space decomposition is 10.95 times faster than FIELD II with "use_triangles" for a peak error of 10% and 11.05 times faster for a peak error of 1%.

Transient FIELD II calculations that subdivide the aperture into small rectangular sources with "use_rectangles" reach a peak error of 10% with a temporal sampling frequency of $f_s=32$ MHz in 3.9926 s. FIELD II with "use_rectangles" achieves a peak error of 1% with a temporal sampling frequency of $f_s=48$ MHz in 221.6569 s. Therefore, the FNM with time-space decomposition is 8.2 times faster than FIELD II evaluated with subdivided rectangular sources for a 10% peak error and 359.81 times faster than FIELD II

evaluated with subdivided rectangular sources for a 1% peak error. As for the time-harmonic results shown in Table II, only the four fastest methods (on average) are tabulated, so FIELD II results obtained with "use_rectangles" are not included in Table III.

4. Smoothed impulse response calculations

Transient calculations with the smoothed impulse response in Eq. (7) evaluate the pressure at 85 time points on a smaller 81×86-point spatial grid that is offset from the piston face. The offset is required in order to avoid the singularity in Eq. (7) on the piston face. For calculations of the time-harmonic pressure generated by the triangular source depicted in Fig. 2 and evaluated within an 81×86-point subset of the grid shown in Fig. 3, the smooth impulse calculation converges to a peak error of 10% with a temporal sampling rate of $f_s=32$ MHz. This computation is completed in 1.0122 s, which is 2.08 times longer than the time required for the corresponding FNM calculation evaluated on a larger 81×101-point spatial grid. Time-harmonic calculations with the smoothed impulse response achieve a peak error of 1% for a temporal sampling rate of $f_s=128$ MHz. This computation is completed in 4.1261 s, which is 6.7 times longer than time required to obtain the FNM result with 1% peak error in Table II.

IV. DISCUSSION

A. Time and error calculations

While computer processor speed and memory has increased substantially in recent decades, the size and complexity of ultrasound therapy and imaging simulations has grown accordingly. Simulations of large ultrasound therapy arrays are now applied to thousands of transducer elements and computational volumes spanning hundreds of wavelengths in three dimensions, and simulations of diagnostic imaging arrays have demonstrated a corresponding increase in the number of active elements and the number of scatterers. As a result, large simulations of ultrasound phased arrays can require 24 h or longer on modern computers.

For these large simulations, the evaluation of computational time and numerical error is essential. The computation time remains the primary bottleneck in these time-consuming calculations, but fair comparisons of computation time also require calculations of the numerical error. In recent years,

evaluations of the numerical error have been neglected due to the slow convergence of the impulse response and methods that approximate the impulse response. Figures 4 and 6 demonstrate this slow convergence, which is further emphasized by the time-harmonic reference field that requires 100 000 Gauss abscissas for convergence to 15 significant digits and by the transient reference field that requires a sampling frequency of $f_s = 524.288$ GHz for convergence to five significant digits.

The rapid convergence of the FNM demonstrated in Figs. 4 and 6 suggests that the FNM is ideal for calculating near-field pressure reference fields. In Fig. 4, time-harmonic FNM calculations converge within 15 significant digits in less than one-third of the time that the impulse response requires for convergence within five significant digits. Likewise, in Fig. 6, transient FNM calculations with time-space decomposition converges within five significant digits in less than one-fifth of the time that the impulse response requires for convergence within two significant digits. In these simulations of a triangular piston source excited by a pulse with a center frequency of 2 MHz, impulse response calculations require a sampling rate of 1 GHz to achieve only two significant digits of accuracy, whereas the FNM with time-space decomposition requires only nine Gauss abscissas applied to each integral and a sampling rate of 16 MHz to achieve two significant digits of accuracy throughout the near-field region.

B. Advantages of the FNM for time-harmonic and transient calculations

The computational advantages of the FNM are obtained from several sources. First, the FNM replaces time-consuming calculations of inverse trigonometric functions with a ratio of polynomials in the integrand. This reduces the computation time without increasing the numerical error. Second, the FNM reduces the numerical error by subtracting a singularity in the integrand. This step, which reduces the numerical error without significantly increasing the computation time, is particularly effective in eliminating numerical problems that occur along the edge of the source and throughout the paraxial region. Third, the FNM defines a single analytical expression that describes the pressure throughout the near-field region, whereas the impulse response requires multiple expressions to define the field generated by a single source. Thus, relative to calculations that employ exact or approximate calculations of the impulse response, convergence is faster with the FNM, and the FNM expressions are easier to evaluate.

The advantage of the FNM with time-space decomposition is that an integral expression with temporal and spatial dependencies is replaced with an equivalent expression that instead evaluates N spatial integrals for each edge of the triangular source and weights the result of each integral with an analytical temporal term. This results in greatly reduced overhead for transient near-field calculations, considering that the impulse response requires sampling rates of $f_s = 128$ MHz for a peak error of 10% and $f_s = 1$ GHz for a peak error of 1% for the source geometry in Fig. 2. The FNM

eliminates these high sampling rates, which therefore facilitates much more efficient utilization of computer memory.

C. FIELD II

The FIELD II calculations with "use_triangles" are evaluated within the same 81×101 spatial grid defined previously for these near-field calculations, whereas the same calculations with subdivided rectangular subapertures (i.e., "use_rectangles") are evaluated in an 81×86 spatial grid that includes an offset from the piston face. The offset is required for these near-field calculations; otherwise, the error grows excessively large on the piston face, which translates into much longer computation times for 10% and 1% peak errors. This occurs because subdividing the aperture introduces a numerical singularity on the piston face. Although FIELD II reduces the sampling frequency relative to other impulse response calculations, the exact impulse response consistently outperforms FIELD II for these time-harmonic near-field calculations, and the FNM evaluated with Gauss quadrature outperforms both of these by a wide margin. Furthermore, the FNM with time-space decomposition is also considerably faster than FIELD II for transient near-field calculations, and the FNM with time-space decomposition, unlike FIELD II with "use_rectangles," allows the computational grid to extend up to the piston face.

D. Smoothed impulse response

Unlike the FNM and the exact impulse response, the smoothed impulse response requires an offset from the piston face for near-field calculations. This offset is required because the denominator in Eq. (7) produces a numerical singularity on the piston face. Despite evaluating the near-field pressure on a smaller 81×86-point spatial grid, the smoothed impulse response is slower than the FNM and the exact impulse response for time-harmonic calculations, as demonstrated in Fig. 4 and Table II. The exact impulse response is faster than the smoothed impulse response for these time-harmonic calculations because the exact impulse response is evaluated with Gauss quadrature, and Gauss quadrature generally converges much faster than other numerical integration methods that uniformly sample the integrand. For transient calculations with both exact and approximate impulse response expressions, uniform sampling is required for convolutions with the FFT. In these transient calculations, the smoothed impulse response gains some advantage over the exact impulse response by evaluating the pressure at a smaller number of spatial grid points and by reducing the problems with aliasing at higher frequencies. Nevertheless, as demonstrated in Figs. 4 and 6, the smoothed impulse response converges more slowly than the FNM for time-harmonic and transient near-field calculations.

V. CONCLUSION

A fast near-field method is presented for numerical calculations of the pressure generated by a triangular source. For time-harmonic near-field computations, the FNM expression in Eq. (9) achieves smaller peak errors in less time than the exact impulse response, the smoothed impulse response,

and the FIELD II program. The results show that the FNM is 4.39 times faster than the exact impulse response for a 10% peak error, and the FNM is 3.44 times faster than the exact impulse response for a 1% peak error. The FNM is at least an order of magnitude faster than FIELD II and the smoothed impulse response for time-harmonic calculations compared at 10% and 1% peak error values. In transient near-field computations, the FNM in Eq. (10) combined with time-space decomposition achieves a substantial reduction in the computation time relative to exact and approximate impulse response calculations for a given peak error value. Transient near-field pressures are evaluated with a Hanning-weighted broadband pulse, and the resulting transient calculation is transformed into the superposition of six spatial integrals. The results demonstrate that the FNM with time-space decomposition is 3.89 and 38.19 times faster than the impulse response for peak errors of 10% and 1%, respectively, evaluated on an 81×101 spatial grid at 85 time points. Comparisons between smoothed impulse response results evaluated on the smaller 81×86-point offset spatial grid and the FNM with time-space decomposition evaluated on the larger 81×101-point spatial grid indicate that the FNM with time-space decomposition is 2.08 times faster than the smoothed impulse response for a 10% peak error, and the FNM with time-space decomposition is 6.7 times faster for a 1% peak error. Compared to the FIELD II program, the FNM is at least an order of magnitude faster for 10% and 1% peak error values. The results also suggest that the FNM, which eliminates the numerical problems that are encountered in exact and approximate impulse response calculations, provides a superior reference for near-field pressure calculations evaluated with time-harmonic and transient inputs.

On the sound field of a circular membrane in free space and an infinite baffle

Nokia Research Center, Helsinki, Finland

An enhanced method for calculating the radiation characteristics of a tensioned circular membrane in free space is presented using an analytical solution to the infinite integral in the free-space Green's function in cylindrical coordinates. This enables direct calculation of the surface pressure series coefficients by equating the coefficients of the resulting Bessel series in a set of simultaneous equations. Eliminating both numerical integration and least-squares minimization improves calculation speed and accuracy. An infinite baffle is introduced to provide an indication of what the theoretical limit of the bass performance would be using a very large enclosure. Furthermore, analytical solutions to the pressure field integrals are presented. A force transmission coefficient is introduced, which is the ratio of the total radiation impedance to the motional impedance. The motional, radiation, and diaphragm impedances of the damped membrane are calculated, together with the near- and far-field pressure responses and efficiency. A comparison is made between the on-axis response (without damping) calculated using this method and using a finite element model. It is demonstrated that good correlation between the two calculation methods can be achieved provided the elements are small enough and a sufficiently large model is used at the frequency extremes. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354041]

I. INTRODUCTION

Interest in electrostatic loudspeakers continues due to their superior performance[1] in terms of low distortion and relatively flat frequency response when suitably damped. Recent advances in digital amplifiers enable improvements in efficiency due to the fact that the reactive current drawn by the static capacitance does not produce the losses that occur with an analogue amplifier. If the loudspeaker has no damping or other kinds of resistance, then there are virtually no losses at all. However, damping, in the form of small holes in the electrodes, is usually applied in order to control the vibrational modes of the membrane. Hence it is useful to derive formulas for the motional input impedance of such a loudspeaker, since this enables its efficiency to be calculated.

The most commonly used model for a loudspeaker is the rigid piston, which assumes global loading over the surface. However, this is not necessarily appropriate in the case of a membrane where there is very strong localized coupling with the acoustic load. Because it is so light, most of the moving mass of the membrane is due to the surrounding fluid medium. Also, because it is acoustically transparent, it would be interesting to see how the pressure field might differ from that of a rigid piston which forms an effectively opaque sound source.

Additionally, the analytical solution to the pressure field of a circular membrane provides a useful benchmark for fluid-structure coupled simulation using the finite element modeling (FEM) method. The latter requires the membrane to be simulated in a virtual anechoic chamber filled with air elements. In this study the analytical solution is used as a reference in order to determine how large this space needs to be in order to match the far-field response. In theory, the anechoic space should be at least as large as the near-field or Fraunhofer zone, which is known to extend further from the source at higher frequencies.[2] Without a baffle, the source becomes a dipole, so the near field extends further from the source at low frequencies too, due to the proximity effect, which, in microphone terminology,[3] is sometimes referred to as "bass tip-up."

The electrostatic circular membrane loudspeaker is one of only a few kinds of transducer which can be completely simulated analytically (except turbulent flow effects between the electrodes and other nonlinear effects are not considered here). By contrast, the electrodynamic speaker is notoriously difficult to model rigorously, due to complicated cone geometries and scattering of the rear wave by the magnet and basket structures. Nearly 20 years after it was first published, Streng's method[4,5] for calculating the sound radiation characteristics of a circular stretched membrane in free space is still the best available. The secret to its success is the ingenious use of a trial function for the surface pressure term of the Kirchhoff-Helmholtz boundary integral, which is derived from Bouwkamp's solution[6] to the free space wave equation in oblate spheroidal coordinates. In fact, this is a somewhat special function since it appears to lead to the simplest possible analytical solution, especially regarding the evaluation of the impedances and near-field pressure. Unlike Streng,

---
[a)]Electronic mail: tim.mellow@nokia.com

though, the current paper presents a Bessel series matching that eliminates the need for numerical integration and least mean square minimization in the solution.

Whereas the sound radiation from a membrane in free space is calculated using the *dipole* part of the Kirchhoff-Helmholtz boundary integral formula[7] together with a power series expression for the surface *pressure*, the sound radiation from a membrane in an infinite baffle is calculated using the *monopole* part of the Kirchhoff-Helmholtz boundary integral formula together with a similar power series expression, but this time for the surface *velocity*.

Hence, the derivation for the latter has some similarities with that of a plane wave passing through a hole in an infinite screen.[6,8–10] The sound scattered from the hole can be considered as that radiated from a resilient disc in an infinite baffle if the (constant) driving pressure over its surface is equivalent to that of the incident wave in the absence of any obstacle. However, unlike the hole or resilient disc, the membrane does not exhibit infinite velocity near its perimeter, due to the fact that it is anchored at its rim. Hence, the solution to the wave equation for the surrounding medium has to be coupled to that of the membrane and solved simultaneously. Suzuki and Tichy[11] solved the coupled equations for a circular plate, but their formulation relied upon numerical integration. In a previous analysis of a membrane by the present authors,[12] numerical integration was avoided, but the least mean squares algorithm was used to solve the coupled equations, which caused some numerical difficulties. In this paper, the deflection trial function is expanded using a Bessel series so that the coefficients can be calculated directly without either least squares minimization or numerical integration.

The parameters chosen for the undamped FEM and analytical responses are the same as those used by Streng[4] for a 250-mm-diam membrane in free space in order to allow direct comparison. Otherwise, analytical characteristics are calculated for a 500-mm-diam membrane with and without damping in order to represent a typical full frequency range commercial design.

II. MEMBRANE IN FREE SPACE

A. Boundary conditions

The equations that follow are written in axisymmetric cylindrical coordinates, with w as the radial ordinate and z as the axial ordinate. The electrostatic driving pressure $\tilde{p}_I$ is used as the input in a wave equation for the membrane. The tilde denotes a harmonically time varying quantity where the factor $e^{i\omega t}$ is suppressed. The membrane deflection $\tilde{\eta}(w)$ (in the z direction) is then used as a parameter to couple it to the surrounding loss-free acoustic medium. Hence the membrane and free space wave equations must be solved simultaneously. The membrane, with radius a, lies in the xy plane as shown in Fig. 1 with its center at the origin and the uniform driving pressure $\tilde{p}_I$ is applied to its surface in the z direction. The pressure field on one side of the xy plane is the symmetrical "negative" of that on the other, so that

$$\tilde{p}(w,z) = -\tilde{p}(w,-z). \tag{1}$$
FIG. 1. Geometry of membrane.

Consequently, there is a *Dirichlet* boundary condition in the plane of the membrane where these equal and opposite fields meet, so that

$$\tilde{p}(w,0) = 0, \quad w > a. \tag{2}$$

On the front and rear outer surfaces of the membrane, there is the coupling condition

$$\frac{\partial}{\partial z}\tilde{p}(w,z)\big|_{z=0\pm} = -ik\rho c\tilde{u}_0(w),$$

$$= k^2\rho c^2 \eta(w), \quad 0 \leqslant w \leqslant a \tag{3}$$

where $\tilde{u}_0(w)$ is the normal particle velocity in the z direction at the surfaces and k is the wave number given by

$$k = \frac{\omega}{c} = \frac{2\pi}{\lambda}, \tag{4}$$

where ω is the angular frequency of excitation, ρ is the density of air or any other surrounding medium, c is the speed of sound in that medium, and λ is the wavelength. Values of 1.18 kg/m^3 and 345 m/s are assumed for ρ and c, respectively. The perimeter of the membrane is fixed, which leads to the following boundary condition:

$$\tilde{\eta}(a) = 0. \tag{5}$$

Streng[4,5] showed that the surface pressure distribution $\tilde{p}_+(w_0)$ for any flat axially symmetric unbaffled source (or sink), based upon Bouwkamp's solution[1] to the free space wave equation in oblate spheroidal coordinates could be written as

$$\tilde{p}_+(w_0) = -\tilde{p}_-(w_0) = \sum_{m=0}^{\infty} \tilde{A}_m \left(1 - \frac{w_0^2}{a^2}\right)^{m+(1/2)}, \qquad (6)$$

where $\tilde{A}_m$ are the as yet unknown power series coefficients.

B. Solution to the free space wave equation

1. Rigorous solution

The expression for the pressure field is the same as that given by Eq. (15) (evaluated at $b=a$) in a recent paper on the sound field of disk in a finite circular baffle.[13] The reason why the same formula can be applied to a nonrigid source is that it just describes the sound field due to an arbitrary pressure distribution at the source given by Eq. (6), regardless of the deflection/velocity distribution,

$$\tilde{p}(w,z) = -a \sum_{m=0}^{\infty} \tilde{A}_m \Gamma\left(m + \frac{3}{2}\right) \int_0^{\infty} \left(\frac{2}{\mu a}\right)^{m+(1/2)} J_{m+(3/2)}$$
$$\times (\mu a) J_0(\mu w) e^{-i\sigma z} d\mu, \qquad (7)$$

where

$$\sigma = \begin{cases} \sqrt{k^2 - \mu^2}, & 0 \le \mu < k \\ i\sqrt{\mu^2 - k^2}, & \mu > k \end{cases} \qquad (8)$$

and the power series coefficients $\tilde{A}_m$ are related to normalized dimensionless coefficients τ_m by

$$\tilde{A}_m = \tau_m (m + 3/2) \frac{\tilde{p}_I}{2}. \qquad (9)$$

Applying the boundary condition of Eq. (3) and truncating the power series limit leads to an expression for the surface particle displacement $\tilde{\eta}(w)$ as follows:

$$\tilde{\eta}(w) = \frac{1}{k^2 \rho c^2} \frac{\partial}{\partial z} \tilde{p}(w,z)\big|_{z=0\pm}$$
$$= i \frac{a\tilde{p}_I}{2k^2 \rho c^2} \sum_{m=0}^{\infty} \tau_m \Gamma\left(m + \frac{5}{2}\right) \int_0^{\infty} \left(\frac{2}{\mu a}\right)^{m+(1/2)}$$
$$\times J_{m+(3/2)}(\mu a) J_0(\mu w) \sigma d\mu. \qquad (10)$$

The solution[13] to the infinite integral is given by

$$\tilde{\eta}(w) = i \frac{\tilde{p}_I}{2k^2 a \rho c^2} \sum_{m=0}^{M} \tau_m I_m(w,k), \qquad (11)$$

where

$$I_m(w,k) = I_{mR}(w,k) + iI_{mI}(w,k), \qquad (12)$$

the real part of which is defined by

$$I_{mR}(w,k) = \sqrt{\pi} \sum_{q=0}^{Q} \sum_{r=0}^{R} \frac{(-1)^{q+r} \Gamma(m+5/2)}{(q!)^2 r! \Gamma(r+m+5/2)}$$
$$\times \frac{\Gamma(q+r+1)}{\Gamma(q+r+5/2)} \left(\frac{ka}{2}\right)^{2(q+r)+3} \left(\frac{w}{a}\right)^{2q}, \qquad (13)$$

and the imaginary part is defined by

$$I_{mI}(w,k) = \sqrt{\pi} \sum_{q=0}^{Q} \sum_{r=0}^{R} \frac{(-1)^{q+r+m} \Gamma(m+5/2)}{(q!)^2 r! \Gamma(r-m-1/2)}$$
$$\times \frac{\Gamma(q+r-m-1/2)}{\Gamma(q+r-m+1)} \left(\frac{ka}{2}\right)^{2(q+r-m)} \left(\frac{w}{a}\right)^{2q}. \qquad (14)$$

Let

$$\left(\frac{w}{a}\right)^{2q} = \sum_{n=1}^{\infty} a_n J_0(\alpha_n w/a), \qquad (15)$$

where α_n is the nth zero of $J_0(\alpha_n)$ [i.e., nth solution of $J_0(\alpha_n)=0$]. Multiplying through by the normalizing function $J_0(\alpha_n w/a)$ and integrating over w while applying the property of orthogonality leads to

$$a_n = \frac{\displaystyle\int_0^a (w/a)^{2q} J_0(\alpha_k w/a) w dw}{\displaystyle\int_0^a J_0(\alpha_n w/a) J_0(\alpha_k w/a) w dw}$$
$$= \frac{{}_1F_2(q+1);1, q+2;-\alpha_n^2/4)}{(q+1) J_1^2(\alpha_n)}, \qquad (16)$$

where the following identities[14,15] have been used:

$$\int_0^a J_0(\alpha_n w/a) J_0(\alpha_k w/a) w dw = \begin{cases} a^2 J_1^2(\alpha_n)/2, & \alpha_k = \alpha_n \\ 0, & \alpha_k \ne \alpha_n, \end{cases}, \qquad (17)$$

$$\int_0^a \left(\frac{w}{a}\right)^{2q} J_0(\alpha_k w/a) w dw = \frac{a^2 {}_1F_2(q+1;1,q+2;-\alpha_k^2/4)}{2(q+1)}. \qquad (18)$$

Hence

$$\tilde{\eta}(w) = i \frac{\tilde{p}_I}{2k^2 a \rho c^2} \sum_{m=0}^{M} \tau_m \sum_{q=0}^{Q} ({}_m B_q(ka) + i {}_m S_q(ka))$$
$$\times \sum_{n=1}^{N} \frac{{}_1F_2(q+1;1,q+2;-\alpha_n^2/4)}{(q+1) J_1^2(\alpha_n)} J_0(\alpha_n w/a), \quad (19)$$

where S and B are dipole cylindrical wave functions. S has been named the Streng function[13] as defined by

$${}_m S_q(kb) = \sqrt{\pi} \sum_{r=0}^{R} \frac{(-1)^{q+r+m}(ka/2)^{2(q+r-m)}}{r!(q!)^2(m+5/2)_{r-2m-3}(q+r-m-1/2)_{3/2}} \qquad (20)$$

and B has been named the Bouwkamp function[13] as defined by

$${}_m B_q(kb) = \sqrt{\pi} \sum_{r=0}^{R} \frac{(-1)^{q+r}(ka/2)^{2(q+r)+3}}{r!(q!)^2(m+5/2)_r(q+r+1)_{3/2}}. \qquad (21)$$

where $(x)_n$ is the Pochhammer symbol.

T. Mellow and L. Kärkkäinen: Membrane in free space and baffle

2. High frequency approximation

At high frequencies, the following approximation can be used:

$$I_m(w,k) \approx a^2 \Gamma\left(m + \frac{5}{2}\right) \int_0^\infty \left(\frac{2}{a\mu}\right)^{m+(1/2)} J_{m+(3/2)}$$

$$\times (a\mu) J_0(w\mu) k d\mu, \tag{22}$$

the solution[16] to which is given by

$$I_m(w,k) \approx ka\left(m + \frac{3}{2}\right)\left(1 - \frac{w^2}{a^2}\right)^{m+(1/2)}. \tag{23}$$

Let

$$\left(1 - \frac{w^2}{a^2}\right)^{m+(1/2)} = \sum_{n=1}^\infty a_n J_0(\alpha_n w/a), \tag{24}$$

so that multiplying through by the normalizing function $J_0(\alpha_k w/a)$ and integrating over w while applying the property of orthogonality leads to

$$a_n = \frac{\displaystyle\int_0^a (1-(w/a)^2)^{m+(1/2)} J_0(\alpha_k w/a) w dw}{\displaystyle\int_0^a J_0(\alpha_n w/a) J_0(\alpha_k w/a) w dw}$$

$$= \Gamma\left(m + \frac{3}{2}\right)\left(\frac{2}{\alpha_n}\right)^{m+(3/2)} \frac{J_{m+(3/2)}(\alpha_n)}{J_1^2(\alpha_n)}, \tag{25}$$

where Sonine's integral[14] has been used as follows:

$$\int_0^a \left(1 - \frac{w_0^2}{a^2}\right)^{m+(1/2)} J_0(\alpha_n w_0/a) w_0 dw_0$$

$$= \frac{a^2}{2} \Gamma\left(m + \frac{3}{2}\right)\left(\frac{2}{\alpha_n}\right)^{m+(3/2)} J_{m+(3/2)}(\alpha_n) \tag{26}$$

together with Eq. (17). Hence

$$\tilde{\eta}(w) \approx \frac{i\tilde{p}_I}{2k\rho c^2} \sum_{m=0}^\infty \tau_m \Gamma\left(m + \frac{5}{2}\right) \sum_{n=1}^\infty \left(\frac{2}{\alpha_n}\right)^{m+(3/2)}$$

$$\times \frac{J_{m+(3/2)}(\alpha_n)}{J_1^2(\alpha_n)} J_0(\alpha_n w/a). \tag{27}$$

C. Membrane wave equation

The loudspeaker configuration is shown in Fig. 2, with stationary electrodes on either side of the membrane, each at a distance d from it. The steady state wave equation for the membrane deflection $\tilde{\eta}(w)$ can be written with the inherent membrane forces on the left and the external forces on the right:

$$(T\nabla^2 - i\omega z_s - \omega^2 \rho_D h)\tilde{\eta}(w) = \tilde{p}_+(w) - \tilde{p}_-(w) - \tilde{p}_I, \tag{28}$$

where
FIG. 2. Electrostatic loudspeaker configuration.

$$\nabla^2 = \frac{\partial^2}{\partial w^2} + \frac{1}{w}\frac{\partial}{\partial w}, \tag{29}$$

where $\tilde{p}_+(w)$ and $\tilde{p}_-(w)$ are the front and rear pressure distributions, respectively, due to the surrounding acoustic medium, T is the tension (which is evenly distributed throughout the membrane), ρ_D is the density of the membrane material, h is its thickness, S is its surface area (given by $S = \pi a^2$), and z_s is an arbitrary specific acoustic impedance which is defined by

$$z_S = R_S + ikcM_S - \frac{C_{ED}}{ikcS}\left(\frac{E_P}{d}\right)^2, \tag{30}$$

where R_S and M_S are the distributed resistance and mass, respectively, of the perforations in the electrodes on either side of the membrane, which are usually designed to damp its vibration modes[17,18]. For the purpose of this analysis, it is assumed that the mass is negligible and that the resistance is linear and will not vary with frequency. The remaining term is the "negative impedance"[1] that results from the increase in electrostatic attraction toward each electrode as the membrane approaches it. The capacitance C_{ED} between the electrodes is given by

$$C_{ED} = \varepsilon_0 S/d, \tag{31}$$

where ε_0 is the permittivity of free space. Due to the push-pull arrangement, it is assumed that the change in capacitance on each side of the membrane, as it is displaced, will tend to balance out. Hence the electrostatic forces will hardly vary, providing there is enough tension. The total driving force $\tilde{F}_I$ is related to the driving pressure $\tilde{p}_I$ and input voltage $\tilde{e}_{in}$ by

$$\tilde{F}_I = S\tilde{p}_I = 2C_{ED}\frac{E_P}{d}\tilde{e}_{in}, \tag{32}$$

where E_P is the membrane polarizing voltage and d is the membrane to electrode spacing. Whilst applying Eq. (1) to the rear pressure term, Eq. (28) can be written in the "Helm-

holtz" form using the modified diaphragm wave number k_D' as follows:

$$(\nabla^2 + k_D'^2)\tilde{\eta} = \frac{1}{T}(2\tilde{p}_+(w) - \tilde{p}_I), \tag{33}$$

where

$$k_D'(k) = k_D(k)\sqrt{1 - i\frac{z_S}{k_D(k)\sqrt{\rho_D h T}}}, \tag{34}$$

$$k_D(k) = \omega/c_D = kc/c_D, \tag{35}$$

and

$$c_D = \sqrt{\frac{T}{\rho_D h}}, \tag{36}$$

where c_D is the speed of sound in the membrane.

D. Solution of the dynamic membrane wave equation

The solution to membrane wave equation, Eq. (33), subject to the edge constraint of Eq. (5), is essentially a two-dimensional counterpart to the Kirchhoff-Helmholtz volume integral as follows:

$$\tilde{\eta}(w) = \frac{1}{T}\int_0^{2\pi}\int_0^a (2\tilde{p}_+(w_0) - \tilde{p}_I)G(w|w_0)w_0 dw_0 d\phi_0. \tag{37}$$

The Green's function[7] for the membrane can be written using the modified wave number k_D' and suppressing the axial term in ϕ and ϕ_0 as follows:

$$G(w|w_0) = \frac{1}{\pi}\sum_{n=1}^{\infty} \frac{J_0(\alpha_n w/a)J_0(\alpha_n w_0/a)}{J_1^2(\alpha_n)(\alpha_n^2 - k_D'^2 a^2)}, \quad 0 \leq w \leq a, \tag{38}$$

where α_n is the nth zero of $J_0(k_D'a)$ such that $J_0(k_D'a)=0$ when $k_D'a=\alpha_n$. Inserting Eqs. (6), (9), and (38) in Eq. (37) and integrating over the surface of the membrane and baffle yields

$$\tilde{\eta}(w) = -\frac{a^2}{T}\tilde{p}_I\sum_{n=1}^{\infty} \frac{J_0(\alpha_n w/a)}{J_1(\alpha_n)(\alpha_n^2 - k_D'^2 a^2)}\left(\frac{2}{\alpha_n} - \sum_{m=0}^{\infty}\tau_m\Gamma\left(m + \frac{5}{2}\right)\right.$$
$$\left.\times\left(\frac{2}{\alpha_n}\right)^{m+(3/2)}\frac{J_{m+(3/2)}(\alpha_n)}{J_1(\alpha_n)}\right), \tag{39}$$

where the following identity[14] has been used:

$$\int_0^a J_0(\alpha_k w_0/a)w_0 dw_0 = a^2 J_1(\alpha_k)/\alpha_k, \tag{40}$$

together with Eq. (26).

E. Final set of simultaneous equations for the power series coefficients

1. Rigorous solution

Equating the right-hand sides of Eqs. (19) and (39) and then equating the coefficients of $J_0(\alpha_n w/a)$, yields the following set of $M+1$ simultaneous equations in τ_m:

$$\sum_{m=0}^{M} {}_m\Psi_n(k_D'a,ka)\tau_m = 1, \quad n = 1,2,\ldots,M+1, \tag{41}$$

where

$${}_m\Psi_n(k_D'a,ka) = \frac{\alpha_n}{2J_1(\alpha_n)}\left\{\Gamma\left(m + \frac{5}{2}\right)\left(\frac{2}{\alpha_n}\right)^{m+(3/2)}\right.$$
$$\times J_{m+(3/2)}(\alpha_n) - \frac{\alpha_n^2 - k_D'^2 a^2}{\alpha^2(ka)}$$
$$\times\sum_{q=0}^{Q}({}_m\mathbf{S}_q(ka) + i{}_m\mathbf{B}_q(ka))$$
$$\left.\times\frac{{}_1F_2(q+1;1,q+2;-\alpha_n^2/4)}{q+1}\right\} \tag{42}$$

and

$$\alpha(ka) = a\omega\sqrt{\frac{2a\rho}{T}} = ka\sqrt{\frac{2a\gamma P_0}{T}}, \tag{43}$$

where the infinite series have been truncated to orders M, Q, and R. $\mathbf{S}$ and $\mathbf{B}$ are dipole cylindrical wave functions defined in Eqs. (20) and (21), respectively. The dimensionless parameter α is the fluid-loading factor, where P_0 is the static pressure defined by $P_0 = \rho c^2/\gamma$ and γ is the adiabatic index. The calculations were performed using, in the case of the damped membrane, 50 digit precision with $M=10+ka$ and $Q=R=2M$. In the case of the undamped membrane, 100 digit precision was used with $M=10+5ka$ and again $Q=R=2M$.

2. High frequency approximation

For large values of ka, the following high-frequency approximation can be obtained by equating the right-hand sides of Eqs. (27) and (39) and then equating the coefficients of $J_0(\alpha_{0n}w/a)$ so that

$${}_m\Psi_n(k_D'a,ka) \approx \Gamma\left(m + \frac{5}{2}\right)\left(\frac{2}{\alpha_n}\right)^{m+(1/2)}\frac{J_{(m+3/2)}(\alpha_n)}{J_1(\alpha_n)}$$
$$\times\left\{1 - \frac{ika(\alpha_n^2 - k_D'^2 a^2)}{\alpha^2(ka)}\right\}. \tag{44}$$

F. Impedance and efficiency

1. Input impedance

The total volume velocity $\tilde{U}_0$ produced by the membrane is equal to the integral of its velocity $\tilde{u}_0(w)(=i\omega\tilde{\eta}(w))$ from Eq. (10) over its surface as follows:

$$\widetilde{U}_0 = ikc \int_0^{2\pi} \int_0^a \widetilde{\eta}(w)w\,dw\,d\phi$$

$$= \frac{a\widetilde{F}_I}{2k\rho c} \sum_{m=0}^{M} \tau_m \Gamma\left(m + \frac{5}{2}\right) \int_0^\infty \left(\frac{2}{a\mu}\right)^{m+3/2}$$

$$\times J_{m+3/2}(a\mu)J_1(a\mu)\sqrt{k^2 - \mu^2}\,d\mu, \tag{45}$$

where the identity of Eq. (40) has again been used. Finally, after solving the infinite integral[15]

$$\widetilde{U}_0 = \frac{\widetilde{F}_I}{2\rho c} \sum_{m=0}^{M} \tau_m \left\{ 1 - {}_2F_3\left(\frac{m}{2} + \frac{3}{4}, \frac{m}{2}\right.\right.$$
$$\left. + \frac{5}{4}; \frac{3}{2}, m + \frac{3}{2}, m + \frac{5}{2}; -k^2a^2\right)$$
$$\left. - i\frac{{}_2F_3\left(\frac{m}{2} + \frac{1}{4}, \frac{m}{2} + \frac{3}{4}; \frac{1}{2}, m+1, m+2; -k^2a^2\right)}{ka(m + 1/2)_{1/2}(m + 5/2)_{-1/2}} \right\}. \tag{46}$$

The mechanical motional impedance z_{mi} is simply the ratio of the applied force $\widetilde{F}_I$ to the average membrane velocity. It can also be expressed in terms of the volume velocity

$$z_{mi} = \frac{\widetilde{F}_I}{\widetilde{u}_0} = \frac{S\widetilde{F}_I}{\widetilde{U}_0} = 2S\rho cZ_I, \tag{47}$$

where the normalized motional input impedance Z_I is given by

$$Z_I = \frac{\widetilde{F}_I}{2\rho c\widetilde{U}_0}. \tag{48}$$

Then z_E is the electrical input impedance, which is given by

$$z_E = \frac{z_{ES}z_{EM}}{z_{ES} + z_{EM}}, \tag{49}$$

where z_{ES} is the *static* electrical impedance given by

$$z_{ES} = \frac{1}{i\omega C_{ED}} = \frac{d}{i\omega\varepsilon_0 S} \tag{50}$$

and z_{EM} is the *motional* electrical impedance given by

$$z_{EM} = \frac{z_{mi}}{2(C_{ED}E_P/d)^2}. \tag{51}$$

The input impedance for a damped membrane is shown in Fig. 3. Since the static impedance dominates, the motional impedance is plotted separately in Fig. 4.

2. Radiation impedance

The total radiation force $\widetilde{F}_R$ acting upon the membrane can be found by integrating the surface pressure from Eq. (6) over its surface as follows:

FIG. 3. Electrical input impedance of push-pull electrostatic loudspeaker in free space where $a=250$ mm, $h=12$ μm, $T=700$ N/m, $\rho_D=1400$ kg/m^3, $E_P=3000$ V, $d=2$ mm, $r=1$ m and $R_S=100$ Ns/m^3.

$$\widetilde{F}_R = -\int_0^{2\pi} \int_0^a \widetilde{p}_+(w_0)w_0\,dw_0\,d\phi_0 = -\frac{\widetilde{F}_I}{2} \sum_{m=0}^{M} \tau_m. \tag{52}$$

Let a membrane force transmission coefficient ζ be defined by

$$\zeta = -2\widetilde{F}_R/\widetilde{F}_I \tag{53}$$

or simply the ratio of the total radiation impedance (on both sides) to the motional impedance. Then from Eq. (52)

$$\zeta = \sum_{m=0}^{M} \tau_m. \tag{54}$$

The acoustic radiation impedance z_{ar} is then given by

$$z_{ar} = \frac{\widetilde{F}_R}{S\widetilde{U}_0} = \frac{\rho c}{S}(R_R + iX_R), \tag{55}$$

where R_R is the normalized radiation *resistance* given by $R_R = \Re(\zeta Z_I)$ and X_R is the normalized radiation *reactance* given by $X_R = \Im(\zeta Z_I)$. This result is plotted in Fig. 5 together with the radiation impedance of a rigid disk in free space for comparison.
FIG. 4. Motional part of electrical impedance in free space with the same parameters as in Fig. 3.
FIG. 5. Normalized radiation impedance in free space with same parameters as in Fig. 3 and radiation impedance of a rigid disk in free space.

3. Efficiency

Now it is easy to calculate the efficiency which is simply equal to $100^* R_R/R_I$ and is shown in Fig. 10 along with the far-field on-axis pressure response and peak displacement.

4. Diaphragm impedance

The mechanical diaphragm impedance z_{md} is the difference between the input impedance and the radiation impedance on both sides where

$$z_{md} = \frac{\widetilde{F}_I - 2\widetilde{F}_R}{\widetilde{u}_0} = \frac{S(\widetilde{F}_I - 2\widetilde{F}_R)}{\widetilde{U}_0} = 2S\rho c(R_D + iX_D), \quad (56)$$

where R_D is the normalized diaphragm *resistance* given by $R_D = \Re(Z_I(1-\zeta))$ and X_D is the normalized membrane *reactance* given by $X_D = \Im(Z_I(1-\zeta))$. This result is plotted in Fig. 6. The various impedances are shown on an equivalent electrical circuit in Fig. 7.

G. Near-field pressure response

1. Near-field pressure as an integral expression

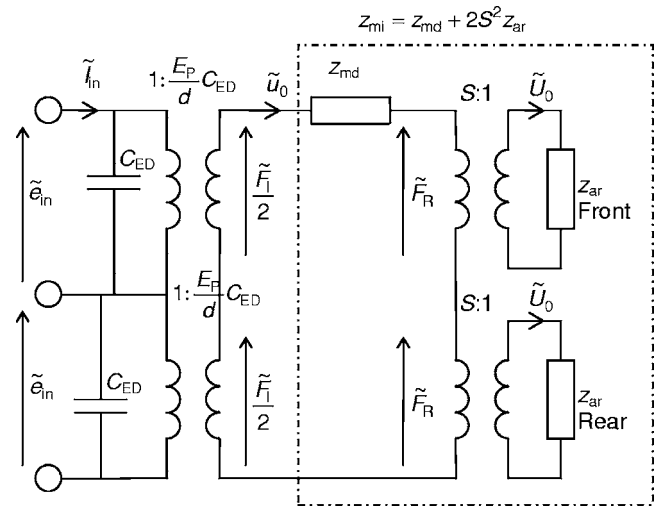
After truncating the summation limit, Eq. (7) can be separated into finite and infinite integrals as follows:
FIG. 6. Normalized diaphragm impedance in free space with the same parameters as in Fig. 3.


FIG. 7. Equivalent electrical circuit.

$$\widetilde{p}(w,z) = -\frac{\widetilde{p}_I}{2}\sum_{m=0}^{M}\tau_m\Gamma\left(m + \frac{5}{2}\right)(I_{\text{Fin}}(m,w,z)$$

$$+ I_{\text{Inf}}(m,w,z)), \quad (57)$$

where

$$I_{\text{Fin}}(m,w,z) = a\int_0^k \left(\frac{2}{a\mu}\right)^{m+(1/2)} J_{m+(3/2)}(a\mu)$$

$$\times J_0(w\mu)e^{-iz\sqrt{k^2-\mu^2}}d\mu \quad (58)$$

and

$$I_{\text{Inf}}(m,w,z) = a\int_k^\infty \left(\frac{2}{a\mu}\right)^{m+(1/2)} J_{m+(3/2)}(a\mu)$$

$$\times J_0(w\mu)e^{-z\sqrt{\mu^2-k^2}}d\mu, \quad (59)$$

2. Solution of the finite integral

Substituting $\mu = k\sqrt{1-t^2}$ in Eq. (58) in order to simplify the exponent yields

$$I_{\text{Fin}}(m,w,z) = 2\left(\frac{2}{ka}\right)^{m-(1/2)}$$

$$\times \int_0^1 \frac{J_{m+(3/2)}(ka\sqrt{1-t^2})J_0(kw\sqrt{1-t^2})}{(1-t^2)^{(m/2)+(3/4)}}e^{-ikzt}tdt. \quad (60)$$

The Bessel functions in Eq. (60) can then be expanded using the following Lommel expansion:[19]

$$\frac{J_n(ka\sqrt{1-t^2})}{(1-t^2)^{n/2}} = \sum_{m=0}^\infty \left(\frac{ka}{2}\right)^m \frac{t^{2m}}{m!}J_{n+m}(ka), \quad (61)$$

which leads to

T. Mellow and L. Kärkkäinen: Membrane in free space and baffle

$$I_{\text{Fin}}(m,w,z) = 2\sum_{p=0}^{\infty}\sum_{q=0}^{\infty}\left(\frac{ka}{2}\right)^{p-m+(1/2)}\left(\frac{kw}{2}\right)^{q}$$

$$\times\frac{J_{p+m+(3/2)}(ka)J_{q}(kw)}{p!q!}\int_{0}^{1}e^{-ikzt}t^{2(p+q)+1}dt. \tag{62}$$

The integral in Eq. (62) can be solved using the identity[14]

$$\int_{0}^{1}e^{-ikzt}t^{2(p+q)+1}dt = \frac{\gamma(2p+2q+2,ikz)}{(ikz)^{2(p+q)+2}}, \tag{63}$$

where γ is the incomplete gamma function. Inserting Eq. (63) in Eq. (62) and truncating the summation limits gives the final solution to Eq. (60) as follows:

$$I_{\text{Fin}}(m,w,z) = 2\sum_{p=0}^{P}\sum_{q=0}^{Q}\frac{1}{p!q!(ikz)^{2(p+q+1)}}\left(\frac{ka}{2}\right)^{p-m+(1/2)}$$

$$\times\left(\frac{kw}{2}\right)^{q}J_{p+m+(3/2)}(ka)J_{q}(kw)$$

$$\times\gamma(2p+2q+2,ikz). \tag{64}$$

3. Solution of the infinite integral

a. Expansion of the Bessel functions. Substituting $\mu = k\sqrt{t^2+1}$ in Eq. (59) in order to simplify the exponent yields

$$\frac{J_n(ka\sqrt{t^2+1})}{(t^2+1)^{n/2}} = \begin{cases} 2\sum_{m=0}^{\infty}\dfrac{(-1)^m}{1+\delta_{0m}}J_{2m}(ka)J_{2m}(kat), & n=0 \\[2ex] \left(\dfrac{2}{kat}\right)^n\sum_{m=0}^{\infty}\dfrac{(-1)^m}{m!}(2m+n)\Gamma(m+n)\times J_{2m+n}(ka)J_{2m+n}(kat), & n\neq 0, \end{cases} \tag{69}$$

where δ_{0m} is the Kronecker delta function. If both Bessel functions were to be expanded (in a procedure similar to that of Williams[20]) using the Lommel expansion of Eq. (66), together with the following identities[14]

$$\int_{0}^{\infty}e^{-kzt}t^{2(p+q)+1}dt = \frac{\Gamma(2p+2q+2)}{(kz)^{2(p+q)+2}}, \tag{70}$$

$$\gamma(2p+2q+2,ikz) - \Gamma(2p+2q+2)$$
$$= -\Gamma(2p+2q+2,ikz), \tag{71}$$

the resulting solution

$$I_{\text{Fin}} + I_{\text{Inf}} = 2\sum_{p=0}^{P}\sum_{q=0}^{Q}\frac{1}{p!q!(ikz)^{2(p+q+1)}}\left(\frac{ka}{2}\right)^{p-m+(1/2)}\left(\frac{kw}{2}\right)^{q}$$

$$\times J_{p+m+(3/2)}(ka)J_{q}(kw)\Gamma(2p+2q+2,ikz) \tag{72}$$

$$I_{\text{Inf}}(m,w,z) = 2\left(\frac{2}{ka}\right)^{m-(1/2)}\int_{0}^{\infty}\frac{J_{m+(3/2)}(ka\sqrt{t^2+1})}{(t^2+1)^{(m/2)+(3/4)}}$$

$$\times J_0(kw\sqrt{t^2+1})e^{-kzt}tdt. \tag{65}$$

The Bessel functions in Eq. (65) can expanded in two possible ways. The first is the Lommel expansion[19] as follows:

$$\frac{J_n(ka\sqrt{t^2+1})}{(t^2+1)^{n/2}} = \sum_{m=0}^{\infty}(-1)^m\left(\frac{ka}{2}\right)^m\frac{t^{2m}}{m!}J_{m+n}(ka), \tag{66}$$

and the second is Gegenbauer's summation theorem[14]

$$\frac{J_n(ka\sqrt{t^2+1})}{(t^2+1)^{n/2}} = \Gamma(n)\left(\frac{2}{kat}\right)^n\sum_{m=0}^{\infty}(m+n)J_{m+n}(kat)$$

$$\times J_{m+n}(ka)C_m^n(0), \tag{67}$$

where C_m^n is the Gegenbauer[14] polynomial given by

$$C_m^n(0) = \begin{cases} 1, & m=n=0 \\[2ex] \dfrac{\cos(m\pi/2)\Gamma(n+m/2)}{(m/2)!\Gamma(n)}, & m\neq 0 \text{ or } n\neq 0, \end{cases} \tag{68}$$

where n is a positive real integer. Inserting Eq. (68) in Eq. (67) and noting that, due to the cosine term, all odd terms of the Gegenbauer polynomial are zero, yields

would only converge for $z^2 \geq a^2 + w^2$ and would therefore be of limited value. On the other hand, expanding both Bessel functions using the summation theorem leads to an integral of the form

$$\int_{0}^{\infty}J_{2p+m+(3/2)}(kat)J_{2q}(kwt)e^{-kzt}t^{-1}dt, \tag{73}$$

which can be solved, but the solution is in the form of an expansion and is therefore slow to compute. Hence, the following solution uses the Lommel expansion for one Bessel function and the summation theorem for the other and then exchanges them so that convergent solutions are obtained, in turn, for $0 < w^2 + z^2 \leq a^2$ and $w^2 + z^2 \geq a^2$ (providing $z > 0$).

b. Solution when the distance from the center of the membrane to the observation point is greater than the membrane's radius Expanding $J_{m+(3/2)}(ka\sqrt{t^2+1})$ in Eq. (65) with Eq. (66) and $J_0(kw\sqrt{t^2+1}))$ with Eq. (69) yields

$$I_{\text{Inf}}(m,w,z) = 4\sum_{p=0}^{\infty}\sum_{q=0}^{\infty}\frac{(-1)^{p+q}}{p!(1+\delta_{0q})}\left(\frac{ka}{2}\right)^{p-m+(1/2)}$$

$$\times J_{p+m+(3/2)}$$

$$\times (ka)J_{2q}(kw)\int_0^{\infty}e^{-kzt}J_{2q}(kwt)t^{2p+1}dt. \quad (74)$$

The integral in Eq. (74) can be solved using the following identity:[14]

$$\int_0^{\infty}e^{-kzt}J_{2q}(kwt)t^{2p+1}dt = \frac{\Gamma(2p+2q+2)}{(k^2z^2+k^2w^2)^{p+1}}$$

$$\times P_{2p+1}^{-2q}\left(\frac{z}{\sqrt{z^2+w^2}}\right), \quad (75)$$

so that, after truncating the summation limits, the final solution is given by

$$I_{\text{Inf}}(m,w,z) = 4\sum_{p=0}^{P}\sum_{q=0}^{Q}\frac{(-1)^{p+q}\Gamma(2p+2q+2)}{(1+\delta_{0q})p!(k^2z^2+k^2w^2)^{p+1}}$$

$$\times\left(\frac{ka}{2}\right)^{p-m+(1/2)}J_{p+m+(3/2)}(ka)J_{2q}(kw)$$

$$\times P_{2p+1}^{-2q}\left(\frac{z}{\sqrt{z^2+w^2}}\right). \quad (76)$$

This expression converges for $w^2+z^2\geq a^2$ and can therefore be used in that region, providing $z>0$.

c. Solution when the distance from the center of the membrane to the observation point is less than the membrane's radius Expanding $J_{m+(3/2)}(ka\sqrt{t^2+1})$ in Eq. (65) with Eq. (69) and $J_0(kw\sqrt{t^2+1}))$ with Eq. (66) yields

$$I_{\text{Inf}}(m,w,z) = 2\left(\frac{2}{ka}\right)^{2m+1}\sum_{p=0}^{\infty}\sum_{q=0}^{\infty}\frac{(-1)^{p+q}\Gamma(p+m+3/2)}{p!q!}$$

$$\times(2p+m+3/2)\left(\frac{kw}{2}\right)^q J_{2p+m+(3/2)}(ka)$$

$$\times J_q(kw)\int_0^{\infty}e^{-kzt}J_{2p+m+(3/2)}(kat)t^{2q-m-(1/2)}dt. \quad (77)$$

The integral in Eq. (77) can be solved using the identity of Eq. (75) so that, after truncating the summation limits, the final solution is given by

$$I_{\text{Inf}}(m,w,z) = 2\left(\frac{2}{ka}\right)^{2m+1}\sum_{p=0}^{P}\sum_{q=0}^{Q}\frac{(-1)^{p+q}(2p+m+3/2)}{q!(k^2z^2+k^2a^2)^{q-(m/2)+(1/4)}}$$

$$\times(p+1)_{m+(1/2)}\Gamma(2p+2q+2)\left(\frac{kw}{2}\right)^q$$

$$\times J_{2p+m+(3/2)}(ka)J_q(kw)P_{2q-m-(1/2)}^{-2p-m-(3/2)}\left(\frac{z}{\sqrt{z^2+a^2}}\right). \quad (78)$$

This expression converges for $w^2<a^2+z^2$ and can therefore be used in the region $0<w^2+z^2<a^2$, providing $z>0$. The normalized near-field pressure response of the membrane is shown in Fig. 8 for various values of ka. The calculations

FIG. 8. Near-field pressure response in free space with the same parameters as in Fig. 3.

were performed using 50 digit precision with $M=P=50$ and $Q=100$.

H. Far-field pressure response

The far-field pressure is derived using the same procedure as shown in Part K of Sec. II of a recent paper [13] to give
FIG. 9. On-axis pressure response of push-pull electrostatic loudspeaker in free space where $a=250$ mm, $h=12$ μm, $T=700$ N/m, $\rho_D=1400$ kg/m^3, $e_{\mathrm{in}}=2000$ V$_{\mathrm{rms}}$, $E_P=3000$ V, $d=2$ mm, $r=1$ m, and $R_S=100$ Ns/m^3.

$$\widetilde{p}(r,\theta) = -i\frac{a\widetilde{p}_I}{4r}e^{-ikr}D(\theta) = -i\frac{E_P}{d}C_{\mathrm{ED}}\frac{a\widetilde{e}_{\mathrm{in}}}{2rS}e^{-ikr}D(\theta), \quad (79)$$

where the directivity function $D(\theta)$ is given by

$$D(\theta) = ka\cos\theta \sum_{m=0}^{M}\tau_m\Gamma\left(m+\frac{5}{2}\right)\left(\frac{2}{ka\sin\theta}\right)^{m+(3/2)}$$

$$\times J_{m+3/2}(ka\sin\theta), \quad (80)$$

which, for $\theta=0$ (i.e., on-axis), simplifies to

$$D(0) = ka\sum_{m=0}^{M}\tau_m = ka\zeta, \quad (81)$$

using ζ from Eq. (54). (The on-axis response of a resilient disk in free space is given by setting $\zeta=1$.) The on-axis pressure then simplifies to

$$\widetilde{p}(r,0) = -i\frac{ka^2}{4r}\widetilde{p}_I e^{-ikr}\zeta = -i\omega\frac{E_P}{d}C_{\mathrm{ED}}\frac{\widetilde{e}_{\mathrm{in}}}{2\pi rc}e^{-ikr}\zeta. \quad (82)$$

Taking into account that $\widetilde{I}_{\mathrm{in}}\approx i\omega C_{\mathrm{ED}}\widetilde{e}_{\mathrm{in}}$, leads to

$$\widetilde{p}(r,0)|_{b=a} \approx -\zeta\frac{E_P}{d}\cdot\frac{\widetilde{I}_{\mathrm{in}}}{c}\cdot\frac{e^{-ikr}}{2\pi r}, \quad (83)$$

which, in the case of $\zeta=1$, is Walker's equation.[21] A better approximation is given by

$$\zeta \approx 2\rho c/(R_S+2\rho c), \quad (84)$$

which leads to what could be termed the "modified Walker's equation." The on-axis pressure response with damping is shown in Fig. 9, together with the efficiency and peak displacement at $w=0$. Figure 10 shows a comparison of the on-axis responses with and without damping (the level is reduced in order to accommodate the large undamped excursions), together with the high frequency approximation, where the SPL is given by: SPL$=20\log_{10}|\widetilde{p}(r,0)/(20\times10^{-6})|$. The normalized directivity function $20\log_{10}|D(\theta)|/|D(0)|$ is plotted in Fig. 11 for various values of ka.

III. MEMBRANE IN AN INFINITE BAFFLE

A. Boundary conditions

The membrane shown in Fig. 1 is now mounted in an infinite baffle in the xy plane with its center at the origin and the uniform driving force $\widetilde{p}_I$ is applied in the z direction. The membrane deflection $\widetilde{\eta}(w)$ is then to be used as a parameter to couple it to the surrounding loss-free acoustic medium.

The monopole source elements and their images together form the membrane source. Since they are coincident in the plane of the infinite baffle, they combine to form elements of double strength. Hence our membrane may be modeled as a "breathing" membrane in free space. Due to the symmetry of the pressure fields on either side of the plane of symmetry, we have the following Neumann boundary condition on the front and rear surfaces of the infinite baffle:

$$\frac{\partial}{\partial z}\widetilde{p}(w,z)|_{z=0\pm} = 0, \quad a < w \leqslant \infty. \quad (85)$$

Also, on the front and rear outer surfaces of the membrane, there is the coupling condition

$$\frac{\partial}{\partial z}\widetilde{p}(w,z)|_{z=0\pm} = -ik\rho c\widetilde{u}_0(w),$$

$$= k^2\rho c^2\eta(w) \quad 0 \leqslant w \leqslant a. \quad (86)$$

FIG. 10. On-axis pressure response with the same parameters as in Fig. 9, except $e_{\mathrm{in}}=40$ V$_{\mathrm{rms}}$, and with $R_S=0$ (undamped).
FIG. 11. Normalized far-field directivity function in free space with same parameters as in Fig. 9.

In the actual physical system (as opposed to the "breathing membrane" model), the pressure field on one side of the xy plane is the symmetrical "negative" of that on the other, so that

$$\tilde{p}(w,z) = -\tilde{p}(w,-z). \tag{87}$$

Again, the perimeter of the membrane is fixed, which leads to the boundary condition of Eq. (5). On the surface of the membrane, the velocity distribution $\tilde{u}_0(w_0)$ is defined, according to Bouwkamp's solution[6] to the free space wave equation in oblate spheroidal coordinates, as

$$\tilde{u}_0(w_0) = \sum_{m=0}^{\infty} \tilde{A}_m \left(1 - \frac{w_0^2}{a^2}\right)^{m+(1/2)}, \tag{88}$$

where $\tilde{A}_m$ are the as yet unknown power series coefficients.

B. Solution to the free space wave equation

Using the King integral and taking into account the double layer source, the pressure distribution is defined by

$$\tilde{p}(w,z) = 2\int_0^{2\pi}\int_0^a g(w,z|w_0,z_0)$$

$$\times \frac{\partial}{\partial z_0}\tilde{p}(w_0,z_0)\big|_{z_0=0+}w_0 dw_0 d\phi_0, \tag{89}$$

where the Green's function[14] is defined, in axisymmetric cylindrical coordinates, by

$$g(w,z|w_0,z_0) = \frac{i}{4\pi}\int_0^{\infty} J_0(\mu w)J_0(\mu w_0)\frac{\mu}{\sigma}e^{-i\sigma|z-z_0|}d\mu, \tag{90}$$

where σ is defined by Eq. (8). Substituting Eqs. (86), (88), and (90) in Eq. (89) and integrating over the surface of the membrane yields

$$\tilde{p}(w,z) = ka\rho c\sum_{m=0}^{\infty}\tilde{A}_m\Gamma\left(m+\frac{3}{2}\right)\int_0^{\infty}\left(\frac{2}{a\mu}\right)^{m+(1/2)}$$

$$\times J_0(w\mu)J_{m+(3/2)}(a\mu)\frac{e^{-i\sigma z}}{\sigma}d\mu, \tag{91}$$

where Sonine's integral of Eq. (26) has been used (with $\mu = \alpha_{0n}/a$). Setting $z=0$ yields the surface pressure as follows:

$$\tilde{p}_+(w_0) = ka\rho c\sum_{m=0}^{\infty}\tilde{A}_m\Gamma\left(m+\frac{3}{2}\right)\int_0^{\infty}\left(\frac{2}{a\mu}\right)^{m+(1/2)}$$

$$\times J_0(w_0\mu)J_{m+(3/2)}(a\mu)\frac{1}{\sigma}d\mu. \tag{92}$$

C. Formulation of the coupled problem

Let the power series coefficients $\tilde{A}_m$ be related to normalized dimensionless coefficients τ_m by

$$\tilde{A}_m = \frac{\tau_m(m+3/2)}{2\rho c}\tilde{p}_I. \tag{93}$$

Substituting this together with Eq. (92) in Eq. (37) and integrating over ϕ_0 leads to the following coupled equation:

$$\tilde{\eta}(w) = \frac{2\pi}{T}\tilde{p}_I\int_0^a\left(\sum_{m=0}^{\infty}\tau_m I_m(w_0,k) - 1\right)G(w|w_0)w_0 dw_0. \tag{94}$$

The infinite integral I_m is defined by

$$I_m(w_0,k) = ka\Gamma\left(m+\frac{5}{2}\right)\int_0^{\infty}\left(\frac{2}{a\mu}\right)^{m+(1/2)}$$

$$\times J_0(w_0\mu)J_{m+(3/2)}(a\mu)\frac{1}{\sigma}d\mu$$

$$= I_{mR}(w_0,k) + iI_{mI}(w_0,k), \tag{95}$$

where the solution[10] to the real part is given by

$$I_{mR}(w_0,k) = \sqrt{\pi}\sum_{q=0}^{\infty}\sum_{r=0}^{\infty}\frac{(-1)^{q+r}\Gamma(m+5/2)\Gamma(q+r+1)}{(q!)^2 r!\Gamma(r+m+5/2)\Gamma(q+r+3/2)}$$

$$\times\left(\frac{ka}{2}\right)^{2(q+r+1)}\left(\frac{w_0}{a}\right)^{2q}. \tag{96}$$

and the solution[10] to the imaginary part is given by

$$I_{mI}(w_0,k)$$

$$= \sqrt{\pi}\sum_{q=0}^{\infty}\sum_{r=0}^{\infty}\frac{(-1)^{q+r+m+1}\Gamma(m+5/2)\Gamma(q+r-m-1/2)}{(q!)^2 r!\Gamma(r-m-1/2)\Gamma(q+r-m)}$$

$$\times\left(\frac{ka}{2}\right)^{2(q+r-m)-1}\left(\frac{w_0}{a}\right)^{2q}. \tag{97}$$

For large ka, an approximation[16] is given by

$$I_m(w_0,k) \approx (m+3/2)\left(1-\frac{w_0^2}{a^2}\right)^{m+(1/2)}. \tag{98}$$

D. Bessel series expansion of the membrane deflection

Using the power series of Eq. (88) together with Eq. (93), the deflection can also be expressed as

$$\widetilde{\eta}(w) = \frac{\widetilde{u}_0(w)}{i\omega} = \frac{\widetilde{p}_I}{2ik\rho c^2}\sum_{m=0}^{\infty}\tau_m\left(m+\frac{3}{2}\right)\left(1-\frac{w^2}{a^2}\right)^{m+(1/2)},$$

$$0 \leqslant w \leqslant a. \tag{99}$$

Using the Bessel series expansion from Eqs. (24) and (25), Eq. (99) can be written

$$\widetilde{\eta}(w) = \frac{\widetilde{p}_I}{2ik\rho c^2}\sum_{m=0}^{\infty}\tau_m\Gamma\left(m+\frac{5}{2}\right)\sum_{n=1}^{\infty}\left(\frac{2}{\alpha_n}\right)^{m+(3/2)}$$

$$\times\frac{J_{m+(3/2)}(\alpha_n)}{J_1^2(\alpha_n)}\times J_0(\alpha_n w/a), \quad 0 \leqslant w \leqslant a. \tag{100}$$

E. Final set of simultaneous equations for the power series coefficients

1. Rigorous solution

Inserting Eq. (38) in Eq. (94), equating the right-hand sides of Eqs. (94) and (100), while integrating over the surface of the membrane using the identities of Eqs. (18) and (40) and then equating the coefficients of $J_0(\alpha_n w/a)$ yields the following set of $M+1$ simultaneous equations in τ_m;

$$\sum_{m=0}^{M}{}_m\Psi_n(k_D'a,ka)\tau_m = 1, \quad n = 1,2,\dots,M+1, \tag{101}$$

where

$${}_m\Psi_n(k_D'a,ka) = \frac{\alpha_n}{2J_1(\alpha_n)}\left\{-ika\Gamma\left(m+\frac{5}{2}\right)\left(\frac{2}{\alpha_n}\right)^{m+(3/2)}\right.$$

$$\times J_{m+(3/2)}(\alpha_n)\frac{\alpha_n^2 - k_D'^2 a^2}{\alpha^2(ka)}$$

$$+ \sum_{q=0}^{Q}({}_{m+1}\mathbf{P}_q(ka) + i\,{}_{m+1}\mathbf{T}_q(ka))$$

$$\left.\times\frac{{}_1F_2(q+1;1,q+2;-\alpha_n^2/4)}{q+1}\right\}, \tag{102}$$

where $\mathbf{P}$ and $\mathbf{T}$ are monopole cylindrical wave functions. $\mathbf{P}$ has been named the Spence function[10] as defined by

$${}_{m+1}\mathbf{P}_q(ka) = \sqrt{\pi}\sum_{r=0}^{R}\frac{(-1)^{q+r}(ka/2)^{2(q+r+1)}}{r!(q!)^2(m+5/2)_r(q+r+1)_{1/2}} \tag{103}$$

and $\mathbf{T}$ has been named the Stenzel function[10] as defined by

$${}_{m+1}\mathbf{T}_q(ka) = \sqrt{\pi}\sum_{r=0}^{R}\frac{(-1)^{q+r+m+1}(ka/2)^{2(q+r-m)-1}}{r!(q!)^2(m+5/2)_{r-2m-3}(q+r-m-1/2)_{1/2}}, \tag{104}$$

where the infinite series have been truncated to orders M, Q, and R. $\mathbf{P}$ and $\mathbf{T}$ are monopole cylindrical wave functions. The dimensionless parameter α is the fluid-loading factor, as defined by Eq. (43), and $(x)_n$ is the Pochhammer symbol. The calculations were performed using, in the case of the damped membrane, 50 digit precision with $M=10+ka$ and $Q=R=2M$. In the case of the undamped membrane, 100 digit precision was used with $M=10+5ka$ and again $Q=R=2M$.

2. High frequency approximation

For large values of ka, the following high-frequency approximation can be obtained by the same method as for the rigorous solution, except that Eq. (98) is used instead of Eq. (97) and the identity of Eq. (18) is replaced by Eq. (26) so that the solution is, not surprisingly, the same as that given in Eq. (44).

F. Impedance and efficiency

1. Input impedance

The total volume velocity $\widetilde{U}_0$ produced by the membrane is equal to the integral of its velocity $\widetilde{u}_0(w)$ ($=i\omega\widetilde{\eta}(w)$) from Eq. (99) over its surface as follows:

$$\widetilde{U}_0 = ikc\int_0^{2\pi}\int_0^a\widetilde{\eta}(w)w\,dw\,d\phi = \frac{S\widetilde{p}_I}{2\rho c}\sum_{m=0}^{\infty}\tau_m, \tag{105}$$

where $S = \pi a^2$ is the area of the membrane. The parameters z_{mi}, z_E, z_{ES}, and z_{EM} are given in Eqs. (47) and (49)–(51), respectively. The normalized motional input impedance Z_I is given by
FIG. 12. Electrical input impedance of push-pull electrostatic loudspeaker in infinite baffle where $a=250$ mm, $h=12$ μm, $T=700$ N/m, $\rho_D=1400$ kg/m^3, $E_P=3000$ V, $d=2$ mm, $r=1$ m, and $R_S=100$ Ns/m^3.

$$Z_I = \frac{\widetilde{F}_I}{2\rho c \widetilde{U}_0} = \left(\sum_{m=0}^{M} \tau_m \right)^{-1}. \tag{106}$$

The input impedance for a damped membrane is shown in Fig. 12. Since the static impedance dominates, the motional impedance is plotted separately in Fig. 13.

2. Radiation impedance

The total radiation force $\widetilde{F}_R$ acting upon the membrane can be found by integrating the surface pressure from Eq. (92) over its surface as

$$\widetilde{F}_R = - \int_0^{2\pi} \int_0^a \widetilde{p}_+(w_0) w_0 dw_0 d\phi_0$$

$$= \frac{\widetilde{F}_I}{2} ka \sum_{m=0}^{\infty} \tau_m \Gamma \left(m + \frac{5}{2} \right)$$

$$\times \int_0^{\infty} \left(\frac{2}{a\mu} \right)^{m+(3/2)} \frac{J_1(a\mu) J_{m+(3/2)}(a\mu)}{\sqrt{k^2 - \mu^2}} d\mu, \tag{107}$$
FIG. 13. Motional part of electrical impedance in infinite baffle with the same parameters as in Fig. 12.
FIG. 14. Normalized radiation impedance in infinite baffle with the same parameters as in Fig. 12 and radiation impedance of a rigid disk in an infinite baffle.

where the identity of Eq. (40) has again been used. After solving the infinite integral,[15] the force transmission coefficient, defined in Eq. (53), is given by

$$\zeta = \sum_{m=0}^{M} \tau_m \left\{ 1 - {}_2F_3 \left(\frac{m}{2} + \frac{3}{4}, \frac{m}{2} + \frac{5}{4}; \frac{1}{2}, m + \frac{3}{2}, m + \frac{5}{2}; -k^2a^2 \right) \right.$$

$$\left. + ika \frac{{}_2F_3 \left(\frac{m}{2} + \frac{5}{4}, \frac{m}{2} + \frac{7}{4}; \frac{3}{2}, m+2, m+3; -k^2a^2 \right)}{(m+5/2)_{-1/2}(m+5/2)_{1/2}} \right\}. \tag{108}$$

The acoustic radiation impedance z_{ar} is then given by Eq. (55), where R_R is the normalized radiation resistance given by $R_R = \Re(\zeta Z_I)$ and X_R is the normalized radiation reactance given by $X_R = \Im(\zeta Z_I)$. This result is plotted in Fig. 14 together with the radiation impedance of a rigid disk in an infinite baffle for comparison.

3. Efficiency

Now it is easy to calculate the efficiency which is simply equal to $100^* R_R/R_I$ and is shown in Fig. 17 along with the far-field on-axis pressure response and peak displacement.

4. Diaphragm impedance

The mechanical diaphragm impedance z_{md} is the difference between the input impedance and the radiation impedance on both sides, as defined by Eq. (56), where R_D is the normalized diaphragm *resistance* given by $R_D = \Re(Z_I(1-\zeta))$ and X_D is the normalized membrane *reactance* given by $X_D = \Im(Z_I(1-\zeta))$. This result is plotted in Fig. 15. The various impedances are shown on an equivalent electrical circuit in Fig. 7.
FIG. 15. Normalized diaphragm impedance in infinite baffle with the same parameters as in Fig. 12.

G. Near-field pressure response

1. Near-field pressure when the distance from the center of the membrane to the observation point is greater than the membrane's radius

Using the same procedure as in a recent paper for a resilient disk in an infinite baffle,[10] it can be shown that

$$
p(r,\theta) = -\pi\tilde{p}_I \sum_{m=0}^{M} \sum_{p=0}^{P} \frac{\tau_m h_{2p}^{(2)}(kr) P_{2p}(\cos\theta)}{(m+(5/2))_p \Gamma((1/2)-p)\Gamma(2p+(1/2))}
$$

$$
\times \left(\frac{ka}{2}\right)^{2p+2} {}_1F_2\left(p+1; p+m+\frac{5}{2}, 2p+\frac{3}{2}; -\frac{k^2a^2}{4}\right).
$$

(109)

This solution converges providing $r \geq a$.

2. Near-field pressure when the distance from the center of the membrane to the observation point is less than the membrane's radius

a. Near-field pressure as an integral expression. After truncating the summation limit and inserting Eq. (93), Eq. (91) can be separated into finite and infinite integrals as follows:

$$
\tilde{p}(w,z) = \tilde{p}_I \sum_{m=0}^{M} \tau_m \Gamma\left(m+\frac{5}{2}\right)(I_{\text{Fin}}(m,w,z) - iI_{\text{Inf}}(m,w,z)),
$$

(110)

where

$$
I_{\text{Fin}}(m,w,z) = \frac{ka}{2}\int_0^k \left(\frac{2}{a\mu}\right)^{m+(1/2)} J_{m+(3/2)}(a\mu)
$$

$$
\times J_0(w\mu)\frac{e^{-iz\sqrt{k^2-\mu^2}}}{\sqrt{k^2-\mu^2}}d\mu
$$

(111)

and

$$
I_{\text{Inf}}(m,w,z) = \frac{ka}{2}\int_k^\infty \left(\frac{2}{a\mu}\right)^{m+(1/2)} J_{m+(3/2)}(a\mu)
$$

$$
\times J_0(w\mu)\frac{e^{-z\sqrt{\mu^2-k^2}}}{\sqrt{\mu^2-k^2}}d\mu.
$$

(112)
FIG. 16. Near-field pressure response in infinite baffle with the same parameters as in Fig. 12.

b. Solution of the finite integral. Using the same procedure as in a recent paper for a resilient disk in an infinite baffle,[10] it can be shown that

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

T. Mellow and L. Kärkkäinen: Membrane in free space and baffle   2473

$$I_{\text{Fin}}(m,w,z) = -\sum_{p=0}^{P}\sum_{q=0}^{Q}\frac{1}{p!q!(ikz)^{2(p+q)+1}}\left(\frac{ka}{2}\right)^{p-m+(1/2)}$$
$$\times\left(\frac{kw}{2}\right)^{q}J_{p+m+(3/2)}(ka)J_{q}(kw)$$
$$\times\gamma(2p+2q+1,ikz). \tag{113}$$

c. Solution of the infinite integral. Similarly, it can be shown that[10]

$$I_{\text{Inf}}(m,w,z) = \left(\frac{2}{ka}\right)^{2m+1}\sum_{p=0}^{P}\sum_{q=0}^{Q}\frac{(-1)^{p+q}(2p+m+3/2)}{q!(k^2z^2+k^2a^2)^{q-(m/2)-(1/4)}}$$
$$\times (p+1)_{m+(1/2)}\Gamma(2p+2q+1)\left(\frac{kw}{2}\right)^{q}$$
$$\times J_{2p+m+(3/2)}(ka)J_{q}(kw)P_{2q-m-(3/2)}^{-2p-m-(3/2)}$$
$$\times\left(\frac{z}{\sqrt{z^2+a^2}}\right). \tag{114}$$

The normalized near-field pressure response of the membrane is shown in Fig. 16 for various values of ka. The calculations were performed using 50 digit precision with $P=M=10+ka$ and $Q=2P$.
H. Far-field pressure response

The far-field pressure is derived using the same procedure as shown in Part I of Sec. II of a recent paper[10] to give the same result as Eq. (79), except that the directivity function $D(\theta)$ is now given by

$$D(\theta) = ka\sum_{m=0}^{M}\tau_m\Gamma\left(m+\frac{5}{2}\right)\left(\frac{2}{ka\sin\theta}\right)^{m+(3/2)}$$
$$\times J_{m+(3/2)}(ka\sin\theta), \tag{115}$$

which is the same as for the free space membrane except for the absence of the $\cos\theta$ term because the free space membrane is a dipole, whereas the baffled membrane is a monopole. For $\theta=0$ (i.e., on-axis), this simplifies to

$$D(0) = ka\sum_{m=0}^{M}\tau_m = \frac{ka}{Z_I}, \tag{116}$$

using Z_I from Eq. (106). Hence the on-axis pressure simplifies to

$$\tilde{p}(r,0) = i\frac{ka^2}{4r}\tilde{p}_I e^{-ikr}\frac{1}{Z_I} = i\omega\frac{E_P}{d}C_{\text{ED}}\frac{\tilde{e}_{\text{in}}}{2\pi rc}e^{-ikr}\frac{1}{Z_I}. \tag{117}$$

Taking into account that $\tilde{I}_{\text{in}}\approx i\omega C_{\text{ED}}\tilde{e}_{\text{in}}$, leads to

$$\tilde{p}(r,0)|_{b=a} \approx \frac{1}{Z_I}\cdot\frac{E_P}{d}\cdot\frac{\tilde{I}_{\text{in}}}{c}\cdot\frac{e^{-ikr}}{2\pi r}, \tag{118}$$

which, in the case of $Z_I=1$, is Walker's equation.[21] A better approximation is given by

$$Z_I \approx 1 + R_S/(2\rho c), \quad ka > 2, \tag{119}$$

which leads to what could be termed the "modified Walker's equation." The on-axis pressure response with damping is shown in Fig. 17, together with the efficiency and peak dis-

placement at $w=0$. In Fig. 18 is shown a comparison of the on-axis responses with and without damping (the level is reduced in order to accommodate the large undamped excursions), together with the high frequency approximation, where the SPL is given by: $\text{SPL}=20\log_{10}|\tilde{p}(r,0)/(20\times 10^{-6})|$. The normalized directivity function $20\log_{10}|D(\theta)|/|D(0)|$ is plotted in Fig. 19 for various values of ka.

IV. FINITE ELEMENT MODEL

Abaqus CAE v6.5-5 was used for the finite element analysis. In order to save processing power, only a quarter membrane was simulated. The analysis was carried out in two steps using a cylindrical coordinate system. In the first step, a boundary condition was applied to rim of the quarter membrane, which blocked axial or tangential displacement, but allowed radial displacement. Also, a boundary condition of zero tangential displacement was applied to its two straight edges. A pretension T was applied to the rim node set using the formula

$$\text{Force per node} = 0.5\pi aT/(\text{No. of nodes}). \tag{120}$$

The second step was a steady-state dynamics analysis in which an evenly distributed pressure of $\tilde{p}_I=1$ Pa was applied to the membrane surface. A limitation is that there is no obvious way to simulate the viscous acoustic resistance presented by a perforated screen or mesh. The elements used for the simulation are described in Table I.

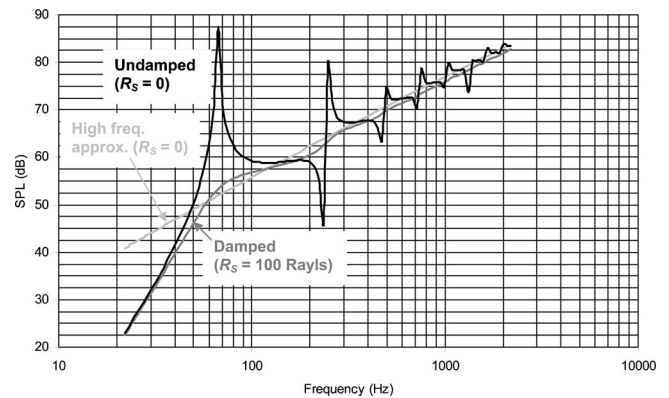
The membrane was surrounded by a quarter-sphere of air with a radius of 0.5 m. The outer curved surface of this quarter-sphere was coated with a skin of infinite elements in order to prevent reflections. The air space was created as two separate front and rear segments, which both had their adjoining faces partitioned where they met the rim of the membrane. Each was tied to one of the surfaces of the membrane and, in the case of the unbaffled membrane, to each other beyond the rim. Hence, in order to simulate an infinite baffle, the coupling between the air segments was omitted so that the rigid boundary condition at the baffle was created auto-
FIG. 17. On-axis pressure response of push-pull electrostatic loudspeaker in infinite baffle where $a=250$ mm, $h=12$ μm, T=700 N/m, $\rho_D=1400$ kg/m³, $e_{\text{in}}=2000$ V$_{\text{rms}}$, $E_P=3000$ V, $d=2$ mm, $r=1$ m, and $R_S=100$ Ns/m³.


FIG. 18. On-axis pressure response with same parameters as in Fig. 18, except $e_{in}=40$ V$_{rms}$, and with $R_S=0$ (undamped).

matically without having to create a separate baffle surface. This also allowed the same mesh to be used for both simulations.

The outer curved edges of the air space were seeded with a node density of 80 nodes/m (or 6 nodes/wavelength in free space at 4.6 kHz). The edges of the membrane were seeded with higher density of 400 nodes/m (or 6 nodes/wavelength in the membrane at 4.7 kHz), as were also the adjacent edges of the air space to which its edges were tied. The remaining straight edges of the air space were left unseeded. Free meshing was used throughout. The total number of air elements was 588 757 with minimum and maximum angles of 7.5° and 143.4°, respectively. The number of membrane elements was 4824 with minimum and maximum angles of 29° and 115°, respectively. The finite size of the air space produced some errors below 170 Hz, so the analysis at these frequencies was performed using a 2.5 m radius quarter-sphere with a coarser mesh density to save memory and processing time. The on-axis responses without and with a baffle are shown in Figs. 20 and 21, respectively.

V. DISCUSSION

At low to medium frequencies, the analytical calculations and FEM results show excellent agreement, as can be seen in Figs. 20 and 21. However, above 1 kHz some divergence occurs. This is in no doubt partly due to the discretization of the finite element model, which has a density of 6 elements per wavelength at the highest frequency shown. There could also be some differences due to the fact that the FEM response was calculated at a distance 0.5 m from the source and then adjusted to 1 m by subtracting 6 dB, whereas the analytical result was calculated using the far-field asymptotic expression. The analytical calculations for the free space membrane without damping show good agreement with Streng's results[5] too.

It is interesting to see how the free space radiation impedance in Fig. 5 is an almost monotonic function when compared with that of a rigid disc. In this respect, it is more like that of a resilient disc in free space [13] (or "freely suspended disc"),[14] which is perhaps not surprising, considering that the membrane is essentially a more or less evenly distributed pressure source (i.e., transparent) rather than velocity one (i.e., opaque). As can be seen from the near-field pres-
FIG. 19. Normalized far-field directivity function in infinite baffle with same parameters as in Fig. 17.

sure plots of Fig. 8, the surface pressure becomes more evenly distributed at higher values of ka. However, one important difference between a membrane and a resilient disc is that the membrane is clamped at its outer edge whereas the resilient disc is free and therefore not realizable.[13] Interestingly, the real part of the membrane's radiation impedance at low frequencies is greater than that of the rigid disk, possibly due to the fact that its perimeter is clamped so that most of the sound is radiated from the center, with the remainder acting as a semibaffle to mitigate the acoustic "short-circuit" between the front and rear surfaces.

The baffled radiation impedance in Fig. 14 is also a fairly smooth function, compared to that of a rigid disk, and is therefore closer to the characteristic of a resilient disk in an infinite baffle[10] (or plane wave diffracted through a circu-

FIG. 20. On-axis pressure response in free space without damping: comparison of analytical and FEM models, where $a=125$ mm, $h=12$ μm, $T=100$ N/m, $\rho_D=1667$ kg/m^3, $p_I=1$ Pa, $r=1$ m, and $z_S=0$.

FIG. 21. On-axis pressure response in infinite baffle without damping: comparison of analytical and FEM models, where $a=125$ mm, $h=12$ μm, $T=100$ N/m, $\rho_D=1667$ kg/m^3, $p_I=1$ Pa, $r=1$ m, and $z_S=0$.

lar aperture)[6]. As can be seen from the near-field pressure plots of Fig. 16, the surface pressure eventually becomes more evenly distributed at higher values of ka and so converges towards the flat pressure distribution of a resilient disk.

It can be seen from Figs. 4 and 13 that the motional impedance in the "piston range" above 440 Hz (or $ka>2$) is mainly resistive, as is also the radiation impedance shown in Figs. 5 and 14. In this region, as the commonly used term "piston range" suggests, the diaphragm effectively radiates sound power into the surrounding space and it is here that the efficiency (see Figs. 9 and 17) is highest. The rising on-axis response in this region appears to be fairly consistent with that predicted by Walker's equation, a fairly detailed discussion of which is provided by Baxendall[1] (edited by Borwick). This equation generally describes the free space on-axis pressure response (with some damping) between the fundamental resonance and the point at which the diaphragm inertia, together with the acoustic (mainly radiation) resistance, starts to take control. If the electrode structure were to be partitioned into concentric rings, as described by Walker,[21] the on-axis response in the piston range could, in theory, be equalized and it would be interesting to see this included in the model. Also, the polar responses of Figs. 11 and 19 could be widened without losing power. The effect of the baffle is to equalize the on-axis response in the lower frequency range ($ka>2$) so that, with electrode partitioning, it could be fairly flat all the way from the fundamental resonance to the high frequency roll-off, at which the diaphragm inertia begins to dominate.

The motional impedance has a minimum value at the fundamental resonance, which is at 67 Hz in free space (see Fig. 4) and 53 Hz in a baffle (see Fig. 13). Here, the efficiency is lowest because most of the power is being dissipated in the acoustic damping resistance. (This behavior is in contrast with that of an electrodynamic loudspeaker, which tends to be most efficient at the suspension resonance and then becomes less efficient with increasing frequency.) Not surprisingly, adding a baffle greatly improves the efficiency in this region. Below the fundamental resonance, the slope of
the on-axis response is 18 dB/octave in free space and 12 dB/octave in a baffle.

VI. CONCLUSIONS

A more direct method has been presented for calculating the radiation characteristics of a circular membrane in free space than previously available. Furthermore, the method has been extended to allow for the inclusion of an infinite baffle. In particular, equations have been derived for the motional impedance and diaphragm impedance, as well as expansions for the pressure field. The final equations for calculating the power series coefficients of the free space and baffled membranes are remarkably similar in form. Most of the terms are the same, but are just arranged differently. However, the pressure field is much easier to calculate for the baffled membrane when the distance to the observation point is greater than its radius.

It has also been shown how this model can be used as a benchmark for simulation using tools such as FEM. It is not intended, though, in this analytical versus FEM comparison, to select a "winner." On the contrary, the two approaches appear to be somewhat complementary. Whereas FEM is better suited to complicated geometries, analytical simulations tend to be limited to simply geometry, typically axisymmetric (i.e., two-dimensional). On the other hand, the analytical approach has distinct advantages at the frequency extremes and in deriving far-field asymptotic expressions. Furthermore, describing a model with equations provides us with a greater insight into the actual physics of the problem.

Multiload procedure to measure the acoustic scattering matrix of a duct discontinuity for higher order mode propagation conditions

Azzedine Sitel, Jean-Michel Ville,[a] and Felix Foucart
Laboratoire Roberval FRE UTC-CNRS No. 2833, Université de Technologie de Compiègne,
BP 20529 F60205, Compiègne Cedex, France

A procedure for measuring the acoustic scattering matrix coefficients of a duct discontinuity for higher order acoustic duct mode propagation conditions is described and tested. The technique requires measurement of pressure waves per mode coming in and out of the discontinuity. Assuming N cut-on modes, the $(2N)^2$ scattering matrix coefficients are determined after repeating the experiment for N linearly independent pressure distributions for at least two load configurations. Experiments were conducted for a straight duct and a reactive chamber. A good agreement was found between experiment and theory except near cut-off frequencies. The overdetermination method based on four loads was shown to improve the results. An analytical simulation of the experiment was developed to compute the influence on the $[S]$ calculation of an error in temperature and total modal pressure assumed to be representative of a real measurement situation. This simulation with a discussion explains the discrepancies between experiment and theory. The test with the chamber shows that the load method fails as expected in determining the coefficients associated to the wave coming in the discontinuity from the open end side because of the property of the middle duct to filter modes making the results very sensitive to uncertainties. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354040]

I. INTRODUCTION

Sound propagation in duct systems is a problem of considerable practical interest for automotive, building, and aeronautic industries. A pipe system is usually considered as a network of straight ducts coupled together via various passive elements such as mufflers, bends, T-sections, etc. In order to analyze and optimize sound transmission, reflection, and radiation through and from those basic elements a formalism based on transfer matrix method[1,2] has been developed and most often used by manufacturers to design, for example, exhaust lines and air conditioning circuits. The scattering matrix formalism which uses the traveling wave amplitudes as state variables has been shown to be more attractive than transfer or mobility matrices since it reflects the fundamental waveguide nature of the problem allowing one to develop, for example, a general proposal for analyzing acoustic two-port networks[3,4] or to deduce acoustic energy dissipation or production in a multiport.[5]

Over the years a number of papers have been published on techniques based on two-loads and two source methods to perform measurements of the scattering matrix for plane wave propagation condition.[6,7]

Until now no specific measurement procedure which can be applied in higher order mode propagation conditions has been achieved. Only investigations on experimental methods to measure reflection and transmission matrices of discontinuities in a duct have been conducted.[8,9]

The aim of the paper is to present and test a method to measure the scattering matrix $[S]$ of a discontinuity for higher order mode propagation conditions. Unlike the reflection or transmission matrices, the scattering matrix of size $2N \times 2N$ (N being the number of cut-on modes) gives a more complete description of the discontinuity. Indeed it is independent of the open end duct conditions and can then be integrated in computer programs used for the conception of complex duct networks.

In Sec. II, after presenting the definition of the scattering matrix, the theory which the method is based on is described. In Sec. III, the experimental facility, the two duct discontinuities tested, and the procedure which leads to the determination of the scattering matrix are detailed. In the Sec. IV the experimental results are compared with theory for both duct configurations. Moreover an analytical simulation of the experiment is performed to study the sensibility of the $[S]$ coefficients to some parameters of the experiment such as temperature, microphone locations, and modal coefficients and used to explain some discrepancies observed between experiment and theory.

II. THEORETICAL BASIS

A. Definition of the scattering matrix $[S]$ of a discontinuity

The scattering matrix $[S]$ of a discontinuity (in grey in Fig. 1) located between the axial coordinates z_L on side I and z_R on side II (L and R mean, respectively, the left side and right side of the discontinuity) and linked to two waveguides is a linear relationship between the incoming pressure wave
FIG. 1. Waves coming in and out of the discontinuity in gray from sides I and II.

vector $\{P^{in}\}_{2N}=\{P^{I+}_{mn}(z_L), P^{II-}_{mn}(z_R)\}^t_N$ and the outcoming pressure wave vector $\{P^{out}\}_{2N}=\{P^{I-}_{mn}(z_L), P^{II+}_{mn}(z_R)\}^t_N$ where N is the number of modes in both cross sections:[10]

$$\{P^{out}\}_{2N} = [S]_{2N\times 2N} \times \{P^{in}\}_{2N} \quad \text{with} \tag{1}$$

$$[S] = \begin{bmatrix} [S^{11}]_{N\times N} & [S^{12}]_{N\times N} \\ [S^{21}]_{N\times N} & [S^{22}]_{N\times N} \end{bmatrix}_{2N\times 2N}.$$

This matrix, which depicts only the discontinuity, is independent of the upstream and downstream acoustic conditions and is filled by $(2N)^2$ coefficients:

$$S^{kl}_{mn,pq}, \quad k,l = 1,2 \quad \text{and} \quad m,n,p,q = 1,2,\dots,N.$$

The physical meaning of each elementary matrix is as follows: $[S^{11}_{mn,pq}]_{N\times N}$ is the reflection of the wave coming in the element from the left side; $[S^{21}_{mn,pq}]_{N\times N}$ is the transmission of the wave coming in the element from the left side; $[S^{22}_{mn,pq}]_{N\times N}$ is the reflection of the wave coming in the element from the right side; $[S^{12}_{mn,pq}]_{N\times N}$ is the transmission of the wave coming in the element from the right side.

B. Theory of the procedure to measure the scattering matrix [S] of a discontinuity

In no flow conditions, the fluid is assumed to be ideal and linear acoustic theory to be valid. As the discontinuity under test is connected to and between two hard wall cylindrical ducts with radius a (main duct) at axial coordinates z_L and z_R (Fig. 1), the acoustic pressure distribution in the main duct is written[11] in cylindrical coordinates (r, Θ, z) as

$$p(r,\theta,z,t) = \sum_{m=-\infty}^{+\infty} \sum_{n=0}^{\infty} P_{mn}(z)\Psi^a_{mn}(r,\theta)e^{-i\omega t}, \tag{2}$$

where $\Psi^a_{mn}(r,\theta)=J_m(\chi_{mn}/a)e^{im\theta}$ are the eigenfunctions; the integers m and n are, respectively, the angular wave number and the radial number ($m=0$, $n=0$ is the plane wave); J_m is the Bessel function of the first kind of order m; χ_{mn}/a is the nth root satisfying the radial hard wall boundary condition on the wall of the main duct $J'_m(\chi_{mn}/a)=0$. The total modal pressure coefficients $P_{mn}(z)$ in the cross sections located at axial coordinates z_L and z_R are given by the following relationship:

$$P_{mn}(z) = [P^+_{mn}(z) + P^-_{mn}(z)], \tag{3}$$

where pressure waves traveling in the positive and negative z directions are depicted, respectively, in regions I and II by $P^{I\pm}_{mn}(z)=P^{I\pm}_{mn}(0)e^{\pm ik_{mn}z}$ and $P^{II\pm}_{mn}(z)=P^{II\pm}_{mn}(0)e^{\pm ik_{mn}z}$. k_{mn}

$= \sqrt{k^2-(\chi_{mn}/a)^2}$ is the axial wave number of mode (m,n) in the main duct, $k=2\pi f/c_0$, f the frequency, and c_0 the speed of sound in air.

The $(2N)^2$ coefficients of $[S]$ are solutions of the following system deduced from Eq. (1):

$$[S^{kl}_{mn,pq}]_{2N\times 2N} = [P^{out}]_{2N\times 2N} \times [P^{in}]^{-1}_{2N\times 2N}. \tag{4}$$

To fill the $2N$ columns of $[P^{out}]_{2N\times 2N}$ and $[P^{in}]_{2N\times 2N}$, $2N$ linearly independent modal pressure distributions have to be produced and measured by the experiment in both cross sections located at z_L and z_R and incident and reflected modal pressure waves separated.

III. THE EXPERIMENTAL SETUP AND DATA PROCESSING

The measurement of $[S]$ was carried out with the duct facility built under a grant with E.E.C. during the Ducat program,[12] which was already used to measure reflection and transmission matrices.[9] The pressure distributions measured in two closed cross sections before and after the duct under test by two pairs of microphones are Fourier Lommel's transform[13] then the incident and reflected modes are separated.[9] If N is now the number of cut-on modes, a "selective" computation of the $2N\times 2N$ coefficients of $[S]$ is then performed after a process based on the generation of N independent incident fields for two- or six-load cases depending on the direct or overdetermination procedure is achieved. The load method was chosen instead of the source[7] one because of practical considerations.

A. Hardware

The facility is installed in the anechoic chamber of the University of Technology of Compiegne. The equipment is made of 0.5-m-long duct components with 0.01-m-thick steel wall which all have a 0.148-m internal diameter except of course part of the test duct element. From the left to the right of the schema (Fig. 2) are shown the following elements:

(1) Absorbent element to avoid reflection upstream.
(2) The source section with three acoustic drivers flushed mounted in a z line. The axial distance between two drivers is 0.15 m. All this section can rotate over 360°.
(3) The measurement duct element I which can rotate over 360° is supporting a boom traversing on the radius with a B&K sound intensity probe attached and directed toward the z axis. The distance between the 1/4 in. microphones is 0.054 m according to well-known conditions.[8,13,14]
(4) The 0.5-m-long duct element which will be part of the test configuration.
(5) The measurement duct element II is identical to the duct element I.

Noise is radiated in the anechoic chamber through an unflanged inlet duct which constitutes the load. The different load conditions will be created by changing only the length of this duct. Angular and radial displacements are provided by step by step motors. A working station automatically op-

erates the rotation of the source section, the choice of the axial source, and the displacements of the probe in the r and Θ directions. It also supplies the noise generation to sources and the acquisition through an analog-digital converter of the signals issued from the four microphones.

B. The data processing

The experimental procedure is divided into the following steps:

(1) For each load and source configuration:

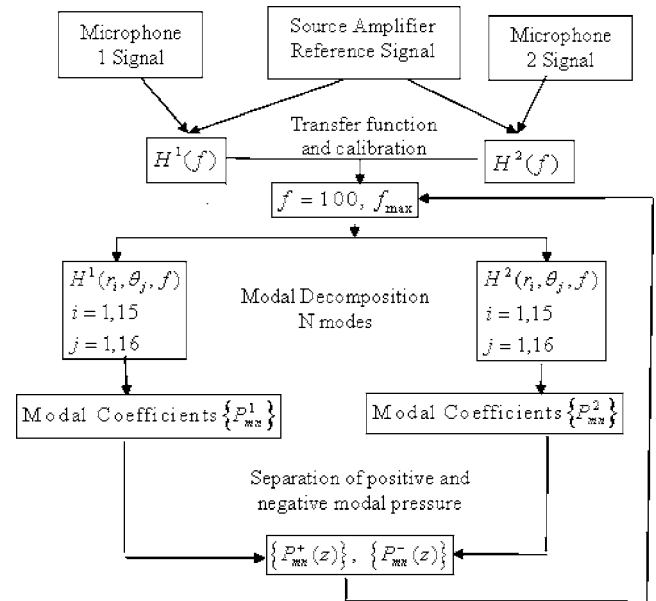
   (a) Collect the frequency spectra of the total modal coefficients in two closed cross sections located in both measurement duct elements.

   (b) Separate the incident and reflected modal pressure vectors.

(2) Postprocess the incident and reflected modal pressure vectors on both sides of the test duct element for the N source configurations and two or several loads to get the in and out wave matrices in z_L and z_R.

(3) Compute the scattering matrix.

1. Data collection and reduction

During the first step described in Fig. 3 the acoustic driver is driven with a white noise signal that is band limited to 0–2700 Hz. For this duct radius and frequency range the total adimensional wave number ka is lower than 3.8. Therefore only $N \leqslant 5$ modes (0,0); (± 1,0); (± 2,0) are cut-on. The transfer functions between the amplifier and microphone signals provide, after calibration, the amplitude and phase of the local total acoustic pressure normalized by the level of the amplifier. The origin of the z axis is then given by the reference phase that is in the source z axis position. A 240-point discretization of the acoustic pressure field measured in each of the two pairs of cross-section areas is achieved by rotating the measurement duct section at 16 positions equally spaced by 22.5° and displacing the probe to 15 radial positions.


Then modal decomposition by a Fourier-Lommel's transform[8,13] for $m = -7$ to $+7$ and $n = 0$ to 3 is achieved leading to the cut-on or cut-off complex modal pressure coefficients in both pairs of cross-section areas. The incident and reflected modal vectors are then separated and computed at z_L and z_R.

All this procedure is repeated for all source configurations and loads. To compute the 100 coefficients of the matrix $[S]$, at least 10 experiments (5 source configurations and 2 loads) have to be performed. The 5 source configurations and loads have been chosen[8] to ensure generation of linearly independent input modal vectors. The coordinates of the source and the characteristics of the loads used are given in Table I.

2. Data postprocessing (Fig. 4)

At the end of the first step the modal coefficient vectors $\{P_{mn}^{I+}(z_L)\}\{P_{mn}^{II+}(z_R)\}$ of the positive waves and $\{P_{mn}^{I-}(z_L)\}$ $\times\{P_{mn}^{II-}(z_R)\}$ of the negative waves are available at each side of the discontinuity for each source and load configurations and the matrices $[P^{in}]_{2N \times 2N}$ and $[P^{out}]_{2N \times 2N}$ are filled. The scattering matrix is then deduced from the relationship Eq. (4) during the second step as shown in Fig. 4.

Equation (4) can be solved in two ways:

(1) With the "selective" method, the rank of $[S]$ is linked to the number of cut-on modes and will then depend upon the frequency. Only the propagating modes are taken into account assuming that the influence of the cut-off modes can be neglected.

(2) With the "global" method, the rank of $[S]$ is constant being independent of the frequency and fixed in relation to the higher limit of the frequency band studied, i.e., 2700 Hz, $N = 5$ and the rank of $[S] = 100$ in our experiment. The overall modal basis is considered including the nonpropagating modes.

FIG. 4. Flow chart of the scattering matrix coefficients calculation.

C. The configurations tested

The axial positions z_R and z_L defined in Fig. 1 correspond, respectively, to the axial coordinates of the two microphones located on each side of the duct under test. Then the duct element for which the scattering matrix is measured is 1 m long including the 0.5-m-long test duct and parts of the measurement ducts. The two discontinuities tested are symmetrical in relation to the duct axis and to the axial centerline. The first configuration is a 0.5-m-long element duct which is identical to the other elements. It has been chosen to become a reference test because its theoretical scattering matrix is well known (Appendix B) and also because the experimental conditions are more favorable with respect to the stationary wave problem. The second configuration is a reactive type chamber shown in Fig. 5 which introduces more complicated measurement conditions. It is made with the reference 0.5-m-long straight duct in which a 5.5-cm-diam axisymmetric cylindrical duct is mounted.

IV. ANALYSIS OF THE EXPERIMENTAL RESULTS

To analyze the experimental results several theoretical developments have been achieved:

Later on in this paper (Sec. V C 2), the experimental results of the calculation of a $[S]$ coefficient (Fig. 19) deduced from both techniques will be compared and show they provide nearly the same result. Therefore the "selective" method has been chosen to solve Eq. (4). It is well known that this direct method based upon the inversion of the $[P^{in}]_{2N \times 2N}$ matrix [Eq. (4)] leads to numerical problems. To avoid this difficulty an overdetermination technique[15,16] often used to solve a system where the number of equations $L \times N$ ($L > 2$) is higher than $2N$ the number of unknowns was developed. The scattering matrix $[S]$ is then now deduced from the relationship:[17]

$$[S]_{2N \times 2N}^T = [[^*[P^{in}]_{2N \times (L \times N)}$$
$$\times [P^{in}]_{2N \times (L \times N)}^T]^{-1}$$
$$\times {}^*[P^{in}]_{2N \times (L \times N)}] \cdot [P^{out}]_{2N \times (L \times N)}^T. \quad (5)$$

The columns of the rectangular matrices $[P^{in}]_{2N \times (L \times N)}$ and $[P^{out}]_{2N \times (L \times N)}$ are filled by repeating N experiments associated to N source configurations for $L = 4$ or 6 load configurations ensuring[8] again that the $L \times N$ pressure distributions are linearly independent.

FIG. 5. The reactive muffler located between z_L and z_R.

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Sitel *et al.*: Acoustic scattering matrix measurement   2481

(1) A theoretical calculation of $[S]$ for both configurations which the experimental results are compared with.

(2) An analytical simulation of the experiment and an error calculation on the determination of $\{P_{mn}^{I+}(z_L)\}$ and $\{P_{mn}^{I-}(z_L)\}$ by the separation procedure to discuss the discrepancies between experiment and theory.

Among the $(2N)^2 = 100$ coefficients $(N=5)$ of $[S]$ only typical results for the plane wave and for higher order modes $m=1$ and 2 are presented emphasizing the symmetry properties of both discontinuities.

A. Influence of errors

The resulting error on the calculation of $[S]$ will depend on two things: (1) the errors in the input measured data, i.e., temperature, transfer functions, and position of the microphones; and (2) the sensivity to errors in the input data of the calculation formulas, i.e., induct modal decomposition, incident and reflected waves separation, and calculation of $[S]$.

During a previous study[14] on the influence of errors on the two-microphone separation method assuming plane wave propagation condition, some practical conclusions about the overall length of the duct, the reflective conditions on the source and open end sides were drawn in order to keep error in the transfer function estimate at 1% in the magnitude and 0.6° in phase. Also as a result of this study, a condition on the distance d between microphones which has to be respected in order to avoid a very large sensitivity to errors in input data during the separation procedure was deduced. In our experiment this distance d was chosen equal to 5.4 cm in order to respect this condition leading to an upper frequency limit of 2700 Hz (Sec. III A). For higher order mode propagation conditions, the sensitivity to the modal decomposition technique in the microphone location and signal to noise ratio was already discussed during previous works.[18] Assuming the technique to be a generalization of this developed for plane wave case[8,19] the optimal distance of separation was extended to higher order mode propagation conditions.

The calculation of error presented in this paper based upon a direct simulation of the experiment described in the following begins by the separation procedure and includes the calculation of $[S]$, then excluding the sensitivity to errors in the input data to the modal decomposition stage which is therefore considered as a known input data to the simulation program as shown in Fig. 6. Moreover, an analytical calculation of the error produced by the separation process based on a first-order Taylor expansion of the calculation formulas is presented in Appendix D. Results of this study will emphasize for higher order mode propagation condition the high sensitivity of this step to errors in input data such as temperature and total modal pressure when the frequency becomes very close to the cut-off mode frequency while for the plane wave the sensitivity to the error on temperature can be neglected compared to the error on total modal pressure.[20]

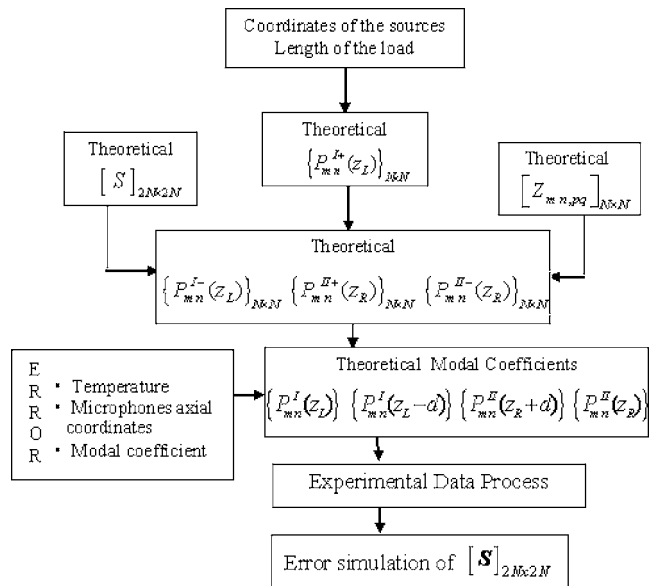
Another effect to be considered is the influence from the nonpropagating mode on the measurement of $[S]$. According to a study which discusses this matter for the plane wave case[14] the microphones should not be placed closer than about 10 mm from the discontinuity or a sample to avoid the


FIG. 6. Flow chart of the error estimation by a simulation process of the experiment.

effect of near field. For higher order mode propagation condition when the frequency approaches the cut-off frequency the influence of the evanescent mode increases as the "damping" length becomes long. In the present study the modal basis which the decomposition technique is calculated with, includes all modes up to $m = \pm 7$, $n = 3$ whatever the frequency is (Sec. III B 1) avoiding the influence of the evanescent modes up to the separation step included in the frequency band studied. Another problem is to include in the calculation of the matrix $[S]$ the conversion coefficients in reflection and transmission from a cut-on mode to a cut-off mode which assumes the modal basis used in Eq. (4) is extended to the nonpropagating modes. It will be shown in Sec. V C 2 that for an axisymmetric discontinuity in the frequency domain down to the cutoff frequency of the $(0,1)$ and as the distance between the discontinuity and the measurement cross section is far enough, the influence of the evanescent modes can be neglected. This assumption was already verified in previous studies where reflection and transmission matrices were measured.[8,9]

Then the direct simulation program has provided the calculation of error produced through the matrix scattering formulas for a 5° error on temperature and (1°, 5%) error on, respectively, the phase and the amplitude of the total modal pressure coefficients measured in both cross section values assumed to be representative of a real measurement situation.

B. Theoretical simulation of the experiment

1. Theory of the simulation

Figure 7 shows the duct arrangement used to simulate the experiment. It is made of the duct element located between z_L and z_R and defined by its theoretical scattering matrix $[S]$. On the left side of this duct element a semi-infinite duct is supporting the source section and on the right side a finite length duct is radiating outside through an infinite baffled open end. The total pressures in the four cross sections where the microphones are located are then calculated
FIG. 7. Duct configuration of the simulation process.

Experiment (2 loads : - - -) ; Experiment (6 loads : ———)

Theory : — — —

FIG. 8. Comparison with theory for the straight duct configuration of $|S_{00,00}^{2,1}|$, the experimental transmission coefficient vs ka of the plane wave mode traveling from the left to the right side deduced from the direct and overdetermination methods.

analytically for each source and load configuration listed in Table I. To perform this simulation the following analytical calculations have to be carried out:

(1) The scattering matrix $[S]$ (Appendices A and B).
(2) The impedance matrix $[Z_{mn,pq}]_{N \times N}$ of the open end reflection.[19]
(3) The incident pressure matrix in the semi-infinite duct $\{P_{mn}^{I+}(z_L)\}_{N \times N}$ deduced for each of the N source configurations (Table I) assuming a point source defined by its amplitude $A_s = 1$ and phase $\varphi_s = 0$ and located at (z_s, θ_s, a).
(4) The modal pressure coefficients in both duct cross-section areas for all sources and loads configurations given in Table I (Appendix C).

2. The simulation procedure

The flow chart of the simulation procedure is described in Fig. 6. Its validation was carried out by introducing the theoretical values of $[S]$ and verifying that when no errors are assumed the procedure results in the same matrix $[S]$. The sensitivity of $[S]$ to errors on the following parameters were then studied by introducing errors on the temperature, modulus and phase of the modal pressure coefficients, and axial positions of the microphones.

C. Experimental results

1. Straight duct

Influence of the number of loads on the experimental results. The advantage of the overdetermination procedure over the direct method is clear in Fig. 8 where the variations of the transmission coefficient of the plane wave $S_{00,00}^{1,2}$ vs ka for two and six loads are compared with theory. All "instabilities" in the high frequency domain have been avoided when the overdetermination method is performed. As a consequence, all other results presented in the paper were carried out with the overdetermination method with six loads.

Analysis of some $[S]$ coefficients. The modulus of the transmission coefficients $[S_{00,00}^{1,2}; S_{00,00}^{2,1}]$ and reflection ones $[S_{00,00}^{1,1}; S_{00,00}^{2,2}]$ for the plane wave $(0,0)$ coming in the discontinuity from the left and right sides respectively, are plotted versus ka up to 3.8 and compared to the analytical results in Fig. 9. In Fig. 10 the same results are presented for the higher order mode case $(-1,0)$. At once the three following comments have to be made:
(1) The experimental curves $S_{m0,m0}^{2,1}$, $S_{m0,m0}^{1,1}$ are nearly superimposed on, respectively, $S_{m0,m0}^{1,2}$, $S_{m0,m0}^{2,2}$ for $m = 0, -1$ verifying the symmetry property of the element with respect to its median plan.
(2) The experiment underestimates the theoretical transmission coefficients for both modes near the cut-off frequency, for $1.5 < ka < 2$ and for ka close to 3. Also a slow increase with frequency from 0 at the cut-off frequency to 1 instead of the step function predicted by theory is evident for $m = -1$.
(3) The experimental reflection coefficients oscillate between 0 and 0.2 reaching higher values near cut-off frequencies in opposite to the theory which predicts no reflection.

FIG. 10. For the straight duct configuration: (a) Comparison with theory of $|S^{2,1}_{-10,-10}|$ and $|S^{1,2}_{-10,-10}|$ the transmission coefficients vs ka of mode $(-1,0)$ traveling, respectively, from the left to the right side and from the right to the left side; (b) $|S^{1,1}_{-10,-10}|$ and $|S^{2,2}_{-10,-10}|$ the experimental reflection coefficients vs ka of mode $(-1,0)$ coming in the straight duct from the left side and from the right side, respectively.

The effect on the coefficients $S^{2,1}_{-10,-10}$ and $S^{1,1}_{-10,-10}$ of a 5° discrepancy on temperature and $(1°, 5\%)$ error on, respectively, the phase and the amplitude of modal pressure coefficients in two of the cross-section areas was estimated with the simulation procedure. In Fig. 11 the comparison between simulated and experimental results points out that these coefficients are very sensitive to errors but only in the frequency domain very close to the cut-off mode frequency. In Appendix D, this influence is shown to come from the sensitivity of the separation procedure in the input data such as temperature and total modal pressure explaining only part of the difference between experiment and theory. Indeed the periodic oscillation on the reflection coefficient and the slow variation of the transmission coefficient noticed before on mode $m=-1$ are not due to errors but caused by a physical phenomenon which is probably, as justified in the following, produced by a vibration of the duct wall. Indeed, the step variation of the theoretical transmission coefficient at the cut-off frequency and the nonreflection assume that the normal velocity on the wall is zero. But it is well known that this condition is not realistic and a coupling between acoustic duct cavity and duct wall vibration always occurs and can become stronger particularly when the frequency approaches by upper values the mode cut-off frequency.

Typical experimental results of the conversion coefficients of mode $m=-1$ into $m=0$ in transmission and reflection for waves coming in the discontinuity from the left and the right sides, respectively, are plotted in Fig. 12. All coefficients are lower than 0.1 except near the cut-off frequencies of modes. This result verifies the property of axisymmetry of the element which leads theoretically to no conversion between angular modes. Moreover, the couples of curves

FIG. 13. Comparison for the reactive duct configuration between theory and experiment of: (a) $|S^{2,1}_{00,00}|$ and $|S^{1,2}_{00,00}|$ the transmission coefficients vs ka of mode $(0,0)$ traveling, respectively, from the left to the right side and from the right to the left side; (b) $|S^{1,1}_{00,00}|$ and $|S^{2,2}_{00,00}|$ the reflection coefficients of mode $(0,0)$ coming in the element, respectively, from the left side and from the right side.

FIG. 14. Comparison for the reactive duct configuration between theory and experiment of: (a) $|S^{2,1}_{+10,+10}|$ and $|S^{1,2}_{+10,+10}|$ the transmission coefficients vs ka of mode $(+1,0)$ traveling, respectively, from the left to the right side and from the right to the left side; (b) $|S^{1,1}_{+10,+10}|$ and $|S^{2,2}_{+10,+10}|$ the reflection coefficients vs ka of mode $(+1,0)$ coming in the element from the left side and from the right side, respectively.

through the duct element which contains the chamber for waves traveling from the left and the right sides are plotted for $m=0$, 1, and 2 and compared to the analytical results in Figs. 13, 14, and 16, respectively.

For the plane wave $m=0$ (Fig. 13) the agreement between experiment and theory is good but some differences have to be noticed:

(1) For $1.5 < ka < 2$ and around $ka=3$ the experimental transmission coefficient is smaller than the theoretical one as already observed before with the straight element and justified by a vibroacoustic coupling.

(2) The symmetry of the discontinuity with respect to its median plan is verified for $ka < 2$. The small diameter duct is filtering the pressure distributed on mode $m=1$ for $1.8 < ka < 2.51$ and $m=2$ for $3.05 < ka < 4.16$ (Table II) leading to a worse signal to noise ratio downstream of the chamber and then noisier coefficients $S^{1,2}_{00,00}$ and $S^{2,2}_{00,00}$ for waves traveling from the right to the left.

(3) Just below $ka=3.8$ the cut-off frequency of the mode $(0,1)$ the shift between experimental and theoretical minima and maxima is produced because the conversion of mode $(0,1)$ into $(0,0)$ is not taken into account by the analytical model.

The incident pressure $\boldsymbol{P}^{I+}_{10}(z)$ on mode $m=1$ on the source side is filtered by the chamber for $1.84 < ka < 2.51$ (Table II). Then in the analysis to follow the results associated to the waves traveling from the left and right sides of the chamber are discussed separately. Indeed Fig. 14 points

out the following:

(1) $S^{2,1}_{10,10}$ and $S^{1,1}_{10,10}$, the transmission and reflection coefficients for waves traveling from the left to the right, agree well with the theory.

(2) For ka up to 2.51 as $\boldsymbol{P}^{I+}_{10}(z)$ is filtered by the chamber, on the open side the pressure level is very low. The measurements of both coefficients $S^{1,2}_{10,10}$ and $S^{2,2}_{10,10}$ are based on the incoming wave traveling from the right side of the chamber. This pressure wave results from the reflection by the duct inlet of the wave which was already transmitted through the chamber. The pressure coming out on the left side of the chamber which is used to measure $S^{1,2}_{10,10}$ has then been filtered two times. This explains why in this frequency domain the signal to noise ratio becomes so low that such an important discrepancy occurs between experiment and theory and also why this error is more important on the transmission coefficient than on the reflection one. This effect is well reproduced (Fig. 15) by the simulation of the experiment where it was assumed a 5° discrepancy on temperature and 1°, 5% on,

TABLE II. Cut-off ka frequencies of duct with radius a and b.

(m,n)	ka ($a=7.48$ cm)	ka ($b=5.5$ cm)
$(0,0)$	0	0
$(\pm1,0)$	1.8412	2.51
$(\pm2,0)$	3.0542	4.16
FIG. 15. For the reactive duct configuration simulation of $|S^{2,1}_{+10,+10}|$ and $|S^{1,2}_{+10,+10}|$ the transmission coefficients vs ka of mode $(+1,0)$ with a 5° error on temperature and $(1°,5\%)$ error on, respectively, the phase and the amplitude of the modal pressure coefficients.

respectively, the phase and the amplitude of modal pressure coefficients in the two cross sections. This result emphasizes also that the measurement of this coefficient in this propagation condition is very sensitive to errors on the experimental parameters.

(3) For $ka > 2.51$ the symmetry of the discontinuity with respect to its median plan is verified even for the plane wave case because the coefficients which are associated to the waves traveling from the right to the left are noisier than those traveling from the left to the right.

The incident pressure distributed on mode $(2,0)$ is cut-off by the chamber for all the ka spectrum studied (Table II). The interpretation of the experimental results (Fig. 16) developed for the mode $(1,0)$ when it is cut-off has to be extended for the $(2,0)$ mode to all ka studied. Indeed the trans-
FIG. 16. Comparison for the reactive duct configuration with theory of: (a) $|S^{2,1}_{+20,+20}|$ and $|S^{1,2}_{+20,+20}|$ the experimental transmission coefficients vs ka of mode $(+2,0)$, respectively, from the left to the right side and from the right to the left side; (b) $|S^{1,1}_{+20,+20}|$ and $|S^{2,2}_{+10,+10}|$ the experimental reflection coefficients vs ka of mode $(+2,0)$ coming in the element from the left side and from the right side, respectively.
FIG. 17. For the reactive duct configuration, experimental conversion coefficients vs ka for mode $(-1,0)$ into $(0,0)$: (a) $|S^{2,1}_{00,-10}|$ and $|S^{1,2}_{00,-10}|$ transmission, respectively, from the left to the right side and from the right to the left side; (b) $|S^{1,1}_{00,-10}|$ and $|S^{2,2}_{00,-10}|$ reflection coming in the element from the left side and from the right side, respectively.

mission coefficient $S^{2,1}_{20,20}$ and the reflection one $S^{1,1}_{20,20}$ related to the wave traveling from the left to the right agree with theory. But the measurement of $S^{1,2}_{20,20}$ transmission coefficient resulting from the wave traveling from the right to the left is completely wrong while the reflection coefficient $S^{2,2}_{20,20}$ is better determined allowing one to verify the symmetry of the discontinuity with respect to the chamber median plan.

In Fig. 17 are plotted conversion coefficients in transmission and reflection of the mode $(-1,0)$ into the plane wave. Again the coefficients agree with theory, which predicts a zero value because of the axisymmetry of the geometry but only for the wave traveling from the left to the right. The computation by the simulation program of the conversion coefficients in reflection with errors on temperature and modal coefficients reproduces the experimental curves as shown in Fig. 18, verifying the high sensitivity of this measurement to uncertainties.

In Fig. 19, the results of the measurement of $|S^{2,1}_{10,10}|$, the modulus of the transmission coefficient versus ka already presented in Fig. 14, are compared with the results deduced when the modal basis used for the calculation of $[S]$ includes all five modes in the complete frequency domain meaning that the influence of the evanescent mode is taken into account. As both curves are superimposed, we can deduce that in our test configuration the nonpropagating modes can be neglected.

V. CONCLUSIONS

An experimental procedure was achieved to measure the scattering matrix of a duct discontinuity for higher order mode propagation conditions. Straight and reactive type silencer duct configurations were tested and the experimental
FIG. 18. For the reactive duct configuration, simulation with a 5° error on temperature and $(1°, 5\%)$ errors on, respectively, the phase and the amplitude of the modal pressure coefficients of $|S_{00,-10}^{1,1}|$ and $|S_{00,-10}^{2,2}|$ the conversion coefficients vs ka in reflection for mode $(-1,0)$ into $(0,0)$ respectively coming in the element from the left side and from the right side.

results compared with theory. The analysis of the results performed mode per mode on the straight configuration showed that the overdetermination procedure with six loads improves the results. An analytical procedure of the experiment was developed and used to point out the sensitivity of the experimental parameters errors on $[S]$ measurements. Indeed, it was shown to be important but localized very near the mode cut-off frequency. The other differences between theoretical and experimental variations of the transmission and reflection coefficients are explained by the assumption of the non-realistic theoretical hard duct wall condition. The symmetry properties of the straight duct geometry with respect to the duct axis and its medium plan were verified experimentally.

The experiment with the reactive chamber has pointed out the filtering effect of a reduction of the diameter of the duct on acoustic modal propagation. Experimental and theoretical results agree in the frequency domain where the modes are cut-on in all test configurations. When the modes are cut-off by the smaller diameter duct the experimental results associated to the incident wave coming from the source side also agree with theory. But the method is unable to measure $[S]$, especially the transmission coefficient associated to the wave traveling from the open end side in this frequency domain. The simulation also shows that, in these conditions, the method is very sensitive to errors leading clearly to wrong results. When the discontinuity is not symmetric with respect to its middle plan, the two source technique or a permutation of the chamber has to be applied to improve the results.
FIG. 19. For the reactive duct configuration experimental $|S_{+10,+10}^{2,1}|$ the transmission coefficient vs ka of mode $(+1,0)$ traveling from the left to the right side deduced from selective and global methods.

APPENDIX A: CALCULATION OF THE SCATTERING MATRIX FROM A GIVEN TRANSFER MATRIX

The transfer matrix $[T]_{N\times N}$ of a duct element like this shown in Fig. 1 is defined by

$$\begin{Bmatrix} P^{II} \\ V_z^{II} \end{Bmatrix}_{2N} = [T]_{2N\times 2N} \times \begin{Bmatrix} P^{I} \\ V_z^{I} \end{Bmatrix}_{2N}. \qquad (A1)$$

P and V_z are, respectively, the total pressure and the axial acoustic particle velocity vectors expressed versus their modal description by

$$\{P^{I}, V_z^{I}\}_{2N} = \{P_{mn}^{I}(z_L), V_{z,mn}^{I}(z_L)\}_N^t, \qquad (A2)$$

$$\{P^{II}, V_z^{II}\}_{2N} = \{P_{mn}^{II}(z_R), V_{z,mn}^{II}(z_R)\}_N^t.$$

It is well known that the axial acoustic particle velocity is deduced from the pressure by[1]

$$V_{z,mn}(z) = Y_{mn}^a (P_{mn}^+(z) - P_{mn}^-(z)) \qquad (A3)$$

with $Y_{mn}^a = (k_{mn}^a / \rho_0 c_0 k)$.

Developing Eq. (A1) and replacing these total acoustic quantities versus the incident $(+)$ and reflected $(-)$ pressure and axial particle velocities two relationships are deduced:

$$\{P_{mn}^{II+}(z_R)\}_N + \{P_{mn}^{II-}(z_R)\}_N = [X^+]_{N\times N} \cdot \{P_{pq}^{I+}(z_L)\}_N$$
$$+ [X^-]_{N\times N} \cdot \{P_{pq}^{I-}(z_L)\}_N, \qquad (A4)$$

$$\{P_{mn}^{II+}(z_R)\}_N - \{P_{mn}^{II-}(z_R)\}_N = [W^+]_{N\times N} \cdot \{P_{pq}^{I+}(z_L)\}_N$$
$$+ [W^-]_{N\times N} \cdot \{P_{pq}^{I-}(z_L)\}_N, \qquad (A5)$$

where

$$[X^\pm]_{N\times N} = ([T^{11}]_{N\times N} \pm [\text{diag}(Y_{mn}^a)]_{N\times N} \cdot [T^{12}]_{N\times N}), \qquad (A6)$$

$$[W^\pm]_{N\times N} = [\text{diag}(Y_{mn}^a)]_{N\times N}^{-1} \cdot ([T^{21}]_{N\times N}$$
$$\pm [\text{diag}(Y_{mn}^a)]_{N\times N} \cdot [T^{22}]_{N\times N}). \qquad (A7)$$

As the scattering matrix is given by Eq. (1) and using Eqs. (A5) and (A6) the expressions of the four elementary matrices of $[S]$ vs $[X^\pm]_{N\times N}$ and $[W^\pm]_{N\times N}$ are deduced:

$$[S^{1,1}]_{N\times N} = [[[X^-]_{N\times N} - [W^-]_{N\times N}]^{-1} \cdot ([W^+]_{N\times N}$$
$$- [X^+]_{N\times N})]_{N\times N}, \qquad (A8)$$

$$[S^{1,2}]_{N\times N} = 2[[X^-]_{N\times N} - [W^-]_{N\times N}]_{N\times N}^{-1}, \qquad (A9)$$

$$[S^{2,2}]_{N\times N} = [-[[X^-]_{N\times N}^{-1} - [W^-]_{N\times N}^{-1}]^{-1} \cdot ([X^-]_{N\times N}^{-1}$$
$$+ [W^-]_{N\times N}^{-1})]_{N\times N}, \qquad (A10)$$

$$[S^{2,1}]_{N\times N} = [[[X^-]_{N\times N}^{-1}$$
$$- [W^-]_{N\times N}^{-1}]^{-1} \cdot ([X^-]_{N\times N}^{-1} \cdot [X^+]_{N\times N}$$
$$- [W^-]_{N\times N}^{-1} \cdot [W^+]_{N\times N})]_{N\times N}. \qquad (A11)$$
FIG. 20. Schema of the straight duct configuration.

FIG. 21. Schema of the reactive chamber configuration.

APPENDIX B: CALCULATION OF THE TRANSFER MATRICES OF THE STRAIGHT DUCT AND OF THE REACTIVE CHAMBER CONFIGURATIONS

The scattering matrices of both configurations are deduced from their transfer matrices using the relationships given in Appendix A. Then in the following paragraphs only the transfer matrices of both configurations are calculated.

The straight duct (Fig. 20). If N modes are cut-on in a straight duct with radius a located between z_L and z_R, its transfer matrix is defined[1] also by Eqs. (A1) and (A2). If $V_{z,mn}(z)$ is given by Eq. (A3), the transfer matrix of a straight element of radius a and length l is[1]

$$[T_{a,l}]_{2N\times 2N} = \begin{bmatrix} [\mathrm{diag}(\cos(k_{mn}^a l))]_{N\times N} & [\mathrm{diag}((i/Y_{mn}^a)\cdot\sin(k_{mn}^a l))]_{N\times N} \\ [\mathrm{diag}(iY_{mn}^a\cdot\sin(k_{mn}^a l))]_{N\times N} & [\mathrm{diag}(\cos(k_{mn}^a l))]_{N\times N} \end{bmatrix}_{2N\times 2N}. \tag{B1}$$

Reactive muffler (Fig. 21). If N modes are cut-on in the main duct with radius a, the transfer matrix of the duct element located between z_L and z_R is deduced by

$$[T]_{2N\times 2N} = [T_{a,l_a}]_{2N\times 2N}[T^{\mathrm{Const}}]_{2N\times 2N}$$
$$\times [T_{b,l_b}]_{2N\times 2N}[T^{\mathrm{Exp}}]_{2N\times 2N}[T_{a,l_a}]_{2N\times 2N}. \tag{B2}$$

$[T_{a,l_a}]_{2N\times 2N}$ is the transfer matrix of straight duct with radius a and length l_a. $[T_{b,l_b}]_{2N\times 2N}$ is the transfer matrix of straight duct with radius b and length l_b.

The transfer matrix of an expansion $[T^{\mathrm{Exp}}]_{2N\times 2N}$ is deduced by inversing the transfer matrix of the constriction matrix given by

$$[T^{\mathrm{Const}}]_{2N\times 2N} = \begin{bmatrix} [F]_{N\times N} & [0]_{N\times N} \\ [0]_{N\times N} & [G]_{N\times N}^{-1} \end{bmatrix}_{2N\times 2N}. \tag{B3}$$

$[F]_{N\times N}$ and $[G]_{N\times N}$ are deduced from the continuity boundary conditions on pressure and axial particle velocity in the duct crosssection S where the area modification occurs:[8]

$$F_{pq,mn} = \frac{1}{N_{pq}^b}\int\int_{S_b}\Psi_{mn}^a\Psi_{pq}^{b*}rdrd\theta, \tag{B4}$$

$$G_{mn,pq} = \frac{1}{N_{mn}^a}\int\int_{S_a}\Psi_{pq}^b\Psi_{mn}^{a*}rdrd\theta.$$

$N_{mn}^{b,a} = S_{b,a}J_m^2(\chi_{mn})[1-(m^2/\chi_{mn}^2)]$ is the normalization factor. $S_a = \pi(a)^2$ and $S_b = \pi(b)^2$.

APPENDIX C: COMPUTATION OF THE PRESSURE IN THE TWO PAIRS OF DUCT CROSS SECTIONS DURING THE SIMULATION PROCEDURE OF THE EXPERIMENT

The expression of the incident pressure $\{P_{mn}^{\mathrm{I}+}(z_L)\}_N$ distributed on N cut-on modes produced by a point source (Fig. 6) in the semi-infinite duct at z_L is given by[8]

$$\{P_{mn}^{\mathrm{I}+}(z_L)\}_N = \{\alpha_{mn}A_S e^{i(\varphi_S - m\theta_S + k_{mn}(z_L - z_S))}\}_N, \tag{C1}$$

where $\alpha_{mn} = 1/2ik_{mn}N_{mn}^a$, $A_S = 1$, and $\varphi_S = 0$ are, respectively, the phase and amplitude of the point source, θ_S and z_S are angular and axial positions of the point source.

The transmission matrix $[T_R]_{N\times N}$ of the duct element (Fig. 6) located between z_L and z_R is defined as a function of the incident and transmitted pressures distributed on the cut-on modes of the main duct by[9]

$$\{P_{mn}^{\mathrm{II}+}(z_R)\}_N = [T_R]_{N\times N}\cdot\{P_{mn}^{\mathrm{I}+}(z_L)\}_N. \tag{C2}$$

If $[R^{\mathrm{I}}(z_L)]_{N\times N}$ and $[R^{\mathrm{II}}(z_R)]_{N\times N}$ are the reflection matrices in both cross-section areas located at z_L and z_R apart from the discontinuity (Fig. 7) the incident and reflected pressures in z_L and z_R distributed on cut-on modes of the main duct are related by

$$\{P_{mn}^{\mathrm{II}-}(z_R)\}_N = [R^{\mathrm{II}}(z_R)]_{N\times N}\cdot\{P_{mn}^{\mathrm{II}+}(z_R)\}_N \quad\text{and} \tag{C3}$$

$$\{P_{mn}^{\mathrm{I}-}(z_L)\}_N = [R^{\mathrm{I}}(z_L)]_{N\times N}\cdot\{P_{mn}^{\mathrm{I}+}(z_L)\}_N.$$

The reflection matrix in z_R is deduced from the reflection matrix $[R^{\mathrm{II}}(z_{\mathrm{end}})]_{N\times N}$ in the open cross-section area located at z_{end} computed from a theoretical model which assumes an infinite baffle condition.[21]
FIG. 22. The relative uncertainty vs ka on the determination of the incident $(1,0)$ modal pressure by the separation technique to $5°$ in T or 5% in modulus of total modal coefficient.

FIG. 23. The relative uncertainty vs ka on the determination of the incident plane wave pressure by the separation technique to $5°$ in T or 5% in modulus of total modal coefficient.

$$[R^{\text{II}}(z_R)]_{N\times N} = [\text{diag}(e^{-ik_{mn}E})]_{N\times N}^{-1} \cdot [R^{\text{II}}(z_{\text{end}})]_{N\times N}$$
$$\times [\text{diag}(e^{+ik_{mn}E})]_{N\times N}. \tag{C4}$$

$[T_R]_{N\times N}$ and $[R^{\text{I}}(z_L)]_{N\times N}$ are deduced from the scattering matrix for a given length E load with the relationships:

$$[T_R]_{N\times N}$$
$$= [[I]_{N\times N} - [S^{22}]_{N\times N} \cdot [R^{\text{II}}(z_R)]_{N\times N}]^{-1}_{N\times N} \cdot [S^{21}]_{N\times N}, \tag{C5}$$

$$[R^{\text{I}}(z_L)]_{N\times N}$$
$$= [[S^{11}]_{N\times N} + [S^{12}]_{N\times N} \cdot [R^{\text{II}}(z_R)]_{N\times N} \cdot [T_R]_{N\times N}]_{N\times N}. \tag{C6}$$

The total acoustic pressures in the four cross sections located at $z_L, z_{L+d}, z_R,$ and z_{R+d} are then deduced by adding the incident and reflected pressures:

$$\{P_{mn}^{\text{I,II}}(z_{L,R})\}_N = \{P_{mn}^{\text{I,II}+}(z_{L,R})\}_N + \{P_{mn}^{\text{I,II}-}(z_{L,R})\}_N, \tag{C7}$$

$$\{P_{mn}^{\text{I,II}}(z_{L,R}+d)\}_N = [\text{diag}(e^{+ik_{mn}d})]_{N\times N} \cdot \{P_{mn}^{\text{I,II}+}(z_{L,R})\}_N$$
$$+ [\text{diag}(e^{-ik_{mn}d})]_{N\times N} \cdot \{P_{mn}^{\text{I,II}-}(z_{L,R})\}_N. \tag{C8}$$

This calculation is performed for $q=1$, N source configurations $(z_S, \theta_S)^q$ and all loads (Table I).

APPENDIX D: ANALYTIC SOLUTION OF THE ERROR CALCULATION ISSUED FROM THE SEPARATION TECHNIQUE

The complex incident and reflected modal pressures P_{mn}^+ and P_{mn}^- are solutions of the following system[19] where $P_{mn}^{1,2}$ are the total modal pressures in two cross sections separated by a distance d (Fig. 2):

$$P_{mn}^+ = \frac{P_{mn}^1 e^{-ik_{mn}d} - P_{mn}^2}{e^{-ik_{mn}d} - e^{ik_{mn}d}},$$

$$P_{mn}^- = \frac{P_{mn}^2 - P_{mn}^1 e^{ik_{mn}d}}{e^{-ik_{mn}d} - e^{ik_{mn}d}}. \tag{D1}$$

If $\Delta P_{mn}^{1,2}$, Δk_{mn}, and Δd are, respectively, the uncertainties on the total modal pressures $P_{mn}^{1,2}$, axial wave number, and distance, the error on $P_{mn}^\pm$ can be deduced from

$$\Delta P_{mn}^\pm \simeq \xi_{mn}^\pm \Delta P_{mn} + \eta_{mn}^\pm(d\Delta k_{mn} + k_{mn}\Delta d), \tag{D2}$$

where

$$\xi_{mn}^\pm = \frac{\partial P_{mn}^\pm}{\partial P_{mn}^1} + \frac{\partial P_{mn}^\pm}{\partial P_{mn}^2} = \frac{\pm e^{\mp ik_{mn}d} \pm 1}{e^{-ik_{mn}d} - e^{ik_{mn}d}},$$

$$\eta_{mn}^\pm = \frac{\partial P_{mn}^\pm}{\partial(k_{mn}d)} = \pm 2 \cdot i\left(\frac{P_{mn}^1 - P_{mn}^2\cos(k_{mn}d)}{(e^{-ik_{mn}d} - e^{ik_{mn}d})^2}\right).$$

Assuming a reflecting condition where the conversion is neglected:

$$P_{mn}^- = P_{mn}^+ R_{mn,mn} \Rightarrow \begin{cases} P_{mn}^1 = P_{mn}^+(1 + R_{mn,mn}) \\ P_{mn}^2 = P_{mn}^+(e^{ik_{mn}d} + e^{-ik_{mn}d}R_{mn,mn}) \end{cases}$$

the coefficient $\eta_{mn}^\pm$ becomes

$$\eta_{mn}^\pm = \pm 2iP_{mn}^+\left(\frac{(1 - e^{ik_{mn}d}\cos(k_{mn}d)) + R_{mn,mn}(1 - e^{-ik_{mn}d}\cos(k_{mn}d))}{(e^{-ik_{mn}d} - e^{ik_{mn}d})^2}\right).$$

If the hard wall reflection condition $|R_{mn,mn}| = 1$ and $\Phi(R_{mn,mn}) = 0$ is assumed, $\eta_{mn}^\pm = \pm iP_{mn}^+$ and Eq. (D2) is leading to the relationship which gives the error on the incident and reflected modal pressure relative to the incident modal pressure:

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Sitel *et al.*: Acoustic scattering matrix measurement   2489

$$\Delta P_{mn}^{\pm} / P_{mn}^{\pm} \simeq \xi_{mn}^{\pm} \cdot (\Delta P_{mn} / P_{mn}^{\pm}) + i(d \cdot \Delta k_{mn} + k_{mn} \cdot \Delta d). \tag{D3}$$

The uncertainty Δk_{mn} on the axial wave number k_{mn} is deduced from the uncertainties on T the temperature and on f_{mn}^c cut-off frequency of mode (m,n) by

$$\Delta k_{mn} \simeq \frac{\partial k_{mn}}{\partial c_0} \frac{\partial c_0}{\partial T} \Delta T + \frac{\partial k_{mn}}{\partial f_{mn}^c} \Delta f_{mn}^c = \mu_{mn}' \Delta T + \mu_{mn} \Delta f_{mn}^c, \tag{D4}$$

where $c_0 = 20\sqrt{273+T} \simeq 330.45 + 0.607T$. As

$$f_{mn}^c = \frac{c_0}{2\pi} \frac{\chi_{mn}}{a}, \text{ it is easy to show that}$$

$$\Delta f_{mn}^c \simeq 0.607 \frac{\chi_{mn}}{2\pi a} \Delta T + \frac{c_0}{2\pi a} \Delta \chi_{mn} + \frac{\chi_{mn} c_0}{2\pi a^2} \Delta a, \tag{D5}$$

where $\mu_{mn} = (2\pi/c_0)^2 f_{mn}^c / k_{mn}$ and $\mu_{mn}' \simeq 0.607 k_{mn}/c_0$. $\Delta \chi_{mn}$ is an error issued from the measurement duct wall boundary condition and Δa the error on the measurement duct radius.

From the relationships (D3) and (D4) the relative uncertainty $\Delta P_{mn}^+ / P_{mn}^+$ to errors in T, χ_{mn}, a can then be deduced. The contributions to the relative error $\Delta P_{mn}^+ / P_{mn}^+$ vs ka of a $5°$ error in temperature and 5% error in the modulus of the total modal pressure are plotted in Fig. 22 for a mode $(1,0)$ and Fig. 23 for the plane wave. These curves point out that for the plane case the error on the pressure measurement is more important than this on the temperature as shown in a previous study[20] while for a higher order mode both contributions are similar in amplitude and become very sensitive when the frequency tends to be near to the cut-off mode frequency.

Far field propagation measurements of high-amplitude periodic signals generated by the U. S. Army Research Laboratory's Mobile Acoustic Source (MOAS) have been made. The MOAS is a large horn-coupled electropneumatic loudspeaker capable of producing sound at a few hundred hertz with a maximum overall sound pressure level of 155 dB re 20 μPa at 1 m. The possible influence of nonlinear effects have been investigated because the measurements exhibit greater sound pressure levels at high harmonics than are predicted by a linear propagation model. Between 100 and 375 m, nonlinearly predicted spectra obtained via a generalized Burgers equation-based model are consistently closer to measured spectra than are linear predictions, according to calculations of mean absolute error. These comparisons strengthen the assertion that nonlinearity is, in fact, the primary cause of disagreement between the measured and linearly predicted spectra at high frequencies. Comparisons between the nonlinear model and measurements, however, yield increased errors for greater propagation distances ($\sim$1 km) and for measurements made later in the afternoon. For these cases, the nonlinear model calculations generally predict greater sound pressure levels at high frequencies than are actually present in the MOAS measurements. Despite the increased errors for these latter comparisons, the nonlinear model still typically performs better than the linear model. This provides additional confirmation of the presence of nonlinearity in the propagation, but may also point to the need to account for atmospheric variability in the numerical model to provide improved predictions. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2345934]

I. INTRODUCTION

In the past, the role of nonlinearity in the propagation of high-amplitude sound has been given considerable attention in a variety of contexts. Relevant studies have utilized analytical, numerical, and experimental methods to study various aspects of the problem. However, a review of the literature reveals only a limited number of experiments dedicated to the measurement of finite-amplitude effects in outdoor continuous-wave sound propagation. Theobald[1] studied the vertical propagation of periodic waveforms over a maximum range of 76 m. Webster and Blackstock[2] subsequently performed a similar study over a comparable range with band-limited noise waveforms. Both of these studies showed clear evidence of nonlinear propagation in that the measured high-frequency sound pressure levels were significantly greater than those predicted with linear theory.

Our main purpose in this article is to describe the results of recent field experiments with a high-amplitude acoustic source that also show evidence of nonlinear effects. The source for these measurements was the U. S. Army Research Laboratory's Mobile Acoustic Source[3] (MOAS), which is a large electropneumatic loudspeaker. These experiments with the MOAS have been carried out as part of a multifaceted effort to study nonlinearity in the propagation of noise from high-performance jet aircraft[4] over moderate ranges. Because of the potential impact that takeoffs and low-altitude training runs may have on nearby communities, nonlinearity in ground-to-ground propagation is of considerable interest. Consequently, these controlled-source measurements were conducted over several hundred meters at near-grazing incidence, for which ground effects can play a considerable role. Also, as is typical with outdoor propagation experiments, wind, turbulence, and temperature profiles affect the recorded waveforms.

Because multiple phenomena influence the propagation, an important aspect of the measurement analysis is a comparison against the results of a numerical model[5] that is based on the generalized Burgers equation (GBE). The GBE is a widely established nonlinear model equation that can correctly predict the effects of second-order nonlinearity for lossy parabolic propagation of acoustic pressure waveforms. However, because the GBE does not incorporate all the phenomena that affect outdoor measurements, a comparison of

FIG. 1. (Color online) Photograph of the U.S. Army Research Laboratory's Mobile Acoustic Source (MOAS).

FIG. 2. (Color online) Microphone ranges and heights for the MOAS propagation measurements.

the numerical results against the measurement may give some indication of the relative importance of nonlinear effects at a given frequency for a particular test. Theobald[1] also made numerical comparisons against his periodic-waveform measurements using a modified form of an algorithm developed by Pestorius and Blackstock.[6] Agreement between measured versus numerically calculated levels for the first three harmonics was good over short distances, but significantly worsened for the second and third harmonics by the maximum measurement distance of 76 m. Computed results were obtained using only one cycle of the input waveform that was scaled to match the time-averaged level of the fundamental frequency.

In the remainder of this paper, the MOAS and the measurement setup are first described. Measurement results for a number of cases are then presented and discussed. Finally, after a brief discussion of the numerical model, comparisons between measured and both nonlinearly and linearly predicted spectra are examined and analyzed.

II. MEASUREMENT SUMMARY

A. The mobile acoustic source

The U. S. Army Research Laboratory has a large horn-coupled electropneumatic loudspeaker known as the Mobile Acoustic Source (MOAS). The horn is a 10-Hz exponential horn that is 17.1 m long and has a mouth diameter of 2.3 m. Acoustic pressure signals are generated by a valve that modulates the flow of compressed air. The MOAS, which has a nominal frequency response range of 10–500 Hz, was primarily designed to simulate the acoustical signature of a tank. Measurements of the MOAS conducted by the National Center for Physical Acoustics at the University of Mississippi[7] indicate maximum output levels of 155 dB *re* 20 μPa at 1 m. The MOAS is shown mounted on its flatbed trailer in Fig. 1, where the horn's axis is located 3 m above the ground.

B. Measurement array and environment

The propagation measurements were conducted on 12 February 2004 at the Blossom Point field test facility in Blossom Point, MD between 13:00 and 14:45 Eastern Standard Time (EST). Bruel and Kjaer 12.7-mm free-field microphones (Type 4190) were located along the loudspeaker centerline according to the layout in Fig. 2. Microphone poles were placed at 10, 100, 250, and 375 m, and an existing tower was used to collect data at 1092 m. The measurement elevation angles were 0°, 0.7°, and 1.4°, relative to the 10-
m on-axis microphone. The 1.4° measurement angle is approximate because the tower height was insufficient to place the 1092-m microphone along the same angle as the rest of the microphones, which were located nominally at 1.45°. Microphones were also placed on the ground at each pole location and at the tower. All microphones were pointed at the source (normal incidence), which yields a nominally flat (±1 dB) amplitude response for the Type 4190 microphones out to 20 kHz. With the exception of the tower data at 1092 m, microphone data acquisition was carried out using National Instruments 24-bit PXI-4472 cards sampling at 96 kHz. At the tower, waveform data were acquired with a National Instruments 16-bit NI-DAQ 6036-E card sampling at 200 kHz and were then multiplexed over four channels, yielding an effective sampling frequency of 50 kHz per channel.

The ground along the propagation path was fairly flat, nominally soft, and covered by long grass and other vegetation. Because of hardware failure, meteorological information at the site was not recorded during the measurements. However, data from the Naval Surface Warfare Center Dahlgren laboratory located approximately 10 km (6 mi) from the measurement site provided a reasonable estimate of average weather conditions based on a comparison between Blossom Point and Dahlgren data made the day before.

According to the Dahlgren data, between 13:00 and 14:45 EST, the ambient pressure was approximately constant at 1.0 atm, the temperature range was 4 °–5 °C, and the relative humidity varied between 70% and 77%. Wind speeds ranged between 1 and 6 m/s with a variable direction. Because of the uncertainty in the ambient conditions, the values for atmospheric absorption and dispersion calculations in the propagation model were assumed to be constant at 1 atm for ambient pressure, 4 °C for temperature, and 73% for relative humidity.

C. Measured waveforms

For the propagation measurements, a variety of periodic waveforms with fundamental frequencies ranging from 50–400 Hz were used as signal inputs. Sine, triangle, and square waves were all used, but the MOAS frequency re-
FIG. 3. Measured MOAS waveforms along 1.4° for a 300-Hz input sine wave. Distance labels correspond to the microphone ranges shown in Fig. 2.

FIG. 4. (Color online) Measured MOAS harmonic levels along 1.4° for a 300-Hz input sine wave. In this as well as subsequent figures, OASPL signifies overall sound pressure level and is referenced to 20 μPa.

sponse and inherent distortion were such that its ability to acoustically transmit the supplied electrical signals was rather poor. Consequently, the type of input waveform was later found to be largely irrelevant. In addition to the periodic signals described, pink noise was also used. However, the limited frequency response of the MOAS resulted in a natural bandpass filtering of the noise signal and, consequently, significantly lower amplitudes for the pink noise tests.

As an example of a typical measurement, recorded waveforms along 1.4° for a 300-Hz sine wave input are shown in Fig. 3. Although a sinusoidal electrical signal was supplied, the resultant waveform at 10 m is quite nonsinusoidal and significantly skewed, but it is periodic with a fundamental frequency of 300 Hz. The waveform skewness at close range could be related to the compressed-air nature of the source that results in a net volume increase over a cycle. Similarly skewed, nonsinusoidal waveforms recorded at close range for a 100-Hz sinusoidal input to the MOAS have been reported by Sabatier.[7]

D. Measured spectra as a function of range

Because the difference between nonlinear and linear propagation is often greatest at high frequencies that are not readily visible in time waveform comparisons, the emphasis hereafter will be on trends in the measured and predicted spectra at these frequencies. The measured spectra for the 300-Hz test waveforms shown previously in Fig. 3 along 1.4° are displayed in Fig. 4. For purposes of clarity, only the levels at each of the harmonic frequencies, rather than full spectra, are displayed. The overall sound pressure level (OASPL) for each spectrum is located in the figure legend. Approximately 11 s of data were used to calculate the PSD for each case, both to allow fine-scale spectral resolution and to mitigate the effect of fluctuations in waveform amplitudes caused by wind variability. The measured harmonic levels for the same 300-Hz sine wave test, but along 0.7°, are shown in Fig. 5. Similar spectral results are obtained for both propagation angles at most distances, but there are some notable differences in the rates of high-frequency spectral decay of the 1092-m spectra. This greater variability, which is
seen in the majority of the 1092-m measurements, directly impacts the ability to model the propagation out to that distance.

Some discussion of observed ground effects in the spectra is also merited. The broadband spectral results of a propagation measurement with a pink noise input are helpful in this regard. Displayed in Fig. 6 are measured spectra for a pink noise along 0.7°. A comparison of these spectra with those from the 300-Hz sine wave test in Fig. 5 reveal the presence of several spectral minima that occur at similar frequencies. In Fig. 6, the lowest frequencies at which a spectral minimum occurs for each curve (e.g., approximately 85 Hz at 10 m and 250 Hz at 100 m) closely matches those predicted by a ground reflection model using flow resistivity values corresponding to soft terrain. The particular ground interaction model used accounts for the interaction of spherically spreading waves with a finite-impedance ground[8] as well as the effects of atmospheric turbulence.[9] The results of the ground reflection model and the consistency of the measured frequencies of the lowest spectral minima indicate that these minima are due to the superposition of the direct and ground-reflected waveforms at the microphone. At higher frequencies, spectral minima are not nearly as defined. This
FIG. 5. (Color online) Measured MOAS harmonic levels along 0.7° for a 300-Hz input sine wave.

Gee *et al.*: Nonlinear propagation of periodic signals
FIG. 6. (Color online) Measured MOAS spectra along 0.7° for input pink noise.

FIG. 7. (Color online) Measured MOAS harmonic levels at three microphone heights at a range of 375 m for a 300-Hz input sine wave. The time of the test was 13:34 EST.

minima broadening is likely caused by atmospheric turbulence and is predicted by the ground reflection model when turbulence is included. Because the frequencies at which these minima occur also vary somewhat from test to test, other atmospheric inhomogeneities and curved ray propagation likely influence some of the measurements.

Spectral calculations as a function of range have been made for many more cases; however, the spectra shown are sufficient to highlight important aspects of the measurements obtained, as well as to point out the measurement system noise floor. Consideration of the system noise floor is particularly important in analyses of the 375-m and 1092-m data. From the preceding figures, it is evident that for the microphones mounted on the pole at 375 m, the system noise floor was approximately −20 dB re 20 μPa/$\sqrt{\text{Hz}}$. For the 1092-m data, the noise floor was about −15 dB re 20 μPa/$\sqrt{\text{Hz}}$. Given these noise floors, the upper frequency limit of all analyses presented hereafter has been limited to where the signal-to-noise ratio is approximately 10 dB.

E. Measured spectra as a function of height

One other important aspect in describing the measurement is to consider the stability and quiescence of the atmosphere, because atmospheric homogeneity is assumed in the numerical model. Unfortunately, because detailed meteorological data at the measurement site are not available, an alternate means of examining the local atmospheric conditions has been used. The effect of the atmosphere on acoustic propagation may be studied by comparing spectra as a function of microphone height at the same range. For a perfectly still, homogeneous atmosphere, there should be general agreement between harmonic levels for the 0.7° and in 1.4° microphones at a given range. There will be differences in individual harmonics, caused by the differences in the direct and ground-reflected paths as a function of height, but the overall trend in spectral decay as a function of frequency should remain the same. Variation from a common trend for different microphone heights indicates some form of atmospheric variability.

Harmonic levels at 375 m are shown as a function of height for two cases: the 300-Hz sine wave test previously
discussed, which occurred at 13:34 EST, and a 400-Hz square wave test conducted at 14:33 EST. The results for these two tests typify the change in ambient conditions that occurred during the latter measurements. Displayed in Figs. 7 and 8 are harmonic spectral levels as a function of microphone height at 375 m for the 300-Hz sine wave and 400-Hz square wave tests, respectively. As may be anticipated, the microphones located on the ground in both cases yield lower levels than for those microphones located off the ground. This is likely due to the additional losses caused by propagation along the ground at grazing incidence; consequently, ground microphone data are not considered further. For the microphones located off the ground, however, there is a significantly different behavior between the two tests with regard to the harmonic amplitudes at 7.6 m (0.7°) and 12.2 m (1.4°). For the 300-Hz test, the 0.7° levels are only slightly greater than the 1.4° levels at high frequencies. However, for the 400-Hz square wave test, the differences are much greater and increase as a function of frequency. This comparison implies that an assumption of a quiescent, homogeneous atmosphere is less appropriate for measurements taken toward the end of the day. This apparent degra-
FIG. 8. (Color online) Measured MOAS harmonic levels at three microphone heights at a range of 375 m for a 400-Hz input square wave test made later in the afternoon, at 14:33 EST.

Gee *et al.*: Nonlinear propagation of periodic signals

dation of stable atmospheric conditions for later tests directly impacts accompanying propagation predictions made using the numerical model described below.

Although this summary of the complete MOAS field experiment has been carried out with relatively few cases, the waveforms and spectra shown are representative of the entire test. After a brief overview of the numerical model used to obtain nonlinear and linear propagation predictions, comparisons between measured and predicted spectra for various cases are presented and discussed.

III. NUMERICAL MODEL OVERVIEW

A. The generalized Burgers equation

In this section, the nonlinear numerical model used in the comparisons against the MOAS field experiment is described. A parabolic model equation that has been used extensively to treat the problem of nonlinear propagation through a lossy medium is the Burgers equation. In its most basic form, the Burgers equation describes plane-wave propagation through a thermoviscous medium; however, other formulations have incorporated geometrical spreading[10] and arbitrary absorption and dispersion.[11] One form of the generalized Burgers equation (GBE), on which the numerical model is based, may be written for assumed spherical spreading as

$$\frac{\partial p}{\partial r} = \frac{\beta}{2\rho_0 c_0^3} \frac{\partial p^2}{\partial \tau} + \psi(\tau)p - \frac{1}{r}p. \tag{1}$$

In Eq. (1), $p(r,\tau)$ is the acoustic pressure, r, the range variable, β, the coefficient of nonlinearity, ρ_0, the ambient density, c_0, the small-signal sound speed, $\tau = t - (r - r_0)/c_0$, the retarded time of propagation between r_0 and r, and $\psi(\tau)$, a generalized absorption and dispersion operator that acts on p. In the context of the current propagation problem, $\psi(\tau)$ represents atmospheric absorption and dispersion. An additional term may be included in the GBE to treat atmospheric stratification (e.g., see Ref. 12), but because atmospheric inhomogeneity is not modeled in this work, the term has been neglected.

B. GBE solution technique

The solution technique to the GBE employed in this research is an adaptation from previous work carried out at the University of Texas at Austin and the University of Mississippi, where hybrid time-frequency domain nonlinear propagation algorithms have been developed and refined. The time-frequency domain solution method originated with Pestorius and Blackstock,[6] who investigated finite-amplitude noise propagation in a one-dimensional tube and developed an algorithm to numerically propagate acoustic pressure waveforms. The nonlinear portion of the propagation was carried out in the time domain, and the small-signal portion of the propagation (boundary-layer absorption and dispersion) was handled in the frequency domain. Pierce[13] has demonstrated that the "Pestorius algorithm" reduces to the GBE appropriate for plane-wave propagation in a one-dimensional duct.

Anderson[14] developed an alternative to the Pestorius algorithm in his study of spherically decaying N waves. To eliminate the need for weak shock theory, which Pestorius' method employed, adaptive step sizing was used to ensure that the waveform was singly valued for all range steps. Following Anderson's initial work, improvements to the "Anderson algorithm" were made by others also interested in the nonlinear propagation of transients.[15–17]

The present numerical solution to the GBE in Eq. (1) has been developed from a study of the Pestorius and Anderson methodologies. The algorithm most closely resembles the Anderson approach because it employs an adaptive step size. However, because Anderson's code and its subsequent modifications have been intended primarily for the propagation of transients, some elements of the model are more closely linked to the work of Pestorius, who dealt with continuous-wave signals. Implementation details for the model may be found in Ref. 5.

IV. COMPARISON RESULTS AND ANALYSIS

In this section, comparisons are made between measured spectra and predicted spectra obtained by numerically propagating recorded waveforms both linearly and nonlinearly. The linear predictions, which have been obtained by removing the nonlinear term from Eq. (1), are equivalent to free-field extrapolations of the input spectrum using atmospheric absorption and spherical spreading. Use of approximately 11 s of data (2^{20} samples) in the numerical propagation constitutes a significant difference from Theobald's study, in which only a single cycle of the recorded waveform was used.[1] As with the PSD calculations in Sec. II, the use of relatively long waveforms as inputs to the numerical models allows for both fine-scale resolution and a large number of ensemble averages when calculating a predicted PSD. Note that a long input waveform and a greater number of averages are not expected to reduce errors between measured and predicted spectra if atmospheric and ground effects cause the actual propagation path to significantly differ from the straight numerical propagation path. An increased waveform length, however, has been found to help minimize variability in predicted spectra caused by wind-induced waveform amplitude fluctuations. Finally, data collected at 100 m, rather than at 10 m, have been used as inputs to the model because the 10-m on-axis microphone was found to be located within the geometrical near field of the MOAS, where an assumption of spherical spreading is not valid.[5]

In order to quantitatively compare the results of the nonlinear and linear models, an assessment of the overall error of a given model relative to the measurement is needed. The metric that has been selected for the purpose of these comparisons is the mean absolute error, in dB, between the measured PSD and a predicted PSD. For example, the mean absolute error, $\overline{E_{M,N}}$, between the measured PSD (PSD_M) and nonlinearly predicted PSD (PSD_N) may be written as

$$\overline{E_{M,N}} = \langle |PSD_M - PSD_N| \rangle, \tag{2}$$

where $\langle \ \rangle$ is the expectation operator and the spectral densities are calculated in dB. The mean absolute error between
FIG. 9. (Color online) Measured and predicted spectra at 375 m, $\theta = 0.7°$, for pink noise input. The input for the predictions was the measured waveform at 100 m.

FIG. 10. (Color online) Measured and predicted harmonic levels at 375 m, $\theta = 0.7°$ for a 300-Hz input sine wave. The input for the predictions was the measured waveform at 100 m.

the measurement and linear prediction, $\overline{E_{M,L}}$, is calculated by replacing PSD_N in Eq. (2) with the linearly predicted PSD (PSD_L). In each of the comparisons between measurement and model, $\overline{E_{M,N}}$ and $\overline{E_{M,L}}$ are calculated over the frequency range where the measured levels are at least 10 dB above the system noise floor.

The comparisons that follow are broken into two broad categories. First, results from the pink noise test are analyzed because its relatively low OASPL at 100 m make the test suitable as a sort of linear benchmark between the real-world data and the simplified models. Next, comparisons between the results from various tests with periodic waveforms are made and analyzed.

A. Pink noise comparison

The OASPL of the pink noise spectrum at 100 m was 99.9 dB *re* 20 μPa (see Fig. 6), which is significantly lower than the tests with periodic waveforms. This case is useful in determining the level of agreement between the models and the measurement that is achieved when nonlinear effects appear to be minimal and when the atmosphere is relatively homogeneous. For this comparison, the recorded 100-m waveform at 0.7° has been propagated out to 375 m.

Shown in Fig. 9 is the measured 375-m PSD for 0.7°, along with the nonlinearly and linearly predicted spectra calculated from numerical propagation from 100 m. The nonlinear and linear predictions differ noticeably above 3.5 kHz, but result in the same predicted OASPL (88.4 dB *re* 20 μPa) and generally follow the decay of the measured PSD out to 6 kHz. For this case, $\overline{E_{M,N}}$ and $\overline{E_{M,L}}$ are, respectively, 2.9 and 2.6 dB, which means that the linear prediction has slightly less error than the nonlinear prediction but both models have less than 3 dB of mean absolute error between 0 and 6 kHz. The maximum difference between both models and the measurement occurs at about 2.5 kHz, where a relative spectral maximum at 100 m is propagated outward with a free-field assumption and is then compared to a measured relative spectral minimum at 375 m. This maximum error is likely due to differences in multipath interference effects at higher frequencies. This pink noise comparison indicates that the
linear and nonlinear free-field models are useful for comparing with general trends observed in the measured spectra when the atmosphere is reasonably homogeneous. It also indicates, however, that agreement at specific frequencies may be poor because of the variation in multipath interference as a function of range.

B. Periodic signal comparisons

1. 100–375-m comparisons

The first set of comparisons with periodic source waveforms is carried out between 100 and 375 m, as was done with the pink noise test. The fact that virtually all periodic waveform measurements made over this range reveal a significant difference between linearly predicted and measured spectra at high frequencies suggests that nonlinearity influences the propagation. The results of comparisons between the measurement and the numerical predictions for three cases are now shown: the previously discussed 300-Hz sine-wave test along both 0.7° and 1.4° (see Figs. 4 and 5), as well as a 400-Hz sine-wave test along 0.7°. The 300-Hz measurement and predictions at 375 m along 0.7° and 1.4° are, respectively, shown in Figs. 10 and 11. The 400-Hz results along 0.7° are displayed in Fig. 12. Again, only the levels at each of the harmonics are shown for purposes of clarity. Calculations of $\overline{E_{M,L}}$ and $\overline{E_{M,N}}$ are shown in Table I for each of the three tests. Both the graphical and tabulated results reveal that the nonlinearly predicted spectra match the measurements significantly better than the linear predictions. As with the pink noise comparison, there are significant discrepancies at individual frequencies, but $\overline{E_{M,N}} < 3$ dB for each of these cases. These comparisons indicate that nonlinear propagation is the primary cause of the discrepancy between linearly predicted and measured spectral levels at high frequencies.

2. 100–1092-m comparisons

The results for the 100-375-m comparisons confirm that nonlinear effects are present in the propagation of periodic signals from the MOAS. Another point of discussion is the influence of nonlinearity in the propagation beyond 375 m
FIG. 11. (Color online) Measured and predicted harmonic levels at 375 m, $\theta=1.4°$ for a 300-Hz input sine wave. The input for the predictions was the measured waveform at 100 m.

out to 1092 m. The 300-Hz sine-wave test discussed previously was selected for study because of the good agreement achieved between the nonlinear model and measurement between 100 and 375 m. The 100-m waveforms at 0.7° and 1.4° were again used as inputs and this time were propagated out to 1092 m using the nonlinear and linear models. The results of the spectral comparisons are displayed in Figs. 13 and 14 and the mean absolute errors calculated in Table II. Although these results are not shown, nearly identical graphical and quantitative results were obtained when the 375-m recorded waveforms, rather than the 100-m recorded waveforms, were used as inputs to the model. In both cases considered here, as well as for the majority of other measurements performed, the nonlinearly predicted harmonic levels at 1092 m are consistently greater than the measured levels and yield a greater mean absolute error than the 100−375-m comparisons. For the 0.7° propagation angle, $\overline{E_{M,L}}$ is still significantly greater than $\overline{E_{M,N}}$, but for 1.4°, the two error calculations are approximately equal.

The trends seen in the 1.4° results for the 300-Hz test are common for several different tests at one or sometimes both propagation angles in that $\overline{E_{M,L}}$ and $\overline{E_{M,N}}$ are nearly
FIG. 12. (Color online) Measured and predicted harmonic levels at 375 m, $\theta=0.7°$ for a 400-Hz input sine wave. The input for the predictions was the measured waveform at 100 m.

TABLE II. Linear and nonlinear mean absolute errors, in dB, for the 100−1092-m comparisons in Figs. 13 and 14. See Eq. (2) and accompanying text for the definitions of $\overline{E_{M,L}}$ and $\overline{E_{M,N}}$.

Frequency/angle	$\overline{E_{M,L}}$	$\overline{E_{M,N}}$
300-Hz/0.7°	12.2	3.9
300-Hz/1.4°	6.2	6.4

equal and the measured spectrum falls between the nonlinear and linear predictions. Although the exact cause of the general increased disagreement between nonlinearly predicted and measured spectra over the larger propagation range has not been ascertained, some qualitative discussion is merited. Generally good agreement between the 300-Hz measurement and the nonlinear model was achieved for the 100–375-m comparisons, despite neglecting phenomena such as ground effects, turbulence, and a nonuniform atmosphere. Over a significantly longer range, each phenomenon could more significantly affect the rate of nonlinear energy transfer in the propagating waveform. As an example, the effects of turbulence, while often negligible over shorter distances, would certainly play a larger role over an increased propagation range. The results of a study of the average effect of turbulence on shock-wave rise times[18] have indicated that a steepened waveform passing through turbulence unsteepens more quickly than for passage though a quiescent medium. A more rapid unsteepening could account for the experimentally observed accelerated reduction in the high-frequency sound pressure levels. Also, a homogeneous, quiescent atmosphere and straight-ray propagation have been assumed in the numerical calculations, whereas the influence of a realistic sound-speed profile and curved rays could substantially affect the measured results at a given microphone over a longer range. For example, upwind propagation could cause ray tube divergence, thereby reducing sound amplitudes along a given ray and slowing the rate of nonlinear distortion.

3. Comparisons for later measurements

Another comparison that shows the potential for meteorological affects to influence the ability to measure nonlinearity may be made with the 400-Hz square wave measurement made later in the afternoon. It was shown previously in the discussion of measured spectra as a function of microphone height that this measurement exhibited increased dependence of level on height at high frequencies relative to earlier tests (cf. Figs. 7 and 8). In conjunction with this apparent decrease in atmospheric homogeneity, concordance between nonlinear model and measurement significantly
FIG. 16. (Color online) Measured and predicted harmonic levels at 250 m, $\theta=1.4°$ for a 400-Hz input square wave. The input for the predictions was the measured waveform at 100 m.

lessens. Figure 15 compares the 1.4° measured harmonic levels at 375 m with those predicted from numerical propagation from 100 m for the 400-Hz square wave test. The 100-m-based numerical calculation significantly overpredicts the measured sound pressure levels at high frequencies. To further investigate the cause of this discrepancy, the numerical propagation path was divided up using the intermediate measurement at 250 m (cf. Fig. 2) and separate calculations were performed for the 100–250-m and 250–375-m ranges. The results of these comparisons are shown in Figs. 16 and 17, respectively. Although the algorithm continues to slightly overpredict the spectral levels between 250 and 375 m, agreement is substantially better over the shorter propagation distances. The agreement is quantified with calculations of $\overline{E_{M,L}}$ and $\overline{E_{M,N}}$ in Table III. The fact that significantly better agreement is achieved with these shorter-range calculations than with the full 100–375-m range indicates that atmospheric effects can greatly impact conclusions regarding the nonlinearity of the propagation, even over relatively short distances.

Range	$\overline{E_{M,L}}$	$\overline{E_{M,N}}$
100–375 m	9.1	7.8
100–250 m	8.0	2.7
250–375 m	5.3	2.9

V. CONCLUSIONS

Finite-amplitude propagation effects have been measured in the outdoor propagation of periodic signals generated using the U.S. Army Research Laboratory's Mobile Acoustic Source (MOAS). For most cases, the results of the nonlinear model based on the generalized Burgers equation compare favorably with the measurement and demonstrate significantly less mean absolute error than results from a linear model. This is true despite the fact that the nonlinear model assumes free-field propagation through a homogenous atmosphere and therefore neglects some of the conditions of the actual experiment. The results of the comparisons indicate that effects of nonlinear propagation are readily observable between 100 and 375 m, despite overall sound pressure levels (OASPL) at 100 m that are less than 115 dB re 20 μPa for all measurements (see the legend in Fig. 5, where the maximum OASPL is 114.6 dB re 20 μPa). Based on OASPL alone, these results indicate that nonlinearity is very likely to occur in high-amplitude jet noise propagation, for which levels at 100 m may be 10–15 dB greater than for the MOAS. This corroborates earlier statements of Webster and Blackstock,[2] who reached a similar conclusion based on the results of their relatively short-range propagation experiments. Other comparisons shown in the present work are also important, specifically for the cases of propagation over greater distances and measurements made later in the afternoon, where agreement between the nonlinear model and experiment are not as good. They point to the need for the application of more sophisticated modeling techniques and additional research to better understand and predict the finite-amplitude propagation of continuous waveforms through a spatially and temporally variable atmosphere.

Technique to minimize couplant-effect in acoustic nonlinearity measurements

Li Sun, Salis S. Kulkarni, Jan D. Achenbach, and Sridhar Krishnaswamy[a)]

Center for Quality Engineering and Failure Prevention, Northwestern University, Evanston, Illinois 60208

A modified technique to measure acoustic nonlinearity in fatigued components is proposed in this paper. The advantage of the proposed technique is that it minimizes measurement errors due to the couplant between the transducers and the specimen. Measurements are performed on a fatigued steel 4340 specimen and the coefficients of variation of the nonlinearity parameter are calculated. It is shown that the coefficients of variation of the nonlinearity parameter obtained using the proposed technique are approximately half of that obtained using the conventional technique. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354023]

I. INTRODUCTION

The nucleation and growth of a fatigue crack in a metal is generally preceded by a process of damage accumulation at the microstructural level. As the number of fatigue cycles increases, the damage accumulation involves the formation of dislocation monopoles, followed by dislocation loops and dipoles, dislocation veins, persistent slip bands, and subsequent nucleation of microcracks.[1,2] These changes in the microstructure due to damage accumulation introduce changes in the material response, and in particular lead to nonlinear stress-strain response. Therefore by measuring the changes in the material nonlinearity, the damage accumulated during the fatigue process can be estimated. To characterize the material nonlinearity, the usual way is to launch a single frequency ultrasonic wave into the specimen and receive the signal at a certain distance. Due to the material nonlinearity, the single frequency wave is distorted and second and higher harmonics are generated.[3–7] As a result, the received signal not only consists of the component at the transmitting (fundamental) frequency, but also the second and higher harmonics whose amplitudes increase as the material nonlinearity increases. Hence, the material nonlinearity in a specimen can be quantified in terms of the amplitude of the fundamental and higher harmonics generated by propagating a monochromatic ultrasonic wave. This phenomenon of distortion of an acoustic wave due to material nonlinearity is generally referred to as acoustic nonlinearity. The above discussion indicates that acoustic nonlinearity can be used as a parameter to monitor the precrack fatigue damage process.[8]

Conventional techniques to measure changes in the acoustic nonlinearity during fatigue are mostly based on measuring the amplitudes of the fundamental and the second harmonic generated using either bulk or surface waves. Experimental results demonstrating the changes of acoustic nonlinearity during fatigue process using bulk waves have been reported in papers on fatigued stainless steel 410-Cb,[9,10] titanium alloys[11] and 2024-T4 aluminum alloy.[10,12] Similar experiments done using surface acoustic waves have also been reported on fatigued 7073-aluminium,[13] titanium alloy Ti-6Al–4V and inconel 718,[14] and concrete.[15]

The most common way to make acoustic measurements is by using contact piezoelectric transducers. To facilitate signal transmission, a couplant layer is applied between the transducer and specimen. However, the couplant layer leads to variations in ultrasonic measurements, and the results are sensitive to coupling pressure, couplant layer thickness and viscosity, etc.[16] A self-calibrating ultrasonic technique for crack depth measurement using surface waves, which eliminates the couplant effect, was proposed by Achenbach *et al.*[17] Their basic idea is to perform a set of four measurements which enable the elimination of the couplant response in linear ultrasonic measurements.

Couplant variability is especially problematic for acoustic nonlinearity monitoring of fatigue damage since these measurements have to be made repeatedly as a component is fatigue cycled, and variations in measurement due to the couplant make quantitative comparisons difficult. This is true for both laboratory measurements where the transducers may be repeatedly removed during fatigue cycling and reattached periodically for acoustic nonlinearity measurements, and measurements using permanently mounted transducers where the couplant can be expected to degrade with time as the fatigue cycling progresses. In this paper, we propose a method to minimize the effect of the couplant in the acoustic nonlinearity measurements. Since we are primarily interested in minimizing the couplant effects during fatigue monitoring, we present results comparing the nonlinearity measurements based on the second harmonic generation using both the conventional method and the proposed method. The proposed method can also be extended in a straightforward manner to minimize couplant effects for nonlinearity measurements based on higher harmonic generation. This is demonstrated by comparing the nonlinearity measurements based on third harmonic generation using the conventional method and the proposed method.

II. ACOUSTIC NONLINEARITY MEASUREMENT

For the one-dimensional problem of longitudinal wave propagation through a solid containing mobile dislocations, the amplitude of the fundamental at a distance l from the source can be approximated as[18,19]

$$A_1(l) = A_1(0)f_1(\alpha_1, l), \tag{1}$$

where $A_1(0)$ is the fundamental amplitude at the source and $f_1(\alpha_1, l)$ is a function of the attenuation coefficient α_1 at the fundamental frequency and the propagation distance l. Since we are primarily interested in monitoring the fatigue process, the effect of dislocations on the generation of higher harmonics as well as their effect on attenuation need to be considered. For longitudinal waves at a fixed distance from the source, it can be shown that the amplitude of the second harmonic is proportional to the square of the fundamental, and the amplitude of the third harmonic is proportional to the cube of the fundamental.[18–20] The amplitude of the nth harmonic at a distance l from the source can therefore be represented in the following form:

$$A_n(l) = \gamma_n[A_1(0)]^n f_n(\alpha_1, \alpha_2, \ldots, \alpha_n, l), \quad (n=2,3), \tag{2}$$

where $\gamma_n (n=2,3)$ are the parameters which depend on the fundamental frequency and material properties such as density, microstructure, and second- and third-order elastic constants. The parameters $\gamma_n (n=2,3)$ are expected to increase with the increase of the material nonlinearity during the fatigue process, and henceforth are referred to as nonlinearity parameters. In Eq. (2), $f_n(\alpha_1, \alpha_2, \ldots, \alpha_n, l), (n=2,3)$ is a factor which takes into account the attenuation and α_n is the attenuation coefficient for nth harmonic. Note that the attenuation factor $f_n(\alpha_1, \alpha_2, \ldots, \alpha_n, l), (n=2,3)$ depends on the attenuation parameters of the fundamental, second harmonic, up to the nth harmonic. Explicit expressions for the attenuation factor for the second harmonic and third harmonic are available in the literature.[18,19]

Similar to the case of longitudinal waves, an initially sinusoidal surface acoustic wave (SAW) also generates higher harmonics in a nonlinear medium.[21,22] A detailed discussion of various aspects of SAWs in nonlinear elastic media appears in Mayer's work.[23] Numerous mathematical theories of the evolution of nonlinear surface waves, which provide surface displacements and velocity profiles, have been proposed in the literature.[23–27] The theories for SAWs in nonlinear media (see for example Mayer[23]) also predict that at a fixed distance from the source, $A_2 \propto A_1^2$, $A_3 \propto A_1^3$. In what follows we assume that the attenuation effect for SAWs can be accounted for in a manner similar to that for the longitudinal waves, as expressed by Eqs. (1) and (2).

In the following, models for the conventional acoustic nonlinearity measurement technique and the proposed couplant-effect-minimization measurement technique are developed. Note that they are applicable for both longitudinal and surface acoustic waves. To develop these models, the following assumptions are made:

- The relevant components of the measurement system—amplifier, preamplifier, transducers, are linear, i.e., there is no harmonic generation in these components.
FIG. 1. Configuration for nonlinearity measurement.

- There is no harmonic generation due to the couplant layer between the transducers and the specimen (reasonable given that the layer is typically very thin).

From the above assumptions, it follows that the material is the sole contributor to the observed nonlinearity.

A block diagram of nonlinearity measurements using contact transducers is shown in Fig. 1 with transducer 1 ($T1$) located at position (1) and transducer 2 ($T2$) located at position (2). The couplant layers between the two transducers and specimen are denoted as $C1$ and $C2$, respectively.

The following notation is used in the remainder of the paper:

$D_i(\omega)$–amplitude of the input voltage to transducer i as a function of frequency ω

$G_i(\omega)$–response function of transducer i when it is used as a transmitter

$R_i(\omega)$–response function of transducer i when it is used as a receiver

$C_i(\omega)$–couplant response function at position i

$P_{ij}(\omega)$–function that takes into account the attenuation of the signal received by transducer j at frequency ω when the input signal is transmitted at frequency ω from transducer i

$\bar{P}_{ij}(\omega_1, \omega_2)$–function that takes into account the attenuation of the signal received by transducer j at frequency ω_2 when the input signal is transmitted at frequency ω_1 from transducer i

$V_{[j](\omega_2)}^{[i](\omega_1)}$–amplitude of the signal received at transducer j at frequency ω_2 when the input signal is transmitted at frequency ω_1 from transducer i.

The response function of the transducer in transmission is the frequency response of the transducer for converting the electrical energy into sound energy, while the response function of the transducer in reception is the frequency response of the transducer for converting the sound energy into electrical energy. The response function of the couplant is the frequency response of the couplant for transmitting sound energy. It takes into account the effect of attenuation and depends on the contact pressure, couplant layer thickness and viscosity. It should be noted that in the following discussions we will only consider the *amplitude* frequency response, and will not explicitly track the phase response.

A. Conventional acoustic nonlinearity measurements

In the conventional approach, one transmits a signal at frequency ω_0 through transducer 1 and measures the amplitude of the signal at frequencies ω_0 and $n\omega_0 (n=2,3)$ at transducer 2. From the above assumptions, it follows that the voltage signal received by transducer 2 at frequency ω_0 is given by

$$V^{[1](\omega_0)}_{[2](\omega_0)} = [D_1(\omega_0)G_1(\omega_0)C_1(\omega_0)]P_{12}(\omega_0)C_2(\omega_0)R_2(\omega_0). \tag{3}$$

The above is a completely linear measurement. Note that here $P_{12}(\omega_0)$ takes into account the attenuation of the acoustic wave at fundamental frequency ω_0 when it travels from position 1 to position 2 in the specimen. The term in the square bracket can be identified with the injected fundamental $A_1(0)$ and the attenuation term $P_{12}(\omega_0)$ with the function $f_1(\alpha_1,l)$ in Eq. (1).

Next we consider the voltage signals received by transducer 2 at frequency $n\omega_0$ ($n=2,3$) due to signal generated at frequency ω_0 by transducer 1. These are nonlinear contributions. As mentioned earlier, the amplitude of the nth harmonic is proportional to the nth power of the amplitude of the fundamental signal. Therefore we can write

$$V^{[1](\omega_0)}_{[2](n\omega_0)} = \overline{\gamma_n}[D_1(\omega_0)G_1(\omega_0)C_1(\omega_0)]^n \bar{P}_{12}(\omega_0,n\omega_0)$$
$$\times C_2(n\omega_0)R_2(n\omega_0), \quad (n=2,3) \tag{4}$$

where $\overline{\gamma_n}(n=2,3)$ are functions of the material nonlinearity. Note that the constant $\overline{\gamma_n}(n=2,3)$ are different from the constants $\gamma_n(n=2,3)$ introduced in Eq. (2) since we are now relating the voltage amplitudes while earlier we were relating the displacement amplitudes. As fatigue progresses, we can expect $\overline{\gamma_n}(n=2,3)$ to change and therefore they serve as indicators of the accumulated damage. Note that $\bar{P}_{12}(\omega_0,n\omega_0)$ takes into account the attenuation of the acoustic signal received by transducer 2 at frequency $n\omega_0$ when the input signal is transmitted at frequency ω_0 from transducer 1, and we can identify it with the function $f_n(\alpha_1,\alpha_2,\ldots,\alpha_n,l),(n=2,3)$ in Eq. (2).

From Eqs. (3) and (4) one can derive the following expression:

$$\hat{\gamma}_n = T_R \frac{C_2^n(\omega_0)}{C_2(n\omega_0)} \frac{V^{[1](\omega_0)}_{[2](n\omega_0)}}{(V^{[1](\omega_0)}_{[2](\omega_0)})^n} \quad (n=2,3), \tag{5}$$

where

$$\hat{\gamma}_n = \frac{\overline{\gamma_n} \cdot \bar{P}_{12}(\omega_0,n\omega_0)}{P_{12}^n(\omega_0)} \quad \text{and} \quad T_R = \frac{R_2^n(\omega_0)}{R_2(n\omega_0)}.$$

Note that $\hat{\gamma}_n$ is defined in terms of $\overline{\gamma_n}$, which depend on the material nonlinearity, and $P_{12}(\omega_0,n\omega_0)$ and $P_{12}(\omega_0)$ which are functions of the attenuation coefficients. Both the material nonlinearity and the attenuation are expected to increase with fatigue.[28,29] For cases where the change in attenuation due to fatigue is significantly less than the change in the material nonlinearity, we expect $\hat{\gamma}_n$ to increase with fatigue.

Since we are only interested in calculating the changes in $\hat{\gamma}_n$ as fatigue progresses, it is not essential to calculate the quantity T_R, which depends on the response of transducer 2 and is expected to remain constant for the entire duration of the experiment. The couplant responses at ω_0 and $n\omega_0$ may change from measurement to measurement (as fatigue cycling proceeds) because of possible couplant degradation, changes in couplant thickness or contact pressure which are difficult to control. In conventional measurements, the changes in couplant response are neglected and the changes in the material nonlinearity during fatigue are quantified by calculating γ_n^{con}, with

$$\gamma_n^{con} = \frac{V^{[1](\omega_0)}_{[2](n\omega_0)}}{(V^{[1](\omega_0)}_{[2](\omega_0)})^n}, \quad (n=2,3) \tag{6}$$

at different cycle numbers. Obviously the above measurement of acoustic nonlinearity does not take into account the couplant effect, and as such great care will need to be taken to ensure that the couplant response is identical from measurement to measurement.

B. Modified acoustic nonlinearity measurements

As pointed out in the previous section, the couplant response is usually neglected when measuring the acoustic nonlinearity. But as the measured signals are sensitive to the couplant response, and since in general it is not easy to keep the coupling constant, large variations in the ratio $V^{[1](\omega_0)}_{[2](n\omega_0)}/(V^{[1](\omega_0)}_{[2](\omega_0)})^n$ are likely to be observed. This makes comparisons of the nonlinearity parameter as a function of fatigue cycling very difficult. To minimize the couplant effects, a modified technique to measure the acoustic nonlinearity is suggested in this paper. This requires that, in addition to the measurements required by the conventional technique, two more measurements be carried out:

- Transmit a signal at frequency $n\omega_0$ through transducer 1 and measure the amplitude of the signal at $n\omega_0$ at transducer 2. Similar to Eq. (3), the received signal can be written as

$$V^{[1](n\omega_0)}_{[2](n\omega_0)} = [D_1(n\omega_0)G_1(n\omega_0)C_1(n\omega_0)]P_{12}(n\omega_0)$$
$$\times C_2(n\omega_0)R_2(n\omega_0). \tag{7}$$

- Transmit a signal at frequency ω_0 through transducer 2 and measure the amplitude of the signal at $n\omega_0$ at transducer 1. Following Eq. (4), the measured signal in terms of the response function is given by

$$V^{[2](\omega_0)}_{[1](n\omega_0)} = \overline{\gamma_n}[D_2(\omega_0)G_2(\omega_0)$$
$$\times C_2(\omega_0)]^n \bar{P}_{21}(\omega_0,n\omega_0)C_1(n\omega_0)R_1(n\omega_0). \tag{8}$$

Using Eqs. (3), (4), (7), and (8) and the fact that $\bar{P}_{12}(\omega_0,n\omega_0)=\bar{P}_{21}(\omega_0,n\omega_0)$, we can show that

$$\tilde{\gamma}_n = T_{GR} \left[\frac{V^{[1](\omega_0)}_{[2](n\omega_0)} V^{[2](\omega_0)}_{[1](n\omega_0)}}{(V^{[1](\omega_0)}_{[2](\omega_0)})^n V^{[1](n\omega_0)}_{[2](n\omega_0)}} \right]^{1/2} \left[\frac{D_1(n\omega_0)}{D_2^n(\omega_0)} \right]^{1/2},$$
$$(n=2,3), \tag{9}$$

where

$$\tilde{\gamma}_n = \frac{\overline{\gamma_n} \cdot \bar{P}_{12}(\omega_0,n\omega_0)}{[P_{12}^n(\omega_0)P_{12}(n\omega_0)]^{1/2}} \quad \text{and}$$

$$T_{GR} = \left[\frac{R_2^n(\omega_0)}{G_2^n(\omega_0)} \frac{G_1(n\omega_0)}{R_1(n\omega_0)} \right]^{1/2}.$$

It is seen from Eq. (9) that the couplant response does not appear in the expression for $\tilde{\gamma}_n$, i.e., the couplant effect has been *theoretically* eliminated. As pointed out earlier, it is not necessary to measure T_{GR} (dependent on instrumentation only) since it is expected to remain constant throughout the entire duration of the experiment. Therefore, in the modified technique, the changes in the material nonlinearity during fatigue can be quantified by calculating γ_n^{mod}, where

$$\gamma_n^{\mathrm{mod}} = \left[\frac{V_{[2](n\omega_0)}^{[1](\omega_0)} V_{[1](n\omega_0)}^{[2](\omega_0)}}{(V_{[2](\omega_0)}^{[1](\omega_0)})^n V_{[2](n\omega_0)}^{[1](n\omega_0)}} \right]^{1/2} \left[\frac{D_1(n\omega_0)}{D_2^n(\omega_0)} \right]^{1/2},$$

$$(n = 2,3) \qquad (10)$$

at different cycle numbers. Observe that γ_n^{mod} is a quantity which depends on the material nonlinearity and attenuation. As mentioned earlier, both the material nonlinearity and the attenuation are expected to increase with fatigue. If the changes in the attenuation are significantly less than the changes in the material nonlinearity, we can expect γ_n^{mod} to increase with fatigue.

It should also be pointed out that the measured values of γ_n^{mod} and γ_n^{con} are expected to be quantitatively different as their expressions involve different combinations of the material nonlinearity and attenuation parameters.

III. RESULTS AND DISCUSSION

In the present work, the nonlinearity measurements are preformed for surface acoustic waves. There are two reasons for using SAWs instead of bulk waves: (a) they are easy to generate on structural components of general shape, (b) the energy density associated with SAWs is confined to the surface in a narrow spatial region, where most damage is generally accumulated during fatigue. Experimental results are presented for both the conventional and modified techniques.

The measurement system consists of a 5 MHz broadband piezoelectric transducer located at position 1 (or 2) and a 10 MHz piezoelectric transducer broadband located at position 2 (or 1) (see Fig. 1). Note that these transducers have quite a broad (but not flat) response bandwidth about their center frequencies. The distance between the two transducers was 1.8 cm. The generating signals at 5, 10, and 15 MHz were 20-cycle Hanning window-modulated tonebursts. Measurements were made on a dogbone steel 4340 specimen with thickness=2.75 mm, width=15.0 mm, and length =190 mm. The yield strength of the steel specimen was measured to be 1200 MPa, the ultimate tensile strength 1300 MPa, and the Young's Modulus 205 GPa. The specimen was subjected to a stress controlled uniaxial sinusoidal load (frequency 10 Hz) for 100 000 cycles in an MTS fatigue
FIG. 2. Graphical comparison of the second harmonic nonlinearity measurements obtained using the conventional technique and the modified technique. The comparisons are presented for four different input signals: 57, 90, 125, and 153 V.

machine. The stress cycling was as follows: σ_{max} was set to be 950 MPa while σ_{min} was set to be 95 MPa ($R = \sigma_{\mathrm{min}}/\sigma_{\mathrm{max}} = 0.1$, $\sigma_{\mathrm{mean}} = 500$ MPa).

It is not the purpose of this paper to discuss the evolution of the acoustic nonlinearity parameter as a function of fatigue cycling (that will be reported elsewhere). Rather, the purpose here is to show that the proposed method provides a more robust measurement of the acoustic nonlinearity than conventional methods. To establish this, acoustic nonlinearity measurements were carried out after the specimen was removed from the fatigue machine (after 100 000 cycles) using both the conventional method and the modified method. Several sets of measurements were made to obtain some statistics on the scatter in the experimental measurements due to variability in the couplant. Each set of measurements was made by removing the transducers and placing them again on the specimen, not necessarily with the same contact pressure, and each time a fresh couplant layer was applied.

Second Harmonic Measurements. The second harmonic nonlinearity measurements using the conventional and modified techniques are presented. The measurements were repeated eight times and for each set of measurements four different transducer drive voltages were used: $V1 = 57$ V, $V2 = 90$ V, $V3 = 125$ V, and $V4 = 153$ V. The normalized nonlinearity parameter obtained using both the conventional and modified techniques is shown in Fig. 2.

For the case of conventional technique, each γ_2^{con} is normalized by its mean value, and for the case of modified technique, each γ_2^{mod} is normalized by its mean value. It is

TABLE I. Second harmonic nonlinearity measurements at four different input signals.

| Input | 57 V | | 90 V | | 125 V | | 153 V | |
	γ_2^{con}	γ_2^{mod}	γ_2^{con}	γ_2^{mod}	γ_2^{con}	γ_2^{mod}	γ_2^{con}	γ_2^{mod}

Standard deviation	1.69	1.10	1.64	0.92	1.34	0.75	1.30	0.62
COV	0.0916	0.0597	0.0934	0.0508	0.0804	0.0410	0.0819	0.0338
FIG. 3. Graphical comparison of the third harmonic nonlinearity measurements obtained using the conventional technique and the modified technique. The comparisons are presented for four different input signals: 90, 125, 153, and 183 V.

seen from the figure that the scatter in the nonlinearity measurements obtained using the modified technique is less than that obtained using the conventional technique. This observation is quantified by presenting the results for nonlinearity measurements and the corresponding statistical quantities in Table I.

The coefficient of variation (COV), defined as the ratio of the standard deviation to the mean value, is used as an error estimator to compare the conventional technique with the modified technique. The advantage of this error estimator as compared to the standard deviation is that it is a dimensionless, scale-invariant quantity. It is seen that for all the four different input signals, the COV of γ_2^{mod}—the parameter quantifying the scatter in the material nonlinearity following the modified technique is approximately half of that of γ_2^{con}—the parameter quantifying the scatter in the material nonlinearity following the conventional technique. While the decrease in scatter is significant, we believe that the primary cause of the residual scatter in the modified measurements is attributable to instrumentation limitations. To see this, we separately analyzed the COV for each set of experimental measurements—$V_{[2](\omega_0)}^{[1](\omega_0)}$, $V_{[2](2\omega_0)}^{[1](\omega_0)}$, $V_{[1](2\omega_0)}^{[2](\omega_0)}$, and $V_{[2](2\omega_0)}^{[1](2\omega_0)}$. The corresponding values are 0.079, 0.087, 0.096, and 0.084, respectively. Note that the COV for $V_{[1](2\omega_0)}^{[2](\omega_0)}$ is the largest. This is the least optimal measurement because it corresponds to the case where transducer 2 (central frequency at 10 MHz) is driven at 5 MHz and transducer 1 (central frequency at 5 MHz) is used to receive the second harmonic (10 MHz) signal. Therefore both the generation and the reception are

nonoptimal. To overcome this limitation, broadband transducers with flat responses and with negligible intrinsic harmonic generation need to be used.

Third Harmonic Measurements. The experimental results and corresponding statistical quantities for the third harmonic nonlinearity measurements are shown in Fig. 3 and Table II, respectively.

The measurements were repeated six times, and for each set of measurements four different transducer drive voltages were used: $V1 = 90$ V, $V2 = 125$ V, $V3 = 153$ V, and $V4 = 183$ V. To avoid the much higher second harmonic frequency components from saturating the receiver and amplifier, a 15 MHz high-pass filter and an additional 20 dB amplification in the receiver were employed in the third harmonic measurements.

Similar to the results obtained for the second harmonic case, the COV of γ_3^{mod} is approximately half of that of γ_3^{con}. This again demonstrates that the modified technique will help to reduce the variability and therefore increase the robustness in the acoustic nonlinearity measurements based on higher harmonic generation. It is worth reiterating that the measured values of γ_n^{mod} and γ_n^{con} are quantitatively different as their expressions involve different combinations of the material nonlinearity and attenuation parameters. The same is true for the parameters γ_2^{mod} and γ_3^{mod} which also involve different measures of the acoustic nonlinearity in combination with material attenuation, and as such it is not possible to directly compare the two quantities.

IV. CONCLUSIONS

The main points of this paper are:

(1) Acoustic nonlinearity measurements can be useful for monitoring fatigue damage in metallic components. Conventional acoustic nonlinearity measurements are susceptible to large scatter due to variations in coupling between the transducers and the specimens. This is especially problematic when acoustic nonlinearity measurements need to be made at different cycles for fatigue damage monitoring.

(2) A modified method for acoustic nonlinearity measurements is proposed that minimizes the couplant effect. It is shown that the scatter in the results using the modified technique is roughly half of that using the conventional technique for both second and third harmonic measurements.

(3) The experimental results obtained here were using surface acoustic waves, but the method to minimize the couplant effect is equally applicable for nonlinearity measurements using longitudinal waves.

Efficiency of time-reversed acoustics for nonlinear damage detection in solids

Antonio S. Gliozzi, Michele Griffa, and Marco Scalerandi[a]

CNISM- Dip. Fisica, Politecnico di Torino, Corso Duca degli Abruzzi 24-10129 Torino, Italy

Time-reversed acoustics (TRA) has been developed in the last few years as a powerful tool for several applications, based on the theoretical properties emerging from the time reversal invariance of the wave equation. TRA is expected to be a good basis for the development of imaging techniques in the field of nondestructive evaluation. For this purpose, however, data processing is necessary to discriminate between images due to defects (in general nonlinear scatterers) and images due to linear inclusions, boundaries, etc. We propose here an approach based on the filtering of the time signals. The image of the scatterer is obtained through numerical simulations of the back propagation in a fictitious reference specimen. We validate the approach using the inversion of synthetic data. We also estimate the robustness of the procedure in the presence of constraints that can occur in any experimental procedure. © 2006 Acoustical Society of America.
[DOI: 10.1121/1.2345955]

I. INTRODUCTION

Time-reversed acoustics (TRA) refers to a process in which a propagating elastic wave field (e.g., a vibration velocity field) is reversed in time and irradiated back toward the source from which it was generated.[1,2] Since time reversal invariance[1] is verified by the wave equation, at least in linear, low attenuative, media, the irradiated field is expected to focus back on the source and, generally, reconstruct the signal.[3] The robustness of time reversal is corroborated by the observation that multiple scattering improves the quality of the procedure.[4,5] An additional advantage of TRA is also its potentiality in obtaining super-resolution.[6,7]

Furthermore, the validity of time reversal has been proven in solids.[8–10] More recently, Tanter *et al.*[11] and Cunningham *et al.*[12] have proven reversibility in nonlinear elastic media, at least under certain conditions.

As a consequence of the many theoretical expectations, TRA has been widely applied in different fields such as geophysics,[13–15] medical imaging[16] and applications,[17] oceanography,[18] wave guides,[19] acoustic tomography,[20] etc.

In this context, we are mostly interested in applications of TRA to defect imaging in solids. The idea stems from the consideration that in a TRA experiment the irradiated signal focuses back onto the source of the original signal. Defects in the propagation medium, behaving like scatterers, are expected either to be additional sources in the wave propagation or to partly break time reversal. One major task, however, remains to be solved for achieving optimal application of TRA to defects imaging and detection. It is indeed important to be able to discriminate images produced by real defects, which in general have nonlinear properties, from images due to linear inclusions, local changes in the modulus or boundaries, which also behave as scatterers. The so-called Decomposition de l'Operateur de Retournement Temporal (DORT) method[21] may be implemented to obtain selective focusing on different scatterers. Nevertheless, for early damage detection, it is often necessary to focus on extremely weak scatterers, and this may be particularly difficult. Addressing this issue is the major goal of the present contribution.

Applications of TRA to imaging in the field of nondestructive evaluation have been recently proposed.[22–24] Aluminum plates[25] and composite panels[26] have been studied by comparing the TRA reconstructed signal with the input signal. Any distortion is claimed to be an indicator of the presence of wave scattering due to the presence of damage. TRA has also been applied to detect damage in complex geometrical structures.[27] In particular, simulations have shown that the energy of the reversed wave field focuses on the scatterers, hence indicating a novel imaging procedure.[9,10,28]

In this paper, we suggest a novel procedure to obtain selective focusing on nonlinear scatterers. We also introduce additional novelties with respect to the existing approaches. First of all, we consider systems in which the surfaces of the specimens, or part of them, are not easily accessible. As a consequence we will not exploit, as is usually done, all the information of the received signals along a given direction, which may be one side of a plate[23] or a radial circumference for cylindrical specimens.[27]

In addition, we consider an experimental setup in which effects of boundaries of the specimen are important. As a consequence, we use information intrinsic also to the transmitted signals and not only to the backscattered ones. Finally, we underline that the geometry used here does not have any partial/complete symmetry. For instance, the time of flights from the defect to the receivers differs largely from one receiver to another, which may render the choice of the reversal time window a crucial point in the procedure. This problem does not appear when receivers, as usually done, are

[a]Author to whom correspondence should be addressed. Electronic mail: marco.scalerandi@infm.polito.it

arranged with a certain symmetry with respect to the scatterer (e.g., scatterer in the center of the specimen and receivers on the surfaces).

We make use of computational time reversal as a technique for imaging: After filtering of signals obtained from forward propagation in a damaged specimen, the results of simulations of the back propagation lead to the detection and characterization of regions where scatterers are located. The approach is tested by using synthetic data. In the next section, we describe the considered specimen, which includes both a linear inclusion and a nonlinear scatterer, and the nonlinear hysteretic model used to produce synthetic data.[29,30] We remark that the procedure and validity of the results proposed here are independent from the choice of the nonlinear elastic model. Forward data are indeed expected to be provided by a real experiment. In Sec. III, we present different procedures for treating signals before reversal.[31] In Sec. IV, we evaluate the robustness of the procedure by introducing some of the possible intrinsic sources of constraints/inaccuracies in real experiments, such as noise in the signals or weak sources of nonlinearity distributed in the specimen. Finally, in Sec. V, we further validate the proposed approach with a full three-dimensional (3D) simulation, with a configuration closer to that of a real experiment in which, e.g., only one surface of the specimen is available for transducers placement.

II. FORWARD PROPAGATION

A time-reversed acoustics (TRA) experiment consists of three successive steps:

- Generation of acoustic/ultrasonic waves in a specimen and detection of the signal (e.g., vibration velocity) as a function of time in several locations by means of a large number N of transducers acting as receivers and possibly embedded in the system. If that is not possible, a scanning laser can supply the signals from N different positions. Let us call $\boldsymbol{u}_j(t)$ the signal received by the transducer j $(j=1,\ldots,N)$ located in the position (x_j, y_j); note that the signal is a vector.
- Processing and time reversal of the received signal at each receiver. Let us call $\boldsymbol{v}_j(t)$ the processed signal.
- Reinjection of the time reversed signals in the specimen by each transducer, now used as a transmitter.

As discussed in the next section, the latter two points are numerically performed, while the former is expected to be experimentally realized. In this sense, we use numerical simulations as tools for post-processing experimental data and define the imaging procedure. Simulations are indeed the only tool for implementing successfully the procedure proposed here when nonlinear scatterers are located in the bulk of the specimen. On the contrary, when the focusing point is localized on the surface, the third step can be realized experimentally, by scanning the surface of the specimen, e.g., with a laser interferometer, to detect the focal point.

Here we produce synthetically the set of received signals, using a 2D model, which corresponds to an approxima-
FIG. 1. Representation of the plate used in the simulations. Transducers are indicated with a vertical line along their extension. Receivers are represented by small dots and few of them are marked with a number.

tion of a 3D specimen with no out-of-plane components of either stresses or strains. A few results using a 3D specimen will also be provided in Sec. V.

A. The specimen

For our simulations a 2D aluminium plate has been chosen as a test specimen (see Fig. 1). It has dimensions 12 cm × 6 cm and elastic properties given by the Lamè constants $\lambda = 51.08$ GPa and $\mu = 26.32$ GPa. Density is assumed to be $\rho = 2700$ Kg/m^3. Consequently the wave velocity in the material is $v_L = 6176$ m/sec and $v_S = 3122$ m/sec for the longitudinal and shear components, respectively. Attenuation in the material is chosen to be very high (to have the worst condition for time reversal) and therefore only few reflections from the boundaries will be considered. The boundaries of the specimen are considered fixed and not accessible to receivers, to simulate a specimen embedded in a larger structure.

Two scatterers are located as shown in Fig. 1. The larger one is a square-shaped linear inclusion of size 5 mm × 5 mm, with the same density as the bulk and a 20% reduction in both Lamé constants. The defect is a small nonlinear scatterer with length 10 mm and width 0.1 mm. The two have been located in arbitrary positions, far from each other. The configuration with the scatterers far from the center has been chosen in order to be far from the optimal configuration for reconstruction (e.g., defects in the center and/or equidistant from receivers). In fact, here influence from the boundaries is present in the signals.

The specimen is equipped with three extended transducers (size 10 mm × 1 mm). Each of them is designed to force a stress into the specimen with Gaussian modulated profile (with center angular frequency $\omega = 1.2$ MHz). The choice of three transducers is motivated by the need to have a uniform coverage of the specimen by the wave field. Results of the TRA procedure however do not seem to be affected by the number/location of the transducers and by the signal type.

Finally, $N = 124$ receivers are placed in a square arrangement around the zone that have to be investigated. A few receivers have been labeled with a number of reference. As will be discussed later, not all the received signals will be used for temporal inversion.

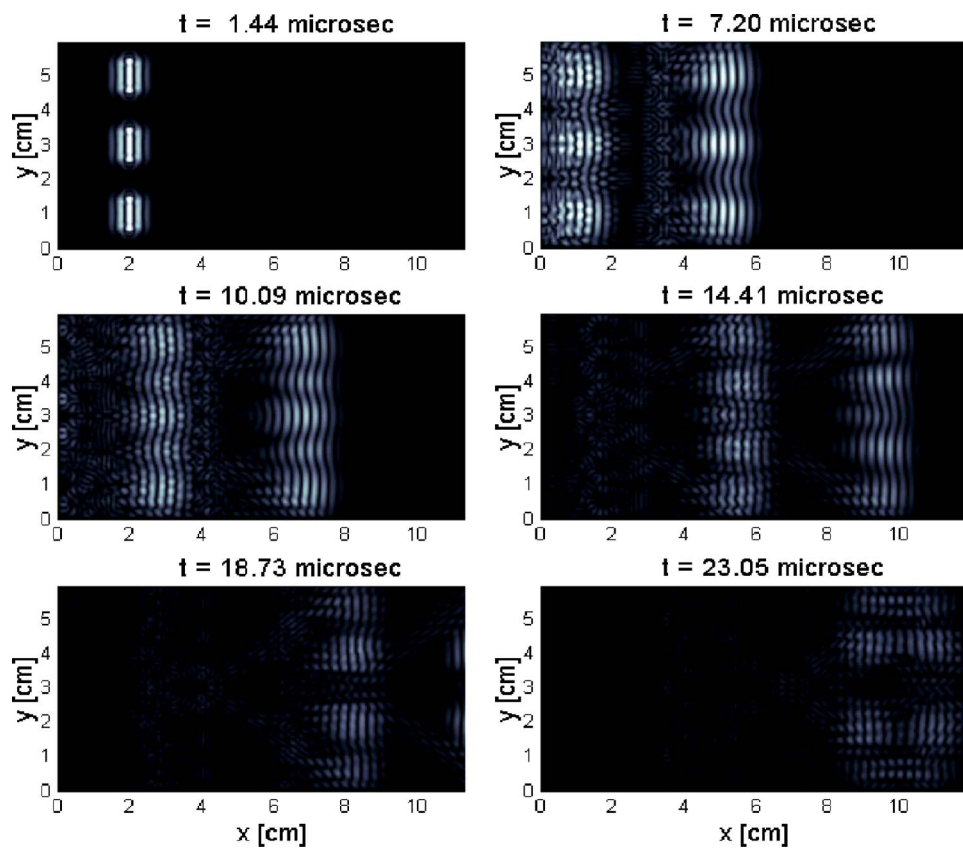

FIG. 2. Snapshots of the vibration velocity at successive times during the forward propagation in the plate with a linear and a nonlinear scatterer.

B. The model

To simulate the propagation of ultrasonic waves in the specimen of Fig. 1, a two-dimensional (2D) approach to the simulation of ultrasonic wave propagation in nonclassical nonlinear (NCNL) media has been used.[32] The method is described elsewhere[33] and its correctness demonstrated by qualitative and quantitative comparison with experimental data.[34–37] In particular, the model predicts mode conversion between shear and longitudinal waves, both due to the propagation of a nonplane wave[34] and both that generated at the reflection from an interface between different materials.[36] The issue is not discussed further here due to space limitations, but has been widely demonstrated in the mentioned references.

The approach represents the extension to 2D of a previously proposed 1D model,[29,30,38] based on a spring model,[35] applied together with a Preisach-Mayergoyz (PM) space treatment.[39] The material is discretized into a large number of elements (1200×600 in our simulations). Each of these is described by the usual linear elastodynamic equation of state in which stress is proportional to strain through the elastic stiffness tensor. The nonlinearity is introduced in the approach by including nontrivial boundary conditions on each element. This is obtained by defining thin space regions ("interstices") between adjacent cells that may be used to describe imperfections in the material.[35] The choice of a rigid interstice corresponds to imposing continuity of stresses and displacements between cells, i.e., absence of defects. Elastic interstices describe linear inclusions or delaminations.[40] Interstices switching from a rigid to an elastic state and vice versa during the crossing of the propagating wave describe a

nonlinear inclusion. Finally, when a PM space is introduced in order to model the transitions between the two states, regions with nonlinear hysteretic properties are modeled.[29,30,33]

C. Results

The chosen configuration of three transducers produces the propagation of a wave front (close to a plane wave) in the specimen, so that almost the whole of the specimen is excited with the same stress amplitude. In Fig. 2, snapshots of the vibration velocity at selected times during the propagation are reported. As expected, both the linear and the nonlinear inclusions are too small to produce appreciable effects.

The signals at two selected receivers (R) are reported in Fig. 3 and compared with the signals obtained in the absence of any inclusion/defect (reference specimen). The arrivals of the waves after multiple scattering from the specimen boundaries are clearly visible. For instance, the signal at 10 μsec for $R1$ corresponds to the wave reflected by the left edge of the specimen; the signal at 22 μsec at $R6$ corresponds to the superposition of the wave fronts reflected from the left and right boundaries. The correspondence with the reference signal is very good, confirming the difficulty to detect the presence of the two inclusions from the forward propagation only. A slight mismatch is only visible at $R6$, which is located very close to the linear scatterer. We deduce the greater influence of the inclusion on the propagation compared to the influence of the defect.
FIG. 3. Temporal signals recorded at the receivers number 1 (R1) and 6 (R6), see Fig. 1. The horizontal component of the vibration velocity vector is reported. The reference data refer to results for a homogeneous specimen, i.e., without the two scatterers.

III. IMPLEMENTATION OF TRA

To implement computational time reversal, the signals $u_j(t)$ recorded at each transducer j should be processed, time reversed, and reinjected into a reference fictitious specimen with the same geometry and boundary conditions of the previous one, but without inhomogeneities and defects. Injection is applied at the same time from all receivers, now used as actuators. The phase delay between the reinjected signals $v_j(t)$ should produce focusing on the position of the source of the original wave. It is to be noted that, in our problem, we can consider different sources: The three emitters used in the forward propagation problem, the linear, and the nonlinear scatterers and the boundaries.

A. Signals processing

Signals generated in the forward propagation have to be properly treated before being reinjected in the specimen. The very first step consists in the selection of the time window, characterized by a length Δ of the time signal to be reversed and an initial time T. Here we use a time window of 18 μsec, starting from 7 μsec. It is worth noting that the choice of the time window is not a trivial issue. More sophisticated choices could be made accounting for the fact that, due to the different distances of the receivers from the scatterers/sources, the optimal selected time window can in principle be different for each receiver. The issue is, however, beyond the scope of this contribution.

As a second step, the selected portion of the signal should be time reversed and additional processing may be introduced, in order to exploit the properties of time reversed propagation in detecting the positions of scatterers in a se-

lective way, distinguishing between boundaries, linear inclusion, and nonlinear defect. We propose three different treatments of the received signals, denoted in the following as *reversal*, *subtraction*, and *filtering* processes. The procedures have been designed so that in each one the portion of the signal due to the larger source, already localized in the previous processing step, is eliminated. We define an operator $\check{R}$ as $\check{R}(u_j)(t) = u_j(T + \Delta - t)$. The three treatments proceed as follows:

- Reversal processing: It corresponds to the usual TRA procedure. The injected signal is defined as $v_j(t) = \check{R}(u_j)(t)$, $0 < t < \Delta$. Unfortunately, as visible from Fig. 3, the three transducers are by far the stronger sources producing the signal $u_j(t)$. Therefore, in this standard procedure the portion of the signal due to scatterers is negligible.

- Subtraction processing: Before time reversal, we subtract from the received signal the reference signal $u_{jo}(t)$, i.e., the signal recorded at the same positions in the absence of any scatterer. It follows: $v_j(t) = \check{R}(u_j)(t) - \check{R}(u_{jo})(t)$. This processing analysis aims to eliminate the portion of the signal generated from the transducers only. Unfortunately, such an approach requires a baseline reference, which is not always available with the desired accuracy. It follows that the main advantage of using TRA for imaging purposes is lost. Also, in this procedure most of the signal is expected to be due to the linear scatterer, rather than to the (more interesting) nonlinear one.

- Filtering processing: The final goal of processing is to eliminate the portion of the signal due to the linear scatterer. For this purpose, considering that the nonlinear defect is the only source of nonlinearity in the specimen, we expect it to be the source for the portion of the signal containing higher order harmonics. Therefore, before reversal, we process the signal using a filter, which allows the elimination of all the components close to the fundamental angular frequency ω (center frequency of the injected signal). It follows that, without any need of a reference signal, only components generated by the defect are maintained in the received signal. The injected signal has the form: $v_j(t) = \check{R}(u_j^F)(t)$, where F denotes that the signal has been filtered. In the following a bandpass filter between 1.8ω and 4ω has been used.

Results for the three procedures are reported in Fig. 4 for selected receivers. The processed signals are similar when only a reversal is performed, reflecting the symmetry in the placement of the three transducers. On the contrary they are very different in the other two cases (bottom two rows), reflecting the asymmetries in the placement of the scatterers. Indeed, the signal at $R5$, which is aligned with the nonlinear scatterer (see Fig. 1), is almost null when the subtraction processing is applied, while rather large when filtering. The opposite occurs for $R6$, aligned with the linear inclusion. Note in Fig. 4 the different scales on the y axes. While after
FIG. 4. Results of the processing of the signals at receivers number 5 and 6 (see Fig. 1) before reinjection into the specimen. The horizontal component of the force per unit surface is reported in the selected time window. (a) First row: received signal; (b) second row: reversal of the received signal; (c) third row: reversal of the signal obtained subtracting the reference signal; and (d) fourth row: reversal of the band-pass filtered received signal.

subtraction about 25% of the signal is used for reversal, only about 2% remains after filtering. It follows that noise may play a crucial role, as discussed in Sec. IV.

B. Results

As a final step of the TRA implementation, the processed signals $v_j(t)$ are injected back into the specimen at the same time from all transducers. Simulations of the propagation of the time-reversed field are performed using a homogeneous linear specimen (no scatterer), in order not to introduce any bias from an *a priori* knowledge of the defect location. Note that here the vectorial form of the reversed signal is maintained in the injection (i.e., both components of the received signals are reinjected). Receivers in experiments may not be able to keep the vectorial information. However, as discussed later, the imaging procedure is still effective.

In Fig. 5, we plot the map of the velocity field at the time corresponding to best focusing during the reversed propagation for the three processing procedures described in the previous subsection: reversal, subtraction, and filtering, from top to bottom. As expected, albeit at different times, best focusing is obtained on the three transducers, on the linear inclusion and on the nonlinear scatterer, respectively. In each of them, the temporal evolution of the wave field does not indicate evidence of focusing on other sources except the ones indicated in the plot. A very slight evidence of focusing on the nonlinear inclusion is only present in the wave field corresponding to the subtracted reversal process, which indeed was to be expected. The reduced focusing of energy on the central transducer in the upper plot is due to the choice of the distribution of receivers.

In this contribution, we are interested in the last proposed procedure only, which is novel, to our knowledge, with respect to existing TRA approaches and does not re-

quire any reference signal. Therefore, we further discuss,
FIG. 5. Snapshots of the vibration velocity as obtained in the simulations of the reversed signals at the time corresponding to best focusing for the three implementations proposed. First row: reversal; second row: subtraction; third row: filtering.
FIG. 6. Snapshots at successive times of the velocity wave field during back propagation in the case of filtering.

here and in the following, the case of filtering. In Fig. 6 snapshots of the velocity field are reported at selected times during reversed propagation. The time-reversed wave field appears at positions farther from the source (the nonlinear scatterer) first, i.e., the upper and right rows of receivers. At a later time (14–15 μsec), the receivers close to the defect start playing a role, but the wave field remains unfocused. Progressive focusing occurs between 16 and 18 μsec revealing a reasonably good image of the scatterer. At later times, defocusing occurs again. No evidence of focusing in regions far from the scatterer (i.e., phantom images) is present.

C. Improvements of the imaging procedure

Images of the wave field at the time corresponding to best focusing (see Fig. 5) constitute a first indicator of the quality of the imaging procedure. In these plots, however, several pieces of information are lost. For example, the possible focusing on other scatterers and the images of the ray paths from the receivers to the focusing point. To capture these details an alternative mapping of the wave field data can be proposed as follows.

Let us call $w(x,y;t)$ the function describing one variable (vibration velocity, strain, stress, etc.) in any position (x,y) and at any time (t). We introduce the following function:

$$M(x,y) = \max[w(x,y;t)]_t \qquad (1)$$

which represents, in any position, the maximum value the variable w assumes in time. The function M is expected to present maxima wherever focusing occurs and also secondary maxima where the unfocused paths from the N receivers interfere coherently toward the focusing point, hence identifying the ray paths. Here, we have chosen the variable w to

be the modulus of the local displacement vector field.

An image of the map M corresponding to the same simulation of Fig. 6 is reported in the upper row of Fig. 7. The map clearly indicates focusing on the nonlinear scatterer and a maximum in the position of the receivers which are mostly contributing to the reconstruction (i.e., receivers close to the scatterer). Some ray paths are also identified, although not particularly meaningful here.

To improve the imaging procedure, we note that Fig. 7 shows that only few transducers contribute to the reconstruction of the image. Also, the time series in Fig. 4 illustrate that some transducers reinject a signal of very small amplitude (e.g., $R6$). Since focusing is determined mostly by keeping proper phase delays between signals injected from different positions, independent of amplitudes, we introduce the possibility of amplifying the injected signals differently at different positions. Therefore, we introduce a further signal processing step: $z_j(t) = A_j * v_j(t)$, where A_j is the amplification factor. To obtain equal contributions from all transducers, we define $A_j = 1/\max[\|v_j(t)\|]_t$. The corresponding z_j signals are therefore each normalized to one.

Results of the simulation using normalized signals are reported in the second row of Fig. 7, where the map of the function M is reported. The improvement of the reconstructed image is evident, with a much larger energy being focused on the scatterer than that being injected at the transducers. Ray paths are more meaningful and give indication of the progressive focusing. In the third row of Fig. 7 we also analyze the effect of reinjecting normalized signals using only one component of the recorded wave field (in particular the x component). The reconstructed map remains reasonably good, albeit with a deterioration of the image with respect to the previous case.

Not normalised

Normalised

Only x-component

Averaged
FIG. 7. Maps of the maximum of the displacement [see Eq. (1)] for different implementations of the procedure. (a) First row: standard procedure; (b) second row: normalizing all the injected signals to 1; (c) third row: normalizing the signals and reinjecting only the horizontal component of the recorded signal; and (d) fourth row: averaging the map over a square with size equal to the distance between adjacent receivers.

Finally, in the bottom row of Fig. 7 we also show how a mathematical smoothing on the map M leads to a significant improvement of the quality of the image of the defect location. This plot corresponds to the same image of the second row, but averaged on a square of size corresponding to the distance between two adjacent receivers (3 mm).

IV. ROBUSTNESS OF THE IMAGING PROCEDURE

This section is devoted to testing the robustness of the filtering procedure for the purpose of nonlinear defect imaging. We investigate the effects on the quality of the image of various constraints/errors that may be intrinsic to the experi-

mental procedure of detection of the forward signals. In all cases, we show the robustness of the imaging process to be valid only up to a certain point.

All results reported in this section refer to plots of the matrix M [see Eq. (1)], obtained implementing the filtering procedure, with normalized signals and maintaining the vectorial information in the backward injection.

A. Effects of the number of transducers

In Fig. 8, we report the reconstructed images obtained using a different number of transducers. Except for the plot in the bottom-right corner, transducers are always taken equidistant on the four sides of a square. In the bottom-right plot, only transducers localized on the two vertical arrays are used, which may be an easier configuration from an experimental point of view.

As expected the quality of the image decreases with a decrease in the number N of transducers available. In fact, decreasing N, the maxima of energy become more and more focused on the transducers positions: Fewer transducers mean fewer rays converging on the defect location and, consequently, less constructive interference. Nevertheless partial focusing is still evident in the case $N=22$.

Note that the need of a quite large number of transducers should not be considered a technical obstacle. In fact, receivers for the forward propagation may be easily substituted by a scanning laser interferometer, as mentioned. Emitters in the reversed propagation are used only in the numerical simulation, where an arbitrarily large number of emitters can be used without difficulties.

B. Effects of noise in the received signal

Clearly, synthetic data are not affected by noise. On the contrary, in every experimental system, noise is present and contaminates the received signals. To simulate a realistic condition, we artificially perturb the received signals with a randomly generated additive noise before processing:

$$\boldsymbol{u}_j^n(t) = \boldsymbol{u}_j(t) + \gamma_j(t),$$

where $\gamma_j(t)$ is a random white noise signal with zero average. Therefore, for each of its components k, $\langle \gamma_k(t) \rangle = 0$ and $\langle \gamma_k(t') \gamma_k(t) \rangle = (\gamma_0^2/4) * \max[u_k(t)]_t * \delta(t,t')$. Typical effects on the signal are reported in Fig. 9 for the receiver number 1 and two choices of γ_0. As expected, the effect on the received signal (upper row) is small. On the contrary, it increases enormously in the filtered signal (second row). In the case of a larger γ_0, the effect of the noise is comparable with the original signal (see third row).

Despite the large effect of noise, the reconstructed images of the defect remain acceptable up to a noise level of $\gamma_0 = 0.1$ (see Fig. 10). Not surprisingly, the procedure does not work any longer at the largest value of γ_0, where no evidence of focusing is observable. Rather unexpected is the robustness of the procedure at $\gamma_0 = 0.1$, considering the quality of the injected signals. The result is an indicator that the noise, albeit very large, produces an unfocused wave field superimposed to the wave field generated by the nonlinear
FIG. 8. Maps of the maximum of the displacement [see Eq. (1)] for different numbers of used receivers. The bottom right corner corresponds to the results obtained when only two vertical arrays of receivers are used.

scatterer. The former is distributed on the full specimen, resulting in a local energy which is very small compared to that which focuses on the scatterer.

C. Effects of a distributed weak nonlinearity

Similar encouraging results concerning the robustness of the proposed procedure are also obtained when analyzing the capability of the approach to detect the scatterer in the presence of a distributed nonlinearity. For this purpose we consider a specimen with several weak nonlinear scatterers (about 5–10% of the nonlinearity of the defect) distributed randomly in space. To quantify such distributed nonlinearity, we define a parameter α which defines (as a percent area) the zone in which nonlinear scatterers are distributed, hence giving the density of nonlinear scatterers.

The signals obtained from the simulation of the forward propagation differ only very slightly from the ones obtained in the absence of weak scatterers. On the contrary, such a nonlinearity has an enormous influence on the filtered and reversed signals already at $\alpha=5\%$ (see Fig. 11).

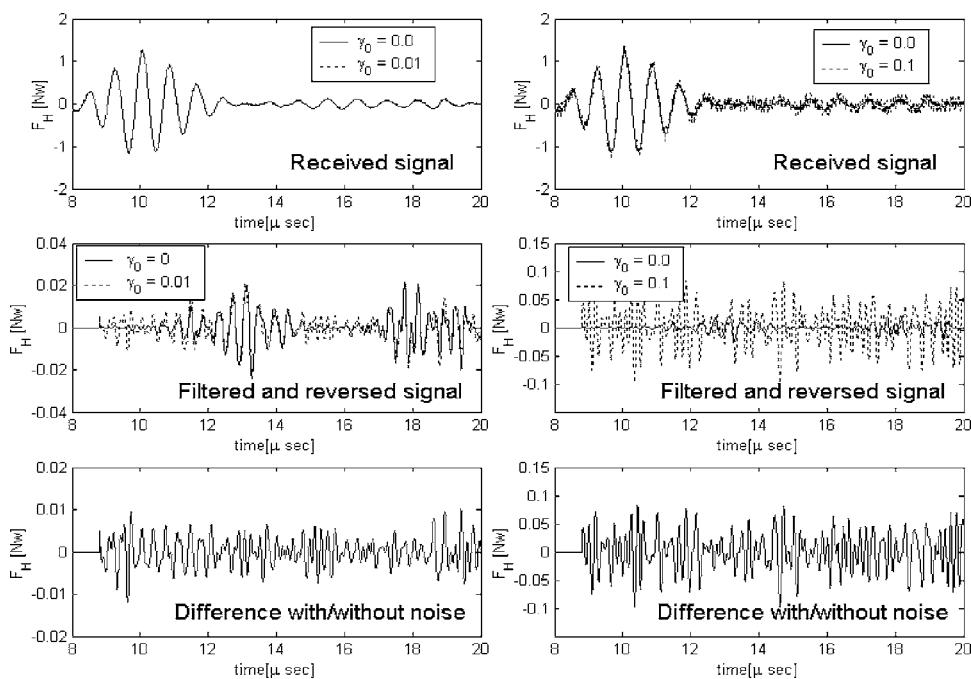
Despite the huge effect on the injected signals, reconstruction of the defect image remains good up to $\alpha=10\%$


FIG. 9. Comparison of the temporal signals at receiver 1 (see Fig. 1) in the presence or absence of an additive noise on the received signal. First column: weak noise level; second column: large noise level.
FIG. 10. Maps of the maximum of the displacement [see Eq. (1)] for different noise levels.

FIG. 11. Temporal signals at receiver 1 [see Fig. 1] for different levels of distributed nonlinearity in the specimen.

(see Fig. 12). Note the significant energy focusing close to the transducers used in the forward problem. Such focusing is due to the fact that, in the forward propagation problem, nonlinear scatterers close to the source have been excited at a larger amplitude than scatterers far from it.

V. EXPERIMENTAL FEASIBILITY

So far, we have used a 2D model of elastic (ultrasonic) wave propagation in heterogeneous specimens, which is an approximation of a 3D model of propagation in a very thin plate, under the special conditions of plane stress propagation. Such approximation has been widely used in the literature (see, e.g., Refs. 25–28 and 41–44) to prove feasibility and properties of imaging methods based upon numerical simulation and processing of real data.

Nevertheless, it may be argued if the method proposed here still works in conditions closer to the experimental ones, e.g., when measurements of in-plane vibrations are not possible. Therefore, in this section we present an application of the proposed procedure to a 3D specimen, using the extension of the 2D approach to account also for displacements/stresses in the Z direction.

We consider a thin plate (10 cm × 2.5 cm × 1 cm) with Lamè constants $\lambda = 106$ GPa and $\mu = 71$ GPa. Density is assumed to be $\rho = 8000$ Kg/m^3. A small nonlinear scatterer (5 mm × 3 mm × 2 mm) is located in $x = 5$ cm, $y = 1.5$ cm, and $z = 0.5$ cm. One transducer is localized on the upper surface in $x = 4$ cm, $y = 1.2$ cm, injecting a Gaussian modulated wave with center frequency $\omega = 0.7$ MHz. Forty-five receivers are localized on the upper surface ($z = 0$) along five parallel arrays (see Fig. 13 where the position of the arrays is clear).

The data processing and the simulation of the time reversed propagation is performed following the same procedure as before (filtering with normalization) and a 3D matrix M is defined [analogous to Eq. (1)]. In Fig. 13, slices of the matrix M at different depths are reported (darker grey tones denote larger intensities). On the upper surface ($z = 0$), the position of the receivers is evident. At the same time, we can observe focusing of the energy on the position occupied by
FIG. 12. Maps of the maximum of the displacement [see Eq. 1] for different distributed nonlinearity levels.

the nonlinear scatterer, while no focusing is evident in planes further from $z=5$ mm. Results are in good agreement with that obtained in the 2D approximation (see, e.g., Fig. 7).

A 3D representation of the matrix M is also reported in Fig. 14: We report sections along three lateral surfaces and a diagonal cut from a line of receivers to the defect center. Again, focusing on the scatterer location is visible.

VI. DISCUSSION

All studies reported in the literature point out that TRA, compared with other damage localization methods, remove

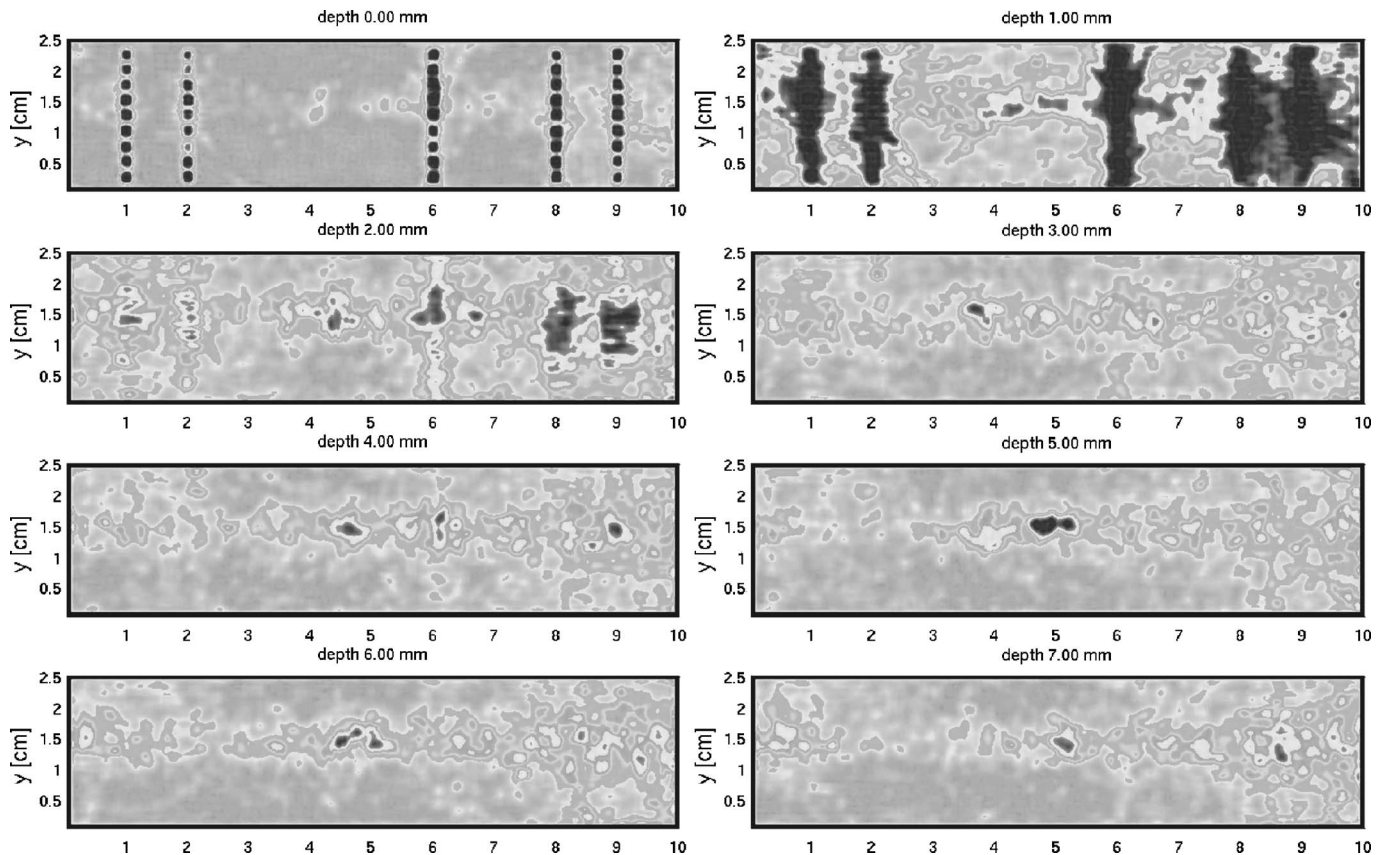
the requirements of a reference system for comparison.[24] This is one of its major advantages. Nevertheless, in our opinion, this is not always the case. In fact, increasing the complexity of the specimen, small defects may not be detected in the reconstructed TRA image, due to the presence of stronger scatterers in the sample. Indeed, in this contribution, we have considered the case of weak scatterers, which give an almost negligible signature on the received signals (see Fig. 3). As a result, as shown in Fig. 5, a linear inclusion, or even the presence of boundaries or of the transducers


FIG. 13. Maps of the maximum of the displacement in a 3D numerical experiment. The various rows represents cuts at different depths as indicated. The nonlinear scatterer was located in $x=5$ cm, $y=1.5$ cm, and $z=0.5$ cm. Darker grey tones denote larger intensities.
FIG. 14. 3D maps of the maximum of the displacement in the same case as Fig. 13. Four reference planes are reported, the diagonal one intersecting one array of transducers and crossing the center of the nonlinear scatterer. Darker grey tones denote larger intensities.

themselves, may reduce the efficiency of the procedure and make difficult, for traditional TRA, to detect a nonlinear defect.

As a consequence, we have proposed here to exploit features intrinsic in the nonlinear properties of small defects to maintain the possibility to avoid using a reference system, as proposed elsewhere in a different context.[45,46] Indeed, the harmonics content of the received signals may be due only to the presence of nonlinear features in the specimen. It follows that, selecting such higher order components corresponds to subtracting a reference signal, without the need of it. As we have shown, the procedure can be easily implemented and leads to selective focusing on defects with nonlinear characteristics.

The method proposed here has been tested using synthetic data, produced by a numerical code based on a model proven to be reliable in the description of the propagation of elastic waves in nonlinear hysteretic media.[29] In the paper, a 2D configuration has been considered, which is far from being technically realisable (e.g., a laser interferometer can measure the out of plane components of the vibration velocity, fixed boundary conditions are usually not realistic, etc.). Nevertheless, we believe that the theoretical analysis reported here might be an important preliminary step toward a practical realisation and the results obtained for a simple 3D case (Sec. V) further confirm our belief. Furthermore, the capability to suggest novel experimental approaches is, in our opinion, one of the purposes of numerical modeling, as demonstrated by the large number of papers in which new signal processing analysis methods and theories have been tested also using numerical simulations.[23,41–44]

We remark again that imaging, in this contribution, is considered as the postprocessing of the data, realized through the simulation of the backward propagation of the time-reversed signals. To implement such an approach, is therefore necessary to record a sufficient number of forward signals from the experiment and to provide a detailed information about the elastic and geometrical properties of the specimen (in its intact state), in addition to the details about the boundary conditions adopted in the experiment.

Several issues have also been raised in the paper and probably need further attention when lab data have to be used for the localization of nonlinear scatterers. Figures 10 and 12 seem to indicate a good robustness of the procedure to the presence of noise or specimen heterogeneities (also nonlinear). On the contrary, it seems that in the case of a low Q material a good reconstruction may be obtained only when in the forward propagation experiment time signals are picked in a large number of different locations, which may be a drawback for applications unless a scanning laser is available. Nevertheless, when attenuation is low, longer signals can be used, hence compensating for the number of transducers.

Using longer signals also should help increase the resolution, thanks to the more consistent mode-conversion effect between shear and longitudinal waves. That may be useful for reconstruction of the shape of the scatterer. At this stage, the focal area is strongly determined by the kind of signal used in the forward propagation problem. A more careful analysis has to be carried on about this issue.

The scattering of acoustic waves by objects located inside a waveguide is discussed, assuming that the scattering amplitude for the object in an extended uniform medium is known. The scattering process is described by using an expansion of the scattering amplitude in terms of spherical harmonics. An appropriate multipole decomposition of the waveguide Green's function is developed and the effective scattering amplitude in the waveguide is obtained. An important property of the effective scattering amplitude, the generalized optical theorem, is obtained and its implications for scattering in a waveguide are discussed. The scattering problem is formulated entirely and explicitly in terms of the waveguide Green's functions, which makes this approach very flexible in regard to the choice of the incident field. It also establishes the connection between propagation and scattering and allows for the independent computation of the propagation and scattering aspects of the problem. This is the main advantage of using the scattering amplitude in an extended uniform medium as an input. The connection of this work with previous work in scattering in waveguides is discussed. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354077]

I. INTRODUCTION

The scattering of acoustic waves by an object imbedded in a heterogeneous acoustic medium is the problem addressed in this paper. The heterogeneity may originate from nonuniform density and sound speed, the presence of boundaries and interfaces, or a combination of all these factors. The difficulty in solving this problem arises from the fact that one has to enforce boundary conditions both on the surface of the scattering object as well as on the interfaces and boundaries. For nonuniform media, additional difficulties arise, since only numerical solutions are usually available. However, a promising way of tackling those problems is to assume that the single object scattering problem in an extended uniform medium can be solved independently and then formulate the waveguide scattering problem in such a way as to incorporate this result into the full solution of the problem. The pseudopotential introduced by Huang and Yang[1] offers a convenient starting point since it separates the implementation of both sets of boundary conditions. With this approach, the scattering properties of the object are subsumed in a series of field-dependent source terms added to the wave equation, the solution of this equation must then satisfy proper boundary conditions on the medium's boundaries.[2]

The basic formulation of the approach adopted in this work was presented in Ref. 2. In Ref. 3 the method was further developed and used to obtain the generalized optical theorem for a scattering object embedded in an inhomogeneous medium. Its use in scattering problems in ocean acoustics is elaborated on here. The formulation is entirely based on Green's function that makes the approach independent of particular assumptions about the incident field, as all incident fields can be obtained with the Green's functions and appropriate source functions. Also the formulation is independent of any particular explicit expression for the Green's functions. An explicit operational procedure is obtained to produce the proper multipoles of the waveguide Green's functions that enter in the scattering equations. If one examines previous formulations of this problem, one notices that a great deal of effort is involved in computing transformations from cylindrical to spherical coordinates and basis functions.[4,10] While those calculations are unavoidable when one has to carry out computations they are not necessary when obtaining the basic equations as demonstrated in this article and in Refs. 2 and 3. This simplification allowed the authors to discuss the energy flux in the scattering process in a relative simple and transparent way culminating in the derivation of the generalized optical theorem taking into account all the multiple interactions of the scattered acoustic field with boundaries and other spatially varying acoustic properties of the waveguide. The only other discussion of the optical theorem in underwater acoustics known to the authors, namely Ref. 13, neglects those interactions.

There are other approaches to this problem that are explicit designed with numerical computations as the goal and thus differ in spirit from the work presented here. A particularly interesting work is the one in Ref. 5 where multiple boundary interactions for a cylindrical object in a waveguide is discussed through an ingenious numerical approach. Similarly, the problem of acoustic scattering by an elastic spherical shell near a perfectly reflecting plane boundary was discussed in Ref. 6 by the method of images. In Ref. 7 one finds another interesting approach to this problem, which is also pragmatically oriented toward numerical computations. In this paper we emphasize a general formulation of the prob-

lem, delaying as much as possible the use of explicit expressions for the Green's functions, the scattering amplitudes, etc. This allows further analysis, such as obtaining the optical theorem. This, of course, does not preclude numerical calculations but permits one to explore how far one can go before resorting to computations.

The general formulation is presented in Sec. II. In Sec. III we discuss the generalized optical theorem. Since all necessary derivations are similar to those in Refs. 2 and 3, they are not repeated here. In Sec. IV we present results pertaining to scattering in an ideal waveguide (computations for more realistic waveguides will be presented in a future work). In order to illustrate the effect of boundary interactions, these results are compared with results for the same problem obtained using Ingenito's[4] approximate formulation of the scattering problem. Finally, in Sec. V we summarize and further discuss the results.

II. SCATTERING IN AN INHOMOGENEOUS MEDIUM

In this section the general results obtained in Ref. 2 will be presented in the context of an ocean acoustic waveguide. As the derivation parallels that of Ref. 2, it will be omitted here. In this formulation the scattering in an extended and uniform medium with sound speed c of a cw plane wave with frequency $\omega/2\pi$ by an arbitrary scattering object is characterized by an operator T given by the following projection of the scattering amplitude into spherical harmonics:

$$T_{lm,l'm'}(k) = \frac{i^{l-l'}}{4\pi} \int d\hat{\mathbf{p}} \, Y_{lm}^*(\hat{\mathbf{p}}) \int d\hat{\mathbf{q}} \, Y_{l'm'}(\hat{\mathbf{q}}) f(\hat{\mathbf{p}}, \hat{\mathbf{q}}). \quad (1)$$

In Eq. (1) $f(\hat{\mathbf{p}}, \hat{\mathbf{q}})$ is the scattering amplitude defined in the usual way in terms of the asymptotic limit for $r \rightarrow \infty$ of the scattered wave field created by the scattering of an incident plane wave by the object.[8] Note that the expression in Eq. (1) differs from the one in Ref. 2 by a wavenumber factor $k = \omega/c$.

The procedure developed in Ref. 2 can be used to obtain equations describing scattering in a general case and it can be formulated without a specific expression for the Green's function in the waveguide. This Green's function obeys Bergmann's extension of the Helmholtz equation[9] to a nonuniform fluid plus appropriate boundary conditions:

$$\rho(\mathbf{r}) \, \mathbf{\nabla} \cdot \left(\frac{1}{\rho(\mathbf{r})} \, \mathbf{\nabla} G_0(\mathbf{r}, \mathbf{r}_0) \right) + k(\mathbf{r})^2 G_0(\mathbf{r}, \mathbf{r}_0) = \delta(\mathbf{r} - \mathbf{r}_0).$$

$$(2)$$

In order to use the operator T as an input in the computation of scattering in an arbitrary medium, one must assume that in a neighborhood fully containing the object in the arbitrary medium the acoustic wavenumber and the density can be assumed to be locally uniform. Thus, for $\mathbf{r}$ and $\mathbf{r}_0$ in this region, that is for $d+\varepsilon > |\mathbf{r} - \mathbf{r}_T| > d$ and $d+\varepsilon > |\mathbf{r}_0 - \mathbf{r}_T| > d$, where d is the largest linear dimension of the object and ε is positive (perhaps very small), $G_0(\mathbf{r}, \mathbf{r}_0)$ can be written as

$$G_0(\mathbf{r}, \mathbf{r}_0) = g_T(\mathbf{r} - \mathbf{r}_0) + G_0^{\text{NS}}(\mathbf{r}, \mathbf{r}_0),$$

$$(3)$$

$$g_T(\mathbf{r}) = -\frac{e^{ik_T r}}{4\pi r}, \quad k_T = k(\mathbf{r}_T).$$

That is, the Green's function inside a region of uniform density and sound speed can be split into two parts: a singular one, which is just the Green's function in the equivalent unbounded medium, and a nonsingular part enforcing the boundary conditions.

The techniques employed in Ref. 2 lead to an equation for the waveguide Green's function when a scattering object is present in terms of a set of partial wave coefficients that are determined by a linear algebraic equation for the new coefficients. Thus the Green's function for a waveguide with a scattering object inside can be written as

$$G(\mathbf{r}, \mathbf{r}_0) = G_0(\mathbf{r}, \mathbf{r}_0) - \sum_{lm} \sum_{l'm'} G_{lm}^{\text{out}}(\mathbf{r}, \mathbf{r}_T) T_{lm,l'm'} a_{l'm'}. \quad (4)$$

For nonspherically symmetric scatterers the above equation is valid for $\mathbf{r}$ outside the enclosing sphere, that is, it is valid when the point $\mathbf{r}$ is outside of a sphere whose diameter is equal to the largest linear dimension of the scattering object.

The coefficients a_{lm} obey the following equation:

$$a_{lm} = G_{lm}^{\text{inc}} - \sum_{l'm'} \sum_{l''m''} K_{lm,l'm'}(\mathbf{r}_T) T_{l'm',l''m''} a_{l''m''}. \quad (5)$$

The new quantities introduced in the above equations are as follows:[2,3]

$$G_{lm}^{\text{out}}(\mathbf{r}, \mathbf{r}_T) = D_{lm}^*(\mathbf{\nabla}') G_0(\mathbf{r}, \mathbf{r}')|_{\mathbf{r}'=\mathbf{r}_T} \quad \text{for } \mathbf{r} \neq \mathbf{r}_T, \quad (6)$$

$$G_{lm}^{\text{inc}}(\mathbf{r}_T, \mathbf{r}_0) = D_{lm}(\mathbf{\nabla}) G_0(\mathbf{r}, \mathbf{r}_0)|_{\mathbf{r}=\mathbf{r}_T} \quad \text{for } \mathbf{r}_0 \neq \mathbf{r}_T, \quad (7)$$

and

$$K_{lm,l'm'}(\mathbf{r}_T) = D_{lm}(\mathbf{\nabla}) D_{l'm'}^*(\mathbf{\nabla}') G_0^{\text{NS}}(\mathbf{r}, \mathbf{r}')|_{\mathbf{r}=\mathbf{r}'=\mathbf{r}_T}. \quad (8)$$

In the above equations $D_{lm}(\mathbf{\nabla})$ is a differential operator, a polynomial of degree l in the partial derivative operators ∂_x, ∂_y, and ∂_z, defined as follows:[3]

$$D_{lm}(\mathbf{\nabla}) = \frac{(2l+1)!!}{k_T^l} \frac{1}{l!} \int d\hat{\mathbf{s}} \, Y_{lm}(\hat{\mathbf{s}})^* (\hat{\mathbf{s}} \cdot \mathbf{\nabla})^l$$

$$= \frac{4\pi i^l}{k_T^l} \frac{(-1)^m}{2^l l!} N_{lm} (p_x - ip_y)^m \partial_u^{l+m} (u^2 - p^2)^l \Big|_{u=p_z},$$

$$(9)$$

where $\mathbf{p} = -i\mathbf{\nabla}$, $p^2 = -\nabla^2$, and N_{lm} is the normalization factor for the spherical harmonics. The resulting equations, Eqs. (4) and (5), show that, in the presence of boundaries and/or a heterogeneous medium, there is a coupling among the scattered partial waves, even for spherically symmetrical scatterers. One should also notice that the only quantity related to the scattering target that appears in the coupling matrix, Eq. (8), is its position relative to the boundaries. This indicates that no matter what the nature of the target is, this coupling matrix determines the coupling among the scattered partial waves induced by the inhomogeneities of the medium, such as spatially varying acoustic properties, interfaces, and boundaries.

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

D. K. Dacol and D. G. Roy: Scattering in waveguides   2519

The equation for the Green's function, including scattering by an object at $\mathbf{r} = \mathbf{r}_T$, can now be written as

$$G(\mathbf{r}, \mathbf{r}_0) = G_0(\mathbf{r}, \mathbf{r}_0) - \sum_{lm} \sum_{l'm'} D_{lm}^*(\boldsymbol{\nabla}')$$
$$\times |G_0(\mathbf{r}, \mathbf{r}')| \mathbf{T}_{lm,l'm'}(\mathbf{r}_T) D_{l'm'}(\boldsymbol{\nabla}'')$$
$$\times |G_0(\mathbf{r}'', \mathbf{r}_0)|_{\mathbf{r}'=\mathbf{r}''=\mathbf{r}_T}, \tag{10}$$

where the effective scattering operator, $\mathbf{T}(\mathbf{r}_T)$, is given by

$$\mathbf{T}(\mathbf{r}_T) = T(k_T) - \mathbf{T}(\mathbf{r}_T)K(\mathbf{r}_T)T(k_T), \quad \text{or} \tag{11}$$

$$\mathbf{T}(\mathbf{r}_T) = T(k_T)[I + K(\mathbf{r}_T)T(k_T)]^{-1}.$$

The scattering term in Eq. (10) can be interpreted as stating that a multipole decomposition of the incident field, $D_{l'm'}(\boldsymbol{\nabla}'')G_0(\mathbf{r}'', \mathbf{r}_0)|_{\mathbf{r}''=\mathbf{r}_T}$, is scattered into a multipole decomposition of the outgoing scattered field, $D_{lm}^*(\boldsymbol{\nabla}')G_0(\mathbf{r}, \mathbf{r}')|_{\mathbf{r}'=\mathbf{r}_T}$. In the case of a layered medium, this result, apart from differences in notation, coincides, formally, with that obtained by Sammelmann and Hackman.[10] However, the formulation presented here in terms of the waveguide Green's function with an explicitly operational procedure to obtain the proper multipole expansion seems to be more general, although equivalent to other formulations that start with an explicit expansion of the acoustic field in cylindrical coordinates and then carry out a projection into spherical harmonics.[4,10].

As an example to illustrate the structure of the above equations, let us consider the case where the wavelength of the incident field on the object is much larger than a typical dimension of the object. In this case it is a reasonable approximation to consider the object an isotropic scatterer where only the terms with $l=0$ contribute to the scattered field. One obtains in this case the following expression for the Green's function, including the scattered field:

$$G(\mathbf{r}, \mathbf{r}_0) = G_0(\mathbf{r}, \mathbf{r}_0) - \frac{4\pi f}{1 + 4\pi f G_0^{NS}(\mathbf{r}_T, \mathbf{r}_T)}$$
$$\times G_0(\mathbf{r}, \mathbf{r}_T)G_0(\mathbf{r}_T, \mathbf{r}_0), \tag{12}$$

where $f = T(k_T)_{00,00}$ is the isotropic scattering amplitude. Thus, one sees that in the inhomogeneous medium the effective scattering amplitude is

$$f_{\text{eff}} = \frac{f}{1 + 4\pi f G_0^{NS}(\mathbf{r}_T, \mathbf{r}_T)}. \tag{13}$$

The denominator in Eqs. (12) and (13) is a consequence of the multiple interactions between the scattered field and the boundaries and other spatially varying acoustic properties of the waveguide. The most obvious consequence of Eq. (13) is that the effective scattering amplitude varies with the position of the scattering object. The closer the object is to a boundary or interface the stronger this effect will be. Another consequence is that even if the scattering amplitude in the extended and uniform medium is not resonant, it is possible for the effective scattering amplitude to be resonant. If f is resonant, then the resonant frequency will be shifted in f_{eff}; see, for example, Ref. 11. The implications of this reso-

nance shift for bubbles near a pressure release surface are discussed in Ref. 12.

III. THE GENERALIZED OPTICAL THEOREM

An important relation satisfied by the effective scattering operator defined in Eq. (11) can be obtained by examining the energy flux across a surface that encloses the scattering object. A lucid discussion of energy fluxes in a scattering context is presented in Ref. 13. Those authors use Ingenito's[4] approximate description of scattering in a waveguide that neglects multiple interactions of the scattered field with the waveguide's boundaries, interfaces, and other spatially varying acoustic properties. Thus, their discussion is incomplete in this regard. The discussion presented in this section uses the full scattering description developed in Sec. II and addresses the impact of those multiple interactions on the energy conservation in the scattering process. A detailed derivation of the generalized optical theorem for scattering in an inhomogeneous medium is presented in Ref. 3 and, with very minor changes, that derivation is applicable to scattering in an oceanic waveguide. Unless explicitly stated, the discussion follwing is not restricted to a layered medium.

Consider the case of a nonenergy-absorbing medium and an object that also does not absorb energy. Then the total energy flux across a closed surface that surrounds the scattering object but excludes the point source is zero since all the incident acoustic energy eventually leaves the volume enclosed by the surface. The incident field carries part of this energy and part of it is in the scattered field but none is dissipated into heat or other forms of energy. The total energy flux across the closed surface is

$$F_T = \frac{1}{2i\omega} \int d\mathbf{S} \cdot \left(G(\mathbf{r}, \mathbf{r}_0)^* \frac{1}{\rho(\mathbf{r})} \boldsymbol{\nabla} G(\mathbf{r}, \mathbf{r}_0) \right.$$
$$\left. - G(\mathbf{r}, \mathbf{r}_0) \frac{1}{\rho(\mathbf{r})} \boldsymbol{\nabla} G(\mathbf{r}, \mathbf{r}_0)^* \right). \tag{14}$$

Using the divergence theorem and the equation satisfied by the full Green's function $G(\mathbf{r}, \mathbf{r}_0)$, Eq. (10), one obtains

$$F_T = \frac{1}{2i\omega\rho(\mathbf{r}_T)} G_{\text{inc}}^{\dagger}[\mathbf{T}^{\dagger} - \mathbf{T} + 2ik_T\mathbf{T}^{\dagger}\mathbf{T} + \mathbf{T}^{\dagger}$$
$$\times (K^{\dagger} - K)\mathbf{T}]G_{\text{inc}}. \tag{15}$$

In the above equation, the $G_{lm}^{\text{inc}}(\mathbf{r}_T, \mathbf{r}_0)$, defined in Eq. (7), are considered to be components (labeled by the partial wave indexes lm) of a vector G_{inc} and, $\mathbf{T}^{\dagger}$ is the Hermitian conjugate of $\mathbf{T}$, that is $(\mathbf{T}^{\dagger})_{lm,l'm'} = (\mathbf{T}_{l'm',lm})^*$. Since G_{inc} is arbitrary (the source position is arbitrary), in order for the total flux to be equal to zero the expression between square brackets on the right-hand side of Eq. (15) must also be equal to zero. Thus, the generalized optical theorem for the effective scattering operator can be stated as the following relationship between the components of $\mathbf{T}$:

$$2ik_T\mathbf{T}^{\dagger}\mathbf{T} = \mathbf{T} - \mathbf{T}^{\dagger} + \mathbf{T}^{\dagger}(K - K^{\dagger})\mathbf{T}. \tag{16}$$

In a similar way it can be shown that for a nonenergy-absorbing scattering object the scattering operator T obeys a similar generalized optical theorem:[14]

$$2ik_T T^\dagger T = T - T^\dagger. \tag{17}$$

Comparing Eqs. (16) and (17), one sees that the formal difference between them is related to the operator K. This operator accounts for multiple interactions between the scattering object and the boundaries and other spatial variations of the waveguide acoustic properties. The multiple bounces between the object and a boundary are simple to visualize, but a position dependence of the sound speed or density will have similar effects. For example, suppose the object is in a sound channel corresponding to a minimum of the sound speed as a function of depth. Some of the energy scattered off the object will be redirected toward the object by refraction and rescattered by the object, cumulative repetition of this process also leads to the presence of the operator K in the expression for the effective scattering operator. The explicit presence of K in Eq. (16) indicates that those multiple scattering processes trap a fraction of the energy incident on the object. If the object is assumed to be in a homogeneous layer, then the quantitative importance of K depends on the ratio between a typical dimension of the object and its distance from the layer boundaries, the greater this ratio the larger the impact of the multiple scattering processes that K incorporates. This is related to the phenomena of trapped modes and complex resonances in waveguides containing a scattering obstacle (see Ref. 15 for a detailed discussion of trapped modes and further references on this matter).

As in Ref. 13, let us introduce the quantities $\Phi_{inc}(\mathbf{r})$, the incident field, and $\Phi_{sct}(\mathbf{r})$, the scattered field. The velocity vectors associated with those fields are defined as $\mathbf{V}_\alpha = (1/i\omega\rho(\mathbf{r}))\nabla\Phi_\alpha(\mathbf{r})$. The total flux can be written as $F_T = F_{inc} - E + W_{sct}$. The incident flux, F_{inc}, is zero, since the source is outside the volume delimited by the closed surface, W_{sct} is the scattered energy flux involving only $\Phi_{sct}(\mathbf{r})$, and E is the extinction term that involves the negative of the contribution to the total flux due to the interference of the incident and scattered fields:

$$W_{sct} = \mathrm{Re}\left\{ \oint d\mathbf{S}\cdot\mathbf{V}_{sct}^*\Phi_{sct} \right\},$$

$$E = -\mathrm{Re}\left\{ \oint d\mathbf{S}\cdot[\mathbf{V}_{sct}^*\Phi_{inc} + \mathbf{V}_{inc}^*\Phi_{sct}] \right\}. \tag{18}$$

Procedures similar to the ones that lead to Eq. (17) yield

$$W_{sct} = \frac{1}{2i\omega\rho(\mathbf{r}_T)}G_{inc}^\dagger[2ik_T\mathbf{T}^\dagger\mathbf{T} + \mathbf{T}^\dagger(K^\dagger - K)\mathbf{T}]G_{inc}, \tag{19}$$

$$E = \frac{1}{2i\omega\rho(\mathbf{r}_T)}G_{inc}^\dagger[\mathbf{T} - \mathbf{T}^\dagger]G_{inc}.$$

Thus, the generalized optical theorem states that, in the absence of energy absorption by the object and the medium, the scattered power is equal to the power subtracted from the incident field by its interference with the scattered field. In the case of an energy-absorbing object, equations such as (15) and (19) still hold but (16) does not as Eq. (17) is no longer true since a term due to energy absorption by the scattering object is missing. In this case the expression for

the power extinguished from the incident field is still given by the corresponding equation in Eq. (19). In the case of an energy-absorbing medium the procedures that yielded Eqs. (15) and (19) generate extra terms that have to do with the power absorbed by the medium in the volume enclosed by the closed surface across which the fluxes were computed. It is clear that it is not empirically possible to separate extinction effects due to scattering and absorption by the scattering object from the effects of energy absorption in the medium.

IV. NUMERICAL EXAMPLES

In this section, results for scattering in a simple waveguide using the approach developed in Sec. II are compared with results obtained using Ingenito's approximation,[4] which neglects the multiple interactions between the scatterer and the boundaries. An ideal waveguide is considered here to be a planar waveguide with a uniform fluid medium filling the space between the plane boundaries, the upper boundary being a pressure-release surface while the bottom boundary is acoustically hard. While the acoustically hard boundary condition is not very realistic for ocean waveguides, it is used here to provide an illustration of the relationship between boundary conditions and the multiple scattering effect. A detailed study of the impact of more realistic bottoms on the multiple scattering effect will be delegated to a future article.

The method of images allows the expression of the Green's function for this ideal waveguide as a superposition of the free space Green's functions for the acoustic medium. If the partial wave expansion for the scattering matrix of the object is also known, this simplifies considerably the computations. In the following the scattering object is taken to be a sphere with a pressure-release surface that has a simple and well-known expression for its scattering amplitude in terms of partial waves.

In the case of the waveguide, the Green's function can also be expressed as a superposition of Green's functions for the unbounded medium:[16]

$$G_0(\mathbf{r},\mathbf{r}_0) = \sum_{n=-\infty}^{\infty} (-1)^n[g(\mathbf{r}-\mathbf{r}_0^+ - 2nh\hat{\mathbf{e}}_z) - g(\mathbf{r}-\mathbf{r}_0^- - 2nh\hat{\mathbf{e}}_z)], \tag{20}$$

where $\mathbf{r}_0^\pm = \mathbf{R}_0 \pm z_0\hat{\mathbf{e}}_z$. In particular, one has for the nonsingular part of the Green's function [defined in Eq. (3)],

$$G_0^{NS}(\mathbf{r},\mathbf{r}_0) = -g(\mathbf{r}-\mathbf{r}_0^-) + \sum_{n\neq 0} (-1)^n[g(\mathbf{r}-\mathbf{r}_0^+ - 2nh\hat{\mathbf{e}}_z) - g(\mathbf{r}-\mathbf{r}_0^- - 2nh\hat{\mathbf{e}}_z)]. \tag{21}$$

The Green's function in an unbounded medium with wavenumber k has a well-known form:

$$g(\mathbf{r}-\mathbf{r}') = -\frac{e^{ik|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} = \frac{1}{4\pi^2}\int d\mathbf{K}\frac{e^{i\mathbf{K}\cdot(\mathbf{R}-\mathbf{R}')+ik_z(K)|z-z'|}}{2ik_z(K)}, \tag{22}$$

where the capital letters indicate vectors in the xy plane and

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

D. K. Dacol and D. G. Roy: Scattering in waveguides   2521

$$k_z(K) = \sqrt{k^2 - K^2} \text{ if } k \geqslant K \text{ and } k_z(K)$$
$$= i\sqrt{K^2 - k^2} \text{ if } K > k. \tag{23}$$

A few useful quantities are obtained from the partial wave expansion of the free space Green's function, (in the following $k_T = k$, the wavenumber in the homogeneous fluid-filled half-space):

$$D_{lm}(\nabla)g(\mathbf{r} - \mathbf{r}_0)|_{\mathbf{r}=\mathbf{r}_T} = -ikh_l^{(1)}(ks)Y_{lm}^*(\hat{\mathbf{s}})|_{\mathbf{s}=\mathbf{r}_0-\mathbf{r}_T},$$
$$\text{for } \mathbf{r}_0 \neq \mathbf{r}_T. \tag{24}$$

Similarly, one obtains

$$D_{lm}^*(\nabla')g(\mathbf{r} - \mathbf{r}')|_{\mathbf{r}'=\mathbf{r}_T} = -ikh_l^{(1)}(ks)Y_{lm}(\hat{\mathbf{s}})|_{\mathbf{s}=\mathbf{r}-\mathbf{r}_T},$$
$$\text{for } \mathbf{r} \neq \mathbf{r}_T. \tag{25}$$

Another useful quantity is the reduced coupling operator $K^g(\mathbf{r}_T)$, with matrix elements given by the following expression:

$$K_{lm,l'm'}^g(\mathbf{r}_T) = -D_{lm}(\nabla)D_{l'm'}^*(\nabla')g(\mathbf{r} - \mathbf{r}')|_{\mathbf{r}=\mathbf{r}_T^+, \mathbf{r}'=\mathbf{r}_T^-}. \tag{26}$$

In order to obtain an expression for $K_{lm,l'm'}^g(\mathbf{r}_T)$, the integral representation for the Green's function in Eq. (22) will be used. First, one should notice that

$$D_{lm}(\nabla)\exp(i\mathbf{q} \cdot \mathbf{r}) = 4\pi\left(\frac{iq}{k}\right)^l Y_{lm}(\hat{\mathbf{q}})^*\exp(i\mathbf{q} \cdot \mathbf{r}). \tag{27}$$

Notice that the above result is entirely algebraic. That is, it is valid even if $\mathbf{r}$ or $\mathbf{q}$ or both have complex components. In the case of complex components, one should write $(-1)^m Y_{l-m}(\hat{\mathbf{q}})$ instead of $Y_{lm}(\hat{\mathbf{q}})^* = (-1)^m Y_{l-m}(\hat{\mathbf{q}}^*)$, that is, the complex conjugation in Eq. (27) does not apply to the argument of the spherical harmonic. However, for conciseness of notation, the form in Eq. (27) is preferable. In the same way one also obtains

$$D_{lm}^*(\nabla)\exp(-i\mathbf{q} \cdot \mathbf{r}) = 4\pi\left(-\frac{iq}{k}\right)^l Y_{lm}(\hat{\mathbf{q}})\exp(-i\mathbf{q} \cdot \mathbf{r}). \tag{28}$$

Thus, for the coupling operator one has this expression

$$K_{lm,l'm'}^g(\mathbf{r}_T) = -(4\pi)^2(i)^l(-i)^{l'}$$
$$\times \int \frac{d\mathbf{K}}{(2\pi)^2}Y_{lm}(\hat{\mathbf{k}}^+)^*Y_{l'm'}(\hat{\mathbf{k}}^-)\frac{e^{2ik_z(K)z_T}}{2ik_z(K)}, \tag{29}$$

where $\mathbf{k}^{\pm} = \mathbf{K} \pm k_z(K)\hat{\mathbf{e}}_z$. The above integral can be carried out, and one obtains

$$K_{lm,l'm'}(\mathbf{r}_T) = \delta_{m,m'}L_{l,l'}^m(2z_T), \tag{30}$$

where

$$L_{l,l'}^m(z) = 4\pi(i)^l(-i)^{l'}N_{lm}N_{l'm}\frac{e^{ikz}}{z}$$
$$\times \sum_{p=0}^{l+l'}\left(-\frac{1}{ikz}\right)^p \partial_x^p[P_l^m(x)P_{l'}^m(-x)]|_{x=1}. \tag{31}$$

The quantity N_{lm} is the normalization factor of the spherical harmonics, that is, $Y_{lm}(\hat{\mathbf{r}}) = N_{lm}P_l^m(\cos\hat{\theta})e^{im\varphi}$. The finite sum in Eq. (31) is due to the fact that the product of Legendre functions on the right-hand side of this equation is a polynomial of degree $l+l'$. That K is diagonal in m and m' is a consequence of the cylindrical symmetry of the environment. One notices that $L_{l,l'}^m(z)$ depends only on $|m|$. This dependence on $|m|$ is due to the fact that in the presence of an acoustic point source and a scattering sphere the original cylindrical symmetry is replaced by reflection symmetry across the plane that contains the source and sphere positions and is perpendicular to the bounding surface plane. It follows from Eq. (33) that $l \geqslant |m|$ and $l' \geqslant |m'|$ thus $L_{l,l'}^m(z) \equiv 0$ unless $l_S \geqslant |m|$, where l_s is the smallest of l and l'.

Thus the results in Eqs. (24), (25), and (30) considerably simplify solving Eqs. (4) and (5) for the case of acoustic scattering by a sphere in the ideal waveguide. Thus one obtains the following expressions:

$$G_{lm}^{inc}(\mathbf{r}_T,\mathbf{r}_0) = -ik\sum_{n=-\infty}^{\infty}(-1)^n[h_l^{(1)}(ks)$$
$$\times Y_{lm}^*(-\hat{\mathbf{s}})|_{\mathbf{s}=\mathbf{r}_T-\mathbf{r}_0^+-2nh\hat{\mathbf{e}}_z} - h_l^{(1)}(ks)$$
$$\times Y_{lm}^*(-\hat{\mathbf{s}})|_{\mathbf{s}=\mathbf{r}_T-\mathbf{r}_0^--2nh\hat{\mathbf{e}}_z}], \tag{32}$$

$$G_{lm}^{out}(\mathbf{r},\mathbf{r}_T) = -ik\sum_{n=-\infty}^{\infty}(-1)^n[h_l^{(1)}(ks)Y_{lm}(\hat{\mathbf{s}})|_{\mathbf{s}=\mathbf{r}-\mathbf{r}_T^+-2nh\hat{\mathbf{e}}_z}$$
$$- (-1)^{l+m}h_l^{(1)}(ks)Y_{lm}(\hat{\mathbf{s}})|_{\mathbf{s}=\mathbf{r}-\mathbf{r}_T^--2nh\hat{\mathbf{e}}_z}], \tag{33}$$

$$K_{lm,l'm'}(\mathbf{r}_T) = \delta_{m,m'}\left\{L_{l,l'}^m(2z_T) - \sum_{n\neq 0}(-1)^n \times [L_{l,l'}^m(-2nh) - L_{l,l'}^m(2z_T - 2nh)]\right\}. \tag{34}$$

The above equations plus the expression for the free space scattering operator for the object allows one to solve Eq. (5) for a_{lm} and then use Eq. (4) to obtain the Green's function for the waveguide in the presence of a scattering object. In the example discussed here, the scattering object is a pressure-release sphere of radius a and the scattering operator for the sphere can be written as

$$T_{lm,l'm'} = f_l\delta_{l,l'}\delta_{m,m'}, \quad f_l = \frac{i}{k}\frac{j_l(ka)}{h_l^{(1)}(ka)}. \tag{35}$$

The fact that in this example the scattering object is a sphere simplifies the structure of the algebraic equations for a_{lm}, since the equations for different values of m are not coupled as both $K_{lm,l'm'}(\mathbf{r}_T)$ and $T_{lm,l'm'}$ are diagonal in m. The linear algebraic equations for a_{lm} are solved numerically by trun-
FIG. 1. Scattering in an ideal waveguide by a pressure-release, 10 m radius sphere. The horizontal distance from the scattering sphere to either the acoustic point source or the observation point is 1 km. The observation point and the source are both at a depth of 50 m in a 100 m deep waveguide. The depth of the center of the sphere varies between 10 and 90 m. The cw point source has a frequency of 75 Hz. This figure illustrates the variation of the scattered and total fields as the depth of the scattering sphere changes.

cating the partial wave expansion. The maximum value for l is taken as $l_{max} = \text{Int}(ka) + 5$, which reflects the fact that in the partial wave expansion for scattering by a sphere the contributions from terms with $l > ka$ are negligible. The total number of partial wave coefficients a_{lm} is $l_{max}(l_{max} + 2)$.

Results are presented in Figs. 1–6 which show the outcome of calculations for acoustic scattering in an ideal oceanic waveguide by a pressure-release, 10 m radius, sphere. In Figs. 1–6 the horizontal distance from the scattering sphere to either the acoustic point source or the observation point is 1 km. The source and the target are both at a depth of 50 m in a 100 m deep waveguide. The depth of the center
FIG. 2. This figure is similar to Fig. 1, except that in this figure the cw point source has a frequency of 150 Hz. This figure illustrates the variation of the scattered and total fields as the depth of the scattering sphere changes.
FIG. 3. This figure is similar to Figs. 1 and 2, except that in this figure the cw point source has a frequency of 300 Hz. This figure illustrates the variation of the scattered and total fields as the depth of the scattering sphere changes.

of the sphere varies between 10 and 90 m. These figures illustrate the variation of the scattered and total fields as the depth of the scattering sphere changes. The scattered field computed taking into account multiple interactions with the boundaries is compared with a computation that neglects those interactions, an approximation introduced by Ingenito.[4] There were substantial differences between the two results in those examples. In particular, notice the different impacts of the surface and bottom boundary conditions on the multiple scattering effect. Clearly the pressure-release condition at the surface has a weaker impact than acoustically hard condition
FIG. 4. Scattering in an ideal waveguide by a pressure-release, 10 m radius sphere. The horizontal distance from the scattering sphere to either the acoustic point source or the observation point is 1 km. The source and the scattering sphere are both at a depth of 50 m in a 100 m deep waveguide. The depth of the observation point varies between 0 (surface) and 100 m (bottom). The cw point source has a frequency of 75 Hz. This figure illustrates the variation of the scattered and total fields as the depth of the observation point changes.
FIG. 5. This figure is similar to Fig. 4, except that in this figure the cw point source has a frequency of 150 Hz. This figure illustrates the variation of the scattered and total fields as the depth of the observation point changes.

at the bottom. Those differences were larger at lower frequencies than at higher ones, which is a consequence of the fact that the matrix elements of the coupling operator K decrease with increasing frequency mostly due to the rapid variations of the oscillating exponential factor in Eq. (31). In Figs. 3–6, the source and the scattering sphere are both at a depth of 50 m in a 100 m deep waveguide. The depth of the observation point varies between 0 (surface) and 100 m (bottom). Those figures illustrate the variation of the scattered and total fields as the depth of the observation point changes. Again the scattered field computed, taking into account multiple interactions with the boundaries, is compared with Ingenito's approximate expression for the scattered field. The most obvious pattern in the differences between the two results is the variation with frequency noted before. The differences decrease as frequency increases. The differences between the full scattered field and Ingenito's approximation are due mostly to the strong bottom reflections originated by the acoustically hard boundary. Other calculations, not exhibited here, show that configuration geometry is also very important. Certain source-target-observation point configurations are more sensitive to multiple scattering effects than others. In particular off-plane scattering, that is, scattering off the vertical plane that contains the source and the scattering object, is more sensitive to those multiple scattering effects than in-plane scattering.
V. SUMMARY

In this paper the theory of acoustic scattering by an object in a bounded medium such as a layered oceanic waveguide was formulated in such a way as to use the scattering amplitude computed in an unbounded, homogeneous medium as input. The main results are an extension of the partial wave expansion method for scattering in an ocean acoustics waveguide and the generalized optical theorem obeyed by the effective scattering amplitudes. The impact of multiple scattering between the object and the boundaries was discussed with both analytical and numerical examples. The circumstances where one expects the greatest impact of those interactions on observable quantities were discussed. The generalized optical theorem for scattering in a bounded environment such as a waveguide was derived, and it shows that the boundary interactions alter the balance between scattered and incident energy in comparison with scattering in an unbounded medium. The scattering formulation presented here is somewhat similar to that of Sammelmann and Hackman.[10] However, here it is in an operational form that is more straightforward to use, for example, this new formulation allowed for a simple and elegant derivation of the optical theorem, which provided significant insights in the physics of scattering in a bounded medium.

To advance the present understanding of the frequency dependence of compressional wave velocity and attenuation in marine sediments a series of well-constrained *in situ* acoustic transmission experiments (16 to 100 kHz) were performed on intertidal sediments. The processing techniques incorporated *in situ* spreading losses, sediment to transducer coupling and thorough error analyses. Significant variations in velocity and attenuation were observed over scales of tens of meters within the same sediment type. Velocity was generally nondispersive in sands, while highly variable silt velocities prevented any meaningful dispersion estimates from being determined. The attenuation coefficient was proportional to frequency for 75% of the experimental sites. The measured compressional wave properties were compared to predictions from the Grain-Shearing model. For the sandy sites, the phase velocities predicted by the Grain Shearing model exceed those measured, while predicted phase velocities agreed with measured group velocities at specific locations for the silty sites. For both silts and sands predicted dispersions are comparable to the intrinsic errors in group velocity and hence undetectable. The attenuation coefficients predicted by the Grain Shearing model adequately describe the measured attenuation coefficients, within the observed variability.

I. INTRODUCTION

A wide range of commercial and academic marine disciplines, from oil and gas surveying[1] to marine archaeology,[2] require knowledge of the geotechnical properties of the seafloor. The inversion of geoacoustic properties obtained through remote refraction/reflection profiling represents a promising approach for obtaining these *in situ* geotechnical properties for large volumes of seafloor sediment. Conversely, marine sonar applications require accurate predictions of the geoacoustic properties of seabed sediments, in order to enhance object detection through active sonar techniques. In order to perform the inversions/predictions required for these applications, the frequency dependencies of the more commonly used compressional wave properties need to be determined accurately for a range of sediment types. Although there is a long history of good work in this field, the diversity of sediment types and the wide range of frequencies of interest means that further measurements are required to determine the frequency dependencies and to refine theories.

In situ transmission tests offer a compromise between laboratory and remote techniques, and therefore present a promising manner of examining the frequency dependence of compressional wave velocity and attenuation coefficient in marine sediments. A highly flexible experimental geometry allows the compressional wave properties of a well-defined volume of sediment to be measured over a wide frequency range. Furthermore, the sediment disturbance associated with probe deployment can be minimized through careful consideration of the deployment techniques and experimental geometry adopted.

There are, however, other practical difficulties associated with performing such measurements that have tended to limit the number of published *in situ* compressional wave datasets available, generally to a single sediment type or a single frequency. Although it is clear that the use of data from a single research project, using a single acquisition device and common data processing techniques, are inherently more directly comparable, this lack of data has promoted the use of data compilations to incorporate wider ranges of frequencies and sediment types. In order to generate data, which allows generic frequency-dependent relationships to be examined, it is important that the repeatability of the acoustic signal emitted by the source is quantified, a factor that will depend on both the coupling of the transducers to the sediment and the electronic signal transmitted to the source. Some processing techniques also require that corrections for spreading losses are applied, and while the assumption that spreading losses are the same in water and sediment is approximately true in some cases, the use of *in situ* spreading losses would be more relevant.

These experiments utilized a single data acquisition system and enhanced data processing techniques to measure both compressional wave velocity and attenuation coefficient, with corresponding intrinsic errors. The frequency range investigated, i.e., 16 to 100 kHz, spans those used by sub-bottom profilers and those incorporated by laboratory techniques. The frequency dependence of these properties

TABLE I. A summary of published research on velocity dispersion in marine sediments, with **N** denoting no dispersion and velocities expressed in terms of the velocity of water ν_w, where absolute values are not available. A lack of published information is indicated by a dash.

Frequency (kHz)	Velocity	Degree of dispersion	Sediment type	First author and reference
14–100	1704–1712 m s^{-1}	**N**	*In situ* sand	Hamilton (Ref. 5)
15–1500	$1.189 \cdot \nu_w$	**N**	Reconstituted sand/silt/clay	McLeroy (Ref. 6)

0.125–400	$1.05 \cdot \nu_w$–$1.17 \cdot \nu_w$	11.4%	*In situ* sand	Williams (Ref. 10)
50–350	-	0.5%	Reconstituted sand	Wingham (Ref. 11)
3–200	$0.93 \cdot \nu_w$–$0.99 \cdot \nu_w$	4%–6%	Artificial silt/clay	Hampton (Ref. 12)
20–100	-	25 m s^{-1}	*In situ* sand	Gorgas (Ref. 13)
1–30	1580–1720 m s^{-1}	8.9%	*In situ* sand	Turgut (Ref. 14)
0.125–50	1580–1755 m s^{-1}	11.1%	*In situ* sand	Stoll (Ref. 15)

were examined using empirical fits, while the validity of the grain-shearing model[3,4] was investigated.

II. PRESENT UNDERSTANDING OF COMPRESSIONAL WAVE PROPERTIES

There is still contention over the frequency dependence of both compressional wave velocity and attenuation coefficient in marine sediments. A significant volume of literature exists to support both nondispersive[5–8] and dispersive[9–15] relationships (see Table I). Doubt has been expressed as to the applicability of laboratory based studies to *in situ* values[6,8,11,12] (owing to sediment disturbance), while the large variations in velocity dispersion observed by different studies (0.5% to 11.4%) highlights the need for a series of experiments that examines a large range of sediment types and frequencies in a well-constrained manner. Also, error analyses presented in earlier pioneering works generally refer to the standard deviation arising from variability. As the field matures, it is necessary to examine instead the intrinsic error associated with the experimental and processing techniques adopted.

The frequency dependence of compressional wave attenuation coefficient α (in dB m^{-1}) is typically expressed using

$$\alpha = k_A f^{\,q}, \tag{1}$$

where k_A is the constant of proportionality[5] and q is the exponent of frequency, f. Published measurements of compressional wave attenuation coefficients in marine sediments are presented in Table II. Though a number of researchers report an attenuation coefficient that is proportional to frequency[5,6,16–20] from 40 Hz to 1.5 MHz, there is some concern over this relationship for a number of reasons. These are namely the deviation from unity of certain published exponents of frequency[5,17,20] or a lack of statistical validation.[16,18,19] The difficulty of reliably determining the frequency dependence of the attenuation coefficient is highlighted by a compilation of data from fine-grained sediments.[21] Although this presents an optimum exponent

of 1.12, it is stated that, within 95% confidence limits, it is impossible to distinguish between this optimum exponent and an exponent of unity. Finally, attenuation coefficients measured at low frequencies[22,23] (5 to 250 Hz) are less than those predicted by the linear extrapolation of higher frequency data,[5] hence implying that the frequency dependence of attenuation coefficient may differ in this low frequency range. Attenuation coefficients that do not vary with frequency in a linear manner are observed by a number of authors.[7,9,12,21,24–27] Alternative data compilations observe "some evidence" for nonlinear frequency dependence, with nonlinear regions occurring between 10 and 100 Hz in sands and 1 to 10 kHz in silts.[23]

III. *IN SITU* EXPERIMENTS

A series of well-constrained *in situ* acoustic transmission experiments were performed on inter-tidal sediments along the south coast of England. These experiments utilized a new acoustic probe system, the Sediment Probing Acoustic Detection Equipment (SPADE).[28] The SPADE consists of a source and a pair of matched receivers (Fig. 1) that were deployed individually in aluminium channels. The use of a fixed rig, which may allow the relative positions of the probes to be more accurately defined, was declined, owing to the associated reduction in the flexibility of the system. The source consists of a section of piezoceramic material with a convex emitting face. This operates in an untuned manner over the usable frequency range of 16 to 100 kHz, while the matched receivers possess sensitivities of −189 to −198 dB *re* 1 V/μPa over this range. The waveforms selected for the transmission experiments consisted of a series of tonal pulses,[28,29] each possessing 10 cycles modulated by a Blackman-Harris envelope[30] with central frequencies from 16 to 100 kHz, in 2 kHz increments. Signals emitted by the SPADE are repeatable to the sampling period of ±1 μs and ±3.2% in amplitude, while water tests and field trails confirmed that received signals accurately resemble shifted, scaled versions of the voltage signals sent to the source transducer.[29]

TABLE II. Summary of published research on the frequency dependence of a compressional wave attenuation coefficient in marine sediments, including measured attenuation coefficients, exponent q of frequency dependence, and sediment type. A lack of published information is indicated by a dash.

Frequency (kHz)	Attenuation coefficient (dB m^{-1})	Exponent q	Sediment type	First author and reference
3.5–100.0	0.6–74.3	0.94–1.1	*In situ* sand to clay	Hamilton (Ref. 5)

20–300	3–34	Nonlinear	Glass beads	Hovem (Ref. 27)
0.2–4.7	0–4	Nonlinear	*In situ* silt	Best (Ref. 7)

The present project chose to examine intertidal sediments only, as this allowed the positions and orientations of the probes to be measured as accurately, and more easily, than would have been possible for a similar deployment in completely submerged sediments. This, however, introduces the risk of encountering partially saturated sediments. Gas bubbles can be introduced into marine sediment through a variety of mechanisms (e.g., the anaerobic decomposition of organic matter[31]) and have been observed in both intertidal sediments[32] and wholly submerged sediments.[33] Until 2003, bubbles with radii less than 500 μm could not be resolved by the present bubble sizing techniques available, namely, the x-ray CT scanning of pressurized cores.[34] Therefore published *in situ* acoustic measurements from "saturated" sediments have assumed full saturation.

In order to allow the attenuation coefficient of the sediment to be measured, it was essential that the beam patterns associated with the SPADE are known. The receiver's beam pattern[28] varies from an almost omnidirectional field at 1 kHz to a much more directional field at 100 kHz. The relatively simple geometry of the transmission experiments allowed estimated changes in the amplitude of the received signal, which arise from the receiver orientations, to be incorporated into the intrinsic error budget (Sec. IV).

The pressure field emitted by the source was modeled using a modified version of a technique used to predict spreading losses for circular array transducers.[35] This considered the source to be a segment of a cylinder from which sound radiates outward, which was subdivided into a two-dimensional (2-D) grid of elements (Fig. 2). The manipulation of Eq. (10) in Borsboom *et al.*[35] results in the following expression for the pressure at a field-point X and angular frequency ω:

$$P(X,\omega) = W(\omega) \cdot dx \cdot dy \sum_{n=1}^{N_1} \sum_{m=1}^{N_2} \frac{e^{-i\omega R'/v} \cdot e^{-i\omega R_{n,m}/v}}{2\pi R_{n,m}}, \quad (2)$$

where $W(\omega)$ is the spectrum of the selected voltage pulse; dx and dy are the size of the elements in the x and y directions, respectively; N_1 and N_2 are the number of integration steps in each direction; $R_{n,m}$ is the distance from source element n,m to field point X; and R' is the minimum distance between point X and the transducer surface. The pressure response at field-point X associated with a given frequency ω can be
FIG. 1. SPADE source (left) and receiver (right), both inserted in aluminium channels to assist their deployment into the sediment.
FIG. 2. Geometry used in the simulation of the pressure field emitted by the source, denoted by the shaded area segment S_p. An example field point X is displayed, along with the distance R from source element dS, the minimum distance to the source R', the parameters defining the source (r and θ) and the coordinate system used. From Borsboom *et al.* (Ref. 35).

FIG. 3. SPADE deployment during fieldwork, with image (a) of receivers positioned at approximately the same S-R separation, lying on either side of the central line marked by the measuring pole. Diagrammatic plan view (b) displays measured perpendicular distance, D, and offsets, Y_1 and Y_2, to receivers, with subsequent receiver deployments indicated at positions 2 and 3. In order to clearly display the offsets, the plan view has been rescaled, with offsets used in the fieldwork ranging from 1 to 10% of the S-R separations used.

obtained from the temporal maximum of the inverse Fast-Fourier Transform of $P(X, \omega)$. The pressure field was computed for the horizontal plane that intercepts the center of the source, as the use of a common depth for source and receivers in the fieldwork performed ensured that all receiver deployments lie in this plane. Deviations from this common depth are incorporated into the error budget (Sec. IV).

The model was verified through calibration signals measured using the SPADE source and receivers in a water tank.[29] Transmitted signals were detected by placing the receivers in the horizontal plane that intercepts the center of the SPADE source. The goodness of fit between the observed and modeled decay ranged from 0.79 and 1.00, representing a good to excellent fit. Discrepancies between the predicted and measured decays lay within the error limits in the experimental setup, i.e., $\pm 2°$ in the horizontal angle, $\pm 1°$ in the vertical angle, ± 0.02 m in source-receiver (S-R) separation, and ± 0.01 m in depth. Hence, the pressure model described above adequately predicts the pressure emitted by the SPADE source in nondispersive media.

Pressure fields were simulated for pulses with central frequencies from 16 to 100 kHz (in increments of 2 kHz) and compressional wave velocities from 1300 to 1800 m s^{-1} (in increments of 100 m s^{-1}), i.e., the range of velocity values obtained from field data analysis. Near-to-farfield transitions were computed as the distance from the center of the source to the last axial maximum.[36] These lay less than 0.43 m from the source for all compressional wave velocities measured and all frequencies used.

The experimental procedure involved inserting the source and a pair of receivers vertically into the sediment, with the inclination of the probes to the vertical accurate to $\pm 2°$. The two receivers were deployed at approximately the same S-R separation astride the perpendicular to the source face (Fig. 3). While the experimental/processing techniques adopted herein only require a single source and receiver, the use of two receivers increased the quantity of data that could

be collected. The center of the source and receivers were placed at a common depth of 1 m (± 0.02 m), which reduced the possibility of interfering arrivals from seabed surface reflections, while allowed sediment samples to be readily obtained from the sediment volume through which the acoustic wave propagated. The receivers were positioned at approximately the same S-R separation, with S-R separations calculated from the measured perpendicular distances, D, and offsets, Y_1 and Y_2 [see the plan view in Fig. 3(b)]. S-R separations varied from 1.0–8.1 m, all of which were located in the farfield. A series of acoustics pulses were transmitted, consisting of 5 shots at each central frequency from 16 to 100 kHz (in increments of 2 kHz). The receivers were removed and redeployed at a closer S-R separation before the same series of acoustics pulses was transmitted. The successive use of closer S-R separations ensured that previous deployments did not disturb sediment that later deployments would reexamine. Tidal windows allowed the examination of between three to seven S-R separations at each location.

In the silts, the source and receivers could be deployed through the manual application of a vertical force to the top of the aluminium channels. In the sands this was not possible and hence a modified box corer (width 0.13 m and breadth 0.21 m) was used. This was initially inserted in the sediment to a depth of 1 m and the sand within it excavated. The probes were then inserted and, after the removal of the box corer, the sediment refilled. This allowed the majority of sediment through which the acoustic pulses propagates to remain undisturbed, with the range of disturbed sediment around each probe (<0.1 m) much less than the S-R separations examined.

To minimize the risk of encountering unsaturated sediments, sites were selected to lie in coastal regions of the United Kingdom with relatively low tidal ranges (i.e., less
FIG. 4. Geographical location of the intertidal sites examined, including (a) three sandy sites (Sites 1 – 3) and (b) three silty sites (Sites 4 – 6) used in this study. Grey regions denote land.

than 1.5 m). Six sites were examined in total, including three sand sites (Sites 1–3) located at the mouth of Poole Harbour [see Fig. 4(a) and Table III] and three silt sites (Sites 4–6) located in Southampton Water and the Beaulieu estuary [see Fig. 4(b) and Table III]. At each site between two and four specific locations were examined in order to allow any natural sediment variability to be assessed.

At each location sediment samples were collected from a depth of 1 m and the temperature and salinity of the pore water was recorded (see Table IV). The grain size distribution at each site was obtained from between 6 to 12 sediment samples collected from the insonified sediment volume. In addition, a single push core was collected from each site, from which porosity was measured at 1 cm intervals along the core using a multisensor core logger.[37] The geotechnical properties are presented in Table III, which quotes mean values with standard deviations. The sediments were classified using standard sedimentological procedures[38,39] as medium to fine sands, with porosities from 29.3%–34.5%, and coarse to medium silts, with porosities from 63.2%–80.1%. Although great care was taken to select visually uniform sites the actual variabilities in mean grain diameter M varied from 0.07 to 0.35 ϕ for sandy sites and 0.15 to 0.30 ϕ for silty sites. Larger scale heterogeneities, such as shells, shell fragments, and pebbles with diameters from 2 mm to 10 cm,

were observed at Sites 1, 2, and 4.

IV. DATA PROCESSING TECHNIQUES

Established acoustic transmission processing techniques were adapted to both assess the repeatability of the transducer to sediment coupling and to incorporate the sound pressure fields directly relevant to the sediment type under examination. In the present section we summarize these techniques, with the reader referred to Robb et al.[28] for a more detailed discussion. Any deviations from assumptions used by these processing techniques were accounted for through the error analysis employed.

Common preprocessing steps[28] were applied to both the voltage signals sent to the source transducer and the received signals. While the majority of received signals resembled shifted, scaled versions of the voltage signals sent to the source transducer with negligible distortions (Fig. 5), some distorted waveforms were detected. These were attributed to the presence of interfering signals, arising from scatter from sediment heterogeneities and reflections from the sediment surface, and were omitted from the following analysis.

The technique adopted to calculate the group velocity of the sediment optimized data from a range of S-R separations. Arrival times t_A were obtained from a correlation of the ana-

lytical received signal with the analytical voltage signal sent to the source transducer. These arrival times are related to the S-R separation d, the group velocity ν and a constant time lag associated with SPADE t_L through

$$t_A = d/\nu + t_L. \tag{3}$$

The group velocity at each frequency was therefore obtained from the reciprocal of the gradient of a linear least-squares fit between arrival time and S-R separation. The total error in arrival time, t_E, was calculated by combining the intrinsic timing error in the digital acquisition card (± 1 μs) with the error introduced through the use of analytical signals at the correlation stage (± 10 μs) in quadrature.[28] This allowed the standard deviation in velocity σ_V, which was adopted as the relevant error, to be computed from

$$\sigma_V = \sqrt{t_E^2 / N(\overline{d^2} - \overline{d}^2)}, \tag{4}$$

where N is the number of data points to which the linear fit is applied and the overscore notation denotes the statistical mean.[40] The intrinsic errors for the dataset examined ranged from ± 20 to ± 70 m s^{-1} in sands and ± 10 to ± 25 m s^{-1} in silts.

The technique developed to calculate attenuation coefficient incorporates both the spreading losses relevant to the sediment under examination and the effects of variable transducer to sediment coupling in the error analysis. The received pulse was resampled to 10 MHz and the signal amplitude $A(f,d)$ assigned the value of the maximum peak-to-peak voltage. The resulting amplitude is a function of the following processes:

$$A(f,d) = V_O(f) \cdot S_T(f) \cdot G(f,d) \cdot R_T(f) \cdot R_e(f) \cdot C \cdot e^{-\alpha_n(f)d}, \tag{5}$$

where spreading losses $G(f,d)$ are a function of frequency f and S-R separation d. The amplitude of the voltage signal transmitted to the source $V_O(f)$, the Transmit Voltage Response of the source transducer $S_T(f)$, the response of the receiving transducers $R_T(f)$, the electronic gain of the receiving amplifiers $R_e(f)$, and the attenuation of the sediment in nepers m^{-1} $\alpha_n(f)$ are all functions of frequency, while the coupling term C is considered constant[28] at each location examined. The comparison of the received signal amplitudes at a single frequency, correction for spreading losses using simulated sound pressure fields applicable to the sediment under examination (see Sec. III), and taking natural-logarithms reduces Eq. (5) to

$$\ln(A_C) = B_1 - \alpha_n d, \tag{6}$$

where A_C represents the amplitudes with spreading losses accounted for and B_1 is a constant. Hence, at each location and frequency, a weighted linear least-squares fit was to applied to $\ln(A_C)$ against d, the gradient of which is equal to the effective attenuation coefficient α_n in nepers m^{-1}.

Intrinsic errors[28] in attenuation coefficient were computed by combining errors arising from the resolution of the acquisition card; the variability of the coupling parameter; the use of pressure fields computed at discrete velocities only; and uncertainties in the measured gain of the receiving amplifiers. For the magnitude of the received amplitudes observed (5.7 mV to 10 V), the error associated with coupling variability represents the dominant element. The approximate error in each value of $\ln(A_C)$, Δ, was obtained from

$$\Delta = A_e / A_C, \tag{7}$$

where A_e is the resulting error in A_C. Hence, the error in the attenuation coefficient, σ_α, was obtained from

$$\sigma_\alpha = \sqrt{\frac{\overline{\overline{\Delta}}}{N(\overline{\overline{d^2}} - \overline{\overline{d}^2})}}, \tag{8}$$

where a double overline denotes a weighted mean.[40] The resulting intrinsic errors ranged from ± 1 to ± 7 dB m^{-1} for all sites examined.

This approach cannot be used without first checking the effect of neglecting the asymmetry of the errors in Δ, an inherent omission arising from the use of symmetric errors in corrected amplitudes. Such analysis of the data showed that the attenuation coefficients obtained using asymmetric errors and those obtained using the approach above differ by less than 0.07 dB m^{-1}, while errors in attenuation coefficient[28] differ by less than 17.5%.

V. EXPERIMENTAL RESULTS

The compressional wave velocities and attenuation coefficients are displayed in Fig. 6, for predominantly sandy sites (Sites 1 to 3), and Fig. 7, for the predominantly silty sites (Sites 4 to 6). In these figures, data at certain frequencies and locations have been omitted, where distorted waveforms resulted in insufficient degrees of freedom for the application of the linear fits (see Sec. IV).

The common frequency dependencies presented in the literature for velocity and attenuation coefficient were tested for their applicability to these intertidal sites. They include the hypotheses that compressional wave velocity is independent of frequency,[16] and that both compressional wave velocity and attenuation coefficient are proportional to frequency.[5] These hypotheses were tested using a weighted

mean and a weighted linear least-square fit, respectively.[40] The weighted linear least-square fits are expressed as

$$v = v_A \cdot f + c_1, \qquad (9)$$

$$\alpha = k_A \cdot f + c_2, \qquad (10)$$

where v_A, and k_A are the constants of proportionality, and c_1 and c_2 are respective values of velocity and attenuation coefficient corresponding to a frequency of zero. Note that Eq. (10) is a modified version of Eq. (1), with $q=1$. The inclusion of the term c_2 accounts for the possibility of a nonlinear relationship between the attenuation coefficient and frequency outside the frequency range examined here.

For each hypothesis, the deviation of the measured compressional wave property from a weighted fit was converted

into a confidence limit using the χ^2 distribution.[41] Confidence limits greater than or equal to 95% are considered to indicate an acceptable statistical probability that the weighted fit accurately represents the measured values. The results of the frequency-dependence analysis are displayed in Fig. 6, Fig. 7 and Table V, with standard deviations quoted as the relevant errors. As analysis did not support velocities that were proportional to frequency for either sandy or silty sites (standard deviations in ν_A were greater than ν_A) results from Eq. (9) are omitted from both Table V and the following discussion.

Confidence limits for weighted mean velocities were greater than 95% for seven of the nine predominantly sandy locations. This supports the hypothesis of negligible velocity dispersion from 16 to 100 kHz for these sandy sediments within the observed errors. For the predominantly silty sites, confidence levels in the weighted mean were extremely low for Sites 4 and 5, while nondispersive velocities were supported for Site 6. The velocities at Sites 4 and 5 display a sharply oscillatory nature, particularly at lower frequencies, which conceals any fundamental frequency-dependent trends that may be present. Although the depth at which the probes were deployed (1 m) and the S-R separation used (8.1 m) introduces the possibility of interference from surface reflections for frequencies less than 60 kHz, the omission of distorted waveforms from the analysis (Sec. IV) rules out this interference as a cause of these oscillations. It is more likely that velocities at these sites are dominated by a considerable degree of variability. This argument is supported by the more spatially variable nature (Sites 4 and 5 display relatively

large variabilities in the mean grain diameter; see Table III) and a more heterogeneous nature (shells were observed at Site 4) of these sediment volumes.

The statistical analysis indicates that, from 16 to 100 kHz, attenuation coefficient is proportional to frequency for both sandy and silty sediments, with confidence limits greater than the threshold value of 95% for three quarters of the locations examined (Table V). Constants of proportionality k_A are greater in sands than in silts, ranging from 0.14 to 0.52 dB m^{-1} kHz^{-1} (with errors less than ±0.05 dB m^{-1} kHz^{-1}) in the sands and 0.1 to 0.2 dB m^{-1} kHz^{-1} (with errors less than or equal to ±0.04 dB m^{-1} kHz^{-1}) in the silts.

For comparison purposes, the velocities were converted to velocity ratios, using pore water velocities (1425 to 1483 m s^{-1}) computed[29] from salinities and temperatures measured at the experimental sites (Table IV). Velocity ratios varied from 1.06 to 1.26 (±1.1 to ±4.5%) at the sandy sites, and 0.92 to 1.04 (errors less than ±1.9%) at the silty sites. While these values broadly agree with velocity ratios published by Richardson *et al.*[42] (0.98 to 1.12 for subtidal medium sands to clays), the velocity ratios for the silts extend below those previously measured. This may be a consequence of the presence of free-gas bubbles in the silts, which may be introduced by either the intertidal nature of the sediments or the biogenic decomposition of organic material (Total Organic Contents ranged from 3% to 11% in the silts). The effect of free gas on the compressional wave velocity depends on the relationship between the insonifying frequencies and the resonant frequencies of the bubbles.[43,44] At frequencies less than resonance, the velocities of partially saturated sediments are less than those of saturated sediments, while at frequencies greater than resonance the velocities of partially saturated and saturated sediments are approximately the same. Of direct relevance to this work are previous *in situ*

measurements of compressional wave velocities in partially-saturated beach sands,[32] which recorded velocity ratios as low as 0.09 for frequencies of 800 Hz. The much higher velocity ratios observed in the present project indicates that either the frequencies examined in this project (16 to 100 kHz) are approximately equal to or greater than the resonance frequencies or the sediments examined in this project possess extremely small fractions of gas bubbles.

Attenuation coefficients ranged from 2 to 52 dB m^{-1} at the sandy sites and 1 to 23 dB m^{-1} at the silty sites, values that agree with previously published results for subtidal sediments over a similar frequency range.[9,21] The variability of geoacoustic properties was examined using the maximum range of velocities and attenuation coefficients spanned by a single frequency (see Table V). The sandy sites possessed the greater variability than the silty sites, particularly for an attenuation coefficient. Unfortunately this could not be related to porosity changes, owing to the collection of a single push core from each site, while no correlation was observed with the observed variability in the mean grain diameter.

VI. MODELING OF *IN SITU* COMPRESSIONAL WAVE PROPERTIES

The measured *in situ* compressional wave properties were compared to those predicted by the grain-shearing (G-S) model.[3,4] The G-S model[3,4] considers marine sediments to act as unconsolidated granular media and considers a new type of dissipation arising from grain-to-grain contacts, which has fundamentally different properties to the more classical dissipation mechanisms of viscosity or Coulomb friction.[45] This intergranular dissipation allows elastic type behavior to arise from intergranular interactions rather than finite frame moduli.

In order to predict the phase speed and attenuation coefficient of the two waves supported (one compressional and one shear), the G-S model requires 14 geotechnical input parameters and frequency.[4] For certain parameters, only generic site-independent values could be determined. A nominal depth of 1 m was used, while the rms grain roughness was evaluated from porosity versus mean grain diameter regression equations presented by Buckingham.[4] The parameters describing the microscopic interactions at grain boundaries, namely the compressional and shear coefficients and strain-hardening index, cannot be measured. These are typically obtained through fitting the G-S model to measured compressional and shear properties at a known porosity, mean grain diameter and depth (which become the reference porosity, mean grain diameter, and depth, respectively). This model fitting step requires the knowledge of at least three of the four acoustic properties predicted by the theory, i.e., compressional and shear phase velocities and attenuation coefficients. As only two parameters have been measured for the intertidal sediments under consideration, this step cannot be undertaken. Hence the compressional and shear coefficient, strain-hardening index and reference porosity, mean grain diameter and depth that are used in the present implementation of the G-S model are taken from previously published implementations of the G-S model, values that can be considered to be fixed for all siliciclastic sediments.[4]

For the remaining parameters, a range of input values could be determined for each site examined and therefore the limits of predicted velocities and attenuations could be predicted for each site. *In situ* measured values were used for porosities and mean grain diameters (see Table III), while the properties of the fluid, namely bulk modulus and density, were determined from measured salinities and temperatures using the standard equations of state[46] (see Table IV). The densities and bulk moduli of the grains were obtained from the literature,[29] with densities ranging from 2650 to 2750 kg m^{-3} and bulk moduli ranging from 32 to 49 GPa.

The compressional wave properties predicted by the G-S model are displayed in Figs. 6 and 7 for the sandy and silty sites, respectively. For the sandy sites the phase velocities predicted exceeded those measured. Predicted dispersions were less than 1.7% ($<$35 m s^{-1}), both of which are comparable to the intrinsic errors in group velocity and are therefore undetectable. Measured attenuation coefficients were adequately described, within the observed variability, by the predicted attenuation coefficients (2.6 to 40.5 dB m^{-1}).

It is interesting to note that the compressional wave velocities predicted by Wood's Equation[47] for a suspension agrees more closely with measured velocities than those predicted by the G-S model (for the relevant range of physical parameters compressional wave velocities predicted by Wood's Equation range from 1700 to 1821 m s^{-1} for Site 1, 1629 to 1780 m s^{-1} for Site 2, and 1619 to 1738 m s^{-1} for Site 3). This indicates that the values presented for the compressional and shear coefficients for subtidal sands[4] overpredict normal and tangential stresses associated with intergranular sliding that are present in the intertidal sediments examined in the present project. The difference in these stresses between subtidal and intertidal sediments can be

postulated to be due to the different processes that govern the supply, deposition, and dynamics of the sediment in each environment.

For the silty sites the predicted phase velocities (1435–1559 m s^{-1}) agree well with measured velocities at Site 4 and tend to overestimate measured group velocities at Sites 5 and 6. Dispersions are 1.1% (17 m s^{-1}), which are either less than or comparable to the intrinsic errors in group velocity ($<\pm25$ m s^{-1}) and hence undetectable. Attenuation coefficients predicted by the G-S model vary from 1.8 to 30.8 dB m^{-1} for the frequency range examined. These broadly agree with measured attenuation coefficients at Sites 4 and 5 and overestimate measured attenuation coefficients at Site 6.

While the agreement between measured and predicted attenuations implies that the loss mechanism incorporated by the G-S theory is applicable to both sandy and silty sediments, it is interesting to consider the effects of additional scattering losses. It is unlikely that Rayleigh scattering from sediment grains is a significant source of energy loss, as the smallest wavelength examined (16 mm) was much greater than the maximum grain diameter encountered ($<$1 mm). This is supported by the observation that Rayleigh scattering is only significant for frequencies greater than 500 kHz in sands[10] with mean grain diameters of approximately 414 μm (1.27ϕ), i.e., coarser than those examined within this project. Any additional scattering losses present are more likely to arise from larger scale scattering centers or spatial variability in the sediment across the insonified volumes (see Sec. III).

VII. CONCLUSIONS

In this work we focused on ascertaining the frequency dependence of compressional wave velocity and an attenuation coefficient in marine sediments over the frequency range 16 to 100 kHz. This was achieved through a series of well-constrained *in situ* transmission experiments performed in intertidal sediments. The processing techniques adopted incorporated *in situ* spreading losses, a quantitative assessment of coupling and waveform variability, and a thorough error analysis.

The compressional wave velocity ratios ranged from 1.06 to 1.26 (±1.1 to $\pm4.5\%$) at the sandy sites and 0.92 to 1.04 ($<\pm1.9\%$) at the silty sites. Attenuation coefficients ranged from 2 to 52 dB m^{-1} at the sandy sites and 1 to 23 dB m^{-1}, with intrinsic errors less than ±7 dB m^{-1}. A significant variability was observed in both the velocity and attenuation coefficient between the measurement locations, which are separated by tens of meters in geologically homogenous sediments. This suggests that acoustic propagation measurements made over distances on the meter-to-decimeter scale could be difficult to translate to the average seabed acoustic properties of a larger area. The sandy sites possessed greater variability than the silty sites, particularly in the case of an attenuation coefficient.

An analysis of the common frequency dependencies observed in the literature indicated that, from 16 to 100 kHz, velocity was nondispersive for the majority of the sandy locations examined. For the silty locations, the frequency de-

pendency of velocity was more difficult to ascertain, with nondispersive velocities only supported at Site 6. This is attributed to the more spatially variable and heterogeneous nature of the silty sites concealing any fundamental frequency-dependent trends present. The attenuation coefficient was found to be proportional to frequency from 16 to 100 kHz for both sand and silt sediments, within confidence limits of 95%, for three-quarters of the locations examined.

The grain-shearing (G-S) model was applied as detailed in Buckingham.[4] For the sandy sites the phase velocities predicted by the G-S model exceed those measured. This indicates that the stresses associated with intergranular sliding differ between the subtidal and intertidal environment, a possible consequence of the different processes that govern the supply, deposition, and dynamics of the sediment in each environment. For the silty sites, the predicted phase velocities agree with measured group velocities at specific locations. For both silts and sands, predicted dispersions are comparable to the intrinsic errors in group velocity and hence undetectable. The attenuation coefficients predicted by the G-S adequately describe the measured attenuation coefficients, within the observed variability. Finally, it should be noted that the validation of the geoacoustic models examined has been considerably impaired by the variability of the measured velocities and attenuation coefficients.

Sound speed and attenuation measurements in unconsolidated glass-bead sediments saturated with viscous pore fluids

Brian T. Hefner[a] and Kevin L. Williams

Applied Physics Laboratory, College of Ocean and Fisheries Sciences, University of Washington, 1013 N.E. 40th Street, Seattle, Washington 98105

As part of a recent ocean sediment acoustics experiment, a number of independent sound speed and attenuation measurements were made in a well-characterized sandy sediment. These measurements covered a broad frequency range and were used to test both Biot-Stoll theory and Buckingham's more recent grain-to-grain shearing model. While Biot theory was able to model the sound speed well, it was unable to predict the attenuation measured above 50 kHz. This paper presents a series of measurements made in the laboratory on a simple glass-bead sediment. One goal of these measurements was to test the hypothesis that the attenuation measured at-sea was a result of scattering from shells within the sediment. The laboratory sediments used were saturated with fluids with different viscosities in order (assuming that Biot-Stoll theory is correct) to shift the dispersion into the frequency range of the measurement system. The measured attenuation in the glass-bead sediments exhibited the same frequency dependence as observed in the ocean experiment even though no shells were present. The laboratory results motivated development of a sediment model which incorporates both fluid viscosity and grain-to-grain interactions as embodied in a simple frequency-dependent, imaginary frame modulus first suggested by Biot. © *2006 Acoustical Society of America.*

I. INTRODUCTION

In the study of sediment acoustics, there is an ongoing debate about the nature of dispersion and attenuation in unconsolidated, sandy sediments. Many measurements have been made in sandy sediments, both *in situ* and in the laboratory, as well as in simpler unconsolidated glass-bead sediments. The results of these experiments have led to two differing conclusions. Some measurements seem to indicate that attenuation in these sediments varies as the first power of the frequency, f^1, with little or no significant dispersion. This view has found its most vocal support in Hamilton[1] and has recently been revisited by Buckingham who argues that this conclusion is supported by current research into the properties of dry sand.[2–4] Both Hamilton and Buckingham have argued that the sediment is best described by a viscoelastic model. Both of these approaches determine the relevant parameters through empirical fits to the data limiting their predictive value.[5] The approaches differ, however, in that Hamilton's approach is purely empirical while Buckingham believes that the attenuation is due to friction between the sand grains.[4] Buckingham postulates that the relevant parameters can be determined from the fluid and sand properties although it is not clear at this point in the theory's development how this would be done.

Due to the porous nature of the sediment, some researchers theorize that the relative motion of the pore fluid and the sediment frame should lead to viscous damping of the acoustic wave. Biot theory provides a successful description of sound propagation through porous materials[6,7] and has thus been applied to modeling sand sediments. The attenuation predicted by Biot theory, however, varies as f^2 at low frequencies and $f^{1/2}$ at high frequencies which contradicts some of the measurements in sandy sediments. The sound speed is also predicted to exhibit significant dispersion in the frequency range where the transition between these two limiting attenuations takes place. Some researchers, most notably Stoll,[8] note that there are deviations from the f^1 frequency dependence in many measurements as well as evidence of dispersion indicating that viscous losses due to the motion of the pore fluid may be important. Indeed, many measurements have been successfully modeled with Biot theory by assuming complex frame moduli to account for frictional losses at the grain contacts. This modified theory has come to be known as Biot-Stoll theory.[9] Biot theory has an advantage over the viscoelastic models of Hamilton and Buckingham in that the relevant parameters in the theory can in principle be measured, although not without some effort. Biot-Stoll theory remains empirically driven, however, in that the complex frame moduli are generally determined from a best fit to the data.

With the number of measurements available, it might seem strange that a consensus has not been reached on the proper description of sound propagation in sediments. The problem lies not with a lack of experimental effort but rather in the difficulties inherent in performing these measurements. Usually it is not possible to make sound speed and attenuation measurements over a frequency range broad enough to observe the dispersion predicted by Biot-Stoll theory nor is it usually possible to fully characterize the sedi-

FIG. 1. (a) Sound speed and (b) attenuation measured during SAX99. Details of these measurements can be found in Ref. 12. Also shown are the sound speed and attenuation predictions for Biot theory (solid line) and the Buckingham model (dashed line) using the parameters given in Table I.

ment. Realizing the importance of overcoming these difficulties, a number of researchers, utilizing different measurement techniques, came together to determine both the sound speed and attenuation in the sediment at a single site during a recent high-frequency sediment acoustics experiment (SAX99).[10,11] Extensive efforts were made to determine the properties of the sediment and several researchers measured the sound speed in the sediment over a frequency range of 125 Hz–400 kHz and attenuation over a frequency range of 2.6–400 kHz. Details of these measurements can be found in Ref. 12.

Despite the broad range of frequencies and careful measurement of the sediment properties, the results of the SAX99 experiments have not been successful in resolving the sediment acoustics debate. Both Biot-Stoll theory and Buckingham's model have been applied to the data and both have their respective strengths and weaknesses as shown in Fig. 1. Biot-Stoll theory captures the dispersion in the sound speed across most of the frequencies with the exception of the two lowest frequency measurements. The measured attenuation deviates, however, from that predicted by Biot-Stoll theory at the highest frequencies and appears to follow the f^1 frequency dependence observed previously. Consequently, Buckingham's model fits the attenuation well at these high frequencies with only a slight deviation at the lower frequency measurements. His theory is not as successful in modeling the sound speed as it predicts a curvature in the dispersion that is opposite that of the measured values and only fits the data over a limited frequency range.

As Williams et al.[12] points out, these results are one of four separate measurements that indicate that the sound speed in sand sediments at low frequencies is lower than at high frequencies. This is consistent with the predictions of Biot and the authors speculate that the deviation in attenuation at high frequencies may be due to scattering within the sediment from either volume inhomogeneities or shell and shell fragments. In order to test this hypothesis, a series of laboratory measurements were made in simple glass-bead sediments. The measurements were performed using one of the systems which was used during SAX99 to measure sound speed and attenuation over the 100–260 kHz frequency range. Although this range was extended down to 60 kHz for the laboratory experiments, it is still not low enough to observe significant dispersion for glass beads saturated with water. To overcome this limitation, a second glass-bead sediment was saturated with silicone oil, which has a viscosity of approximately 0.1 Pa s. Biot theory predicts that by increasing the viscosity, the region of significant dispersion should shift upward in frequency and hence should be observable with the measurement system. Biot theory also predicts that attenuation scales with viscosity. Details of the sediments as well as the measurement system are discussed in Sec. II. This experiment is similar to the measurements made by Seifert et al.[13] In those measurements, several different fluids were used to vary the viscosity of the pore fluid from 0.001 to 1 Pa s. However, they observed an f^2 frequency dependence in the attenuation whereas the measurements presented here show an f^1 dependence over a similar range of frequencies. For the measurements in a silicone oil saturated sediment, significant dispersion is observed in the current experiments. These results are similar to those of SAX99 in that the attenuation deviates from Biot theory over the same frequency range while the sound speed is well described by Biot theory. The measurement results and model comparisons are shown in Sec. III. These results do not support the scattering hypothesis for the SAX99 results. While Biot does not capture all aspects of the data, a model which combines the effects of viscosity (Biot theory) with frame losses (perhaps attributable to grain-to-grain shearing[4] or squirt flow[14]) is able to describe all three data sets. This model is developed in Sec. IV while the implications of the data-model comparisons using this hybrid model are discussed in Sec. V.

II. EXPERIMENTAL PROCEDURE

The system used to make the laboratory sound speed and attenuation measurements was previously used during at-sea experiments.[10,12] This diver-deployed system is able to make sound speed measurements in the 100–200 kHz frequency range and attenuation measurements in the 100–260 kHz frequency range. The system consists of four ITC 6148 transducers (two receivers and two transmitters) which allow measurements to be made over four separate paths. During the experiment the path lengths were from 22 to 44 cm and the transducers were inserted into the sediment to a depth of 10 cm. Because this system was designed to be diver-deployed, it was relatively compact and thus easy to use for laboratory based measurements.

TABLE I. Parameters used in calculating the effective density fluid model and Buckingham model results. The hybrid model results were also calculated using these parameters except for the material exponent and rigidity coefficient.

Parameter	Value		
	SAX99	Water/beads	Si100/beads
Bulk modulus of grains or glass beads (K_g)	3.2×10^{10} Pa	7.0×10^{10} Pa	7.0×10^{10} Pa
Mass density of grains or glass beads (ρ_g)	2690 kg/m^3	2500 kg/m^3	2500 kg/m^3
Bulk modulus of pore fluid (K_f)	2.395×10^9 Pa	2.23×10^9 Pa	9.68×10^8 Pa
Mass density of pore fluid (ρ_f)	1023 kg/m^3	1000 kg/m^3	968 kg/m^3
Sound speed pore fluid (c_f)	1530 m/s	1493 m/s	1000 m/s
Viscosity of pore fluid (ν)	0.001 05 kg/m s	0.001 kg/m s	0.098 kg/m s
Porosity (β)	0.385	0.384	0.36
Permeability (κ)	2.5×10^{-11} m^2	1.1×10^{-10} m^2	8.43×10^{-11} m^2
Tortuosity (α)	1.35	1.45	1.47
Material exponent ($n=m$)	0.0901	0.0467	0.3902
Ragidity coefficient ($\gamma_T = \gamma_P + (4/3)\gamma_S$)	2.6823×10^8 Pa	3.871×10^8	1.472×10^6 Pa

The sediments in the laboratory measurements were composed of well-sorted glass-beads which had diameters in the range of 0.43–0.30 mm and a minimum roundness of 90%, according to the manufacturer's specifications. Two fluids were used to saturate the glass beads: water and a silicone oil with a viscosity of 0.098±0.0048 Pa s as determined by the manufacturer. Biot theory predicts that by increasing the viscosity of the pore fluid, the dispersion in the sound speed should shift to higher frequencies.[7] By shifting the dispersion up in frequency, it should be observable in the frequency range of the attenuation array. It should also provide a second test of Biot theory in that the attenuation should scale with the viscosity of the pore fluid. In the measurements of Seifert *et al.* this scaling was not observed leading them to the reject Biot's porous medium description of the unconsolidated sand sediment.[13]

In order to ensure that bubbles would not be present in the sediments, a vacuum was applied to the fluid before the sediment was added and allowed to degas over several days. In order to withstand the vacuum, two stainless steel oil drums were chosen as tanks for the sediments. These drums had an inner diameter of 54.6 cm and a depth of 83.5 cm. The glass beads were added to the degassed fluids in 10 cm layers and the glass bead/fluid combination was degassed and then stirred after each layer was added. Over the course of the experiments, the sediments were stirred and a vacuum was applied to the tanks periodically to remove any bubbles that may have formed. The glass-bead/water sediment had a depth of 37 cm with a water layer above it that was 36 cm thick. The glass-bead/silicone oil sediment had a depth of 23 cm with a 22-cm-thick layer of silicone oil above it.

The properties of each sediment, including that of SAX99, are given in Table I. The properties of the SAX99 sediment were measured using a number of different methods the details of which are given in Ref. 12. The bulk modulus and density of the glass beads were provided by the manufacturer, Potters Industries Inc., and are consistent with reported values of glass found in the literature. The bulk modulus of the water was determined from the average sound speed measurement in the water. The density and vis-

cosity of the silicone oil was provided by the manufacturer, Silchem, and the bulk modulus of the oil was determined from its measured sound speed.

The remaining properties important for the application of Biot theory and which are often difficult to measure in sand sediments are the porosity, β, permeability, κ, and the tortuosity, α. The porosity of the glass-bead/water sediment was determined by taking samples of the sediment with a known volume and measuring the density before and after removing the water by drying the sample in an oven. The value of 0.384 is reasonably close to the random close packing limit for identical spheres. The same procedure could not be applied to the silicone oil sediment because the vapor pressure of the oil is much higher than that of water and a sample of the sediment could not be dried. The random close packed limit of 0.36 was assumed here instead. It may seem reasonable to assume that the porosity should be the same in both cases, but this assumption was rejected because the macroscopic properties of the sediments were found to be significantly different. The silicone oil sediment was found to heal much faster than the water sediment when stirred or when transducers were inserted and removed from the sediment. Also, during degassing, bubbles were able to move out from the interior of the silicone oil sediment much faster and easier than from the water saturated sediment. It is hypothesized that this is due to the higher viscosity of the silicone oil which allows the beads to slide relative to one another during settling with less friction due to hydrodynamic lubrication.[15] It seems more likely that the beads are able to reach a denser ground state in silicone oil than they would in water. (Note: if we assume that the porosity of the silicone oil/glass bead mixture was equal to that of the water/glass bead mixture, the dispersion predicted by Biot theory would still shift to the same frequencies, while the mean sound speed would be lower. This dependence of the mean sound speed on the porosity can be seen in the sensitivity analysis shown in Fig. 1 of Ref. 12. The conclusions drawn from the data/model comparisons in Sec. III therefore remain unchanged.)

The hydraulic permeability was calculated using the Kozeny-Carmen relation,[16]

$$\kappa = \frac{\beta^3 d^2}{180(1-\beta)^2}, \qquad (1)$$

where d is the average diameter of the glass beads. This relationship was tested for the water/glass-bead sediment using a constant head permeameter and the value calculated using the Kozeny-Carmen relation was found to fall within the error of the measurement. A measurement of the tortuosity is notoriously difficult to make for unconsolidated sediment and as a result an expression derived by Berryman for a collection of spheres was used.[17] The expression,

$$\alpha = \frac{2}{1+\beta}, \qquad (2)$$

relates the tortuosity to the porosity and gives a lower value than the expression that was used previously by Berryman to describe sintered glass-bead packs.[18] As Berryman shows in Table 1 of Ref. 17, the expression given in Eq. (2) fits the analytical values for ordered unconsolidated glass-bead packs whereas the previous expression is a better fit to sintered glass-bead packs. As a result, Eq. (2) is used for the tortuosities of the glass-bead sediments. The permeability and tortuosity were measured for the SAX99 sediment and the values used for the data/model comparisons were chosen such that they provided the best fit to the sound speed data while still falling within the uncertainty for the measurement.[12] The use of these values for the SAX99 sediment as opposed to results of Eqs. (1) and (2), reflects the availablity of measurements of the material parameters of SAX99 sediment and the fact that the above mentioned equations are only applicable to collections of spheres.

Because the diameter of the tanks were smaller than the original attenuation array, the array was reconfigured for use in the tanks. The new arrangement maintained the original electronics and transducer mounts, while repositioning the transducers such that they sat at the corners of a rectangle. For each transmitter, one receiver was mounted close to provide a short path length, while the second transducer was mounted further away to provide a longer path length. The sound speed was determined using the difference in phases between a pulse received at two different transducers.[19] As a result, the difference in path lengths, ΔP, is the important distance for this measurement. For the water/glass-bead sediment $\Delta P_1 = 25.99$ cm and $\Delta P_2 = 25.95$ cm while for the silicone oil/glass-bead sediment $\Delta P_1 = 14.39$ cm and $\Delta P_2 = 14.97$ cm. The reduction in path length for the silicone oil was necessary in order to overcome the signal loss due to the increased attenuation. The attenuation was determined from the spectral amplitudes using the method described in Ref. 19. This technique also depends on the difference in the two path lengths. The sound speed and attenuation measurements for both sediments were performed using the original attenuation array over a frequency range of 80–260 kHz. However, due to the large attenuation, measurements above 200 kHz could not be made in the silicone oil saturated sediment.

For each measurement, the transducers were first placed in the overlying fluid layer and the sound speed and spectral amplitude of the pulse in the fluid were measured. The transducers were then inserted into the sediment. The depth of the tranducers in the water/glass-bead sediment was 10 cm while in the silicone oil/glass-bead sediment it was 11.4 cm. The tank was then shaken by hand for approximately 2 min then allowed to sit for 4–6 h to allow the sediment to settle. The sound speed and spectral amplitude were then measured and after the transducers were removed from the sediment, the sound speed and spectral amplitudes in the fluid were again measured. Once the transducers were removed from the tank, the sediment was again shaken and allowed to settle overnight.

In order to extend the lower limit of the frequency range of the array, a Reson TC4040 was introduced which was able to operate in the 60–100 kHz range. The difference in path length for the new array was $\Delta P_1 = 7.82$ cm in water and $\Delta P_1 = 4.53$ cm in silicone oil. Unfortunately, there was an unresolved problem with the phase of the output pulse of the new array which produced an offset in the measured sound speed. Consequently these phase speed measurements were discarded. The attenuation measurements were unaffected by this problem and are presented here.

III. RESULTS AND MODEL-DATA COMPARISONS

The sound speed ratio and attenuation measured in each sediment are presented in Fig. 2. Each data point is the mean of measurements of approximately 20 realizations of each sediment, where a realization represents a complete cycle of the shaking procedure discussed earlier. The error bars on each data point reflect the uncertainties in the path lengths as well the distribution of the measured values. As predicted by Biot theory, the sound speed in the silicone oil/glass-bead sediment exhibits greater dispersion than the water/glass-bead sediment. However, contrary to Biot theory, both media show a frequency dependence for the attenuation that is greater than $f^{1/2}$. A linear fit to the attenuation shows that the attenuation follows an $f^{1.06}$ dependence for the water/glass-bead sediment and an $f^{0.99}$ dependence for the silicone oil/glass-bead sediment.

Note that in Fig. 2(a), the size of the data circles represent the uncertainty associated with the precision of the measurements (without the uncertainty in the position of the transducers). This indicates that there is a peak in the sound speed centered at 160 kHz. This apparent curvature is most likely a consequence of errors due to the response of the transducers at the edges of the operational frequency range of the attenuation array and not a property of the medium.

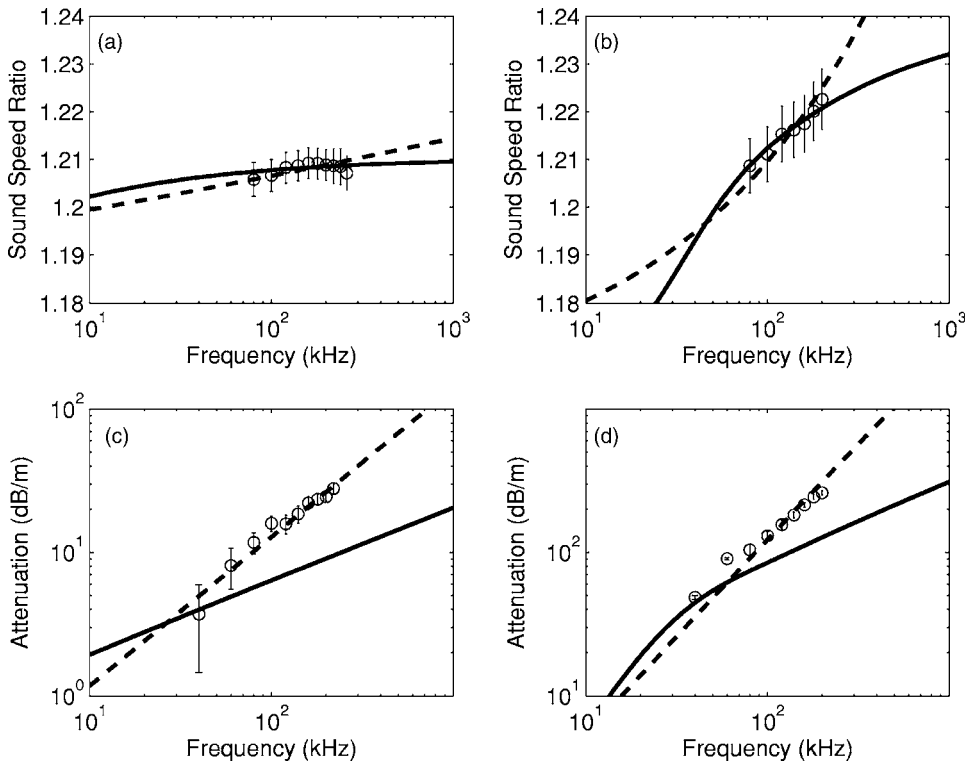
In order to test Biot theory against these data, it is necessary to know certain material parameters in order to determine the sound speed and attenuation. A majority of these parameters are discussed in the previous section and are given in Table I, but there are two notable exceptions. For both glass-bead sediments, the frame bulk modulus, K_b, and the shear modulus, μ_b, are unknown. Williams has shown that in most sand sediments, because the bulk and shear frame moduli are much smaller than the other moduli, they


FIG. 2. Sound speed measurements made in a glass-bead sediment saturated with (a) water and (b) silicone oil. Attenuation measurements made in a glass-bead sediment saturated with (c) water and (d) silicone oil. Also shown are the predictions of the EDFM (solid line) and the Buckingham model (dashed line) using the parameters given in Table I. The error bars on the data points represent uncertainties in the position of the hydrophones as well as the distribution of multiple measurements in each sediment. The size of the data circles in (a) represent the uncertainty in the precision of the measurements (without the uncertainty in the position of the transducers).

can be neglected with only minor errors (0.5%) in the high frequency sound speed and attenuation.[20] Taking the $K_b = \mu_b = 0$ limit of Biot theory yields the effective density fluid model (EDFM) which gives the complex wave number for the compressional wave. The EDFM along with the fluid, solid, and sediment properties in Table I yield the solid lines in Fig. 2. In both sediments, the EDFM captures the measured sound speed values but does not capture the high frequency behavior of the attenuation. Although the EDFM does not capture the details of the attenuation, it does predict an increase in attenuation between the water and silicone oil sediments due to the increase in viscosity that is on the same order as the increase in the measured attenuation. Consequently, both the frequency scaling and frequency dependence contradict what was measured by Seifert et al.[13] Note that in the experiments by Seifert et al., the sediment samples were compressed in a triaxial cell while in the current measurements the sediment was allowed to settle under gravity. This compaction could potentially influence the acoustical behavior of the medium and lead to attenuation values different from those observed in the present study. While the results presented here contradict the results of the experiments by Seifert, the current results are consistent with those of Costley and Bedford.[21] In their work, they varied the viscosity from 0.001 to 0.003 Pa s and found that the attenuation at 105 kHz followed the predictions of Biot theory over this range. In those experiments, the measurements were performed in a tank, similar to the work presented here, as opposed to the traxial cell used by Seifert.

The compressional wave number in the grain-to-grain shearing model of Buckingham can be expressed as[4]

$$k^2 = \frac{\omega^2 \rho}{H + \gamma_T(-i\omega T)^n}, \quad (3)$$

where ω is the radial frequency, $\rho = (1-\beta)\rho_s + \beta\rho_f$ is the average density of the sediment, $H = (\beta/K_f + (1-\beta)/K_s)^{-1}$ is the bulk modulus of the sediment evaluated from Wood's equation, $\gamma_T = \gamma_p + 4/3\gamma_s$ is the rigidity coefficient, and n is the material exponent. Note that the rigidity coefficient is a combination of Buckingham's compressional and shear rigidity coefficients. Since a shear wave measurement was not made and cannot be used to determine the values of n and γ_s, the rigidity coefficients can be combined into a single constant which must be fit to the data along with the material exponent. Note that the assumption of $n = m$ made in Buckingham's derivation has also been made here.

The sound speed and attenuation given by Buckingham's model are shown as the dashed lines in Fig. 2 and the values of γ_T and n are given in Table I. For the water/glass-bead sediment, the values of these parameters are the same order of magnitude as those determined for the SAX99 data. For the silicone oil sediment, n is an order of magnitude larger while γ_T is two orders of magnitude smaller. It may be that the large viscosity of the silicone oil brings into doubt the approximation made in Eqs. (58) and (59) in Ref. 4, which stems from the assumption that viscous effects at the grain contacts are negligible. If these approximations are not made, the number of unknowns increases to three (this again assumes that the shear and compressional values are the same), the determination of which is beyond the scope of this paper.

IV. COMBINING FLUID VISCOSITY AND FRAME LOSS EFFECTS

The success of Biot theory in *predicting* (a) the frequency dependence of the dispersion and (b) the scaling of the attenuation with viscosity indicates that the relative motion of the pore fluid and the sediment frame plays a significant role in sound propagation through fluid-saturated granular materials. Any theory of sound propagation should therefore account for this interaction. The failure of Biot theory to account for the frequency dependence of the attenuation suggests that a second loss mechanism is present. Although Buckingham's model was able to fit the attenuation data, the model does not have any predictive ability at this point in its development. However, it does suggest that grain-to-grain interactions may be the second mechanism that is missing from the Biot description of the media. As a starting point, a model is developed here that combines two attenuation mechanisms: viscous flow and grain-to-grain shearing. Buckingham, in his model derivation, examines the need to account for viscous flow losses and concludes that they are negligible compared to grain friction losses. This combined model is again addressed here, but instead of assuming a simple wave propagation model, the grain-to-grain shearing losses are incorporated directly into Biot theory.

In Ref. 4, Buckingham derives expressions for the mean stress in a unit volume of granular material due to a large number of grain-to-grain contacts. The stress associated with radial sliding due to grains being compressed normal to one another is

$$\sigma_{zz}(t) = \lambda_p h_p(t) \otimes \frac{dv_z(t)}{dz} \tag{4}$$

and associated with translational sliding due to shearing at the grain contacts is

$$\sigma_{xz}(t) = \eta_s h_s(t) \otimes \frac{dv_x(t)}{dz}, \tag{5}$$

where λ_p and η_s are constants which contain information about the microsliding events, $h_{p,s}(t)$ are the material impulse response functions (MIRFs) for radial and translational shearing, and the symbol $\otimes$ denotes a temporal convolution (for a detailed discussion of radial and translational sliding see Ref. 4).

Instead of considering the grains and fluid as a single composite medium as in Ref. 4, the grains and fluid will be treated as separate constituents as in Biot theory. Although the grains are not locked together to form a matrix as in Biot theory, the grain-to-grain interactions give rise to a viscoelastic matrix through the "pores" of which the fluid is allowed to move. The elastic constants of this matrix can be determined by considering the components of the strain tensor and how they relate to the stresses given by Eqs. (4) and (5). Consider first the shear strain in the frame matrix,

$$\epsilon_{ij} = \frac{1}{2}\gamma_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right). \tag{6}$$

This strain will produce a shear stress within the matrix due to the translational sliding of the grains against on another. From Eq. (5), the shear stress is

$$\sigma_{ij} = \eta_s h_s(t) \otimes \left\{\frac{dv_i(t)}{dx_j} + \frac{dv_j(t)}{dx_i}\right\}, \tag{7}$$

where $v_i = \dot{u}_i$. Assuming that the disturbance in the matrix has a harmonic time dependence, $e^{-i\omega t}$, then Eq. (7) becomes

$$\sigma_{ij} = 2\mu_b(\omega)\epsilon_{ij}, \tag{8}$$

where

$$\mu_b(\omega) = -i\omega\eta_s H_s^*(i\omega) \tag{9}$$

and $H_s^*(i\omega)$ is the complex conjugate of the temporal Fourier transform of $h_s(t)$.

For the second elastic modulus of the granular matrix, consider the response of a unit cube of the matrix to a uniform pressure. This pressure gives rise to a change in the volume of the cube equal to $e = \nabla \cdot \mathbf{u}$ and will also produce radial sliding at the grain contacts due to the compression of the grains. Using Eq. (4), the stress-strain relation in this situation becomes

$$\sigma = \lambda_p \nabla \cdot [h_p(t) \otimes \mathbf{v}]. \tag{10}$$

Once again assuming a harmonic compression, the stress-strain relation becomes

$$\sigma = K_b(\omega)e, \tag{11}$$

where

$$K_b(\omega) = -i\omega\lambda_p H_p^*(i\omega) \tag{12}$$

and $H_p^*(i\omega)$ is the complex conjugate of the temporal Fourier transform of $h_p(t)$. The dynamic elastic moduli of the matrix are therefore the grain-to-grain shear modulus, $\mu_b(\omega)$, and the grain-to-grain bulk modulus, $K_b(\omega)$.

The temporal Fourier transforms of the MIRFS in Eqs. (9) and (12) are given approximately by[4]

$$H_s^*(i\omega) \approx \frac{\Gamma(1-m)}{(-i\omega t_s)^{1-m}} \tag{13}$$

and

$$H_p^*(i\omega) \approx \frac{\Gamma(1-n)}{(-i\omega t_p)^{1-n}}, \tag{14}$$

where Γ is the complement of the incomplete gamma function, m, n are the material exponents, and $t_{s,p}$ are the stress relaxation time constants. The approximations are valid assuming that $\omega t_{s,p} \ll 1$. With these expressions, the elastic moduli can be written as

$$\mu_b(\omega) = \gamma_s(-i\omega T)^m \tag{15}$$

and

$$K_b(\omega) = \gamma_p(-i\omega T)^n, \tag{16}$$

where the shear and compressional rigidity coefficients are

$$\gamma_s = \frac{\eta_s}{t_s} \Gamma(1-m)\left(\frac{t_s}{T}\right)^m \tag{17}$$

and

$$\gamma_p = \frac{\lambda_p}{t_p} \Gamma(1-n)\left(\frac{t_p}{T}\right)^n. \tag{18}$$

The time constant T has been introduced to keep terms raised to the fractional powers n and m dimensionless. The expressions are independent of T and hence it is taken to be $T = 1$ s. These expressions for the frame moduli can be used in Biot's equations. A detailed discussion of Biot's equations can be found in Ref. 9 while a concise presentation is found in Eqs. (1)–(8) of Ref. 12.

The form of the expressions for the moduli given by Eqs. (15) and (16) are not new and were first suggested by Biot in the development of a phenomenological approach to solid dissipation in porous medium[6,7] and later explored in detail, outside the context of Biot theory, by Kjartansson.[22] Kjartansson was motivated by early measurements on absorption of sound in rocks which found that the energy lost per cycle or wavelength, Q, was independent of the frequency. To account for this, he proposed a model for the elastic moduli which has essentially the same form as Eqs. (15) and (16). For the shear modulus, and likewise for the bulk modulus, the phase angle between the stress and the strain can be determined by rewriting the modulus as

$$\mu_b(\omega) = \gamma_s |\omega T|^m \exp\left(-i\frac{m\pi}{2}\mathrm{sgn}(\omega)\right). \tag{19}$$

The Q is directly related to this phase angle and from this expression for the shear modulus,

$$\frac{1}{Q} = \tan\left(\frac{m\pi}{2}\right). \tag{20}$$

Because of this property, the model is often referred to as the constant Q (CQ) model.

Kjartansson showed that this model could be expressed as an infinite set of viscoelastic Zener elements.[22] As a consequence of this construction, the CQ model is causal. Buckingham has also shown this directly in the development of his model.[2] The introduction of CQ frame moduli into Biot theory was investigated by Turgut,[23] who numerically integrated the Kramers-Krönig relations and also found that this viscoelastic Biot theory was causal. The models proposed by Biot and Kjartansson and explored by Turgut were all phenomenological and did not make any assumptions about the physics behind the model.

To examine the properties of the hybrid model [the Biot model incorporating frame loss via Eqs. (15) and (16)], it is easiest to look first at the behavior of the shear wave. In the hybrid model, the shear wave number becomes

$$k_s^2 = \omega \frac{\rho_{\mathrm{eff}}^{(s)}}{\mu_b(\omega)}, \tag{21}$$

where

$$\rho_{\mathrm{eff}}^{(s)} = \rho_f \left(\frac{\alpha(1-\beta)\rho_s + \beta(\alpha-1)\rho_f + \dfrac{i\rho\beta\eta F(\omega)}{\rho_f \kappa \omega}}{\rho_f(\alpha-\beta) + \dfrac{i\beta\eta F(\omega)}{\kappa\omega}} \right) \tag{22}$$

and μ_b is the viscoelastic shear modulus given by Eq. (15). For a detailed derivation of this expression see p. 19 of Ref. 9. All of the constants in $\rho_{\mathrm{eff}}^{(s)}$ can be measured directly. Following Buckingham, the material exponent, m, and the rigidity coefficient, γ_s, can be evaluated given a measurement of the shear speed and attenuation at a single frequency. Writing the shear modulus as

$$\gamma_s(-i\omega T)^m = \gamma_s(\omega T)^m(\cos(m\pi/2) - i\sin(m\pi/2)), \tag{23}$$

the material exponent can then be found from

$$m = \frac{2}{\pi} \tan^{-1}\left(\frac{\mathrm{Im}(\rho_{\mathrm{eff}}^{(s)}/k_s^2)}{\mathrm{Re}(\rho_{\mathrm{eff}}^{(s)}/k_s^2)}\right), \tag{24}$$

and the rigidity coefficient is then

$$\gamma_s = \frac{\omega^2 \rho_{\mathrm{eff}}^{(s)}}{(-i\omega T)^m k_s^2}, \tag{25}$$

where $k_s = \omega/c_s - i\alpha_s$, c_s is the shear wave speed, and α_s is the attenuation. During SAX99, the shear wave speed and attenuation were measured[11] at 1 kHz and were $c_s = 120$ m/s with a range of $97-147$ m/s and $\alpha_s = 30$ dB/m with a range of $21-40$ dB/m. Using these values, the material exponent, m, has a best fit of 0.0506 to the mean sound speed and attenuation. The rigidity coefficient has a best fit of 1.82×10^7 Pa to the mean values of the sound speed and attenuation.

The shear speed and attenuation are shown as the solid lines in Fig. 3. Also shown in this figure are the predictions of the Buckingham model and the predictions of Biot theory with a complex shear modulus with no frequency dependence. For this complex shear modulus, the best fit to the mean values of the sound speed and attenuation is $2.83 \times 10^7 - i2.25 \times 10^6$ Pa.

In Ref. 2, Buckingham attempts to address the question of whether it is necessary to account for viscous losses due to global or local motion of the pore fluid when modeling sound propagation in marine sediments. In order to do this, he introduces viscous loss terms into the equation of motion for the saturated sediment. The solution to the resulting wave equation indicates a frequency dependence for both the sound speed and attenuation from which he is able to draw two conclusions. In his combined model, the intergranular friction appears to dominate at lower frequencies while the pore fluid viscosity dominates at high frequencies. Also, the sound speed varies with frequency as $f^{1/2}$ in the high frequency regime where the pore fluid viscosity dominates.

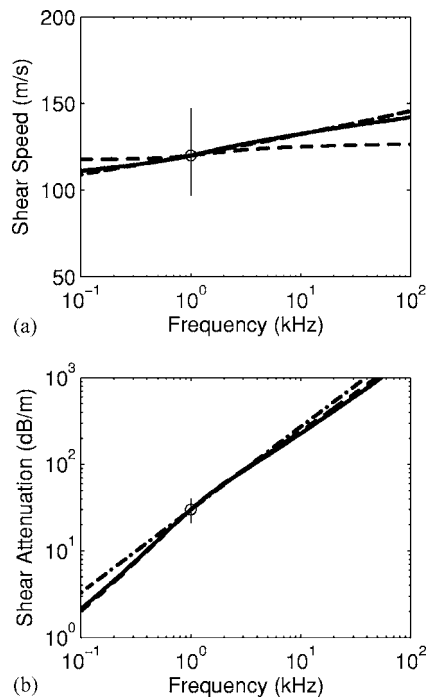
The asymptotics of Eq. (21) indicate that in both high and low frequency limits, the intergranular friction is the dominant loss mechanism, while from Fig. 3 both mechanisms play important roles in the midfrequency range. This is similar to the results of Biot-Stoll theory. Brunson has shown that Biot theory with complex shear moduli is able to account for details of the measured attenuation, specifically the


FIG. 3. (a) Shear wave speed and (b) attenuation. The data point at 1 kHz is a shear wave measurement made during SAX99 by Richardson (Ref. 11). The shear wave speed and attenuation predicted by Biot theory (dashed line), the Buckingham model (dot-dashed line), and the hybrid model (solid line). Each of these models was fit to the data point.

"knee" in Fig. 6 of Ref. 24 that a linear fit would miss. (See also Fig. 1 of Ref. 3 for further deviations from the f^1 dependence for shear attenuation.) From the similarities in the behavior of the hybrid model and Biot-Stoll theory in Fig. 3 it seems that the hybrid model would also be able to capture these details in the attenuation. A true test, as seen in Fig. 3(a), would be a measurement of the shear speed across a large frequency range, however this measurement may be prohibitively difficult in sandy sediments.

In Buckingham's model, the grain-to-grain friction is due to a number of random micro-asperity sliding events, each one of which is assumed to be identical regardless of whether the grain-to-grain motion is radial or compressional. Since the material exponents characterize these individual events, it is reasonable to assume that they have the same values. Buckingham presents limited evidence in the form of data-model comparisons that support this conclusion for his model. However, assuming that $n=m$ in the hybrid model does not yield a curve which will fit the at-sea or laboratory attenuation. In fact, the resulting attenuation is nearly indistinguishable from the Biot-Stoll result. This suggests that m and n may not be equal. For the remainder of this analysis we will relax this constraint and allow n to be a free parameter. Using the values for the shear rigidity coefficient and the corresponding material exponent, the remaining coefficient and exponent can be determined for the compressional wave through a best fit to the sound speed and attenuation data. The data-model comparisons presented here support the conclusion that n and m are not equal.

The compressional sound speed and attenuation predicted by the hybrid model for the SAX99 sediment are pre-sented in Figs. 4(a) and 4(d). Both n and γ_p were determined from a best fit to the data and were found to be $n=1.088$ and $\gamma_p=41.96$ Pa. This hybrid model succeeds in combining the effects of fluid viscosity and frame loss and follows the data better than either the Biot or Buckingham model individually. The model also contradicts Buckingham's conclusions about the importance of losses due to viscous flow for the compressional wave. Whereas he concludes that viscous loss is the dominant mechanism at high frequencies, the hybrid model predicts that viscous loss dominates in the midfrequencies while granular friction is the dominant mechanism at high and low frequencies. This is similar to the asymptotics of the shear wave where granular friction also dominates at both the high and low frequencies. Since the frequency dependence of the frame bulk modulus is nearly linear, for low frequencies granular friction will dominate the attenuation since the attenuation due to viscous flow goes as f^2. Also, since Biot theory gives an $f^{1/2}$ dependence at high frequencies, granular friction will again dominate asymptotically.

In order to compare the hybrid model to the data from the glass-bead sediments, four variables need to be determined: n, m, γ_p, and γ_s. Unlike the at-sea data there are no shear wave measurements to use to determine the shear rigidity coefficient and exponent. The results for the at-sea data, however, suggest that the shear modulus may be negligible compared to the other moduli. Setting $\mu_b=0$ for the hybrid model yields both sound speed and attenuation predictions that are nearly indistinguishable from the EDFM predictions. Consequently, for the glass-bead sediments, the shear rigidity coefficient is taken as $\gamma_s=0$. The predictions of the hybrid model are shown in Figs. 4(b) and 4(e) for the water and glass-bead sediment and in Figs. 4(c) and 4(f) for the silicone oil and glass-bead sediments.

For water and glass beads, the grain-to-grain shearing parameters were determined to be $n=0.915$ and $\gamma_p=182.94$ Pa. For the silicone oil and glass beads, the grain-to-grain shearing parameters were determined to be $n=1.059$ and $\gamma_p=57.89$ Pa. The hybrid model captures the data very well in both cases and with values for the grain-to-grain parameters that are consistent with the at-sea sediment. This differs from the Buckingham model for which the material exponent increases by a factor of 10 relative to the water/glass-bead sediment. This change in the material exponent indicates that for the Buckingham model the increase in attenuation and dispersion must be due to a *decrease* in the strain-hardening at the micro-asperities even though the viscosity of the pore fluid was increased by a factor of 100. In the hybrid model, the increase in attenuation is due to the increase in the viscosity of the pore fluid, while the attenuation due to the grain-to-grain friction is nearly identical to that observed in the previous glass-bead sediment and in the SAX99 sediment.

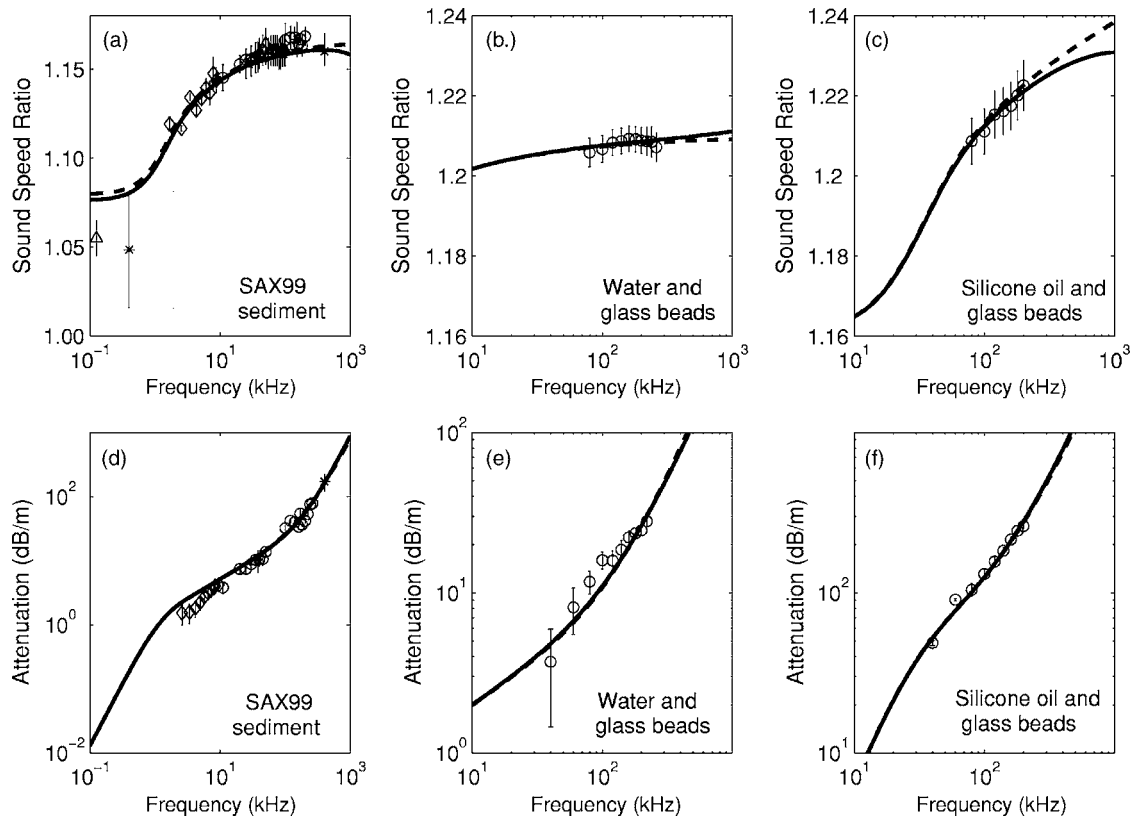
Not only are the grain-to-grain shearing parameters similar in all three sediments, but the material exponent is very nearly equal to one, as can be seen in Table II. This suggests that the hybrid model with $n=1$ may yield predictions that compare favorably to the data. The results of the hybrid model with $n=1$ and γ_p taken as the free parameter


FIG. 4. (a)–(c) Sound speed and (d)–(f) attenuation predictions using the hybrid model for the sediment at SAX99, the water and glass-bead sediment, and the silicone oil and glass-bead sediment. The grain-to-grain shearing parameters in the hybrid model were determined in two ways. For the solid line, the values of both the compressional rigidity coefficient, γ_p, and the material exponent, n, which gave the best fit to both the sound speed and attenuation data were found. For the dashed line, the material exponent was set to $n=1$ while the value of γ_p was determined from the best fit.

are shown as the dashed lines in Fig. 4. For the attenuation, the two curves are practically indistinguishable while for the sound speeds the deviation is most pronounced at high frequencies where the grain-to-grain losses are greatest. Even with this deviation, the model still compares favorably to the data.

V. HYBRID MODEL WITHOUT "STRAIN-HARDENING"

The success of the hybrid model with $n=1$ has implications for the theoretical framework of the grain-to-grain shearing mechanism that Buckingham develops in Ref. 4. The material exponent is defined as $n=E_p/\theta_p$, where E_p is the elastic response of the micro-asperity contact and θ_p reflects the nonlinear response of the viscous damping at the contact. Thus $n=1$ means that elastic and viscous responses

TABLE II. Material exponents and compressional rigidity coefficients used in the hybrid model for each sediment. The parameters were determined from a fit to the data allowing both parameters to be free in the first case and fixing $n=1$ in the second case.

Sediment	Fit with two free parameters		Fit with one free parameter	
	n	γ_p (Pa)	n	γ_p (Pa)
SAX99	1.088	41.96	1.00	146.82
Water/glass beads	0.915	182.94	1.00	54.79
Si100/glass beads	1.059	57.89	1.00	115.55

are equal, which is extremely unlikely since they are unrelated to one another. This may also mean, however, that the "strain-hardening" is actually absent from the grain-to-grain interactions, i.e., $\theta_p=0$, and the viscosity of the fluid film remains linear during the micro-sliding event.

To understand why this may be the case, consider the differential equation of motion for the micro-sliding event given in Eq. (16) in Ref. 4,

$$\frac{1}{E}\frac{d\chi}{dt} + \frac{1}{\xi(t)}\chi = \varepsilon\,\delta(t). \tag{26}$$

If the dashpot, $\xi(t)$, is no longer a function of time, the strain-hardening coefficient θ_p is zero and $\xi(t)=\xi_0$. The solution to the equation of motion becomes

$$\chi = \chi_0 e^{-(E/\xi_0)t}\,\mathrm{sgn}[\varepsilon\,\delta(t)]. \tag{27}$$

The time-dependent part of the solution is the pulse shape function, or MIRF,

$$h(t) = \frac{E}{\xi_0}e^{-(E/\xi_0)t}, \tag{28}$$

and the mean pulse amplitude becomes

$$\bar{a} = \chi_0\frac{\xi_0}{E}. \tag{29}$$

Using these new expressions, the stress associated with radial and translational sliding given in Eqs. (4) and (5) is unchanged, but the constants now become

$$\lambda_p = \chi_{0p} \nu_p \bar{b} t_p, \qquad \eta_s = \chi_{0s} \nu_s \bar{b} t_s, \tag{30}$$

where $\bar{b}$ is a proportionality constant defined in Ref. 4, the stress relaxation time constants are

$$t_p = \frac{\xi_{0p}}{E_p}, \qquad t_s = \frac{\xi_{0s}}{E_s} \tag{31}$$

and the MIRFs are now

$$h_p(t) = t_p^{-1} e^{-t/t_p} \tag{32}$$

and

$$h_s(t) = t_s^{-1} e^{-t/t_s}. \tag{33}$$

We can now obtain expressions for the shear and bulk moduli by taking the Fourier transforms of the MIRFs,

$$H_p(\omega) = \frac{1}{1 - i\omega t_p}, \qquad H_s(\omega) = \frac{1}{1 - i\omega t_s} \tag{34}$$

and substituting these into the expressions for the shear and bulk moduli in Eqs. (9) and (12). The new frequency dependent moduli then become

$$\mu_b(\omega) = \frac{\eta_s}{1 + i\dfrac{1}{\omega t_s}} \tag{35}$$

and

$$K_b(\omega) = \frac{\lambda_p}{1 + i\dfrac{1}{\omega t_p}}. \tag{36}$$

It is reasonable to assume that the spring constant, E, associated with the compressibility of the grain asperities and hence related to the elastic properties of the grain ($>10^9$ Pa), is much larger than the viscosity of the fluid flim, ξ_0, which should be related to the viscosity of the bulk fluid (<0.1 Pa s). If this is the case then $\omega t_p \ll 1$ and the bulk modulus is approximately

$$K_b(\omega) = -i\gamma_p \omega, \tag{37}$$

which has the same form as Eq. (16) when $n=1$ and with $\gamma_p = \lambda_p t_p$. The data model comparisons given in Sec. IV are therefore applicable for this linear form of the grain-to-grain shearing model.

In the Appendix, we show that for $K_b, \mu_b \ll K_r, K_f$, the hybrid model can be expressed as

$$k^2 = \frac{\omega^2 \rho_{\text{eff}}}{K(\omega)} \tag{38}$$

where

$$K(\omega) = H_{\text{eff}} + K_b(\omega) \frac{\left(1 - \dfrac{2H_{\text{eff}}}{K_r}\right)(\tilde{\rho} - \rho_f) + \rho_f - \rho_{\text{eff}}}{\rho + \tilde{\rho} - 2\rho_f}$$

$$+ \mu_b(\omega) \frac{\tilde{\rho} - \rho_{\text{eff}}}{\rho + \tilde{\rho} - 2\rho_f}. \tag{39}$$

This expression extends the EDFM to include the effects of a weak frame stiffness or loss in the effective bulk modulus of the medium. As expected, the frequency dependent modulus $K(\omega)$ reduces to H_{eff} and the wave number reduces to the EDFM result when the frame moduli are set to zero. Note that this expression does not depend on the form of the bulk moduli only that they are much less than the pore fluid and grain material moduli. This expression is a good approximation to the full hybrid model solution over most of the frequency range and begins to deviate at high frequencies. For the SAX99 parameters and the rigidity coefficients in Table II, the error in the attenuation at 100 kHz is 1.2% which increases to 7% at 1 MHz. The sound speed error is 0.0002% at 100 kHz which increases to 0.02% at 1 MHz.

The form of the frequency dependent bulk modulus in Eq. (36) is identical to the Biot model with grain contact squirt flow and shear drag (BICSQS model) proposed by Chotiros and Isakson[14] with the exception of a purely real asymptotic frame bulk modulus. For the shear modulus, the expressions differ between the two models, but the asymptotic values are the same. In their fits to the SAX99 data, the frequency dependent bulk modulus is responsible for fitting the lowest frequency SAX99 data, which we have not attempted to fit. It is the shear modulus which largely determines the fit to the high frequency attenuation data. This ignores the shear speed and attenuation data at 1 kHz collected during SAX99 which, similar to Buckingham's model and the hybrid model, determines the two free parameters of the frequency dependent shear modulus. Applying the BIC-SQS model to the shear data using the parameters given in Table I, yields a relaxation frequency of $f_\mu = 2$ Hz significantly lower than the 56 kHz value found by the Chotiros and Isakson. Note that this fitting procedure does not treat the permeability as a free parameter as in Ref. 14, but we do not feel that the permeability allows sufficient freedom to fit both the shear data point and the high frequency compressional attenuation. However, if the requirement to fit the lowest frequency sound speed data points is relaxed, the parameters in the bulk modulus can be adjusted to fit the compressional attenuation data as in the linear hybrid model above. This leaves open the question of which, if either, of these two models is physically correct. Both will yield valid fits that are indistinguishable and a definitive test will require comparisons of the model parameters to measurable properties of the sediment. However neither model has been developed to the point where this comparison can be performed.

VI. CONCLUSIONS

The purpose of this experiment was to make sound speed and attenuation measurements in a simple glass-bead sediment and to observe how these measurements changed as the viscosity of the pore fluid was increased by two orders of magnitude. Several conclusions can be drawn from the measurements and the data/model comparisons with Biot-Stoll theory:

1. Biot theory correctly predicted that the frequency range

over which the most significant dispersion occurs should shift into the frequency range of our measurement system as the viscosity increased.

2. While the frequency dependence of the attenuation differed from the predictions of Biot theory, the theory was also able to predict how the attenuation scales with viscosity.

3. From this we conclude that the relative motion of the pore fluid through the sediment frame plays a significant role in both the dispersion and the attenuation, in contrast to the conclusion reached by Buckingham, and must be taken into account to properly model sound propagation through sand sediments.

4. Measurements of attenuation in the SAX99 sediment indicated that the high frequency attenuation follows a linear frequency dependence as opposed to the $f^{1/2}$ dependence which is predicted by Biot theory. It was suggested that this excess attenuation might have been due to scattering from shells or shell fragments. This linear frequency dependence was also observed in the glass-bead sediments in the absence of scatterers suggesting that the mechanism for this excess attenuation is more fundamental to a granular medium such as losses at the grain contacts.

Since Buckingham's grain-to-grain shearing model could be *adjusted* to fit the frequency dependence of the attenuation, while Biot theory was able to *predict* the sound speed dispersion in all three sediments, we constructed a hybrid model which incorporated grain-to-grain shearing physics into the frame moduli in Biot theory. The resulting theory captured both the motion of the viscous pore fluid and the interactions of the grain contacts. The process of combining these models did not explicitly violate the physics behind either of the models and in fact the incorporation of complex, frequency dependent moduli into Biot theory was first suggested by Biot himself.

Fits of the hybrid model to the data implied that the exponent in Buckingham's theory should be $n=1$. This further implies that the viscous response of the asperity contacts can be treated as linear which means that "strain-hardening" suggested by Buckingham is absent. With this assumption, a linear version of grain-to-grain shearing can be incorporated into Biot theory to give the proper frequency dependence for the complex moduli. The resulting bulk modulus has a form that is similar to that proposed in the BICSQS model, however at this point in the development of both models, neither has been developed to the point where the material properties of the sediment can be compared to the relevant parameters in the models. Therefore, the frame loss embodied in Eqs. (15) and (16) may be due to neither, one, or both of these mechanisms. Regardless, we believe the experiment/model comparisons given here imply that Biot's suggestion of adding frame loss phenomenologically using the form of Eqs. (15) and (16) is viable.

Finally, Eq. (38) can be used with Eqs. (15), (16), and (39) to model unconsolidated sand sediments as a fluid, while at the same time accounting for frame loss, with only a small loss in accuracy over the full model developed in Secs.

IV and V. We believe this simplified fluid model can be useful for application oriented work as well as basic research where porous media effects are being studied within a larger context, e.g., long range, shallow water propagation and scattering.

APPENDIX: EXTENDING THE EDFM TO INCLUDE FRAME MODULI

Here, we revisit Biot's equations in order to derive an approximate solution similar to the effective density fluid model (EDFM) which incorporates the frame bulk and shear moduli to second order. Using the potentials[25] $(\Phi_s, \Phi_f, \Psi_s, \Psi_f)$ defined in terms of the displacement vectors of the skeletal frame $\mathbf{u}$ and the fluid $\mathbf{U}$ as

$$
\begin{aligned}
\mathbf{u} &= \nabla\Phi_s + \nabla \times \mathbf{\Psi}_s, \\
\beta(\mathbf{u} - \mathbf{U}) &= \nabla\Phi_s + \nabla \times \mathbf{\Psi}_s.
\end{aligned}
\tag{A1}
$$

Biot's equations for the scalar potentials are given as (using a plane wave solution $\exp[i(\mathbf{k}\cdot\mathbf{r} - \omega t)]$)

$$
-k^2 H\Phi_s + k^2 C\Phi_f = -\rho\omega^2\Phi_s + \rho_f\omega^2\Phi_f,
\tag{A2}
$$

$$
-k^2 C\Phi_s + k^2 M\Phi_f = -\rho_f\omega^2\Phi_s + \frac{\omega^2\alpha\rho_f}{\beta}\Phi_f + \frac{i\omega F\eta}{\kappa}\Phi_f.
\tag{A3}
$$

In Eqs. (A2) and (A3), k is the wave number, α is the structure constant or tortuosity, η is the pore fluid viscosity, ρ_s is the sediment particle density, ρ_f is the pore fluid density, and

$$
k = \frac{\omega}{c}, \quad \omega = 2\pi f,
$$

$$
\rho = \beta\rho_f + (1-\beta)\rho_s,
$$

$$
H = \frac{(K_r - K_b)^2}{D - K_b} + K_b + \frac{4\mu}{3},
$$

$$
C = \frac{K_r(K_r - K_b)}{D - K_b},
\tag{A4}
$$

$$
M = \frac{K_r^2}{D - K_b},
$$

$$
D = K_r\left[1 + \beta\left(\frac{K_r}{K_f} - 1\right)\right] = \frac{K_r^2}{H_{\text{eff}}},
$$

$$
H_{\text{eff}} = \left(\frac{(1-\beta)}{K_r} + \frac{\beta}{K_f}\right)^{-1},
\tag{A5}
$$

where f is the frequency, c is the sound speed, ρ is the total mass density, K_r is the bulk modulus of the individual sediment grains, K_f is the bulk modulus of the pore fluid, and H_{eff} corresponds to the bulk modulus of the sediment found

for the EDFM when $K_b = \mu_b = 0$ in H, C, and M. The parameter F represents the deviation from Poiseuille flow as the frequency increases and is discussed in detail in Ref. 12 and the references cited therein.

If $K_b, \mu_b \ll K_r, K_f$, Biot's coefficients can be approximated to second order in the frame moduli as

$$H \approx H_{\text{eff}} + \left(1 - \frac{2H_{\text{eff}}}{K_r}\right)K_b + \frac{4\mu_b}{3},$$

$$C \approx H_{\text{eff}}\left(1 - \frac{K_b}{K_r}\right),$$

$$M \approx H_{\text{eff}}. \tag{A6}$$

Note that this approximate form for the coefficients produces the same results as the full coefficients for the "jacketed" and "unjacketed" tests introduced by Biot[9,26] to help understand the significance of these coefficients. Using Eqs. (A2) and (A3) with the approximate coefficients given in Eq. (6), the wave number for longitudinal waves can be found from

$$k^2 = \frac{-b\left(1 \pm \sqrt{1 - \frac{4ac}{b^2}}\right)}{2a}, \tag{A7}$$

where the $(-)$ sign corresponds to the fast wave, the $(+)$ sign corresponds to the slow wave, and

$$a \approx H_{\text{eff}}(K_b + 4\mu_b/3),$$

$$b \approx H_{\text{eff}}(2\rho_f - \rho - \tilde{\rho})$$
$$- \left[\left(1 - \frac{2H_{\text{eff}}}{K_r}\right)\tilde{\rho} + \frac{2H_{\text{eff}}}{K_r}\rho_f\right]K_b - \frac{4\mu_b}{3},$$

$$c = \tilde{\rho}\rho - \rho_f^2,$$

$$\tilde{\rho} = \frac{\alpha\rho_f}{\beta} + \frac{iF\eta}{\kappa\omega}. \tag{A8}$$

Since the frame moduli are assumed to be much smaller than the material moduli, the square root can the approximated by its Taylor series, where terms higher than second order are neglected. The resulting approximate wave number for the fast wave can be written as

$$k^2 = \frac{\omega^2 \rho_{\text{eff}}}{K}, \tag{A9}$$

where ρ_{eff} is the complex effective density for the EDFM and defined in Ref. 12. The effects of the frame moduli are contained in the effective bulk modulus

$$K = H_{\text{eff}} + K_b \frac{\left(1 - \frac{2H_{\text{eff}}}{K_r}\right)(\tilde{\rho} - \rho_f) + \rho_f - \rho_{\text{eff}}}{\rho + \tilde{\rho} - 2\rho_f}$$
$$+ \mu_b \frac{\tilde{\rho} - \rho_{\text{eff}}}{\rho + \tilde{\rho} - 2\rho_f}. \tag{A10}$$

For the complex moduli used in Ref. 12, the error in the sound speed relative to the full Biot model using this approximation is less than 0.02% and the error in the attenua-tion is less than 1% over a frequency range extending from 100 Hz to 10 MHz.

An investigation into the effects of underwater piling noise on salmonids

Underwater piling was undertaken in 2003 in Southampton Water on the South Coast of England. Monitoring was simultaneously undertaken of the waterborne sound from impact and vibropiling and its effects on brown trout in cages at increasing distances from the piling. Brown trout (*Salmo trutta*) were used as a model for salmon (*Salmo salar*), which were the species of interest but were not readily available. No obvious signs of trauma that could be attributed to sound exposure were found in any fish examined, from any of the cages. No increase in activity or startle response was seen to vibropiling. Analysis using the dB_{ht} metric indicated that the noise at the nearest cages during impact piling reached levels at which salmon were expected to react strongly. However, the brown trout showed little reaction. An audiogram of the brown trout was measured by the Auditory Brainstem Response method, which indicated that the hearing of the brown trout was less sensitive than that of the salmon. Further analysis indicated that this accounted for the relative lack of reaction, and demonstrated the importance of using the correct species of fish as a model when assessing the effect of noise. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2335573]

I. INTRODUCTION

It has been documented that the driving of piles in water causes high levels of underwater noise. Measurements made of piling using piles of 0.7 m diameter on the River Arun in southern England indicated a peak-to-peak Source Level of 191 dB $re1$ μPa @ 1 m (Nedwell *et al.*, 2002). Measurements made of the noise from piling using piles of 4.3 m diameter during the construction of offshore windfarms in the UK indicated a peak-to-peak Source Level of 260 dB $re1$ μPa @ 1 m for 5 m depth, and 262 dB $re1$ μPa @ 1 m at 10 m depth, associated with a Transmission Loss given by $22 \log(R)$, where R is the range (Nedwell *et al.*, 2003b). Such levels of sound may have an effect on marine species. A report for Caltrans on piling in San Francisco Bay indicated mortality to several species of fish at ranges of up to 50 m (Abbott, 2005). Intense sound from piling may also have an effect on hearing. McCauley *et al.* (2003) reported damage to the ears of a pink snapper caused by the impulsive noise of an airgun having a peak-to-peak Source Level of 222.6 dB $re1$ μPa @ 1 m and deployed at a range of 400–800 m from the caged fish. Enger (1981) reported damage to the ciliary bundles on the sensory cells of the inner ear of cod caused by sound at frequencies of 50 to 400 Hz at a level of 180 dB.

In September 2003, piling was undertaken in Southampton Water, a shallow inlet on the South Coast of England, adjacent to the quayside of a ferry terminal. There was concern that the construction work might adversely impact local fish populations, and, in particular, the migration of salmon up Southampton Water into the River Test, a Special Area of Conservation (SAC). A limit of 90 dB_{ht}(*Salmo salar*) at half-channel width was set as a noise limit by the regulator (the UK Environment Agency), with the intent of leaving half of the channel open for migration; the dB_{ht} metric is discussed in Sec. III B. Consequently, monitoring was undertaken of the waterborne sound generated by the piling operations. Simultaneously, the opportunity was taken to monitor the effects of the noise on fish in cages at increasing distances from the piling.

II. FIELD WORK

A. Location of measurements

The piling was carried out adjacent to a quay, in otherwise open water conditions. A total of ten piles, four 914 mm in diameter and six 508 mm in diameter, were driven. Vibrodriving was used for driving the piles, the duration being approximately 20 min per pile. At the end of the operation 3 of the 10 piles were driven to final depth by impact driving

for dynamic test purposes, the duration of each test being between one and three minutes, with approximately 20 blows during the period.

B. Fish response monitoring

Hydrophones and fish cages for reaction monitoring were located at 30, 54, 96, 234, and 417 m from the piling. The cages were 1 m cubes, made from a mild steel angle and covered with plastic mesh of 25 mm square aperture and suspended 2.5 m below the water surface. A closed circuit television camera was placed in each cage. A control cage was suspended in a dock 6 km from the site of the piling, where the piling noise had fallen below background levels.

Although the species of interest was salmon (*Salmo salar*), suitable fish were not available and instead farmed brown trout (*Salmo trutta*) were substituted as a close relative, which it was thought would react similarly. As is noted in Sec. III B, this assumption proved to be invalid.

C. Fish behavioral reactions

The video recordings were reviewed to identify any changes in behavior that might have resulted from the piling noise. These data were reviewed "blind," with the reviewer unaware of the condition of exposure. Two types of behavior were investigated.

(i) Startle reactions, which are here defined as sudden C-shaped flexure of the fish's body, described by Blaxter and Hoss (1981). The analysis of the startle reactions was based on a frame-by-frame inspection of the video at the start-up instant of each vibropiling session and for the next 5 s;

(ii) Fish activity level; captive fish that are exposed to irritating stimuli commonly show "milling behavior," in which the fish swim faster and make random turns. These were measured by counting the number of times fish entered the camera's field of view within a two-minute observation period.

Due to the fish being caged avoidance reaction (i.e., fleeing the noise) could not be directly observed, and the activity level was used as a measure of the behavioral effect. It may be commented, however, that human experience would indicate that the avoidance of noise may well occur at lower levels of noise than an increase in activity, and startle probably occurs at relatively high levels of noise. Since the caged fish could not flee, the experiment was imperfect in that it probably did not demonstrate the lowest level of sound at which avoidance of the piling noise occurred.

1. Reactions during vibropiling

No startle response was seen for any of the piles driven by vibropiling.

Table I gives the activity level observations for the 2 min period prior to piling and then for the first 2 min during vibropiling; they are seen to have remained similar before and after the start of piling. The control and event activity levels were compared using the nonparametric Mann-Whitney U-test (Campbell, 1974) with the null hypothesis that activity levels were not significantly different at the

TABLE I. Fish activity statistics (No. of movements per 2 min period) for vibropiling.

| Range (m) | Mann-Whitney U test | | | | |
	Before	During	U	Z	P
30	147.5	152.5	69.5	0.1443	0.8852
54	150.5	149.5	71.5	−0.028	0.9769

$P = 0.05$ level; it was found that there was no significant difference in activity level following the commencement of vibropiling ($P = 0.001$).

2. Reactions during impact piling

One pile of 914 mm diameter and two of 508 mm were impact driven. No startle reactions were observed at any of the five locations.

Activity levels recorded before and during the impact piling sessions are given in Table II. Fish activity is seen to have remained similar in most cases before and after the start of impact piling. The Mann-Whitney U test shows that there was no significant difference in activity level following the commencement of pile driving ($P = 0.001$) in cages at 30, 96, 234, and 417 m; a 36% increase in fish activity level was, however, observed in the cage at 54 m, which was significant at the $P = 0.05$ level.

III. LABORATORY STUDIES

A. Electron microscope examination of the inner ear of the trout (*Salmo trutta*)

The fish were initially examined under an optical microscope after the end of the piling operation for any evidence of swim bladder rupture, eye haemorrhage, or eye embolism as a result of exposure to the sound from the piling; none was found. The saccule, the primary auditory region of the fish ear (Popper and Fay, 1993), was investigated for evidence of trauma to the inner ear ultrastructure. Five fish from each of the cages were examined for ultrastructural damage to the hearing organs; the examiner was unaware of which fish came from which cage. A typical Scanning Electron Micrograph (SEM) of saccular hair cells from *S. trutta* is presented in Fig. 1, which is from a central region of the macula. The image shows apical hair cell bundles with an anterior positioned kinocilia, surrounded by approximately 40 cilia arranged in 4 to 5 consecutively shorter rows in a format common to many fish species (e.g., Platt and Popper, 1981; Lovell *et al.*, 2005). Each hair cell is separated from

neighboring cells by an area of epithelium bearing short (<1 μm) microvilli. No obvious signs of trauma that could be attributed to sound exposure were found in any fish examined, from any of the cages.

B. Fish audiograms

1. Quantifying the effects of noise on species

The response of marine animals to a given sound is dependent on the species since these vary greatly in hearing sensitivity and frequencies range. A metric has been described (Nedwell *et al.*, 2003a), (Nedwell *et al.*, 2004) termed the $dB_{ht}(Species)$ scale, which may be regarded as a generalization of the dB(A) metric used for the rating of the behavioral effects of noise on humans and hence that is indicative of how much a species will be affected by that sound. It is an estimate of the level that the sound is above the hearing threshold of the species and hence is an indication of the likely perception by, or "loudness" of the sound to, that species. Initial research with fish (Nedwell, in preparation) indicates that at levels of 90 dB or more above the species' threshold of hearing [i.e., of 90 $dB_{ht}(Species)$ or more] strong avoidance of sound occurs.

2. Inadequacies of brown trout as a model for salmon

At the time of the experimental measurements, it was noted that, despite the piling reaching levels of noise at which salmon, *S. salar,* were expected to react [i.e., in excess of 90 $dB_{ht}(S. salar)$], the brown trout, *S. trutta,* were showing no obvious signs of reaction. It was suspected that this was a result of the hearing of the latter being less sensitive. Since there was no audiogram available for the brown trout, this was determined by the Auditory Brainstem Response (ABR) method, and compared with previous published audiograms of salmon (Hawkins and Johnstone, 1978), in order to attempt to explain this unexpected observation. It should be noted, however, that the latter audiogram was obtained by the behavioral method, which in humans has been noted to yield slightly different results from ABR audiograms.
FIG. 2. Audiograms for the brown trout (*Salmo trutta*) and the salmon (*Salmo salar*). Salmon audiogram from Hawkins and Johnstone (1978).

3. The ABR method

The ABR method was similar to that described by Kenyon *et al.* (1998). Fish were held in a cradle in a water tank and a pair of electrodes placed cutaneously on the cranium such that they spanned the VIIIth nerve, recording the evoked auditory response to sound. The sound stimulus of several periods of a sine wave at a given frequency was generated by two underwater projectors within a water tank. Responses were averaged over 2000 presentations. The level of the stimulus was reduced until the stimulus trace was no longer discernible in the response trace. The sound level at which the stimulus trace was just discernible was taken as the threshold level for that frequency. The procedure was carried out using four fish at all of the frequencies tested, and 24 fish at frequencies between 300 and 1000 Hz.

Figure 2 shows the resulting *S. trutta* audiogram, as well as that for *S. salar* from Hawkins and Johnstone (1978). First, it should be noted that the latter audiogram was obtained by the behavioral method, which may give slightly different results from the ABR method. Nevertheless, it may be seen that, despite being a close relative with morphologically similar hearing, the audiogram of the brown trout is significantly different from that of the salmon. It is less sensitive, and broader and flatter in frequency response, with effective hearing from 30 Hz to above 1 kHz. It was concluded that the common assumption that closely related species will have similar hearing abilities is not reliable. Consequently, the data recorded during the piling were reprocessed using the brown trout audiogram to yield $dB_{ht}(S. trutta)$ values in addition to the $dB_{ht}(S. salar)$ values recorded on-site at the time of the noise measurements; these data are presented in Sec. IV.

IV. ANALYSIS OF NOISE MEASUREMENTS

A. Introduction

The piling was recorded using Brüel & Kjær hydrophones calibrated to International Standards, and conditioned by Brüel & Kjær charge amplifiers, before being digitized,
FIG. 3. The average peak-to-peak sound pressure level as a function of range, for the impact piling case, in dB$_{ht}$(*Species*) units, for two diameters of pile.

archived, and analyzed using a program written in the National Instruments LabVIEW environment that calculated one second dB$_{ht}$(*Species*) values.

B. Results

It was found that the unweighted Source Level of the impact piling of the 508 mm diameter pile was 193 dB *re*1 μPa @ 1 m, with a linear Transmission Loss rate of 0.13 dB per meter, and for the 914 mm diameter pile the Source Level was 201 dB *re*1 μPa @ 1 m and the Transmission Loss 0.13 dB per meter.

Figure 3 presents the dB$_{ht}$ levels of the impact piling as a function of range. The levels recorded at each of the measurement positions are indicated on the figure; for each of the two pile diameters driven the values of the noise in dB$_{ht}$(*Species*) units for both species have been plotted. It will be noted that the levels are different for the same data for the two different species since they have different hearing ability and frequency range of hearing. The figure may therefore be interpreted as indicating "loudness" for the two species as a function of range. Also illustrated in the figure is the 90 dB$_{ht}$(*Species*) limit at which it is believed noise becomes intolerable.

For each set of results a least squares best fit of the data has been calculated, the results being

$$SPL = 85 - 0.12R \ dB_{ht}(S. \ salar) \quad \text{and} \quad SPL = 62$$

$$- 0.09R \ dB_{ht}(S. \ trutta), \tag{1}$$

for the 914 mm diameter pile, and

$$SPL = 85.4 - 0.16R \ dB_{ht}(S. \ salar) \quad \text{and} \quad SPL = 70.7$$

$$- 0.17R \ dB_{ht}(S. \ trutta), \tag{2}$$

for the 508 mm diameter pile.

In general, the dB$_{ht}$(*S. salar*) levels are higher than the dB$_{ht}$(*S. trutta*) levels. This is to be expected, as the hearing of the salmon is more sensitive than that of the brown trout. It is noticeable that there is a significant difference in Transmission Loss for the case of *S. trutta* for the two pile diameter cases. It is thought likely that this might have been due to the fit of Source Level and Transmission Loss to the data being poor in the case of the 914 mm diameter pile.

In respect of the results for *S. trutta,* it may be seen that both the measured and the estimated levels near to the piling are well below the level at which a mild reaction would be expected to occur. In other words, no reaction would be expected by *S. trutta* at any range from the piling. By comparison, the results for *S. salar* would indicate that a mild reaction would be expected at a range of about 60–80 m, and an increasingly stronger reaction as this range was reduced. These results may explain the relative lack of a reaction to the piling from the brown trout *S. trutta*, and indicate the importance of using the correct species of fish as a model when assessing the effect of noise.

V. CONCLUSION

In summary we have the following.

(1) Observations were made of caged brown trout (*S. trutta*) during vibropiling of four 914 mm and six 508 mm diameter piles. The brown trout was used as a model for salmon (*S. salar*), which were not readily available.

(2) No reaction to vibropiling was noted at any of the cages. No startle reactions were observed for the impact driving. However, there was a 36% increase in the fish activity level observed in the cage at 54 m, which was significant at the $P = 0.05$ level, although in the two cages nearest to the piling (at 30 and 54 m), no significant difference in activity level was detected.

(3) Despite the noise from the piling at the nearest cages reaching levels at which salmon, *S. salar,* were expected to react strongly, the brown trout, *S. trutta,* showed little reaction. An audiogram of the brown trout measured by the Auditory Brainstem Response method indicated that the hearing of the brown trout was less sensitive than that of the salmon. Analysis using the dB$_{ht}$ metric indicated that this could account for the relative lack of reaction, and indicated the importance of using the correct species of fish as a model when assessing the effect of noise.

Echo energies of single-beam echo sounders are inverted for the sediment mean grain size via a combination of theoretical and empirical relationships. *In situ* measurements of the seafloor mass density have revealed the presence of a thin transition layer between the water and the sediment. Within this layer, which has a thickness of order 1 cm, the density continuously changes from the water value to the sediment bulk value. The associated impedance gradient affects the normal-incidence reflection coefficient at high frequencies, when the product of wave number and layer thickness is of order unity or higher. A mapping algorithm recognizing this gradient is applied to echo sounder data acquired in three different areas, and for five sounder frequencies between 12 and 200 kHz. Compared with a scheme that relies on the Rayleigh reflection coefficient of a discrete interface, an overall improvement of several phi units in the grain size mapping is achieved by taking the gradient into account. A necessary condition to reach agreement between the acoustic and the ground truth grain size is that the thickness of the transition layer increases with a decreasing grain size. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2345907]

I. INTRODUCTION

The most reliable method to obtain information on the ocean sediment grain size is the gathering of bottom samples followed by a laboratory grain size analysis. However, this process is time consuming and expensive. Remote sensing by acoustic means has long been recognized as a potential method to speed up the process, but there are many problems to overcome. Difficulties include the challenge to separate effects of grain size from those due to density gradients, morphological features, the presence of benthic flora and fauna, anthropogenic influences, etc., which can all influence the process of echo formation.

Acoustic seafloor mapping is an active field of research, which encompasses a variety of sonar systems and processing techniques. Of particular interest to the present study is recent work by Davis *et al.*,[1] who inferred the sediment mean grain size for a Clyde Sea survey area using empirical relationships between sediment properties and the acoustic reflection coefficient. A broadband sonar with a dominant frequency of 1 kHz was used in that work. A similar route is followed in the present paper, but because higher frequencies are used it is found necessary to allow for gradients within the sediment surface layer. Indeed, physical properties such as the porosity and density are often subject to a gradient along the top few centimeters of the sediment.[2–5] The presence of an acoustic impedance gradient considerably influences the normal-incidence reflection coefficient R. At low frequencies the gradient is of little consequence, whereas at

higher frequencies it has the effect of lowering R to below the Rayleigh reflection coefficient of an abrupt interface.[3] This frequency dependence becomes manifest if the product of wave number and transition layer thickness is of order unity or higher.[6] Ainslie[7] summarizes measurements and shows that a more precise condition for the onset of frequency-dependent effects is for the product of acoustic frequency and layer thickness to exceed about 200 m/s. For example, Lyons and Orsi[4] suggest that frequency-dependent measurements[8,9] of normal-incidence reflection loss from a sand sediment may be caused by a strong density gradient at the water-sediment interface. Knowledge of the thickness of the transition layer is required to account for the impedance gradient in modeling the reflection coefficient. In order to explain the measurements of Chotiros *et al.*,[9] the required layer thickness is approximately 20 mm.[7] In the present paper, an empirical relationship based on published data is derived for the thickness of this layer as a function of sediment mean grain size. When high-frequency echo sounder data are inverted for sediment properties, we hypothesize that allowance for the transition layer may yield a substantial improvement of the grain size mapping accuracy. The chief purpose of this paper is to investigate this hypothesis.

It is important that empirical relationships between sediment physical properties and acoustic quantities are used with care, because empirical laws are always based on a limited amount of available data. The nature of any scatter in these data is lost after regression. Data collected in a different part of the world, or in another season, for example, may not be adequately represented by empirical laws. When ground truth is available, the usefulness of empirical relationships can be judged by the extent to which the acoustical

prediction of the grain size matches the ground truth. The present paper evaluates echo sounder data at five frequencies in the range 12–200 kHz, collected in three different geological areas. Ground truth is available for each area in the form of a bottom grab grain size analysis. When acoustic grain size predictions obtained with an impedance step change model and an impedance gradient are compared, the overall improvement offered by gradient is sizable. The degree of the improvement is found to depend on the sounder frequency and geological area, but the observed trend does suggest a wide applicability of the proposed grain size mapping model.

This paper is organized as follows. Section II describes the data processing and the conversion of measured reflection coefficients to sediment mean grain size via empirical relationships. The description starts out with the assumption of an impedance step change, and thenceforth expands the theory to accommodate an impedance gradient. Section III provides an overview of the survey areas, acoustic data, and available ground truth. In Sec. IV the methods described in Sec. II are applied to the data described in Sec. III and the resulting acoustic grain size is presented in maps, and quantitatively compared with the ground truth. Section V summarizes the findings.

II. DESCRIPTION OF THE MAPPING TECHNIQUE

The proposed mapping technique relies on empirical relationships between the sediment grain size and its acoustic properties. Ground truth is available for all test sites described in Sec. III. A subset of the available bottom grabs is used for calibration purposes, and the remaining grabs are used for a comparison between the acoustic prediction of the mean grain size and the ground truth. A straightforward implementation of the mapping method uses the Rayleigh reflection coefficient in conjunction with empirical relationships derived by Bachman[10] relating the sediment grain size to density and sound speed. The Rayleigh reflection coefficient treats the water and the seafloor as two homogeneous media with an abrupt interface, and is independent of the frequency. A more sophisticated approach considers a continuous transition of the impedance, which introduces a frequency-dependent reflection coefficient. Bachman's correlations control the sediment properties beneath the interface. The two approaches are detailed in the following, and grain size maps produced with both methods are presented in Sec. IV. The treatment starts with a complete description of the working method for the discrete interface, and continues with the changes required for the frequency-dependent approach.

A. Reflection coefficient (measurement)

The following description of the working method applies to the data from all test sites. Echo signals are extracted from the recordings as a first step in the data processing. Their envelopes are squared and integrated to yield the echo energy. The integration offers the significant advantage that it does not require algorithms to separate the initial bottom return, associated with the specular reflection from the center of the sonar footprint, from the trailing scattering contributions. Moreover, echo-to-echo energy fluctuations tend to be smaller than echo-to-echo peak amplitude fluctuations. However, there is a built-in assumption that the scattering contributions to the energy obey the same dependence on sediment composition as the specular reflection from a smooth surface of the same impedance. A simple energy conservation argument suggests that this is the case, and a numerical justification is provided by Williams.[11]

The energy flux density E_{RX} of the received echoes depends on the energy E_{TX} of the transmitted sounder pulses according to

$$E_{RX} = \frac{\exp(-4\alpha H)}{4H^2} R^2 E_{TX}, \tag{1}$$

where H denotes the distance between the echo sounder and the seafloor and R the amplitude reflection coefficient of the smooth surface. To discriminate between the energy loss due to transmission into the sediment and attenuation associated with the traveled distance $2H$, the energies are compensated for the spherical spreading factor $1/4H^2$ and the absorption $\exp(-4\alpha H)$. H is determined from the echo return time and the sound speed, and the absorption coefficient α is calculated with the formulas of Francois and Garrison.[12] Temperature and salinity are necessary ingredients in their description of the absorption. *In situ* measurements of the temperature, and a default salinity of 35 psu were used. Remaining uncertainties in the temperature and salinity only have a small effect on the outcome of the calculations, since the water depth difference between the shallowest and deepest parts of each survey area is relatively small.

As the echo sounder source levels are not known and the recorded data uncalibrated, the calculated echo energies have only a relative significance. Absolute values of the reflection coefficient are derived with the help of a few selected bottom grabs that serve to calibrate the energies for an entire data set.

B. Reflection coefficient (model)

1. Impedance step change

To convert measured echo energies into sediment mean grain size,[13] Bachman's regression equations are adopted for the continental shelf and slope environments, denoted by T (terrace) in his paper. That is to say,[10]

$$c_s = 1952 - 86.3M_z + 4.14M_z^2 \tag{2}$$

and

$$\rho_s = 2380 - 172.5M_z + 6.89M_z^2 \tag{3}$$

for the sediment sound speed c_s in m s^{-1}, and the sediment mass density ρ_s in kg m^{-3}, as a function of the mean grain size M_z. The link between the mean grain size and the echo energy is established via the Rayleigh reflection coefficient

$$R = \frac{Z_s - Z_w}{Z_s + Z_w}, \tag{4}$$

where $Z = \rho c$ denotes the characteristic acoustic impedance. For the water side of the interface, the values $\rho_w = 1024$ kg m^{-3} and $c_w = 1529$ m/s are inserted.[14,15] These numbers correspond to Bachman's "standard seawater" with a reference temperature of 23 °C and a presumed salinity of 35 psu. The straightforward equations (1)–(4) suffice to convert echo energies into mean grain size by equating the acoustic reflection coefficient in Eq. (1) to the model reflection coefficient (4), provided that a calibration factor is available. Since the energy of the received echoes E_{RX} is subject to an arbitrary scaling factor, a calibration factor C is required to calculate the R according to

$$R = \frac{2CH}{\exp(-2\alpha H)} \sqrt{E_{RX}}. \tag{5}$$

The factor $C = E_{TX}^{-1/2}$ is a constant for each data set and takes care of dimensional issues. A subset of N bottom grabs is selected for calibration. All echoes within a given search radius from the grab positions are collected and their mean energy is computed. Subsequently, N factors C_n are computed by matching the acoustic reflection coefficient Eq. (5) to the ground truth reflection coefficient Eq. (4), which is calculated via Eqs. (2) and (3) with the grab sample mean grain size. The overall calibration factor C is taken as the root mean square value of the C_n.

A large search radius yields a large number of echoes for which echo-to-echo intensity fluctuations cancel out, whereas a small radius increases the probability that the bottom grab, collected in the center of the search disk, is indeed representative of the echoes. A compromise is found in a value of 200 m, which is used for all data sets described in Sec. III. Typical echo counts for this search disk radius vary from 4 for the Vestfjorden 38 kHz excursion, to 1000 for the Cleaver Bank 12, 38, and 200 kHz survey. The need to perform some averaging is indicated by the standard deviation of the echo energy, which is typically between 30% and 100% of the mean value. Following calibration, a reflection coefficient is obtained for all echoes via Eq. (5). Subsequently, Eqs. (2)–(4) are inverted to find the mean grain size for the individual echoes.

2. Impedance gradient

The above-noted recipe assumes a step change in impedance at the boundary between water and sediment, with uniform properties on either side of the boundary. Thus $R(M_z)$ is independent of frequency. In reality there is always a thin transition region of thickness typically 5–50 mm,[2–5,16–18] implying an average density gradient of order 10^4–10^5 kg m^{-4} (0.01–0.1 g/cm^3/mm). At frequencies of order 100 kHz or higher this gradient cannot be ignored.[3,4,7,19] Specifically, the reflection coefficient is expected to decrease with increasing frequency, owing to the decreasing impedance contrast on a wavelength scale.[3]
FIG. 1. Illustration of the impedance gradient, Eq. (6), that connects the water impedance Z_w to the bulk sediment impedance Z_s.

In order to calculate the reflection coefficient, we assume that uniform semi-infinite layers of impedance Z_w (water) and Z_s (sediment) are separated by a continuous transition layer of finite thickness h (Fig. 1). The transition layer is modeled as an impedance profile of the form

$$Z(z) = Z_w \frac{\text{sech}^2(az/h)}{[1 - \tanh(a)\tanh(az/h)]^2}, \tag{6}$$

$$a = \cosh^{-1} \sqrt{\frac{Z_s}{Z_w}}. \tag{7}$$

This functional form ensures a continuous impedance at both boundaries and a continuous gradient dZ/dz at the lower boundary. We further assume that the normal-incidence reflection coefficient is a function of the impedance profile alone and does not depend on density and sound speed separately. With this second assumption we can simplify the calculations by constructing an effective density profile

$$\rho_{eff}(z) = \frac{\rho(z)c(z)}{c_w} \tag{8}$$

such that, with $c_{eff}(z) = c_w$ everywhere, the impedance is identical to that of the equation for $Z(z)$. The advantage of this specific functional form is that it is amenable to analytical solution.[6,20] Substrate properties (ρ_s, c_s) are from Bachman.[10] The sediment absorption coefficient is unimportant for this calculation, and is chosen arbitrarily to be zero.

It is necessary to obtain an estimate of the transition layer thickness before the above-presented theory can be applied to our echo sounder data. For this purpose the quantity z_{90} is introduced, which denotes the depth in the transition layer at which 90% of the density difference between the water and the sediment is reached. Figure 2 shows z_{90} values, inferred from measured density or porosity profiles,[3–5,17,21,22] for different grain sizes ranging from 1-2 φ (medium sand) to 9-10 φ (medium clay). (φ is defined as $-\log_2$ of the grain diameter in millimeters) A least-squares regression is carried out on these data (shown as a solid line in the figure), resulting in the empirical fit

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

van Walree et al.: Mean grain size mapping   2557
FIG. 2. *In situ* measurements of the layer thickness parameter z_{90} vs grain size. The origin of these data is as follows. Cn: Carbó (Ref. 3) with C1 = sand, C2 = mud. Ln: Lyons and Orsi (Ref. 4) with L1=227-BS-BC, L2=260-BS-BC, L3=264-BS-BC, L4=268-BS-BC, L5=89-1-KW-DC, L6 =89-2-KW-DC, L7=124-1-KW-DC, L8=413-2-PC-DC, L9=413-3-PC-DC, L10=490-PC-DC, L11=250-BS-BC. Pn: Pouliquen and Lyons (Ref. 5) with P1=Venere Azzurra, P2=Portovenere, P3=Tellaro, P4=Punta della Mariella. T1: Tang *et al.* (Ref. 17) T2: Tang (Ref. 21) for the z_{90} value and Miller (Ref. 22) for the corresponding grain size value. The solid line is a linear regression to these measurements, with the outlier marked L11 excluded: $\log_{10}z_{90}=0.092\times M_z+0.81$. The dashed line results from the acoustical optimization described in Sec. IV C: $\log_{10}z_{90}=0.075\times M_z+1.05$.

$$\log_{10}z_{90} = (0.092 \pm 0.052) \times M_z$$
$$+ (0.81 \pm 0.31) \quad (z_{90} \text{ in mm}). \quad (9)$$

The layer thickness h follows from the functional form Eq. (6) as $h=z_{90}/0.652$. Two points from the Lyons and Orsi measurements[4] are omitted from the regression. The first one is labeled L11 in Fig. 2 and is left out because it is an outlier whose inclusion strongly influences the outcome of the regression. The second omission is a measurement with a very thin transition layer, resulting in a zero value of the transition layer thickness z_{90}. All other available *in situ* measurements in Fig. 2 are used for the regression.

The value of the data plotted in Fig. 2 could be increased by including error estimates for the z_{90} measurements. Such estimates could be made from the original measurements, but we are not able to estimate the uncertainty in layer thickness from the publications cited. In the case of one publication,[5] it is likely that the method used to analyze the profiles results in a lower limit for the z_{90} value.

Although the observed correlation in Fig. 2 is not overwhelming, its use at least allows the incorporation of first-order frequency-dependent effects. The validity of this assumption can be judged by the success or otherwise of the overall method in the inversion of the reflection coefficient —which in turn can be judged by comparison with grain size analysis of the grab samples.

With the above-presented assumptions and approximations, the reflection coefficient R is uniquely determined by the frequency f and mean grain size M_z. The reflection coefficient is calculated using the method of Ainslie.[20] Figure 3
FIG. 3. The reflection coefficient $R(M_z)$ for a set of frequencies between 3 and 300 kHz. In the low-frequency limit the appropriate curve, marked "Rayleigh," is equivalent to the frequency independent reflection coefficient of Sec. II B.

shows the reflection $20\log_{10}|R|$ vs M_z for a pertinent set of frequencies. For any known frequency a curve such as those in Fig. 3 can be used as a lookup table to invert R measurements (if calibrated) for the mean grain size. Results presented in Sec. IV are calculated in this manner.

III. OVERVIEW OF THE SURVEY AREAS

The echo sounder data under consideration were acquired during five separate sea trials covering three different areas. Sediment samples were collected in all areas for ground truth. One particular area, the Cleaver Bank, has been surveyed on three occasions, with a total of five different sounder frequencies. In the following the five acoustic data sets and the ground truthing procedures are briefly described.

A. Cleaver Bank

The Cleaver Bank, some 130 km northwest of the Netherlands (Fig. 4), was surveyed with a 150 kHz echo sounder in October 2000. It is a part of the North Sea that offers a sedimentary diversity from soft and flat ("sandy Mud") to hard and rough ("sandy Gravel"). The ship sailed ten longitudinal tracks on a square measuring 10×10 nautical miles. The water depth in the area varies between 30 and 60 m. Raw echo sounder signals were recorded for offline analysis. Soon after, in November 2000, the Cleaver Bank was revisited with a 66 kHz sounder. The same ten legs were sailed. Finally, in November 2004, the area was subject to a multibeam echo sounder expedition. In this last survey, a dense pattern of east-west tracks was sailed (shown in the inset of Fig. 4). A triple-frequency, single-beam echo sounder operating at 12, 38, and 200 kHz was also operated during this survey, which yielded valuable echo sounder data at three new frequencies.

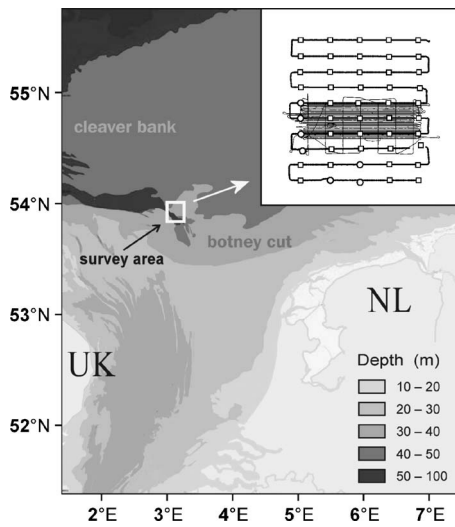
A comprehensive description of the Cleaver Bank geology and ground truth is found in Van Walree *et al.*[23] Only a summary of the ground truthing is given here. Fifty grab


FIG. 4. Overview map of the Cleaver Bank trials area between United Kingdom and the Netherlands. The inset shows a magnified portion with tracks sailed on several occasions as well as the October 2000 bottom grabs (white markers).

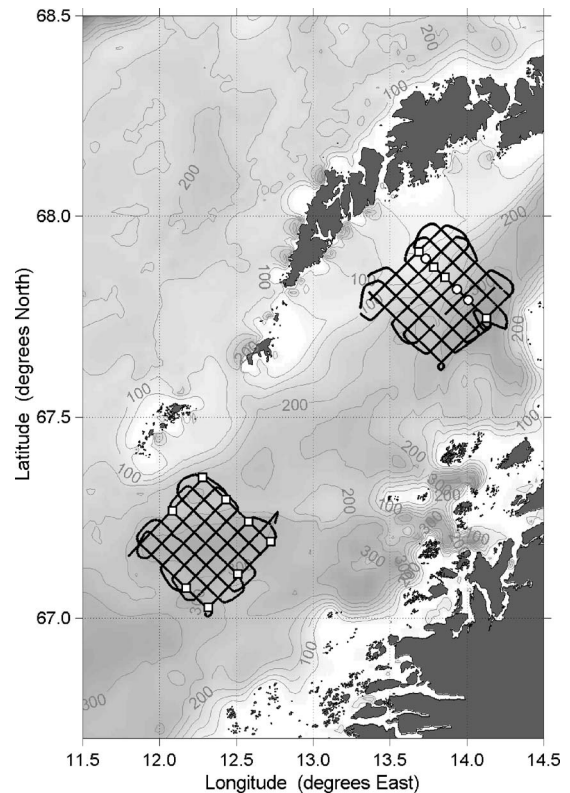
FIG. 5. Map of the Norwegian Vestfjorden trials area. The echo sounder survey consists of two isolated grids and features a number of bottom grabs indicated by white markers.

samples were collected with Van Veen and Hamon grabs during the original October 2000 sea trials. The laboratory analysis of the bottom grabs consisted of the following steps. The samples were dried and sieved with a 2 mm mesh to separate the gravel and shells from the smaller grains. Subsequently the biogenic and clastic components were separated to determine the shell and gravel fractions of each grab. The remaining sand and mud portions of the original grab were subjected to a granulometric analysis by optical microscopy, after which the respective sand and mud fractions could be determined. To remove a gravel bias from the mean grain size, the cumulative grain size distribution was rescaled to a value of 100% at a grain size diameter of 2 mm. Subsequently, the mean grain size M_z was calculated according to

$$M_z = \frac{3\varphi_{10} + 4\varphi_{50} + 3\varphi_{90}}{10}, \tag{10}$$

where the phi values are defined by minus $\log_2$ of the grain diameter in millimeters. The subscripts indicate percentiles such that, for example, 10% of the grab has a grain size smaller than φ_{10}. The definition, Eq. (10), departs from the more common definition, Eq. (11), because the laboratory analysis returned the φ_{10} and φ_{90} percentiles rather than the φ_{16} and φ_{84} percentiles.

The 4-year time span between the grab sample analysis in 2000 and the survey in 2004 introduces some uncertainty in the validity of the ground truth. Previous work[23] revealed that the ground truth obtained in 2000 showed a great overall correspondence with a geological map from 1987. Therefore one may presume that overall seabed changes over a time span of four years are small in this area. Nonetheless, caution is required with local assessments of the sediment type, for instance because of the presence of wandering sand ribbons that overlie the gravel bed.[23]


B. Vestfjorden

The Norwegian Vestfjorden area was surveyed with a 38 kHz echo sounder in May/June 2001. Two sites along the axis of the fjord were selected for the acoustic measurements, each with dimensions of roughly 15×15 nautical miles. The water depth ranges from 100 to 350 m. At both sites the ship track forms a grid of seven by seven legs in the shape of a carpet beater (Fig. 5). Fifteen bottom grabs were collected, spread over the two sites, whose laboratory analysis is detailed in Ref. 24. Incidental gravel was left out of the cumulative distribution. The mean grain size was calculated according to Folk,[13]

$$M_z = \frac{\varphi_{16} + \varphi_{50} + \varphi_{84}}{3}. \tag{11}$$

C. Stavanger

The final test site is located in the coastal area of Norway, in the vicinity of the city of Stavanger (Fig. 6). Measuring approximately 20×20 nautical miles, a grid was surveyed with a 38 kHz sounder in October 2002. The bathymetry is relatively flat with a depth between 250 and 285 m (Fig. 10), except for a few sea-mounts in the eastern part of the area, near the island of Utsira, which rise some 50 to 100 m above the nominal seabed. Thirty-five bottom grabs were collected along one horizontal and one vertical leg of the survey. The laboratory analysis is described by Ref. 25.
FIG. 6. Map of the Norwegian trials area near Stavanger. The echo sounder survey consists of a sparse grid, with a more dense series of legs surrounding the ground truth regions indicated by the white markers.

Pebbles were removed from the grab before the grain size distribution was determined. The mean grain size was subsequently calculated via Eq. (11).

IV. RESULTS AND DISCUSSION

A. Grain size maps

The calculations presented in Sec. II lead to a recipe for converting echo energies into mean grain sizes. Some averaging is required in order to map the mean grain size without the distraction of echo-to-echo fluctuations. The most convenient averaging method is found to depend on the data set under examination. For all cases of sailed grids with a large separation between the legs, a moving median filter of length 25 is applied to the echo energies before the mean grain size is inferred. A median filter removes outliers, while it preserves step changes of the input parameter. This procedure is applied to all but the Cleaver Bank 2004 data with the 12, 38, and 200 kHz sounders. For the latter survey the legs are closely spaced, and the number of echoes (7×10^5 at each frequency) is large enough to support a map with full seafloor coverage. To this end the relevant section of the seafloor is divided into 490×45 bins measuring 33×110 m. For each bin the mean echo energy is calculated, and this value is turned into a mean grain size value for that particular bin by the methods of Sec. II.

In the following the mean grain size mapping is qualitatively illustrated with three example maps. Subsequently the fidelity of the mapping algorithms is quantified for the entire collection of echo sounder data by means of scatter plots. Figure 7 presents the results for the 150 kHz Cleaver Bank sea trials conducted in October 2000. The first graph gives the bathymetry and the other graphs show the acoustic mean grain size obtained on the assumption of an impedance step
FIG. 7. Top graph: bathymetry of the Cleaver Bank survey area. Middle graph: 150 kHz mean grain size map obtained with the impedance step change (S). Bottom graph: alternative grain size map obtained with the impedance gradient (G).

change (S) or gradient (G). The ground truth mean grain size is also included. A round marker indicates that a grab is used for the calibration procedure. Thus, on average the acoustic grain size is forced to match the ground truth for the round markers. The merits of the mapping technique should therefore be judged from the regions adjacent to the remaining
FIG. 8. Amplitude reflection coefficient for the Cleaver Bank 150 kHz data. The maps for the impedance step change (*S*) and impedance gradient (*G*) differ by a scaling factor only.

square markers, which are not used for calibration. Application of the abrupt impedance transition leads to a considerable mismatch for the great majority of square markers, which represent the sandy and gravelly parts of the survey area. The dynamic range of the acoustic mean grain size is simply too large. Matters are noticeably improved by replacing the discrete impedance mismatch with a gradient. The dynamic range of the acoustic mean grain size is decreased and the resulting map resembles the ground truth with a remarkable overall fidelity.

For the sake of completeness an intermediate step in the calculation, the amplitude reflection coefficient, is presented

for the Cleaver Bank 150 kHz data. It is plotted in Fig. 8 for both impedance transition types. In case of the step change the reflection coefficient is unrealistically high and the physically impossible $R > 1$ occurs. In contrast, the impedance gradient lowers the reflection coefficient by an order of magnitude, consistent with the measurements of Kimura and Tsurumi[26] or the predictions of, e.g., Carbó[3] and Lyons and Orsi.[4] The *S* and *G* reflection coefficients in Fig. 8 are identical apart from a scaling factor. Indeed, the mean grain size calibration procedure described in Sec. II just leads to a different echo energy scaling for the *S* and *G* cases. This applies not only to the Cleaver Bank 150 kHz data but to all sounder frequencies and survey areas. Maps of the reflection coefficient are omitted for the remaining examples.

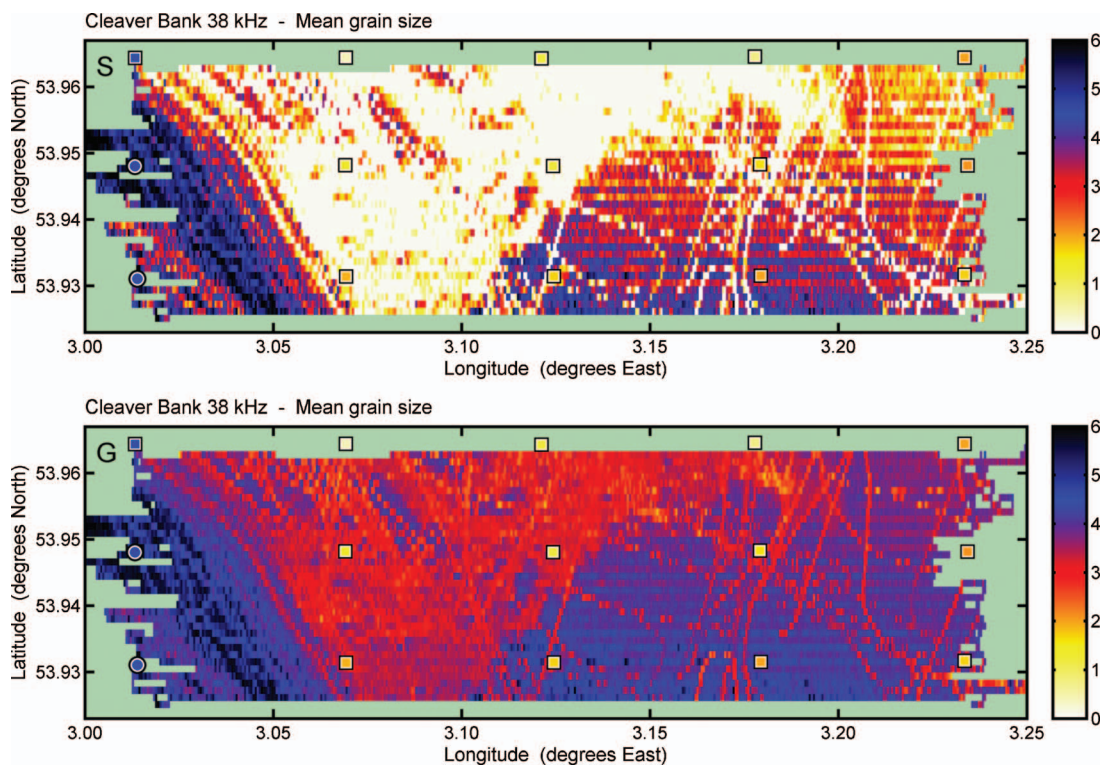
The second example is the Cleaver Bank 38 kHz data set, illustrated with mean grain size maps in Fig. 9. The change from the *S* to the *G* impedance profile lowers the contrast of the acoustic mean grain size, similar to the 150 kHz case. However, where the modification was about right at 150 kHz, the gradient overcompensates at 38 kHz. On the chosen color scale the result is close to a red-blue binary grain size. Again the mud trench at the left side is tuned to the proper grain size value by the calibration procedure. The sandy part of the survey area (bottom right) roughly achieves the same blue grain size as the mud calibration area. In contrast to the blue, there is a red colored area representing the gravelly sand and sandy gravel described in Ref. 23. Whereas the acoustic grain size exceeds the ground truth values for the *S* transition, the situation is reversed when the gradient is applied.


FIG. 9. Cleaver Bank 38 kHz grain size maps obtained with the *S* (top) and *G* (bottom) impedance transitions. The horizontal zebra stripe pattern noticeable in the right half is an artifact apparently related to the ship sailing direction. Calibration grabs are indicated by round markers and the remaining grabs by square markers.

There are two additional features in Fig. 9 that leap to the eye. First, the right half of each map is characterized by a pattern of horizontal stripes. This phenomenon appears to be related to the ship sailing direction, alternately eastward and westward, although the mechanism remains unclear. The dependence of the echo energy on the ship course is also present at 200 kHz, and to a lesser degree at 12 kHz. A perhaps more striking feature of Fig. 9 is the occurrence of a large number of thin-linear features, with a marked deviation of ~2 phi units in the inferred mean grain size, corresponding to higher echo energies. The features run in arbitrary directions and are independent of the ship sailing direction. They are also clearly visible in the 200 kHz data, whereas they are just barely noticeable in the 12 kHz data. Section IV D discusses the possible origin of these thin-linear features and their relevance.

As a third and final example the mean grain size is mapped for the Stavanger 38 kHz data in Fig. 10. This trials area has an overall finer-grained seafloor than the Cleaver Bank and features a five- to tenfold increase of the water depth. The bathymetry in the top graph is relatively flat, and, unlike the Cleaver Bank area, there is no strong correlation between the depth and the sediment type. An exception is found in the neighborhood of the bathymetrical features (sea mounts) toward the Norwegian coast, at the east side of the grid. This is where the bottom grabs with the largest grains were collected. The calibration grabs were chosen on a section of the horizontal leg where both the grab sample constitution and the echo energies vary little. Two grabs in this region contained some gravel and were left out of the calibration set.

The mean grain size map obtained by application of the impedance step change is shown in the middle panel. Again, the contrast of the acoustic grain size again is too high, similar to the Cleaver Bank results in Figs. 7 and 9. Use of the impedance gradient yields a noticeably better agreement between the acoustic prediction and the ground truth.

B. Scatter plots

So far the merits of the method proposed in Sec. II have been judged by visual comparison of acoustic grain size maps with the ground truth. For a more quantitative comparison all available data are combined into scatter plots (Fig. 11), including the Vestfjorden area and the sounder frequencies not covered by Figs. 7, 9, and 10. Figure 11 shows the acoustic versus the ground truth mean grain size, calculated for the S and G impedance transition types. Survey areas and echo sounder frequencies are differentiated by markers with various shapes and colors. The acoustic grain size was calculated from the arithmetic mean energy of all echoes within a search radius of 200 m from each grab. Notice that the area of the markers in Fig. 11 is proportional to the number of echoes found. Tiny markers carry less significance than big ones.

It is recalled that there are calibration grabs that are forced to coincide, on average, with the ground truth. These calibration grabs are among the softer sediments for each data set. The performance of the algorithms must therefore
FIG. 10. Bathymetry of the Stavanger 38 kHz survey (top graph). Mean grain size maps obtained with the impedance step change (middle graph) and impedance gradient (bottom graph) are shown. Again, calibration grabs are indicated by round markers and the remaining grabs by square markers.

follow from inspection of the larger grains toward the left side of Fig. 11. On the whole the impedance step change yields a considerable amount of scatter and an overall depar-
FIG. 11. Scatter plots that combine the results for all survey areas and frequencies. Results are shown for the S and two G impedances. The middle panel corresponds to a gradient given by the fit to the *in situ* layer thickness measurements (solid line in Fig. 2), whereas the bottom panel shows the minimum rms case (dashed line in Fig. 2; explained in Sec. IV C). Marker areas are proportional to the number of echoes used for the acoustic grain size calculation. Notice that the acoustic grain size has been clipped to a value of −10 for the topmost graph.

TABLE I. Correlation coefficients and weighted rms values for all survey areas and sounder frequencies; grabs denotes the number of contributing grabs.

| Survey | Grabs | Impedance step change | | Impedance gradient | |
		Correlation coefficient	rms	Correlation coefficient	rms
Cleaver Bank 12 kHz	16	0.92	3.52	0.92	1.63
Cleaver Bank 38 kHz	16	0.71	2.65	0.73	1.68
Cleaver Bank 66 kHz	48	0.74	1.13	0.77	2.32
Cleaver Bank 150 kHz	48	0.71	15.7	0.75	0.67
Cleaver Bank 200 kHz	16	0.80	4.29	0.82	0.87
Vestfjorden 38 kHz	14	0.79	1.51	0.85	0.68
Stavanger 38 kHz	34	0.69	0.81	0.71	0.66
All together	192	0.59	7.91	0.77	1.36

ture from the ideal solid line $M_{z,\text{ac}}=M_{z,\text{bg}}$, where $M_{z,\text{ac}}$ denotes the acoustic mean grain size and $M_{z,\text{bg}}$ the ground truth (bottom grab) mean grain size. The error is largest for the Cleaver Bank 150 kHz data, followed by the 200 kHz frequency. At 66 kHz the $M_{z,\text{ac}}$ seem about right, albeit with some scatter around the mean. For the finer-grained Norwegian test sites ($f=38$ kHz) the overall mismatch is smaller, but still the deviations range up to 4 phi units.

A very different picture is obtained for the impedance gradient in the middle graph. At each frequency the amount of scatter is decreased, and on the whole the acoustic mean grain size is closer to the ground truth. The scatter reduction is most obvious at 150 kHz, where the impedance gradient brings the acoustic mean grain size remarkably close to ground truth. Substantial progress is also made at 200 kHz. The Cleaver Bank 12 kHz data remain below the ideal line, whereas the Cleaver Bank 38 and 66 kHz data end up above this line. Within each data set the impedance gradient reduces the scatter along the ordinate, but the slope is subject to a residual error. Figure 11 also shows that the 38 kHz data, originating from three different areas, form a consistent subset of the scatter plot without apparent discontinuities between test sites.

Two quantities are calculated to quantify the influence of the impedance transition type on the conversion of echo energy to grain size: the correlation coefficient between $M_{z,\text{ac}}$ and $M_{z,\text{bg}}$, and the rms value of their difference, weighted by the number of echoes K_n contributing to the nth grab acoustic grain size

$$\text{rms} = \left(\frac{\sum\limits_{n=1}^{N} K_n (M_{z,\text{ac}}(n) - M_{z,\text{bg}}(n))^2}{\sum\limits_{n=1}^{N} K_n} \right)^{1/2}. \tag{12}$$

The weighting diminishes the contribution of grabs with poor statistics, such as the 150 kHz outlier with $M_{z,\text{ac}}>8$, for which there are only two echoes within the search radius. Nonetheless, the overall influence of the weighting on the rms values is small.

Table I shows that the impedance gradient improves the

correlation coefficient for all data sets. An improvement is also observed when all grabs and sounder frequencies are considered together. The so-called P values associated with the correlation coefficients are not tabulated. P gives the probability that the calculated correlation coefficient arises by chance. Since all P are vanishingly small ($\ll 10^{-2}$) the calculated correlation coefficients are significant.

Despite the strong correlations, the correlation coefficient does not properly reflect the merits of the impedance gradient. The correlation coefficient tells us to what extent there exists a linear relationship between the acoustic and the grab sample mean grain size. It neglects the strength of the relationship, represented by the slope of $M_{z,ac}$ vs $M_{z,bg}$ in the scatter plots. For this reason the correlation coefficient achieves high values already for the discrete impedance interface, despite the considerable mismatch in absolute terms. $M_{z,ac}$ and $M_{z,bg}$ are well correlated for either impedance transition type. The rms values in Table I provide a more useful criterion to judge the benefits of the methods. These values clearly demonstrate the overall superiority of the impedance gradient. For all frequencies and areas the gradient method delivers a substantial improvement, except for the Cleaver Bank 66 kHz data. Although the impedance gradient does reduce the scatter within the latter data set, the $M_{z,ac}$ are actually pushed away from $M_{z,bg}$. In fact, with both the 38 and 66 kHz sounders it is difficult to discriminate between sandy and muddy sediments in the Cleaver Bank area.

C. Dependence of the transition layer thickness on grain size

Sections IV A and IV B showed grain size maps and scatter plots based on a regression of the form $\log_{10} z_{90} = aM_z + b$ [see Eq. (9) and Fig. 2]. There is, however, a sizable scatter in the underlying *in situ* measurements. In order to get an idea of the sensitivity of the mapping fidelity to the values of the slope a and intercept b, the mapping is repeated for several combinations of a and b values. For each combination the steps described in Sec. II are repeated, including calibration, and the total weighted rms is computed for all available data (cf. the bottom row in Table I). Figure 12 shows the outcome of these calculations. The smallest encountered rms values are of order unity, with some ambiguity in the slope and a considerable ambiguity in the intercept. The latter ambiguity is due to the calibration procedure, which, regardless of the nominal layer thickness, forces the acoustic grain size to coincide with that of the calibration grabs. (The corresponding amplitude reflection coefficient drops rapidly with an increasing intercept value and achieves totally unrealistic values of order 10^{-3} at $b = 2.5$.) Figure 12 has a minimum rms of 0.90 at $a = 0.075$ and $b = 1.05$. A scatter plot is created for these values and shown in the bottom graph of Fig. 11. The low rms is evidenced by a further reduction of the scatter, compared with the middle graph that was obtained for the fit to the *in situ* transition layer thickness data. Most markers are now within 1 phi unit of the ideal solid line. Little improvement is nonetheless observed at 66 kHz, which data carry little weight and have a small vote in the total weighted rms.
FIG. 12. Total weighted rms difference [Eq. (12)] between the ground truth and the acoustic prediction of the mean grain size. The rms values are calculated for a grid of combinations of the slope a and intercept b of the assumed relationship $\log_{10} z_{90} = aM_z + b$ (z_{90} in millimeters).

Perhaps the most important conclusion from Fig. 12 is that a constant transition layer thickness does not work. A zero (or negative) slope leads to acoustic grain size predictions that disagree strongly with the ground truth. The functional form $\log_{10} z_{90} = aM_z + b$ was just chosen as the simplest assumption of some existing relationship between z_{90} and M_z, and there may be better guesses. Nonetheless, in order to account for the measured echo energies, regardless of the precise functional form it appears that the transition layer thickness must increase with a decreasing grain size.

D. Plough marks

It is hypothesized that the thin-linear features observed in the grain size maps of Fig. 9 correspond to furrows caused by fishing gear dragged over the seafloor. Beam trawlers were witnessed during the November 2004 acoustic survey, and are known to operate regularly in this part of the North Sea. The hypothesis is corroborated by a morphological map (not shown) produced by means of the multibeam echo sounder operated during the same survey. This map shows a crisscross of "plough marks" normally associated with trawling, some of which precisely match the coordinates of the thin-linear features in Fig. 9. A closer examination of the Cleaver Bank 38 kHz data reveals that the echo energy in some furrows rises to as much as 10 dB above that of the surroundings. It is also observed that the excess energy is carried by the initial bottom return and that the energy in the echo tail is not noticeably altered. The energy rise is also pronounced at 200 kHz, whereas it is only weakly present in the 12 kHz data.

Research on the physical effect of beam trawls on the seafloor has shown that the penetration depth in sandy sediments is typically of order 5 cm.[27,28] There is a large spread in reported lifetimes of the plough marks, which may last from less than one day to over one year,[29,30] depending on the environment, type of fishing gear, and the method of monitoring. A record of beam trawl disturbance in another part of the North Sea[31] shows that the surface roughness in a

fishing sector characterized by sand waves and some ripples was reduced, but that the particle size distribution was not altered. Similar conclusions were obtained for an experiment in the Adriatic Sea.[32] A recent cruise in the Bering Sea[33] revealed mean grain size changes of only ~0.02 phi units before and after experimental trawling on a sandy seafloor. The dramatic increase in the echo energy during the Cleaver Bank 2004 survey suggests that the trawl force not only flattens the surface, but that it may also compress the top layer. Alternatively, upwhirling surface particles may be carried away by currents to deposit elsewhere, promoting the more tightly packed subsurface layer to the new top layer. Destruction of the impedance gradient could thus account for the increased acoustic mismatch. Although the explanation of the plough mark acoustics is not central to the present paper, their pronounced acoustic fingerprint at least illustrates the importance of the condition of the sediment top few centimeters on the normal-incidence reflection coefficient.

V. CONCLUSIONS

In previous work, empirical relationships were used to transform measured reflection coefficients of a low-frequency sonar into sediment mean grain size.[1] A central assumption was the applicability of the Rayleigh reflection coefficient, describing a discrete interface between two homogeneous media. In the present paper it is shown that this assumption is no longer valid at higher frequencies of, say, 10 kHz and beyond. A considerable improvement in the grain size conversion is obtained by allowing for the presence of a thin transition layer, within which the acoustic impedance gradually changes from the water value to the sediment bulk value. This impedance gradient is due to a density gradient of order $5 \times 10^4 \, \text{kg m}^{-4}$, which stretches over a layer of only a few centimeters. A grain size mapping algorithm that takes this impedance gradient into account is applied to echo sounder data collected at three sites, and for a total of five sounder frequencies in the 12–200 kHz range. An overall improvement of several phi units is obtained over an algorithm employing the Rayleigh model. Out of seven data sets, the only one not to show an improvement is the Cleaver Bank 66 kHz survey. Residual errors of ~2 phi units between the acoustic and the ground truth grain size, even with the gradient correction, are nonetheless still sizable, which may point to incompleteness of the physical model or to survey areas not adequately described by the employed empirical relationships. It is finally shown that the acoustic grain size prediction is irreconcilable with the ground truth if a constant transition layer thickness is adopted. Agreement requires the layer thickness to increase with a decreasing grain diameter.

A stochastic representation of environmental uncertainty and its coupling to acoustic wave propagation in ocean waveguides

Steven Finette
Acoustics Division, Naval Research Laboratory, Washington, D.C. 20375

It is argued that a quantitative measure of incomplete environmental knowledge or information (i.e., environmental uncertainty) should be included in any simulation-based predictions linked to acoustic wave propagation. A method is then proposed to incorporate environmental uncertainty directly into the computation of acoustic wave propagation in ocean waveguides. In this regard, polynomial chaos expansions are chosen to represent uncertainty in both the environment and acoustic field. The sound-speed distribution and acoustic field are therefore generalized to stochastic processes, where uncertainty in the field is interpreted in terms of its statistical moments. Starting from the narrow angle parabolic approximation, a set of coupled differential equations is derived in which the coupling term links incomplete environmental information to the corresponding uncertainty in the acoustic field. Propagation of both the field and its uncertainty in an isospeed waveguide is considered as an example, where the sound speed is described by a random variable. The first two moments of the field are computed explicitly and compared to those obtained from independent Monte Carlo solution of the conventional (deterministic) parabolic equation that describes the acoustic wave properties. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Numerical simulation of acoustic wave propagation in ocean waveguides has served as an indispensable tool for the exploration, interpretation, and prediction of acoustic field properties in complex ocean environments. An application of simulation techniques to predict field properties or the subsequent effect of these properties on sonar system performance represents a particular example of simulation-based prediction. The validity of simulation-based prediction depends, to a large extent, on the assumption that either all environmental information necessary for the solution of the problem is known or, if this information is only partially available, that the resulting uncertainty in one's knowledge of the environment can be objectively quantified and included in the result.[1] If neither of these conditions is satisfied, the prediction is flawed and conclusions or decisions based on the results are of questionable validity. Since environmental knowledge is always incomplete for acoustic propagation under realistic ocean waveguide conditions, it has recently been argued that a prediction of acoustic field properties would benefit from the inclusion of a quantitative measure of environmental uncertainty.[2,3] The idea of embedding uncertainty directly into the simulation framework and elevating its status to a subject worth studying on its own merits represents a paradigm shift in a wide range of disciplines.[4–6] The purpose of this paper is to describe a rather general approach for the direct inclusion of environmental uncertainty into the dynamical formulation of acoustic propagation, with the goal of improving simulation-based prediction of the acoustic field. An example of the method is given for a simple stochastic waveguide environment in or-

der to illustrate the approach in a setting where numerical implementation issues are not a significant factor. Before discussing a method for the objective assessment of environmental uncertainty and its subsequent effect on the acoustic field, the term "uncertainty" and the phrase "environmental knowledge" need some elaboration.

A general, rigorous definition of uncertainty is rather difficult to present even though one has an intuitive sense of the term's meaning in the above comments. An informal and somewhat more restrictive definition is relevant for this discussion: uncertainty, in the context of simulation-based prediction, represents the lack of complete knowledge (information) concerning a property or set of properties that must be specified in order to model and simulate a physical system. The system addressed here is comprised of an acoustic field and the waveguide environment that supports the propagating field. In a simulation of acoustic wave propagation, the representation of, say, both the sound-speed field and bathymetry by correlation functions or power spectra is an acknowledgment that complete information about the system response is not known. The spectra or correlation functions then represent the current state of available knowledge about the environment and can be used to place bounds on the set of possible system responses that can be computed. One can interpret the spectrum as a reflection of uncertainty in the environmental description of the system, with the implication that a range of possible system responses should be simulated in order to fully characterize the propagation consistent with the available information. While the range of possible simulated responses due to incomplete environmental information might be considered as a measure of natural

variability, the source of this variability is an information deficit rather than some physical mechanism governing system behavior. Though there are features in common, one should not consider natural variability in measured data as an exact counterpart to uncertainty in simulation-based prediction. A consequence of this uncertainty is to effectively introduce additional degrees of freedom into the simulation, and their effect on propagation should be taken into account in simulation-based prediction schemes. In the following sections a general method is considered for explicitly including these additional degrees of freedom within the dynamics. The emphasis is on the influence of environmental uncertainty in the specification of the sound-speed distribution and its subsequent effect on acoustic field propagation. The emphasis on sound-speed uncertainty covers a broad range of practical scenarios commonly encountered in ocean acoustics simulation. A sound-speed distribution can be represented by the set of numerical values of the field on a discrete computational grid over a time interval $[t_{\text{initial}}, t_{\text{final}}]$, during which the system dynamics is evolved. A simulated acoustic field propagating through this distribution might accumulate significant natural variability in amplitude and phase. Suppose, however, that the sound-speed information is only partially specified at a subset of grid points and then interpolated to other points on the grid or, instead, it is specified through second-order statistical information (correlation function or power spectrum) where higher order information is neglected (but not zero). In these cases environmental uncertainty occurs in the specification of the sound-speed distribution and it should be reflected in a range of possible simulated acoustic field responses, in addition to any natural variability that can occur as the field propagates through the waveguide.

It is important to note that uncertainty, as considered above, is quite distinct from numerical errors that inevitably arise when a mathematical formulation of a propagation model is discretized, implemented on a computer, and solved with finite precision arithmetic. Errors arising from this processing have been studied in numerical analysis for over 50 years and constitute a rather mature subject area. Here it is emphasized that, in addition to numerical errors, incomplete knowledge of the waveguide's environment may significantly limit the ability to make valid predictions from the results of numerical simulation unless the effects of environmental uncertainty are included in the simulation process.

A probabilistic framework is described in the following sections to quantify incomplete environmental knowledge and the resulting uncertainty in the acoustic field. Probability distributions are interpreted here as natural representations of uncertainty. In this sense the system—comprised of both the environment and the dynamics—loses its deterministic structure and is described probabilistically. Statistical moments are considered appropriate quantitative metrics for describing uncertainty in terms of the spread of a distribution. While moments are not a unique indicator of uncertainty, they are chosen here because the first few moments of the acoustic field have simple physical interpretations. It is therefore natural to extend the notion of environmental parameters and fields, treated deterministically in a single numerical simula-

tion, and replace them with random variables and stochastic processes that naturally include uncertainty. Note that this generalization does not necessarily imply that the sound speed and acoustic field are true stochastic processes but rather, for the purpose of including uncertainty in the dynamics, it is convenient to treat them mathematically as if they were stochastic processes. In this manner, a probability-weighted representation of possible sound-speed distributions is considered as well as the subsequent effect of these distributions on the acoustic field (also probability weighted). While the distinction between uncertainty and variability becomes somewhat blurred in this view, it does not affect the quantitative analysis presented here.

The approach represents these random variables and processes explicitly in terms of stochastic basis expansions. Doing so implies that the deterministic wave equation is replaced by a stochastic wave equation. The solution of this equation yields the stochastic process representing the acoustic field; statistical moments of the field can be computed directly from the solution. Additional complexity is involved in solving a stochastic differential equation, but it is mitigated by several factors that may yield potential advantages over alternative approaches for obtaining moments of the acoustic field, such as Monte Carlo sampling[7] and moment equation methods.[8,9] Below, a brief comparison is made between these well-known methods and the formulation discussed in the following sections.

Monte Carlo techniques are commonly applied to a deterministic wave equation whose parameters and/or fields are specified by repeated sampling from probability distributions on these quantities in order to obtain members of an environmental ensemble. Using members of the ensemble, multiple deterministic realizations of the acoustic field are computed from the equation and then postprocessed to obtain the moments. The basic methodology is relatively straightforward and can be applied to any wave equation describing the acoustic field. One problem with this approach is that large numbers of realizations are required and the rate of convergence is slow because it follows the law of large numbers with standard deviation proportional to $1/\sqrt{R}$, where R is the number of realizations.[7,10] In addition, the convergence is not monotone. For relatively simple wave equations and environments, the CPU time necessary to generate the set of realizations is manageable. However, for complex problems such as the case where the sound-speed distribution is determined directly from fluid dynamics computations, the CPU time can exceed the capabilities of modern supercomputers.[10] The individual realizations give little direct insight into the field statistics and must be further processed to obtain the moments. The stochastic expansion approach using polynomial chaos (PC) basis functionals, summarized in Sec. II, effectively includes all realizations of the stochastic pressure field without resorting to explicit sampling from probability distributions and the subsequent computation of multiple solutions of the wave equation. This method often yields comparable results that are several orders of magnitude faster than those obtained from Monte Carlo sampling.[11,12] Individual realizations can be obtained directly from the random process computed using the PC

expansion approach. In contrast to a realization-based sampling method, the compact formulation involving PC expansions can be very useful for the analysis of multiple subsystems that are coupled together, with uncertainty in one system transferred to another. An example is a three-component model. In the first subsystem, environmental uncertainty in the temperature and salinity distributions is introduced into the fluid dynamic equations of motion and a phenomenological equation relating sound speed to temperature and salinity. Uncertainty linked to the sound-speed distribution is then transferred to the second subsystem consisting of acoustic propagation through the uncertain environment. The third subsystem is comprised of signal processing applied to the resulting stochastic acoustic field received on a sensor array.

Introduced into ocean acoustics by Dozier and Tappert,[13,14] moment equation formulations of wave propagation develop separate evolution equations governing each moment of the acoustic field rather than the field itself. A number of different equations have been proposed for propagating full field or modal moments, with each approach dependent on several mathematical and physical assumptions having varying degrees of generality and rigor. These efforts have included, for example, both deep[13,15] and shallow[16,17,20] water environments with formulations in terms of either full field[18,19] or modal[20–22] moments. The complexity of these equations typically increases with increasing moment order. In contrast, polynomial chaos expansions compute the moments from the random process itself; the process is obtained explicitly as the solution to a set of coupled differential equations that include both the propagation dynamics and coupling between environmental and acoustic field uncertainties. The moments are not directly propagated in the PC formulation, but are obtained indirectly through this solution, and separate equations for the individual moments are not necessary. From the point of view of simulation-based prediction, the moments derived from the polynomial chaos method are interpreted as measures of the effect of environmental uncertainty on acoustic field structure, rather than as measures of natural variability associated with the field. The compact form of the solution allows for some flexibility in both additional manipulation and further analysis; as mentioned above, such a manageable representation is quite useful when analyzing a system in which uncertainty is transferred between subsystems.

Polynomial chaos expansions are obtained from a theorem in the theory of random processes under the major assumption that the process in question is second order, i.e., has finite second moment. This assumption represents a very reasonable property satisfied by a large class of physical systems. Truncation of the resulting infinite series expansions is necessary for numerical computation, and ensures a form of closure.[23] Information on the higher order moments is retained in the truncated expansions. While these series expansions provide the best approximation of the process (in the sense of minimizing the mean-squared error) given the particular level of approximation, the implications of truncation on the numerical accuracy and convergence rate for the moments depends on the type of problem, the random process to

be approximated, and the choice of basis functional; these issues are a subject of current research.[23–25] The Markov approximation is not explicitly assumed in the polynomial chaos formulation, though the correlation structure of the medium plays an important role in determining the rate of convergence.[23] The polynomial chaos method can be considered as a mathematical formalism for representing uncertainty though it does not introduce new physics into the problem. Instead, all the physics and the coupling between environmental uncertainty and the resulting acoustic field uncertainty are present in a generalized "wave equation" for the expansion coefficients that results from applying this formalism.

Section II discusses the general theoretical framework for polynomial chaos expansions. These expansions are applied in Sec. III to develop equations that describe propagation of the acoustic field in the presence of environmental uncertainty, when propagation is approximated by the narrow-angle parabolic equation. The equations are then solved for the case of an isospeed stochastic waveguide, and the results are compared to independent Monte Carlo estimates of the first and second field moments obtained by computing multiple field realizations from the deterministic parabolic equation. Section IV presents a summary and conclusions.

II. REPRESENTATION OF UNCERTAINTY IN TERMS OF STOCHASTIC BASIS EXPANSIONS

This section describes a mathematical framework for representing incomplete environmental knowledge and linking it to uncertainty in the acoustic field. While the discussion is not rigorous, enough details are presented so that the generality of the method is clear and references to more rigorous presentations are included. Before considering stochastic expansions, it is helpful to note that the representation of random processes by stochastic basis expansions may be considered as a generalization of the way one can represent deterministic functions by polynomial expansions. The Stone-Weierstrass approximation theorem[26] allows for the expansion a square-integrable function $f(x)$ in terms of a complete set of basis functions (in this case polynomials in the variable x). A monomial expansion is simply given by $f(x) = \sum_{m=0}^{\infty} a_m x^m$. The monomials form a complete set of functions in a Hilbert space. While these polynomials are not orthonormal, they are linearly independent. The basis functions can be made orthonormal by application of the Gram-Schmidt procedure. For polynomials of more than one variable, a deterministic multinomial expansion can be written as a multiple sum with the general form $f(x_1, x_2, \cdots, x_n) = \sum_{m_1 \ldots m_n}^{\infty} a_{m_1 m_2 \ldots m_n} x_1^{m_1} x_2^{m_2} \cdots x_n^{m_n}$.

As mentioned in the Introduction, uncertainty is described here within the framework of probability theory. The approach assumes that uncertainty in the acoustic field is attributed to incomplete environmental knowledge of the sound-speed distribution, and can be quantified using the statistical moments of the field. Therefore, environmental parameters and fields are not described by numbers or deterministic functions but rather in terms of random variables or

stochastic processes. This description implies that the pressure field is also specified by a stochastic process whose moments carry information about the effect of environmental uncertainty. A natural probabilistic method for describing uncertainty has evolved from research in stochastic finite elements[27] that builds on earlier mathematical work by Wiener, who dealt with the problem of treating Brownian motion as a stochastic process.[28] His work introduced a particular type of stochastic basis expansion, termed polynomial chaos expansions, to describe random processes. It is worth mentioning that the word "chaos" was invoked by Wiener before its more familiar use in nonlinear dynamics; the two subjects, however, are independent of each other. The research in stochastic finite elements significantly extended Wiener's original work by systematically applying polynomial chaos expansions in a dynamical framework,[27] merging these expansions with stochastic differential equations[10–12] and interpreting them in terms of uncertainty in the system response.[29–31]

Assume that the environmental parameters or fields are describable by second-order random variables or stochastic processes, i.e., they have finite variance. For generality, it is convenient to define a probability space[27,32] as a triple (Π, Θ, Ξ), where Π denotes a sample space (the set of all elementary distinguishable outcomes of a random trial or experiment), Θ is an event space (or sigma-algebra) consisting of a suitably restricted set of subsets of Π, and Ξ is a probability (or probability measure) defined on all the subsets in Θ. Let $\theta \in \Theta$, i.e., θ represents a possible outcome (random event, realization) of an experiment associated with Θ. The probability measure is a set function operating on Θ that assigns a probability to each event $\theta = \theta_\alpha$. In the context of ocean acoustics, Π could represent the set of possible complex pressure field values that can be measured in continental shelf environments throughout the year. An event space Θ might then contain subsets of possible field values that can be measured during the summer months off the coasts of New Jersey and Oregon for a particular frequency band and source level. The quantity $\theta = \theta_\alpha$ then represents a particular pressure distribution (realization) measured under the above conditions, with a weighting or likelihood of occurrence determined by the probability measure Ξ.

Let $\mu(\theta)$ be a second-order process considered as a function of the arbitrary event θ. A theorem in the theory of stochastic processes[33] states that one can always represent this process as a series expansion, $S(\theta)$, in terms of a complete set of orthogonal random polynomials $\{\Phi_d, d = 1, 2, \dots\}$ that are functions of random variables $\xi_{j_i}(\theta)$ for positive integers $j_1, j_2, \dots$. It will be apparent in what follows that including the quantity θ is a useful notation for distinguishing between stochastic and deterministic quantities. The expansion is guaranteed to converge to $\mu(\theta)$ in the mean-squared sense,

$$\langle (\mu(\theta) - S_N(\theta))^2 \rangle \to 0 \quad \text{as } N \to \infty, \tag{1}$$

where S_N is the Nth partial sum of the series S and $\langle \rangle$ represents an ensemble average with respect to a probability measure to be discussed shortly. Explicitly, the expansion for the

second-order space-time process μ can be written in the form[27]

$$\mu(\mathbf{r}, t; \theta) = b_o(\mathbf{r}, t)\Phi_o + \sum_{j_1=1}^{\infty} b_{j_1}(\mathbf{r}, t)\Phi_1(\xi_{j_1}(\theta))$$

$$+ \sum_{j_1=1}^{\infty} \sum_{j_2=1}^{j_1} b_{j_1 j_2}(\mathbf{r}, t)\Phi_2(\xi_{j_1}(\theta), \xi_{j_2}(\theta))$$

$$+ \sum_{j_1=1}^{\infty} \sum_{j_2=1}^{j_1} \sum_{j_3=1}^{j_2} b_{j_1 j_2 j_3}(\mathbf{r}, t)\Phi_3(\xi_{j_1}(\theta), \xi_{j_2}(\theta), \xi_{j_3}(\theta)) + \cdots.$$

$$\tag{2}$$

The functionals Φ_d are named the polynomial chaos of order d, and specify a complete orthogonal basis in a Hilbert space of second-order random variables.[27] The polynomial chaos are multivariate orthogonal functionals since they are functions of the random variables ξ_{j_i} describing the uncertainty. The sum in Eq. (2) is carried out according to the order d in such a manner that lower order terms are evaluated first. The word "order" refers to the highest power of the random polynomials appearing in the basis functionals; it is not to be confused with the use of the same word in the phrase "second-order process." Equation (2) describes a second-order stochastic process as an infinite series expansion in terms of sums of products of stochastic basis functionals and deterministic expansion coefficients $b_{j_1 j_2}, \dots$. Such a separation between stochastic and deterministic quantities is a special case of a general result in the theory of second-order stochastic processes, in which a spectral representation can be found that separates the process into stochastic and deterministic contributions.[27] The series in Eq. (2) has been written as a space-time process in which the coefficients contain the space, $\mathbf{r} = (x, y, z)$, and time, t, dependence and the basis functionals Φ_d are independent of these variables. For the example discussed here, the random variables $\xi_{j_1}, \xi_{j_2}, \dots$ are linked to uncertainty in the sound-speed distribution. In practical applications, the infinite series representation in Eq. (2) must be truncated to a finite number of terms for any order. In general, if the highest order polynomial is d, then the total number of expansion terms for an n-dimensional random vector $\boldsymbol{\xi}$ will contain $(n+d)!/n!d!$ terms.[11,12]

The basis functionals can be explicitly identified from the Wiener-Askey class of multivariate orthogonal functionals;[12] these include (but are not limited to) the familiar Hermite, Laguerre, and Legendre polynomials. Once the deterministic expansion coefficients, $b_{j_1 j_2 \dots}$, are computed, Eq. (2) contains a complete probabilistic description of the stochastic process and associated uncertainty. The set of stochastic functionals $\{\Phi_d\}$ forms a complete orthogonal basis set in this Hilbert space in the sense that the ensemble average of a pair of basis functionals is given by[12,27]

$$\langle \Phi_d \Phi_{d'} \rangle \equiv \int_\Theta \Phi_d(\boldsymbol{\xi})\Phi_{d'}(\boldsymbol{\xi})W(\boldsymbol{\xi})d\boldsymbol{\xi} = \langle \Phi_d^2 \rangle \delta_{dd'}, \tag{3}$$

where $W(\boldsymbol{\xi})$ is a probability density function defined through Ξ, and the integral is over the support of the random vector $\boldsymbol{\xi} = \{\xi_{j_1}, \xi_{j_2} \dots\}$. The choice of density function or probability

measure depends on the particular class of polynomial chaoses[11,12,27] chosen for the problem. The multivariate density function acts as a weighting factor on the random variables $\boldsymbol{\xi}$, that characterize uncertainty in the system. For example, if $\boldsymbol{\xi}$, represents a multidimensional Gaussian random variable, then the corresponding polynomial chaos basis functionals are the Hermite polynomials and the weighting (density) function W is a multidimensional Gaussian density function. On the other hand, Laguerre and Legendre polynomials are weighted by gamma and uniform distributions, respectively. From the point of view of uncertainty and its propagation through the system, the basis functionals link the relative weightings of both the environmental and acoustic field realizations that comprise the process, while the deterministic coefficients limit the set of possible realizations through the constraints imposed by the dynamics of wave propagation. These points will be clarified in the next section in terms of an example. Monte Carlo simulation represents a special case of Eq. (2) where a particular realization or outcome of a trial $\theta = \theta_\alpha$ is selected.[11] In effect, polynomial chaos expansions allow for all possible realizations to be computed simultaneously and described in a relatively compact form. An equivalent determination of individual realizations using Monte Carlo sampling can be accomplished for each θ_α directly from Eq. (2), provided the coefficients are known.

For notational convenience the series in Eq. (2) is written in the simplified notation[12,27] $\mu(\theta) = \Sigma_{q=0}^{\infty} c_q \Lambda_q(\boldsymbol{\xi}(\theta))$ where a one-to-one mapping relates the terms in this expression with those of Eq. (2). This form will be used throughout the text and involves a renumbering of Eq. (2) with the polynomials of lower order counted first; except for the indexing convention, Λ and Φ are identical,[12,27] though note that q does not generally represent the order of the expansion. For example, a polynomial chaos expansion of order 3 and random dimension 2 contains two random variables and a total of ten terms. It can be written compactly in the form $\mu(\boldsymbol{r}, t; \theta) = \Sigma_{q=0}^{9} c_q(\boldsymbol{r}, t) \Lambda_q(\boldsymbol{\xi}(\theta))$, where the identification of terms in this sum with those of Eq. (2) is given by e.g., $c_3 \Lambda_3 = b_2 \Phi_1(\xi_2), c_4 \Lambda_4 = b_{11} \Phi_2(\xi_1, \xi_1), c_7 \Lambda_7 = b_{211} \Phi_3(\xi_2, \xi_1, \xi_1)$, etc. The bases Λ_q also satisfy the orthogonality relation given by Eq. (3). An explicit example of the use of this polynomial chaos expansion is given in Sec. III after dynamical equations are developed to link both environmental and acoustic field uncertainty with propagation.

III. UNCERTAINTY EQUATIONS IN THE NARROW-ANGLE PARABOLIC APPROXIMATION

A. General formulation for arbitrary sound-speed distribution

The mathematical framework discussed in the previous section is applied here to develop equations for propagation within an uncertain waveguide environment, where the acoustic field is described by a narrow-angle parabolic approximation to the Helmholtz equation. In this approximation, the (deterministic) parabolic equation has the form[34]

$$2ik_o \frac{\partial \psi(r,z)}{\partial r} + \frac{\partial^2 \psi(r,z)}{\partial z^2} + k_o^2(N^2(r,z) - 1)\psi(r,z) = 0, \quad (4)$$

where the acoustic pressure $P(r,z)$ in range r and depth z is related to an envelope function $\psi(r,z)$ by the relation $P(r,z) \approx \sqrt{(2/\pi k_o r)}e^{i(k_o r - (\pi/4))}\psi(r,z)$ in the far-field approximation. The function $N(r,z)$ is the index of refraction, $c_o/c(r,z)$, relative to a reference wave number $k_o = \omega/c_o$ and $i = \sqrt{-1}$. To account for environmental uncertainty in the water column, the deterministic sound-speed field is now generalized to a stochastic process by the ansatz: $c(r,z;\theta) \Rightarrow \bar{c}(r,z) + \delta c(r,z;\theta)$. The function $\bar{c}(r,z)$ describes the deterministic mean field; $\delta c(r,z;\theta)$ represents the stochastic contribution with θ denoting an arbitrary element of Θ containing possible realizations of the sound-speed field weighted by the probability measure Ξ. For ocean acoustics problems the sound-speed perturbations represented by δc are quite small relative to $\bar{c}$, and it is assumed here that $\langle (\frac{\delta c}{\bar{c}})^2 \rangle \ll 1$, where $\langle \rangle$ denotes ensemble average.

Substitution of $c(r,z;\theta)$ into the index of refraction, and keeping only the first-order term in a binomial expansion of the sound speed, gives

$$n^2(r,z;\theta) \approx c_o^2 \left[\frac{1}{\bar{c}^2(r,z)} \left(1 - \frac{2\delta c(r,z;\theta)}{\bar{c}(r,z)} \right) \right].$$

Therefore, Eq. (4) is generalized to the following stochastic differential equation:

$$2ik_o \frac{\partial \psi(r,z;\theta)}{\partial r} + \frac{\partial^2 \psi(r,z;\theta)}{\partial z^2} + k_o^2 \left(\frac{c_o^2}{\bar{c}^2(r,z)} - 1 \right) \psi(r,z;\theta)$$
$$- \frac{2c_o^2 k_o^2 \delta c(r,z;\theta)}{\bar{c}^3(r,z)} \psi(r,z;\theta) = 0. \quad (5)$$

Note that $\psi(r,z) \Rightarrow \psi(r,z;\theta)$, because ψ is now a function of the stochastic process $\delta c(r,z;\theta)$. Assuming both the sound-speed perturbation and the envelope function are second-order stochastic processes, each process can be expanded in terms of polynomial chaos basis functionals $\Lambda(\boldsymbol{\xi}(\theta))$,

$$\delta c(r,z;\theta) = \sum_{s=0}^{\infty} \alpha_s(r,z) \Lambda_s(\boldsymbol{\xi}(\theta)), \quad (6a)$$

$$\psi(r,z;\theta) = \sum_{q=0}^{\infty} \gamma_q(r,z) \Lambda_q(\boldsymbol{\xi}(\theta)), \quad (6b)$$

where $\alpha_s(r,z), \gamma_q(r,z)$ are the deterministic uncertainty coefficients for the sound speed and envelope processes, respectively. Substituting Eqs. (6) into Eq. (5), multiplying the result by $\Lambda_l(\boldsymbol{\xi}(\theta))$, and projecting onto this basis by ensemble averaging each term yields

$$2ik_o\sum_{q=0}^{\infty}\frac{\partial\gamma_q(r,z)}{\partial r}\langle\Lambda_q\Lambda_l\rangle + \sum_{q=0}^{\infty}\frac{\partial^2\gamma_q(r,z)}{\partial z^2}\langle\Lambda_q\Lambda_l\rangle$$

$$+ k_o^2\left[\left(\frac{c_o^2}{\bar{c}^2(r,z)}-1\right)\right]\sum_{q=0}^{\infty}\gamma_q(r,z)\langle\Lambda_q\Lambda_l\rangle$$

$$-\frac{2c_o^2k_o^2}{\bar{c}^3(r,z)}\sum_{q=0}^{\infty}\sum_{s=0}^{\infty}\alpha_s(r,z)\gamma_q(r,z)\langle\Lambda_q\Lambda_s\Lambda_l\rangle = 0. \quad (7)$$

It is assumed for the forward problem that the stochastic process describing the uncertainty in the sound-speed field is known or can be estimated from data (i.e., the coefficients α_s are known). By applying the orthogonality condition on the chaos basis functionals [Eq. (3)] to the terms in Eq. (7), one then obtains an infinite set of deterministic, coupled partial differential equations for the uncertainty coefficients of the envelop field,[3]

$$2ik_o\frac{\partial\gamma_l(r,z)}{\partial r} + \frac{\partial^2\gamma_l(r,z)}{\partial z^2} + k_o^2\left[\frac{c_o^2}{\bar{c}^2(r,z)}-1\right]\gamma_l(r,z)$$

$$-\frac{2c_o^2k_o^2}{\bar{c}^3(r,z)\langle\Lambda_l^2\rangle}\sum_{q=0}^{\infty}\sum_{s=0}^{\infty}\alpha_s(r,z)\gamma_q(r,z)\langle\Lambda_q\Lambda_s\Lambda_l\rangle = 0.$$

$$(8)$$

The last term in Eqs. (8) represents the coupling of uncertainty between the sound-speed distribution and the envelope function determining the acoustic field. These coupled equations are rather general, describing the propagation of the envelope and its associated uncertainty constrained by both the dynamics imposed by the narrow-angle parabolic equation and the stochastic sound-speed environment. The particular propagation characteristics included in the formulation (e.g., scattering, dispersion, and attenuation) depend on the choice of wave equation and boundary conditions. Solving Eqs. (8) for the uncertainty coefficients $\gamma(r,z)$ $\equiv[\gamma_1,\gamma_2,\ldots,\gamma_\infty]$ completely determines the process describing the stochastic pressure field and its corresponding uncertainty, since

$$P(r,z;\theta) \approx \sqrt{\frac{2}{\pi k_o r}}e^{i(k_o r-(\pi/4))}\psi(r,z;\theta)$$

$$= \sqrt{\frac{2}{\pi k_o r}}e^{i(k_o r-(\pi/4))}\sum_{q=0}^{\infty}\gamma_q(r,z)\Lambda_q(\boldsymbol{\xi}(\theta)). \quad (9)$$

Note that the dummy index l in Eq. (8) has been replaced here by the dummy summation index q in Eq. (9).

B. Solution for the stochastic acoustic field in an isospeed waveguide

An analytic solution of Eq. (8) together with several moments of the acoustic field are computed here for an idealized stochastic waveguide in order to illustrate the theory. An isospeed environment with a pressure release surface and a rigid bottom is considered, in which the sound-speed field is chosen to be a Gaussian random variable. This environment is shown in Fig. 1 for a waveguide of water depth D with a source located at a depth z_0 below the surface. A
FIG. 1. Spatially homogeneous stochastic waveguide environment used in the analysis. The boundary conditions on the surface and bottom are pressure release and rigid bottom, respectively.

stochastic waveguide is equivalent to a family of deterministic waveguide environments[35] where each member corresponds to a single realization of the sound-speed field and the likelihood of any realization is determined by a probability distribution. In this particular case each member is drawn from a Gaussian distribution. While the model does not represent a realistic waveguide environment, its simplicity allows us to compute the moments explicitly and illustrate the methodology in a transparent manner without the additional complexity of dealing with numerical issues related to Eqs. (8). Numerical solutions of Eqs. (8) for spatially varying sound-speed environments are beyond the scope of this paper.

The Gauss-Hermite functionals will be used as the specific bases in the polynomial chaos expansions to describe both the stochastic acoustic field and sound-speed distribution. This is not an essential choice and different basis sets could be used, for example, to separately specify the environment and acoustic processes. While convergence of the series expansion in Eq. (2) is assured for second-order processes,[12,33] the rate of convergence is dependent on the choice of basis for a given environment. For a single random variable ξ the Gauss-Hermite polynomials, $\Lambda_n(\boldsymbol{\xi})\rightarrow H_n(\xi)$, satisfy the orthogonality condition[36]

$$\int_{-\infty}^{\infty}e^{-\xi^2}H_n(\xi)H_{n'}(\xi)d\xi = \pi^{1/2}2^n n!\,\delta_{nn'}, \quad (10)$$

for integer n and with $W(\boldsymbol{\xi})=e^{-\xi^2}$. Isospeed sound-speed perturbations δc are represented here as a zero-mean, Gaussian random variable with unit variance, $\xi\sim\mathbf{N}(0,1)$. The sound-speed distribution can then be expressed by $c(r,z)\Rightarrow c=\bar{c}+\sigma\xi$, where σ is the standard deviation of the sound-speed fluctuations. This implies that the PC series representation [Eq. (2)] reduces to a one-dimensional expansion of order d. Note that this dimensionality does not refer to the number of space dimensions in the problem; here, a two-dimensional waveguide is considered so that the expansion coefficients are functions of both range and depth. The Gauss-Hermite polynomials need to be scaled since the weighting function appearing in Eq. (10) does not represent a unit variance distribution. Replacing ξ by $\xi/\sqrt{2}$, the scaled basis functions, denoted by $He_n(\xi)$, can be written in the form $He_n(\xi)=(2^{-n/2}/\sqrt{n!})H_n(\xi/\sqrt{2})$. Using Eq. (10), this choice of PC basis functional satisfies the orthonormality condition

Steven I. Finette: Stochastic representation of uncertainty

$$\langle He_n(\xi)He_{n'}(\xi)\rangle = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}e^{-\xi^2/2}He_n(\xi)He_{n'}(\xi)d\xi = \delta_{nn'},$$

$$(11)$$

consistent with the random sound-speed perturbation having zero mean and unit variance. The condition expressed in Eq. (11) is a particular case of Eq. (3) for which the basis functionals have been normalized to unity. These basis functionals can be determined explicitly from the recursion relation

$$\xi He_n(\xi) = \sqrt{n+1}He_{n+1}(\xi) + \sqrt{n}He_{n-1}(\xi),$$

$$(12)$$

subject to the constraints $He_{-1}=0, He_0=1$. This expression is obtained using the recursion relation[26,36] for $H_n(\xi)$ and its relationship with $He_n(\xi)$ given above. The first few orthonormal Gauss-Hermite functionals for one-dimensional polynomial chaos of order $n=1,2,3$ are then given explicitly by

$$He_1(\xi) = \xi, \quad He_2(\xi) = \frac{\xi^2-1}{\sqrt{2}}, \quad He_3(\xi) = \frac{\xi^3-3\xi}{\sqrt{6}}. \quad (13)$$

By substituting the Gauss-Hermite bases into Eq. (6a), the sound-speed perturbation term can be written as $\delta c = \alpha_o He_o + \alpha_1 He_1 + \cdots = \sigma\xi$. Only the second term survives with the identification of α_1 as the standard deviation, σ, of the perturbation consistent with the $N(0,1)$ assumption. Substituting this nonzero term into Eqs. (8) eliminates the sum over s and gives the following set of coupled equations for the lth uncertainty coefficient:

$$2ik_o\frac{\partial\gamma_l(r,z)}{\partial r} + \frac{\partial^2\gamma_l(r,z)}{\partial z^2} + k_o^2\left[\frac{c_o^2}{\bar{c}^2}-1\right]\gamma_l(r,z)$$

$$-\frac{2c_o^2k_o^2\sigma}{\bar{c}^3\langle He_l^2\rangle}\sum_{q=0}^{\infty}\gamma_q(r,z)\langle He_q\xi He_l\rangle = 0. \quad (14)$$

Using Eq. (11) and Eq. (12), the ensemble averages appearing in the coupling term can be explicitly computed, with the result that any γ_l is determined by the partial differential recursion equation

$$2ik_o\frac{\partial\gamma_l(r,z)}{\partial r} + \frac{\partial^2\gamma_l(r,z)}{\partial z^2} + D\gamma_l(r,z) - E\sqrt{l}\gamma_{l-1}(r,z)$$

$$-E\sqrt{l+1}\,\gamma_{l+1}(r,z) = 0, \quad (15)$$

where $D\equiv k_o^2((c_o^2/\bar{c}^2)-1)$ and $E\equiv 2c_o^2k_o^2\sigma/\bar{c}^3$. It is convenient to write this equation in vector-matrix form for $\boldsymbol{\gamma}$,

$$2ik_o\frac{\partial\boldsymbol{\gamma}}{\partial r} + \frac{\partial^2\boldsymbol{\gamma}}{\partial z^2} + [A]\boldsymbol{\gamma} = 0, \quad (16)$$

where the uncertainty coupling matrix $[A]$ is symmetric and tridiagonal. For a sixth-order expansion the matrix is given explicitly by

$$[A] = \begin{bmatrix} D & -E & 0 & 0 & 0 & 0 \\ -E & D & -\sqrt{2}E & 0 & 0 & 0 \\ 0 & -\sqrt{2}E & D & -\sqrt{3}E & 0 & 0 \\ 0 & 0 & -\sqrt{3}E & D & -2E & 0 \\ 0 & 0 & 0 & -2E & D & -\sqrt{5}E \\ 0 & 0 & 0 & 0 & -\sqrt{5}E & D \end{bmatrix}.$$

$$(17)$$

The off-diagonal components represent the "magnitude" of the environmental uncertainty since these matrix elements are functions of σ. In general, $[A]$ is a function of spatial coordinates associated with the sound-speed field $c(r,z)$. This is clear from Eqs. (8) and prevents an analytic solution in cases of arbitrary sound speed. However, Eq. (16) has constant coefficients by virtue of the assumed independence of $\bar{c}+\delta c$ on position and it can be solved exactly by performing a similarity transformation to diagonalize the coupling matrix.[37]

Define $[G]=[\{g_1\},\{g_2\}\ldots]$ as the eigenvector matrix associated with $[A]$, where the jth column vector $\{g_j\}$ represents the jth eigenvector. Multiplying Eq. (16) on the left by $[G]^{-1}$, the inverse of the eigenvector matrix, and using the identity matrix $[G][G]^{-1}=I$, an uncoupled vector differential equation for the transformed uncertainty coefficient vector $\hat{\boldsymbol{\gamma}}=[G]^{-1}\boldsymbol{\gamma}$ is obtained,

$$2ik_o\frac{\partial\hat{\boldsymbol{\gamma}}}{\partial r} + \frac{\partial^2\hat{\boldsymbol{\gamma}}}{\partial z^2} + [\Omega]\hat{\boldsymbol{\gamma}} = 0. \quad (18)$$

The diagonal matrix $[\Omega]=[G]^{-1}[A][G]$ contains the eigenvalues $\boldsymbol{\lambda}=\{\lambda_1,\lambda_2,\ldots\}$ of $[A]$; since the coupling matrix is real and symmetric, the eigenvalues are also real. The solution of Eq. (8) for this simple ensemble of environments now reduces to solving Eq. (18) for each transformed uncertainty coefficient $\hat{\gamma}_l(r,z)$ and performing an inverse operation to obtain $\gamma_l(r,z)$. These latter coefficients determine the stochastic pressure distribution through Eq. (9). The lth transformed coefficient satisfies a narrow-angle parabolic equation of the form

$$2ik_o\frac{\partial\hat{\gamma}_l}{\partial r} + \frac{\partial^2\hat{\gamma}_l}{\partial z^2} + \lambda_l\hat{\gamma}_l = 0; \quad l=0,1,2,\ldots, \quad (19)$$

subject to initial and boundary conditions. The solution of Eq. (19) for $\hat{\gamma}_l$ can be obtained by a separation of variables where $\hat{\gamma}_l(r,z)=R(r)Z(z)$. Substituting this product into Eq. (19) leads to a solution of the form

$$\hat{\gamma}_l(r,z) = \hat{C}_l[\hat{A}_l\sin(\varepsilon z) + \hat{B}_l\cos(\varepsilon z)]e^{i\eta r/2k_o}, \quad (20)$$

where $\varepsilon=\sqrt{\lambda_l-\eta}$. The separation constant, η, and $\hat{A}_l,\hat{B}_l,\hat{C}_l$, are determined by the boundary and initial conditions. The boundary conditions can be obtained by starting with the relationship between the stochastic acoustic field and the envelope function. Using Eq. (6b) and Eq. (9), the pressure release surface condition leads to the result $P(r,0) = \sqrt{2/\pi k_o}re^{i(k_o r-(\pi/4))}\Sigma_{l=0}^{\infty}\gamma_l(r,0)He_l(\xi)=0$. For arbitrary ξ, this implies that $\gamma_l(r,0)=0$. Note that the dummy index q has been replaced here by the dummy index l. Similarly,

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Steven I. Finette: Stochastic representation of uncertainty   2573

the rigid bottom condition gives $[\partial \gamma_l(r,z)/\partial z]_{z=D}=0$. The boundary conditions on the transformed coefficients can be obtained by using the corresponding vector forms and multiplying them on the left by $[G]^{-1}$. For arbitrary l,

$$\hat{\gamma}_l(r,0) = 0, \tag{21a}$$

$$\left|\frac{\partial \hat{\gamma}_l(r,z)}{\partial z}\right|_{z=D} = 0. \tag{21b}$$

Applying the constraints specified in Eqs. (21) to Eq. (20) forces $\hat{B}_l$ to vanish. The function ε is restricted to the discrete set of values $(2m-1)(\pi/2D), m=1,2,\ldots,M$, where m is limited to those M integers that satisfy the constraint $\chi = \sin^{-1}(k_z/k) \leq 15°$, consistent with the narrow-angle approximation. The separation constant is determined from ε, and after the depth-dependent modes in Eq. (20) are normalized to unity, one obtains the following result:

$$\hat{\gamma}_l(r,z) = \sqrt{\frac{2}{D}} \sum_{m=1}^{M} C_{ml} \sin\left[(2m-1)\frac{\pi z}{2D}\right]$$

$$\times e^{\{i[\lambda_l - [(2m-1)(\pi/2D)]^2]r\}/2k_o}, \tag{22}$$

where the constant C_{ml} is to be computed from the initial condition and the additional subscript anticipates a dependence on mode number. A Gaussian starter field is considered for the initial condition,[38] so that the envelope evaluated at the range origin is given by

$$\psi(0,z) = \sqrt{k_o} e^{-(k_o^2/2)(z-z_o)^2}. \tag{23}$$

To apply the initial condition, the inverse transform is applied to the vector $\hat{\gamma}: \hat{\gamma}=[G]\gamma$, where the components of $\hat{\gamma}$ are given by Eq. (22). Each γ_l is therefore a linear combination of $\hat{\gamma}_l$, weighted by the eigenvectors of the coupling matrix $[A]$. Equating the polynomial chaos solution [Eq. (6b)] for $\psi(r,z;\theta)$ with Eq. (23) at range $r=0$ yields $\sum_{l=0}^{L}\gamma_l(0,z)He_l(\xi)=\sqrt{k_0}e^{-(k_0^2/2)(z-z_0)^2}$. Explicitly, one obtains

$$\sum_{l=0}^{L}\left[\sum_{u=1}^{L} g_{lu}\left\{\sqrt{\frac{2}{D}}\sum_{m=1}^{M} C_{mu}\sin\left((2m-1)\frac{\pi z}{2D}\right)\right\}\right]He_l(\xi)$$

$$= \sqrt{k_o}e^{-(k_o^2/2)(z-z_o)^2}, \tag{24}$$

where L is the number of terms (i.e., order) retained in the truncated polynomial chaos expansion. Limiting the series representation of the random process to a finite number of terms introduces a truncation error in the estimation of the field moments.[24] The above equation can be solved for the coefficients C_{mu} by first multiplying Eq. (24) by He_r and ensemble averaging both sides. Noting that on the right-hand side $\langle He_r \rangle = \langle He_r He_0 \rangle = \delta_{r0}$,

$$\sum_{u=1}^{L} g_{ru}\sqrt{\frac{2}{D}}\left\{\sum_{m=1}^{M} C_{mu}\sin\left[(2m-1)\frac{\pi z}{2D}\right]\right\}$$

$$= \sqrt{k_o}e^{-(k_o^2/2)(z-z_o)^2}\delta_{r0}, \tag{25}$$

Multiplying Eq. (25) by another member of the orthonormal set of eigenvectors, $\sqrt{2/D}\sin[(2m'-1)(\pi z/2D)]$, and integrating over the waveguide depth yields

$$\sum_{u=1}^{L} g_{ru} C_{mu} = \sqrt{\frac{2k_o}{D}}\left\{\int_0^D \sin\left[(2m-1)\frac{\pi z}{2D}\right]\right.$$

$$\left.\times e^{-(k_o^2/2)(z-z_o)^2}dz\right\}\delta_{r0}. \tag{26}$$

Operating on Eq. (26) with $[G]^{-1}$ gives the coefficients in the form

$$C_{mu} = \sqrt{\frac{2k_o}{D}}a_{u1}\Gamma(m,z_0), \tag{27}$$

where a_{u1} represents the uth element of the inverse of the first eigenvector and $\Gamma(m,z_o)$ is the definite integral in Eq. (26). Substituting Eq. (27) into Eq. (22) gives the explicit solution to Eq. (19) for the uth transformed uncertainty coefficient,

$$\hat{\gamma}_u(r,z) = \frac{2\sqrt{k_o}}{D}a_{u1}\sum_{m=1}^{M}\Gamma(m,z_o)\sin\left[(2m-1)\frac{\pi z}{2D}\right]$$

$$\times e^{\{i[\lambda_u - [(2m-1)(\pi/2D)]^2]r\}/2k_o} \tag{28}$$

Finally, the stochastic pressure field is obtained in the far field using Eq. (9) and Eq. (28),

$$P(r,z;\theta) \approx \sqrt{\frac{2}{\pi k_o r}}e^{i(k_o r - (\pi/4))}$$

$$\times \sum_{q=0}^{Q}\left[\sum_{u=0}^{Q} g_{qu}\hat{\gamma}_u(r,z)\right]He_q(\xi(\theta)), \tag{29}$$

where the quantity in brackets is $\gamma_q(r,z)$ and Q is the chosen truncation order.

C. Comparison of the polynomial chaos solution with Monte Carlo results

A comparison is now made between the analytic solutions for the first two statistical moments obtained from Eqs. (28) and (29), and independent Monte Carlo computations. The latter are based on computing multiple realizations of the acoustic field using the analytic solution of the deterministic parabolic equation given by Eq. (4). A comparison of Eq. (4) with Eq. (19) indicates that separation of variables can also be applied to solve Eq. (4). The resulting solution of the deterministic narrow angle equation, P_{det}, is then given by

$$P_{\text{det}}(r,z) = e^{-i(\pi/4)}\sqrt{\frac{8}{\pi r}}\left(\frac{1}{D}\right)\sum_{m=1}^{M}\Gamma(m,z_o)\sin\left[(2m-1)\frac{\pi z}{2D}\right]$$

$$\times e^{i([k^2-[(2m-1)(\pi z/2D)]^2-k_o^2]/2k_o+k_o)r}. \tag{30}$$

where $k=\sqrt{k_r^2+k_z^2}$ is the total wave number and Eq. (30) was obtained using both the same boundary /initial conditions and narrow-angle constraint on the number of modes that was discussed above for the polynomial chaos solution. The comparison involves the first and second-order moments of the field computed at frequencies of 50 and 300 Hz. The Monte Carlo estimates of the moments are obtained from Eq. (30) in the standard manner, drawing

3000 realizations of the sound-speed field from a Gaussian distribution with $\bar{c}=1500$ m/s and $\sigma=5$ m/s. A source depth of $z_o=40$ m and waveguide depth $D=200$ m are used in the computation. The polynomial chaos estimate of the moments incorporates the same values of $\bar{c}, \sigma, z_o$, and D.

With the Gauss-Hermite basis functionals, acoustic field moments based on the polynomial chaos expansion are computed from Eq. (9), noting that the envelope is given explicitly by the double summation in Eq. (29). The coherent mean field $\langle P(r,z;\theta) \rangle$ is obtained by ensemble averaging both sides of Eq. (9) and using $He_0(\xi)=1$ in conjunction with the orthogonality condition $\langle He_q He_0 \rangle = \delta_{q0}$. The result is

$$\langle P(r,z;\theta) \rangle = \sqrt{\frac{2}{\pi k_o r}} e^{i(k_o r - (\pi/4))} \gamma_0(r,z). \quad (31)$$

The autocovariance, R_{pp}, which includes the field variance as a special case, is defined by the expression

$$R_{pp}(r_1,z_1;r_2,z_2) \equiv \langle [P(r_1,z_1;\theta) - \langle P(r_1,z_1;\theta) \rangle]$$
$$\times [P(r_2,z_2;\theta) - \langle P(r_2,z_2;\theta) \rangle]^* \rangle, \quad (32)$$

where * denotes complex conjugation. Substituting Eq. (9) and Eq. (31) into Eq. (32) and invoking orthogonality of the basis functions gives

$$R_{pp}(r_1,z_1;r_2,z_2) = \frac{2}{\pi k_o \sqrt{r_1 r_2}} e^{ik_o(r_1-r_2)}$$
$$\times \sum_{q=1}^{Q} \gamma_q^*(r_1,z_1) \gamma_q(r_2,z_2) \quad (33)$$

for the autocovariance of the pressure field between points 1 and 2. Note that the sum in Eq. (33) starts at unity rather than zero. The field autovariance for any $(r_1=r_2,z_1=z_2)$ is a special case of Eq. (33) and can be written concisely as

$$R_{pp}(r,z;r,z) = \frac{2}{\pi k_o r} \sum_{q=1}^{Q} |\gamma_q(r,z)|^2. \quad (34)$$

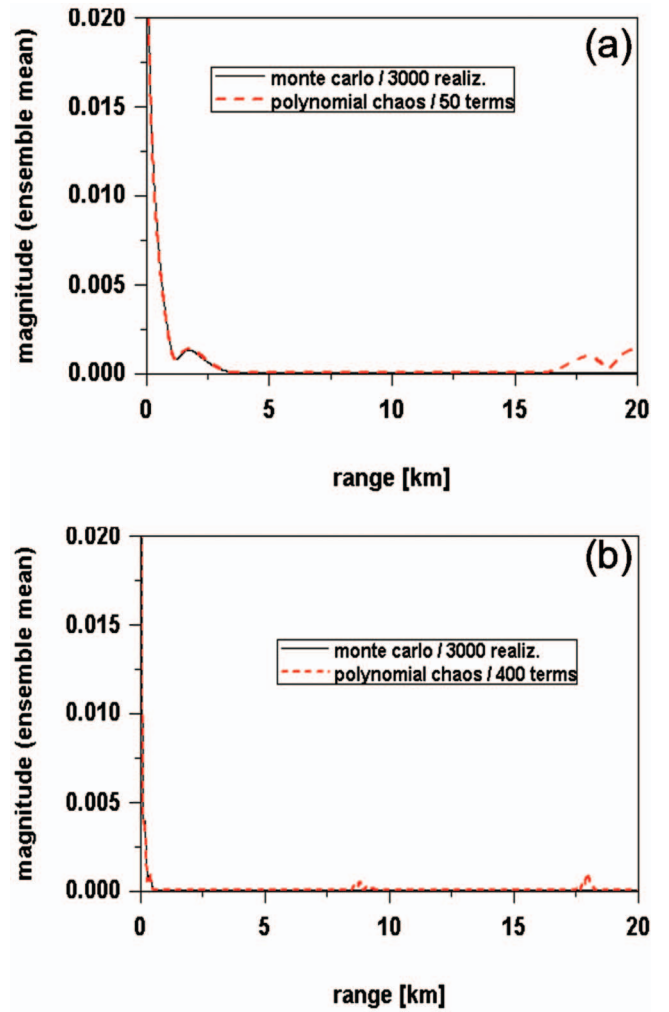
When the ensemble mean in Eq. (31) is negligible, $10 \log_{10} R_{pp}(r,z;r,z)$ gives an unreferenced estimate of coherently averaged transmission loss. Figure 2 shows the magnitude of the coherent mean field over a range of 20 km computed from Eq. (31) for both frequencies. The black curve in each case corresponds to the Monte Carlo estimate of the magnitude of the first moment obtained from 3000 realizations using Eq. (30), and the number of terms Q in the truncated polynomial chaos expansion is $Q=50$ for the 50-Hz case and $Q=400$ for the 300-Hz case. Coherence degradation occurs at a shorter range for the 300-Hz case (containing 21 modes) relative to the 50-Hz case (with three modes). First moment estimates using polynomial chaos expansions are in excellent agreement for both frequencies, with discrepancies for $r>16$ km at 50 Hz and near ranges 8.5 and 18 km at 300 Hz. The autovariance is illustrated in Fig. 3 for both frequencies. The comparison is again very good with $Q=50$ for the 50-Hz case and $Q=400$ for the 300-Hz case, though a discrepancy exists at a range of about 18 km for propagation at both frequencies.The errors may be related to a conver-


FIG. 2. Comparison of the magnitude of the first moment (coherent mean) of the stochastic pressure field, using polynomial chaos expansions and Monte Carlo sampling: (a) for 3 modes at 50 Hz; (b) for 21 modes at 300 Hz.

gence issue linked to truncation of the series representation in Eq. (29). Some additional comments on this point are given after the results for the autocovariance are presented.

The normalized autocovariance was computed from Eq. (33) for a fixed depth slice where $(r_1=5$ km, $z_1=40$ m, $r,z)$ and is presented in Fig. 4. Polynomial chaos results are again in excellent agreement with those using Monte Carlo-based realizations for 50 Hz, though an additional correlation occurs in the 300-Hz example at a range of about 14 km. Similar results are found for other range/depth choices (not shown). Because the PC expansion can be viewed as a generalized spectral expansion,[11,27] this spurious correlation, identical in form to the correct one located at a range of 5 km, is tentatively interpreted here as a form of wraparound caused by the series truncation to a finite order. Other computations (not illustrated) show that the location of these peaks changes as a function of the number of terms in the expansion. When Q is increased, the distance between the true correlation and the spurious contribution increases. Further work is needed to examine this source of error.

D. Application of polynomial chaos expansions in realistic environments

It appears that a fairly high-order chaos expansion is necessary to achieve a good comparison with moments independently computed through Monte Carlo sampling, considering the simple structure of the waveguide environment used in the above example. A recent analysis of one-dimensional propagation in unbounded random media[23] indicates that, in the case where the spatial correlation length of the medium is infinite (corresponding to the isospeed case discussed here), the convergence of the PC expansion is non-uniform in range and a significant number of terms are necessary for convergence of the truncated series. However, for media with finite correlation lengths, such as those found in typical ocean waveguides, that analysis predicts that the number of terms necessary for convergence decreases significantly.[23] The convergence rate in both cases depends on both the correlation length and the strength of the sound-speed perturbations. The example considered in Secs. III B and III C involves bounded multipath propagation in a two-dimensional waveguide and, while idealized, has the advantage of being both analytically tractable and illustrative of the general methodology. On the other hand, in light of the

above comments the example would appear to present a particularly difficult case for polynomial chaos expansions due to the infinite correlation length assumed for the medium.

In the remainder of this section a brief outline of an application of polynomial chaos expansions to a more realistic ocean environment is presented, with details left to a future analysis. The problem considers a linear, spatially diffuse internal wave field in a horizontally stratified ocean waveguide. A sound-speed perturbation, $\delta c(x,y,z,t)$, produced by the internal wave field is presumed to be specified by a zero mean random field related to a water particle's random displacement, $\Delta(x,y,z,t)$, from its equilibrium position. This relationship is given by the expression[39]

$$\delta c(x,y,z,t) \cong A N^2(z) \Delta(x,y,z,t). \quad (35)$$

In this equation, A is a constant and $N(z)$ is the (deterministic) buoyancy frequency.

It is assumed that the expansion in Eq. (6a) describing the sound-speed perturbation as a stochastic process is known when solving the forward problem, i.e., computing

the pressure field from Eqs. (8) and (9). It was assumed earlier that δc was characterized by a single random variable ξ. Realistic ocean environments have finite correlation lengths and this leads to a more complex expansion. If the correlation function is known or can be estimated, another form of stochastic expansion may be used to specify δc as a random field in terms of a set of uncorrelated random variables $\{\xi_1, \ldots, \xi_m\}$. The Karhunen-Loeve expansion[27] (also known as principle component analysis or empirical orthogonal function expansion) of the sound-speed perturbation can be written as

$$\delta c(x,y,z,t;\theta) = AN^2(z) \sum_{m=0}^{\infty} \sqrt{\lambda_m} \xi_m(\theta) f_m(x,y,z,t), \quad (36)$$

where λ_m and $f_m(x,y,z,t)$ are the eigenvalues and eigenfunctions, respectively, of the particle displacement correlation function. This function is related to the sound-speed correlation function by

$$\langle \delta c(x,y,z,t) \delta c(x',y',z',t') \rangle$$
$$= A^2 N^2(z) N^2(z') \langle \Delta(x,y,z,t) \Delta(x',y',z,t') \rangle, \quad (37)$$

where θ has been dropped from the notation. Note that both δc and Δ are wide-sense stationary in x,y and t but not in depth. A series of the form in Eq. (36) is optimal in the sense that the mean-square error that results from truncating the sum is minimized for any number of terms retained. The random particle displacement can be expressed explicitly as a linear superposition of internal wave modes with random amplitudes[40]

$$\Delta(x,y,z,t)$$
$$= \sum_{k_x} \sum_{k_y} \sum_{m} G(k_x,k_y,m) W_m(k,z) e^{i(k_x x + k_y y - \omega(k,m)t)}. \quad (38)$$

In this expression, W_m are depth-dependent internal wave eigenmodes, k is the horizontal wave number, and G correspond to a set of zero-mean Gaussian random variables related to the spectral density of the internal wave field, E, of the mth mode by $E(k_x,k_y,m) = \langle G(k_x,k_y,m) G^*(k_x,k_y,m) \rangle$. The dispersion relation between wave number and frequency is given by $\omega(k,m)$. It can be shown[13] that the eigenfunctions f_m in Eq. (36) are given by $W_m(k,z) e^{i(k_x x + k_y y - \omega(k,m)t)}$ and the eigenvalues are given by components of the spectral energy density of the internal wave field, $E(k_x,k_y,m)$. With these identifications, Eq. (36) can be used instead of Eq. (6a) to derive a set of uncertainty equations where the sound-speed perturbations are linked to a linear stochastic internal wave field. The polynomial chaos expansion in Eq. (6b) is still employed as a generic expansion for the envelope field; the resulting series solution for the envelope field is guaranteed to converge for a second-order process, though the rate of convergence would depend on the choice of polynomial chaos basis functionals. Note that while the envelope field is a function of the $\xi_{m'}$ it is not possible to choose a Karhunen-Loeve expansion for the envelope field because the correlation function of the envelope is unknown for the forward problem. The number of terms in the sum needed to specify δc depends on the correlation structure of the sound-speed

distribution; spatial scales of the distribution are embedded in f_m. The eigenvalues weight the importance of the spatial scales included in the uncertainty computation, with the number of terms retained in Eq. (36) determined by the (monotonic) decay rate of the eigenvalues which, in turn, depends on the correlation structure.[11] Two general limiting cases are worth noting: more terms are required in Eq. (36) as the process approaches white noise, while typically only a few terms are necessary for smoothly varying processes, and at the lower limit a spatially uniform field is described by one term. The latter limiting case corresponds to the detailed example discussed earlier. It is expected that a relatively high-dimensional chaos expansion would be required, depending on the spatial frequency band of interest chosen for the internal wave spectrum. On the other hand, based on previous applications of the method it is presumed that a low order is probably sufficient.[11,27,29–31] The resulting uncertainty equations would be solved numerically to obtain the both uncertainty coefficients and the moments.

IV. SUMMARY AND CONCLUSIONS

Simulation-based prediction involves a complex scientific hypothesis in which uncertainty plays a central role. This paper offers a solution to the problem of how statistical characterization of incomplete environmental knowledge can be included within the framework of simulation-based prediction. A dynamical formulation of the problem is presented using a probabilistic approach that leads to stochastic, rather than deterministic wave propagation when uncertainty is included and associated with the sound-speed distribution. Environmental uncertainty linked to sound speed is explicitly coupled to the corresponding uncertainty in the acoustic field and effectively "propagates" through the waveguide along with the field. Measures of the spread of the acoustic field distribution (i.e., statistical moments) are interpreted as quantitative estimates of the effect of environmental uncertainty on acoustic field structure. Polynomial chaos basis functionals are chosen to represent incomplete knowledge of both the sound speed and acoustic fields, and a set of coupled, deterministic partial differential equations are derived for the expansion coefficients describing the stochastic acoustic field. An alternative method for including incomplete environmental information in the dynamics of wave propagation takes a different probabilistic approach, making use of Bayesian inference to describe uncertainty.[41]

The equations are solved exactly for the special case of an isospeed stochastic waveguide within the narrow-angle parabolic approximation and where the variance of the sound-speed fluctuations is small. The sound-speed field is treated as a Gaussian random variable, and Gauss-Hermite functionals are used as a specific example of PC expansion bases. The results for the first two moments are compared to the same moments independently estimated by Monte Carlo analysis of the deterministic narrow-angle parabolic equation, and show that the truncated polynomial chaos expansions reproduce the Monte Carlo estimates of the moments. It should be emphasized that the general method is not limited to either a single source of uncertainty or to the assump-

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Steven I. Finette: Stochastic representation of uncertainty   2577

tions used in the example from Secs. III B and III C. Distributions of sound speed with finite spatial correlation lengths should yield good results with far fewer terms in the polynomial chaos expansion than are needed here. With spatially varying environmental distributions, uncertainty coefficients can be computed numerically from Eq. (8).

Conventional wisdom would say that adding more physics and/or decreasing the grid resolution would lead to better predictions and decreasing uncertainty. However, there are several reasons to question this conclusion. The additional physical parameters or fields may be incompletely specified as mentioned in the Introduction, and this might lead to poorer quality predictions from simulation. Increased spatial and temporal resolution, by itself, may not improve simulation-based prediction unless the physics at those scales is properly incorporated. Uncertainty in the physics at small spatial and temporal scales that is not explicitly modeled can adversely affect the predictions[42,43] by propagating, via the system dynamics, to larger scales of interest. Polynomial chaos expansions may play a significant role in relating uncertainty at different scales, since the expansion coefficients are functions of the space-time correlation structure of the medium.[11] In addition, it is not clear that more "complex" models (i.e., those that include additional physics but do not incorporate uncertainty) have a better predictive capability than simpler models that include uncertainty in their computations. It is possible that embedding a polynomial chaos representation of uncertainty within a relatively simple environmental description of an ocean waveguide may have a better simulation-based predictive capability than a model containing a very detailed environmental representation but without the inclusion of uncertainty in that representation.

The polynomial chaos basis expansion method is one approach for developing a unified theoretical formulation of uncertainty within a strong mathematical framework. It forms a natural foundation for a dynamical formulation of environmental uncertainty and its inclusion into the dynamics of wave propagation, though additional research is needed to address both the numerical issues associated with truncated expansions and applicability of the method to more realistic waveguide environments.

Scattering from the mixed layer base into the sound shadow

Daniel L. Rudnick[a] and Walter Munk

*Scripps Institution of Oceanography, University of California at San Diego,
La Jolla, California 92093-0225*

Long-range sound transmissions in the ocean are largely controlled by the SOFAR wave guide. The agreement between the measured and predicted arrival patterns is generally excellent, except for an observed extension downward by many hundreds of meters from the lower caustics into the deep sound shadow. The deepening of early arrivals is proposed to be associated with the sharp transition zone marking the lower boundary of the surface mixed layer. This mixed layer base (MLB) is distorted by internal waves. Multiple collisions of the ray-like acoustic transmission with the wavy MLB lead to a mean deepening of the lower caustics of $2\gamma_a^{-1}\sigma^2 \approx 35$ m per collision, where $\gamma_a = (1/C)dC/dz = 1.13 \times 10^{-2}$ km^{-1} is the (fractional) abyssal adiabatic sound speed gradient and $\sigma^2 = 2 \times 10^{-4}$ is the variance in MLB slope. There are typically 20 such collisions in a 1000 km transmission. Monte Carlo numerical experiments yield statistics of ray inclination, range, travel time, and lower turning point. The resulting time front includes a deepening by several hundred meters. The acoustic signatures provide the possibility for monitoring upper ocean processes with abyssal acoustic arrays. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2338813]

I. INTRODUCTION

An acoustic pulse at megameter ranges is typically dispersed over 3–5 s (the SOFARGRAM). The first second sees the arrivals of steep rays that span the ocean from top to bottom. These are followed by rays of diminishing steepness and increasing concentration near the axis, with the final arrivals along the sound axis (the famous SOFAR *finale*). As the insonification lifts off the bottom, the region below the lower turning point (LTP) of refracted rays is expected to lie in the sound shadow. In fact, signals are observed many hundred meters beneath the caustics associated with LTPs. The deep arrivals are an anomaly to an otherwise excellent agreement with geometric optics (except for the *finale*). Diffraction cannot account for the observed penetration into the ray shadow (Worcester, 1977; Dziecuich *et al.* 2004).

The upper ocean is associated with two marked boundaries: one at the ocean surface, the other at the base of the mixed layer (MLB). Recent observations have revealed a remarkable sharpness of the MLB, capable of the reflection of low-frequency acoustics. Multiple reflections from a MLB distorted by internal waves may account for the observed shadow penetration.

II. PENETRATION INTO THE ABYSSAL SHADOW ZONE

Since the early days of the U.S. Navy Sound Surveillance System (SOSUS) it has been known that late "forbidden" rays are in fact recorded on deep receiving arrays, but the published accounts are very few. Spiesberger and Tappert (1996) refer to "shadow-zone arrivals" in their 3700 km transmissions from Hawaii toward the mainland and spoke of the "the demise of the idea of axially trapped energy."

Dushaw *et al.* (1999) refer to an "interesting, and perhaps new, type of 'ray' arrival which appears to occur well into the shadow zone of the predicted arrival…; the apparent stability of these arrivals, together with the detection of similar arrivals at several other deep arrays in both the Atlantic and Pacific oceans, rules out bottom interaction as the origin of these arrivals. To date, no known mechanism, e.g., diffraction leakage from the caustics or diffusion of acoustic energy by internal wave scattering, can explain the extreme depth diffusion of acoustic energy that must be occurring."

Figure 1 shows results of transmissions from an ATOC source on Pioneer Seamount toward the bottom-mounted horizontal SOSUS line array **n** (Dushaw *et al.*, 1999). For all but the earliest arrivals, the receiver depth is beneath the predicted lower turning points of the rays, yet the signal is clearly received. The authors note that the deep arrivals are stable, and that they occur very near the time of the predicted caustics above. The same result is found for transmissions to other SOSUS arrays, all in the range of one or two megameters. We will discuss the deep arrivals in terms of *reflection* from a wavy MLB. This serves as a simple model to generate the required statistics, but needs to be generalized to account for the later *refracted* arrivals with upper turning points well below the MLB.

III. OBSERVED SOUND SPEED AND THE MIXED LAYER BASE IN THE NORTH PACIFIC

The North Pacific Acoustic Laboratory (NPAL) Spice04 experiment had the objective of quantifying the effect of upper-ocean sound speed fluctuations on long-range acoustic propagation. In May-June 2004, the NPAL group deployed three acoustic moorings along a 1000-km section in the North Pacific, with end points at 34°53'N, 148°25'W and 33°25'N, 137°41'W. Subsequent cruises in September-October 2004 and March-April 2005 afforded opportunities

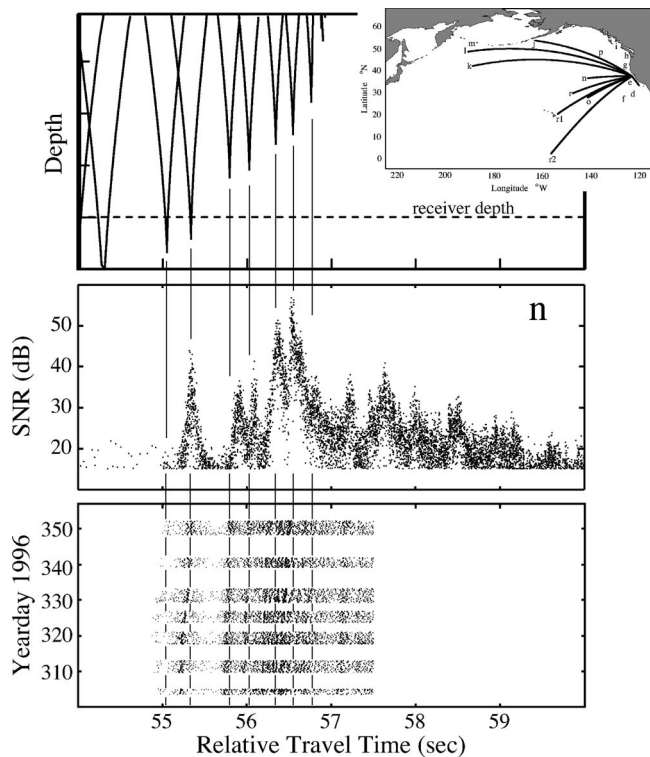

FIG. 1. Predicted time fronts (top) and measured intensities for transmissions from the ATOC source on Pioneer Seamount to SOSUS stations **n** and **o** (adapted from Figs. 3 and 6 of Dushaw *et al.*, 1999). The lowest panel shows the recorded intensities of individual transmissions during year days 300 to 360 in 1996 as a function of transmission time (relative units). The central panel shows the corresponding signal to noise ratios based on all transmissions between January 1996 and March 1997.

to measure hydrography along the section. Observations of temperature, salinity, and pressure were obtained during the first two cruises using the newly developed Underway CTD (Rudnick *et al.*, 2004), a device designed to collect profiles while under way so as not to require ship time or to interfere with other operations. The last cruise was dedicated to measuring fine-scale hydrography using a SeaSoar.

Representative profiles from these three cruises show seasonal changes in the mixed layer and its base. The mixed layer is at its deepest, near 100 m, in late winter or early spring (Fig. 2: April profile). The mixed layer shoals rapidly in the spring, due to increased surface heating, and is near its shallowest in late spring or early summer (see June). The mixed layer warms throughout the summer to its warmest, least dense, state in the fall (see September). The MLB is defined by remarkably sharp gradients in temperature, and therefore sound speed, in a vertical span of about 10–20 m. The net change in sound speed across the MLB can be larger than 10 m/s (see September). This change is equivalent to about 1/5 the variation in sound speed over the entire ocean depth, and five times the change through the mixed layer above the MLB.

For the purpose of this paper, the ocean sound channel is modeled analytically (the "canonical" profile) with a discontinuous transition at 70 m depth at the MLB (Fig. 2). The sound speed in the mixed layer is at the adiabatic gradient, with no net change in heat content relative to the canonical profile above the MLB. The resulting sound speed change at
FIG. 2. (Color) Sound speed profiles (lower scale) from April 2005, June 2004, and September 2004, representative of spring, summer, and fall in the northeast Pacific. The sharp gradient at the bottom of the mixed layer first forms in June and deepens to about 100 m at the end of the winter storms (a weak deep residual from the previous year is evident in the June profile). The black line (upper scale) is a fit of the canonical profile to the situation in spring. In this paper the mixed layer is modeled by a discontinuity at 70 m depth with no net exchange of heat.

the MLB is about 4 m/s. Observations are consistent with velocity jumps up to 15 m/s, only 1% of the sound speed but one-third of the total variation in the ocean column (ignoring the associated density jumps). Even so, the jump is of course dwarfed by the 80% velocity contrast and the 800:1 density contrast at the sea-air boundary.

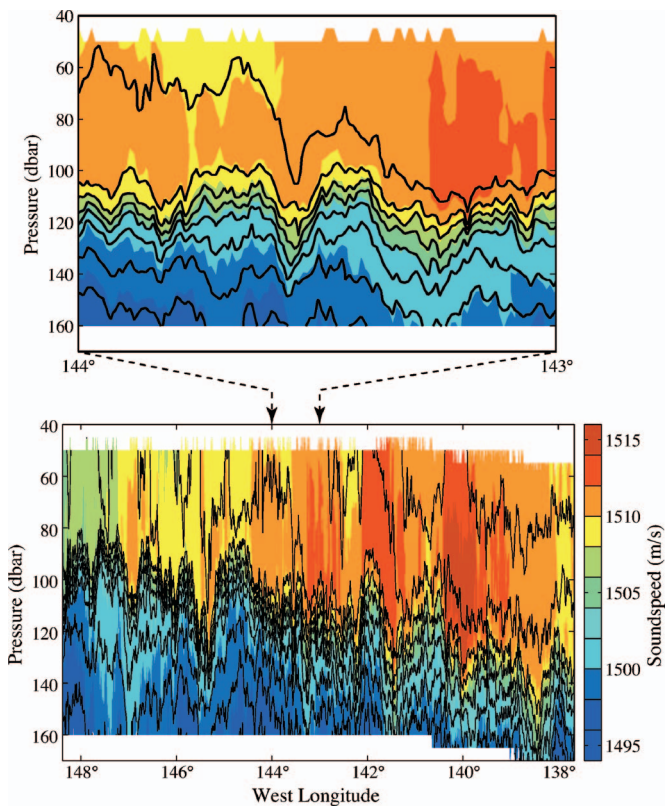
Internal waves at the mixed layer base. A SeaSoar tow during the March-April 2005 cruise focused on the MLB (Fig. 3). The nominal depth range 50–150 m was profiled initially, completing a cycle in less than 3 min, resulting in a horizontal resolution of at least 720 m at the tow speed of 4 m/s. As the tow proceeded to the east, the mixed layer deepened, from near 80 to near 140 m, so the SeaSoar profiling range was lowered. The MLB is clear in the figure as a transition from relatively well-mixed water above to stratification below. Statistics of MLB displacement and slope were calculated over wavelengths from the length of the tow (1000 km) to the Nyquist wavelength of 1440 m. Root-mean-square MLB displacement and slope were rms ζ =8.6 m and 0.0034 rad, respectively. The spectrum of slope (Fig. 4) was white out to the Nyquist frequency at a level of about $F_m(k_1)=0.02$ rad^2/cpm (cycles per meters). Previous SeaSoar tows at constant pressure and along isopycnals reveal that the slope spectrum is white at the highest observed


FIG. 3. (Color) Sound speed as color from April 2005 in the northeast Pacific. Black lines are isopycnals (contour interval 0.1 kg/m^3). The total range is almost exactly 1000 km. The transition at the bottom of the mixed layer is clearly indicated. SeaSoar cycled only over the 100 m surrounding the mixed-layer base, yielding a horizontal resolution of 720 m. Mean depth of the 25.36 isopycnal (corresponding roughly to the 1499 m/s sound speed contour) is 115 m. The rms displacement (after removing the trend) is 8.6 m, rms slope is 0.0034. Because the displacement spectrum has a −2 slope, the slope spectrum is white. Thus the rms slope is strongly dependent on horizontal resolution (Nyquist wave number).

wave numbers of order 0.1 m^{-1}. (Hodges and Rudnick, 2006).

The processes causing the MLB to heave are likely mesoscale eddies and internal waves. It is worthwhile to compare the observed statistics to those obtainable through the
FIG. 4. Slope spectrum of the 25.36 isopycnal. The high wave number termination is determined by the sampling resolution.

Garrett–Munk (GM) spectrum. The observed rms MLB displacement of 8.6 m compares favorably to the GM value of 7.6 m. The GM slope spectrum is white, as is the observed spectrum, but the observed spectral density of 0.02 rad^2/cpm is well below the GM value of 0.08 rad^2/cpm. Shortcomings in the GM model are well known, and the rapidly changing stratification near the MLB is a particular challenge. The details of projecting the traditional GM displacement spectrum to the slope spectrum are cumbersome and uninteresting (Appendix A).

Short internal waves with lengths comparable to the acoustic wavelength are associated with Bragg scatter with scattering coefficients vastly smaller than those associated with specular reflections (Brekhovskikh and Lysanov, 1991 Chap. 9). For a very rough estimate of the wave number cut-off appropriate to specular reflection, consider the dimension of a "ray tube" with Fresnel scaling $\sqrt{\lambda R'}$ where λ is the acoustic wavelength and R' a suitable length scale. In a homogeneous ocean this is the total range r; in a periodic wave guide, R' is related to the ray loop range R. For the canonical sound channel, Flatté et al. (1979, Chap. 9) demonstrate that R' is a small fraction of the ray loop range. Taking $R' = R/10 = 5$ km, and $\lambda_{ac} = 10$ m (150 Hz), the resulting Fresnel scale is 220 m, as compared to the 100 m cut-off adopted in this paper. Dzieciuch (2006) finds that the acoustic transmissions are insensitive to internal waves with vertical scales of less than the acoustic wavelength λ_{ac}. The associated horizontal scale is larger by at least an order of magnitude. Accordingly, for $\lambda_{ac} = 10$ m (150 Hz) we adopt a cutoff wavelength of 100 m, or $k_1^* = 0.01$ cpm. Assuming that the spectrum remains white at the level observed to a cutoff wave number k_1^* cpm, the slope variance is $\sigma^2 = F_m(k_1) \times k_1^* = 0.02 \times 0.01 = 2 \times 10^{-4}$ rad^2 (0.8° rms). The reader will appreciate the uncertainty of this estimate associated with the uncertainty in the termination of the slope spectrum.

A quite different consideration has been suggested by Klymak and Moum (2006): a transition near 10^{-2} cpm from internal waves to turbulence. This implies a failure of the discrete IW dispersion $k(j, \omega)$ at the higher wave numbers, where "the weak selective interactions" of the internal waves are replaced by "strong promiscuous interactions" of the turbulent Fourier components (Phillips, 1966). But if such a transition occurs, it is not clear how it would lead to a marked reduction in the reflectivity of a turbulent versus a wave distorted MLB. One may hope that the acoustic measurements can shed some light upon whether the termination is governed by the acoustic frequency or determined by some intrinsic properties of the ocean dynamics.

IV. STATISTICS OF A SINGLE BOUNCE

A. Refraction versus reflection

Figure 5 sketches the perturbations associated with the steep gradients in the bottom boundary of the mixed layer. The MLB gradients (red) are typically an order of magnitude above those associated with the canonical gradients (black) at that depth. Accordingly, the loop AB_2C_2 is shortened relative to the canonical AB_1C_1. For a given angle of incidence, the loop range varies inversely with the gradient dC/dz and
FIG. 5. (Color) Modification of ray geometry by mixed layer base (MLB). The canonical profile (black) is modified by a mixed layer with steep lower boundary (red) and discontinuous boundary (blue). For a level MLB (top) there is no change in the depth of the lower turning point (LTP). For a downward tilting MLB with angle α, both the refracted and reflected rays are steepened by 2α and the LTPs are equally deepened.

so typically $\mathbf{AC_2} \ll \mathbf{AC_1}$. Ray curvature is proportional to sound speed gradient, and as $dC/dz \to \infty$, $\mathbf{AC_2} \to 0$: the downward refracted ray approaches the configuration of the reflected ray (blue). The turning sound speed and depth of the LTP are unchanged; they are specified by the incident inclination θ_i and sound speed C (or slowness $S = 1/C$) at the MLB (assumed level), according to Snell's law

$$S_{\text{MLB}} \cos \theta_i = \widetilde{S}, \tag{1}$$

where S_{MLB} is the slowness at the MLB and $\widetilde{S}$ is turning slowness.

But there is a change in turning depth for an inclined MLB. For a downward sloping MLB (as shown in the following), the *reflected* (blue) ray is steeper than the incident ray by twice the MLB inclination,

$$\theta_r = -\theta_i + 2\alpha. \tag{2}$$

The same "law of reflection" holds for a downward *refracted* ray (red). For simplicity the following discussion is in terms of a reflection at the MLB boundary.

There is total reflection for $C_{\text{mix}} \geqslant \widetilde{C} = 1/\widetilde{S}$ (the refracted ray turns within the layer). For $C_{\text{mix}} < \widetilde{C}$ there is partial reflection (Brekhovskikh and Lysanov, 1991, 3.1.12, neglecting the density contrast)
FIG. 6. Ray reflection from a MLB tilted by internal waves with inclination $\alpha(x)$. At the crest and trough ($\alpha=0$) the angles of incidence and reflection are of equal magnitude, $\theta_r = -\theta_i$. Reflections are steepened to the left of the trough (A), and flattened to the right. Reflections are upward for $\frac{1}{2}\theta_i \leqslant \alpha_i (B \to C)$. The boundary is screened for $\alpha > \theta_i$.

$$R = \frac{\sin \theta - \sqrt{n^2 - \cos^2 \theta}}{\sin \theta + \sqrt{n^2 - \cos^2 \theta}}, \quad n = \frac{S_{\text{mix}}}{S_{\text{MLB}}} = \frac{C_{\text{MLB}}}{C_{\text{mix}}} \leqslant 1 \tag{3}$$

and $R=1$ for $n>1$, with R^2 designating the fraction of reflected energy. The subscripts "MLB" and "mix" refer to the bottom and top of the shaded transition layer. For the canonical profile in Fig. 2 with 4 m/s difference between the sound speed above and beneath the transition, the critical angle is 4.1°: only very flat rays are totally reflected. Observations are consistent with velocity jumps up to 15 m/s, corresponding to 8° of critical incidence. Later, we consider a glancing ray of angle 0.6° and a steep ray of angle 8.9°. Assuming $n=1530/1540=0.9935$ consistent with observations, the glancing ray is totally reflected and the steep ray has $R=0.19$.

B. Screening

Incident rays on a wavy reflecting boundary will see only that part of the boundary that is inclined toward the ray. For an incident ray of inclination θ_i the part of the boundary whose inclination $\alpha > \theta_i$ is said to be "screening" (Beckmann and Spizzichino, 1987; the designation "shadowed," sometimes used in the literature, is here reserved to the abyssal acoustic shadow). "Second-order screening," which shadows some of the boundary with $\alpha < \theta_i$ (Fig. 6), is ignored.

Inclinations at the MLB are reasonably well represented by a Gaussian probability density function

$$p(\alpha) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{\alpha^2}{2\sigma^2}\right), \tag{4}$$

where σ is the standard deviation of MLB inclination. The conditional PDF of illuminated inclination, given an incident ray of inclination θ_i, is taken as

$$p_{ill}(\alpha | \theta_i) = \begin{cases} \dfrac{p(\alpha)}{D(\theta_i)}, & \alpha < \theta_i \\ 0, & \alpha \geqslant \theta_i \end{cases} \tag{5}$$

where $D(\theta_i)$ is the Gaussian cumulative distribution function (CDF)

$$\langle(\alpha - \langle\alpha\rangle)^2\rangle = \langle\alpha^2\rangle - \langle\alpha\rangle^2 = \sigma^2 + \theta_i\langle\alpha\rangle - \langle\alpha^2\rangle. \quad (10)$$

But the variance is not a good indicator of the spread because of the large asymmetry between positive and negative α, and it is best to refer to the PDF in Fig. 7.

Upward reflections off the MLB are possible, and all subsequent statistics include these relatively few upward reflections. An alternate approach would be to assume that the upward reflections soon encounter the MLB again, and are reflected downward. A statistical model with only downward reflections is achievable using PDF (5) with θ_i on the right-hand side replaced by $\frac{1}{2}\theta_i$. The results from such a model are qualitatively similar to those shown in this paper.

C. Steepening

Rays incident on the MLB with inclination θ_i are reflected (refracted) with inclination

$$\theta_r = -\theta_i + 2\alpha. \quad (11)$$

The change in inclination per bounce is

$$\delta\theta_r = 2\alpha \quad (12)$$

with a mean negative value of $2\langle\alpha\rangle$ [Eq. (8)]. All other statistics follow from the previous discussion (allowing for a factor 2). Though the *expected* value $\langle\delta\theta_r\rangle$ is negative, e.g., steepening (though diminishing rapidly with increasing θ_i), there is significant probability of positive $\delta\theta_r$ (flattening).

D. Deepening

Deepening is associated with the change in turning slowness $\delta\widetilde{S}$. From Snell's law

$$\widetilde{S} = S\cos\theta_r \quad (13)$$

and accordingly

$$\delta\widetilde{S}/S = \delta\cos\theta_r = \cos(-\theta_i + 2\alpha) - \cos(-\theta_i)$$
$$= 2\sin(\theta_i - \alpha)\sin\alpha \approx 2(\theta_i - \alpha)\alpha = 2\beta, \quad \beta \equiv \theta_i\alpha - \alpha^2,$$
$$(14)$$

assuming small angles. The expected value is

$$\langle\beta\rangle = \theta_i\langle\alpha\rangle - \langle\alpha^2\rangle = -\sigma^2. \quad (15)$$

The variance is

$$\langle\beta^2\rangle - \langle\beta\rangle^2 = 2\sigma^4 - \sigma^2\theta_i\langle\alpha\rangle + \sigma^2\theta_i^2. \quad (16)$$

Beneath 2 km depth, the gradient in sound slowness $S(z) = 1/C(z)$ approaches the adiabatic value

$$\gamma_a = (1/S)dS/dz = 0.0113 \text{ km}^{-1}. \quad (17)$$

Hence the turning depth $\widetilde{z}$ changes with turning slowness $\widetilde{S}(z)$ according to

$$\delta\widetilde{z} = \gamma_a^{-1}\delta\widetilde{S}/S \approx 2\gamma_a^{-1}\beta. \quad (18)$$

Remarkably, the expected value $\langle\beta\rangle = -\sigma^2$ is independent of θ_i, and this makes

FIG. 7. (Color) (a) Probability density function of slope α as a function of the incident ray inclination θ_i, scaled by rms MLB inclination σ. The green curve shows the upper termination of the illuminated α. The expected value $\langle\alpha\rangle$ increases with increasing θ_i from $-\sqrt{2/\pi}\sigma$ to 0 (red). (b) Probability density function of $\beta/\sigma^2 = \delta\cos\theta/2\sigma^2$ with an expected value of -1 (red). The maximum value of β is shown by the green curve.

$$D(\theta_i) = \int_{-\infty}^{\theta_i} p(\alpha)d\alpha = \frac{1}{2}\left[1 + \text{erf}\left(\frac{\theta_i}{\sqrt{2}\sigma}\right)\right]. \quad (6)$$

The normalization by the Gaussian CDF ensures that

$$\int_{-\infty}^{\infty} p_{ill}(\alpha|\theta_i)d\alpha = 1. \quad (7)$$

The distribution of illuminated MLB inclination is thus a clipped, normalized Gaussian (Fig. 7).

The illuminated mean and mean-square MLB inclinations are

$$\langle\alpha\rangle = -\sigma^2 p(\theta_i)/D(\theta_i), \quad \langle\alpha^2\rangle = \sigma^2 + \theta_i\langle\alpha\rangle, \quad (8)$$

and the recurrence relation is

$$\langle\alpha^n\rangle = (n-1)\sigma^2\langle\alpha^{n-2}\rangle + \theta_i^{n-1}\langle\alpha\rangle. \quad (9)$$

The variance is

$$\langle \delta \widetilde{z} \rangle = -2\gamma_a^{-1}\sigma^2 = -35 \text{ m} \qquad (19)$$

a convenient measure of deepening per bounce. Here again the large asymmetry suggests a direct reference to the PDF of β [Fig. 7(b)]:

$$p_{ill}(\beta|\theta_i) = \frac{p_{ill}(\alpha^+|\theta_i) + p_{ill}(\alpha^-|\theta_i)}{\sqrt{(\theta_i^2 - 4\beta)}}, \quad \beta < \frac{\theta_i^2}{4},$$

$$\alpha^\pm = \tfrac{1}{2}(\theta_i \pm \sqrt{\theta_i^2 - 4\beta}). \qquad (20)$$

(Care has been taken to allow for the two roots $\alpha^\pm$ to $\beta = \theta_i \alpha - \alpha^2$.) The expected $\langle \beta \rangle = -\sigma^2$ and so $\langle \widetilde{z} \rangle$ is negative (deepening), but there is a significant chance for $\beta > 0$ (raising the caustic) and for occasional $\beta \ll -\sigma^2$ (large deepening).

E. Stretching

Rays in the ocean waveguide (the ocean "Sound Channel") oscillate about the sound axis between upper and lower turning points at $z^\pm(\widetilde{S})$. Reflections at the undulating MLB lead to perturbations in turning slowness $\delta\widetilde{S}$ and turning depths $\delta\widetilde{z}^\pm$. The associated perturbations in the length R and period T of the ray loops are conveniently given in terms of the action variable $A(\widetilde{S})$ and its derivatives $A' = dA/d\widetilde{S}, A'' = d^2A/d\widetilde{S}^2$ (Appendix B). Expanding $A(\widetilde{S})$ in a Taylor series, the deepening of the lower caustic and the stretching (in range and time) of the loops per bounce are given by

$$\delta\widetilde{z}^- = (\gamma_a S)^{-1}\delta\widetilde{S}, \quad \delta R = -A''\delta\widetilde{S}, \quad \delta T = -A''\widetilde{S}\delta\widetilde{S}, \qquad (21)$$

with $\delta\widetilde{S} = S\delta\cos\theta$. The PDFs of all three variables are derivable from the distribution of $\delta\cos\theta(=2\beta)$. The bias for negative $\delta\cos\theta$ is a property of the cosine function and independent of the bias for negative $\delta\theta$ $(=\tfrac{1}{2}\delta\alpha)$ due to screening. The expected $\langle\delta\cos\theta\rangle = -2\sigma^2$ applies even if there is no screening. For positive A'', deepening is associated with stretching.

V. STATISTICS OF MULTIPLE BOUNCES

A. Reflected angle and its cosine

Long-range acoustic propagation involves multiple bounces off the MLB. Screening will lead to a mean steepening of reflected rays. Also, a growth in the variance of reflected angle θ_r will occur as the repeated bounces are essentially a random walk. The quantity of interest is the cosine of the reflected angle,

$$\cos\theta_r = 1 - \tfrac{1}{2}\theta_r^2 + \cdots. \qquad (22)$$

Therefore the mean value of the cosine will decrease as the variance of reflected angle grows. Through Snell's law this results in a decrease in turning slowness and a deepening of the lower turning point.

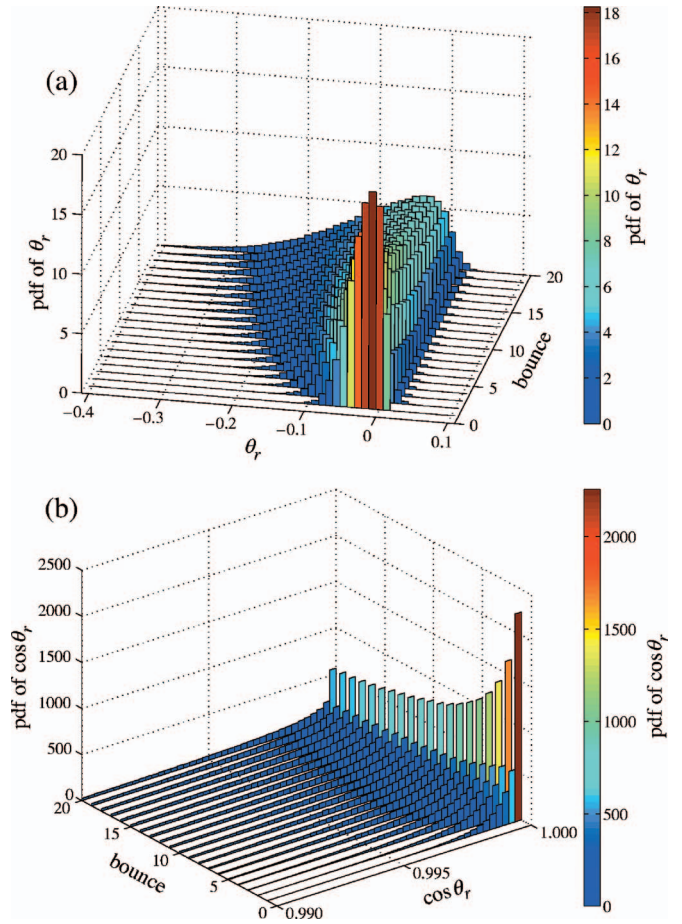
The PDF of α is a function of θ_i, and for multiple reflections, θ_i is itself a random variable as it is a sum of a series of α's. So the PDF of θ_i after N bounces is not easy to calculate analytically (Appendix C). However, it is relatively straightforward to perform a Monte Carlo simulation


FIG. 8. (Color) Probability density function for θ_r and $\cos\theta_r$ as a function of bounce for glancing initial incidence $\theta_0 = 0.0104$ (0.6°).

of the process using the distribution (5) and reflection law (11) iteratively from an initial MLB inclination θ_0 so $\theta^{(n+1)} = \theta_r^{(n)} + 2\alpha^{(n)}$ with the distribution of $\alpha^{(n)}$ a function of $\theta_r^{(n)}$. Statistics were calculated using 100 000 realizations of 20 consecutive bounces, with the variance of MLB inclination as observed, $\sigma^2 = 2 \times 10^{-4}$. Two choices are considered, $\theta_0 = 0.0104$ rad and $\theta_0 = 0.1555$ rad, representative of angles comparable to, and much larger than, σ.

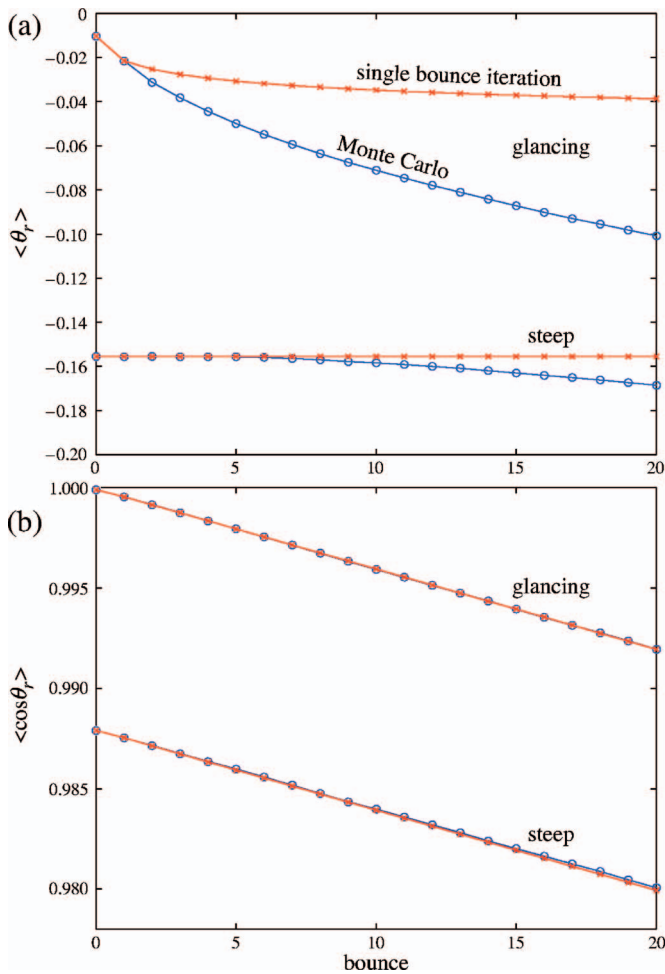
The glancing initial angle is perhaps the best to investigate first, as it will be most affected by screening, and the assumption of a reflecting MLB is most valid. Results are shown for $\theta_0 = 0.0104$ rad as a sequence of PDFs for each of 20 consecutive bounces [Fig. 8(a)]. The PDF for one bounce is the same as that derived analytically (5). As the number of bounces increases, the likelihood of large negative θ_r increases, due to screening and the increase in variance of a random walk. Because upward reflections are allowed, the PDF leaks over to positive θ_r. The mode of the PDF moves slightly toward steeper angles as the number of bounces increases. The mean reflected angle [Fig. 9(a)] steepens as a function of bounce to a value of -0.1008 rad at 20 bounces. As the mode remains relatively small, this increase in the mean is a result of the growing tail toward large negative angles. The true mean from the Monte Carlo calculation can be compared to the mean [Fig. 9(a)] implied by iterative application of the one-bounce mean (8) and the reflection


FIG. 9. (Color) Expected θ_r and $\cos \theta_r$ as a function of bounce for glancing incidence $\theta_0 = 0.0104$ (0.6°) and steep incidence $\theta_0 = 0.1555$ (8.9°). Monte Carlo confirms the linear decrease of $\langle \cos \theta_r \rangle$.

formula (11). The true mean increases more rapidly as the sequence of inclinations are serially correlated, with the distribution of each bounce depending on the value of the previous bounce.

The quantity of interest is the cosine of θ_r, which has a PDF [Fig. 8(b)] with a very strong mode at 1. This mode is an elementary property of a function of a random variable whose slope approaches zero. The mode decreases in magnitude with increasing bounces in favor of a long tail toward smaller values of the cosine. This tail is responsible for the decrease in mean cosine [Fig. 9(b)] in the presence of the still large mode at 1. The mean change in the cosine is constant and independent of incident angle for a single bounce (15), so the mean change for multiple bounces should also be constant. This theoretical result agrees nearly perfectly with the Monte Carlo calculation.

A Monte Carlo calculation with a steeper initial angle of 0.1555 rad yields PDFs different in detail, but with the same general features as that for $\theta_0 = 0.0104$ rad after 20 bounces. Growing tails are responsible for changes in mean values of the reflected angle and its cosine, while the large mode at a cosine of 1 remains. The mean reflected angle [Fig. 9(a)] remains relatively constant over the first five bounces, after which it gradually becomes steeper. As the initial angle is

much greater than rms MLB inclination σ, the PDF of α is essentially Gaussian with little screening. The iterative application of Eqs. (8) and (11) supports this interpretation as it predicts virtually no increase in reflected angle. In fact, the reflected angle does steepen because the increasing variance in θ_r eventually creates angles near zero that are affected by screening. The cosine of θ_r [Fig. 9(b)] displays the expected nearly linear decrease with a slight deviation from theory gradually setting in at large bounces. This effect is likely due to the incipient failure of the small angle approximation leading to (15).

B. Range, time, and lower turning point

Examination of the acoustic rays associated with the sequence of angles of the Monte Carlo calculations requires a characterization of the sound channel (Munk *et al.*, 1995, 2.18).[1] The initial angle of 0.0104 rad, used as an example of a glancing ray (Table I), has a total range of 1000 km after 20 bounces off a flat MLB of depth 70 m. The steep ray, initial angle 0.1555 rad, also has a total range of 1000 km.

For the glancing ray, the PDF of loop range [Fig. 10(a)] after one bounce has a mode near the initial loop range of 50.91 km. After three bounces a mode is established at 49.42 km (the shortest possible range, with angle 0.0803 rad), and a tail toward longer range begins to grow. Mean range (Fig. 11) decreases over the first 5 bounces as the mode at the shortest range is established. Growth in mean range then occurs as the tail in the PDF expands. It may, at first, seem curious that the range would shorten while θ_r grows and $\cos(\theta_r)$ decreases. This shortening is understandable as upper loop length decreases with increasing angle up to the angle of minimum loop length, while lower loop length increases monotonically as the angle steepens from zero. The PDF of total range after 20 bounces [Fig. 10(b)] has a mode at 984 km, and a long tail so that the mean total range is 991 km. Even while the mean total range for a wavy MLB is shorter than the total range for a flat MLB, the mean lower turning depth after 20 bounces of 3.56 km is deeper than the initial lower turning depth of 2.94 km. Mean total travel time is 659.88 s compared to 665.72 s for a flat MLB.

The PDF of loop time is similar to that for range because variations in sound speed relative to its absolute value are small. The PDF of lower turning depth is similar to that of $\cos \theta_r$ through Snells law, and because the abyssal gradient of sound speed is nearly uniform. To save space the PDFs of time and lower turning depth are omitted.

The mean range for the steep ray increases monotonically with bounce (Fig. 11). The result is that the total range for the steep ray (1033 km) is more than 40 km longer than that for the glancing ray, with a suitably longer total travel time (686.63 s). The lower turning depth increases from an initial value of 3.88 to a mean of 4.48 km after 20 bounces. So the steep ray has a similar deepening to that of the glancing ray, as expected from the result of the mean change in cosine, but this lower turning point is significantly farther from the source.

TABLE I. Specifications for rays along the time fronts in Fig. 12. Listed are turning slowness $\widetilde{S}$, inclination at the MLB θ_{MLB}, axial inclination θ_{axial}, loop range R, loop time T, upper turning point $\widetilde{z}^+$, lower turning point $\widetilde{z}^-$, and total travel time t. Points along the refracted, glancing MLB reflected, and steep MLB reflected time fronts are listed. The specifications in column C include the reflected glancing and steep rays whose statistics are discussed in the text.

VI. TIME FRONTS

An emitted acoustic pulse is received at a distant vertical hydrophone array as a series of discrete pulses, each represented by a "time front." The configuration of the time fronts is a function of the field of sound speed; perturbations in sound speed produce changes in the time front. The goal is to interpret the observed perturbations in the time fronts in terms of the ocean processes that cause them.

A. Refracted ray, no mixed layer

Figure 12 illustrates the properties of the canonical sound channel for an axial source and a vertical receiver array at 1000 km. Consider the time fronts +39 and +40, associated with 20 upper turning points (20 bounces) and with 19 and 20 LTPs, respectively, joined at the $+39\frac{1}{2}$ caustic.

The upper panels refer to the classical purely refracted case (no mixed layer). The left panel shows the first and last of the 20 complete ray loops, generated within a narrow beam of source angles extending from 11.1° to 9.6° (Table I). For ray **A**, the steepest, longest and deepest, the 20th loop

extends well beyond 1000 km, and has an UTP at the receiving array. The focus is on ray **C** with a LTP (and hence caustic) at the receiving array.

Time front +40 is generated by varying the source angle from 10.35° (point **C**) to 9.57° (point **E**), or the associated turning slowness from 0.6558 to 0.6574 s/km. For the axial point **D**,

$$r_0 = 1000 \text{ km} = NR(\widetilde{S}_0),$$

which yields

$$\widetilde{S}_0 = 0.6569 \text{ km}, \quad t_0 = NT(\widetilde{S}_0) = 665.873 \text{ s}. \tag{23}$$

For a chosen $\widetilde{S}$, the range and time for $N=20$ complete ray loops is

$$r = NR(\widetilde{S}), \quad t = NT(\widetilde{S}). \tag{24}$$

Suppose r exceeds r_0 by some fractional loop pR according to

$$r - r_0 = NR(\widetilde{S}) - NR(\widetilde{S}_0) = pR(S^*, \widetilde{S}), \tag{25}$$

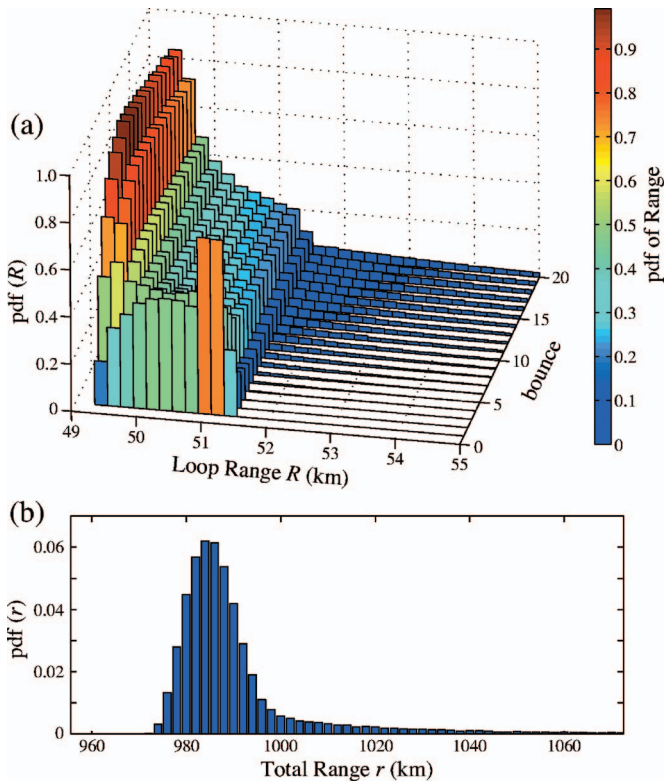
where $S^*(z)$ is the slowness at the intersection of the ray with r_0. Equation (24) is solved for


FIG. 10. (Color) (top) PDF of loop range R as a function of bounce for glancing incidence. (bottom) PDF of total range r from axis after 20 bounces to the lower turning point.

$$z^* = z(S^*), \quad S^* \equiv S^*(\widetilde{S}). \qquad (26)$$

Similarly

$$t - t_0 = NT(\widetilde{S}) - NT(\widetilde{S}_0) \qquad (27)$$

is the delay in axial crossing of ray $\widetilde{S}$ versus that of ray $\widetilde{S}_0$. Ray $\widetilde{S}$ crosses the receiver array at time t^*, with

$$t - t^* = pT(S^*, \widetilde{S}), \qquad (28)$$

so that
FIG. 11. Expected loop range as a function of bounce for glancing and steep incidence. Initial values are shown to the left.

$$t^* - t_0 = NT(\widetilde{S}) - NT(\widetilde{S}_0) - pT(\widetilde{S}). \qquad (29)$$

Thus each chosen $\widetilde{S}$ generates a point z^*, t^* of the time front in z,t space. An equivalent procedure with point **B** for reference yields time front +39. The solutions meet at the caustic ray **C** and are thus reconciled to yield the $39\frac{1}{2}$ V-pattern.

B. Mixed layer, plane MLB

The lower panels of Fig. 12 and Table I are for a mixed layer with a base taken (quite arbitrarily) at 70 m. There are now three pairs of time fronts with LTPs at 1000 km. Points **A**, **B** of the refracted time front lie above this depth. The refracted time front now starts with point **X**, corresponding to the ray tangent to the MLB. The left wing of the time fronts is accordingly clipped. Starting from the same point **X** is the reflected pair of time fronts **X**, **C′**, **D′**, **E′**. A third pair is designated **A″**, **B″**, **C″**, **D″**, **E″** in Fig. 12. All three caustics, **C**, **C′**, **C″** are at the receiver range r_0. The axial inclinations are 10.3°, 10.6°, and 13.8°; incident angles at the MLB are 0.6°, 8.9°, for the reflected rays, while the refracted ray turns below the MLB.

The refracted caustic is at a depth of 2.86 km; the glancing reflected caustic is only slightly deeper at 2.94 km, the steep reflected caustic is at 3.88 km. The refracted and glancing reflected caustics arrive within 3 ms, but the steep reflected arrives 0.16 s earlier. The steep reflected time front arrives earlier with increasing angle (Table I), as does the refracted time front. Interestingly, the glancing time front arrives later as angle increases, thus the progression through points in Fig. 12 is **X**, **C′**, **D′**, **E′**, **E″**, **D″**, **C″**, **B″**, **A″**.

The preceding discussion is for a mixed layer depth of 70 m, characteristic of early winter. Figure 13 shows the seasonal migration of the $+39\frac{1}{2}$ caustic. The trifurcation commences for a mixed layer of 7.2 m; for a MLB at 92 m the leading wing disappears (points **X** and **C′** in the previous figure overlap) and the caustic vanishes. The steep branch continues but the MLB becomes an increasingly weak reflector, and surface reflection (here neglected) takes over.

Thus the mixed layer formation is accompanied by a severe modification in the topology of the time fronts. The numbers cited are for purposes of discussion. The important consideration is that any seasonal variation of the depth of the lower caustic is of the same order, but quite different in origin, of the additional deepening associated with MLB waviness.

C. Mixed layer, wavy MLB

1. Single initial angle

Transmissions from launches at a single given incident angle, bouncing off a wavy MLB, generate an arrival pattern that is conveniently described by a joint PDF in time and depth. The arrival PDF for the glancing ray $\theta_0 = 0.0104$ is created using the Monte Carlo simulation of multiple bounces and summing individual arrivals after 20 bounces in bins 0.01 s in time and 0.05 km in depth [Fig. 14(a)]. For a flat MLB, the glancing ray arrives at point $C′$ on the range-independent time front. The wavy MLB causes most of the

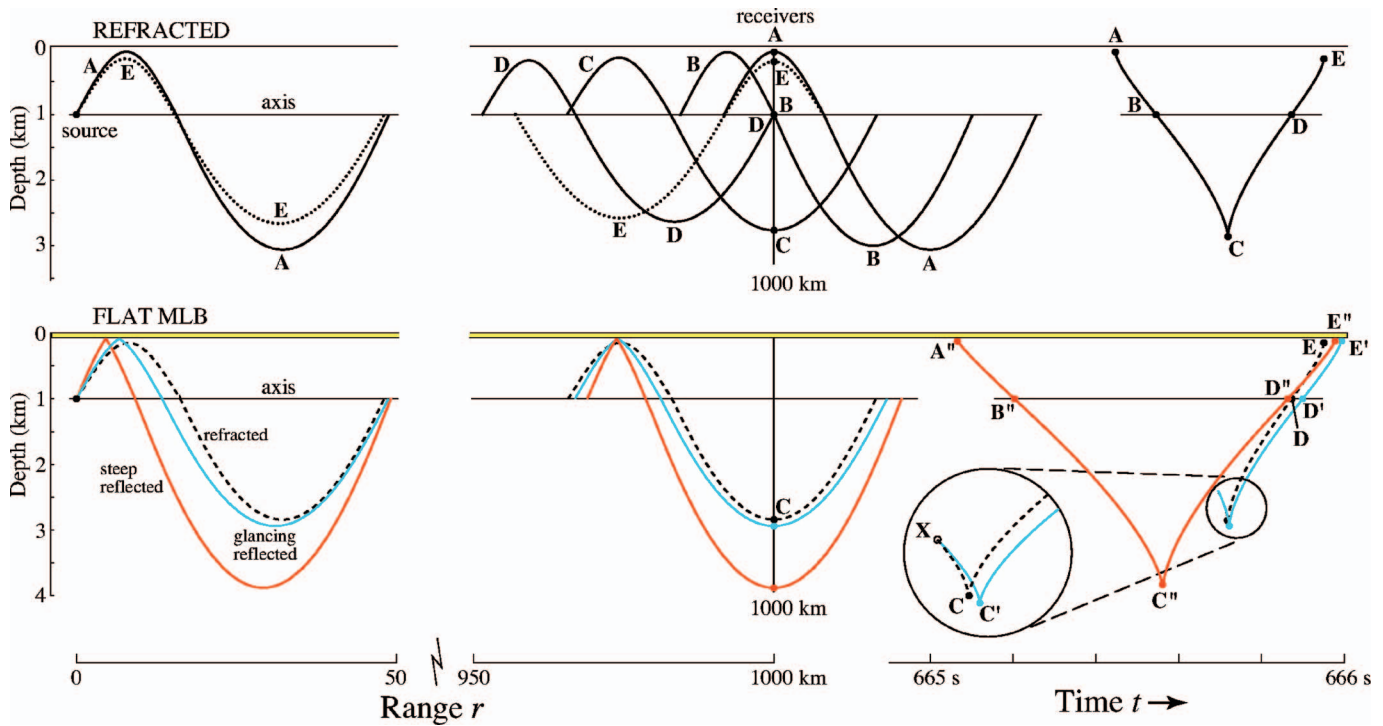
D. L. Rudnick and W. H. Munk: Scattering from mixed layer into shadow


FIG. 12. (Color) Multiple time fronts from a mixed layer. The upper panels correspond to a canonical sound speed profile without mixed layer, the lower panels to a mixed layer of 70 m depth (thin yellow strip). **A** to **E** defines a narrow beam of launch angles; the first and last (20th) complete ray loops are shown, resulting in the time front to the right (black). In the presence of the mixed layer the left wing is clipped, resulting in a refracted time front **X** to **E** (black dashed). Two new pairs of time fronts (blue and red) are associated with reflections from the MLB.

arrivals to lay along the range-independent time front, just as in an experiment with a flat MLB and a range of initial angles. The spreading along the time front occurs across the
FIG. 13. Caustic migration for a 1000 km transmission through a canonical sound profile. R/R marks the location of the lower caustics ID $=-38\frac{1}{2}$, $+39\frac{1}{2}, -40\frac{1}{2}$ for (upper and lower) *refracted* turning points; they are preceded by surface *reflected* (S/R) rays (to the left, not shown) and followed by the axial finale (far to the right, not shown). The remaining plot deals with the $39\frac{1}{2}$ caustic (solid points). MLB/R marks the lower caustics of $+39\frac{1}{2}$ rays reflected at a MLB at stated depths. These lead to a triplication of $+39\frac{1}{2}$ arrivals starting with MLB at 7 m and ending with MLB$=92$ m (the upper turning point of the $+39\frac{1}{2}$ RR rays). The mixed-layer formation is associated with an overall deepening of the lower caustic from 2.9 km (R/R) to 3.9 km (MLB/R), and decrease in travel time by 0.3 s.

folds in the front caused by reflection off the MLB and refraction at depth. A wavy MLB also causes the region between the time fronts to be filled with arrivals, but spreading in the direction *across* the time front is much weaker than that *along* the time front. This asymmetry in spreading is a fundamental result of the model and related to the remarkable robustness of rays in a scattering environment. Arrivals appear at and below the lower turning point C'' for the steep ray. These arrivals well beneath the range-independent time front have similarities to the observations of Fig. 1. Also worth noting is the relative lack of arrivals along the extension C' to X of the time front to zero incident angle. Apparently these arrivals are not likely to be created by multiple bounces off the MLB. Out of the 100 000 transmissions in the Monte Carlo simulation, 95% are received at 1000-km range after exactly 20 bounces off the MLB. The remaining arrivals have a number of MLB bounces different from 20 and are not included in the PDF; most of them have anomalously long ranges (less than 20 bounces) and especially deep lower turning points.

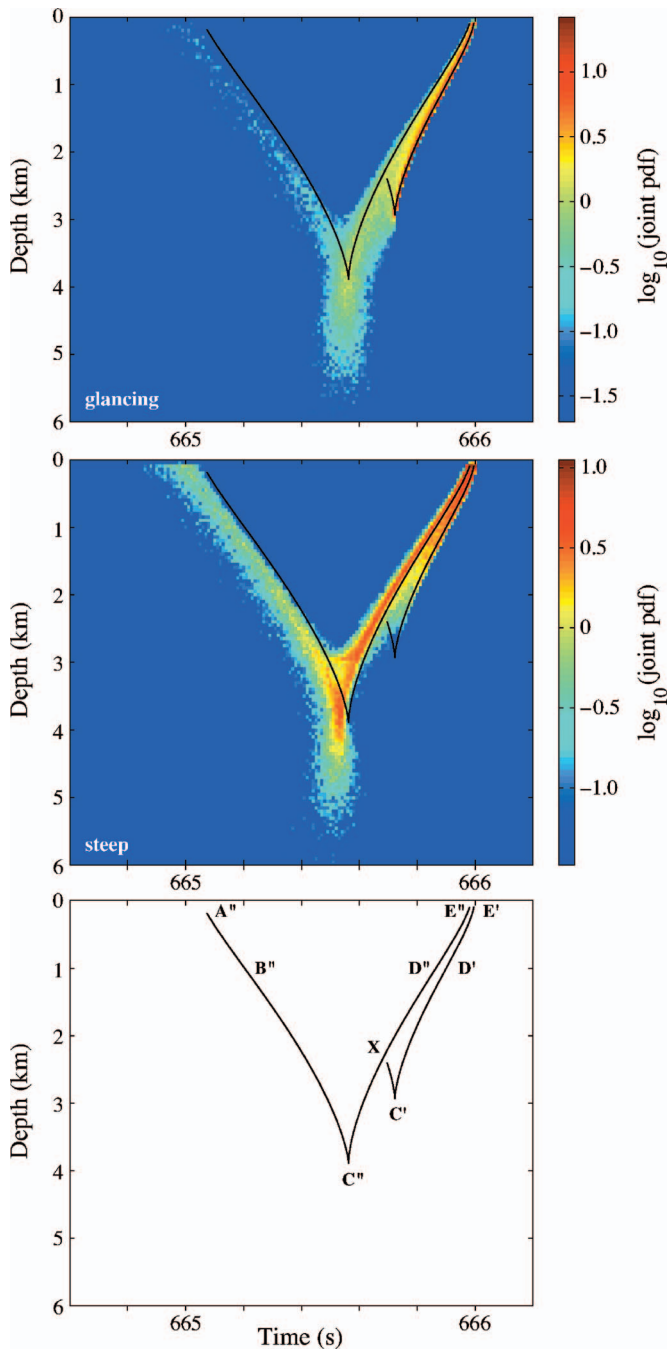
The arrival PDF for the steep ray ($\theta_0 = 0.1555$) is calculated as for the glancing ray [Fig. 14(b)]. The steep ray arrives at C'' for a flat MLB. The time front is filled from E' to D' but not to the lower turning point C' of the glancing ray. The time front has a strong mode between E'' and C'', but some arrivals occur well beneath C''. The scattered arrivals occur *earlier* than for the flat MLB. In each case, the deep arrivals are associated with the tails in the distributions of $\cos \theta_r$. This pair of simulations presents the interesting asymmetry that the initial glancing ray produces arrivals at the lower turning point C'' of the steep ray, but the initial steep


FIG. 14. (Color) Joint PDF of arrivals as a function of time and depth. PDFs are calculated from transmissions starting at glancing incidence (top) and steep incidence (middle). The black line is the range independent time front, with letters indicating certain points (as in Fig. 12) in the bottom panel. Note the penetration of arrivals below the range independent caustic.

FIG. 15. (Color) Joint PDF of arrivals as a function of time and depth. The range of initial incident angle is wide enough to include all rays that arrive on the shown branch of the time front. Three simulations are displayed: 1000-km range (top), 500-km range (middle), and 1000-km range with weak MLB slope variance of one-quarter the observed (bottom). Compare across-front scatter and penetration below the lower turning point in the three simulations.

ray does not produce arrivals at the lower turning point C' of the glancing ray. Most (58%) of the 100 000 transmissions are included in the PDF as they have exactly 20 bounces off the MLB, with the vast majority (92%) of the remainder having fewer bounces.

The simulations with fixed initial angles may be considered "stochastic Green's functions." For the flat MLB, arrivals are at single points (C' and C'', respectively); scattering from the wavy MLB spreads these points along defined time fronts. There is no explicit notion of ray intensity or attenuation in this very simple model. So the PDF is properly in-

terpreted as a measure of the likelihood of a reception, although the PDF bears a resemblance to observations of intensity. This resemblance suggests that observed intensity is a strong function of the density of arrivals.

D. Wide range of initial angles

Simulations using a wide range of initial angles are most comparable to observations using a nondirectional source (Fig. 15). Three simulations are done at 1000- and 500-km

range for $\sigma^2 = 2 \times 10^{-4}$, and at 1000-km range for $\sigma^2 = \frac{1}{2} \times 10^{-4}$. A range of initial angles from 0 to 0.4, by steps of 0.001, are used, and at each step 500 realizations are done. The steepest initial angle is chosen to be large enough that all of the transmissions are past the receiver before the 20th (for 1000-km range) or 10th (for 500-km range) bounce, so none appear in the PDF; using steeper initial angles up to $\pi/2$ would add nothing to the following results. In the interest of simplicity, the model sound channel is taken to be infinitely deep, so bottom effects are not considered. Whether a transmission is included in the arrival PDF is determined only by the number of bounces off the MLB it has experienced, not whether it has encountered the bottom.

For the 1000-km range, the arrival pattern is something of a superposition of the patterns from the glancing and steep rays [Fig. 15(a)]. Features in this all-angle PDF are similar to those for the glancing and steep rays, suggesting again the influence of along-time-front scattering. If the effect of a wavy MLB is important in the ocean, an arrival pattern similar to this one should be observed.

At 500-km range, the most obvious difference is the reduction in across-time-front scatter [Fig. 15(b)]. Penetration of arrivals beneath the lower turning point of the range-independent ray is only marginally deeper at the 1000-km than at 500-km range, suggesting that penetration is a relatively weak function of range. The general features of the 1000- and 500-km simulations may be compared to observations to address the plausibility of the scattering processes in the simulation.

The final simulation is at the 1000-km range, but with weak MLB slope variance of one-quarter the observed value. Across-time-front scatter and penetration beneath the lower turning point are both reduced compared to the full-strength simulation. The implication is that penetration into the shadow zone is a strong function of MLB slope variance.

E. Robustness in a scattering environment

In the early days of ocean acoustic tomography, the discovery that time fronts maintained their integrity in a scattering environment came as a pleasant surprise (Spiesberger *et al.* 1980; Munk *et al.*, 1995, p. 362). It should not have been; it is a manifestation of the principle discovered by Fermat in 1655 that between fixed source and receiver a ray path is defined by a parabolic extremum in travel time, so that travel time does not vary to first order with perturbation of the path.

The time fronts in Fig. 14 were constructed by two quite distinct methods: the color coding designates the density of "hits" at the 1000-km range in 100 000 Monte Carlo realization of the wavy MLB, using one (or many) fixed launch angles. The black lines were generated for a range-independent ocean by varying the launch angles and deriving the time and depth at the 1000-km range in accordance with Eqs. (24) to (29). There is a striking resemblance between the two time fronts so derived (the small but systematic displacement is of course crucial).

There have been extensive discussions of the stability of the early arrivals. An important variable is the second action
FIG. 16. The stability parameter $\alpha_B(\widetilde{S})$. For the canonical profile (with no mixed layer) the upper stability curve continues to the left until surface reflection, with the points **A** to **E** corresponding to the points shown in Fig. 12 on the pair of time fronts +39 and +40 emerging from the lower caustic $+39\frac{1}{2}$. Point **X** has an upper turning point at $z = -70$ m. For a surface mixed layer of 70 m thickness, the $+39\frac{1}{2}$ pair of refracted time fronts is shortened to **X** to **E**. Two new pairs of $+39\frac{1}{2}$ time-fronts lie along a second branch of $\alpha_B(\widetilde{S})$: **X**, **C′**, **D′**, **E′** for near-grazing incidence on the MLB, and **A″** to **E″** for steep incidence.

derivative A'' (for positive A'' the scattered signal arrives early). Brown *et al.* (2005) discuss the ray-based "stability parameter" α_B and the mode-based "waveguide invariant" β_B:

$$\alpha_B(\widetilde{S}) = \frac{A(\widetilde{S})A''(\widetilde{S})}{A'^2(\widetilde{S})}, \quad \beta_B = \frac{ds_{\text{gr}}}{ds_{\text{ph}}} \tag{30}$$

and show them to be equivalent in asymptotic mode theory[2] (adding the subscript B to distinguish these from the variables introduced earlier). This parameter plays a central role in long-range propagation through a range-independent environment with weak range-dependent scatterers (see a recent volume edited by Kuperman and D'Spain 2002). The group slowness s_{gr} is proportional to t, and the phase slowness $s_{\text{ph}} = \widetilde{S}$ is closely related to the vertical source angle, so $\beta \sim dt/d\theta \rightarrow 0$ indicates a focusing in time of vertical aperture. Figure 16 shows the stability parameter for a canonical ocean with a reflecting MLB at 70 m. The three branches correspond to the trifurcation. The zero at the termination of α_B is related to the crescendo in the SOFAR finale. The zero crossing of the reflection branch may indicate a prominent observable. (Cusps are related to $dt/dz \rightarrow 0$.)

The stability parameter helps one to understand some of the features of the arrival PDFs (Figs. 14 and 15). The density of arrivals should increase with decreasing $|\alpha_B|$. The lack of arrivals near the beginning of the time front (points **X**, **C′**) is thus related to the large value of $|\alpha_B|$ there, and the high density of arrivals near the MLB (points **E′**, **E″**) is a region of small $|\alpha_B|$. Positive α_B implies anomalously early arrivals

as seen in the left branch of the steep time front (points **A″**, **B″**, **C″**). A more complete investigation of α_B is warranted, but is beyond the ability of the authors.

VII. DISCUSSION

The incentive for this study was provided by recent profiling of the upper ocean. Three sections in the North East Pacific further emphasized the sharp transition at the base of the wind-mixed layer. The layer thickness varies greatly between winter and summer, and its base is distorted by internal waves.

The properties of the MLB play a crucial role in long-range acoustic propagation; in particular, its waviness is associated with a random walk toward deepening turning points of rays in the ocean sound channel. This may account for the long-known experience that acoustic signals are received at depths well exceeding those expected to be insonified (Fig. 1). Screening (incident rays insonifying only part of a wavy boundary) tends to steepen rays. However screening is not essential to the deepening of scattered rays, which is determined by variance in MLB slope and the resulting random walk in reflected angle. The increase in $\langle \cos \theta_r \rangle$ is nearly the same for both glancing and steep rays, whereas screening is negligible for initial angles much greater than the root-mean-square MLB slope (Fig. 9).

Two statistics characterize the deepening in fundamentally different ways. The random walk in reflected angle causes a mean deepening per bounce of the lower turning point by 35 m using observed MLB slope variance and abyssal adiabatic sound speed gradient. So after 20 bounces off the MLB the mean deepening is 700 m. The average that produces this result is over all rays, regardless of their total range. A distinct statistic is the deepening at the lower turning point for given total range (Figs. 14 and 15). In contrast to the deepening for a given number of bounces, the deepening at a given range is a weak function of range and a strong function of MLB slope variance. An analytical treatment of the deepening at given range has not yet been achieved, however the Monte Carlo results seem solid.

Many simplifying assumptions have been made: a ray-optical formulation with a reflecting MLB, a high-wave-number cutoff of the internal wave spectrum, some properties of acoustic screening by the steep internal wave slopes, etc. The shadow penetration of later arrivals with upper turning points below the MLB calls for a more general random walk process, and is presumably associated with the waviness of iso-velocity contours near the upper turning points.

Surface reflections determine the very start of an incoming SOFAR gram, followed by features controlled by mixed layer parameters. Both boundaries, surface and MLB, lead to a trifurcation of the incoming ray-fronts (Dzieciuch *et al.*, 2004). Together they determine the complex structure; the SOFAR overture remains to be composed.

Understanding the penetration into the wave shadow in terms of a simple model provided the focus for this paper. But the motivation is not only for solving an old puzzle. We anticipate monitoring upper ocean processes by abyssal acoustic arrays. This includes not only the profiles of sound speed (temperature) and velocity by the method of ocean acoustic tomography, but also the waxing and waning of the mixed layer, frontal formation, and internal wave intensity.

The last few decades have seen remarkable progress by remote sensing of the ocean from above. But there is much to be learned by "viewing" the ocean from below.

APPENDIX A: TRANSFORMATION OF GM SPECTRUM

The mean-square of vertical displacement is written (Munk, 1981)

$$\langle \zeta^2 \rangle = \sum_j \int_0^{-\infty} d\omega \, F_\zeta(\omega, j),$$

$$F_\zeta(\omega, j) = b^2 \frac{N_0}{N} \frac{\omega^2 - f^2}{\omega^2} E(\omega, j),$$

$$E(\omega, j) = 2\pi^{-1} f \omega^{-1} (\omega^2 - f^2)^{-1/2} (j^2 + J^{*2})^{-1} JE, \quad (A1)$$

where $b = 1300$ m, $N_0 = 3$ cph, $f = \frac{1}{24}$ cph, $E = 6.3 \times 10^{-5}$, and $J = 2.1$ (Garrett and Munk, 1972a). Performing the summation and integration yields

$$\langle \zeta^2 \rangle = \tfrac{1}{2} b^2 E (N/N_0)^{-1} = 53 (N/N_0) \text{m}^2 \quad (A2)$$

or 7.3 m rms near the surface.

Going from vertical mode j to horizontal wave number κ:

$$\kappa = \sqrt{\kappa_1^2 + \kappa_2^2} = \pi b^{-1} \left(\frac{\omega^2 - f^2}{N_0^2 - \omega^2} \right)^{1/2} j \quad (A3)$$

yields

$$F_\zeta(\omega, \kappa) = F_\zeta(\omega, j) dj/d\kappa = \frac{2b^3 E}{\pi^2} f (N_0^2 - \omega^2)^{1/2} \omega^{-3} \frac{J}{j^2 + j^{*2}}. \quad (A4)$$

Substituting for j from Eq. (A2), assuming $j \gg j^* = 3$,

$$F_\zeta(\omega, \kappa) = 2bEJI(\omega)\kappa^{-2}, \quad I(\omega) = \frac{f(\omega^2 - f^2)}{(N_0^2 - \omega^2)^{1/2} \omega^3}. \quad (A5)$$

Integrating over frequency,

$$F_\zeta(\kappa) = \int_f^{N_0} F_\zeta(\omega, \kappa) d\omega = 2bEJ\Omega\kappa^{-2}, \quad (A6)$$

where

$$\Omega \equiv \int_f^{N_0} I(\omega) d\omega = \frac{f}{2N_0} \left[2 \log \frac{2N_0}{f} - 1 \right]$$

for $f \ll N_0$. $\Omega = 0.062$ for $f/N_0 = 1/72$. Assuming horizontal isotropy

$$F_\zeta(\kappa) d\kappa = F_\zeta(\kappa_1, \kappa_2) d\kappa_1 \, d\kappa_2 = F_\zeta(\kappa_1, \kappa_2) \kappa \, d\kappa \, d\theta$$
$$= 2\pi F_\zeta(\kappa_1, \kappa_2) \kappa \, d\kappa,$$

$$F_\zeta(\kappa_1, \kappa_2) = \frac{1}{2\pi\kappa} F_\zeta(\kappa) = \pi^{-1} bEJ\Omega\kappa^{-3}. \tag{A7}$$

Note that $\int_{-\infty}^{\infty} d\kappa_2 \kappa^{-3} = \int_{-\infty}^{\infty} d\kappa_2 (\kappa_1^2 + \kappa_2^2)^{-3/2} = 2\kappa_1^{-2}$ yields the *towed* spectrum

$$F'_\zeta(\kappa_1) = \int_{-\infty}^{\infty} d\kappa_2\, F_\zeta(\kappa_1, \kappa_2) = 2\pi^{-1} bEJ\Omega\kappa_1^{-2} \tag{A8}$$

for $-\infty < \kappa_1 < +\infty$. The *one-dimensional* spectrum is $F_\zeta(\kappa_1) = F'_\zeta(\kappa_1) + F'_\zeta(-\kappa_1) = 2F'_\zeta(\kappa_1)$ with $0 < \kappa_1 < \infty$. Then

$$\langle\zeta^2\rangle = \int_{\kappa_1^*}^{\infty} d\kappa\, F_\zeta(\kappa_1), \quad F_\zeta(\kappa_1) = K(\kappa_1^*)^{-2},$$

$$K = 4\pi^{-1} bEJ\Omega = 0.0136 \text{ m},$$

$$\kappa_1^* = 8\pi^{-1} J\Omega b^{-1} = 2.55 \times 10^{-4} \text{ m}^{-1}, \tag{A9}$$

where the cut-off κ_1^* has been so chosen that $\langle\zeta^2\rangle = K/\kappa_1^* = \frac{1}{2}b^2E = 53 \text{ m}^2$ in agreement with Eq. (A2).

The associated one-dimensional slope spectrum is

$$F_m(\kappa_1) = \kappa_1^2 F_\zeta(\kappa_1) = 4\pi^{-1} bEJ\Omega \text{ rad}^2/\text{rpm}. \tag{A10}$$

Finally going from radians to cycles per meters, $\kappa_1 = 2\pi\tilde{\kappa}_1$,

$$F_m(\tilde{\kappa}_1) = \frac{d\kappa_1}{d\tilde{\kappa}_1} F_m(\kappa_1) = 8bEJ\Omega = 0.086 \text{ rad}^2/\text{cpm}, \tag{A11}$$

compared to 0.02 rad^2/cpm measured.

APPENDIX B: THE ACTION VARIABLE $A(\tilde{S})$

The action variable is defined by

$$A(\tilde{S}) = 2\int_{\tilde{z}^-}^{\tilde{z}^+} dz\sqrt{S^2(z) - \tilde{S}^2}. \tag{B1}$$

For a given sound profile $S(z)$, A is a function of the ray variable $\tilde{S}$. Write A' for $dA/d\tilde{S}$, etc. It can be shown that (Munk *et al.*, 1995)

$$R = -A', \quad R' = -A'',$$

$$T = A + R\tilde{S}, \quad T' = -\tilde{S}A'', \quad T'' \approx -A''. \tag{B2}$$

Consider *partial* loops, from their axial crossing to some depth z between axis and turning points. These can be derived from the partial action

$$pA(S, \tilde{S}) = \int_{z_{ax}}^{z} dz\sqrt{S^2(z) - \tilde{S}^2} \tag{B3}$$

according to

$$pR = -(pA)', \quad pT = pA + \tilde{S}pR. \tag{B4}$$

APPENDIX C: PDF FOR MULTIPLE BOUNCES

It is possible to calculate the joint PDF of inclinations of the MLB from multiple bounces. First consider two bounces. The PDF of MLB inclination α_1 for the first bounce is

$$f(\alpha_1) = \begin{cases} \dfrac{p(\alpha_1)}{D(\theta_0)}, & \alpha_1 < \theta_0 \\[2mm] 0, & \alpha_1 \geq \theta_0, \end{cases} \tag{C1}$$

where θ_0 is the inclination of the incident ray. Note that θ_0 is not a random variable. The conditional PDF of the MLB inclination α_2 for the second bounce given the first MLB inclination α_1 is

$$f(\alpha_2|\alpha_1) = \begin{cases} \dfrac{p(\alpha_2)}{D(\theta_0 - 2\alpha_1)}, & \alpha_2 < \theta_0 - 2\alpha_1 \\[2mm] 0, & \alpha_2 \geq \theta_0 - 2\alpha_1, \end{cases} \tag{C2}$$

where the fact has been used that the first reflection will arrive for the second bounce with an incident angle of $\theta_0 - 2\alpha_1$. Given these distributions, the joint distribution of α_1 and α_2 is (Papoulis, 1991)

$$f(\alpha_1, \alpha_2) = f(\alpha_2|\alpha_1)f(\alpha_1). \tag{C3}$$

The resulting PDF is a normalized joint Gaussian with sharp cutoffs defined by $\alpha_1 = \theta_0$ and $\alpha_2 = \theta_0 - 2\alpha_1$.

The joint PDF of the α's for N bounces can be written as

$$f(\alpha_1, \alpha_2, \ldots, \alpha_N)$$
$$= f(\alpha_N|\alpha_{N-1}, \alpha_{N-2}, \ldots, \alpha_1) \ldots f(\alpha_2|\alpha_1)f(\alpha_1) \tag{C4}$$

where, for $N \geq M \geq 2$,

$$f(\alpha_M|\alpha_{M-1}, \alpha_{M-2}, \ldots, \alpha_1)$$
$$= \begin{cases} \dfrac{p(\alpha_M)}{D\left(\theta_0 - 2\sum\limits_{j=1}^{M-1}\alpha_j\right)}, & \alpha_M < \theta_0 - 2\sum\limits_{j=1}^{M-1}\alpha_j \\[5mm] 0, & \alpha_M \geq \theta_0 - 2\sum\limits_{j=1}^{M-1}\alpha_j. \end{cases} \tag{C5}$$

Of interest is the PDF of the sum of the α's,

$$\gamma = \sum_{j=1}^{N} \alpha_j, \tag{C6}$$

which can, in principle, be calculated by making a substitution like

$$\alpha_N = \gamma - \sum_{j=1}^{N-1} \alpha_j \tag{C7}$$

into Eq. (C4) and then integrating off all the α_j's. Because γ is a sum of random variables, its PDF will approach a normal distribution as N approaches infinity. But the integration of Eq. (C4) does not appear to be analytically tractable.

---

[1]Here the exact relation (Appendices (B1)–(B4)) is used rather than the perturbation expansion (21). Referring to Munk *et al.* (1995) 44-47 and 106-114, in Eq. (2.18.24) replace $\mp$ by $\pm$, and do *not* set $\tilde{S}/S_A = 1$. Action for a reflecting upper boundary is derived in Dzieciuch *et al.* (2004) appendix.

Measurements of temporal coherence of sound transmissions through shallow water

T. C. Yang[a)]

Naval Research Laboratory, Washington, DC 20375

In this paper we report the measurements of temporal coherence of acoustic signals propagating through shallow water using data from three experiments in three different parts of the world, with sound speed standard deviation (STD) varying from 0.3 to 5 m/s near the layer depth. Temporal coherence is estimated from the autocorrelations of broadband channel impulse functions, the latter are deduced from broadband signals transmitted through the ocean during the experiments. The measurements covered three frequency bands: low frequencies below 1.2 kHz, midfrequencies between 2 and 5 kHz, and high frequencies between 18 and 22 kHz. The source-receiver range covers 3, 5, 10, and 42 km. The signal coherence-time is defined and deduced from the data. Motivated by previous theoretical work in deep water on the signal coherence-time as a function of the signal frequency, the source-receiver range, and sound speed STD, a similar but empirical analysis is applied to the measured data in shallow water. While the range dependence agrees with the theory, the data exhibit a different dependence on the signal frequency than the theoretical prediction for deep water. [DOI: 10.1121/1.2345910]

I. INTRODUCTION

The ocean is a dynamic (time varying/random) medium. As a result, acoustic signals propagating through the ocean fluctuate with time. The rate of the signal fluctuation is often described by the signal temporal coherence (i.e., the autocorrelation of the signal normalized by the average signal energy) that measures in a statistical sense the rate of decrease of the signal coherence. The higher the signal fluctuation, the faster the temporal coherence decreases with time. The signal coherence-time is defined as the time by which the signal becomes "uncorrelated" (as when the temporal coherence drops to $1/e$).

Knowing the signal coherence-time is useful for many practical applications. For example, for the detection and localization of narrow band acoustic signals, the signal coherence-time determines the maximum time the signal can be integrated (before losing coherence), which, in turn, determines the maximum temporal processing gain. For matched field processing, the autocorrelation time between the initial field (used as the replica field) and the data field determines for how long the replica field can be used. For adaptive (temporal) signal processing, such as an adaptive channel equalizer in underwater acoustic communications, the rate of signal adaptation is controlled by the temporal stability of the signal or the signal coherence-time.

The practical need has prompted many experimental and theoretical studies of the temporal coherence of acoustic signals. Many experimental works reported in the literature were concerned with low frequency signals propagated to long ranges in deep oceans. Spindel *et al.*[1] and Clark *et al.*[2] focused on signal propagation at 406 Hz up to 250 km.

Williams[3] and Williams *et al.*[4] studied signal propagation at 400 Hz up to 1200 km. Georges *et al.*[5] and Birdsall *et al.*[6] investigated 57 Hz signal propagation to thousands of kilometers. Fitzgerald *et al.*[7] focused on very low frequency (10 Hz) signals. Dyer *et al.*[8] studied a band of frequencies (20–200 Hz) in the Marginal Ice Zone. The measurement results from these experiments can be expressed in terms of the signal phase rate, which is the inverse of the signal coherence-time, as discussed later. Temporal coherence was modeled theoretically using theories of signal propagations in a random medium. Earlier work calculated the signal phase rate using the Rytov approximation.[9] The emphasis was on the influence of internal waves in the deep ocean using the Garrett-Munk internal wave model.[10] The model predicted that the signal coherence-time is proportional to the inverse first power of frequency, inverse square-root power of range, and inversely proportional to the amplitude of the internal waves or the sound speed standard deviation (STD).

In contrast to the abundant work in deep water, there were few measurements on the temporal coherence of acoustic signals propagating in shallow water until recently. Using the ADVENT99 data collected in the Strait of Sicily, Nielsen *et al.* reported snapshot measurements of temporal coherence using linear frequency modulated (LFM) signals.[11] From the same data, using multitone signals, Yang *et al.* reported the temporal coherence of the acoustic signals using matched-field correlation of data fields.[12,13] By decomposing the data into mode space, they also measured the temporal coherence of individual (low) order modes. Both the LFM and multitone showed a signal coherence-time on the order of 20–200 min at frequencies below 1 kHz. Headrick *et al.* deduced the mode correlation from SWARM 95 data received on the WHOI vertical array at a range of 33 km.[14] Rouseff *et al.* measured and modeled the modal temporal coherence us-

[a)]Electronic mail: yang@wave.nrl.navy.mil

ing the data received on the NRL array at a range of 42 km.[15] Mignerey *et al.* reported a significant variation of the matched-field correlation of low frequency signals in the South China Sea, depending very much on the presence or absence of the solitary internal waves.[16] Badiey *et al.* measured the temporal coherence of acoustic signals in very shallow (~15 m) regions.[17]

Given the recent interest on signal propagation in shallow water, and the broadening of interest from low to high frequencies (such as for acoustic communications), the need exists for a systematic measurement of the temporal coherence of signals propagated through shallow waters to determine its relationship to the oceanographic environment. We report in this paper experimental measurements of temporal coherence in three different shallow water areas:[18] Sicily Strait in the Mediterranean, coastal water off New England, and coastal water off New Jersey, covering a frequency range from 200 Hz to 22 kHz and a propagation range from 3–4 km to 40 km. Issues critical to the signal coherence measurement are addressed.

From the measured signal coherence, one can estimate the signal coherence-time as defined later. A question of interest is what is the frequency and range dependence of the signal coherence-time in shallow water (as compared with deep water). For this study, an empirical analysis is used, noting the lack of theoretical predictions for shallow water. Another question of interest is what causes the signal coherence loss. In general, signal coherence loss arrives from sound scattering from the moving sea surface and time-varying oceanographic processes. (Signal coherence-time is infinite in a frozen ocean.) For a bottom mounted source in a downward refractive sound speed profile, acoustic propagation modeling results suggest that the contribution of the surface is minimal (see later). Assuming medium fluctuation is the dominant cause for the coherence loss, an effort is made to determine the relation between the signal coherence-time with the sound-speed STD, using conductivity-temperature-depth (CTD) data taken during the acoustic experiment.

To properly interpret the coherence-time results, one needs to model the influence of the various oceanographic processes (internal waves, turbulence, etc.) on the acoustic signal. Such a study is beyond the scope of this paper. Note that if the signal fluctuation can be described by one statistical distribution (as when there exists only one oceanographic process), the temporal coherence measurement will be independent of time and the size of the ensemble as long as the latter is statistically significant. In the real ocean, there exist various oceanographic processes that evolve with different time scales.

Consequently, the signal coherence measured at one time could be different than that measured at another time. Thus, in addition to the average temporal coherence of the signal, one needs to also study the "instantaneous" temporal coherence of the signal—the former is the average over samples covering a long period of time (hours/days), and the latter is the average over samples covering a short period of time (seconds/minutes). The "instantaneous" signal coherence-time provides a measure (variance) of the tempo-

ral variation of the signal coherence-time; the variance is a function of the acoustic frequency. The mean and variance of the "instantaneous" signal coherence-time can be used to infer the properties of the oceanographic processes responsible for the signal coherence loss.

The data analyzed involve acoustic signals of different carrier (center) frequencies with different bandwidths. Naturally, to compare the results, one needs to ask whether the measurements are influenced by the signal bandwidth. Note that the signal coherence for a (extra) wide band signal is not likely to be the same as that of a narrow band signal. When the signal bandwidth is small compared with the signal frequency, most works have assumed that the signal bandwidth is not an issue with which to be concerned. The bandwidth dependence is studied below by estimating the temporal coherence with a bandpass filter (with different bandwidths) applied to data with a 2 kHz bandwidth. The results showed little bandwidth dependence.

This paper is organized as follows. In Sec. II we describe the definitions and measurement techniques. In Sec. III we illustrate the measurements of the signal temporal coherence at three frequencies and two ranges using the AS-COT01 data, including a discussion on the measurement issues. In Sec. IV we present the results of signal temporal coherence measured from the SWARM95 experiment. In Sec. V we present the results of signal temporal coherence measured from RAGS03 experiment. The range and frequency dependence of the signal coherence-time are studied in Sec. VI. Environmental impacts on the signal temporal coherence are briefly discussed. Section VII is a short summary.

II. DEFINITIONS AND MEASUREMENT TECHNIQUES

Temporal coherence of a signal is defined by the (auto-) correlation of the signals separated by a delay time τ, normalized by the power of the signal, as given by

$$\rho(\tau) \equiv \frac{\langle p^*(t)p(t+\tau)\rangle}{\sqrt{\langle p^*(t)p(t)\rangle\langle p^*(t+\tau)p(t+\tau)\rangle}}, \tag{1}$$

where $\langle \rangle$ denotes the ensemble average and * denotes the complex conjugate. The ensemble average is usually done over time t using the ergodic theorem. The ensemble average can also be over frequencies (i.e., different narrow band signals), or space (i.e., sensors over an array), or combinations of all the above.

Earlier work on deep water data was focused on the phase rate of a narrow band signal.[1–8] A narrow band signal can be represented after quadrature demodulation (i.e., after removing the carrier frequency) as

$$p(t) = R(t)e^{i\phi(t)}, \tag{2}$$

where $R(t)$ is the amplitude and $\phi(t)$ is the phase. It was assumed that the signal variation is predominantly in its phase. Ignoring the amplitude variation, i.e., $R(t+\tau) \approx R(t)$, one finds that the autocorrelation of the pressure field can be approximated by[19,20]

$$\langle p^*(t)p(t+\tau)\rangle \simeq \mu^2\langle e^{-i\phi(t)}e^{i\phi(t+\tau)}\rangle \simeq \mu^2 e^{(-1/2)\dot\phi^2 r^2}, \qquad (3)$$

where τ is the delay time, $\dot\phi$ denotes the time derivative of the signal phase (phase rate), and μ^2 denotes the mean intensity $\langle R(t)R(t+\tau)\rangle \simeq \mu^2$. Using Eq. (3), the temporal coherence as defined by Eq. (1) becomes

$$\rho(\tau) = e^{(-1/2)\dot\phi^2 r^2}. \qquad (4)$$

While noting that the assumptions made above for deep water may not be valid for shallow water, one observes at the same time that the functional dependence of the signal coherence [Eq. (4)] has been widely assumed for data analysis. It will be used later and seems to be valid for a small delay time.

The signal coherence-time, commonly defined by the delay time at which $\rho(\tau)=1/e$, is given by

$$\tau_{1/e} = \sqrt{2}(\dot\phi)^{-1}. \qquad (5)$$

In terms of $\tau_{1/e}$, Eq. (4) becomes $\rho(\tau)=e^{-\tau^2/\tau_{1/e}^2}$. Defining $\dot\phi=2\pi\nu$, one finds that ν is the Doppler spread for a narrow band signal. This can be verified by taking a Fourier transform of the correlation function, Eq. (3). It is evident from Eq. (5) that the Doppler spread is inversely proportional to the signal coherence-time.

For reasons having to do with data analysis (as discussed later in Sec. III), one finds it necessary to measure the signal coherence-time while the signal coherence is high. A practical choice is to define $\tau_{0.8}$, which is the coherence-time at $\rho=0.8$. It is related to the Doppler spread by

$$\nu = \sqrt{\frac{-\ln(0.8)}{2\pi^2}}\,\tau_{0.8}^{-1} \simeq 0.11\tau_{0.8}^{-1}. \qquad (6)$$

$\tau_{0.8}$ has been previously discussed in the context of underwater acoustic communications[18] as communications often require a signaling period with high signal coherence.

For deep water, using the Rytov approximation, earlier theoretical models have suggested that ν should increase linearly with the acoustic frequency and square-root power of the source-receiver range,[9]

$$\nu = \gamma f\sqrt{R}, \qquad (7)$$

where the coefficient γ is proportional to the amplitude of the internal waves. This suggests that the coherence-time $\tau_{0.8}$ should decrease linearly with the inverse of the acoustic frequency and inverse square root of the range. This dependence will be tested with the shallow water data analyzed later.

A second method to measure the temporal coherence of a (narrow band) signal uses matched field correlation.[12,16] A (narrow band) signal field at time t is used as the reference (replica) field and correlated with the signal that follows at a later time, $t+\tau$. It is called matched field correlation since the ensemble average is over the sensors on an array,

$$\rho(t,\tau) = \frac{\displaystyle\sum_{j=1}^{N} p_j^*(t)p_j(t+\tau)}{\sqrt{\displaystyle\sum_{j=1}^{N} p_j^*(t)p_j(t)\sum_{j=1}^{N} p_j^*(t+\tau)p_j(t+\tau)}}, \qquad (8)$$

where $p(t)$ is the reference field. To achieve robustness, it is averaged over blocks of data at different time t or over signals of different frequencies, or both.

A third method to measure the signal temporal coherence uses broadband signals separated by a delay time τ,

$$\rho(t,\tau) = \left\langle \frac{[p^*(t)\otimes p(t+\tau)]_{\max}}{\sqrt{[p^*(t)\otimes p(t)]_{\max}[p^*(t+\tau)\otimes p(t+\tau)]_{\max}}} \right\rangle, \qquad (9)$$

where $[p^*(t)\otimes p(t+\tau)]_{\max}$ means the maximum value of the cross-correlation of the two time series or the convolution of the time-reversed signal (denoted by *) with the other signal. A broadband signal is chosen as the reference signal and correlated with the signals arriving at a later time. The ensemble average will be over signals transmitted at different geotime t, i.e., different reference signals. Broadband temporal correlation can be shown to be equivalent to narrow band correlations summed over frequencies. Given enough data samples, these two measures should yield the same answer, at least in theory. This (third) method will be used extensively for data analysis in this paper.

As shown by Eq. (9), the signal temporal coherence is implicitly a function of t, the signal transmission time (or geotime). The measurement (averaged over data) near time t will be the "instantaneous" signal coherence-time. The measurement of the signal coherence-time could have a large variance depending on the signal frequency and the time scale of the oceanographic processes affecting the signal. The interpretation of the coherence-time data needs to be put in the context of the corresponding propagation environment; whatever models are used needs to reproduce the measured channel impulse responses first.

III. ASCOT01 DATA ANALYSIS: THE MEASUREMENT ISSUES

In this section we analyze the data from the ASCOT01 experiments. It also addresses some of the measurement issues. For example, what are the suitable waveforms for temporal coherence measurement? What is the signal transmission rate to properly sample the temporal coherence? What is the effect of noise on the temporal coherence measurement? What is the minimum size of the samples for temporal coherence measurements? What is the effect of array motion on the measurements? Finally, how is the measurement influenced by the number of multipaths and the signal bandwidth?

The ASCOT01 experiment took place in June of 2001 off the coast of New England along the contour of 100 m depth.[21,22] It was part of joint SACLANTCEN and US experiments. The sound speed is nearly a constant with a velocity of 1465 m/s for depths below 30 m. The sound speed
FIG. 1. (Color online) Measured channel impulse responses as a function of the delay time and geotime (time relative to the first pulse) based on LFM signals transmitted in the ASCOT01 experiment. Color scale is dB. Signal center frequency is 3550 Hz and source-receiver range is 10 km.

increases gradually from 30 m upward to 1500 m/s at 8 m depth. The source was mounted 4 m from the ocean bottom. A vertical line array was deployed at three distances of approximately 2, 5, and 10 km from the source. The data at 5 and 10 km will be used to study the range dependence of the temporal coherence of the signal. At each range, broadband phase-modulated signals were transmitted at three carrier frequencies, 450, 1200, and 3550 Hz. The data at different frequencies will be analyzed to study the frequency dependence of the temporal coherence. The signals at the lower two carrier frequencies had a bandwidth of 400 Hz. At 3550 Hz, signals were transmitted using several different bandwidths extending from 500 to 2000 Hz.

In the following subsections, the analysis focuses on data collected at the range of 10 km using three different carrier frequencies, followed by the data at 5 km. The receiver depth is between 65 and 82 m depth. No significant depth dependence is found in the temporal coherence result.

The signals analyzed were acoustic communication signals, transmitted in packets. Each packet lasted about 10 or 20 s depending on the signal frequency. A packet started with a LFM signal of 0.1 s, followed by a 0.3 s gap, followed by a Barker code signal of 13 symbols, followed by a 0.3 s gap, and then followed by the data signal. For the temporal coherence study, the data were BPSK signals coded with repetitive m-sequences. The m-sequences are "orthogonal" signals such that the signal autocorrelation is sharply peaked with a peak-to-sidelobe ratio of $10 \log N$, where N is the number of symbols used in the sequence. Unless otherwise mentioned, the signal packets were repeated every 2 min over a period of several hours. The LFM signal has the same bandwidth as the m-sequence signal.

LFM signals have been commonly used in the past to measure the channel impulse response functions and estimate the signal temporal coherence. To allow the reverberation to die down, the pulses were usually transmitted on the order of minutes to tens of minutes. It should become clear below that for channels with a short coherence-time, the LFM signal is a poor choice as the channel is too infrequently sampled. This is particularly true at high frequencies. To sample the

channel at a high sampling rate, m-sequence signals are used, transmitted in sequence continuously for an extended period of time. The m-sequence signals sample the channel impulse responses at a period of N/bandwidth s.

A. 3550 Hz at 10 km range

The channel impulse responses were obtained by matched filtering the data with the transmitted signal. The channel impulse responses from the LFM signals are plotted in Fig. 1 displaying the multipath arrivals as a function of delay time and geotime (transmission time); the LFM signals were transmitted every 2 min. The signal bandwidth is 2 kHz. One clearly sees the variation of the channel impulses between packets. One notes in Fig. 1 eight groups of multipath arrivals, with each group consisting of many micropath arrivals. The micropath arrivals are rays that scatter from the ocean inhomogeneities producing microrays. As a result, the arrival times of the micropath arrivals are spread out and their intensities fluctuate with time. The experimental site (in the New England coastal water) is known to have internal waves and turbulence.[22] The effect of these oceanographic processes on the acoustic signal propagation is evident in Fig. 1, particularly the late arrivals.

(One notes a gradual decrease in the delay time in Fig. 1 between the early and late arrivals as geotime increases. The shift in the arrival time of the late arrivals can be explained in terms of the internal tides, which shift the depth of the channel thermocline.[23] See Sec. VI D for further details).

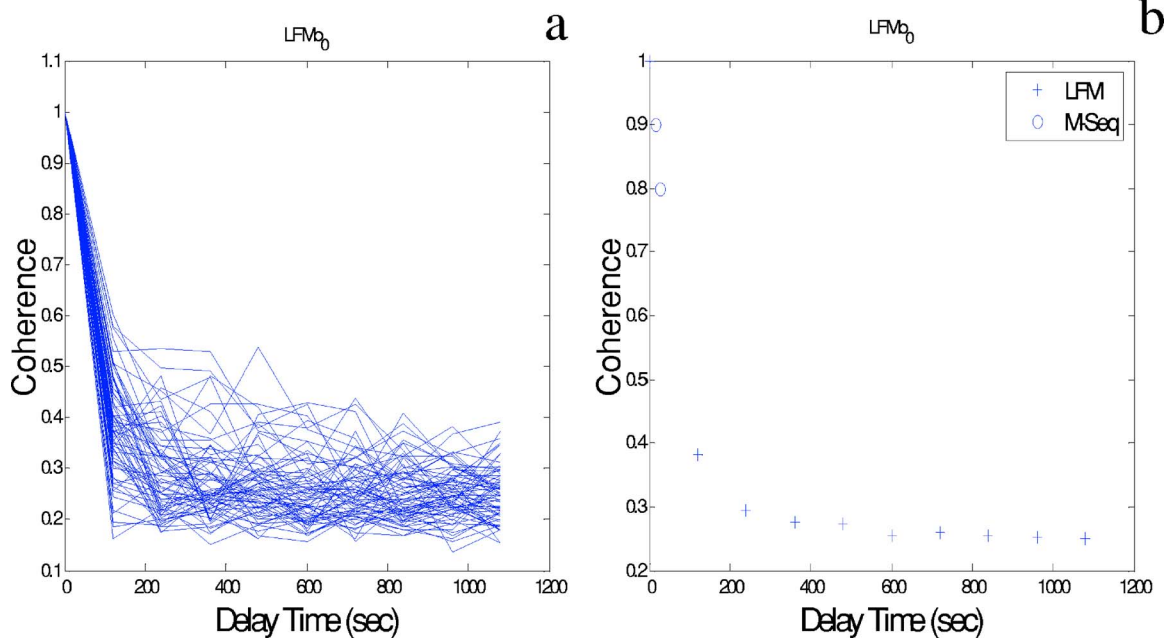
Take one impulse response function as a reference and cross correlate with the impulse responses transmitted at a later time. The maximum values of the correlations are entered in Eq. (9) and one obtains one temporal coherence curve, as shown in Fig. 2(a). Take different impulse response functions as the references; one obtains a distribution of temporal coherence curves at different geotimes, as shown in Fig. 2(a). The average of all the curves is shown in Fig. 2(b), displayed by the data points marked as crosses. One observes that the average coherence decreases to a value of ~ 0.25 over a period of 5–20 min.


FIG. 2. (Color online) Temporal coherence curves measured at a different starting time (a), and averaged over 2.5 h of data using LFM signals (b). This figure shows that the normal method using LFM pulses is inadequate for measuring the temporal coherence at a short delay time. Superimposed in Fig. 4(b) is the measurement from m-sequence data from Fig. 4. Center frequency=3550 Hz, and range=10 km.

Figure 2(a) shows a wide spread in time for a fixed coherence value. For example, for a coherence value at $1/e$, the coherence-time can vary from 120 s to greater than 1000 s. Thus, the conventional definition of coherence-time, defined by the time delay at which the coherence value drops to $1/e$, could not be applied directly to this data. In general, the variance of the coherence-time at a fixed coherence value increases significantly as the coherence value decreases. In this paper, the measurement of the signal coherence-time is based on the time when the coherence drops to 0.8, i.e., $\tau_{0.8}$. The reason is to keep the STD of the (coherence-time) measurements smaller than the average (coherence-time). The coherence-time $\tau_{1/e}$ can be extrapolated from $\tau_{0.8}$ given a model of temporal coherence.

Figure 2(b) shows that the coherence value drops to be-low 0.5 at the first sample, the 120 s delay time. To measure $\tau_{0.8}$, it is necessary to increase the sampling rate using a shorter sampling interval. To this end, the m-sequence data were analyzed next. Each m sequence contained $N=1023$ symbols and lasted 0.51 s. The m sequences were repeated for a total duration of 17 s.

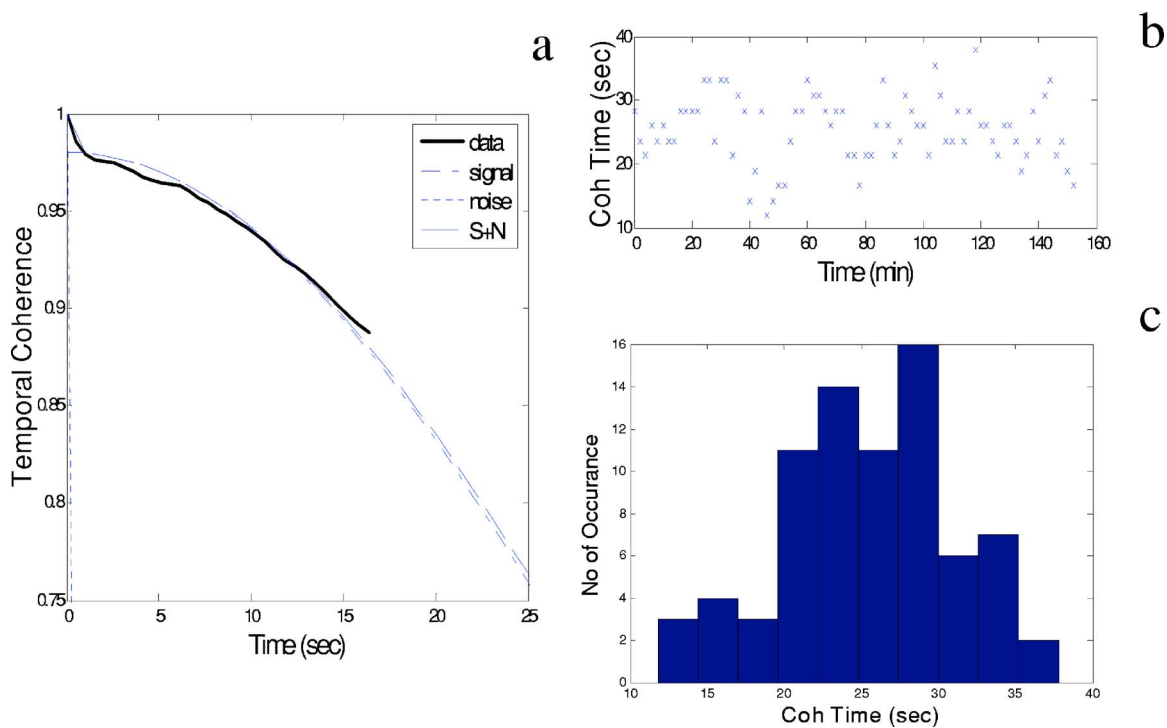
The m-sequence data were processed the same way as the LFM signals. Figure 3 shows the channel impulse response for m sequences for one packet of data. Because the m-sequence signals are nearly orthogonal, with a sidelobe level that is, in principle, $10 \log N$ dB down from the main level, the (circular) matched-filter correlation of the m-sequence data yields a good measurement of the channel impulse response function. Note that the amplitudes and arrival time are pretty stable for multipath arrival with a delay
FIG. 3. (Color online) A typical display of the channel impulse responses measured from consecutive m sequences within a packet as a function of the delay time and geotime. Center frequency is 3550 Hz and range is 10 km. Color scale is dB. The m sequences are commonly used to characterize the channel variation within a packet of acoustic communication signal.


FIG. 4. (Color online) Average temporal coherence of the m-sequence signals, compared with a model of signal and noise (a). "Instantaneous" signal coherence-time as a function of geotime (b). Histogram distribution of the signal coherence-time (c). Center frequency=3550 Hz, range=10 km.

time of less than 50 ms. Significant amplitude fluctuations are noted for arrivals with a delay time greater than 50 ms. This implies that the m-sequence signals are highly coherent within a packet.

Figure 4(a) shows the temporal coherence of the m sequences averaged over 77 packets of data (the solid curve), covering a time span of 2.5 h. Note a sharp decrease of the measured temporal coherence near the origin with a slope very different from the rest of the curve. To explain this, one needs to include the contribution of noise in Eq. (1). Denoting the signal as s and noise as n, thus $p=s+n$. The measured temporal coherence $\rho(\tau)$ is found to be

$$\rho(\tau) = s(\tau)\frac{S^2}{S^2 + N^2} + n(\tau)\frac{N^2}{S^2 + N^2}, \qquad (10)$$

where $s(\tau)$ is the temporal coherence of the signal and $n(\tau)$ is the temporal coherence for the noise. In deriving Eq. (10), it is assumed that the signal and noise are uncorrelated. The coefficients multiplying the signal and noise coherence terms in Eq. (10) are the signal to signal-plus-noise ratio and noise to signal-plus-noise ratio.

One notes that noise is normally assumed uncorrelated in the temporal space. It has in reality a very short coherence-time. The sharp drop of the measured coherence in Fig. 4(a) at a short delay time can be attributed to the noise, as illustrated later. The signal is expected to have a coherence-time much longer than the noise. Consequently, the signal coherence curve should have a slower (absolute) slope than the noise coherence curve. The data with a delay time greater than 1 s are that associated with the signal. One can fit the data in Fig. 4(a) using Eq. (10), assuming that both the signal and noise coherence are modeled by Eq. (6). The

modeled signal and noise coherence curves are shown in Fig. 4(a) as the dash-dotted and dotted lines, respectively, assuming $\tau_{lle}=50$ and 0.1 s for the signal and noise, respectively. (The signal coherence curve is displaced by 0.02 from unity.) The sum of the signal plus noise coherence using Eq. (10) is shown as the dashed line and is found in good agreement with the measured coherence data (solid curve). In fitting the data, one assumes a value of 0.02 for the noise to signal-plus-noise ratio, which is estimated by the contribution of the second term in Eq. (10) at zero delay time. This yields a signal-to-noise ratio of 17 dB, which agrees with the estimation based on the raw data.

The data analysis procedure is to determine the signal coherence from the measured coherence data by removing the noise contribution, which concentrates at a delay time less than 1 s. From the signal temporal coherence, one then estimates the signal coherence-time. From the data shown in Fig. 4(a), one finds the coherence-time of the average signal coherence at a coherence value of 0.8 is about 23 s. One can also obtain the "instantaneous" coherence-time of the signal by applying the above procedure to the temporal coherence curve measured from each packet of the m-sequence data. The measured "instantaneous" coherence-time of the signal is plotted in Fig. 4(b) as a function of geotime of the transmitted packet. Figure 4(c) shows the histogram distribution of the "instantaneous" coherence-time of the signal. From the histogram one obtains a mean coherence-time $\tau_{0.8}$ of around 25 s, approximately the same as the coherence-time of the average signal coherence reported above. One also finds a STD of ~5 s for the mean coherence-time measurement.

The above data were also used to study the bandwidth
FIG. 5. Bandwidth dependence of the average temporal coherence of the signal. Center frequency=3550 Hz, range=10 km.

dependence of the signal temporal coherence. In general, the signal coherence will depend on the signal bandwidth; a wideband signal will have a different temporal coherence than a narrow band signal. In addition to sensing different frequency responses of the propagation channel, a wide band signal can resolve individual (group of) path arrivals and measure the temporal coherence of these paths, which a narrowband signal cannot. To conduct the study, signals of different bandwidths are obtained by applying a bandpass filter to the raw data (mentioned above) using a different filter bandwidth. Temporal coherence is next deduced from the filtered data. Figure 5 shows the measurements of the temporal coherence of the bandpassed signals. One notes very little dependence of the temporal coherence on the signal bandwidth. This result is perhaps expected when the bandwidth of the signal is small compared with the signal carrier frequency, as is the case for the 3550 Hz data. The lack of bandwidth dependence as demonstrated by the 3550 Hz signal will be assumed to be true for signals at other frequencies. This allows us to compare and interpret data of different

bandwidths as presented later without considering the bandwidth as a separate parameter in the equation.

B. 1200 Hz at 10 km range

The channel impulse responses measured from the LFM signals are plotted in Fig. 6. The signals were transmitted every 2 min covering a period of 8 h. The LFM signals had a bandwidth of 400 Hz. Consequently, the temporal resolution in Fig. 6 is not as good (sharp) as that seen in Fig. 1. Nonetheless, one still sees eight groups of multipath arrivals. Figure 6 shows clearly that the multipath arrival time (particularly the last four groups of multipaths) also varies with geotime. The gradual shift of the late arrivals with geotime is similar to that shown in Fig. 1 and can be explained by the shift of the thermocline axis due to (semidiurnal) internal tides.

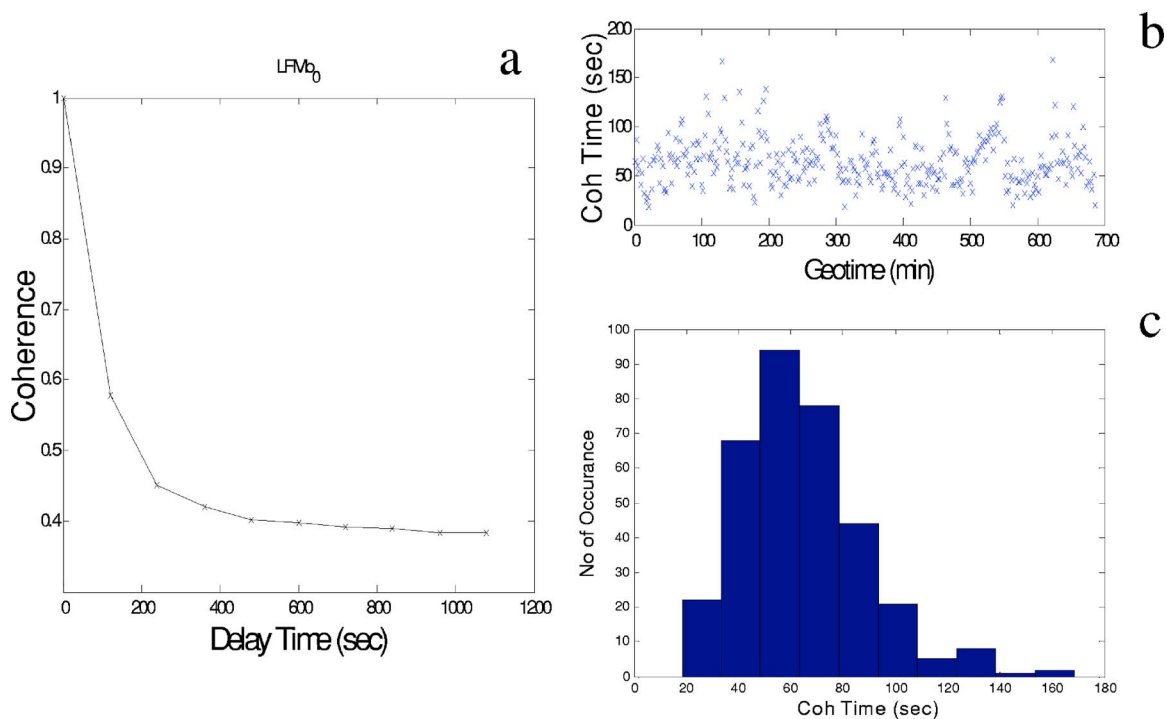
The impulse responses at a different geotime were used as the references and cross-correlated with the impulses responses that follow. For each reference, a temporal coher-
FIG. 6. (Color online) Channel impulse responses at 1200 Hz as a function of the delay time and geotime, based on LFM data received at a range of 10 km during the ASCOT01 experiment. Color scale is dB. The multipath arrival pattern is similar to that shown in Fig. 1.


FIG. 7. (Color online) Temporal coherence measured from data shown in Fig. 6. Average temporal coherence as a function of signal separation time (a). "Instantaneous" signal coherence-time as a function of geotime (b). Histogram distribution of the signal coherence-time (c).

ence curve was obtained. Figure 7(a) shows the average of all the temporal coherence curves. From this, one can estimate the coherence-time of the average signal coherence to be $\tau_{0.8} \simeq 57$ s. One can also estimate the coherence-time $\tau_{0.8}$ for each of the "instantaneous" temporal coherence curves obtained. The results are plotted in Fig. 7(b) to show the temporal variation (time dependence) of the "instantaneous" signal coherence-time. It indicates a cycling period of 30–50 min, which is shorter than the periods of the internal tides. The cause of the temporal variation of the signal coherence-time has not been investigated.

Figure 7(c) shows the histogram of the measured coherence-time. One finds a mean of approximately 64 s and a STD of about 24 s.

C. 450 Hz at 10 km range

The 450 Hz signals had a bandwidth of 400 Hz covering a frequency range of 250 to 650 Hz. Figure 8 shows the measured channel impulse responses deduced from the LFM signals. The signals, transmitted every 2 min, covered a period of 3.5 h. The impulse responses at 450 Hz are clearly different from the impulse responses shown earlier at 1200 or 3550 Hz. Although seven to eight groups of multipath arrivals can also be identified in Fig. 8, one finds that the second and fifth multipaths are the dominant arrivals versus the first to third arrivals in Figs. 1 and 6.

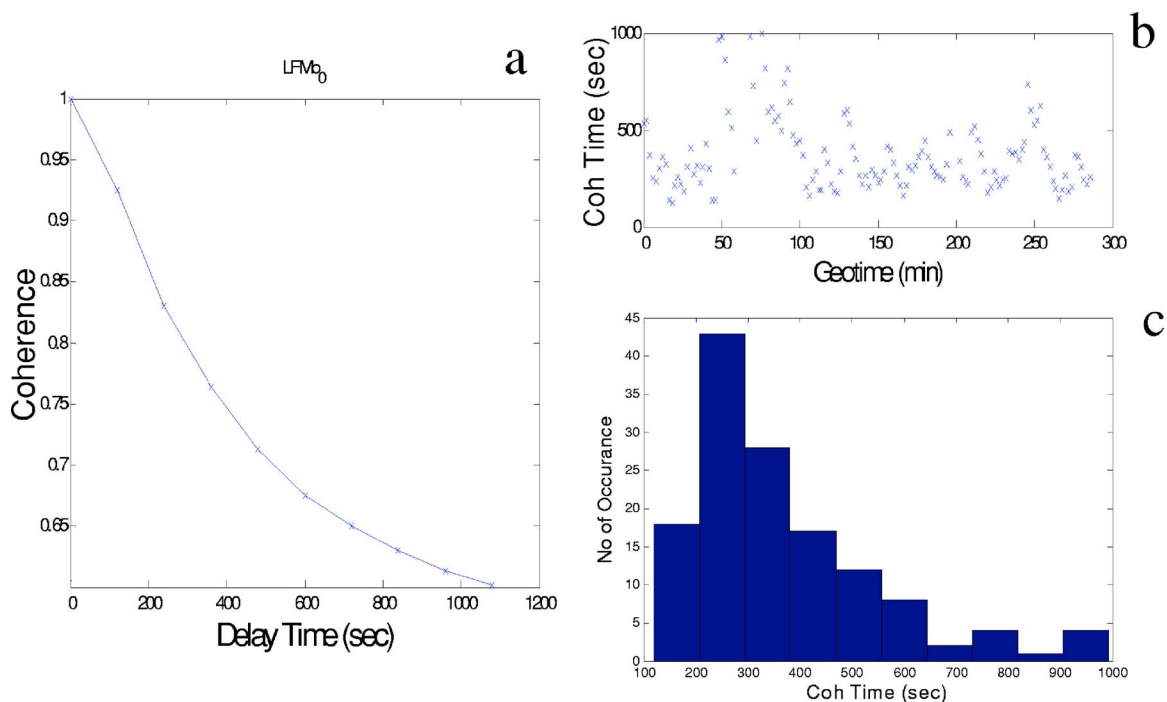
The impulse responses were processed to produce the temporal coherence curves at a different geotime (as de-
FIG. 8. (Color online) Channel impulse responses at 450 Hz as a function of the delay time and geotime based on LFM signals transmitted during the ASCOT01 experiment. Color scale is dB. Source-receiver range is 10 km. Second and fifth arrivals have higher amplitudes than the others. Impulse responses are aligned by the peak amplitude within the first 30 ms of data; data at geotime from 240 to 270 min are misaligned by this method.


FIG. 9. (Color online) Temporal coherence based on data of Fig. 8. Average temporal coherence as a function of signal separation time (a). "Instantaneous" signal coherence-time as a function of geotime (b). Histogram distribution of the signal coherence-time (c).

scribed above). Figure 9(a) shows the average of all the temporal coherence curves. One finds the coherence-time $\tau_{0.8}$ of the average signal coherence to be about 299 s. The coherence-time estimated from each of the temporal coherence curves (described above) is plotted in Fig. 9(b). Figure 9(b) shows the variation (time dependence) of the "instantaneous" signal coherence-time. Figure 9(c) shows the histogram of the measured coherence-time. One finds a mean $\tau_{0.8}$ of approximately 382 s and a STD of about 202 s. The high value of the STD arises from the high "instantaneous" coherence-time during the period of 50–90 min in Fig. 9(c), which is distinctly different from the rest of the time. There is no apparent correlation between the time series of the "instantaneous" coherence-time [Fig. 9(b)] and the multipath arrival time (Fig. 8); the later is related to the tidal cycle.

Note that the STD measured over a short period of time (10–40 min) is much smaller ($\sim$100 s). For a smaller time period (minutes), the STD will be smaller. Thus the STD in the coherence-time could be used as an indicator of the amount of the changes in the acoustic environment (e.g., the sound speed STD) during the measurement periods. See Sec. VI for further study.

D. Data at 5 km range

The data at the 5 km range were processed in the same manner as the data at the 10 km range. Only LFM signals were used. The results for 3550, 1200, and 450 Hz are shown in Figs. 10–15, respectively.

The measured channel impulse responses at 3550 Hz are
FIG. 10. (Color online) Channel impulse responses at a range of 5 km as a function of the delay time and geotime based on LFM signals centered at 3550 Hz from the ASCOT01 experiment. Color scale is dB. Similar arrival pattern as in Fig. 1 but with a nearly doubled multipath spread.

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

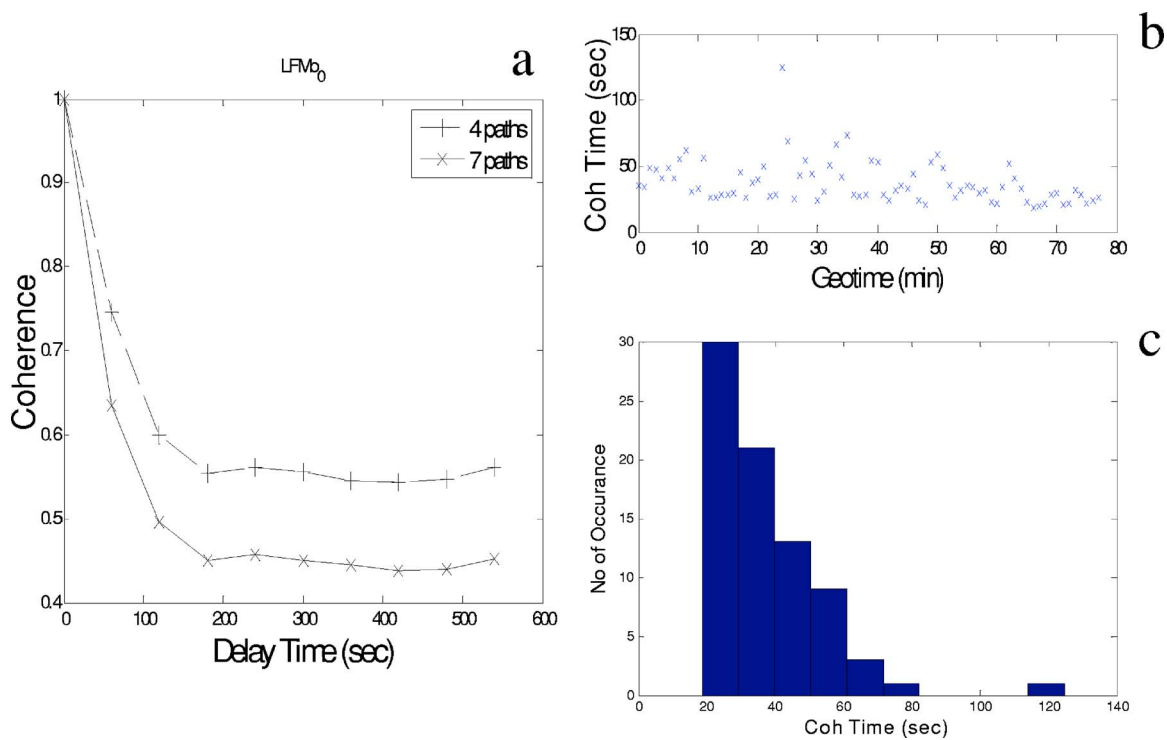
Tsih C. Yang: Temporal coherence of acoustic signals   2603


FIG. 11. (Color online) Temporal coherence measured from date of Fig. 10. Average temporal coherence using the impulse responses containing all seven paths versus only the initial four paths (a). "Instantaneous" signal coherence-time as a function of geotime (b). Histogram distribution of the signal coherence-time (c). Center frequency=3550 Hz, range=5 km.

shown in Fig. 10 as a function of the delay time and geotime. The difference between this data (Fig. 10) and the data at 10 km (Fig. 1) is that the 3550 Hz signals at 5 km had only a bandwidth of 500 Hz. The signals, transmitted every 1 min, covered a period of 1.5 h. The channel impulse responses, deduced from the LFM signals at 1200 Hz, are plotted in Fig. 12. The signals, transmitted every 2.5 min, covered a period of 4 h. The channel impulse responses deduced form the LFM signals at 450 Hz are plotted in Fig. 14. The signals, transmitted every 2.5 min, covered a little more than 3 h. Both the 1200 and 450 Hz signals have a 400 Hz bandwidth, the same as the 10 km case.

One observes seven to eight groups of multipaths in

Figs. 10, 12, and 14. Certain groups of arrivals are clearly split into two subgroups of arrivals in Figs. 12 and 14. Comparing Figs. 10, 12, and 14 with Figs. 1, 6, and 8, one finds that the spreads of the multipath delay times (from the first arrival) at 5 km are almost double that at 10 km. The peak intensity distribution of the 450 Hz impulse responses changes significantly from 10 to 5 km.

The impulse responses were processed (as described above) to produce the temporal coherence curves at a different geotime—using the impulse response at a different time as the reference. coherence-time $\tau_{0.8}$ was estimated from each of the temporal coherence curves.

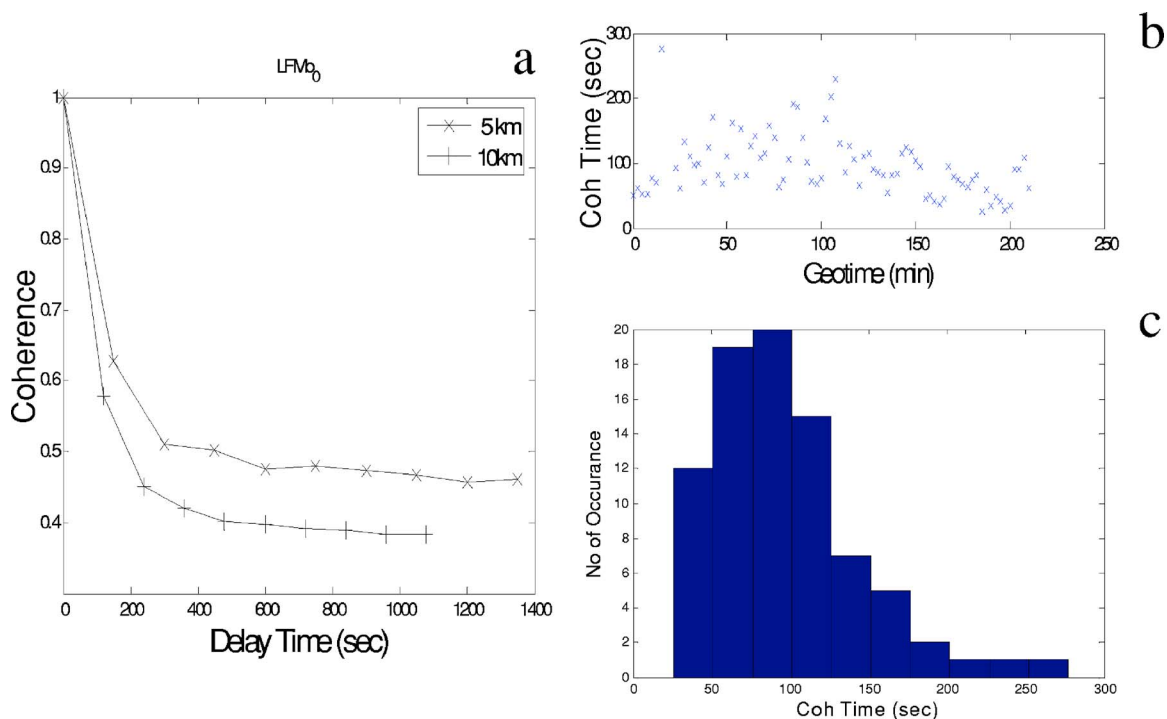
Figure 11(a) shows the average temporal coherence of
FIG. 12. (Color online) Channel impulse responses as a function of the delay time and geotime at a range of 5 km and center frequency of 1200 Hz based on LFM signals from the ASCOT01 experiment. Color scale is dB. Similar multipath arrival pattern as in Fig. 6, but with a nearly doubled delay spread.


FIG. 13. (Color online) Temporal coherence measured from the data of Fig. 12. The average temporal coherence as a function of the signal separation time (a). "Instantaneous" signal coherence-time as a function of geotime (b). Histogram distribution of the signal coherence-time (c). The average temporal coherence of the signal at 10 km [Fig. 7(a)] is also displayed in Fig. 13(a) for comparison.

the signal at 3550 Hz (the solid curve). One finds the coherence-time $\tau_{0.8}$ of the average signal coherence to be about 33 s. Figure 11(b) shows the temporal variation (time dependence) of the "instantaneous" signal coherence-time at 3550 Hz. Figure 11(c) shows the histogram of the measured coherence-time. One finds a mean of approximately 37 s and a STD of about 16 s for the 3550 Hz signal at 5 km.

The signal coherence-time of the 1200 Hz signal at 5 km is shown in Fig. 13. Figure 13(a) shows the average of all the temporal coherence curves (the solid curve) at 5 km. One finds the coherence-time $\tau_{0.8}$ of the average signal coherence to be about 81 s. Superimposed is the previously obtained average temporal coherence curve at 10 km (the

dashed curve). Figure 13(b) show the temporal variation (time dependence) of the "instantaneous" signal coherence-time at 1200 Hz. Figure 13(c) shows the histogram of the measured coherence-time. One finds a mean of approximately 96 s and a STD of about 46 s.

The signal coherence-time of the 450 Hz signal at 5 km is shown in Fig. 15. Figure 15(a) shows the average of all the temporal coherence curves (the solid curve). One finds the coherence-time $\tau_{0.8}$ of the average signal coherence to be about 443 s. Superimposed is the previously obtained average temporal coherence curve at 10 km (the dashed curve). Figure 15(b) shows the temporal variation (time dependence) of the "instantaneous" signal coherence-time at 450 Hz. Fig-
FIG. 14. (Color online) Channel impulse responses as a function of the delay time and geotime at a range of 5 km and center frequency of 450 Hz based on LFM signals from the ASCOT01 experiment. ure 15(c) shows the histogram of the measured coherence-time. One finds a mean of approximately 626 s and a STD of about 368 s.

E. Comments on the coherence measurements

As is well known, the temporal coherence of the signal may vary from path to path. In general, the early arrivals are more coherent than the latter (scattering) arrivals. Hence, measurement of the temporal coherence could depend on the number of multipaths included in the signal. To illustrate this, it is plotted in Fig. 11(a) the average temporal coherence of the signal using only (the impulse responses of) the first four multipaths (the dashed curve) to compare with that using all seven multipaths (solid curve). One finds that the temporal coherence value increases by ~20% at elapsed time >100 s.

The measurements of the signal temporal coherence in this paper include all the "dominant" multipath arrivals. To do so, one must use a sufficiently long time window for measuring the impulse response delay spread, yet not too long to increase the noise contribution. The procedure used here is to increase the window until the (average) coherence value converges to within a certain tolerance. The final time-window-used is the minimum time window-that achieves the convergence value.

One observes that the mean of the coherence-times is generally somewhat higher than the coherence-time estimated from the average of the temporal coherence curves. Note that the former is the average of the ("instantaneous") coherence-time at a fixed coherence value, whereas the latter is deduced from the average of the coherence at fixed elapsed times. Note that the measurements are only available at dis-

crete elapsed times. Hence measurement data are interpolated or extrapolated to determine the coherence-time $\tau_{0.8}$. The details of interpolation and extrapolation, which involves curve fitting, could contribute to the difference between the two different ways of measuring the coherence-time, particularly when the "instantaneous" temporal coherence exhibit high degrees of fluctuations. It is observed in Fig. 2(a) that the variance of the data at a fixed coherence value is much higher than the variance of the data at a fixed elapsed time. Consequently, it is assumed that the coherence-time estimated from the average of the temporal coherence curves is more trustworthy than the mean of the coherence-times. The coherence-time estimated from the average of the temporal coherence curves is entered as the coherence-time $\tau_{0.8}$ in Table I. The STD measured above, which represents the spread (or the temporal variation) of the "instantaneous" coherence-time, is also entered in Table I. This STD represents the environmental influence on the signal coherence-time. It should not be confused with the STD of the measurements (or the measurement error due, for example, to the different sizes of data samples). Note that the measurements of the temporal coherence for a broadband signal use an

TABLE I. coherence-time $\tau_{0.8}$ and the spread of the coherence-time (in parentheses) measured from ASCOT01 data; the later reflects the amount of the temporal variation of the coherence-time due to changes in the propagation environment.

Frequency	$\tau_{0.8}$ at 10 km	$\tau_{0.8}$ at 5 km
3550 Hz	23 (±5) s	33 (±16)
1200 Hz	57 (±24) s	81 (±46)
450 Hz	299 (±202) s	443 (±368)
FIG. 16. (Color online) Results from the SWARM95 experiment. Measured channel impulse responses as a function of the delay time and geotime, showing groups of arrivals. Color scale is dB. Data based on m-sequence signals centered at 400 Hz with a range at 42 km.

average over frequencies. In contrast, the temporal coherence for a narrow band signal is averaged over data at different time. Both use an adequate number of samples.

IV. SWARM 95 DATA ANALYSIS

In this and the next section, the above analysis is applied to data from another site, off the coast of New Jersey. Although the measurement procedures are the same and repetitive as before, the data features (the delay structure and time variations of the channel impulse responses) are very different. How is signal coherence-time related to the channel dynamics is of great interest and will be briefly discussed in Sec. VI.

The SWARM 95 experiment was conducted in July–August of 1995 in the Mid-Atlantic bight continental shelf region east of New Jersey. It was sponsored by the Office of Naval Research with participation from many institutions. Details of the experiment were described in a previous publication.[24] The data to be analyzed here are data from two acoustic sources located upslope in 55 m of water to the NRL vertical line array down slope in 88 m of water. The source receiver range was ~42 km. A 400 Hz source was deployed at midwater depth and a 224 Hz source was deployed near the bottom. The 400 Hz signals had a bandwidth of 100 Hz and the 224 Hz signals had a bandwidth of 16 Hz. The NRL vertical line array (VLA) contained 32 elements spanning the water column from 21 to 85 m.

BPSK data using m sequences were analyzed following the analysis described above. The BPSK signal at 400 Hz used an m sequence of 511 symbols repeated 23 times. Each packet lasted 117.53 s and was repeated continuously with a gap of 242.47 s in between packets. The BPSK signal at 224 Hz used an m sequence of 63 symbols repeated 30 times. Each packet lasted 118.13 s and was repeated continuously with a gap of 181.9 s in between packets.

A total of 179 packets was analyzed for the 400 Hz signal, yielding 4117 measurements of channel impulse responses covering a period of 17.9 h. The channel impulse responses were plotted in Fig. 16 for a receiver at 51 m depth. Temporal coherence was estimated for each packet

using the first m sequence as the reference. The average of all the coherence curves is plotted in Fig. 17(a). It yields a coherence-time $\tau_{0.8} \simeq 40$ s. The "instantaneous" coherence-time estimated from each packet is shown in Fig. 17(b). Figure 17(c) shows the histogram distribution of the "instantaneous" coherence-time. One finds a mean coherence-time of 55 s and STD of 40 s. The high STD is a manifestation of the (significant) environmental change in the SWARM95 area due to the presence of internal waves.

For the same period, the 224 Hz data yield 6450 measurements of channel impulse responses, which are plotted in Fig. 18(a). It showed one dominant group of arrivals. The mean temporal coherence averaged over all packets is plotted in Fig. 18(b), from which one finds the coherence-time $\tau_{0.8} \simeq 130$ s. In this case, one finds significantly larger fluctuations in the measurements of the "instantaneous" coherence-time than in the case of 400 Hz signal. For many packets, the coherence-time is beyond the packet length of 118 s and cannot be reliably estimated.

The SWARM95 experiment had extensive oceanographic measurements, which were carried out almost concurrently with the acoustic measurements.[24] The oceanographic data suggested the presence of solitary internal waves in addition to diffuse internal waves. The solitary internal waves are generated on the shelf edge by interaction of internal tides with the shelf break. These waves occurred on a diurnal cycle. Hence, our analysis was carried over 17 h of data to include the effect of the solitary internal waves. Internal waves are expected to decrease the signal coherence-time. The 400 Hz data indicated a higher standard deviation to the mean ratio than other experimental data (see Table I). The large time variation is presumed to be caused by the internal waves.

V. RAGS03 DATA ANALYSIS

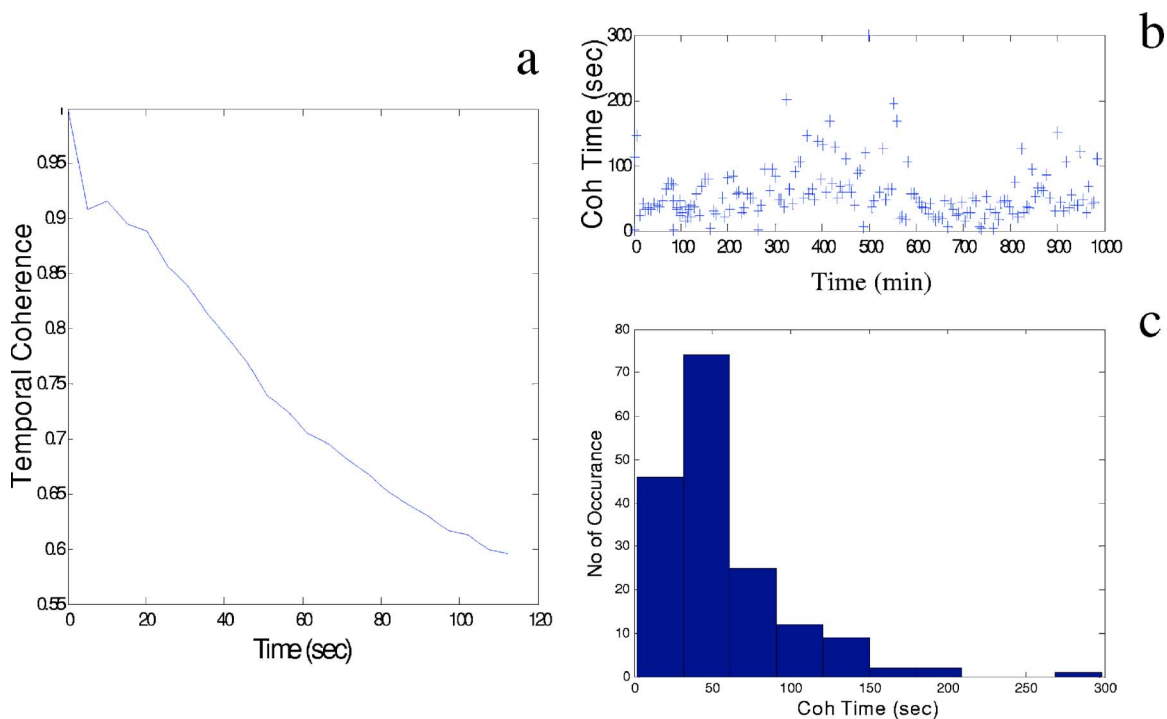
The RAGS03 experiments contained two parts: one conducted in September 2003 for underwater acoustic communications research, and the other in the winter of 2003 for array performance study. The data of interest were from the first part of the experiment that took place in the same area as


FIG. 17. (Color online) Temporal coherence measured from the *m*-sequence data of Fig. 16. Average temporal coherence as a function of signal separation time (a). "Instantaneous" signal coherence-time as a function of geotime (b). Histogram distribution of the signal coherence-time (c).

SWARM95. The measured sound speed profiles are similar to that found in the SWARM95 experiment; both have the summer profile. There were no concurrent oceanographic measurements with the acoustic measurements as in the SWAR95 experiment, except for CTD casts. Backscattering sonar data reveal the existence of solitary internal waves similar to that found in the SWARM95 experiment.

The source was deployed at a depth of approximately 38 m projecting a broadband signal centered at 20 kHz. The receiver contained 8 hydrophones within an aperture of 2 m, at a mean depth around 41 m. Both were moored from the ocean bottom. The mean water depth is about 70 m. The

source and receivers were separated by 3 km. BPSK signals with a bandwidth of 2 kHz were used to deduce the channel impulse responses. Each packet contained ~10 s of data consisting of 19 *m* sequences each with 1023 symbols.

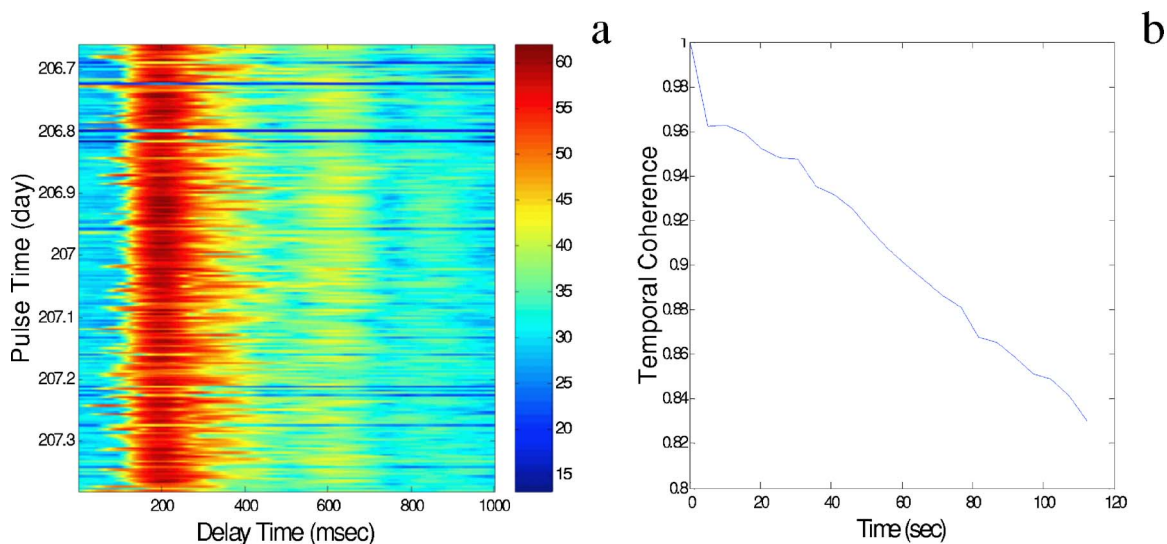
Figure 19(a) shows the matched filtered output of the *m*-sequence data for one packet using the transmitted *m*-sequence signal. One observes that the amplitudes of the impulse responses vary significantly between the received *m* sequences. Figure 19(b) shows the Doppler shift measured from data of individual *m* sequences determined by the peak of the broadband ambiguity function as a function of Doppler frequency and delay time. One sees a substantial varia-


FIG. 18. (Color online) SWARM95 data 224 Hz at a range of 42 km. Channel impulse responses as a function of the delay time and geotime based on *m*-sequence signals (a). Multipath arrivals are not resolved due to the limited bandwidth of the signal (16 Hz). Color scale is dB. Average signal coherence as a function of geotime (b).
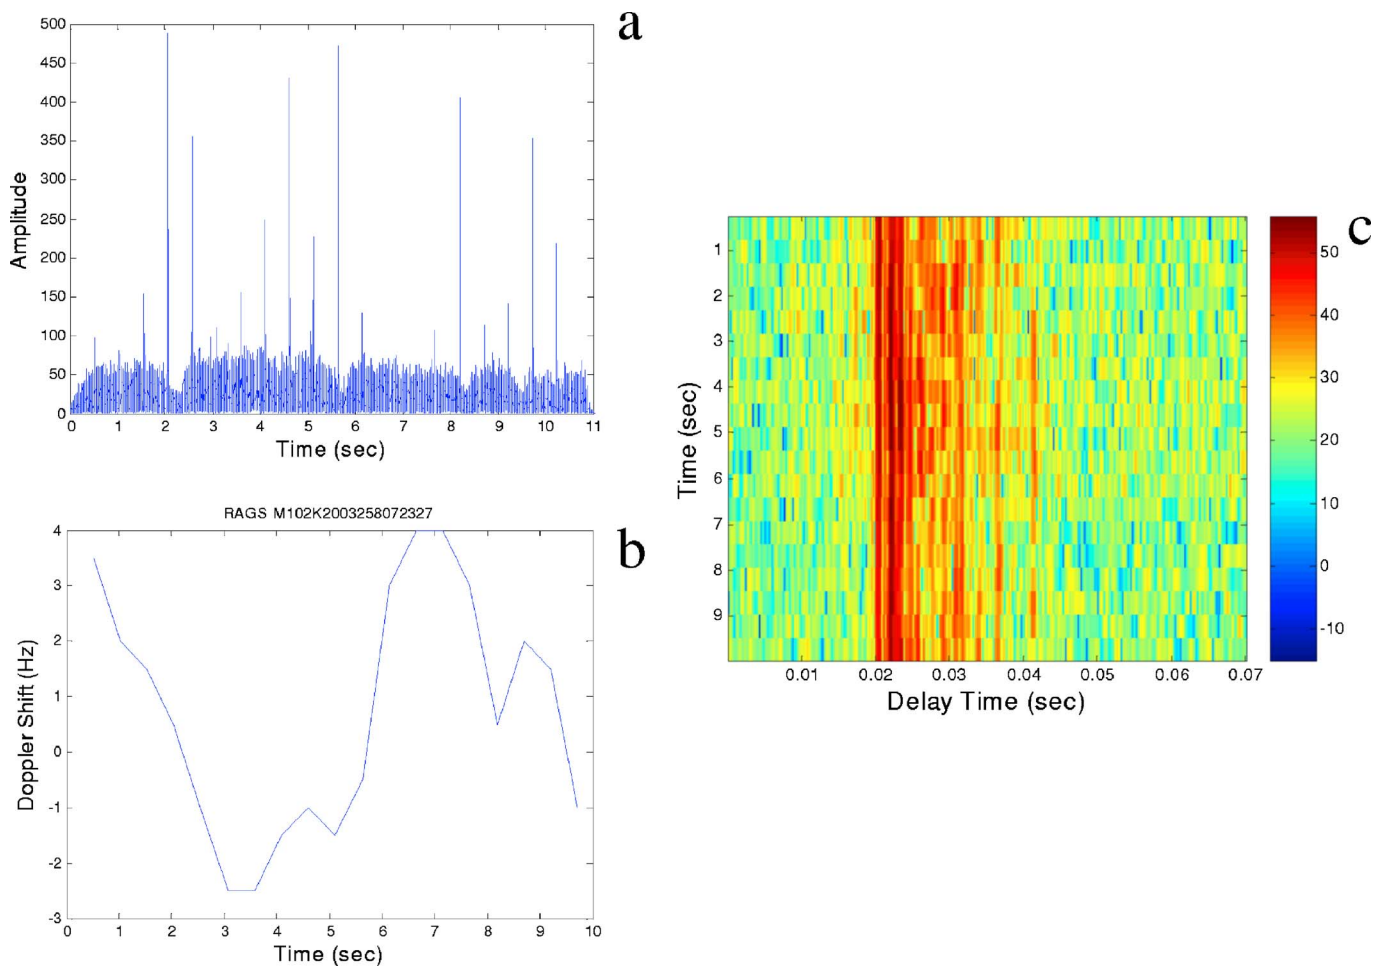

FIG. 19. (Color online) The effect of Doppler shift (array motion) on high frequency (20 kHz) signals. Matched filtered time series of the *m*-sequence signals without Doppler correction (a). Doppler shift measured from individual *m*-sequence signals using the wide band ambiguity function (b). Impulse response measured from the *m*-sequence signals after Doppler correction (c). Color scale is dB. Data were *m* sequences from the RAGS03 experiment. Source-receiver range is 3 km.

tion in the Doppler shift, which is nevertheless small compared with the carrier frequency. The small Doppler ratio (Doppler shift over the carrier frequency) indicates a small source/receiver motion which is consistent with the cable/array motion. After applying the Doppler correction, the measured channel impulse responses are plotted in Fig. 19(c). The amplitudes of the Doppler-corrected impulses vary slightly within the packet.

The above analysis shows that Doppler correction is critical for Doppler sensitive waveforms such as the *m* sequences, particularly at high (20 kHz) frequencies. Without the Doppler correction, one could underestimate the signal coherence-time. At low frequencies, Doppler correction due to array motion is usually negligible since the Doppler shift is often small compared with the frequency resolution.

To estimate the temporal coherence of the signal, the impulses responses of the *m* sequences were processed for each packet of *m*-sequence data, as described in Sec. III A. The average of all the temporal coherence curves is plotted in Fig. 20(a), from which one finds a mean coherence-time $\tau_{0.8} \approx 0.5$ s. Figure 20(b) shows the "instantaneous" coherence-time of individual packets as a function of time. Figure 20(c) shows the histogram of the coherence-time. One finds a mean of 0.5 s and a STD of 0.3 s.

VI. CHARACTERISTIC PROPERTIES OF THE SIGNAL coherence-time

In this section we investigate the range, frequency, and environmental dependence of the signal coherence-time of the data reported above. For that purpose, the data are characterized in terms of simple empirical fits. The result suggests certain power dependence but such dependence needs, without saying, further testing with more data.

A. The range dependence

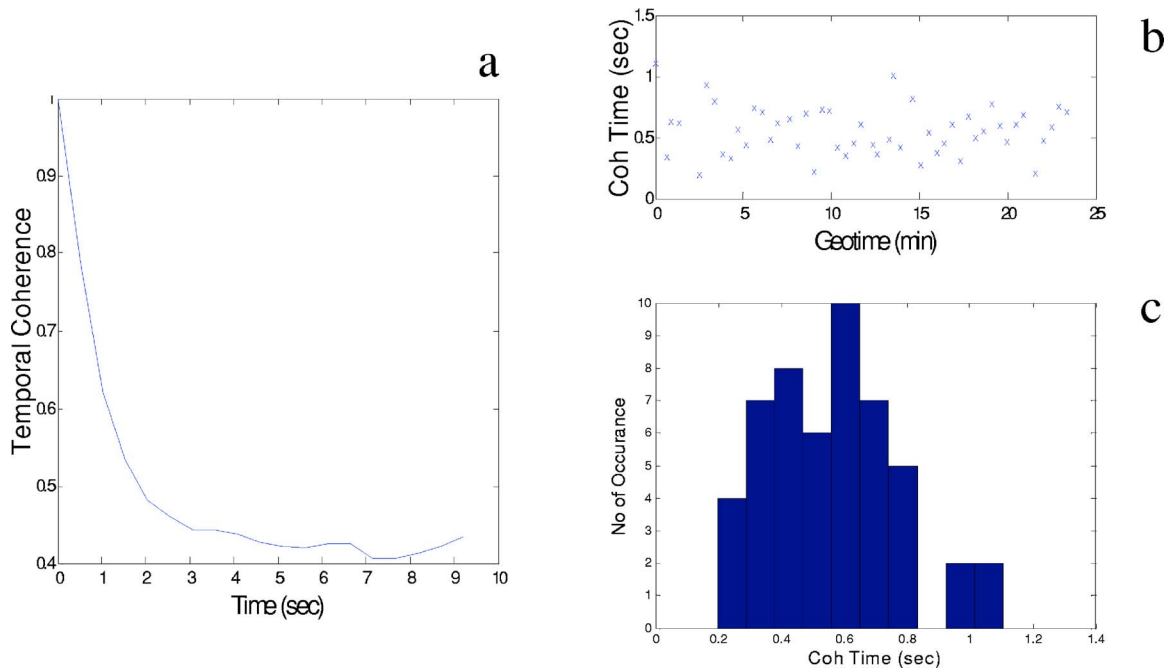
Given the measurement of the signal coherence-time $\tau_{0.8}$ at two ranges from the ASCOT01 data, one can study the range dependence of the signal coherence-time. The measured (mean) signal coherence-time is plotted in Fig. 21 as a function of range for all three frequencies (450, 1200, and 3550 Hz) in a log-log plot. One finds that the data are well fitted with an inverse square-root power dependence on range [see Eqs. (6) and (7)]. Three lines are used to fit the data, which are given by $\tau_{0.8} = \delta R^{-1/2}$, where $\delta = 2.5 \times 10^3$, 6 $\times 10^3$, and 3.2×10^4 for 3550, 1200, and 450 Hz, respectively. The unit of τ is s and R is m.


FIG. 20. (Color online) Temporal coherence of high frequency (20 kHz) signals from the RAGS03 experiment. Average temporal coherence of the *m*-sequence signals as a function of the signal separation time (a). "Instantaneous" signal coherence-time as a function of geotime (b). Histogram distribution of the signal coherence-time (c).

Deep water data showed that the coherence-time decreases as the inverse square root of the range at long ranges; more precisely, the phase rate increases as a square-root power of range.[25] This range dependence was derived theoretically using the Rytov approximation, as discussed above. At short ranges, the phase rate data in the deep ocean indicate a 3/2 power dependence on range for ranges less than 1 km.[25] The above data suggest that the signal coherence-time in shallow water decreases as the square root of range as in deep water. Whether the coherence-time in shallow water at short ranges (also) has a different range dependence is not known.

The ASCOT01 data also contained measurements at 2 km, which could, in principle, be used to address the range dependence. The data are not used in this paper because the data have a high variance and are not conclusive. Note that at a range of 2 km, the signal coherence varies significantly depending on whether the solitary internal waves are within the source-receiver range or not. (At long ranges, one can count on an average number of solitary internal waves in the range.) As such, data over an extended period of time are needed for the temporal coherence measurement to be statistically meaningful. The 2 km range data had a short duration;
FIG. 21. Signal coherence-time plotted as a function of the range at three different frequencies, based on AS-COT01 data at 5 and 10 km ranges.

TABLE II. coherence-time $\tau_{0.8}$ and the spread of the coherence-time (in parentheses) measured off the coast of New Jersey; the later reflects the amount of the temporal variation of the coherence-time due to changes in the propagation environment.

Frequency	$\tau_{0.8}$ at 42 km (SWARM 95)	$\tau_{0.8}$ at 3 km (RAGS03)	$\tau_{0.8}$ at 10 km (Extrapolated)
20 kHz		0.5 (±0.3) s	0.27 (±0.16) sec
400 Hz	40 (±35) s		82 (±72) sec
224 Hz	130 s		266 sec

the short duration may be the reason for the large variance in the 2 km data compared with the mean coherence-time.

B. Frequency dependence

Based on the theoretical work in deep water [Eq. (7)], the coherence-time [Eq. (6)] is expected to decrease as inverse square-root power of range, and inverse linear power of frequency,

$$\tau_{0.8} = (0.11/\gamma)f^{-1}R^{-1/2}. \tag{11}$$

Assuming the inverse square-root dependence on the range (as studied above), one can study the frequency dependence of the coherence-time $\tau_{0.8}$.

The SWARM95 and RAGS03 data were collected at a different range than 10 km (Table II). Using the inverse square-root range dependence, one can extrapolate the coherence-time $\tau_{0.8}$ to a range of 10 km. The results are shown in Table II, last column. The 10 km data are plotted in Fig. 22. One finds that the data can be fitted with an inverse 3/2 power dependence on frequency, as shown by the curve labeled C.

The coherence-time $\tau_{0.8}$ measured from the ASCOT01 data at the 10 km range (Table I) is also plotted in Fig. 22. One finds that the data can also be fitted with an inverse 3/2 power dependence on frequency, as shown by the curve labeled B.
FIG. 22. (Color online) Signal coherence-time plotted as a function of signal frequency based on data from four different experiments. Dashed curves are fit to the data, as described in the text.

In Fig. 22 is also plotted the coherence-time $\tau_{0.8}$ measured during the ADVENT99 experiment, which was presented in Ref. 13. The temporal coherence was measured using matched field correlation, Eq. (8). The data were narrow band signals (200 to 1200 Hz in steps of 100 Hz) received on a vertical line array. The source receiver range was 10 km. One finds that the data are consistent with an inverse 3/2 power dependence on frequency, as shown by the curve labeled A.

In summary, one obtains an empirical fit of the data presented above as

$$\tau_{0.8} = \beta f^{-3/2}R^{-1/2}, \tag{12}$$

where $\beta = 4 \times 10^9$, 3×10^8, and 7×10^7 (m/s)$^{1/2}$ for the ADVENT99, ASCOT01, and SWARM95/RAG03 data, respectively. Using Eq. (6), one finds

$$\nu = \alpha f^{3/2}R^{1/2}, \tag{13}$$

where $\alpha = 0.11/\beta$. One thus finds $\alpha = 0.28 \times 10^{-10}$, 3.6×10^{-10}, and 1.6×10^{-9} (m/s)$^{-1/2}$ for the ADVENT99, ASCOT01, and SWARM95/RAG03 experiments, respectively. The 3/2 power dependence on frequency has not been predicted before.

C. Relation to the sound speed STD

The more random the ocean becomes, the less the signal coherence-time will be. Assuming that the medium fluctuation is the cause for the signal coherence loss, the question is how is the coherence loss related to, or more specifically, how is β (or α) related to the oceanographic activities in the water column. This topic obviously requires a detailed modeling analysis and could benefit from some theoretical predictions. For the purpose of data characterization, it is useful to determine the relation of the above coefficient to the sound speed STD, noting that the latter is related to the amplitude of the internal waves and other fine structures.

Let us examine the sound speed STD in the various experiments. The four experiments, ADVENT99, ASCOT01, SWARM95, and RAGS, all took place in a summer environment with a layer of warm water over the cold water. The water depth was approximately 81 m for the ADVENT99 experiment, 100 m for the ASCOT01 experiment, and varied from 57 to 88 m in the SWARM95 experiment. The average sound speed profiles and the sound speed STD can be found in Refs. 13, 22, and 26 for the ADVENT99, ASCOT01, and SWARM95 environments, respectively. The RAGS experiment took place in the same area as SWARM95 and has a similar sound speed profile as SWARM 95. The sound speed is nearly constant below 30 m with sound speed increasing slightly (ADVENT99), gradually (ASCOT01), or sharply (SWARM95) to a high sound speed found in the warm layer. The gradual to sharp transitions between the warm and cold layers are responsible for different magnitudes of internal waves, which reside primarily at the pycnocline, which often coincides with the thermocline. The primary difference between the three environments is the sound speed STD, which varies from 0.3 m/s in ADVENT99, to 2–3 m/s in ASCOT01 and 5 m/s in SWARM95, as measured at the depth

TABLE III. Environmental dependence.

	Water depth (at receiver)	Thermocline depth	Sound Speed STD (δC)	Alpha of Eq. (13)
ADVENT99	80 m	~5 m	0.3–0.6 m/s	0.027×10^{-9}
ASCOT01	100 m	~8 m	2–3 m/s	0.28×10^{-9}
SWARM95	88 m	~20 m	5 m/s	1.74×10^{-9}

of the thermocline. (The thermocline is not well defined in the ADVENT99 experiment. Because of the uncertainty of sound speed measurement within 5 m of the surface, the data at 10 m are used for ADVENT99.) The acoustic parameters are summarized in Table III.

The sound speed STD (at the pycnocline) is a good indicator of the strength of the internal waves as it is proportional to the amplitude of the internal waves to the first order of approximation.[19] The Adventure Bank has little internal wave activity. The coasts of New England and New Jersey have medium to high amplitude internal waves. Internal waves create shear instabilities and produce turbulence at the boundaries. These instabilities can affect high frequency sound propagation.

To determine if and how the medium fluctuations affect the signal coherence-time (at a fixed frequency and range), one needs to determine the correlation between the sound speed STD (at the thermocline) and the coefficient α of the signal phase rate, Eq. (13). We plot in Fig. 23 the value of α as a function of the sound speed STD as given in Table III. The α data are consistent with a quadratic power dependence on the sound speed STD as shown by the dashed curve; $\alpha = 0.6 \times 10^{-10} (\delta C)^2$.

D. Observations

The above analysis provides an empirical parameterization of the signal coherence-time with respect to the signal frequency, source receiver range, and sound-speed STD. The result is useful for system design and analysis.

From the physics point of view, the question is how is the signal coherence loss related to the environmental conditions—how to predict the signal coherence loss. As remarked above, there exists (to our knowledge) no theoretical analysis for the signal coherence loss in a time varying shallow water environment. The problem is notably difficult, and is beyond the scope of this paper. Nevertheless, some observations can be made from the data and will be discussed later.

It is generally accepted that the signal coherence-time reflects the time scale of the processes responsible for the signal coherence loss. As such, one can infer from the measured coherence-time the underlying processes causing the signal coherence loss. Signal coherence loss can be caused by signal scattering from the medium heterogeneities, rough surfaces, and bottom inhomogeneities. Which processes are dominant depends on the signal frequency, the magnitude of the inhomogeneities, and the roughness of the boundaries. To properly interpret the data, one needs to model the signal propagation that depends on the sound speed profile and bottom attenuation. The measured channel impulse response should be used to guide and verify the modeling results.

Normally, acoustic rays with shallow depletion/elevation (D/E) angles are trapped in the sound waveguide and thus are most sensitive to medium inhomogeneities such as internal waves and turbulence. On the other hand, acoustic rays with steep D/E angles tend to interact more with surfaces and bottom and are thus more affected by the surface roughness, bottom attenuation, and changes in the overall sound speed. To study the effect of the rough surfaces in a downward refractive sound speed profile, it is preferred to use a source near the surface.

The ASCOT01 experiment used a source near the bottom. As noted above, the late arrivals in the ASCOT01 data (e.g., the 3550 and 1200 Hz signals) change slowly with time. The change in arrival time is, in this case, caused by the change of the layer depth (due to internal tide) rather than the surface height (the external tide) or roughness (wind speed). The reason, as pointed out in Ref. 23, is that the high
FIG. 23. (Color online) The coefficient α measured from the data (square) as a function of the sound speed STD.

D/E angle rays have been attenuated, so the signal consists mostly of refracted-bottom-bounced rays. This has also been demonstrated with modeling results in other shallow water environments.[27,28] One finds that the signals from a bottom mounted source, propagated to long ranges, have generally little interaction with the surface in a downward refractive sound speed profile.

Despite the evidence that internal tides affect the multipath arrival time at high frequencies, the internal tides have negligible effect on the signal coherence-time at 3550 Hz in the ASCOT01 environment. This is due to the fact that the signal coherence-time at high frequencies (at the ASCOT01 site) is short (of the order of tens of seconds). This time scale is indicative of the microfine structures (e.g., turbulence). Figure 1 shows rapid fluctuations of the multipath arrivals with time scales on the order of minutes. The results are consistent with the observation that turbulence (and internal waves) has a significant impact on high frequency sound propagation. The instantaneous coherence-time at 3550 Hz [Fig. 4(b)] shows a pattern of random fluctuation, which is expected from random structures like turbulence.

The low frequency (450 Hz) data from the ASCOT0l experiment show, on the other hand, a very stable arrival pattern, particularly for the early arrivals (Fig. 8). (The impulse responses at time 250–270 min are out of alignment, an artifact of data processing.) The instantaneous coherence-times [Fig. 9(b)] are of the same order of magnitude except for certain periods (between 50–100 min in Fig. 8), where the fifth arrival has a high amplitude. Similar observations can be made in Fig. 14 when the third arrival has a high amplitude. At these time periods, the instantaneous coherence-time is higher than other time periods. This is consistent with the fact that a higher coherence-time is obtained when the signal energy is concentrated in a small number of stable multipaths. It is presumed that during these periods, the signals have less scattering and thus have high amplitudes.

The instantaneous coherence-time at 1200 Hz [Fig. 7(b)] shows periodicities on the order of tens of minutes. Similar periodicities are also observed at 450 Hz [Fig. 9(b)]. The origin of this is not known.

The 400 Hz signal from the SWARM95 experiment shows very different properties than the 450 Hz signal from the ASCOT01 experiment, despite the fact that they propagate under similar sound speed profiles. The multipath structures are not as clearly defined in Fig. 16 as in Fig. 8. The multipath arrival times are not as stable in Fig. 16 as in Fig. 8. The reason is that the internal waves off the coast of New Jersey are much stronger than that off New England (See Sec. VI C). Internal waves induce mode couplings in the SWARM95 data,[14,24,27] which smear the arrival pattern as well as temporal stability of the received signals. One notes also that for the 450 Hz signal from the SWARM95 data, the arrival time difference between the early and late arrivals remain approximately unchanged over an 18 h period (Fig. 16), whereas the arrival time difference changes with the tidal cycle in the ASCOT01 data (as discussed above for the 3550 and 1200 Hz signal, a similar pattern was also seen for 450 Hz signal in Fig. 8). The effect of the internal tides on the signal arrival time is also expected for the SWAM95 signal, but such arrival time differences are easily diminished by the mode coupling effect.

The 224 Hz signal in the SWARM95 data show a dominant group of arrivals with approximately the same total delay time as that seen in the 400 Hz signal. Individual multipath arrivals are not identified due to the narrow band (16 Hz) of the signal. This is not an environmental effect.

VII. SUMMARY

In this paper, we conducted a systematic measurement of the temporal coherence of acoustic signals propagating in three shallow water areas. The three environments represent areas of low, medium, and high internal wave activity. The measurements cover low (below 1.5 kHz), mid (2 to 5 kHz), and high frequency data. The receiver range covers 3, 5, 10, and 42 km. The "instantaneous" temporal coherence of the signals is also measured, from which one obtained the time variation of the signal coherence-time as well as its mean and STD. To achieve a statistical mean, the temporal coherence is averaged over hours of data, which are generally considered adequate for high frequency signal fluctuations. For low frequency acoustic signals in an area where solitary internal waves are dominant, data beyond 12 h were used to include the solitary internal wave effect. Otherwise, hours of data should be adequate (for diffuse internal waves). An empirical analysis is conducted on the relationship between the signal coherence-time and the acoustic frequency, the source receiver range, and the sound speed STD. It is found that the dependence on frequency and sound speed STD deviate significantly from a previous theoretical prediction for deep water.

High-frequency channel characterization for M-ary frequency-shift-keying underwater acoustic communications

Wen-Bin Yang[a] and T. C. Yang
Naval Research Laboratory, Washington D.C. 20375

Many ($>$100) packets of pseudo-random signals transmitted during the TREX04 experiments are analyzed in this paper to deduce the narrowband signal envelope amplitude statistics over a wide band (15–19 kHz) of frequencies. The envelope amplitude statistics are found to be non-Rayleigh-type with a long-tail distribution at high amplitudes. Long-term and short-term fading statistics are deduced from the data, exhibiting near lognormal and Rayleigh distributions, respectively. The combined distribution is closely approximated by a K-distribution, which fits the measured amplitude distributions well over a wide band of frequencies. [DOI: 10.1121/1.2346133]

I. INTRODUCTION

As is well known, the communication bit error rate (BER) is heavily influenced by the channel characteristics. Underwater acoustic communication channels differ from radio frequency (RF) communications channels by: (i) A longer multipath delay, which extends over many symbols causing intersymbol interference (ISI), (ii) a higher Doppler spread which implies a shorter channel coherence time, and (iii) a time-varying Doppler shift due to the relative platform speed compared with the sound speed. Under the assumption of wide sense stationary and uncorrelated scattering, the channel properties can be characterized by the scattering function as a function of delay time and Doppler frequencies.[1] The scattering function becomes the channel impulse responses for stationary sources and receivers. The latter is often used to assess the effect of the medium on communication performance. For time-varying oceans, channel characterization is concerned with a statistical description of the impulse response functions (the amplitudes of individual arrivals), which is a study in the time domain. Channel characterization can also be done in the frequency domain using the channel transfer functions (the Fourier transform of the channel impulse responses). Although the two are, in theory, equivalent, they have different implications in practice. This paper addresses the channel characterization in the frequency domain, specifically the signal amplitude envelope statistics, which forms the basis of BER predictions for M-ary frequency-shift-keying (MFSK) signals. The time domain channel characterizations form the basis for performance predications for M-ary phase-shift-keying (MPSK) signals. While the multipath amplitude fluctuation analysis is outside the scope of this paper, the physical insights on multipath fluctuations are needed to understand/interpret the frequency domain results.

Figure 1 shows a snapshot of high-frequency channel impulse responses measured from at-sea data over a period of a little more than 10 s. The signal has a center frequency of 17 kHz and a bandwidth of 5 kHz. Details are given later in the paper. One notes that the channel impulse responses vary on a scale of tenths of a second. The channel coherence time is on the order of 0.2 s. In Fig. 1, one observes five to six strong multipath arrivals, plus numerous late arrivals. Not only does the amplitude of each path change with time, the arrival times of individual paths may also vary with time. This property is different from impulses responses at low ($<$5 kHz) frequencies, where the signal has a coherence time of tens of second and the channel impulse responses remain coherent within a communication packet.[2] Channel characterization (in the time domain) requires a determination of the amplitude and phase (fluctuation) statistics for individual path arrivals. Galvin and Wang[3] measured the fluctuation statistics for a direct path and a surface reflected arrival using parametric sonar. The acoustic signal is centered at 5 kHz with a 2 kHz bandwidth. They found that the amplitudes follow a Rician distribution and the phase statistics is Gaussian-type. There are very few direct experimental measurements in the published literature. The difficulties are that the multipaths arrivals are often clustered together and not easily separable except at short ranges.

The above experimental findings serve as the basis for certain channel characterization models. Geng and Zelinski[4] assumed that the received signal is comprised of a dominant stable component and many smaller, randomly scatter components; hence, the signal follows the Rician fading statistics. Estes *et al.*[5] proposed a different model in which a raised cosine windowing function is used to introduce the nonstationary characteristics of the channel due to platform and boundary movement. Jobst *et al.*[6] proposed a stochastic model in which the temporal and spectral fluctuations are not Rayleigh distributed. The number of eigenrays reaching the receiver is Poisson distributed, with a mean value determined by the Ray theory. Galvin and Coates[7] model the channel using a combination of linear and nonlinear transformation on a Gaussian variables. One notes that there are many channel models in literature. The reasons are due to a lack of: (1) Theoretical understanding of the path fluctuations and the corresponding statistics, and (2) direct experimental measurements of the amplitude fluctuations of individual paths.

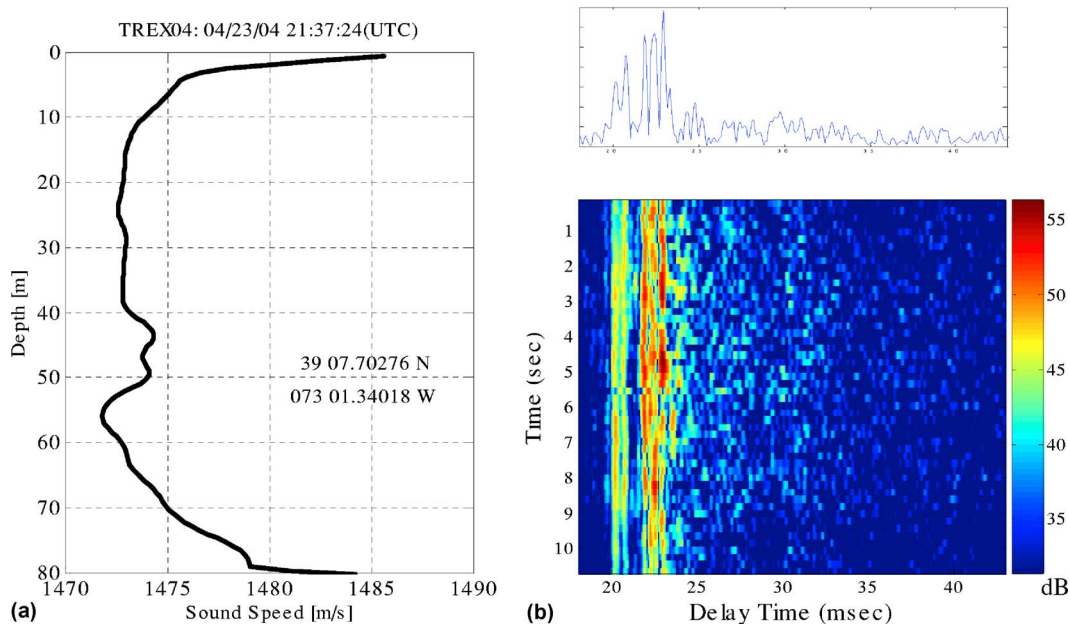

FIG. 1. (Color online) (a) A representative sound speed profile collected during the TREX04 experiment. (b) Channel impulses responses measured from one packet of M-sequence data.

Note that the fluctuation statistics are path and frequency dependent. At low frequencies, one observes that the early arrivals are relatively stable, whereas the late arrivals are random and varying fast with time. The reason is that early arrivals are affected by medium inhomogeneities, which at low frequencies are caused by internal waves, and the late arrivals are scattered returns from the surface and bottom roughness. Since the early arrivals are more dominant, the coherence time is of the order of tens of seconds to minutes (the scale of internal waves). This is not the case at high frequencies, as evidenced by the much shorter coherence time. At high frequencies, the microfine inhomogeneities, e.g., the turbulence, play an important role. A proper channel model must incorporate the physics of signal fluctuations. Whether theoretically motivated or experimental-data based, one needs a channel model to predict the BER for MPSK signals.

For MFSK signals, the symbols are spread over the frequency band and modulated in both frequency and time. Channel characterization is now concerned with the envelope amplitude fluctuation statistics as a function of frequency, i.e., the fluctuations statistics of the amplitudes of the channel transfer function for a given frequency. This is called the narrowband fluctuation statistics, since the frequency bin size is much smaller than the center frequency of the whole band. (Only the absolute value of the amplitude is of interest here, since each symbol is detected by an energy detector.) The BER for MFSK signals depends on the envelope amplitude fading statistics as a function of frequency. Rayleigh and Rician amplitude probability distributions are two commonly assumed models for signal fading in RF communications.[8–10] Narrowband signal fluctuation statistics have been studied at low frequencies (e.g., <1 kHz) based on the theory of sound propagation through internal waves.[11] Rayleigh and Rician statistics are associated with saturated and

partially saturated schemes, in which the multipaths are totally or partially random.[12] For acoustic communications, Catipovic et al.[13] assumed a Rayleigh distribution for MFSK signals.

The envelope amplitude fluctuation statistics for a fixed frequency are very different from that for a fixed path. As remarked above, the amplitudes of some paths may follow a Rician distribution, whereas the other may follow a Rayleigh distribution or something else. In the frequency domain, all multipath arrivals contribute to the fluctuations. Hence, a priori, what the envelope amplitude statistics will be is not clear. (If the time domain amplitude distribution is Rayleigh, the frequency domain amplitude distribution will also be Rayleigh. But this is not the case for the majority of the underwater acoustic channels.) To our knowledge, there are no direct experimental measurements of the envelope amplitude statistics for high-frequency MFSK signaling.

The MFSK symbol duration is, normally by design, of the order of the multipath spread. To avoid ISI interference, the symbol duration (including the guard time if appropriate) should be longer than the multipath spread; but, in practice, this is often not the case. In that case, there will be some ISI coming from the late arrivals beyond the MFSK symbol duration. For MFSK performance prediction, the amplitude statistics used should include the ISI interference according to the signal symbol duration (or the frequency bin size) selected.

For MFSK symbol duration on the order of the multipath delay, one can assume that the (narrowband) signals between adjacent frequency bins are uncorrelated. More specifically, the frequency bin size needs to be greater than the frequency coherence bandwidth, which is of the order of the inverse of the multipath spread. In this case, the envelope amplitude statistics between the different frequency components can be assumed to be independent and identically dis-

tributed, as the channel property is expected to vary slowly with frequency. The data analysis presented below supports this hypothesis.

In this paper, narrowband amplitude envelope statistics are deduced from data collected at sea. The measured distributions deviate significantly from the Rician and Rayleigh distributions and are found to be close to the K-distribution. A physics-based interpretation of the K-distribution is provided. The implication is that the BER for MFSK underwater acoustic communications is worse than that in a RF channel for a given signal-to-noise ratio (SNR), since the BER for a K-distribution is worse than that of Rayleigh and Rician distributions. This is independently verified using frequency-hopping frequency-shift-keying data measured at sea.[14]

The paper is organized as follows. Section II describes the experimental data analysis. Narrowband envelope amplitude distribution statistics are deduced from data covering a wide band (4 kHz) of frequencies. Section III reviews the three amplitude statistical distribution models and compares them with data. Section IV presents the long-term and short-term fading statistics, from which a distribution close to the K-distribution is derived. Section V provides conclusions.

II. CHARACTERISTICS OF THE AMPLITUDE FLUCTUATIONS

A. MFSK modulation

For a narrowband signal, the channel transfer function can be defined by

$$R(t,f) = H(t,f)S(f), \qquad (1)$$

where $H(t,f)$ is the channel transfer function at frequency f, assumed to be time dependent, R is the received signal, and S is the source amplitude. MFSK signals consist of many narrowband signals at frequencies f_k, separated by Δf, where $k = 1, \ldots, K$,

$$R(t,f_k) = H(t,f_k)S(t,f_k), \qquad (2)$$

where $S(t,f_k)$ is the transmitted symbol sequence in frequency bin f_k at time t, and $S(t,f_k) = 0$ or 1. Each symbol has a time duration $\Delta t = 1/\Delta f$. Detection of symbols at the receiver is based on the symbol intensity $|R(t,f_k)|^2$, which is heavily influenced by the channel spectral level $|H(t,f_k)|^2$. Hence, BER modeling/prediction requires knowledge of the statistical distribution of $|H(t,f_k)|$, the envelope amplitude statistics.

To measure the envelope amplitude statistics, one can use

$$|H(t_m,f_k)|^2 = |R(t_m,f_k)|^2/|S(t_m,f_k)|^2, \qquad (3)$$

where $|R(t,f_k)|^2$ and $|S(t,f_k)|^2$ are the spectral level of the received and transmitted signals as a function of frequency at $t_m = m\Delta t$, for the mth symbol. Equation (3) provides a snapshot of the channel transfer function at a particular time as a function of frequency. In the experiment described next, pseudo-random noise signals are used. The pseudo-random signal has a flat spectrum when averaged over many sampling periods. Using $\Delta t = 12.5$ ms, more than 10^5 numbers of realizations of Eq. (3) are obtained from data

to determine the amplitude envelope statistics at a fixed frequency.

The alternative is to use very short pulses or single-frequency continuous waves. For a pulse, if the source has a flat spectrum, i.e., $S(t_m,f_k) \approx S_0$, one has

$$|H(t_m,f_k)|^2 = |R(t_m,f_k)/S(t_m,f_k)|^2 \approx |R(t_m,f_k)|^2/|S_0|^2. \qquad (4)$$

For continuous waves, the source spectrum can be assumed to be a constant. Although in both cases, data processing is simplified somewhat, the shortcoming is that it will take tens of hours or more data to achieve the same statistics (total number of realizations) as obtained using the pseudo-random signals (based on the time-bandwidth product calculation).

B. TREX04 experiment

TREX04 experiment was conducted by the Naval Research Laboratory (Washington D.C.) in April 2004, which took place in the coast of New Jersey. Figure 1(a) shows a sound speed profile based upon measurement at the site. Acoustic communication data were transmitted from a fixed source to a fixed receiver array at the range of 3.4 km. Water depth in the experimental area is about 70 m. The source and receivers were located at about 35 m depth. The vertical array has an aperture of approximately 2 m, and contains eight hydrophones with nonuniform spacing. The data presented below are from a single receiver; little difference is found between the receivers. The data have a high SNR $\geqslant 30$ dB. The recording has a dynamic range 96 dB, so that the recorded data provide sensitive measurements of signal fading.

Various communication signals centered at 17 kHz were transmitted and received at an eight-hydrophone line array. The M-sequence signal was one of the communication signals collected in the TREX04 experiment. It uses a bandwidth of 5 kHz. Each transmitted packet lasted approximately 10.7 s, and contained 53 M-sequences. A total of 134 packets, extended over a period of 1 h and containing 7102 M-sequences, were analyzed.

Figure 1(b) shows the channel impulse responses measured from 53 M-sequences within one packet. The dominant arrivals are confined within 5 ms of arrival time, with numerous weaker late arrivals. Modeling results show these are refractive arrivals as steep; bottom interacting arrivals have been severely attenuated at a range of 3 km. As remarked above, at high frequencies, the signal fluctuates rapidly with geotime.

The M-sequence signals are used to measure the channel transfer function as a function of frequency and time. The M-sequence signals are often referred to as pseudo-random-noise signals, since they have an average spectrum similar to that of white noise. The source spectrum for 53 M-sequences is plotted in Fig. 2(a), where the signal is processed with a frequency bin size $\Delta f = 80$ Hz. The received M-sequence signals have a very different spectrum than the transmitted one. Figures 2(b)–2(d) show three received spectra as a function of frequency and time, which were transmitted at three separate times. One observes significant variations in the signal levels compared with the transmitted signal and with each other. This is a result of random media propagation, which
FIG. 2. (Color online) (a) The source spectrum: The spectrum of the M-sequence signal as a function of frequency and time. (b)–(d) The received M-sequence spectra as a function of frequency and time, based on three different packets transmitted at three different times. The frequency bin size is 80 Hz for all figures.

produces time-varying phases between modes or rays. Destructive interferences between modes or rays cause signal fading at some frequencies (frequency-selective fading). Note that the fading pattern is time dependent and varies significantly from packet to packet. Signal fading is a dominant source for BER for MFSK signals. The objective of the channel characterization in this paper is to determine the envelope amplitude statistics resulting from random media signal propagation.

For $\Delta f = 80$ Hz, the symbol duration is 12.5 ms. Compared with the impulse response shown in Fig. 1(b), one notes that a small portion of the current symbol will leak to the next symbol due to multipath arrivals beyond 12.5 ms, causing a small ISI. Note that for $\Delta f = 160$ Hz, there will be more ISI. On the other hand, for $\Delta f = 40$ Hz, the symbols are ISI free. The ISI is part of the amplitude envelope statistics that must be included for BER calculation/prediction. Thus, in theory, the amplitude envelope distribution will be dependent on the frequency bin size. The data analysis results shown next show a small frequency bin size dependence.

A word of caution is warranted here. One notes that the frequency components (bins) are, in theory, orthogonal to each other; implying that there is no leakage of the symbol energy from one frequency channel to the other. In practice, this may not be the case if there is significant source/receiver motion or rapid time variation in the propagation channel; causing frequency shift for the MFSK symbols. An error in the Doppler shift estimation could cause an energy leak from

adjacent frequency bins (referred to as the co-channel interference). To minimize this effect, the frequency bin width, Δf, is often chosen to be much larger than the uncertainty in the Doppler shift estimation. In this paper, data from fixed sources to fixed receivers are used with near-zero Doppler shift. For this data, the co-channel interference is expected to be negligible.

C. Envelope amplitude statistics

The M-sequence data were transmitted in consecutive packets; each of 15 s duration with built in time gaps. Total transmission time was ~40 min. The M-sequence data are processed first by removing the transducer's frequency response from the received data. The beginning of the M-sequence in each packet is determined by matched filtering the data using either the probe signal before the M-sequence or the first M-sequence; a standard processing technique for communications. The M-sequence data are then Fourier transformed with a window size equal to the symbol duration. The channel spectrum is obtained using Eq. (3); with the received and transmitted data processed in the same way.

One obtains the mean spectral level as a function of frequency, $\Sigma(f_k)$, by summing the spectrum level over all data samples and dividing the result by the number of samples. It is found that $\Sigma(f_k)$ decreases by as much as 5 dB at the edges of the frequency band. Since Eq. (3) is unstable
FIG. 3. Amplitude fading statistics for individual frequency bins (frequency bin size=80 Hz).

close to the edges of the frequency band (where the source spectrum is near zero), the edge frequencies are discarded in our analysis. $\Sigma(f_k)$ in the middle frequency band ($\sim$4 kHz), representing the average system response, is expected to vary little within the frequency band (which is much smaller than the center frequency). The measured $\Sigma(f_k)$ varies by 1–2 dB, and is attributed to the uncertainty in the transducer response curve, which was undersampled in the original (calibration) measurements. This 1–2 dB variation is removed by the following operation:

$$|H'(f_m,f_k)|_{\text{new}} = |H(t_m,f_k)|/\sqrt{\Sigma(f_k)}, \quad (5)$$

where t_m denotes the symbol sequence in time. Henceforth, the corrected data will be denoted by $|H(t_m,f_k)|$ without the "prime."

As the data were transmitted in packets, one can represent the realization in time as $t_m=nT_0+j\Delta t$, where n is the packet number, $n=1,\ldots,134$, T_0 is the time separation between packets, and j is the symbol number within a packet, $j=1,\ldots,856$ and $\Delta t=1/80$ s for $\Delta f=80$ Hz. This yields a total of 114 704 realizations in time for each fixed frequency.

The frequency coherence bandwidth can be measured by cross correlating the channel transfer functions between two different frequencies denoted by its frequency index $k1$ and $k2$,

$$\rho[(k2-k1)\Delta f] = \left\langle \frac{\left| \sum_m H^*(t_m,f_{k1})H(t_m,f_{k2}) \right|}{\sqrt{\sum_m |H(t_m,f_{k1})|^2} \sqrt{\sum_m |H(t_m,f_{k2})|^2}} \right\rangle, \quad (6)$$

where the correlation is done for each packet (summing over j for a fixed n), and then averaged over all the packets (of a duration approximately 1 h). One finds that $\rho<0.2$ when $k1\neq k2$; indicating that the channel transfer functions are uncorrelated between (adjacent) frequency bins. In other words, the frequency coherence bandwidth is <80 Hz.

The probability distribution of the envelope amplitude $|\tilde{H}(t_m,f_k)|$ is determined for each frequency f_k. The results are plotted in Fig. 3 for different frequencies. One finds that

the probability distributions are very similar—suggesting that the envelope amplitudes at different frequencies (within the band) have independent and identical distributions (iid). [In Fig. 3, three frequencies bins have a slightly different distribution than the rest of the frequencies bins. This difference could be easily caused by a small number of events in the high-tail distribution (due to instantaneous interference between the signal and noise) that would shift the probability distribution to what is shown.]

Assuming the iid property, the envelope amplitudes of all frequencies (within the band) are used to increase the statistical samples. The resulting statistical distribution is plotted in Fig. 4(a) (for the 80 Hz frequency bin data).

III. THEORETICAL MODELS AND COMPARISON WITH DATA

In this section, previous well-known amplitude distribution statistics are reviewed and compared with the measured data. For this comparison, one first considers the envelope statistics at a fixed frequency.

A narrowband signal can be represent by $p(f) = H(f)e^{i2\pi f}$, where $H(f)$ is the complex amplitude

$$H(f) = X + iY, \quad (7)$$

where X and Y are often referred to as the in-phase and quadrature components of the signal. Assuming that X and Y are Gaussian random variables with a probability distribution given by

$$p(A) = \frac{1}{2\pi\sqrt{|\Sigma|}} \exp\left[-\frac{1}{2}(A-\langle A\rangle)^T\Sigma^{-1}(A-\langle A\rangle) \right], \quad (8)$$

where $A\equiv[X,Y]^T$, with the superscript T denoting transpose, $\langle A\rangle$ denotes the mean

$$\langle A\rangle \equiv \left\langle \begin{bmatrix} X \\ Y \end{bmatrix} \right\rangle = \begin{bmatrix} \mu_x \\ \mu_y \end{bmatrix}, \quad (9)$$

and Σ is the covariance matrix given by

$$\Sigma = \langle(A-\langle A\rangle)(A-\langle A\rangle)^T\rangle = \begin{bmatrix} \sigma_x^2 & \sigma_{xy} \\ \sigma_{xy} & \sigma_y^2 \end{bmatrix}. \quad (10)$$

Defining

$$\rho_{xy} = \frac{\sigma_{xy}}{\sigma_x\sigma_y}, \quad (11)$$

it can be shown, after some calculations, that the (envelope) amplitude $Z=\sqrt{X^2+Y}$ has a distribution given by

$$p(z) = A(z,\mu_x,\mu_y,\sigma_x,\sigma_y,\rho_{xy}) \cdot \Psi(z,\mu_x,\mu_y,\sigma_x,\sigma_y,\rho_{xy}), \quad (12)$$

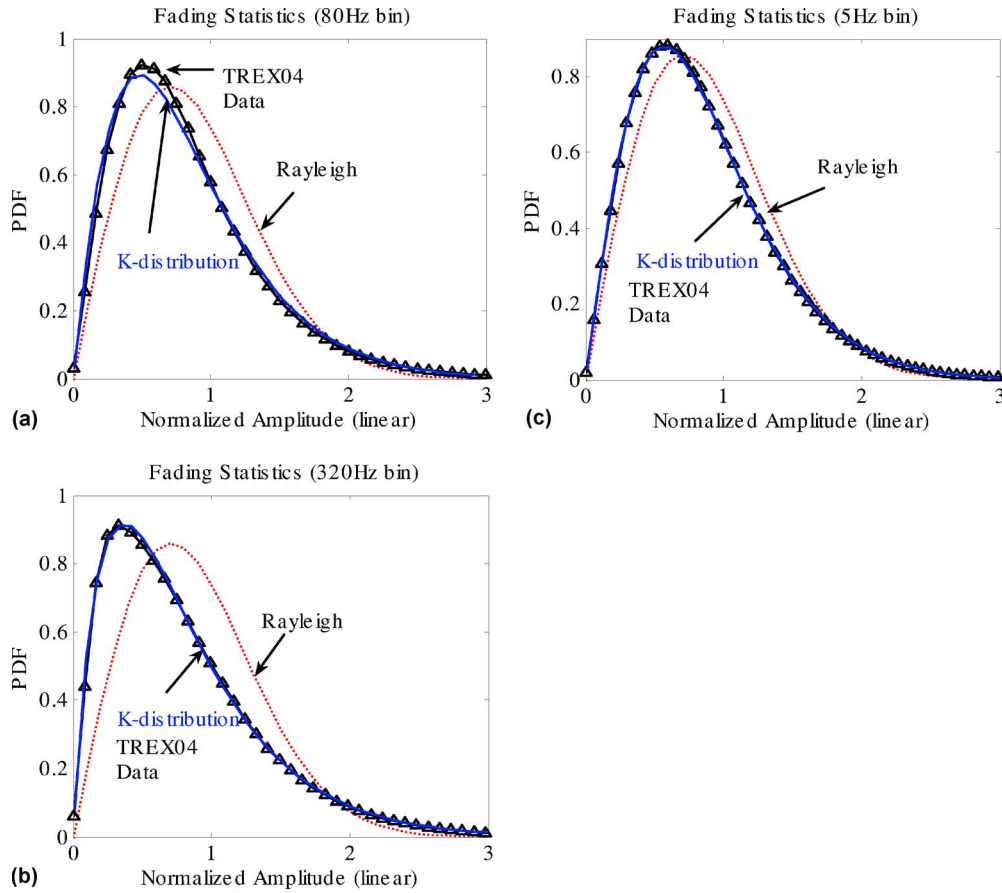
where


FIG. 4. (Color online) Data of Fig. 3 averaged over frequencies, shown with triangles compared with various theoretical distributions: K-distribution, Rayleigh distribution, and Mikhalevsky's model. The distribution using Mikhalevsky's model turns out to be nearly identical to Rayleigh distribution and is not separately plotted. (a) Frequency bin size=80 Hz; (b) frequency bin size=320 Hz; and (c) frequency bin size=5 Hz.

$$A(z,\mu_x,\mu_y,\sigma_x,\sigma_y,\rho_{xy}) = \frac{z}{\sigma_x\sigma_y\sqrt{1-\rho_{xy}^2}}\cdot\exp\left\{\frac{-1}{2(1-\rho_{xy}^2)}\right.$$
$$\times\left[\frac{z^2+2\mu_x^2}{2\sigma_x^2}-\frac{2\rho_{xy}\mu_x\mu_y}{\sigma_x\sigma_y}\right.$$
$$\left.\left.+\frac{z^2+2\mu_y^2}{2\sigma_y^2}\right]\right\}, \quad (13)$$

$$\Psi(z,\mu_x,\mu_y,\sigma_x,\sigma_y,\rho_{xy}) = \frac{1}{2\pi}\int_0^{2\pi}\exp\left\{\frac{-1}{2(1-\rho_{xy}^2)}\right.$$
$$\times[a\cos 2\phi + b\sin 2\phi$$
$$\left.+ c\cos\phi + d\sin\phi]\right\}d\phi, \quad (14)$$

where a, b, c, and d are defined by

$$a = z^2\left(\frac{1}{2\sigma_x^2}-\frac{1}{2\sigma_y^2}\right), \quad b = z^2\left(\frac{\rho_{xy}}{\sigma_x\sigma_y}\right),$$

$$c = z\left[\frac{2\rho_{xy}\mu_y}{\sigma_x\sigma_y}-\frac{2\mu_x}{\sigma_x^2}\right], \quad d = z\left[\frac{2\rho_{xy}\mu_x}{\sigma_x\sigma_y}-\frac{2\mu_y}{\sigma_y^2}\right]. \quad (15)$$

To interpret the above amplitude distributions in the context of signal propagation, the simplest example will be direct path propagation between a source and a receiver. For this case, μ is the (deterministic) signal and $\sigma_x^2=\sigma_y^2=\sigma_N^2$ is the variance of the noise. For propagation through a random medium, μ is the deterministic component of the signal and $\sigma_x^2=\sigma_y^2=\sigma_s^2+\sigma_N^2$ is the sum of the variance of (the random component of) the signal and that of the noise.

Typical underwater acoustic propagation involves many multipaths. In that case, the complex amplitudes are summation of many multipaths, $X=\Sigma_{i=1}^N x_i$, $Y=\Sigma_{i=1}^N y_i$. This case has been studied by Mikhalevsky.[12] He hypothesized that the signal fluctuation is manifested mainly in the signal phase, as defined by $x_i+iy_i=|a_i|e^{i\phi_i}$. Assuming that the variance in phase fluctuation is the same for all multipaths, $\sigma_{\phi_i}^2=\sigma_\phi^2$, and hence $\sigma_{x_i}^2=\sigma_x^2$, $\sigma_{y_i}^2=\sigma_y^2$, the signal envelope amplitude statistics can be grouped into three cases: For unsaturated propagation, $\sigma_\phi=0$, $\mu_x\neq 0$, $\mu_y\neq 0$, $\sigma_x^2=\sigma_y^2=\sigma_N^2$, one finds $\rho_{x,y}=0$, and the envelope amplitude statistics distribution is Rician. For saturated propagations, $\sigma_\phi\to\infty$, one finds $\mu_x\to 0$, $\mu_y\to 0$, $\sigma_x^2=\sigma_y^2=\sigma_N^2$, and $\rho_{x,y}\to 0$. Thus, the envelope amplitude fluctuation approaches the Rayleigh distribution. For partially saturated propagation, which corresponds to $\sigma_\phi\neq 0$, $\mu_x\neq 0$, and $\mu_y\neq 0$, the envelope amplitude distribution depends on σ_ϕ and other parameters of the signal.

It should be pointed out that the above expressions, Eqs. (12)–(15), for the (envelope) amplitude distribution are very general results; which are independent of the propagation model. The only assumptions are that the in-phase and

TABLE I. Mean and variance measured from data.

Frequency bin (Hz)	$\mu_x(\times 10^{-4})$	$\mu_y(\times 10^{-4})$	σ_x^2	σ_y^2	$\rho_{xy}(\times 10^{-4})$
320	−0.501	−0.706	0.5007	0.4993	−0.795
80	−0.925	−1.473	0.5001	0.4999	−0.668
5	−1.636	3.209	0.4998	0.5002	4.857

quadrature components (X and Y) are Gaussian random variables. For data analysis, one can measure the mean and variance of X and Y and their correlation directly from the data $H(f_k)$. Using the TREX04 data analyzed above, the measurement results are given in Table I for three different signal designs (different symbol durations or different frequency bin sizes). Note that in Table I $\rho_{xy} \ll \sigma_x$, σ_y and $\rho_{xy} \approx 0$. As remarked above, for $\rho_{xy} \to 0$, Eqs. (12)–(15), reduce to the Rayleigh or Rician distribution depending on whether or not $\mu^2 = \mu_x^2 + \mu_y^2$ is zero. For the data analyzed here, one notes that $\mu^2 \ll \sigma^2$ (see Table I), and can thus assume $\mu^2 = 0$. It then yields the Rayleigh distribution. In general, $\mu^2 \neq 0$ and one then has the Rician distribution. (The Rayleigh and Rician distributions are widely used in the literature for modeling the performance of communications in the RF world.)

The Rician (amplitude) distribution is given by[15]

$$p_z(z) = \frac{z}{\sigma^2} \exp\left(-\frac{z^2 + \mu^2}{2\sigma^2}\right) I_o\left(\frac{\mu z}{\sigma^2}\right), \quad z \geq 0, \qquad (16)$$

where z is the amplitude and I_o is the modified Bessel function of the first kind of zero order. Equation (16) is obtained from Eq. (12) when $\rho_{x,y} = 0$, $\mu^2 = \mu_x^2 + \mu_y^2$, and $\sigma_x^2 = \sigma_y^2 = \sigma^2$. The first and second moments of z have been calculated[15]

$$E\{Z\} = \sqrt{\frac{\pi}{2}} \sigma \exp(-\bar{K}/2)[(1 + \bar{K}) I_o(\bar{K}/2) + \bar{K} I_1(\bar{K}/2)], \qquad (17)$$

$$E\{Z^2\} = 2\sigma^2 + \mu^2 = 2\sigma^2(1 + \bar{K}), \qquad (18)$$

where $\bar{K} = \mu^2/2\sigma^2$ is referred to as the Rician parameter (known as the power ratio of specular-to-scatter or deterministic-to-random signal). I_1 is the modified Bessel function of the first kind of first order. A special case of the Rician distribution, for $\mu = 0$ (or $\bar{K} = 0$), is the well-known Rayleigh distribution,

$$p_z(z) = \frac{z}{\sigma^2} \exp\left(-\frac{z^2}{2\sigma^2}\right), \quad z \geq 0. \qquad (19)$$

The first and second moments of the Rayleigh distribution are given by

$$E(Z) = \sqrt{\pi/2} \cdot \sigma \qquad (20)$$

and

$$E(Z^2) = 2\sigma^2. \qquad (21)$$

Given the signal parameters measured from the data (Table I, 80 Hz data), it is simple to check if the Rayleigh or Rician model fits the high-frequency underwater acoustic data (the envelope amplitude statistics) reported above [Fig.

4(a)]. The Rayleigh distribution using the parameter values, given in Table II, is shown in Fig. 4(a) to compare with the data. Also shown is the amplitude distribution using Eq. (12), which is practically the same as the Rayleigh distribution. This is expected, since $\bar{K} = \mu^2/2\sigma^2 \sim O(10^{-8})$ (see Table I).

Equation (12), derived with a very general assumption that the in-phase and quadrature components are Gaussian random variables, does not seem to fit the data. (Of course, neither does the Rayleigh distribution.) This conclusion is also checked using a different signaling design, by varying the frequency bin size Δf from 80 Hz to 320 Hz, and to 5 Hz. The measured envelop amplitude distributions and the modeled probability distributions are plotted in Figs. 4(b) and 4(c). These plots again show the disagreement between the model and the data. The mean and variance of the data are summarized in Tables I and II.

It should be noted that the Rician distribution will yield a worse fit to the data since the Rician distribution has a higher percentage of high amplitude data points than the Rayleigh distribution, whereas the data indicate a higher percentage of low amplitude data points than the Rayleigh distribution [Fig. 4(a)] One concludes that the amplitude statistics for high-frequency underwater communication signals is neither Rician nor Rayleigh distribution, as in RF channels.

Next, the discussion will be focused on a popular non-Rayleigh model called the K-distribution, which seems to fit the data very well. In this section, the K-distribution model will be presented and fitted with the data. The motivation, derivation, and interpretation of this model will be given in the next section.

The K-distribution is given by[16]

$$p_z(z) = \frac{4}{\sqrt{\alpha}\Gamma(v)}\left(\frac{z}{\sqrt{\alpha}}\right)^v K_{v-1}\left(\frac{2z}{\sqrt{\alpha}}\right), \quad z \geq 0, \qquad (22)$$

where v is a shape parameter, α is a scale parameter, K_{v-1} is the modified Bessel function of the second kind, of order $v - 1$, and $\Gamma(v)$ is the Gamma function. The first and second moments of the K-distribution are as below:

TABLE II. Parameters for Rayleigh and K-distribution.

Frequency bin (Hz)	K-distribution		Rayleigh
	v	α	σ_r^2
320	1.2850	0.7787	0.5003
80	2.1290	0.4700	0.5003
5	3.7110	0.2695	0.5001

$$E(Z) = \frac{\sqrt{\alpha\pi}}{2} \cdot \frac{\Gamma(v+0.5)}{\Gamma(v)} \qquad (23)$$

and

$$E(Z^2) = \alpha v. \qquad (24)$$

A special case of the K-distribution, as $v \rightarrow \infty$ and $\alpha v = 2\sigma^2$ remains constant, is a Rayleigh distribution given in Eq. (19).

The model prediction using the K-distribution is shown in Figs. 4(a)–4(c) to compare with the data. The parameters for the K-distribution are determined from the mean and variance of the data using Eqs. (23) and (24). Their measured values are given in Table II. One finds fairly good agreement between the model prediction and data.

IV. LONG-TERM AND SHORT-TERM FLUCTUATION STATISTICS

To guide the motivation of the analysis in this section, and the interpretation of the derived model, it helps to point out the main difference between the current work and the previous work. The main difference lies in the underlying mechanism for signal fluctuations (between low and high frequencies) that lead to the Rayleigh/Rician model, on the one hand; and the K-distribution model, on the other hand.

One recalls that an implicit assumption used in deriving Eq. (12) is that the random variables X and Y follow stationary Gaussian statistics. This assumption seems to be valid for low-frequency signal propagation, but perhaps not appropriate for high-frequency signal propagation. High-frequency signals may follow quasi-stationary statistics that involve two time scales associated with long-term fading and short-term fading.[2] Over a short time scale, the high-frequency signal is heavily influenced by the microfine structures (e.g., turbulence) in the ocean. The signal amplitude fluctuation follows a short-term statistics. Over a long time scale, the amplitude fluctuations of the signal will likely be dominated by the fine-structure perturbations of the ocean, assuming that the rapid fluctuations induced by the microstructures have been averaged out. The signal amplitude fluctuations follow long-term statistics, which may be different from the short-term statistics. At the symbol level, the symbol amplitude envelope statistics follow a joint probability distribution, determined by the short-term probability distribution function conditioned on the amplitude distributions dictated by the long-term probability distribution function. This approach will be used in this section. We discuss the theoretical framework, determine the long- and short-term statistics from the data, and show that the overall statistics follow a distribution—numerically very close to the K-distribution.

[Note that the microfine structures have a negligible influence on low-frequency signals and thus can be ignored. Consequently, there is only one time scale for low-frequency signal fluctuation.]

To obtain the long-term statistics, the data will be averaged over a time period of T, such that the short-term signal fluctuation has been averaged out. In the time domain, the received signal is given by

$$r(t) = h(t) \otimes s(t). \qquad (25)$$

Let time be segmented into multiple periods of T,

$$t = nT + j\Delta t \equiv T_n + \tau_j, \qquad (26)$$

where j goes from 1 to $T/\Delta t$. Assuming that $\bar{h}(T_n)$ is the mean (average) channel impulse response over the time period between T_n and T_{n+1}, the long-term statistics are determined by $\bar{h}(T_n)$ for different n. For a given time window (between T_n and T_{n+1}), one can measure the short-term signal fluctuations (during this time window) using

$$\tilde{r}(t) = \bar{h}^{-1}(T_n) \otimes h(t) \otimes s(t), \qquad (27)$$

where $\bar{h}^{-1}(T_n)$ is an inverse filter (as a function of delay time) estimated at geotime T_n.

[The meaning of Eq. (27) can be illustrated with other familiar examples. One notes that Eq. (27) is similar to passive time-reversal (phase conjugation) operation, except that the inverse of the channel response is used instead of the conjugated time-reversed impulse response. Another usage of Eq. (27) will be for a channel in which the signal consists of deterministic eigenray arrivals plus many time-varying micropaths. Equation (27) allows one to remove the mean channel effect (the deterministic eigenrays) so that the fluctuation statistics of the micropaths can be studied.]

The residual impulse response that characterizes the short-term fluctuation is given by

$$\tilde{h}(\tau, T_n) = \bar{h}^{-1}(T_n) \otimes h(t). \qquad (28)$$

The above equation is expressed in the frequency domain as

$$\tilde{H}(f_k, \tau)\big|_{T_n} = H(f_k, t)/\bar{H}(f_k, T_n). \qquad (29)$$

A. Long-term envelope amplitude statistics

The long-term fluctuation statistics is obtained by averaging the signal intensity $|H(f_k, t)|^2$ over a period of T, and taking the square root to obtain one realization of $|\bar{H}(f_k, T_n)|$. The data are processed using $T = 0.2$ and 0.4 s; the results are practically the same. Henceforth, $T = 0.2$ will be used unless otherwise mentioned. How to determine the appropriate time scale T will be addressed later in Sec. IV D. For $T = 0.2$ s, one has 7169 realizations of the signal intensities for each frequency (out of 134 packets).

One finds that $|\bar{H}(f_k, T_n)|$ approximately follows a lognormal distribution. It is thus appropriate to plot the distribution in terms of $y = 20 \log |\bar{H}(f_k, T_n)|$ for a fixed f_k. Figure 5(a) plots the histogram distribution for $20 \log |\bar{H}(f_k, T_n)|$ for different f_k. Note that the distributions for different frequencies (within the band) are approximately the same; they are independently distributed as remarked above. Figure 5(b) also shows the distribution averaged over f_k within the signal bandwidth of 4 kHz.

To model the data, the lognormal distribution given by

FIG. 6. (Color online) Short-term fading statistics ($T=0.2$ s) vs the Rayleigh distribution. (a) Thin lines are distributions for individual frequencies. (b) The line with triangles is for the average over all frequency bins. The smooth thick line in both figures is a fit to the data using the Rayleigh distribution.

$$p(x) = \frac{1}{\sqrt{2\pi}\sigma_x} x^{-1} \exp\left(-\frac{(\ln x - \mu_x)^2}{2\sigma_x^2}\right), \tag{30}$$

is used, where x is $|\bar{H}(f_k, T_n)|$, for $n=1,\ldots N$. Let $u = 20\log_{10}(x)$, the probability distribution for u is

$$p(u) = \frac{1}{\sqrt{2\pi}\sigma_u} \exp\left(-\frac{(u - u_u)^2}{2\sigma_u^2}\right), \tag{31}$$

which is a Gaussian distribution with a mean and variance given by

$$\mu_u = 20\mu_x/\ln 10, \quad \text{and} \quad \sigma_u = 20\sigma_x/\ln 10. \tag{32}$$

One finds that the data in Fig. 5(b) can be fitted with Eq. (31) with $\mu_u = -1.0968$ dB, and $\sigma_u^2 = 9.3468$ dB^2. The distribution of $|\bar{H}(f_k, T_n)|$ has a mean, $\mu_x = -0.128$, and a variance of $\sigma_x^2 = 0.128$ for the digitized data. (Unit of digitization is arbitrary.)

B. Short-term envelope amplitude statistics

The short-term distribution is obtained from data using Eq. (29) for each period of T and then summed/averaged over all periods of data. Again, $T=0.2$ and 0.4 s are used, and the results remain practically the same. Using $T=0.2$ s, the resulting distribution is plotted in Fig. 6(a) for individual

frequency bins. There are 16 realizations for each 0.2 s segment; hence, a total of $16 \times 7169 = 114\,704$ realizations for the short-term statistics for each frequency component. One observes that the majority of frequencies have near-identical distributions. A few frequency components have slightly shifted distributions. They are the manifestation of the shifted distributions in Fig. 3. Invoking the assumption that the distributions for various frequencies are independent and identically distributed, the distributions are averaged over frequencies to obtain a more statistically meaningful measurement. The result is plotted in Fig. 6(b). The data in Fig. 6(b) are well fitted with a Rayleigh distribution [Eq. (19)] in terms of y. It has a mean of $\mu_y = 0.8874$ and a variance of $\sigma_y^2 = 0.5013$.

C. Modeling the overall statistics

Given a long-term distribution of lognormal and a short-term distribution of Rayleigh, the resulting distribution can be calculated and will be shown to be almost like a K-distribution.

For mathematical convenience, consider a fixed frequency, and use the following notation: $x \equiv \bar{H}(f_k, T_n)$, $y \equiv \tilde{H}(f_k, \tau_j)$ and $z \equiv H(f_k, t)$. Equation (29) then becomes

$$z = xy. \tag{33}$$

The probability distribution for z, as x and y are mutually independent, is given by

$$p_Z(z) = \int p_{Z|X}(z|X=x)p_X(x)dx = \int p_{z,x}(z,x)dx$$

$$= \int p_{Y,X}(y=z/x,x)\frac{1}{x}dx = \int p_Y(z/x)p_X(x)\frac{1}{x}dx \tag{34}$$

where the first line of Eq. (34) states that the overall distribution of z is equal to the short-term probability distribution, conditioned on the long-term probability distribution and integrated over the long-term probability distribution. Assuming that the short-term and long-term distributions are independent, it becomes the joint probability distribution in z, x, and is transformed by change of variables to y, x in the second line of Eq. (34).

Substituting the lognormal distribution, Eq. (30), for $P_X(x)$ and the Rayleigh distribution, Eq. (19), for $P_Y(y)$, one finds, after some algebra,

$$p_Z(z) = \int \left(\frac{1}{\sqrt{2\pi}\lambda}\frac{1}{\nu}e^{(\ln \nu - \mu)^2/2\lambda^2} \right) \left(\frac{z}{\nu}e^{-z^2/2\nu} \right)d\nu, \tag{35}$$

where

$$\nu = \sigma_y^2 x^2, \quad \lambda = 2\sigma_x, \quad \mu = 2\ln \sigma_y + 2\mu_x, \tag{36}$$

The K-distribution is a mixture of Rayleigh and Gamma distributions and is defined as below:

$$p_Z(z) = \int \left(\frac{\nu^\beta}{(2\alpha)^{1+\beta}\Gamma(1+\beta)}e^{-\nu/\alpha} \right) \left(\frac{z}{\nu}e^{-z^2/2\nu} \right)d\nu$$

$$= \frac{4}{\sqrt{\alpha}\Gamma(1+\beta)} \left(\frac{z}{\sqrt{\alpha}} \right)^{1+\beta} K_\beta\left(\frac{2z}{\sqrt{\alpha}} \right),$$

$$z \geq 0, \quad \alpha > 0, \quad \beta > -1, \tag{37}$$

where α and β are parameters of the Gamma distribution. It has been proven that lognormal and Gamma distributions are close approximations of each other.[17,18] Consequently, one finds that Eqs. (35) and (37) are numerically close approximations of each other with the following relation between the parameters[19]

$$\mu = \ln(\alpha/2) + \Psi(1+\beta), \quad \lambda^2 = \Psi'(1+\beta),$$

where Ψ and Ψ' are the psi-function and its derivative.

For a consistency check, note that the measured parameters from the long-term statistics are: $\mu_x = -0.128$ and $\sigma_x^2 = 0.128$, and the parameters for short-term statistics are: $\mu_y = 0.8874$, $\sigma_y^2 = 0.5013$. This yields $\mu = -0.9466$ and $\lambda = 0.7155$ based on Eq. (36). From data fitting in Sec. III C (Table II, 80 Hz data), one finds $\alpha = 0.470$, and $\beta = \nu - 1 = 1.129$, which yields $\mu = -0.9454$ and $\lambda = 0.7724$. Thus, both methods approximately yield the same answer.

The above analysis showed that the overall data distribution, based on (the joint probability distributions of) the long-term (lognormal) and short-term (Rayleigh) distributions, follow a distribution which is numerically close to the K-distribution. In numerical modeling of data (Sec. III), the

K-distribution is used because it is a well-established special function, whereas there is not a named special function for Eq. (35). Since all models are numerical fit of the data, for data analysis, it is more convenient to use K-distribution as a substitute.

D. Determination of the time scale *T*

The previous subsections use $T=0.2$ s. Naturally, the question is what is the time scale separating the short term from the long term fluctuations. The time scale T is, in principle, related to the time scale of the appropriate oceanographic processes, which dominate the signal fluctuations at the corresponding frequency domain. The microfine structures of the ocean inhomogeneities (ocean turbulence) have a time scale of milliseconds to seconds, and mostly affect only the high-frequency acoustic signal propagations. The fine structures of the ocean inhomogeneities cover a time scale from seconds to hours. The high-frequency end (corresponding to a time scale of seconds) of the fine structure spectrum affects the high-frequency acoustic signal propagations more, as the wavelengths of the inhomogeneities match more closely with the acoustic wavelengths. The low-frequency part of the inhomogeneities affects the low-frequency acoustic propagations more.

The acoustic signal propagation theory has suggested that the envelope amplitude statistics for fully saturated fluctuations should be Rayleigh distributed. This is expected for a random medium of microfine structures. Indeed, the short-term statistics is well fitted by the Rayleigh distribution. This suggests that the time scale T is related to the time scale of microfine structures. The long-term statistics are then associated with the fine-structure processes. The observed lognormal distribution is consistent with the fact that the distribution is partially saturated.

While there is a qualitative understanding of the effect of the ocean inhomogeneities on acoustic signal propagations, there is no theoretical derivation of T based on the random media propagation theory. In this section, an empirical estimation of T will be pursued based on the "best" fit of the statistical distributions to the data. Note that changing the value of T will affect both the long-term and short-term distributions. Data analysis results indicate that if one uses T significantly different from 0.2 s, the parameters of the overall distribution—deduced from the long-term and short-term statistics—do not agree so well with the parameters of the K-distribution deduced directly from data. This indicates that there is a preferred value for the time scale T that separates the short-term fluctuations from the long-term fluctuations.

The method used to determine T is based on the "goodness of fit" measure of the root-mean-squared error (RMSE), also known as a fit standard error. The RMSE is defined as

$$\text{RMSE} = \sqrt{\text{MSE}} = \sqrt{\frac{1}{L}\sum_{i=1}^{n} (F_i - S_i)^2} \tag{38}$$

where $L = n - m$ indicates the number of independent pieces of information involving the n data points and m parameters of the prospective probability distribution. S_i denotes the sampled statistical function (either the probability distribu-

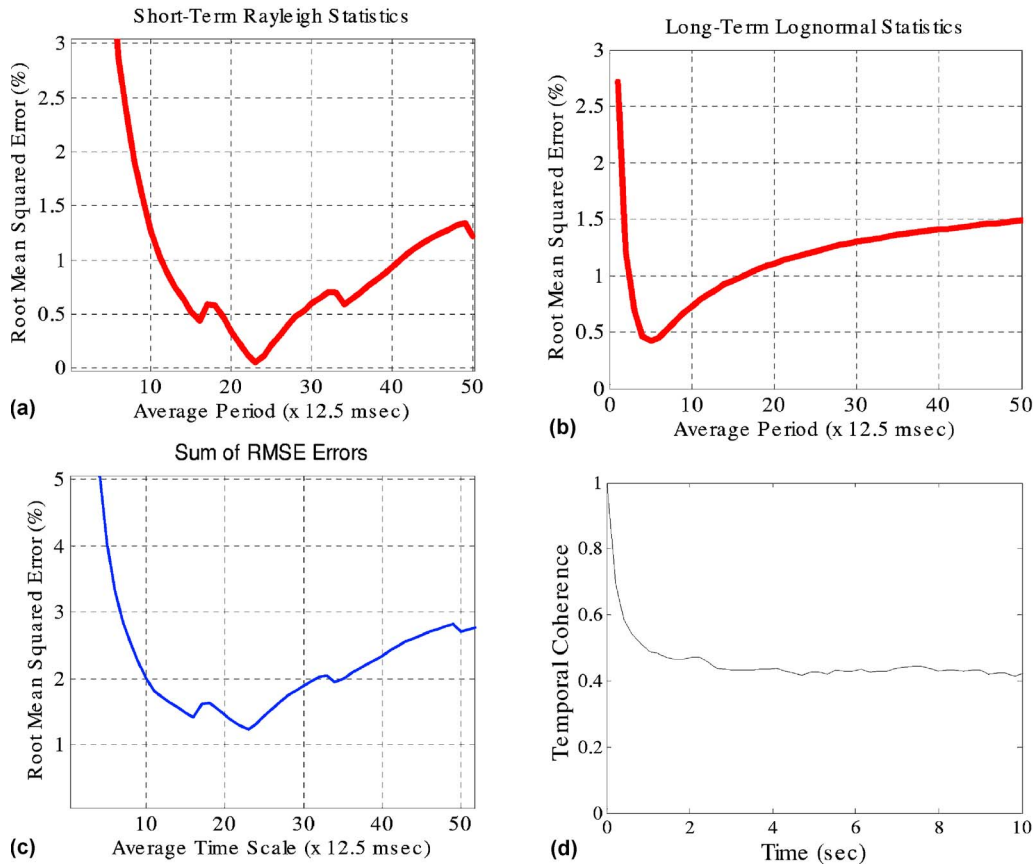

FIG. 7. (a) RMSE between short-term statistics of experimental data and the Rayleigh distribution. (b) RMSE between long-term statistics of experimental data and the lognormal distribution. (c) Sum of long-term and short-term RMSE. (d) The signal temporal coherence vs lag time averaged over >50 packets of data.

tion or the cumulative probability distribution function) based on data at amplitude x_i, $i=1,\ldots,n$. F_i denotes the sampled statistics at amplitude x_i based on the statistical model. For the above data, $L \sim 3 \times 10^5$ for the long-term statistics and $L \sim 5 \times 10^6$ for the short-term statistics.

Equation (38) will be evaluated for different values of T. For each value of T, one obtains the short-term and long-term fluctuation statistics from the data. The short-term and long-term data are fitted with the Rayleigh and lognormal distributions, respectively. The parameters of the distributions are obtained by the best fit with the data. Having determined the parameters for the best fit, one determines the RMSE of the fit using Eq. (38).

Consider the short-term envelope amplitude statistics first. Figure 7(a) shows the RMSE values of Rayleigh statistics as a function of the time scale T. The minimum of the test is located at $T \approx 0.3$ s. One finds that $T = 0.2$ and 0.4 s yield a RMSE$<1\%$. In fact, the RMSE is $\leqslant 1\%$ for T between 0.15 and 0.5 s. It indicates that the Rayleigh distribution is a good fit for the short-term fading statistics during this time window. When T exceeds 0.5 s, the fit deteriorates significantly. This result suggests that for $T>0.5$ s the effects of fine-structure processes are no longer negligible and need to be included.

For long-term statistical distribution, the RMSE between the data and the lognormal distribution is plotted in Fig. 7(b). One finds that the RMSE is $\leqslant 1\%$ for T between 0.04 and 0.21 s, and $\leqslant 1.5\%$ for T between 0.03 and 0.63 s. In fact,

the RMSE remains below 2% for a large window of T [to at least 1.25 s in Fig. 7(b)]. This is consistent with the expectation that the long-term fluctuation should not change significantly with the time window T as long as it is "long term." One notes that there is no theoretical basis that the distribution has to be lognormal, which may just be a convenient choice. Thus, a 2% RMSE is quite reasonable. Figure 7(c) plots the sum of the short-term and long-term RMSE. The minimum occurs around $T \sim 0.25$ s. One finds that $T = 0.2$ and 0.4 s yield a reasonable RMSE.

Figure 7(d) shows the temporal coherence of M-sequence signals determined by the correlation of the first M-sequence signal with the following M-sequence signals.[2] One temporal coherence curve is obtained for one packet. The coherence curves are averaged over many (50) packets. The result is shown in Fig. 7(d). It indicates that the signal coherence time is of the order of 0.2–0.4 s, after that the coherence value goes below 0.5. This result suggests that the signal coherence time can be used as the time scale separating the short-term from the long-term fluctuations, as in this case (high-frequency propagation) both are determined by the microfine (turbulence) disturbances. Whether this is a good assumption remains to be investigated.

We have also evaluated the fit of the data with the theoretical distribution using the Kolmogorov-Simirnov test statistics.[16] The results are very similar and not explicitly shown here.

V. CONCLUSIONS

In this paper, narrowband envelope amplitude (fading) statistics are investigated for high-frequency signals over a wide band of frequencies (15–19 kHz). The envelope amplitude statistics shows a non-Rayleigh or a non-Rician distribution behavior. The conventional models for the envelope amplitude distributions, developed for low-frequency unsaturated, partially saturated, and fully saturated signal fluctuations; do not fit the high-frequency amplitude statistics data. The reason is that these models assume a fading statistics that is valid for all time scales. The above analysis of the high-frequency data indicates two time-scale fading phenomena: Long-term versus short-term fading. The division between the two is determined by using RMSE test, which is about a 0.2 s time scale for the TREX04 data.

It is found that the long-term amplitude fading statistics follow a lognormal distribution, and the short-term amplitude fading statistics follows a Rayleigh distribution. The signal amplitude distribution based on the joint long-term and short-term distributions yields a distribution numerically close to the K-distribution, which is found to be a good fit of the high-frequency data.

Multiple source localization using a maximum *a posteriori* Gibbs sampling approach

Zoi-Heleni Michalopoulou[a]
Department of Mathematical Sciences, New Jersey Institute of Technology, Newark, New Jersey 07102

Multiple source localization in underwater environments is approached within a matched-field processing framework. A maximum *a posteriori* estimation method is proposed that estimates source location and spectral characteristics of multiple sources via Gibbs sampling. The method facilitates localization of weak sources which are typically masked by the presence of strong interferers. A performance evaluation study based on Monte Carlo simulations shows that the proposed maximum *a posteriori* estimation approach is superior to simple coherent matched-field interference cancellation. The proposed method is also tested on the estimation of the number of sources present, providing probability distributions in addition to point estimates for the number of sources. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354027]

I. INTRODUCTION

Acoustic source localization in shallow water environments is a challenging task hampered by the effects of sound interactions with the inadequately understood propagation medium. Loud interfering sources often present in coastal waters mask the source of interest, further complicating localization.

Matched field processing (MFP)[1,2] has been extensively used for source localization in the ocean. The measured acoustic data are compared to field replicas generated with a sound propagation model and estimates are taken to be those parameter values that generate the best match between true and replica fields according to some specified matching criterion.

Variants of MFP have been proposed for localization of multiple sources. Model-based methods in underwater environments were discussed in Refs. 3–8; these multiple source localization techniques typically rely on eigenvector decompositions, modified Bartlett functions, or combination of these two approaches. The CLEAN method, widely used in astronomy for denoising images, was originally proposed in Ref. 1 and subsequently in Ref. 9 for weak source localization in the ocean by canceling strong interferers. In this paper we propose a new processor that estimates multiple source locations with a maximum *a posteriori* (MAP) approach optimized with Gibbs sampling. The processor forms joint posterior probability distributions of locations of multiple sources, source spectra, noise variance, as well as number of sources that are present. It is compared and found superior to simple coherent interference cancellation for multiple source localization through a Monte Carlo performance evaluation. Our method not only produces point estimates of the unknown parameters but probability distributions as well, capturing uncertainty in the estimation problem. With sampling performed from conditional posterior probability distribu-

tions, the method searches the parameter space efficiently, concentrating on regions that generate significant probability.

The structure of the paper is as follows: Section II discusses the CLEAN approach as it pertains to simple matched-field interference cancellation, or, equivalently, multiple source localization using conventional MFP. Section III describes the new processor, deriving conditional posterior distributions that are necessary for the operation of the Gibbs sampler. Section IV compares the proposed processor to a simple coherent cancellation processor, relying on Bartlett ambiguity surfaces and subtraction of strong field components, through a performance evaluation with synthetic data. Estimation of the number of sources is discussed in Sec. V. The effect of environmental mismatch on the performance of the new processor and the simple coherent canceller is addressed in Sec. VI. Section VII summarizes the work and presents conclusions.

II. MATCHED-FIELD PROCESSING AND INTERFERENCE CANCELLATION

In Ref. 1 it was suggested that the CLEAN deconvolution technique,[10,11] widely used since the late 1970s for image enhancement especially in astronomy, might be a suitable tool in localization using MFP in the presence of multiple sources. Estimates of contributions from strong interferers are subtracted from the field received at a set of sensors in an effort to reveal weaker sources of interest which are otherwise masked. Proper subtraction of field components from received signals requires accurate knowledge of how signals propagate from source to receiver. Essentially, we need to subtract from the sensed data the convolution of the source wave form and the medium impulse response, deconvolving interference from the received field.

It was proposed in Ref. 1 that, assuming a perfectly known environment, an ambiguity surface $P(r, z_s)$ (Bartlett, for example) is first constructed:

[a]Electronic mail: michalop@njit.edu

$$P(r, z_s) = \frac{\mathbf{G}(r, z_s)^* \mathbf{X} \mathbf{X}^* \mathbf{G}(r, z_s)}{\|\mathbf{G}(r, z_s)\|^2}, \tag{1}$$

where $\mathbf{G}(r, z_s)$ is a Green's function vector calculated for source range r and depth z_s, and $\mathbf{X}$ is a vector containing received data. Specifically, assuming a strong and a weak source being present:

$$\mathbf{X} = \alpha_{str} \mathbf{G}(r_{str}, z_{s,str}) + \alpha_w \mathbf{G}(r_w, z_{s,w}) + \mathbf{W}, \tag{2}$$

where α_{str} and α_w are the complex amplitudes of the two source signals, r_{str} and r_w are the ranges for the strong and weak source, and $z_{s,str}$ and $z_{s,w}$ are the corresponding depths, $\mathbf{G}(r_{str}, z_{s,str})$ and $\mathbf{G}(r_w, z_{s,w})$ are Green's function vectors calculated at the L receiving phones for the strong and weak source, respectively, and $\mathbf{W}$ is an L-dimensional complex, zero-mean noise vector.

The maximum of this ambiguity surface is expected to lead to the source location estimates $\hat{r}_{str}$ and $\hat{z}_{s,str}$, of the strongest source present. Subsequently, a new surface P_{str} is produced, using now as data the replica field computed at the estimated source location of the previous step:

$$P_{str}(r, z_s) = \frac{\mathbf{G}(r, z_s)^* \hat{\mathbf{G}}_{str} \hat{\mathbf{G}}_{str}^* \mathbf{G}(r, z_s)}{\|\mathbf{G}(r, z_s)\|^2}, \tag{3}$$

where $\hat{\mathbf{G}}_{str} = \mathbf{G}(\hat{r}_{str}, \hat{z}_{s,str})$.

This new ambiguity surface is subtracted from the original surface; the residual ambiguity surface $P_{res}(r, z_s)$ is scanned again for a new source location. The subtraction is repeated until M sources are identified, where M is the number of sources believed to be present. This "cleaning" approach cancels contributions of strong sources-interferers in an incoherent manner, because the subtraction is performed at the ambiguity surface level. In essence, we calculate $P_{res}(r, z_s)$ as follows:

$$P_{res}(r, z_s) = P(r, z_s) - k P_{str}(r, z_s), \tag{4}$$

where k is a factor depending on the strength of the loud source. A more detailed CLEANing process for MFP was developed in Ref. 9.

In our work, we followed the suggestion in Ref. 1 and used as a value for k an estimate of the strength of the loud source $|\hat{\alpha}_{str}|^2$ (similar to Ref. 9). Optimally, a maximum likelihood estimate $\hat{\alpha}_{str}$ of α_{str} under the assumption that the data are embedded in Gaussian, spatially white noise can be obtained as follows:

$$\hat{\alpha}_{str} = \frac{\hat{\mathbf{G}}_{str}^* (\mathbf{X} - \alpha_w \mathbf{G}_w)}{\|\hat{\mathbf{G}}_{str}\|^2}, \tag{5}$$

where $\mathbf{G}_w = \mathbf{G}(r_w, z_{s,w})$.

Estimation using Eq. (5) presumes knowledge of α_w and $\mathbf{G}_w$ which is not available. If, however, the strength of the weak source is much smaller than that of the strong source, that is, $|\alpha_w| \ll |\alpha_{str}|$, $\mathbf{X} \approx \alpha_{str} \mathbf{G}_{str} + \mathbf{W}$ and

$$\hat{\alpha}_{str} \approx \frac{\hat{\mathbf{G}}_{str}^* \mathbf{X}}{\|\hat{\mathbf{G}}_{str}\|^2}. \tag{6}$$

Equation (4) now becomes

$$P_{res}(r, z_s) = P(r, z_s) - |\hat{\alpha}_{str}|^2 P_{str}(r, z_s). \tag{7}$$

The process of Eq. (7) removes from the original ambiguity surface $P(r, z_s)$ some of the contributions of the strong source (provided that the estimate for the strong source power is reasonable); other contributions (namely, $\mathbf{G}^* \alpha_w \mathbf{G}_w \alpha_{str}^* \mathbf{G}_{str}^* \mathbf{G} / \|\mathbf{G}\|^2$ and $\mathbf{G}^* \alpha_{str} \mathbf{G}_{str} \alpha_w^* \mathbf{G}_w^* \mathbf{G} / \|\mathbf{G}\|^2$) are not subtracted. In an attempt to remove as comprehensively as possible the strong source contributions, we propose a coherent application of the previously described CLEAN approach that removes the strong source components at the field rather than the ambiguity surface level. A simple coherent CLEAN process is implemented as follows. Estimates of the source location $\hat{r}_{str}$ and $\hat{z}_{s,str}$ and replica $\mathbf{G}(\hat{r}_{str}, \hat{z}_{s,str})$ are obtained in the way already described. Estimate $\hat{\alpha}_{str}$ is then calculated from Eq. (6). A new ambiguity surface, $P_{res,coh}(r_w, z_{s,w})$, is calculated as follows:

$$P_{res,coh}(r, z_s) = \frac{\mathbf{G}(r, z_s)^* \mathbf{Y} \mathbf{Y}^* \mathbf{G}(r, z_s)}{\|\mathbf{G}(r, z_s)\|^2}, \tag{8}$$

where $\mathbf{Y} = \mathbf{X} - \hat{\alpha}_{str} \mathbf{G}(\hat{r}_{str}, \hat{z}_{str})$. Assuming that two sources, a strong and a weaker one, are present, the ambiguity surface of Eq. (8) corresponds to the contribution of the weak source field, and its maximization is expected to provide the location of the weak source. Again, the success of this method in estimating the location the weak source depends on the quality of $\mathbf{G}(\hat{r}_{str}, \hat{z}_{str})$ and $\hat{\alpha}_{str}$.

III. LOCALIZATION OF MULTIPLE SOURCES WITH MAXIMUM *a posteriori* ESTIMATION AND GIBBS SAMPLING

In Ref. 12 a Gibbs sampling scheme was presented developing an estimate of the joint posterior distribution $p(r, z_s, \alpha, \sigma^2 | \mathbf{X})$, where r and z_s are the source range and depth, respectively, α is the complex spectrum of the source, σ^2 is the variance of additive Gaussian noise, and $\mathbf{X}$ is the observed data at a set of L spatially (vertically here) separated hydrophones. From this joint distribution, the marginal posterior distribution $p(r, z_s | \mathbf{X})$ for source range and depth is calculated, maximization of which leads to MAP estimates for source location.[12,13] The estimate of the joint posterior distribution was derived using a Gibbs sampler[14–18,12] that draws samples in a cyclical fashion from marginal conditional posterior distributions.

The signal model in the frequency domain considered for the single source problem of Ref. 12 is as follows:

$$\mathbf{X} = \alpha \mathbf{G} + \mathbf{W}, \tag{9}$$

where $\mathbf{G}$ is a Green's function vector calculated at the L receiving phones, α is a complex factor containing source amplitude and phase, and $\mathbf{W}$ is an L-dimensional vector, each sample of which is drawn from a complex normal zero mean distribution with variance $2\sigma^2$.

The technique of Ref. 12 is extended in this paper for M sources, $M \geq 1$. The signal model then becomes

$$\mathbf{X} = \sum_{i=1}^{M} \alpha_i \mathbf{G}_i + \mathbf{W}. \tag{10}$$

Here, $\mathbf{G}_i = \mathbf{G}(r_i, z_{si})$, r_i and z_{si} are the range and depth of the ith source, α_i are complex factors containing amplitude and phase information for the ith source. The number of sources M is assumed known.

Using the same prior distributions as in Ref. 12, the joint posterior distribution of all parameters is as follows:

$$p(r_1, z_{s1}, \ldots, r_M, z_{sM}, \alpha_1, \ldots, \alpha_M, \sigma^2 | \mathbf{X})$$

$$\propto \frac{1}{(2\pi)^L} \frac{1}{\sigma^{2L+2}} \exp\left(-\frac{1}{2\sigma^2} \|\mathbf{X} - \sum_{i=1}^{M} \alpha_i \mathbf{G}_i(r_i, z_{si})\|^2\right).$$

(11)

For the marginal posterior distribution of α_i we need to fix r_j, z_{sj}, $j = 1, \ldots, M$, α_j, $j, = 1, \ldots, M$, $j \neq i$, and σ^2 in Eq. (11). The marginal posterior distribution of α_i conditional on all other unknowns can be rewritten as

$$p(\alpha_i | r_1, z_{s1}, \ldots, r_M, z_{sM}, \alpha_j (j = 1, \ldots, M; j \neq i), \sigma^2, \mathbf{X})$$

$$= M_{\alpha i} \exp\left(-\frac{\|\mathbf{G}_i\|^2}{2\sigma^2}\right.$$

$$\left. \times \|\left(\alpha_i - \left(\mathbf{G}_i^*\left(\mathbf{X} - \sum_{j=1,\ldots,M; j \neq i} \alpha_j \mathbf{G}_j\right)\right) / \|\mathbf{G}_i\|^2\right)\|^2\right),$$

(12)

where $M_{\alpha i}$ is a constant with respect to α_i. Complex variable α_i is, thus, normally distributed with mean $(\mathbf{G}_i^*(\mathbf{X} - \Sigma_{j=1,\ldots,M; j \neq i} \alpha_j \mathbf{G}_j))/\|\mathbf{G}_i\|^2$ and variance $2\sigma^2/\|\mathbf{G}_i\|^2$.

The conditional posterior distribution for the variance is identified as an inverse χ^2 distribution:

$$p(\sigma^2 | r_1, z_{s1}, \ldots, r_M, z_{sM}, \alpha_1, \ldots, \alpha_M, \mathbf{X})$$

$$\propto \frac{1}{\sigma^{2L+2}} \exp\left(-\frac{1}{2\sigma^2} \|\mathbf{X} - \sum_{i=1}^{M} \alpha_i \mathbf{G}_i(r, z_s)\|^2\right).$$

(13)

Samples from both the normal and χ^2 distributions can be readily generated.[19]

The conditional distribution of r_i and z_{si} is as follows:

$$p(r_i, z_{si} | r_j, z_{sj} (j = 1, \ldots, M; j \neq i), \alpha_i (i = 1, \ldots, M), \sigma^2, \mathbf{X})$$

$$= K \exp\left(-\frac{1}{2\sigma^2} \|\mathbf{X} - \sum_{j=1}^{M} \alpha_j \mathbf{G}_j(r_j, z_{sj})\|^2\right),$$

(14)

where K is a constant. In the distribution of Eq. (14), r_j and z_{sj} for all j are fixed with the exception of r_i and z_{si}, $i \neq j$. The distribution of Eq. (14) is evaluated on a grid for r_i and z_{si} similar to the implementation in Ref. 20 and following the griddy Gibbs modeling of Ref. 21, because no closed form is known.

Gibbs sampling begins with a set of randomly chosen initial conditions for all unknown parameters (r_i, z_{si}, α_i, and σ^2, $i = 1, \ldots, M$). The process as implemented here first draws a sample from the conditional distribution of range r_1 and source depth z_{s1}; this two-dimensional sample contains the new, updated values of range and depth for the first source and first iteration. Subsequently, a sample is drawn from the Gaussian marginal conditional posterior of α_1 [Eq. (12)]. The same process is repeated for r_j, z_{sj}, α_j, j
FIG. 1. Probability of correct localization vs SNR for 600 Hz for the simple coherent Bartlett canceller and the GS-MAP processor.

$= 2, \ldots, M$. Lastly, a sample is drawn for the variance from the inverse χ^2 distribution of Eq. (13), completing the first iteration. For a large number of iterations, the obtained sample sequences eventually converge to the true joint posterior distribution of r_i, z_{si}, α_i, $i = 1, \ldots, M$, and σ^2.[17,14,15]

IV. PERFORMANCE EVALUATION OF THE MAXIMUM *a posteriori* PROCESSOR

To evaluate the proposed method, we generated synthetic data simulating sound propagating in a shallow water environment. Received field data at a vertical array of 24 phones were generated corresponding to two sound sources. A strong source was at a range and depth of 4 km and 2 m, respectively. A weaker source was at a range and depth of 2.4 km and 48 m. The complex amplitudes of the strong source and weak source were $\alpha_1 = \alpha_{str} = 20 \exp(i/2)$ and $\alpha_2 = \alpha_w = 2 \exp(3i/2)$.

SNR varied between 7 and 24 dB. For the performance evaluation we generated 100 noisy realizations per case. We then performed source localization with a simple incoherent cancellation Bartlett processor [Eq. (7)], a simple coherent cancellation Bartlett processor [Eq. (8)], and the MAP estimator proposed here, and, for each method, estimated probabilities of correct localization. Correct localization is here defined as obtaining estimates between 2.22 and 2.58 km for range and between 42 and 54 m for depth for the weak source and between 3.82 and 4.18 km for range and 0 and 8 m for depth for the strong source. The search interval for range was between 0 and 5 km with a 2 m spacing; the interval for depth was between 0 and 72 m with a 2 m spacing. The Gibbs sampler was run for 2000 iterations, the first 200 of which were discarded. Initial values used in the Gibbs sampler were 10 for σ^2, 100 for complex amplitudes of both sources, 2 km and 18 m for range and depth for the weak source, and 3 km and 18 m for range and depth for the strong source. Experimentation was performed with higher iteration numbers and different initial conditions without significant changes in the results.

Figure 1 shows probability of correct localization for the
FIG. 2. Probability of correct localization vs SVR for 200 Hz for the simple coherent Bartlett canceller and the GS-MAP processor.

FIG. 4. Posterior probability distribution of α_{str}, the complex amplitude of the strong source.

coherent cancellation Bartlett processor and the MAP processor, where both sources transmit at 600 Hz; probability of correct localization as obtained for the incoherent cancellation Bartlett processor was low and is not included in the figure. The two processors perform similarly, with the simple processor being slightly better at high SNRs and the MAP processor optimized via Gibbs sampling being minimally superior at lower SNRs.

Figure 2 shows probability of correct localization versus SNR for the simple coherent Bartlett canceller and the MAP processor for a frequency of 200 Hz; in this case as well, the incoherent canceller provided low probability of correct localization and is not included in the figure. The performance of the MAP processor dominates that of the coherent Bartlett processor for the entire SNR range.

An explanation for the poor performance of the coherent Bartlett-CLEAN processor at this frequency can be found in Fig. 3, which shows probability of source localization for the coherent Bartlett-CLEAN and MAP processors (also shown

FIG. 3. Probability of correct localization vs SVR for 200 Hz for the simple coherent Bartlett canceller, the GS-MAP processor, and a coherent Bartlett canceller that knows exactly the complex amplitude of the strong source.

in Fig. 2) and the probability of correct localization for the coherent Bartlett-CLEAN processor that employs as $\hat{\alpha}_{str}$ the true value of α_{str} [it does not assume $r_{s,str}$ and $z_{s,str}$ to be known, though, and estimates them by maximizing the ambiguity surface of Eq. (1)]. The latter processor is not realistic because information on α_{str} is not typically available but offers an upper performance bound for the coherent Bartlett-CLEAN processor. For high SNRs, this ideal processor outperforms both the MAP and the realistic coherent Bartlett processor. As the SNR decreases, the MAP processor becomes slightly better than the "artificial" processor. The simple coherent processor always lags behind substantially. Figure 3 illustrates that the cause of the poor performance of the simple coherent Bartlett-CLEAN processor lies in the estimation of α_{str}, which is necessary before Eq. (8) is used.

Figure 4 demonstrates why the MAP processor does not suffer greatly from the same problem. The figure shows the posterior probability distribution of the complex amplitude of the strong source as obtained from the MAP processor. There is significant probability concentrated at a phase of 0.5 rad (true value of the phase of that source). There is more uncertainty regarding the source amplitude; we see that the probability distribution exhibits high values for amplitudes roughly between 7 and 24 (the true amplitude is 20). The plot also indicates the point estimate of α_{str} as obtained from the coherent Bartlett-CLEAN processor, which is far away from the true amplitude and phase of the source (it coincides with a secondary mode of the probability distribution). The coherent Bartlett-CLEAN estimator fails to estimate the weak source location using that point estimate. The MAP processor, integrating over the probability distribution of the strong source complex amplitude, correctly identifies the weak source.

More simulations were run with data at frequencies between 200 and 600 Hz. It was observed that for these frequencies the two processors had similar performance. With frequencies at and below 200 Hz, there is a significant advantage in using the proposed MAP-Gibbs sampling processor. Figure 5 shows probability of correct localization as ob-
FIG. 5. Probability of correct localization vs SNR for 100 Hz for the GS-MAP processor.

tained from the new processor for the two sources operating at 100 Hz. Although these probabilities are not particularly high, the processor performs better than the simple coherent processor (not shown here) which fails to successfully localize both sources in every single case.

Observing more closely the MAP-Gibbs sampling coherent cancellation results, we observed that, although even in high SNRs the processor failed in several cases to estimate the two source locations correctly, the approach was, surprisingly, quite successful in depth estimation. Figure 6 shows probability of correct depth estimation for both the simple and the proposed processor. The simple coherent processor has a probability of correct depth estimation between 0.33 and 0.45 for all SNRs with an arbitrary pattern of variations. The proposed processor has a probability of correct depth estimation that increases as SNR increases (as expected) and that reaches 0.88 for a SNR of 24 dB. The ability to identify correctly source depth in an environment with interference
FIG. 6. Probability of correct depth estimation vs SNR for 100 Hz for the simple coherent Bartlett canceller and the GS-MAP processor.

present is significant, because it answers the question of whether a sensed source is submerged or whether it is located at the surface of the water column.

A coherent multiple source localization approach based on MFP was also proposed in Ref. 6. There, the received signal was modeled as follows:

$$\mathbf{X} = \sum_{i=1}^{M} b_i \mathbf{G}_i(r_i, z_{s,i})/\|\mathbf{G}_i(r_i, z_{s,i})\| + \mathbf{W}, \qquad (15)$$

where $\mathbf{G}$ is a Green's function vector calculated at the L receiving phones and $\mathbf{W}$ is an L-dimensional complex, zero-mean noise vector. The model of Eq. (15) combines contributions from M sources without involving source levels, which are actually estimated by our method. Coefficients b_i represent received levels: $|b_i|$ is the strength of the contribution of the ith source at the receiving array. As mentioned in Ref. 6, source levels were avoided in the modeling in order to circumvent correlations between them and source ranges which might potentially complicate the estimation process. Using the model of Eq. (15) and simulated annealing, a search was performed in Ref. 6 for the number of sources, their location, and environmental parameters.

To compare our processor to that of Ref. 6, we performed source localization of two sources using the model of Eq. (15) and estimating posterior distribution $p(r_1, z_{s1}, r_2, z_{s2}, b_1, b_2, \sigma^2 | \mathbf{X})$ using Gibbs sampling. In some cases the results of the process relying on Eq. (15) were practically identical to the results of the processor developed here [which uses the model of Eq. (9)]. In other cases, however, after the strong source was identified, the sampling process was "trapped" in this source's neighboring region; as a result, the weak source was not identified and a second source ("shadow" of the actual strong source) was falsely found. Equation (15) removes the effect of two very different source amplitudes from the data; this "smoothing" might account for the difficulty of the processor relying on Eq. (15) in identifying both sources. The problem can be remedied by applying restrictions prohibiting the Gibbs sampler from searching for the weak source in the vicinity of the strong source. Such restrictions are not necessary for the processor proposed in this work.

V. UNKNOWN NUMBER OF SOURCES

In the preceding section, the number of sources was assumed known and set equal to two. In practice there is no such precise information on the number of sources. In this section, the assumption of a known source count is relaxed; along with complex source amplitudes, locations, and noise variance, the number of sources is estimated as well.

According to the analysis presented in this paper, the joint probability distribution we have so far estimated with Gibbs sampling is in reality a conditional distribution, conditioning being on the number of sources M: $p(\alpha_1, \ldots, \alpha_M, r_1, z_{s1}, \ldots, r_M, z_{sM}, \sigma^2 | M, \mathbf{X})$. Following the Bayesian paradigm, a prior distribution can be specified for M, and, in like manner with the other parameters, a posterior distribution can be estimated from which we can infer the number of sources present.
FIG. 7. Posterior distribution of M vs M and realization number: SNR is 14 dB.

In the absence of specific information on M, we select a uniform prior over a range believed to be realistic:

$$p(M) = \frac{1}{M_2 - M_1 + 1}, \quad M_1 \leq M \leq M_2, \tag{16}$$

where M_1 and M_2 are lower and upper bounds for the expected number of sources.

Having already calculated the joint posterior probability distribution of all unknowns, we then compute the marginal posterior distribution $p(M|\mathbf{X})$, where

$$p(M|\mathbf{X}) = \int_{\sigma^2} \int_{\alpha_M} \cdots \int_{\alpha_1} \int_{r_M} \int_{z_{sM}} \cdots \int_{r_1} \int_{z_{s1}}$$

$$p(\alpha_1, \ldots, \alpha_M, r_1, z_{s1}, \ldots, r_M, z_{sM}, \sigma^2 | M, \mathbf{X}) p(M)$$

$$d_{\alpha_1} \cdots d_{\alpha_M} d_{r_1} dz_{s1} \cdots dr_M dz_{sM} d\sigma^2. \tag{17}$$

Maximizing Eq. (17) yields a MAP estimate of M.

One hundred noisy data realizations were generated to test the estimation of the number of sources; the SNR was 14 dB and the frequency was 200 Hz. Two sources were present as in the previous section. Using prior knowledge, it was assumed that M could vary between 1 and 4. The estimated marginal posterior distributions of M for all realizations are exhibited in Fig. 7. It is evident that most distributions are maximized for $M=2$, the true number of sources. Specifically, 99 out of 100 times the maximum occurs for $M=2$; for one realization, the posterior distribution is maximized for $M=1$.

In addition to the point estimate $\hat{M}=2$, our approach also provides information on the uncertainty in the estimation of the number of sources. From the distribution of Fig. 7, we can see that there is a very small probability of three or four sources being present. It appears that the number of sources is probably two, with one source being the next best choice.
FIG. 8. Posterior distribution of M vs M and realization number: SNR is 11 dB.
FIG. 9. Posterior distribution of M vs M for a single data realization: SNR is (a) 14 dB and (b) 11 dB.

As expected, results deteriorate as the noise increases. Figure 8 shows the marginal posterior distributions of M for all realizations for a SNR of 11 dB. A MAP estimate of 1 is obtained for 50% of the realizations. For the remaining 50%, an estimate $\hat{M}=2$ is obtained, representing the true number of sources.

Figure 9 shows the posterior distribution of M for a *single* data realization for each of the two considered SNRs. The distribution of M for the lower SNR [Fig. 9(b)] exhibits higher variability than the distribution for the higher SNR [Fig. 9(a)] with the probability divided between values 2 and 1 for M because of the increased noise level.

VI. PERFORMANCE EVALUATION OF THE MAP PROCESSOR IN THE PRESENCE OF MISMATCH

Performance evaluation in Sec. IV was performed assuming perfect knowledge of the propagation environment. This assumption is now relaxed and mismatch is introduced in the water column sound speed profile. Figure 10 shows the water column sound speed profile employed both for data
FIG. 10. Sound speed profiles used for data and replica generation.

TABLE I. Probability of correct localization for the strong source for the new MAP-Gibbs sampling and the simple processors for no mismatch and three mismatched sound speed profiles.

Processor	No mis.	Prof. 1	Prof. 2	Prof. 3
MAP-GS	1.00	0.60	0.30	0.24
Simple coherent canc.	1.00	0.18	0.03	0.00

and replica generation in Sec. IV. In the same figure, new sound speed profiles are presented [dashed lines, identified as (1)–(3)] that are used in the present section for data generation; replica generation is still performed with the original, solid-line sound speed profile. The new MAP processor and the simple incoherent Bartlett canceller were then applied to 100 noisy data realizations generated for a frequency of 200 Hz with the three new sound speed profiles. A strong source was again at a range and depth of 4 km and 2 m, respectively, and a weaker source was at a range and depth of 2.4 km and 48 m. The SNR was 17 dB.

Source localization results from both processors deteriorate dramatically even for the smallest mismatch considered here [profile (1) in Fig. 10], with the weak source becoming nonidentifiable. It is of interest, however, that the new processor localizes the strong source at a much better rate than the simple Bartlett canceller. Table I shows probabilities of correct localization for the strong source for four cases: no mismatch, and mismatch as introduced by sound speed profiles (1)–(3). With no mismatch between assumed and true sound speed profiles, the strong source is perfectly localized with both processors. The sound speed mismatch causes the simple coherent cancellation performance to drop very quickly. The MAP-Gibbs sampling performance, although affected by the mismatch, is considerably better than that of the simple processor.

VII. CONCLUSIONS

A MAP matched-field estimation approach was developed for localization of multiple sources. The method, optimized with Gibbs sampling, provides estimates of the number of sources and their locations. The method is, in essence, a deconvolution approach that can remove strong interfering source contributions from the received field for the identification of weaker sources of interest. The new approach was evaluated against simple interference cancellation methods for multiple source localization and was found superior for frequencies around and below 200 Hz. The superiority of the method is attributed to integrating over uncertainty instead of relying on point estimates as other methods do. Unlike previously developed methods, our approach also offers posterior probability distributions of the parameters of interest demonstrating the uncertainty present in the estimation problem. With the marginal conditional distributions of source levels and phases readily available, the approach can also be employed for source signature estimation. The method as presented here does not integrate over environmental uncertainty. Simulations indicate that, even without such integration, the processor is more robust with respect to mismatch than simple coherent cancellation. The proposed method can

be further extended by considering environmental uncertainty; estimates of environmental parameters can be further obtained as in Ref. 18.

Cluster analysis and robust use of full-field models for sonar beamforming

Brian Tracey,[a] Nigel Lee, and Srinivas Turaga[b]

MIT Lincoln Laboratory, 244 Wood Street, Lexington, MA 02420

Multipath propagation in shallow water can lead to mismatch losses when single-path replicas are used for horizontal array beamforming. Matched field processing (MFP) seeks to remedy this by using full-field acoustic propagation models to predict the multipath arrival structure. Ideally, MFP can give source localization in range and depth as well as detection gains, but robustly estimating range and depth is difficult in practice. The approach described here seeks to collapse full-field replica outputs to bearing, which is robustly estimated, while retaining any signal gains provided by the full-field model. Cluster analysis is used to group together full-field replicas with similar responses. This yields a less redundant "sampled field" describing a set of representative multipath structures for each bearing. A detection algorithm is introduced that uses clustering to collapse beamformer outputs to bearing such that signal gains are retained while increases in the noise floor are minimized. Horizontal array data from SWELLEX-96 are used to demonstrate the detection benefits of sampled field as compared to single-path beamforming. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2346128]

I. INTRODUCTION

Horizontal array beamforming for passive sonar is often based on the assumption that the signals impinging on the array arrive via a single propagation path. A model accounting for wave-front curvature across the array may be used near broadside, while a planewave model is used near endfire or for distant sources. However, multipath acoustic propagation is often important in shallow water. The use of a single-path model can therefore introduce a mismatch that reduces the output power of targets and may significantly limit the effectiveness of adaptive interference cancellation techniques.[1] The effects of multipath propagation are most noticeable at endfire, as the ability of horizontal arrays to resolve multipath is best for sources in this sector.[2] The approach described in this paper seeks to improve horizontal array performance near endfire in the presence of multipath.

Matched field processing (MFP) has been investigated as a means for accounting for multipath.[3] MFP uses full-field acoustic models to calculate replica vectors that represent the array response for a three-dimensional grid of possible source locations. Typically, MFP attempts to achieve simultaneous improvements over single-path beamformers in both detection performance (by using physics-based signal models to reduce signal mismatch) and source localization (by providing range and depth in addition to bearing).

Experimental use of MFP has shown that robust range and depth localization is difficult to achieve. In many cases this is due to uncertainty in the environmental inputs required by acoustic propagation models. Robustness can be increased by improving environmental calibration to give a more accurate set of replicas[4–6] or by explicitly accounting for uncertainty.[7–10] Another problem with MFP, especially for horizontal arrays, is that the array response may be very similar for sources at widely separated ranges and depths. Range and depth estimation therefore involves choosing the correct source location from a set of highly ambiguous beamformer outputs, which requires very accurate calibration and high signal-to-noise ratio.[11]

The signal processing approach described below is motivated by two observations. First, simulations described in Sec. III were used to investigate MFP localization accuracy for horizontal arrays when environmental information is uncertain. The results indicate that localization in bearing is much more tolerant of environmental uncertainty than is localization in range and depth. Second, experimental results in Sec. V demonstrate that use of MFP replicas can lead to reduced mismatch losses and therefore potentially better detection. These two observations lead to the following question: Is it possible to use MFP replicas in a way that achieves mismatch reduction, *without* attempting range and depth localization? Answering this question requires a method for collapsing the three-dimensional (3D) MFP beamformer output to bearing.

A simple approach is to maximize over MFP beamformer outputs for all ranges and depths along each bearing. This preserves any gains on signal provided by MFP, but leads to a significant increase in the displayed noise floor. As shown below, the resulting output shows little improvement in signal detectability.

An alternate procedure is developed here that includes a detection stage before collapsing the beamformer output to bearing. The procedure begins by analyzing the set of predicted MFP replicas and representing them by a set of *clusters*.[12] As described in Sec. II, each cluster corresponds to a set of spatial locations that have essentially the same

---

[b] Current address: Department of Brain and Cognitive Science, Massachusetts Institute of Technology, 77 Massachusetts Ave, Cambridge MA.

multipath structure (i.e., replicas that are highly correlated with each other). In standard MFP these locations would appear as highly ambiguous regions in the output. The cluster analysis output is denoted here a "sampled field," as the number of clusters, or distinct multipath structures, is often much smaller than the number of possible three-dimensional source locations (from this point of view, the full set of MFP replicas can be considered an "over-sampled field," as it contains redundant information). Because the set of clusters captures the diversity of multipath predicted by the full-field model, any mismatch reductions provided by the full-field model are retained.

After cluster analysis is complete, beamforming is done using a representative replica vector from each cluster (this gives computational gains relative to MFP,[13] but computational gain is not the primary objective of the current work). The cluster outputs are then analyzed. If a cluster has higher output power than other clusters that are highly correlated with it, it is judged to be signal-like. Otherwise, the cluster is judged to represent either noise or sidelobe energy from a nearby source, and its output power is set to an estimate of the noise level. After this detection stage is complete, the data are collapsed to the bearing dimension. Used in this manner, clustering allows an automated analysis of ambiguous regions in the output so that decisions can be made as to which set of search locations may contain the signal. Similar strategies have been used in analysis of radar outputs.[14] Thus any signal gains in the proposed approach result from the use of full-field replicas, while clustering is used to collapse the beamformer outputs to a bearings-only display.

An alternative method for collapsing MFP output to a bearings-only display has been proposed by Yang and Yates.[15] Their work requires an iterative search over range and depth to refine estimates of source bearing, and therefore it implicitly requires 3D localization. By contrast, the sampled field approach presented here collapses full-field outputs to bearings only without requiring range and depth localization. In cases where the environmental knowledge is good, matched field range and depth localization could be attempted as a follow-on stage to the sampled field bearing localization described here.

Section II below describes cluster analysis in more detail, while Sec. III outlines simulations used to study localization errors due to environmental uncertainty. The cluster-based signal processing approach is detailed in Sec. IV and is labeled sampled field processing (SFP) to distinguish it from standard MFP. Section V analyzes data from the SWellEx-96 experiment, showing that the approach improves signal detectability at endfire as compared to planewave or MFP approaches, especially when adaptive beamforming is employed.

II. CLUSTER ANALYSIS OF FULL-FIELD REPLICAS

Full-field MFP replicas are based on the Green's function, or channel response, for a set of possible source locations in range, depth, and azimuth. The results below use a range-independent normal mode model to calculate the Green's function,[16] although clustering can be applied to the

output of any ocean propagation model. Taking $(x, y) = (0, 0)$ to be at the center of the array, with $z = 0$ at the ocean surface, the Green's function for a sensor at $\mathbf{r}_i = (x_i, y_i, z_i)$ is given by

$$G(f, \mathbf{r}_i, \Theta) = \frac{ie^{-i\pi/4}}{\rho(z_s)\sqrt{8\pi}} \sum_{n=1}^{N} \psi_n(z_s)\psi_n(z_i)\frac{e^{-ik_n r_i}}{\sqrt{k_n}}, \quad (1)$$

where ψ and k_n are the mode shapes and mode horizontal wave numbers at the frequency f, z_s is the source depth, $r_i = \sqrt{(x_s - x_i)^2 + (y_s - y_i)^2}$ is the source-receiver range, and $\Theta = (x_s, y_s, z_s)$ is the source location in three dimensions.

The full-field replica vectors are computed as normalized versions of the Green's function:

$$\mathbf{v}(f, \Theta) = \frac{\mathbf{G}}{|\mathbf{G}|}\sqrt{N}, \quad (2)$$

where $\mathbf{G}$ is a vector of calculated Green's functions for each receiver. By contrast, planewave or range-focued replicas are calculated using a single-path propagation model

$$\mathbf{v}_{pw}(f, \Theta) = e^{-ik\mathbf{r}(\Theta)}, \quad (3)$$

where $k = \omega/c$ is the wave number for a wave traveling at speed c, and $\mathbf{r}(\Theta)$ is a vector of ranges between each array element and the hypothesized source location.

The set of MFP replica vectors can be analyzed using clustering, a technique that automatically breaks a set of observations into *clusters*, or groups of vectors that are similar to each other.[12] This similarity is defined by a distance metric specified by the user. For each cluster, a list of cluster members is returned along with a cluster center. The cluster center can be used as a representative of all the members of the cluster. The clustering algorithms used here require the user to specify a cluster *radius*, which is the maximum distance allowed between any point in a cluster and its center.

When applying clustering to beamforming, a natural distance metric is provided by the mismatch between pairs of replicas. The measure has been used by Cox[17] and is defined as

$$\text{dist}(\mathbf{v}_i, \mathbf{v}_j) \triangleq 1 - \frac{\|\mathbf{v}_i^H \cdot \mathbf{v}_j\|^2}{\|\mathbf{v}_i\|^2 \|\mathbf{v}_j\|^2}, \quad (4)$$

where the frequency domain replica vectors are given by $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$. Replica pairs that are highly correlated will have low mismatch and will tend to be clustered together.

Using this distance metric, a cluster is defined as a set of replicas $\mathbf{v}_i$ that all have a distance from a cluster *center* that is less than some threshold η

$$\text{dist}(\mathbf{v}_i, \tilde{\mathbf{v}}_j^{\text{cen}}) \leq \eta. \quad (5)$$

The cluster center $\tilde{\mathbf{v}}_j^{\text{cen}}$ is chosen from the original set of full-field replicas.

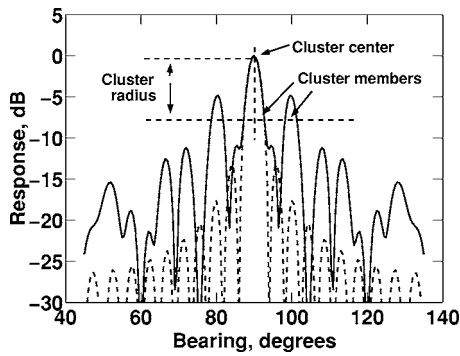
Clustering of MFP replicas can be computationally intensive and requires the use of efficient algorithms. The method used here is a "greedy" algorithm that first computes a matrix containing the mismatch between every pair of vectors. The vector with the largest number of close matches (i.e., replicas with mismatch less than the threshold η) is picked as the first cluster center. All replica vectors closer


FIG. 1. Beam patterns for nominal well-sampled array (dashed line) vs sparse array (solid line). For a sparse array, steering directions that are highly correlated with the main axis of response may be widely separated in space. Clustering provides a way to identify these regions of similar response.

FIG. 2. Plot showing members of an example cluster formed from MFP replicas for a single-line array at 94 Hz. The cluster (with 1.5 dB cluster radius) is well contained in azimuth and does not spread over many azimuthal beams. For a given azimuth, high correlation between many range and depth locations is evident.

than the threshold are assigned to this center. The cluster center and its cluster members are removed from the full set of replicas, and the process is repeated until all replicas are clustered. A more complete description of clustering algorithms is given in the Appendix.

The application of clustering to beamforming can be made clearer by considering a planewave example. Figure 1 compares beampatterns for well-sampled and sparse line arrays steered to a bearing of 90°. The steering angle is equivalent to a cluster center. The beam extent is defined in terms of a maximum allowable loss with respect to the steering angle; this maximum allowable loss is the equivalent of the cluster radius. When high ambiguities are present, as occurs with sparse arrays, beams that are within the specified cluster radius may be spatially disjoint. Clustering provides an automated way to identify these disjoint regions of similar response.

The following simulation example shows how cluster analysis can be applied to MFP replicas. Simulations were performed for a 101 element, 200 m long horizontal line array situated at a depth of 120 m in the Santa Barbara Channel environment[18] (see Table I for details). Full-field MFP replicas were generated for a bearing sector around endfire, for depths across the full water column and for ranges up to 10 km.

A typical cluster generated from the set of MFP replicas is shown in Fig. 2. This plot shows the locations of all MFP replicas that are identified as belonging to the same cluster. The cluster radius in decibels ($10 \log_{10} \eta^2$) is 1.5 dB for this example, meaning that each replica included in the cluster has at most 1.5 dB mismatch with the cluster center.

From Fig. 2 one can observe some characteristics that are generally true of MFP replicas for horizontal arrays. First, bearing is much better resolved than range or depth. This is a result of the array geometry, which has good sampling of azimuthal arrivals but poor sampling of the multipath structure used to infer range and depth. Range and depth estimation therefore requires finding the peak of a set of points that are very highly correlated. Second, although the cluster shown in Fig. 2 extends over many range and depth cells, there are many gaps in its coverage along the bearing shown. Multiple replicas (or clusters) are needed to provide low-mismatch coverage for all source locations along a given azimuth.

The 1.5 dB cluster radius for Fig. 2 was chosen based on beam spacings often used in planewave beamforming. Decisions about how widely to space steering vectors are commonly made by setting a maximum allowable loss relative to the beam's steering angle. While beams can be overlapped at the −3 dB point (corresponding to a 3 dB cluster radius), they may be spaced more finely to reduce loss on targets that lie between beams.

TABLE I. Parameters for sound speed and geoacoustic model used in simulations: z=depth from surface; c_c =compressional sound speed; ρ=density; α_c=compressional wave attenuation. The water column extends to 209 m depth and is followed by a layered seabed.

z (m)	c_c (m/s)	ρ (g/cm^3)	α_c (dB/λ)

FIG. 3. Cumulative distribution functions for localization errors, single line HLA. Mainlobe widths for range, depth, and bearing are shown as dashed lines on each plot. Bearing errors are typically within the mainlobe, while median range and depth errors exceed the mainlobe size.

III. ARGUMENT FOR BEARINGS-ONLY LOCALIZATION

As will be discussed in Sec. IV, clustering enables efficient collapsing of MFP outputs to bearings-only localization. This section motivates why bearings-only localization using MFP replicas is of interest. Ambiguity surface patterns such as those shown in Fig. 2 suggest that bearing estimates found using MFP-derived replicas should be more robust than range or depth estimates. Monte Carlo studies of the effects of environmental mismatch are used here to verify this intuition.

Simulations were carried out for the line array and environment described above. Simulated data was generated for 200 random source locations, all at endfire bearing to the array but with ranges and depths uniformly distributed over the search space (0–200 m depth and 2–10 km range). No noise was added. MFP replica vectors were generated using mismatched environmental models, in which the initial compressional speed in the sediment was perturbed. Perturbations of ±10 and ±20 m/s were used for a series of runs whose results were accumulated. These mismatched replicas were used in beamforming. The 3D location of the peak beamformer output was found for each random source location.

Figure 3 shows the cumulative distribution function (CDF) of MFP localization errors caused by environmental uncertainty. This result shows that bearing errors were generally low, with the median error being roughly 1/3 of the beamwidth. In contrast, the median error in the range and depth dimensions exceeded the estimated mainlobe resolutions in these dimensions, which were estimated as described in.[18] This underscores the difficulty of the 3D localization problem.

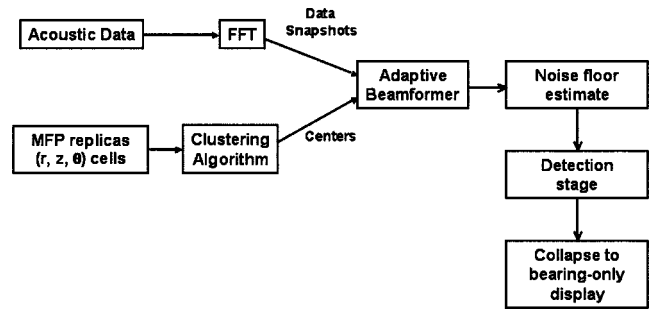
Signal-to-noise ratio (SNR) is another important consideration for MFP localization.[11] As suggested by Fig. 2, many locations in the range/depth plane have very similar response. Estimating the correct range and depth from this flat parameter space therefore requires higher SNR than estimat-


FIG. 4. Proposed signal processing flow for sampled field processing.

ing bearing only.

IV. USE OF CLUSTERS IN PROCESSING

Figure 4 shows a proposed signal processing flow that is motivated by the two previous sections. Those sections introduced the ideas of using clustering (to gain a nonredundant representation of the set of MFP replicas), and of bearings-only localization (to reduce sensitivity to environmental uncertainty and low SNR). The processing chain in Fig. 4 demonstrates how these two ideas can be combined. The steps in processing are as follows.

A. Beamforming stages

The five left-most boxes in Fig. 4 show steps related to beamforming. The steps involved in calculating and clustering the MFP replicas were described in Sec. II. Since the replicas depend on the environment and the array geometry, they need to be recalculated whenever either of these change. Clusters are generated for all frequencies of interest.

The acoustic data collected on the N array elements are transformed into the frequency domain using a short-time Fourier transform. This gives a set of $N \times 1$ data snapshots versus time and frequency. The snapshots are denoted $\mathbf{x}(f_0, t_0)$, where f_0 is the frequency and t_0 is the time of the snapshot. The data shown below were processed using a 2 s Hanning-windowed fast Fourier transform (FFT) with 50% overlap.

The nonadaptive or *conventional* beamformer (CBF) uses a weight vector that is simply a scaled version of the steering vector $\mathbf{w}_c(\cdot) = \mathbf{v}(\cdot)/N$. This normalization ensures that there is unity gain in the look direction. The conventional beamformer output for the direction Θ is given by

$$P_c(f_0, t_0, \Theta) = |\mathbf{w}_c^H(f_0, \Theta)\mathbf{x}(f_0, t_0)|^2. \qquad (6)$$

For simplicity, the dependence on the frequency f_0 and snapshot time t_0 is omitted below.

Adaptive beamforming (ABF) is implemented for the data analysis below using the dominant mode rejection (DMR) algorithm,[19] with a white noise gain constraint added to increase robustness to signal mismatch. DMR is a variant of the minimum variance distortionless response (MVDR) algorithm with diagonal loading. The loaded MVDR weight vector is given by

$$\mathbf{w}_d(\Theta) = \frac{(\hat{\mathbf{R}} + \delta(\Theta)\mathbf{I})^{-1}\mathbf{v}(\Theta)}{\mathbf{v}^H(\Theta)(\hat{\mathbf{R}} + \delta(\Theta)\mathbf{I})^{-1}\mathbf{v}(\Theta)}, \tag{7}$$

where Θ is the beam steering direction, $\delta(\Theta)$ is the direction-dependent diagonal load level, and $\hat{\mathbf{R}}$ is the estimated data covariance matrix. $\hat{\mathbf{R}}$ can be estimated from the data using a time-averaged sample covariance matrix of frequency-domain snapshots

$$\hat{\mathbf{R}} = \frac{1}{L}\mathbf{X}\mathbf{X}^H, \tag{8}$$

where $\mathbf{X}$ is a $N \times L$ data matrix, formed by accumulating L frequency-domain snapshots derived from short-time FFT data on the N sensors. Full-rank processing would require averaging over a long time period $(L \geq N)$, during which motion effects may become significant. Therefore, DMR focuses on the D largest eigenvalues (and corresponding eigenvectors) and deemphasizes the remaining $N\text{-}D$ eigenvalues/eigenvectors by constructing a modified sample covariance matrix $\tilde{\mathbf{R}}$

$$\tilde{\mathbf{R}} = \sum_{k=1}^{D} \lambda_k \mathbf{u}_k \mathbf{u}_k^H + \alpha \sum_{k=D+1}^{N} \mathbf{u}_k \mathbf{u}_k^H, \tag{9}$$

where α is an estimate of the input noise floor. $\tilde{\mathbf{R}}$ is then substituted for $\hat{\mathbf{R}}$ in Eq. (7) to calculate the adaptive weights $\mathbf{w}_d$. These weights are used in Eq. (6) (in place of $\mathbf{w}_c$) to find the adaptive beamformer output power P_a.

The load level δ in Eq. (7) is increased via an iterative process until it satisfies a white noise gain constraint[20]

$$\mathbf{w}_m^H(\cdot)\mathbf{w}_m(\cdot) \leq \frac{\beta}{N}. \tag{10}$$

The constant β above is a "relaxation" parameter, defined as the factor by which the weight norm in Eq. (10) is allowed to to exceed the "white noise gain" of $1/N$ (which is the value of the weight norm without diagonal loading and with white noise as input).

In passive processing applications, such as considered here, data from the signal of interest cannot be excluded when estimating the covariance matrix $\tilde{\mathbf{R}}$. An adaptive beamformer will (mistakenly) interpret any mismatched[21] portions of the signal of interest as noise and will (mistakenly) adapt to and reject this portion of the signal itself, an effect termed *signal self-cancellation* or *signal self-nulling*.[22] Diagonal loading via the white noise gain constraint provides a means for limiting this signal self-cancellation.[22] The white noise gain parameter β in Eq. (10) was set to 2 (3 dB) for the results below, yielding an adaptive processor that is relatively tolerant to signal model mismatch.

B. Noise estimation

After beamforming, the output powers are analyzed to estimate the noise level as a function of bearing. The harmonic mean noise estimator is used here.[23] The noise as a function of bearing θ is estimated as

$$P_N(\theta) = \left(\sum_{k \in \mathcal{K}} P(k)^{-1} \right)^{-1} \tag{11}$$

where $P(k)$ is the beamformer output power (either conventional or adaptive) for the kth cluster, and $\mathcal{K}$ is the set of clusters whose cluster center lies along a bearing within $\pm M$ azimuthal beams of θ. For data processing shown below, $M = 7$. The harmonic mean acts to suppress high-power outputs due to signals so that an accurate noise estimate is obtained. A variety of noise estimation methods are available, and the choice of the harmonic mean estimator is not critical for cluster-based processing.

C. Collapsing to bearing

Two possible methods for collapsing the beamformer outputs to bearing are considered here.

1. Maximize over all outputs along each bearing (ORing)

The simplest way to collapse MFP outputs to bearing only is to maximize over all matched field outputs along each bearing:

$$P_{1-D,mfp}(\theta) = \max_{(r,z)} P(r,z,\theta). \tag{12}$$

A similar collapsing can be done for a cluster-based beamformer. In this case the maximization is over the set $\mathcal{I}$ of clusters whose centers lie on the given bearing

$$P_{\text{SFP-OR}}(\theta) = \max_{i \in \mathcal{I}} P_i(\theta). \tag{13}$$

Because clustering captures the multipath structures described by the MFP replicas, the outputs of Eqs. (12) and (13) are expected to be very similar.

Signal power is preserved when using maximization to collapse beamformer output to bearing only. Unfortunately, maximization has the effect of increasing the noise level. As a thought experiment, imagine that all outputs along a given bearing correspond to noise. Maximizing the outputs gives a result that corresponds to the highest observed noise value, which may be significantly higher than the average noise level. As a result, a signal on an adjacent bearing will have a lower observed signal-to-background ratio. Maximization also tends to emphasize sidelobe energy from nearby sources, which again reduces the signal-to-background ratio.

The operation shown in Eqs. (12) and (13) has been labeled "ORing" in the sonar literature, and the SNR losses it causes are known as "ORing loss."[24,25] This terminology is adopted below. Data results generated using Eq. (12) will be labeled "ORed MFP," while cluster-based results generated using Eq. (13) will be denoted "SFP-OR."

2. Cluster-based detection approach

Clustering provides additional information about the relationship among points in the search space that is not available in standard MFP. The distance in terms of mismatch between cluster centers can be calculated, giving a measure

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

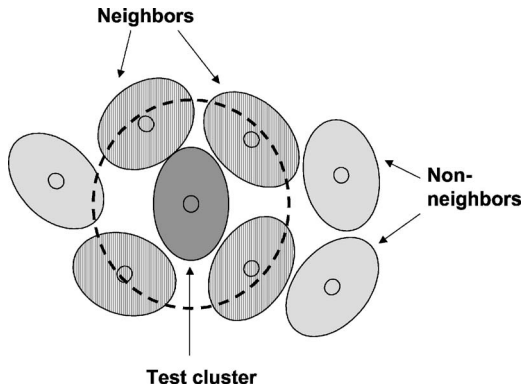
Tracey, Lee, and Turaga: Sampled field processing 2639


FIG. 5. Cartoon showing the proposed peak detection stage. Each cluster is compared to its "neighbors," defined as other clusters that are highly correlated with it. If the test cluster is a local peak or close to the local peak, its output is retained; if not, the cluster power is set to the estimated noise floor. The full set of clusters is then collapsed to bearings only.

of how different regions in the search space are related. A relatively simple method for using this information is described here.

One way to separate signals from noise is to require that a signal should give the peak output power in its local neighborhood. If a test cluster has output power P_{tst}, this cluster may be considered signal-like if

$$P_{\text{tst}} > P_j \quad \forall\, j \in \mathcal{N}_{\text{NB}}, \tag{14}$$

where j is the set of cluster centers in the neighborhood $\mathcal{N}_{\text{NB}}$. While noise outputs will occasionally give local peaks in output power, the majority of noise outputs will not. Noise-generated peaks will be spaced randomly in bearing and will not generate apparent source tracks over time. Sidelobe energy will also be suppressed using this test.

An approach to defining the local neighborhood $\mathcal{N}_{\text{NB}}$ is shown in Fig. 5. The neighborhood is defined as the set of all clusters whose centers are mismatched from the test cluster's center by less than some threshold

$$\text{dist}(\mathbf{v}_{\text{cen}}^{\text{tst}}, \mathbf{v}_{\text{cen}}^{j}) < = \eta_{\text{NB}}, \tag{15}$$

where distance is as defined in Eq. (5). Good results on data have been obtained by setting η_{NB} in the range of 2–3 dB, for cluster radii ranging between 0.5 and 1.5 dB. Typically the cluster neighbors identified as above extend over several adjacent bearings, and include some but not all of the clusters for each bearing.

In practice, a modification to this approach has been found to be helpful. Neighboring clusters that are not locally maximal [as defined in Eq. (14)] but have output power within 1 dB of the local maximum are retained. This modification helps in the situation where a source has energy that is split between two clusters.

The results of this detection stage are collected in a vector δ, whose entries are "1" for clusters that are found to be signal-like and "0" for clusters that are not. The full set of clusters is collapsed to bearing as

$$P_{\text{SFP-DET}}(\theta) = \max_{i \in \mathcal{I}} [P_i(\theta) \cdot \delta_i] + P_N(\theta)[1 - \max_{i \in \mathcal{I}} (\delta_i)], \tag{16}$$

where $\mathcal{I}$ is the set of clustered outputs whose cluster centers lie along θ. Thus, if there are one or more signal-like clusters along the bearing θ, the power output is set to the largest of them. If no signal-like clusters are identified, the power is set to the estimated noise floor.

A summary of the proposed processing method is as follows. Note that the first two steps below are also part of generating the ORed output described in Eq. (13) (SFP-OR).

- The full set of MFP replicas (steering vectors) is clustered, and the cluster centers are used as sampled field replicas.
- The replicas are used in beamforming. Cluster output powers and replica vectors are stored.
- An estimate of the noise floor versus bearing is made using the full set of cluster outputs.
- Each cluster's output power is examined in turn. If this power is higher than the power on any nearby cluster, the cluster is declared to be signal-like. Any neighbors with output powers that are within 1 dB of the peak are also labeled as signal-like.
- A maximization is used to collapse all signal-like clusters on each bearing to a bearings-only display. If no clusters along an azimuth have been labeled as signal-like, the output is set equal to the estimated noise floor.

Data results generated using this approach will be labeled "SFP-DET."

V. RESULTS USING EXPERIMENTAL DATA

Planewave, MFP, and sampled field approaches were tested using data from the SWellEx-96 ocean acoustics experiment (www.mpl.ucsd.edu/swellex96). Data were processed for event S5, in which the towship R/V Sproul towed both deep and shallow sources. These sources each projected a sequence of tones of varying levels. Results are shown for the bottom-mounted HLA North array, an irregularly spaced array of roughly 240 m overall length (see Fig. 6).

The sparse sampling provided by HLA North resulted in increased azimuthal sidelobes. Fig. 6(b) shows the calculated planewave response of HLA North to an endfire source at 148 Hz, one of the tones transmitted by the Sproul. As compared to a fully populated array, HLA North displays significantly elevated sidelobe levels.

The data from event S5 were beamformed using single-path (planewave and range-focused) replicas, MFP replicas, and cluster centers. Identical beamforming parameters were used for all replica types. The data were processed using 2 s FFT windows with 50% overlap. No spatial taper was applied to the array. Beams were linearly spaced in wave number, with 89 beams ranging from −70° to 70°.

Adaptive beamforming (ABF) was implemented using the DMR algorithm described above. As noted, the white noise gain parameter was set to 3 dB to give tolerance against mismatch. In the beamforming, 15 FFT snapshots were averaged in time to estimate the eigenvectors and ei-

FIG. 7. SWellEx-96 bearing-time records (BTRs), 235 Hz projected tone, for event S5. Cosine-spaced planewave beams are used for beamforming. The R/V Sproul was at endfire to the array during the times shown and transmitted tones continuously throughout the event. Note that adaptive beamforming suppresses sidelobe energy at the cost of signal self-nulling. (a) Conventional planewave and (b) adaptive planewave.

genvalues corresponding to the $D=5$ strongest sources in the data. The noise floor for the adaptive beamformer was found by averaging the remaining eigenvalues ($D+1$ through N, where N is the number of array elements).

A. Example planewave and ORed full-field results

This section gives example results for planewave and ORed full-field (MFP and clustered) beamformers. The examples help to illustrate the differences between the beamformers and serve as a preface to the more detailed data analysis in Secs. V B–V D.

Figure 7 shows planewave output versus bearing and time for the 234.5 Hz frequency bin, which contains most of the energy for the 235 Hz tone projected by the deep source. The towed source is at endfire, or 0°. The planewave conventional beamforming result, seen in Fig. 7(a), shows a large amount of energy in grating lobes caused by the array sparsity. Planewave adaptive beamforming, shown in Fig. 7(b), largely rejects this grating lobe energy.

The adaptive beamformer also gives much lower energy on the target track. Since both conventional and adaptive beamformers are normalized to give unit gain on target, one would expect equal power outputs if no mismatch were present. The reduction in along-track target power therefore

represents adaptive self-nulling caused by mismatch between the received signal and the assumed (planewave) signal model.

Figure 8 shows results of applying ORed full-field replicas to the same data. Figure 8(a) shows ORed MFP output [collapsed to bearing using Eq. (12)] while Fig. 8(b) shows SFP-OR output [collapsed to bearing using Eq. (13)]. A cluster radius of 1 dB was used for SFP-OR results. The ORed MFP and clustered beamformer results are very similar. The clustered output shows slightly more target self-nulling due to the fact that clustering uses a coarser sampling of the information contained in the MFP replica field.

A comparison of the towed source track (at endfire, or 0°) in Figs. 7 and 8 shows that use of full-field replicas gives significantly reduced adaptive self-nulling as compared to direct-path beamforming. Figure 8 also shows an increase in the displayed noise floor, or background, as compared with planewave output. This ORing loss reduces the overall signal-to-background ratio and motivates the use of alternate collapsing strategies.

In Figs. 7 and 8 a second apparent track is seen, initially to the right of the main track but moving quickly to the left. The source of this energy is unclear, and the source is not seen in other frequency bins. The main point of interest in Figs. 7 and 8 is the reduced adaptive self-nulling seen on the actual endfire target when full-field replicas are used.
FIG. 8. ORed adaptive MFP and SFP-OR results for the 235 Hz projected tone, collapsed to bearing using Eqs. (12) and (13). Note the increases in both signal and noise levels relative to adaptive planewave results. Little difference exists between sampled field and MFP outputs when this collapsing strategy is used. (a) Adaptive MFP, ORed to bearing and (b) adaptive SFP-OR.

B. Measured mismatch reduction

This section quantifies the reduction in mismatch obtainable using clustered full-field replicas. Mismatch reduction was measured experimentally by using high-SNR tones broadcast by the R/V Sproul as calibration signals. By comparing the maximum beamformer output to the power of the signal received on the array, beamformer mismatch or signal gain degradation (SGD) can be measured as

$$\text{SGD} = \max_i \frac{\|\mathbf{v}_i^H \cdot \mathbf{x}\|^2}{\|\mathbf{v}_i\|^2 \|\mathbf{x}\|^2}, \tag{17}$$

where $\mathbf{v}_i$ are the set of replica vectors and $\mathbf{x}$ is the data, assumed to come from a single source. To verify that a single source dominated the data (and thus the mismatch could be accurately computed), a singular value decomposition was calculated versus time for a covariance matrix estimated by averaging four snapshots. The ratio of the first to second eigenvalues was computed, and SGD estimates were judged to be valid if this ratio exceeded 6 dB.

Figure 9 shows computed SGD versus time for the 234.5 Hz bin. SGD values are shown for planewave replicas and for clustered beamformer outputs computed using different cluster radii. A noticeable mismatch reduction is seen when moving from planewave to clustered replicas. This mismatch reduction is equal to the gain in output power expected for conventional beamforming.
FIG. 9. Measured signal gain degradation vs time for 231.5 Hz frequency bin. Results are shown for planewave replicas and clustered full-field replicas. Results for cluster sizes of 1, 0.5, and 0.25 dB are shown. The clustered full-field replicas provide significant mismatch reductions as compared to planewave replicas.

Some mismatch reduction is observed when changing from a 1 dB cluster radius to a 0.5 dB cluster radius, while little additional reduction is seen when changing from 0.5 to 0.25 dB radii. This indicates that the inputs to the beamformer do not support a more detailed sampling of the pressure field. The remaining uncertainty is likely a combination of errors in estimated array positions and errors in the environmental modeling. This is an example of how detection gains are limited by environmental uncertainty.

Signal gain degradation values were calculated for four strong tones. Normalized histograms of the valid SGD values were generated for planewave and clustered replicas, using a 0.5 dB cluster radius. The resulting estimated probability density functions are shown in Fig. 10. The mismatch grows with frequency, as expected, but is noticeably lower for the clustered replicas. For the lowest three tones, the clustered replicas nearly always have 1.5 dB or less mismatch, while the planewave replicas can experience 2–4 dB mismatch. This dB difference can be greatly amplified in adaptive processing. Reducing mismatch by even a few decibels can dra-
FIG. 10. Probability density of measured signal gain degradation as a function of frequency. Mismatch losses using MFP-derived clusters are always less than 3 dB, while planewave mismatch can be considerably higher.
FIG. 11. Beamformer outputs at a single snapshot, comparing planewave adaptive beamfomer output to adaptive sampled field processing with simple ORing used to collapse to bearings only (SFP-OR). Mismatch reduction leads to less self-nulling and more signal power in the SFP-OR output, but ORing increases the displayed background level.

matically reduce adaptive self-nulling for strong sources, with smaller but still significant effects seen for weaker sources.

C. Comparison of collapsing options in data

As discussed above, collapsing MFP or clustered outputs to bearing using a simple maximization (ORing) leads to an increase in the apparent noise floor. Figure 11 illustrates this problem in more detail. Outputs of the planewave and ORed sampled field beamformers are shown versus bearing at a single snapshot in time. A cluster radius of 1 dB was used for this and all subsequent SFP results. The mismatch reduction obtained by SFP roughly 15 dB signal gain in this snapshot due to reduced target self-nulling (note that a weaker source would suffer less self-nulling loss). However, a noticeable increase in the quiet beams (away from the source) is also seen. This increase is referred to as *ORing loss*.[24]

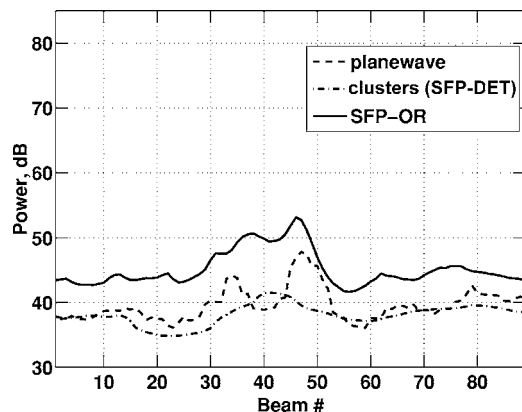
Figure 12 compares noise floors estimated from planewave outputs, from the ORed sampled field outputs (SFP-OR), and from the *full* set of cluster outputs (SFP-DET noise floor, found using Eq. 11). This last noise estimate is used in Eq. (16) to generate the SFP-DET outputs. Visually, the SFP-


FIG. 12. Estimated noise floors for planewave adaptive beamforming, all clusters (SFP-DET noise floor), and SFP-OR results. The SFP-DET noise floor is similar to that of planewave beamforming, but ORing leads to a 5.5 dB increase in the average noise floor of SFP-OR.
FIG. 13. Sampled field outputs using cluster-based detection (SFP-DET) compared to planewave ABF. For bearings that do not contain an identified peak in sampled field outputs, the SFP-DET output is set to the estimated noise floor for all clusters. The resulting display maintains signal gains due to mismatch reduction but minimizes the increase in the noise floor.

DET noise floor estimated from the full set of clusters appears close to the planewave noise level. The average noise floor for the planewave curve is 39.7 dB, while the average noise floor for SFP-DET is 38.1 dB; the small difference is probably due to spillover of signal energy into the planewave noise floor estimate. In contrast, the average noise estimate for the SFP-OR outputs is 45.2 or 5.5 dB higher than the planewave output. This increase is due to the ORing operation of Eq. (13). Figure 12 suggests that the SFP-DET algorithm has the potential to produce a similar noise floor to that of planewave beamforming.

Figure 13 shows the result of applying the SFP-DET approach. The planewave ABF result is shown as a dotted line, while the solid line shows the SFP-DET cluster result. For bearings where no cluster peak was found, the SFP-DET curve shows the underlying noise floor estimate plotted in Fig. 12. The SFP-DET result retains gains on the signal (which is at 0°) while avoiding a large increase in the noise floor. A number of small peaks are seen in the SFP-DET output, which may correspond to either local noise peaks or weak signals. The local SNR for these detections is of the same order of magnitude as similar noiselike peaks seen in the planewave output. An important note is that peaks generated by noise fluctuations will vary randomly, and are not expected to generate consistent tracks over time.

D. Single-tone bearing-time records

Planewave and sampled field beamformers can be usefully compared by forming bearing versus time output plots (BTR's). Results are presented for here both high-SNR and lower-SNR projected tones. Adaptive beamforming (ABF) is used in all cases. Because adaptive self-nulling increases with source level, the gains from mismatch reduction when using SFP-DET are most striking in the loud tone data. However, significant improvements are also seen for the quieter tones.

Figure 14 shows single-frequency beamformer output for the 231 Hz shallow source projected tone. This tone and the 235 Hz result shown above were among the loudest tones broadcast, with source levels of 158 dB re μPa. Planewave
FIG. 14. SWellEx-96 bearing-time records (BTRs), 231 Hz projected tone, for time period with R/V Sproul near aft endfire (center of display). This tone was projected at 158 dB from the shallow source, which transited from roughly 2–4.5 km over the time period shown. Planewave beamforming is compared to SFP-DET sampled field results. Best results are seen with SFP-DET. (a) adaptive planewave and (b) adaptive SFP-DET.

results are shown in Fig. 14(a), while SFP-DET results [generated using Eq. (16)] are shown in Fig. 14(b). The high SNR towed source is visible near 0° in both displays, but the power output along the target track is much lower for the planewave beamformer than for the SFP-DET beamformer during several time periods. Since both beamformers are normalized to give unit gain on target, the difference in power output is attributable to adaptive self-nulling in the plane-wave result. The SFP-DET approach is successful in reducing the signal model mismatch so that the adaptive beamformer suppresses sidelobe energy without suppressing the signal of interest. In addition, the SFP-DET algorithm has a noise floor comparable to the planewave display, resulting in a clear improvement in signal-to-background ratio (SBR).

A similar result is seen in Fig. 15. This figure plots data from the 140 Hz FFT bin, which apparently contained a naturally radiated tone from the R/V Sproul (again near 0°). Note that these results are plotted on a 50 dB dynamic range, while plots above required larger dynamic range to accomodate the extremely high SNR. While the source level for this tone is unknown, it appears to lie in between the "loud" (158 dB) and "quiet" (132 dB) projected tones. Because this tone is not as strong as the 231 Hz projected tone, the reduction in self-nulling obtained by sampled field processing is not as extreme, though an improvement is clearly noticeable.

In Fig. 15, an additional subfigure (b) is added that shows a bearing-time record formed by maximizing over
FIG. 15. Bearing-time records (BTRs) at 140 Hz. This tone appears to be an naturally radiated tone from the R/V Sproul. The SFP-DET sampled field result shows signal gains but maintains a low noise floor. The SFP-DET result performs better than either adaptive planewave or adaptive range-focused beamformers. (a) adaptive planewave, (b) adaptive range-focused, ORed to bearing, and (c) adaptive SFP-DET.

range-focused direct path beamformer output, using five focus ranges uniformly spaced between 2 and 10 km. This covers the same ranges as included in the full-field replicas. This plot was generated to demonstrate that the signal gains observed in SFP-DET outputs are due to the use of full-field replicas, rather the use of range focused replicas. Wavefront curvature is not present for endfire sources, where the towed source is located, so accounting for source range is not expected to affect gain on the towed source (although it does affect off-endfire sources).

Figure 16 shows results for a quieter (132 dB re μPa) projected tone. A number of off-endfire contacts are seen in the ORed range-focused and SFP results that are not seen in
FIG. 16. Bearing-time records (BTRs) for the 237 Hz projected tone. This tone was projected from the source at 132 dB (one of the quieter projected tones). Several additional contacts are seen in the SFP-DET and range-focused outputs that are not seen in the planewave result, and are presumably due to closer-range sources. Again, the SFP-DET shows improved signal-to-background ratio on both the projected tones and observed contacts. (a) adaptive planewave, (b) adaptive range-focused, ORed to bearing, and (c) adaptive SFP-DET.

the planewave results. These are likely closer-range sources whose energy is protected when closer focus ranges are added. Results for the projected tone (near 0°) again show a noticeable signal-to-background gain for SFP-DET as compared to planewave or range-focused results.

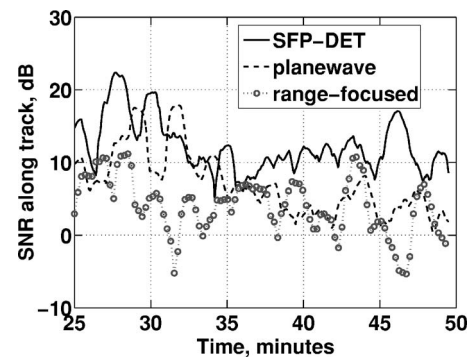
This gain can be quantified in terms of the measured along-track signal-to-background ratio (SBR). Figure 17 shows estimated SBR for the ABF outputs from Fig. 16. The background level for each bearing of interest was estimated by averaging the output for three beams on either side, with an offset of two beams (thus the background for beam 30 is the mean of beams 25–27 and 33–35). SBR estimates were


FIG. 17. Estimated along-track signal-to-background ratios (SBR), 237 Hz projected tone. Estimates are shown for adaptive SFP-DET, planewave, and ORed range-focused outputs. The median SFP-DET along-track SBR exceeds the median planewave SBR by 5.4 dB.

extracted along the observed signal track and smoothed using a 60 s moving average. The ORed range-focused result has the worst along-track SBR, presumably because the ORing operation causes an increase in background level. The SFP-DET approach has improved SBR as compared to planewave beamforming for almost all time intervals, giving an increase in median along-track signal-to-background ratio of roughly 5.4 dB. Higher gains would be expected if along-track SBR were calculated from Figs. 14 and 15, as the effects of adaptive self-nulling on planewave outputs are greater for these louder tones.

VI. SUMMARY

This paper has presented sampled field processing (SFP) as an alternative to matched field processing for exploiting the information about multipath structure provided by acoustic modeling. Unlike MFP, which attempts to simultaneously provide both detection gains and three-dimensional localization, SFP only seeks to provide detection gains. SFP uses cluster analysis to sample the predicted acoustic fields, resulting in a set of beamformer replicas that characterize typical multipath interference structures expected along each bearing. Because horizontal arrays can be used to estimate source bearing more robustly than range or depth, sensitivity to environmental uncertainty can be reduced by collapsing beamformer outputs to a bearings-only display. The information provided by cluster analysis is used in a detection scheme for collapsing beamformer outputs to bearing while preserving signal-to-background gains.

Gains resulting from application of this detection scheme (termed SFP-DET) were demonstrated using SWellEx-96 bottom-mounted horizontal line array data for an endfire source. Compared to adaptive planewave and adaptive range-focused beamformers, SFP-DET achieved better signal gain, because of its use of a full-field signal model. Compared to beamformers that collapse to bearings only by maximization (such as ORed MFP), the cluster-based SFP-DET approach achieved lower background levels. Overall, SFP-DET produced the best signal-to-background ratios of any of the beamformers considered.

The results shown here are for narrow-band (single-frequency) processing. Additional gains can be expected by

broadband processing, which combines signal energy across frequency. A simple form of broadband processing could be accomplished by incoherently averaging narrow-band BTRs such as those shown above. However, better performance would likely be achieved if the SFP-DET algorithm were modified to explicitly use broadband information. For example, a broadband version of Eq. (14) could be created which requires that a test cluster be labeled "signal-like" only if similar signal-like clusters are seen on the same bearing at other frequencies. Broadband processing using cluster analysis remains a topic for future work.

The work presented here has used cluster analysis as a preprocessing stage before beamforming is carried out. Alternatively, one could beamform using all MFP replicas, cluster the replicas corresponding to spatial peaks in the output to identify closely related peaks, and use a detection strategy to collapse these outputs to bearing. In effect, this would constitute a "beamform-cluster-detect" strategy rather than the "cluster-beamform-detect" strategy explored here. Thus, while the SFP approach examined here provided noticeable gains on experimental data, several avenues exist for further development.

ACKNOWLEDGMENTS

APPENDIX: EFFICIENT CLUSTERING ALGORITHMS

The computational problem for clustering replica vectors can be posed as follows: "Find the fewest number of cluster center vectors $\tilde{\mathbf{v}}^{\text{cen}}$ such that the maximum distance between each vector $\mathbf{v}_i$ and the closest center vector $\tilde{\mathbf{v}}_j^{\text{cen}}$ is less than η," where η is the cluster radius. This can be written

$$\max_i \min_j \text{dist}(\mathbf{v}_i, \tilde{\mathbf{v}}_j^{\text{cen}}) \leq \eta. \qquad (A1)$$

The exact solution to this problem is computationally prohibitive to calculate,[26] but approximate solutions can be found. The computational load of clustering full-field replicas was found to be greatly reduced for algorithms with the following characteristics: (1) the clustering method is "greedy," meaning that it will seek a suboptimal solution; and (2) a divide-and-conquer (denoted DnC) approach is used, in which the algorithm operates on subsets of replica vectors to build up the solution. For the cases studied, using a greedy algorithm rather than a more exact method (such as hierarchical clustering) gave a speedup of roughly $1000\times$. DnC gave an additional speedup of $10-20\times$.

A useful greedy clustering method has been proposed by Gonzalez.[26] This algorithm iteratively adds cluster centers by finding the vector that has the greatest distance from the previous set of centers. A simpler inner product clustering

algorithm was also developed. This algorithm first computes the $n \times n$ pairwise distance or mismatch matrix between every pair of vectors. The vector with the largest number of close neighbors, with mismatch less than the threshold, is picked as the cluster center. All replica vectors closer than the threshold are assigned to this center. The cluster center and cluster members are removed from the vectors to be clustered, and the process is repeated until all vectors are clustered. A final step re-assigns all non-centers to the closest center. The inner product method was found to be slightly faster than the Gonzales method and was used for the results shown above.

A divide-and-conquer (DnC) approach, in which the final clustering solution is constructed from the clustering solutions found for each subgroup of replicas, provides additional gains. DnC is implemented as follows: First, a subset of MFP replicas is extracted from the overall set. For the results shown above, every tenth replica was selected. A set of clusters is formed from this small set. A second subset of MFP replicas is extracted, and the projection of these new replicas onto the previous clusters is found. Any of the new replicas that fall within previously identified clusters are assigned to them; the remaining replicas are then clustered themselves, and the new clusters are added to the overall set of clusters. This process repeats until all MFP replicas are assigned to a cluster. Typically, the run time using this approach is dominated by the clustering of the first subset. Several different methods for breaking the MFP replicas up into subsets were examined. The subdivision method used did not have a strong effect on clustering performance.

Continuous thermoacoustic mixture separation

G. W. Swift and D. A. Geller

Condensed Matter and Thermal Physics Group, Los Alamos National Laboratory, MS K764, Los Alamos, New Mexico 87545

The superposition of nonzero time-averaged mole flux $\dot{N}$ on a thermoacoustic wave in a binary gas mixture in a tube produces continuous mixture separation, in which one or more partially purified product streams are created from a feedstock stream. Significant product and feedstock flows occur through capillaries that are small enough to experience negligible thermoacoustic phenomena of their own. Experiments with a 50–50 helium-argon mixture show diverse consequences of nonzero flow, involving the addition of only one simple term $n_H \dot{N}$ to the equation for the heavy component's time-averaged mole flux, where n_H is the mole fraction of the heavy component. A boundary condition for n_H must be imposed on the equation wherever products flow out of the separation tube, but not where feedstock flows in. © *2006 Acoustical Society of America.*

I. INTRODUCTION

In thermoacoustic mixture separation, a sound wave propagating in a gas mixture in a tube causes one component of the mixture to flow in the sound-propagation direction and the other component to flow in the opposite direction.[1–3] The expenditure of acoustic power results in an increase in the Gibbs free energy of the mixture's components, and the energy efficiency of the process is comparable to that of some other practical separation processes.[4] Thermoacoustic separation is caused by oscillating radial thermal diffusion combined with oscillating axial viscous motion. The sound wave's oscillating pressure causes an oscillating radial temperature gradient, which in turn causes radial thermal-diffusion oscillations, inducing a small fraction of the light and heavy components of the mixture to take turns being partially immobilized in the viscous boundary layer near the tube wall. Thus, outside of that boundary layer, the sound wave's axial oscillating motion carries gas that is slightly enriched in the heavy component in one direction during one half of the acoustic cycle and gas that is slightly enriched in the light component in the other direction during the other half of the cycle.[5] In a 2-m-long tube, a 50-50 helium-argon mixture has been separated to yield 70% helium, 30% argon at one end and 30% helium, 70% argon at the other end; and a small enrichment of ^{22}Ne from natural neon has been demonstrated.[6]

The five papers cited above described some of the mathematical physics of this phenomenon. Analytical expressions for the radial dependencies of oscillating temperature, density, mole fraction, and velocity and for the time-averaged molar separation flux were derived in the boundary-layer approximation, initially with no axial concentration gradient[1] and later with an arbitrary concentration gradient.[3] A numerical calculation was described that did not invoke the boundary-layer approximation.[3] Measurements confirmed the calculations, initially with no axial concentration gradient

in a tube where the boundary-layer approximation was adequate,[2] and later in a smaller-diameter tube with an axial concentration gradient.[3]

All of this theoretical work assumed that $\dot{N}_H + \dot{N}_L = 0$, where $\dot{N}_H$ and $\dot{N}_L$ are the time-averaged mole fluxes of the heavy and light components of the gas, respectively. In other words, it was assumed that the heavy and light mole fluxes were exactly equal in magnitude and in opposite directions. Similarly, all of the previous experimental work ensured that there was no bulk time-averaged total mole flux of the gas. In an engineering context, this corresponds to "batch" separation, in which a mixture is loaded into an apparatus, the apparatus is run for some time to accumulate an enriched product in one place and a depleted product in another place, and the products are finally removed. However, most industrial separation processes (e.g., petroleum refining, air separation, isotope enrichment[7–9]) run continuously, with feedstock steadily injected at one place while one or more enriched and depleted products are steadily removed elsewhere. Continuous separation requires nonzero total mole flux $\dot{N}$ superimposed on the separation flows, so that

$$\dot{N} = \dot{N}_H + \dot{N}_L \neq 0. \tag{1}$$

We undertook the work reported here to explore some fundamental aspects of continuous thermoacoustic mixture separation, for which inequality (1) is true.

Reference 3 showed that the first-order thermoacoustic momentum equation is unchanged by mixture-separation effects, and Doppler-shift effects are also negligible at the slow mean flows of interest here. Then the momentum equation shows that the evolution of the complex pressure amplitude p_1 with axial coordinate x is given by

$$\frac{dp_1}{dx} = -\frac{i\omega \rho_m / A}{1 - f_\nu} U_1, \tag{2}$$

where ω is the angular frequency of the oscillation, ρ_m is the mean density of the gas, A is the cross-sectional area of the

tube, U_1 is the complex volume-flow-rate amplitude, and f_ν is the viscous function[10] that depends on the geometry of the tube. The evolution of U_1 with x arises from the laterally averaged first-order continuity equation[10] for $dT_m/dx = 0$

$$i\omega\langle\rho_1\rangle + \rho_m\frac{d\langle u_1\rangle}{dx} = 0, \tag{3}$$

where $\langle\rangle$ indicates an average over the cross-sectional area of the tube. The ideal-gas equation of state gives

$$\frac{\langle\rho_1\rangle}{\rho_m} = \frac{p_1}{p_m} - \frac{\langle T_1\rangle}{T_m}, \tag{4}$$

and Eq. (30) in Ref. 3 with $f = \langle h\rangle$ gives $\langle T_1\rangle$. Combining these and using the ideal-gas identity $\rho_m a^2 = \gamma p_m$ yields the mixture-separation continuity equation

$$\frac{dU_1}{dx} = -\frac{i\omega A}{\rho_m a^2}\{1 + (\gamma-1)[Bf_\nu + Cf_{\kappa D} + (1 - B - C)f_{D\kappa}]\}p_1, \tag{5}$$

where a is the adiabatic sound speed, γ is the ratio of isobaric to isochoric specific heats, and B, C, $f_{\kappa D}$, and $f_{D\kappa}$ are defined in Ref. 3 and discussed in Appendix A here. Continuing through the derivation in Ref. 3, the first opportunity to incorporate nonzero $\dot{N}$ is in Eqs. (43) and (44) of Ref. 3, the latter becoming

$$\dot{N}_{H,m} = n_H\dot{N} - NAD_{12}\frac{dn_H}{dx} \tag{6}$$

with the addition of the convective term $n_H\dot{N}$, where n_H is the mean mole fraction of the heavy component and D_{12} is the binary mass-diffusion coefficient. Thus, the combination of Eq. (6) with Eqs. (41) and (56) of Ref. 3 shows that the mole flux of the heavy component is

$$\dot{N}_H = n_H\dot{N} + \frac{\delta_\kappa}{4r_h}\frac{\gamma-1}{\gamma}\frac{k_T}{R_{univ}T_m}|p_1||U_1|(F_{trav}\cos\theta$$
$$+ F_{stand}\sin\theta) + \frac{\delta_\kappa}{4r_h}\frac{\rho_m|U_1|^2}{m_{avg}\omega A}F_{grad}\frac{dn_H}{dx}$$
$$- \frac{\rho_m}{m_{avg}}AD_{12}\frac{dn_H}{dx}. \tag{7}$$

The first term represents the mole flux of the heavy component that simply accompanies nonzero bulk flow of the gas mixture. The second term represents the thermoacoustic mixture-separation process described qualitatively above, which can cause the heavy component to flow in either direction with respect to its concentration gradient. The third term represents a qualitatively similar process of oscillating radial mass diffusion and axial viscous motion, but one that always works to reduce the magnitude of a nonzero concentration gradient. The fourth term represents ordinary axial mass diffusion, which also always works to reduce the concentration gradient. In Eq. (7) and throughout this paper, $\delta_\kappa = \sqrt{2k/\omega\rho_m c_p}$ is the thermal penetration depth, k is the thermal conductivity, c_p is the isobaric specific heat, r_h is the hydraulic radius of the separation tube (for a circular tube, r_h is half of the circle's radius R), k_T is the molar

thermal-diffusion ratio, $R_{univ} = 8.314$ J/mol-K is the universal gas constant, T_m is the mean temperature, θ is the phase by which p_1 leads U_1, $m_{avg} = n_H m_H + (1 - n_H)m_L$ is the average molar mass, and m_H and m_L are the heavy and light molar masses, respectively. The three real variables F_{trav}, F_{stand}, and F_{grad}, which are generally <0, depend on the properties of the gas and the local geometry of the tube. Analytical expressions for the three F's have been published previously in the boundary-layer limit,[1,3] but in Appendix A here we present analytical expressions for the F's in small circular tubes for the first time. The coupled differential Eqs. (2), (5), and (7), with the expressions for the three F's given in Appendix A, have been implemented in the computer code DELTAE,[11] which has been used to create all the calculated curves in the figures below. In that implementation, Eq. (7) is solved for dn_H/dx and is integrated with respect to x simultaneously with Eqs. (2) and (5) to obtain $p_1(x)$, $U_1(x)$, and $n_H(x)$. The mole fluxes $\dot{N}$ and $\dot{N}_H$ are taken to be independent of x except where feedstock is injected or product is removed.

To solve Eqs. (2), (5), and (7) for $p_1(x)$, $U_1(x)$, and $n_H(x)$, boundary conditions on those three variables must be imposed. The boundary conditions for p_1 and U_1 are the same as for ordinary acoustics in tubes, but boundary conditions for n_H are less familiar. In batch separations, the number of moles of each gas in the apparatus at the end of the separation process is the same as at the beginning, so n_H must satisfy

$$\int n_H(x)\,dV = n_{H,batch}V, \tag{8}$$

where $n_{H,batch}$ is the initial heavy mole fraction of the batch and V is the volume of the apparatus. Continuous separations impose different constraints. In steady state, the number of moles of gas and the number of moles of the heavy component of the gas in the apparatus must be constant, so whatever flows in must flow out. This can be expressed mathematically as

$$\sum_j \dot{N}_{feedstock\,j} = \sum_k \dot{N}_{product\,k}, \tag{9}$$

$$\sum_j n_{H,feedstock\,j}\dot{N}_{feedstock\,j} = \sum_k n_{H,product\,k}\dot{N}_{product\,k}, \tag{10}$$

where the indices j and k account for more than one feedstock and product capillary, respectively. Equation (10) is a global constraint on n_H for continuous separation, similar in principle to the constraint of Eq. (8) for batch separation.

In addition to this global constraint, continuous separation imposes local boundary conditions. In a capillary connected to the separation tube at $x = x_o$ through which a product is removed continuously and which is small enough in diameter that acoustics within it is insignificant and the concentration gradient is zero, Eq. (7) is simply $\dot{N}_{H,product} = n_{H,product}\dot{N}_{product}$. The value of $n_{H,product}$ in that capillary must equal the local value in the separation tube where the capillary is connected. If the product is removed at an end of the separation tube, $\dot{N}$ and $\dot{N}_H$ in the capillary must also

equal their values in the separation tube. Thus, the boundary condition imposed on n_H at an end x_o of the separation tube where a product is removed is simply

$$\dot{N}_H(x_o) = n_H(x_o)\dot{N}(x_o). \tag{11}$$

(The corresponding condition would be

$$\dot{N}_H(x_o^-) - \dot{N}_H(x_o^+) = n_H[\dot{N}(x_o^-) - \dot{N}(x_o^+)] \tag{12}$$

if product were removed somewhere in the middle of the separation tube.)

The algebraic simplicity of the boundary condition given in Eq. (11) disguises at least two interpretations. At the simplest level, Eq. (11) expresses "what goes in must go out" with respect to the region of the separation tube adjacent to the product-removal capillary's entrance. However, Eqs. (7) and (11) together show that the last three terms in Eq. (7) must sum to zero at such a location. This shows that the boundary condition can also be interpreted as a complicated local constraint relating dn_H/dx (which appears explicitly in two of those three terms) to n_H itself (on which most of the variables in all three terms depend implicitly).

In contrast to continuous product removal, continuous feedstock injection does not impose any explicit local boundary condition on the solution to Eqs. (2), (5), and (7) in the separation tube. The total injection flux $\dot{N}_{feedstock}$ and the injection flux of the heavy component, $n_{H,feedstock}\dot{N}_{feedstock}$, add to any time-averaged flows already in the separation tube and compete with the terms of Eq. (7) and boundary conditions imposed elsewhere to determine the local value of n_H, which is not necessarily equal to $n_{H,feedstock}$. If the feedstock capillary had a large enough diameter to support internal thermoacoustics, continuity of n_H at the junction of the capillary and the separation tube would presumably hold. As its diameter was reduced, dn_H/dx at the end of the capillary would steepen, eventually developing what we conveniently treat as a discontinuity here.

The verification of the presence of the first term in Eq. (7), $n_H\dot{N}$, and the boundary condition on n_H expressed in Eq. (11) are the principal quantitative goals of this work. The experiments described below used a helium-argon mixture in a loudspeaker-driven traveling-wave separation tube. Fed with a 50-50 mixture, concentrations at the ends of the tube ranged from 30 to 70%. Feedstock was added and products were removed via capillaries, small enough in diameter to eliminate significant internal thermoacoustic effects but large enough to allow steady flow without requiring high pumping power. Feeding gas to the middle of the separation tube and extracting products at both ends allow simultaneous continuous production of helium-enriched gas and argon-enriched gas. Feeding gas to one end and removing an almost equal amount from the same end allows continuous production of a single more-highly enriched gas at the other end. Measurements under both circumstances provide quantitative confirmation of the $n_H\dot{N}$ term in Eq. (7) and of the boundary condition expressed by Eq. (11).
FIG. 1. Scale drawing of the apparatus. Valves to the right of the drawing, not shown, connected the microcapillaries to the RGA and pumps. Valves to the left of the drawing, not shown, connected the feedstock/product capillaries to the source of gas and other pumps.

II. APPARATUS AND INSTRUMENTATION

Figure 1 illustrates the apparatus we used to investigate these issues. The stainless-steel separation tube was 1-m long and had a 3.3-mm inside diameter. Near one end, access through a valve and a very short, 1-mm-inner-diameter (i.d.) connector allowed rapid evacuation and addition of the gas mixture before each experimental run, to a mean pressure $p_m = 80$ kPa that was measured with a high-accuracy capacitance manometer[12] that had been checked recently against a mercury manometer. At each end of the tube was a bellows-sealed piston epoxied to the face of a loudspeaker. These two driver assemblies were used to maintain the sound wave in the gas, and are described more thoroughly in Ref. 6. They were driven sinusoidally at 200 Hz by two phase-locked signal generators and audio amplifiers. Three piezoresistive pressure transducers[13] and a lock-in amplifier[14] were used to observe the resulting complex pressure amplitude p_1 in the gas at the ends and the middle of the separation tube. Table I summarizes the important dimensions of the apparatus discussed above and other variables that are discussed later.

The heavy mole fraction n_H in the separation tube could be measured at the seven locations that are shown in Fig. 1. At each location, a microcapillary[15] continuously withdrew gas from the separation tube at a rate of $\sim 3 \times 10^{-10}$ mol/s. All seven microcapillaries were 5-cm long and nominally

TABLE I. Properties of 50–50 helium-argon at 80 kPa, 300 K, and 200 Hz, and values for three tubes filled with that gas. The last three rows of the table are for $|p_{1,0}| = 2$ kPa.

	Microcapillary	Capillary	Separation tube

10-μm inside diameter. These fragile microcapillaries were epoxied into larger copper tubes to protect against accidental damage. We found that two of them, henceforth referred to as the "large" microcapillaries, had 30% lower flow impedances than the other five, so the inside diameters of those two may have been 7% larger than the other five. The helium and argon flowing through the microcapillaries were detected by a computer-controlled, quadrupole-type residual gas analyzer[16] (RGA) pumped by a turbopump,[17] the latter backed by an oil-free mechanical pump.[18] A network of bellows valves allowed any of the seven microcapillaries to be connected to the RGA-pump system, which maintained the pressure at $\sim 10^{-6}$ torr in the presence of such flow. Meanwhile, the other six microcapillaries were connected to a second turbopump and second mechanical pump, to maintain high vacuum in all connecting tubing so that opening a valve never dumped a large amount of accumulated gas into the RGA. A measurement of n_H at a single microcapillary involved opening and closing the valves appropriately, waiting 2 min for steady state, and then averaging the RGA mass-4 and mass-40 "partial pressures" for 3 min. This averaging time yielded roughly 1% statistical uncertainty in the supposed ratio of mass-4 partial pressure to mass-40 partial pressure.

However, obtaining n_H from that "partial pressure" ratio was complicated because the RGA is much more sensitive to argon than to helium and because the RGA-pump system's response is nonlinear,[19] with the nonlinearity being different for mass 4 and mass 40. We mapped out this complexity near our operating conditions by recording the RGA's reported partial pressures for known helium-argon mixtures, which we prepared from the pure gases in a 2-liter fan-stirred mixing chamber. These mixtures, ranging in concentration from 35–65 to 65–35, were forced through one small and one large microcapillary with 80-kPa pressure. The RGA results were slightly different for the partial pressures resulting from the large and small microcapillaries. We found

$$\left(\frac{\text{pp}_4}{\text{pp}_{40}}\right)_{\text{true}} = C_L \left(\frac{\text{pp}_4}{\text{pp}_{40}}\right)_{\text{RGA}}, \quad \text{large microcapillaries;} \tag{13}$$

$$\left(\frac{\text{pp}_4}{\text{pp}_{40}}\right)_{\text{true}} = C_S \left(\frac{\text{pp}_4}{\text{pp}_{40}}\right)_{\text{RGA}}$$
$$\times \left[1 - 0.1\left(\frac{\text{pp}_4}{\text{pp}_{40}}\right)_{\text{RGA}}\right], \quad \text{small microcapillaries;} \tag{14}$$

where pp stands for the partial pressure reported by the RGA, $C_L \simeq 7.8$ and $C_S \simeq 8.0$. Based on a number of calibration runs, we suspect that systematic uncertainties in these values contribute about 1% to uncertainty in $(\text{pp}_4/\text{pp}_{40})_{\text{true}}$. The heavy mole fraction is then given by

$$n_H = \frac{1}{1 + (\text{pp}_4/\text{pp}_{40})_{\text{true}}}. \tag{15}$$

At the start of each experimental run (and at the end of the longest full-day runs), we remeasured C_L and C_S with our 50-50 feedstock. These constants changed from day to day by up to 2%. However, we retained the nonlinear coefficient 0.1 in Eq. (14) for all experimental runs.

In laminar flow of an ideal gas, the mole flux through a circular capillary of diameter D from pressure p to zero pressure is obtained from[20]

$$-\frac{dp}{dx} = \frac{128\mu}{\pi D^4} U, \tag{16}$$

where $U = \dot{N} R_{\text{univ}} T/p$ is the volume flow rate and μ is the viscosity. Integrating Eq. (16) from $x=0$ at one end of the capillary to $x=\Delta x$ at the other shows that

$$\frac{[p(0)]^2 - [p(\Delta x)]^2}{2} = \mu \frac{128\Delta x}{\pi D^4} \dot{N} R_{\text{univ}} T \equiv \mu Z \dot{N} R_{\text{univ}} T, \tag{17}$$

where $Z = 128\Delta x/\pi D^4$ includes the geometrical parts of the flow impedance. At the high-pressure end of a microcapillary, the mean free path is only about 1% of the diameter, so the gas should flow as a viscous fluid. However, $p(\Delta x) = 0$ at the low-pressure end, and the assumption of laminar flow is questionable because the mean free path exceeds the capillary diameter. The crossover to the molecular-flow regime, where the mean free path is of the

order of the microcapillary diameter, occurs around p = 0.01 bar, approximately 5 μm from the low-pressure ends of the 5-cm long microcapillaries. Safely ignoring such a small fraction of the microcapillary length, Eq. (17) shows that $\dot{N} \propto [p(0)]^2$. This quadratic dependence was experimentally observed, using the argon partial pressure at the RGA as a proxy proportional to $\dot{N}$. (This proportionality depends on the assumptions that the volumetric pumping speed of argon through the turbopump is independent of argon partial pressure, justified by the pump's specifications, and that the RGA's sensitivity to argon is approximately independent of partial pressure.)

Fittings at the top, middle, and bottom of the separation tube allowed connection of capillaries for feedstock injection and product removal. Figure 1 shows one such capillary at each of those three locations; other arrangements are discussed below as they arise. Each of these stainless-steel capillaries was nominally 127 μm (0.005 in.) inside diameter and 15-cm long. To obtain an accurate value of the geometrical factor Z for each capillary, we used an auxiliary setup in which we timed the displacement of a liquid out of an inverted graduated cylinder while feedstock gas with n_H = 0.50, driven by a known pressure, flowed steadily through the capillary into the graduated cylinder. A mixture of 90% glycerin, 10% water, and a few drops of food coloring provided low vapor pressure, not-too-high viscosity, and easy viewing. Care was taken to avoid effects of surface tension and to account for the changing head of the liquid. Equation (17) and the time derivative of the ideal-gas law, $pU = \dot{N}R_{univ}T$, were used to obtain Z from the measured pressures and volume flow rates. Five measurements were made with each capillary, with flow rates ranging from 1 to 5 μmol/s. No single determination of Z differed from the average for that capillary by 1%. We believe that systematic errors totaled at most 2%. (The measurements showed that the inside diameters of the capillaries were only 5 to 6% larger than their nominal values.)

Later, during mixture-separation experiments, the mole fluxes into and out of the separation tube through these capillaries were controlled by needle valves[21] connected to the feedstock gas through a pressure regulator[22] and to a vacuum pump through an old, homemade rubber-membrane manostat.[23] The flow rates were determined via Eq. (17) by measurements of the pressures at the ends of the capillaries using the piezoresistive transducers shown in Fig. 1 and knowledge of Z obtained as described in the previous paragraph. We accounted for the n_H and T dependences of the gas viscosity. We neglected acoustic streaming's contribution to the pressure difference[24] across the capillaries $|p_1|^2/4p_m$ because it was only 0.04 to 1% of the pressure difference of Eq. (17) for all measurements.

Establishing a desired wave in the separation tube was an iterative procedure, carried out intermittently over a period of an hour or two as steady state was approached. We adopted a standard target of 3.00 kPa amplitude in the center of the tube, and a purely real acoustic impedance $z = Ap_1/U_1$ equal to $\rho_m a$ in the center of the tube to achieve a pure traveling wave there. We made a DELTAE model of the
FIG. 2. Results with no time-averaged total mole flux, plotted as a function of location x along the separation tube. Curves are calculations and points are experimental values. (a) Complex pressure. (b) Heavy mole fraction. (c) Specific acoustic impedance z compared with $\rho_m a$. Upper dashed curve is Re[z] and lower dashed curve is Im[z]. Solid curve near Re[z] is $\rho_m a$.

apparatus with these constraints and with the desired conditions of steady flow. The DELTAE model's complex p_1 at the two ends of the separation tube then served as goals to which experimental measurements could be compared, and adjustments to the complex voltages imposed on the two-driver assemblies were made to bring the experimental p_1's close to their goals. This might seem to be a complicated procedure, because two experimental voltage amplitudes and two experimental voltage phases were being adjusted to try to meet two experimental pressure amplitudes and two experimental pressure phases. However, the overall time phase of the oscillation is a meaningless variable, and the overall amplitude of the wave was reliably changed by any desired fractional amount when the amplitudes of both drive voltages were changed by that same fractional amount. Thus, it was necessary only to measure changes in p_1 at the ends of the separation tube in response to two small changes: A small change in phase difference between the two driver voltages, and a small fractional increase in driver voltage at one driver. The matrix of these measurements was inverted to allow a prediction of the complex drive voltages needed to achieve desired p_1's. Two iterations might have sufficed to bring the wave close to the goal, but $n_H(x)$ was also evolving during the course of these iterations, changing the density and sound speed along the separation tube, so three or four iterations were usually needed.

To illustrate how well this wave-tune-up procedure was typically accomplished and to establish confidence in the measurement techniques, Fig. 2 shows experimental and DELTAE results with no steady flow in the separation tube.

Figure 2(a) compares the experimental and calculated pressure waves, with the zero of phase arbitrarily chosen to be the phase of the calculated p_1 at the middle of the separation tube. The agreement between the calculated and measured complex pressures at the two ends is indicative of how well the tune-up procedure described in the previous paragraph was routinely carried out, and the agreement between the calculated p_1 and measured p_1 at the middle of the separation tube is then one indication of how accurately we are modeling the wave. Figure 2(b) compares experimental and calculated mole fractions, and is a second indication of how accurately we are modeling the wave and its mixture-separation effects. The differences between measurements and calculations in Fig. 2(b) are about 1%, comparable to the expectations outlined above and similar to what was described in Ref. 3. Figure 2(c) shows calculations of specific acoustic impedance $z=p_1A/U_1$ along the tube for this wave, showing how well this arrangement can maintain a purely traveling wave along its entire length, even while the acoustic power decreases from 0.19 W at $x=0$ to 0.08 W at $x=1$ m.

Imposing nonzero mole flux on the separation tube through the feedstock and product capillaries requires a small amount of additional, nonacoustic power to overcome the viscous impedances of the capillaries. In the present experiment, the ideal mechanical power required to isothermally compress the feedstock from 80 kPa to the feedstock pressure and to isothermally compress the products from the product-suction pressure to 80 kPa can be taken as a fair measure of the additional power required. As an example from the high end of the range of flows discussed below, this power totals only 10 mW for 4 μmol/s flowing in through one feedstock capillary and 2 μmol/s flowing out through each of two product capillaries.

To accurately measure $n_H(x)$ with this apparatus, we must be assured that the concentration gradient in each microcapillary is small enough that n_H at the RGA does not differ significantly from n_H in the separation tube where the microcapillary is attached. To perform continuous separations, we must similarly be certain that dn_H/dx in the feedstock capillaries and product capillaries can be neglected, or at least is understood quantitatively. We must also know that acoustic power dissipation in the capillaries is acceptably small. In Appendix B, we analyze these issues for $\dot{N}=0$, using the small-radius limits of the mixture-separation results in Appendix A and other equations of thermoacoustics. The results are summarized in Table I. Without superimposed steady flow, the expected end-to-end mole-fraction differences $|\Delta n_H|$ would be approximately 10^{-8} in the microcapillaries and 3×10^{-4} in the feedstock/product capillaries, both much smaller than the mole-fraction resolution of our apparatus. Table I also shows that the acoustic power dissipated in these capillaries is negligible compared with the ~ 100 mW consumed in the separation tube.

However, in most of the circumstances of interest in this paper, the steady flow in the capillaries overwhelms the oscillating flow, invalidating the analysis in Appendix B. At 1 μmol/s in a feedstock/product capillary, the steady flow equals the amplitude of the oscillating flow at the high-$|p_1|$
FIG. 3. Heavy mole fraction n_H as a function of location x, for feedstock injected at $x=0.5$ m and products removed at $x=0$ and $x=1$ m. Points are experimental values and associated curves are calculations. (a) Product mole fluxes equal. Circles, $\dot{N}_{\text{feedstock}}=3.96$ μmol/s. Squares, 0.99 μmol/s. Triangles, 0.26 μmol/s. (b) Product mole flux at $x=0$ is 25% of product mole flux at $x=1$ m. Circles, $\dot{N}_{\text{feedstock}}=3.63$ μmol/s. Squares, 1.59 μmol/s.

end of the capillary, and the capillary is swept clean by the steady flow in only ten acoustic cycles. In the microcapillaries, the steady flow is about twice the amplitude of the oscillating flow at the high-$|p_1|$ end. Thus, the analysis in Appendix B is probably only valid for flows below about 0.1 μmol/s in the feedstock/product capillaries. Nevertheless, it is hard to imagine how fast steady flows could *increase* the ability of the thermoacoustic phenomena to create a concentration gradient—in the next section, we see that modest steady flows always decrease the gradient. Two microcapillaries (not shown in Fig. 1) leading to the RGA from the left ends of the two product capillaries shown in Fig. 1 were used to verify that the product streams indeed carried the same mole fractions as were observed in the separation tube at the product-capillary entrances.

III. DISCUSSION OF THERMOACOUSTIC RESULTS

Figures 3–5 show the heavy mole fraction in the separation tube under a variety of conditions of nonzero total mole flux of feedstock and product(s). In all cases, calculations and measurements are in good agreement, confirming the presence of the $n_H\dot{N}$ term in Eq. (7) and our understanding of the boundary condition on n_H discussed near Eq. (11). It should be noted that there are no adjustable parameters in the calculations producing the curves in these figures. The calculations integrate Eq. (7), simultaneously with Eqs. (2) and (5), with respect to x, using the experimental values of $p_1(0)$, $p_1(x=1$ m), frequency, mean pressure, $n_{H,\text{feedstock}}$, and $\dot{N}$ in each feedstock and product capillary, and with the boundary condition Eq. (11) imposed on n_H wherever product flows out of the separation tube.

Figure 3 shows n_H versus x for feedstock injection at $x=0.5$ m. In Fig. 3(a), where half of the feedstock is removed at each end of the separation tube, the effect of simply in-
FIG. 4. Heavy mole fraction n_H as a function of location x, for feedstock injected at one end and products removed at one or both ends. Points are experimental values and associated curves are calculations. Circles, 1.13 μmol/s injected at $x=1$ m and removed at $x=0$. Squares, 0.21 μmol/s injected at $x=1$ m and removed at $x=0$. Triangles, 3.36 μmol/s injected at $x=1$ m, 2.88 μmol/s removed at $x=1$ m, and 0.43 μmol/s removed at $x=0$.

creasing $\dot{N}$ in Eq. (7) is apparent: A reduction in the slope $|dn_H/dx|$ and an increase in the curvature of $n_H(x)$ as $\dot{N}$ is increased. These effects are analogous to the slope changes and curvature seen in $T_m(x)$ in thermoacoustic refrigeration by Reid et al.;[25] Reid and Swift,[26] and Reid[27] because $n_H \dot{N}$ and the terms with dn_H/dx in Eq. (7) here are mathematically identical in form to $\dot{m}c_p T_m$ and terms with dT_m/dx in the energy equation in the work of Reid, Swift, and coworkers. To the extent that the implicit n_H and x dependencies of all variables in Eq. (7) could be neglected, that equation would be of the form

$$\dot{N}_H = \alpha + \dot{N}n_H + \beta \frac{dn_H}{dx}, \qquad (18)$$

where α and β can be regarded as constants, so $n_H(x)$ would have an exponential curvature.

Figure 3(b) is less symmetrical than Fig. 3(a) because 20% of the feedstock mole flux is removed at $x=0$ and 80% at $x=1$ m in Fig. 3(b). The slopes are shallower and the curvatures greater on the right half of the figure than on the left half because $\dot{N}$ is greater on the right half, as discussed in the previous paragraph. The heavy mole fraction at $x=0.5$ m is different from $n_{H,\text{feedstock}}=0.50$, with the difference growing as the feedstock mole flux decreases and exerts weaker local influence on $n_H(x)$.

Figure 4 illustrates most clearly the sometimes counter-intuitive nature of the boundary condition for n_H expressed in Eq. (11). For the circles and squares, feedstock with $n_{H,\text{feedstock}}=0.50$ is injected at $x=1$ m and all of the product is removed at $x=0$. One might at first guess that n_H would be close to 0.50 at the feedstock end of the separation tube, but instead n_H is tied firmly to 0.50 at the *product* end of the separation tube. One way to interpret this result is to realize that, in steady state with only one feedstock capillary and one product capillary, what flows out of the product capillary must be exactly what flows in through the feedstock capillary, which has $n_{H,\text{feedstock}}=0.50$. In the context of Eqs. (9) and (10) there is only one term on the right and one on the left, so $n_{H,\text{product}}=n_{H,\text{feedstock}}$. In the context of Eq. (11), the product total mole flux and heavy mole flux must equal their values for the feedstock, so the product's n_H must also equal its value in the feedstock.

For the operating point of Fig. 3(b), in which 20% of $\dot{N}_{\text{feedstock}}$ flows out at $x=0$ and 80% at $x=1$ m, the corresponding global steady-state condition based on Eq. (10) shows that

$$0.20n_H(0) + 0.80n_H(1.0 \text{ m}) = n_{H,\text{feedstock}} = 0.50, \qquad (19)$$

which is indeed the case in Fig. 3(b). The triangles in Fig. 4 also illustrate Eq. (19) for one feedstock and two-product capillaries, though with different numerical values. In contrast to Fig. 3(b), in which the feedstock enters at the center of the separation tube and the two products are removed at the ends, the triangles in Fig. 4 represent a case in which the feedstock enters at one end and the two products are removed at the two ends.

Figure 5 shows how n_H in the two product streams at the ends of the separation tube varies with flow rate, when the feedstock is injected at the middle of the separation tube. Purities decrease with increasing flow rates, and the purity of one product can be enhanced by reducing the fraction of the feedstock that flows into it. For this separation tube running with a 3-kPa traveling wave, product flow rates of the order of 1 to 10 μmol/s cause a significant decrease in purities.

IV. CONCLUSIONS

Measurements confirm that the addition of the simple term $n_H \dot{N}$ to the thermoacoustic mixture-separation equation for the heavy mole flux $\dot{N}_H$ accounts for a nonzero total mole flux $\dot{N}$. The influence of $\dot{N}$ on $n_H(x)$ is similar to that of steady flow on $T_m(x)$ in the stack of a standing-wave refrigerator: As $\dot{N}$ is increased, the magnitude of the slope $|dn_H/dx|$ is reduced and $n_H(x)$ acquires significant curvature. Measurements also show that a boundary condition constraining the solution $n_H(x)$ is imposed wherever steady flow leaves the separation tube and enters a small-diameter capillary with negligible thermoacoustic characteristics of its

FIG. 5. Heavy mole fraction n_H at $x=0$ (points and curves above $n_H=0.5$) and at $x=1$ m (points and curves below $n_H=0.5$) as a function of product mole flux at $x=0$. Feedstock is injected at $x=0.5$ m and removed at $x=0$ and $x=1$ m. Points are experimental values and associated curves are calculations. Circles, feedstock flow equal to twice the $x=0$ product flow. Squares, feedstock flow equal to five times the $x=0$ product flow.

own. Flow out through such a capillary carries whatever mole fraction is present in the separation tube where the capillary is attached. No such boundary condition is imposed by feedstock entering the separation tube through such a capillary.

Capillaries suitable for practical continuous thermoacoustic mixture separation have been demonstrated. Such capillaries are small enough in diameter that they do not develop significant internal concentration gradients, nor do they consume significant acoustic power. Nevertheless they are large enough to carry significant steady flow without prohibitively large steady pressure drops.

ACKNOWLEDGMENTS

APPENDIX A: THERMOACOUSTIC MIXTURE SEPARATION IN CIRCULAR TUBES

The time-averaged mole flux of the heavy component when $dT_m/dx = 0$ is given by Eq. (7), where the three functions F_{trav}, F_{stand}, and F_{grad} depend on the properties of the gas and the radius of the tube. Analytical expressions for the three F's in the boundary-layer limit have been published previously.[1,3] Here we derive such expressions for circular tubes of arbitrarily small radius, starting from Eq. (5) and from Eqs. (47) and (48) of Ref. 3.

Unfortunately, Eq. (48) of Ref. 3 has a minus-sign typographical error; the correct expression is

$$
\dot{N}_{H,2} = \frac{1}{2}\frac{\gamma-1}{\gamma}\frac{k_T/\varepsilon}{R_{\text{univ}}T_m}\Re\left\{\frac{p_1\widetilde{U}_1}{1-\widetilde{f}_\nu}\left[C\left(\frac{\delta_\kappa^2}{\delta_{\kappa D}^2}-1\right)\langle h_{\kappa D}(1\right.\right.
$$
$$
\left.-\widetilde{h}_\nu)\rangle + (1-B-C)\left(\frac{\delta_\kappa^2}{\delta_{D\kappa}^2}-1\right)\langle h_{D\kappa}(1-\widetilde{h}_\nu)\rangle
$$
$$
\left.\left.-B\frac{\sigma-1}{\sigma}\langle h_\nu(1-\widetilde{h}_\nu)\rangle\right]\right\},
\tag{A1}
$$

where the last line here has the sign error fixed. B and C are given in Eqs. (33) and (34) of Ref. 3. Note that B is proportional to the concentration gradient and that C contains one term proportional to B and one term independent of the gradient. The $\langle\;\rangle$ denotes the average over the cross-sectional area, σ is the Prandtl number, the tilde denotes complex conjugation, and

$$
h_j = \frac{J_0[(i-1)r/\delta_j]}{J_0[(i-1)R/\delta_j]},
\tag{A2}
$$

$$
f_j = \frac{2J_1[(i-1)R/\delta_j]}{[(i-1)R/\delta_j]J_0[(i-1)R/\delta_j]},
\tag{A3}
$$

where J_0 and J_1 are the zeroth- and first-order Bessel functions, and j is ν, κD, or $D\kappa$. The coefficient ε and the penetration depths $\delta_{\kappa D}$ and $\delta_{D\kappa}$ are also defined in Ref. 3.

To evaluate averages of the form $\langle h_i(1-\widetilde{h}_j)\rangle$, one can use identity (11.3.20) from Ref. 28

$$
\int_0^z t^\nu J_{\nu-1}(t)dt = z^\nu J_\nu(z) \quad \text{for } \mathrm{Re}[\nu] > 0
\tag{A4}
$$

to verify that

$$
\langle h_j\rangle = f_j.
\tag{A5}
$$

Then one can use Ref. 28's Eqs. (9.1.40)

$$
\widetilde{J_\nu}(z) = J_\nu(\bar{z})
\tag{A6}
$$

and (11.3.29)

$$
\int^z\left\{(k^2-l^2)t-\frac{(\mu^2-\nu^2)}{t}\right\}\mathcal{C}_\mu(kt)\mathcal{D}_\nu(lt)dt
$$
$$
= z\{k\mathcal{C}_{\mu+1}(kz)\mathcal{D}_\nu(lz)-l\mathcal{C}_\mu(kz)\mathcal{D}_{\nu+1}(lz)\}-(\mu
$$
$$
-\nu)\mathcal{C}_\mu(kz)\mathcal{D}_\nu(lz),
\tag{A7}
$$

where $\mathcal{C}$ and $\mathcal{D}$ are any two Bessel functions, to compute

$$
\langle h_i\widetilde{h}_j\rangle = \frac{\delta_j^2}{\delta_i^2+\delta_j^2}f_i + \frac{\delta_i^2}{\delta_i^2+\delta_j^2}\widetilde{f}_j.
\tag{A8}
$$

Combining Eqs. (A5) and (A8) yields the result needed in Eq. (A1)

$$
\langle h_i(1-\widetilde{h}_j)\rangle = \frac{\delta_i^2}{\delta_i^2+\delta_j^2}(f_i-\widetilde{f}_j),
\tag{A9}
$$

and identification of expressions for the F's in Eq. (A1) is straightforward. The results are

$$
F_{\text{trav}} = -\frac{R}{\delta_\kappa}\,\mathrm{Re}\left[\frac{G}{(1-\widetilde{f}_\nu)}\right],
\tag{A10}
$$

$$
F_{\text{stand}} = \frac{R}{\delta_\kappa}\,\mathrm{Im}\left[\frac{G}{(1-\widetilde{f}_\nu)}\right],
\tag{A11}
$$

$$
F_{\text{grad}} = -\frac{R}{\delta_\kappa}\frac{1}{|1-f_\nu|^2}\frac{\sigma}{(1-\sigma)(1-\sigma L)-\varepsilon\sigma}
$$
$$
\times\mathrm{Im}\left[\frac{(\sigma-1)}{\sigma S}f_\nu\left(\frac{\delta_\kappa^2-\delta_{\kappa D}^2}{\delta_\nu^2+\delta_{\kappa D}^2}f_{\kappa D}-\frac{\delta_\kappa^2-\delta_{D\kappa}^2}{\delta_\nu^2+\delta_{D\kappa}^2}f_{D\kappa}\right.\right.
$$
$$
\left.\left.+\frac{(1+\sigma)LQ}{M}\widetilde{f}_\nu+S\right)+\varepsilon G\right],
\tag{A12}
$$

where R is the circle radius, $L = k/\rho_m c_p D_{12}$, and

$$
S = \left(\frac{\delta_\kappa^2}{\delta_{D\kappa}^2}-1\right)f_{D\kappa}-\left(\frac{\delta_\kappa^2}{\delta_{\kappa D}^2}-1\right)f_{\kappa D},
\tag{A13}
$$

$$
Q = \frac{\delta_{\kappa D}^2-\delta_{D\kappa}^2}{\delta_\kappa^2},
\tag{A14}
$$

$$
M = (1+\sigma)(1+\sigma L)+\varepsilon\sigma,
\tag{A15}
$$

$$G = \frac{\sigma L Q}{MS} f_{\kappa D} f_{D\kappa} + \frac{\tilde{f}_\nu}{S}\left(\frac{f_{\kappa D}}{1 + \delta_\nu^2/\delta_{D\kappa}^2} - \frac{f_{D\kappa}}{1 + \delta_\nu^2/\delta_{\kappa D}^2}\right). \quad \text{(A16)}$$

APPENDIX B: THERMOACOUSTICS IN CAPILLARIES

Ignoring the effects of steady flow, the wall-damped Helmholtz equation for pure gases is[10]

$$[1 + (\gamma - 1)f_\kappa]p_1 + \frac{a^2}{\omega^2}(1 - f_\nu)\frac{d^2p_1}{dx^2} = 0, \quad \text{(B1)}$$

with the viscous-dissipation function f_ν and the thermal-dissipation function f_κ in a circular tube of radius R given by

$$f_j = \frac{2J_1[(i-1)R/\delta_j]}{[(i-1)R/\delta_j]J_0[(i-1)R/\delta_j]}, \quad \text{(B2)}$$

where J_n is the nth-order Bessel function, $\delta_\nu = \sqrt{2\mu/\omega\rho_m}$ is the viscous penetration depth, and $\delta_\kappa = \sqrt{2k/\omega\rho_m c_p}$ is the thermal penetration depth, and j is either ν or κ. For small R, Eq. (B2) becomes

$$f_j \simeq 1 - \frac{i}{4}\frac{R^2}{\delta_j^2} - \frac{1}{12}\frac{R^4}{\delta_j^4} + O(R^6). \quad \text{(B3)}$$

Substitution of Eq. (B3) into Eq. (B1) yields, to lowest order in R, the Helmholz equation for a small circular tube

$$\left(1 - \frac{i}{4}\frac{\gamma-1}{\gamma}\frac{R^2}{\delta_\kappa^2}\right)p_1 + \frac{i}{4}\frac{R^2}{\delta_\nu^2}\frac{a^2}{\gamma\omega^2}\frac{d^2p_1}{dx^2} = 0. \quad \text{(B4)}$$

The solution $p_1(x)$ to Eq. (B4) is the sum of positive and negative complex exponentials of x. To conveniently satisfy boundary conditions at the ends of the capillary, the solution can be written in either of two forms

$$p_1 = p_{1,0}e^{-\alpha x}, \quad \text{infinite length}, \quad \text{(B5)}$$

$$p_1 = p_{1,0}\frac{\sinh \alpha(\Delta x - x)}{\sinh \alpha\Delta x}, \quad \text{finite length}, \quad \text{(B6)}$$

for capillaries driven at $x=0$ with a complex pressure amplitude $p_{1,0}$. The first form is for a capillary extending from $x=0$ to infinity, and the second form is for a capillary of length Δx with $p_1=0$ at $x=\Delta x$. Substitution of either form into Eq. (B4) and use of the general identity $a=\lambda f$ relating the sound speed a, the wavelength λ, and the frequency f shows that

$$\alpha^{-1} = \frac{1-i}{\sqrt{2}}\frac{1}{4\pi\sqrt{\gamma}}\frac{R}{\delta_\nu}\lambda \quad \text{(B7)}$$

to lowest order in R. The volume flow rate U_1 is obtained from Eqs. (B5)–(B7) via Eq. (2) taken to the small-R limit

$$U_1(x) = \frac{i\pi R^2(1-f_\nu)}{\omega\rho_m}\frac{dp_1}{dx} \quad \text{(B8)}$$

$$\simeq -\frac{\pi R^4}{8\mu}\frac{dp_1}{dx}, \quad \text{(B9)}$$

which yields the expected Poiseuille fourth-power dependence on radius.[20]

For a gas mixture, f_κ in Eq. (B1) should be replaced by a linear combination of $f_{\kappa D}$ and $f_{D\kappa}$, which are defined in Ref. 3. However, the absence of δ_κ from Eqs. (B5)–(B7) shows that this detail is irrelevant for the determination of α in the present problem.

Table I displays some numerical values for the gas, the microcapillaries, the feedstock/product capillaries, and the separation tube. In the microcapillaries, $|e^{-\alpha\Delta x}| = 2\times 10^{-6}$, so Eq. (B5) is appropriate. The feedstock/product capillaries have $|e^{-\alpha\Delta x}| = 0.06$, so Eq. (B6) would be required for high accuracy, but for simplicity it is not used here.

To estimate the end-to-end concentration difference that develops in a capillary, we begin by considering Eq. (7). The two terms with dn_H/dx typically subtract from the $|p_1||U_1|$ term and are smaller than it. Thus, $\dot{N}_H - n_H\dot{N}$ will never be much larger than the $|p_1||U_1|$ term, and $\dot{N}_H - n_H\dot{N}$ can be neglected when estimating the order of magnitude of dn_H/dx in the capillary. In small enough tubes or at low enough amplitudes, the third term in Eq. (7) can be neglected in comparison to the fourth term, because their ratio

$$\frac{\text{third term}}{\text{fourth term}} = \frac{1}{16\pi}\frac{L}{\gamma\sigma}\frac{R\lambda^2}{\delta_\kappa^3}F_{\text{grad}}\frac{|p_{1,0}|^2}{p_m^2}e^{-2\,\text{Re}[\alpha]x} \quad \text{(B10)}$$

is proportional to $R^4|p_{1,0}|^2$. (Note that F_{grad} is proportional to R^3 for small R.) To obtain Eq. (B10) and subsequent results in this section, it is necessary to use Eqs. (B9), (B7), and (B5), the definitions $\sigma = \delta_\nu^2/\delta_\kappa^2$ and $L = \delta_\kappa^2/\delta_D^2$ given in Ref. 3, and the ideal-gas identities $a^2 = \gamma R_{\text{univ}}T_m/m_{\text{avg}}$ and $p_m = \rho_m R_{\text{univ}}T_m/m_{\text{avg}}$. Based on the numerical values in Table I for Eq. (B10), we neglect the third term in Eq. (7).

With these approximations, Eq. (7) becomes

$$0 \simeq \frac{\delta_\kappa}{2R}\frac{\gamma-1}{\gamma}\frac{k_T}{R_{\text{univ}}T_m}(F_{\text{trav}}\cos\theta + F_{\text{stand}}\sin\theta)|p_1||U_1|$$

$$- N\pi R^2 D_{12}\frac{dn_H}{dx} \quad \text{(B11)}$$

in a capillary. Solving this equation for dn_H/dx and integrating along the length of the capillary, using Eqs. (B5)–(B7) as necessary, with $\theta = 3\pi/4$ from Eqs. (B5) and (B9), and using the small-R limits of F_{trav} and F_{stand}

$$F_{\text{trav}} \propto R^5, \quad \text{(B12)}$$

$$F_{\text{stand}} \simeq \frac{1}{12}\frac{R^3}{\delta_\kappa^3}, \quad \text{(B13)}$$

yields finally

$$\Delta n_H \simeq \frac{1}{384\pi^2}\frac{(\gamma-1)L}{\gamma^2\sigma}k_T\frac{\lambda^2R^4}{\delta_\kappa^6}\frac{|p_{1,0}|^2}{p_m^2} \quad \text{(B14)}$$

for infinite length. Numerical values are given in Table I.

The acoustic power consumed by each capillary can be calculated with

$$\dot{E}_2(0) = \frac{1}{2}\text{Re}[p_1(0)\tilde{U}_1(0)]. \quad \text{(B15)}$$

Substituting Eq. (B9) into Eq. (B15) yields

G. W. Swift and D. A. Geller: Continuous thermoacoustic mixture separation

$$\dot{E}_2 = \sqrt{\frac{\gamma}{32}} \frac{|p_{1,0}|^2}{\rho_m a} \pi R^2 \frac{R}{\delta_\nu} \tag{B16}$$

for infinite length. Numerical values are given in Table I.

Properties of an electrostatic transducer

A. P. Medley,[a] D. R. Billson, D. A. Hutchins, and L. A. J. Davis
School of Engineering, University of Warwick, Coventry, CV4 7AL United Kingdom

A thin and flexible transducer design for use in air is described. It is fabricated from three or more layers of material to form an electrostatic device with many interesting properties. The new acoustic source has an excellent high-frequency response and can be used as an acoustic radiator over a wide range of frequencies, in both the audible and ultrasonic frequency ranges. The frequency response and directivity are both modeled and compared to theory, where it is demonstrated that the device operates in a manner consistent with a plane piston source. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2357702]

I. INTRODUCTION

This paper introduces an electrostatic loudspeaker that is both extremely thin and highly flexible. The device can operate in both the audible and ultrasonic frequency ranges. As a consequence, this new design has many interesting and varied potential applications. For example, the transducer can be produced in the form of a large area planar device, which can be mounted directly onto a wall to provide sound reproduction in a home environment without requiring a bulky enclosure. Furthermore, such a device would be particularly suitable for use in applications where space is at a premium, or where an unconventional or adjustable curvature is required.

The moving coil loudspeaker has existed for many decades and is still by the far the most common method for sound transduction. Although a number of different technologies have been developed, the electrostatic principle has been used in several designs of high performance loudspeakers. Wente[1] in 1917 was the first to describe a device using electrostatic principles. This transducer, which was called a condenser transmitter and was originally used as a microphone for measuring absolute sound intensity, utilized a thin stretched steel membrane, separated from a conducting backplate by a 25-μm-thick air gap. Through experimentation it was shown that such a device had a reasonably uniform sensitivity at frequencies of up to 10 kHz, and an undamped resonant frequency of approximately 17 kHz. Further development of electrostatic loudspeakers was hampered by a lack of suitable materials for the vibrating membrane. Early patents show that gelatin, silk, rubber, and other materials were considered,[2] but the development of thin polymer membranes such as Mylar made the modern designs possible. The lack of bass response from electrostatic speakers means that they are often incorporated into hybrid systems, whereby a standard moving-coil speaker is used for low frequencies.[3] Other developments include the use of multiple electrodes on the moving diaphragms or membranes, so that the proportion of radiating area used can be split into different frequency bands via a crossover network.[4,5]

In recent years there has been increased interest in the use of electrostatic devices for acoustic generation at ultrasonic frequencies. This is because the efficiency of conventional piezoelectric transducers is affected by the large impedance mismatch between the piezoelectric element and air. This can be improved by several methods, such as attaching a metal membrane to the element to act as a vibrating membrane,[6] by using impedance matching layers,[7] or by using piezocomposites to lower the acoustic impedance of the active material.[8] An alternative approach to that of a piezoelectric device is to use a capacitive design. For example, Kuhl *et al.*[9] produced transducers capable of operating in the 50–100-kHz range, and this was the basis upon which all modern capacitive transducers are designed. They basically rely on the use of a flexible electroded membrane, separated by an air gap from a conducting rigid backplate. The response of the device is dominated by the interaction between the membrane and the trapped air, and various models have been proposed to optimize this.[10,11]

It is the aim of this paper to describe a new type of device, which differs from the two basic designs above in that it is comprised of multiple layers, which are all thin and flexible. This paper begins with a description of the basic structure of the transducer, which is then modeled both numerically and analytically so as to predict the frequency response of the device in terms of the layered construction. This is then followed by a series of experimental measurements, using a testing arrangement in which the properties of the speaker can be easily altered. This enabled the results of experimental device responses and modeling to be compared, so as to enable the operation of the device to be fully understood. Finally, the pressure fields radiated from the acoustic transducer have been obtained experimentally over a range of frequencies, and the results compared to a theory, allowing a greater understanding of the behavior of the transducer to be developed.

II. THEORETICAL ANALYSIS

The new acoustic transducer consists of three layers of thin, flexible material, which are sandwiched together to form the device. This is shown schematically in Fig. 1, where it can be seen that a typical device has an insulating

TABLE I. Material properties of the three media relevant to the initial designs shown in Fig. 2.

Layer	Density ρ_i (kg/m³)	Wave velocity (m/s)	
		Longitudinal v_{li}	Shear v_{si}
Aluminum	2700	6250	3080
Air	1.2	343.3	⋯
Paper	780	400	200
layer between two electrically conducting layers. As with conventional electrostatic devices, a dc bias voltage is applied between the front and rear electrodes, attracting the flexible layers to each other. The electrodes can be thin metallic layers (e.g., aluminum), or metallized polymer films (e.g., Mylar). Because the individual layers are so close together, the application of a modest ac voltage signal creates a large electric field, which is highly efficient at moving the foils in the thickness direction, generating sound. However, the device will change characteristics depending on the materials used for each layer in terms of density and thickness, and the thickness of any air gaps between them.

There are many examples of multilayered structures that have been analyzed in terms of their acoustic response, included adhesively bonded joints.[12–14] Theoretical models can be used to predict the response of materials, and to search for defects by looking at the effects these have on the vibrational response.[14] One such method is the matrix transfer approach, as detailed by Brekhovskikh[15] and used by Bresse et al.[16] This method calculates the transmission coefficient as a function of frequency when the structure is excited by an infinite sinusoidal plane wave in air at an arbitrary angle to the structure's surface. All waves in the structure will have a common propagation factor. Therefore, by using the boundary conditions that exist between each layer, a propagation matrix can be established such that the coefficients of reflection and transmission of the top layer can be related to those of the bottom layer of the structure. Thus, a description of the response of the device can be obtained. The original algorithm was originally designed for liquid-coupled and contacting experiments. However, it is sufficiently general to allow air to be defined as the coupling medium and for any number of layers to be modeled. While this through-transmission model does not describe the loudspeaker as a source, it is a useful method for predicting the expected frequency response of such a device in air. The model assumes normal incidence of plane waves, whereas the experimental electrostatic forces would give a uniform excitation of the membranes; however, the mechanical response would be expected to be similar in both cases in terms of the frequency response.

Consider the typical structure shown in Fig. 1, constructed with two aluminum foil outer layers, an inner paper layer, and a 1-mm air gap between each. Table I gives details of the properties of each layer used in the calculation. Figure 2 illustrates the three structures modeled initially, and the corresponding predictions of the transmission frequency response are presented in Fig. 3.

It can be seen that the transmission coefficient approaches unity at low frequencies. This is because the structure is thin compared to the acoustic wavelength. As the frequency increases, the transmission coefficient decreases rapidly towards zero, since the acoustic impedance of the structure becomes much larger than that of the surrounding air. The transmission coefficient then exhibits a series of maxima, corresponding to through-thickness resonances of the layers, which make up the overall structure. These can clearly be seen in Fig. 3(a), in which two resonances occur, the first at 10 kHz and the second at 14.4 kHz. In Fig. 3(c) it can be seen that two resonances are closer together and have tended to merge to become a wider peak in the predicted response.

It is informative to also analyze the structure in terms of a simple mathematical model, as this allows us to examine the likely behavior and motion of the layers within the device. Using the assumption the membranes can be considered to move as a simple frictionless piston resonator, the speaker can be modeled as a simple mass spring system. The air located between the solid layers is compressible and of very low mass. It can thus be considered to behave like a massless spring when compared to the membranes (see Fig. 4).

The equation of motion for the system can be expressed as

$$m_1 \ddot{x}_1 + k_1 x_1 - k_1 x_2 = 0,$$
FIG. 2. Schematic diagram of three typical structures. All devices are constructed from two outer layers of aluminum and an inner layer of paper, separated by 1-mm-thick air gaps. (a) 14 μm aluminum and 90 μm paper; (b) as in (a) but with thicker aluminum (28 μm); (c) as in (a) but with thicker paper (180 μm). The properties of each layer are defined in Table I.

(a)

(b)

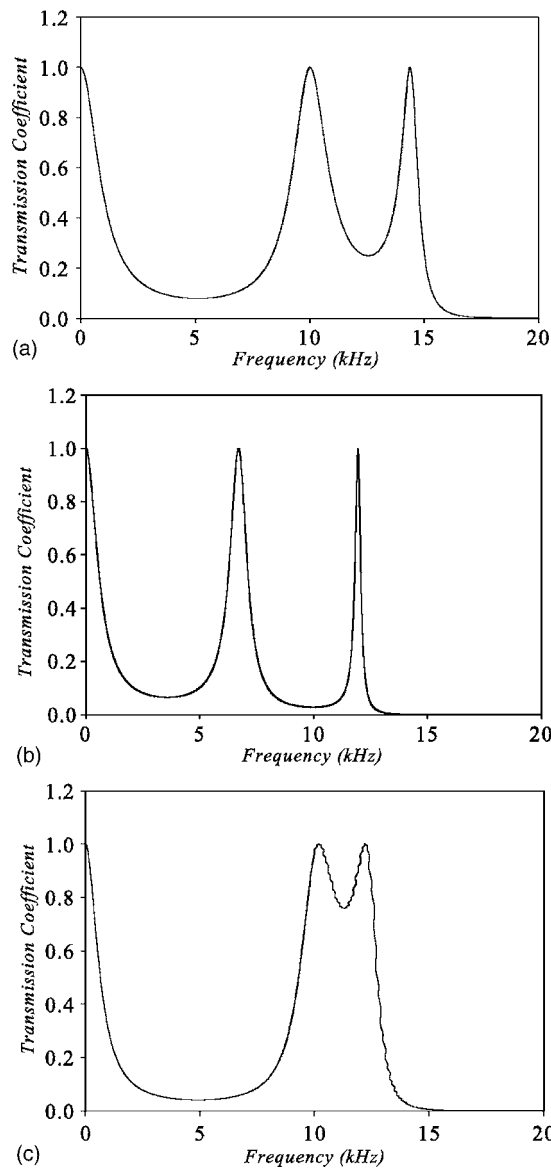
(c)


FIG. 3. (a)–(c) Calculated values of transmission coefficient as a function of frequency for the corresponding multilayered structures shown in Fig. 2 and with the properties of Table I.

$$m_2\ddot{x}_2 - k_1 x_1 + (k_1 + k_2)x_2 - k_2 x_3 = 0,$$

$$m_3\ddot{x}_3 - k_2 x_2 + k_2 x_3 = 0, \qquad (1)$$

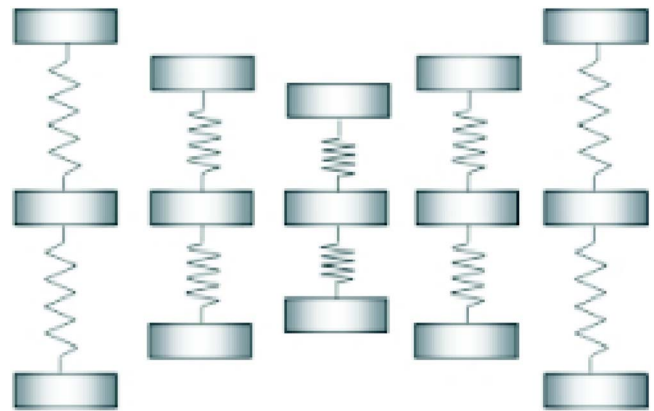
where m_1, m_2, and m_3 are the upper electrode, insulator, and lower electrode membrane masses, respectively, k_1 and k_2 are the spring constants, and x_1, x_2, and x_3 are the displacement of the masses. It should be noted that for simplicity neither
FIG. 4. Modeling assumption for the multilayered acoustic transducer.


FIG. 5. Mode shape for $\lambda = k/m_1$.

the electrostatic force nor negative stiffness caused by the application of a bias voltage has been included. Assuming that the spring constant is the same for both springs, and that the two outer masses are the same, these equations can be rewritten in matrix form as

$$\begin{bmatrix} m_1 & 0 & 0 \\ 0 & m_2 & 0 \\ 0 & 0 & m_1 \end{bmatrix}\begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \\ \ddot{x}_3 \end{Bmatrix} + \begin{bmatrix} k & -k & 0 \\ -k & 2k & -k \\ 0 & -k & k \end{bmatrix}\begin{Bmatrix} x_1 \\ x_2 \\ x_3 \end{Bmatrix} = 0. \qquad (2)$$

Solving this matrix equation enables the eigenvalues of the system to be evaluated:

$$\lambda = 0,$$

$$\lambda = k/m_1,$$

$$\lambda = (2m_1 k + m_2 k)/(m_1 m_2). \qquad (3)$$

The null value eigenvalue corresponds to a rigid body translation, which would not be observed upon application of an ac voltage, thus the actual number of resonant modes is one less than the number of degrees of freedom for the system. Therefore the corresponding eigenvectors of the system are

$$\{-1 \ 0 \ 1\},$$

$$\{1 \ -2m_1/m_2 \ 1\}. \qquad (4)$$

These show that for $\lambda = k/m_1$, as shown in Fig. 5, the two outer masses move in anti-phase, while the central mass remains fixed. For $\lambda = (2m_1 k + m_2 k)/(m_1 m_2)$, as shown in Fig. 6, the two outer masses move in phase with one another and with equal amplitude, such that the distance separating them does not change, while the central mass moves in anti-phase to the movement of both the upper and lower masses with double the amplitude, such that linear momentum is conserved.

The resonant frequencies, f_n, of a simple mass spring system are well known, and for the two cases are given by

$$f_1 = 1/2\pi\sqrt{k/m_1} \quad \text{and} \quad f_2 = 1/2\pi\sqrt{2k/m_2 + k/m_1}. \qquad (5)$$

Therefore, in order to find the resonant frequencies of the system, it is necessary to evaluate the two ratios k/m_1 and k/m_2. Within this model, the spring actually represents the
FIG. 6. Mode shape for $\lambda=(2m_1k+m_2k)/(m_1m_2)$; a fixed distance is maintained between the two outer masses.

air trapped between the layers. Assuming adiabatic compression results in the following expression for the stiffness, k_a, of the air spring:

$$k_a = \gamma PA/d_a, \tag{6}$$

where γ is the adiabatic constant, P is the pressure of the gas between the layers, A is the membrane area, and d_a is the thickness of the air gap between the layers of the structure when the system is at rest. Substituting this equation into Eq. (6) and letting $m_1=\rho_m d_m A$ gives

$$f = 1/2\pi\sqrt{\gamma P/d_a d_m \rho_m} \tag{7}$$

where ρ_m is the density of the membrane and d_m is the thickness of the conducting membrane. The equation above dictates that the resonant frequency increases with P, but decreases if d_a, d_m, or ρ_m increases. Note that the use of a one-dimensional model dictates that the result is independent of surface area (A).

The model so far neglects any mechanical properties of the vibrating membrane that can be assumed to influence the behavior of the system. This, however, can be rectified by considering the frequency response of a flat plate, the formulas for which are known.[17] As the membranes are not placed under significant tension (a factor that can affect platelike behavior in suspended systems), the tension can be ignored. Hence, the resonant frequency of a flat plate whose edges are fixed is given as

$$f = (K/2\pi)\sqrt{Dg/ma^4}, \tag{8}$$

where K is a ratio that is dependent upon the length of the plate edges (for a square plate $K=36$), m is the mass of the membrane, a is the length of a side, and g is the acceleration due to gravity. D is the flexural rigidity per unit length and can be equated to

$$D = Et^3/12(1-\nu^2) \tag{9}$$

where E is the modulus of elasticity, t is the thickness of the membrane, and ν is Poisson's ratio. By substituting $f=1/2\pi\sqrt{k/m}$ into $f=K/2\pi\sqrt{Dg/ma^4}$ the spring constant of the plate model can be evaluated as being equal to

$$k_p = K^2Dg/a^4. \tag{10}$$

In order to substitute this into the developed resonant frequency expression the basic model must be adapted to include a second "plate" spring to account for the mechanical properties of the device. Taking into account the added spring, the equations for the resonant frequency of the system become

$$f_1 = 1/2\pi\sqrt{(k_p+k_a)/m_1},$$

$$f_2 = 1/2\pi\sqrt{(2(k_p+k_a)/m_2) + ((k_p+k_a)/m_1)}. \tag{11}$$

Compliance is a measure of how easily an assembly will move when an electrical signal is applied to it. Mathematically it is the inverse of stiffness and can be calculated by

$$C = 1/k. \tag{12}$$

Therefore, substituting the values for C and setting $m_1 = \rho_{m_1}d_{m_1}A$ and $m_2=\rho_{m_2}d_{m_2}A$, where A is the area of the transducer, the resonant frequency equations of the system become

$$f_1 = \frac{1}{2\pi}\left[\frac{\gamma P}{d_a\rho_{m_1}d_{m_1}} + \frac{K^2Dg}{\rho_{m_1}d_{m_1}Aa^4}\right]^{\frac{1}{2}},$$

$$f_2 = \frac{1}{2\pi}\left[\left(\frac{2\gamma P}{d_a\rho_{m_2}d_{m_2}} + \frac{2K^2Dg}{\rho_{m_2}d_{m_2}Aa^4}\right) + \left(\frac{\gamma P}{d_a\rho_{m_1}d_{m_1}} + \frac{K^2Dg}{\rho_{m_1}d_{m_1}Aa^4}\right)\right]^{\frac{1}{2}}, \tag{13}$$

where the double subscript notation indicates which mass of the system the variable is attributed to. It would be more use if the equation could be related to the speed of sound in a gas, using

$$c^2 = \gamma RT \quad \text{and} \quad P = \rho_a RT. \tag{14}$$

Substituting these equations into the resonant frequency equation and cancelling by RT gives

$$f_1 = \frac{1}{2\pi}\left[\frac{c^2\rho_a}{d_a\rho_{m_1}d_{m_1}} + \frac{K^2Dg}{\rho_{m_1}d_{m_1}Aa^4}\right]^{\frac{1}{2}}, \tag{15}$$

$$f_2 = \frac{1}{2\pi}\left[\left(\frac{2\rho_a c^2}{d_a\rho_{m_2}d_{m_2}} + \frac{2K^2Dg}{\rho_{m_2}d_{m_2}Aa^4}\right) + \left(\frac{c^2\rho_a}{d_a\rho_{m_1}d_{m_1}} + \frac{K^2Dg}{\rho_{m_1}d_{m_1}Aa^4}\right)\right]^{\frac{1}{2}}. \tag{16}$$

It is interesting to note that the modeling procedure used can be extended to include any structure and combination of layers. Equations (15) and (16) indicate that the dominant factors that determine the resonant frequency of the structure are the density, speed of sound, and thickness of the air separating the membranes, and the density and thickness of the membrane material.

To assess the validity of the model against the results obtained from the numerical algorithm, numerical results were calculated using the material properties given in Table I, for the multilayered structures defined in Fig. 2, and plotted as vertical dashed lines in Figs. 7(a) and 7(b) to illustrate

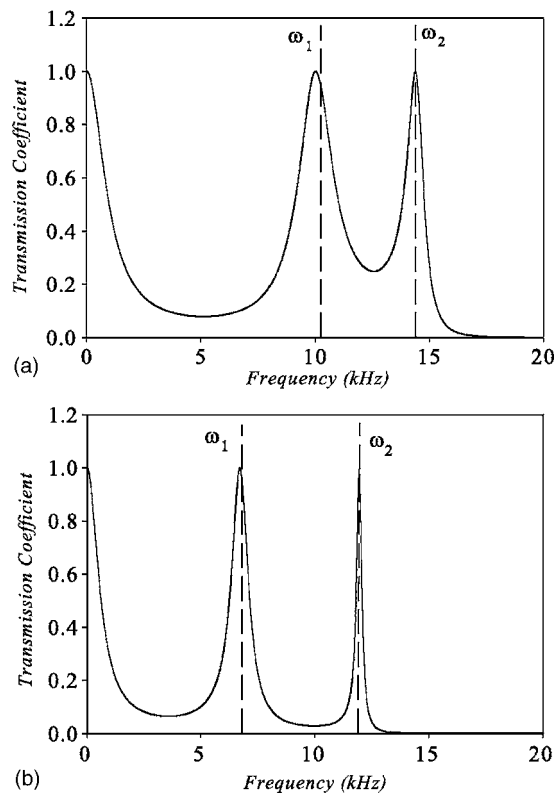
FIG. 9. Apparatus used to allow controlled variations in air gap between three chosen solid layers in an electrostatic device.


FIG. 7. The calculated response of the structure shown earlier in Fig. 2(a) for both the numerical model (solid line) and the analytical model (dotted line).

the single values of the predicted resonant frequencies f_1 and f_2. The predictions of the matrix transfer method given earlier in Fig. 3 are shown as the solid curves. There is a very good agreement between the analytical model and the response predicted by the numerical algorithm.

The analytical model also indicates that the dimensions of the device are an important factor in determining the resonant frequency. The inclusion of a second "plate" spring implies that as the lateral dimensions of the device are reduced, the mechanical properties of the plate dominate the response of the structure. This is illustrated for the particular case of the first resonance, f_1, in Fig. 8 for the structure shown in Fig. 2(a). This demonstrates that for wide devices, the re-
FIG. 8. Theoretical predictions for f_1, showing the individual contributions of the simple air-spring and plate models, and the result of combining them to get an overall response.

sponse is dominated by the air-spring model, but as the width of the device decreases, the plate response becomes more dominant and causes the predicted value of f_1 to increase dramatically. Note that for devices greater than 0.06 m in width, the response is dominated by the air-spring model.

Note that the above analytical model does not include damping. This can be considered by the addition of a damper to the air-spring system.[18] The new resonant frequency f_{1D} that results from damping is defined in terms of the bandwidth $\Delta\omega$ of the resonant peak and its value, as shown in Eq. (17), where an additional term is evident when compared to Eq. (15):

$$f_{1D} = \frac{1}{2\pi} \sqrt{\frac{c^2 \rho_a}{d_a \rho_{m_1} d_{m_1}} + \frac{K^2 Dg}{\rho_{m_1} d_{m_1} A a^4}} \sqrt{1 - \left(\frac{\Delta\omega}{2f_1}\right)^2}. \quad (17)$$

This tends to result in a small reduction in the predicted resonant frequency. The value of $\Delta\omega$ is difficult to predict theoretically and is thus determined experimentally. As a consequence, any alteration in the structure of the transducer that affects the resonance will also affect the value of the damping factor used.

III. EXPERIMENTS WITH A PROTOTYPE DEVICE

An apparatus was constructed to be able to test device configurations with controllable air gaps and layer configurations. The membranes, which measured 100 mm in diameter, were suspended on individual concentric rings, each of which was supported from the base by three springs in a trihedral arrangement. Three micrometers were attached to a top stationary ring, and these were used to push against the springs, thereby enabling the distance between the various membranes making up the device to be accurately controlled, as seen in the photograph of Fig. 9. This arrangement also allowed for the material used in the construction of the transducer to be easily altered.

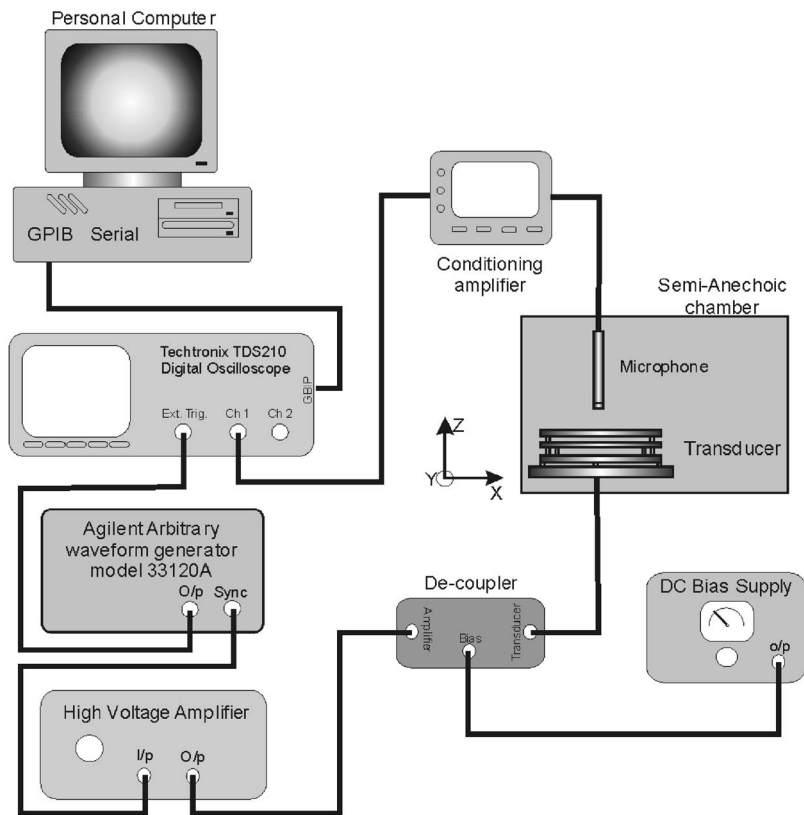
Figure 10 is a schematic diagram of the apparatus used to measure the output from the device. The transducer was placed within an anechoic chamber and driven with a continuous sinusoidal waveform with a peak-to-peak voltage of


FIG. 10. Schematic diagram of the experimental arrangement used in determining the frequency response of the device shown in Fig. 9.

up to 230 V from an Agilent 33120A arbitrary waveform generator plus voltage amplifier, creating an electric field approximately equal to 2.5 MV m^{-1}. An additional 300-V dc bias was applied across the membranes of the transducer, to allow the drive voltage swing to remain undistorted, resulting in an ac to dc ratio of approximately 2/3, and experimentally harmonic distortion was not observed. The bias is necessary in electrostatic devices as the drive forces are always attractive; lack of a dc bias would lead to frequency doubling effects. The resulting acoustical output was measured with a Brüel and Kjær 4138 eighth-inch microphone, in conjunction with a Brüel and Kjær 2690 conditioning amplifier. The microphone had a calibrated frequency response of between 6.5 Hz and 140 kHz, and a maximum sensitivity of 1 mV/Pa. A preamplifier was incorporated into the slender body of the microphone; this had a 0-dB gain and a flat frequency response over the range 1 Hz to 200 kHz. The preamplifier and conditioning amplifier also both supported TEDS (transducer electronic data sheet), a plug and play data acquisition technology that automates the setup and configuration of the microphone with the conditioning amplifier. To automate the whole procedure a Labview™ virtual instrument was written, which enabled the transducer to be driven with a defined waveform over the frequency range 50 Hz to 20 kHz. The driving and measured waveforms were displayed on a Tektronics TDS210 digital oscilloscope and the waveform stored on a PC for future analysis.

A set of experiments was now performed in which the distance between the membranes of the prototype transducer was adjusted and the response from the microphone recorded on-axis at a distance of 10 mm from the front face of the device. Figure 11(a) shows a typical frequency response

from a 100-mm-diam transducer obtained experimentally, with the prediction of the numerical model reproduced alongside for comparison. The device had two 14-μm-thick outer aluminum layers and a 90-μm-thick paper central layer, with symmetrical air gaps of 1.75 mm. It can be seen that two resonant peaks are visible in the experimental data at approximately the same values as that predicted by theory. The large response at low frequencies is not observed experimentally because this would correspond to a rigid body translation. The model looks at the transmission coefficient of the device in air, which is comprised of two effects: the response of the device and the transmission through it. As explained earlier, the transmission coefficient would be predicted to approach unity for a thin device, whereas experimentally this is not measured, hence the differences at low frequencies. In addition, the experimental peak at approximately 3.6 kHz, which is not present in the theoretical predictions, is thought to be due to a standing wave between the transducer front surface and the microphone. Figure 11(b) shows the same comparison for a thicker (20 μm) membrane but a smaller air gap of 1 mm. Now the two resonant peaks are further apart in value, but shifted to higher frequencies.

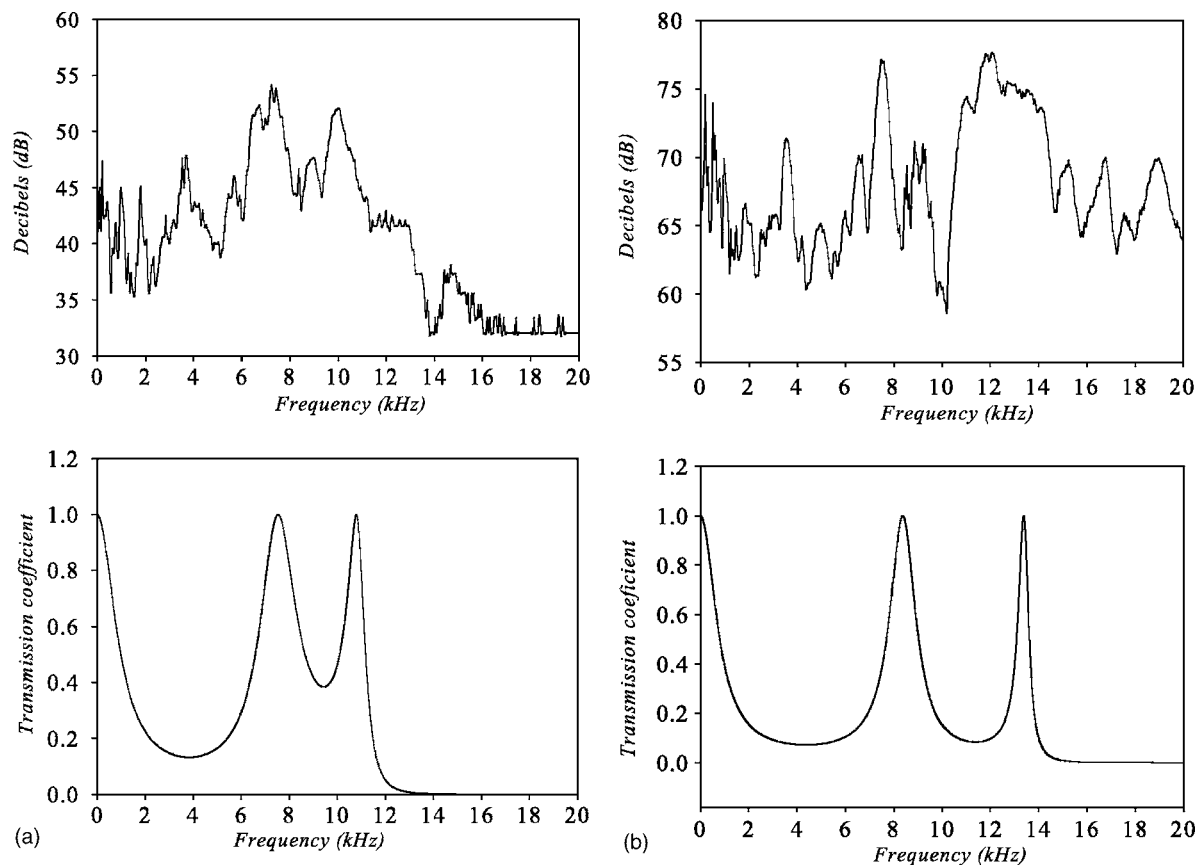
Figure 12 depicts the predictions of both mathematical models and experiment for the value of the first resonant frequency (f_1), as a function of changes in (a) air gap for a constant membrane thickness and (b) membrane thickness for a constant air gap. Models and experiment agree fairly well, apart from small air gaps (<1 mm) at low frequencies, where the numerical solution deviates from other values as explained earlier. The experimental results generally show resonances slightly lower than predicted due to mass loading


FIG. 11. Comparison of experimental frequency response (left) and that predicted numerically (right). (a) Device with 14-μm-thick outer aluminum layers, a 90-μm-thick paper central layer, with symmetrical air gaps of 1.75 mm between each layer. (b) A similar device but with 20-μm-thick aluminum and an air gap of 1 mm. In both instances the transducer had a diameter of 100 mm.

effects, which is a result of the "masses air spring" assumption used in the model. As expected, larger membrane thicknesses and bigger air gaps lead to a reduction in the expected fundamental resonant frequency, enabling the ultimate design goals of low fundamental resonance and wide frequency bandwidth of the device to be achieved.

Experiments were also performed in which the thickness of the central paper membrane was changed. From theoretical considerations, as predicted by Eqs. (15) and (16), this should not affect the value of f_1 [Eq. (15)], a symmetric vibration about this center layer, but should cause f_2 to change via Eq. (16). This was indeed observed experimentally.

During modeling of the transducer it was assumed that the membranes of the device could be considered to move as a simple piston resonator. While a comparison of the results obtained both experimentally and theoretically would seem to support this assumption, a series of experiments has been carried out to ascertain whether the assumption was correct. Using an optical detection system to determine the surface movement of the loudspeaker it was found that the device deviated from the plane piston response by 8%, further validating the initial assumption.

From the above, it can be seen that that the adjustable three-layer prototype device behaved in a manner that was consistent with theoretical predictions. The two resonances predicted by both numerical and analytical solutions were present in experimental data taken on-axis. One of the reso-

nances (at frequency f_1) was a symmetrical vibration about the central layer, whereas the second (at frequency f_2) was an asymmetric vibration with all three layers in motion.

IV. RADIATED FIELDS OF A PRACTICAL DEVICE

The above research confirmed the mode of operation of the electrostatic design and led to a second set of experiments with rectangular transducers whose lateral dimensions could be changed easily and which could be constructed simply by attracting two aluminum membranes to a central paper layer, using the applied dc bias signal. These acoustic sources were thus extremely simple to fabricate using inexpensive materials. The aim of this second set of measurements was to determine the response of these devices and to measure their directivity.

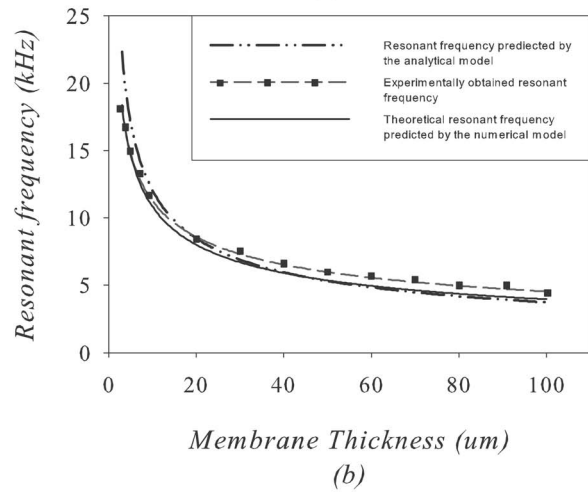
Figure 13 is a photograph showing such a device, together with the measurement microphone. This could be scanned in a horizontal plane using a purpose-built scanning stage, controlled by LabVIEW™ software. The rest of the instrumentation was similar to that shown earlier in Fig. 10. All scans were initiated 3 mm (±0.5 mm) from the front face of the transducer and were performed using a 4-mm step size in both the x and z directions. The recorded field scans were analyzed by extracting the peak-to-peak amplitude and positional data from the measured data. This information was then plotted to create an image of the radiated pressure fields from the transducer under test.


FIG. 12. Predictions of both mathematical models and experiment for the value of the first resonant frequency (f_1), as a function of changes in (a) the air gap for a constant membrane thickness and (b) the membrane thickness for a constant air gap.

The microphone was now scanned spatially in the horizontal (x-z) plane. Figure 14 shows the plots obtained from the same device when driven by a toneburst at (a) 10 kHz
FIG. 13. Photograph of a simple rectangular electrostatic device, showing also the Brüel and Kjær 4138-A microphone mounted onto the scanning stage.
FIG. 14. Experimental radiated field from a 150-mm-square electrostatic source, driven by a toneburst at (a) 10 kHz and (b) 40 kHz.

and (b) 40 kHz. The data is displayed as a gray scale image in which the lighter shades represent higher received acoustic amplitudes. Note the greater number of side lobes and greater directivity at the higher frequency, as expected.

It is interesting to compare these results to those expected theoretically from a plane rectangular piston. This can be achieved using several methods.[19–21] In this work, the Rayleigh integral and convolution approach to predict the theoretical pressure fields from a signal source has been used to produce a numeric model for circular and rectangular sources, based upon the solution defined by Stepanishen[21] and San Emeterio and Ullate,[22,23] respectively. In this procedure the source is considered to act as a planar piston within an infinite baffle. Huygens' principle is then used, whereby the surface of the piston is imagined as being comprised of an infinite number of point sources that each produce a hemispherical pressure wave. In this way, the pressure field can be modeled using a surface integral over the area of the source. Figures 15(a) and 15(b) depict the resulting pressure amplitude for a 150-mm-square transducer, driven with 10- and 40-kHz toneburst signals. These signals were defined by the variable K in the formula used by San Emeterio and Ullate[23] to define a toneburst shape, which can be written as

$$\nu(t) = t^3 e^{-Kft} \cos(2\pi ft). \tag{18}$$

Here, f is the center frequency of oscillation and K is a constant that defines the bandwidth of the resultant waveform. A value of $K=0.4$ was used for both experimental and theoretical studies.

A comparison of Figs. 14 and 15 demonstrates good qualitative agreement between experimental results and the predictions for a plane piston. This is demonstrated further in Fig. 16, where the on-axis spatial variations in pressure amplitude at 10 kHz are plotted, both experimentally and as predicted by theory. Again, good agreement is evident.

V. DISCUSSION AND CONCLUSIONS

A new design of electrostatic transducer has been presented, which uses three solid layers separated by air gaps to produce acoustic signals over a wide frequency range. The basis of this design is that it is both thin and flexible and is hence different from those employed in both traditional electrostatic devices and capacitive devices used in the ultrasonic range.

An initial theoretical analysis showed that the use of three layers allowed more than one resonance to occur, because the central layer could move to create an asymmetric resonance. Experimental studies using a prototype device, in which the layer spacing and thickness could be easily adjusted, confirmed the predictions of theory from both numerical and analytical approaches. A feature of the design is thus that the bandwidth can be extended. In this first study, we have used symmetrical designs; however, it is possible to use different materials and thicknesses for each of the layers, to extend the frequency response and to make the response more uniform in amplitude over the required range. This is a feature of present work.
FIG. 16. Comparison of the measured and theoretical radiated pressure field along the z axis at $x=0$ for a 150–mm-square transducer when excited by a 10-kHz toneburst signal.

The experiments also appeared to confirm that the devices operated as plane pistons. This is to be expected if the force acting across their radiating area is reasonably uniform and that lateral (or "plate") resonances of each layer are absent. The use of thin layer materials and air gaps, coupled with wide lateral dimensions, discourages this behavior and encourage one-dimensional motion. The additional lack of clamping at the device edges also helps in this regard.

The electrostatic sources presented in this paper thus represent an interesting addition to the literature in that they behave like plane pistons and yet are simple to construct from easily available materials. Research is now being performed into their optimization in terms of bandwidth and sensitivity. One interesting aspect is that, being thin and flexible, they are easily contoured into different shapes. In addition, they can be constructed with large radiating surface areas, making them highly directional. These and other interesting aspects of their design are being actively pursued by the authors.

An experimental procedure is described for obtaining the effective acoustic distance between pairs of microphones coupled by a free field, leading to the determination of the position of the acoustic center of the microphones. The procedure, which is based on measuring the modulus of the electrical transfer impedance, has been applied to a large number of microphones. In all cases effects due to reflections from the walls of the anechoic chamber and the interference between the microphones have been removed using a time-selective technique. The procedure of determining the position of the acoustic center from the inverse distance law is analyzed. Experimental values of the acoustic center of laboratory standard microphones are presented, and numerical results obtained using the boundary element method supplement the experimental data. Estimated uncertainties are also presented. The results reported confirm values previously defined in an international standard and extend the frequency range. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2345830]

I. INTRODUCTION

The concept of acoustic center has been widely used in the development and practical realization of free-field reciprocity calibration of microphones.[1–3] The acoustic center of a microphone is defined as follows: "For a sound emitting transducer, for a sinusoidal signal of given frequency and for a specified direction and distance, the point from which the approximately spherical wavefronts, as observed in a small region around the observation point, appear to diverge."[4] In the case of a reciprocal transducer such as the condenser microphone the acoustic center is the same whether the microphone is used as transmitter or receiver. This equivalence is explained by the fact that the diffracted field is equivalent to the radiated field when the radiating/diffracting object is acting in either condition.[5]

The accuracy of the position of the acoustic center as a function of the frequency has a significant influence on the accuracy of the estimated free-field sensitivity. However, only a few attempts to determine this quantity have been found in the literature. Most results have been determined from deviations of the amplitude of the sound pressure from the inverse-distance law, but there have also been a few examples of methods of determining the acoustic center from phase measurements. Jacobsen *et al.* summarized the literature and showed that the various procedures for determining the position of the acoustic center give in general different results for most sound sources, including condenser microphones.[6]

The position of the acoustic center of the microphones can be obtained from measurements of the acoustic transfer impedance between pairs of microphones. The measurement of the transfer function between the microphones is carried out in an anechoic room. However, any real anechoic room is less than perfect, and small reflections from the walls and interference between the microphones will contaminate the transfer function making the estimate of the acoustic center less accurate. The nature of these unwanted effects has been analyzed using statistical methods,[7] and using time-selective procedures.[8] Although time-selective methods can eliminate the unwanted contaminations, application of such methods may affect the accuracy of the estimated acoustic center. In this paper the time-selective technique described in Ref. 8 has been used for removing the unwanted reflections and interference between the microphones. The effect of the time-selective technique on the electrical transfer impedances used for determining the acoustic center is analyzed.

Prediction of the position of the acoustic center requires a precise knowledge of the sound field generated by the microphone when this acts either as a sound source or as a receiver. Thus a precise knowledge of the displacement of the diaphragm of the microphone and its geometry is needed. Some attempts to determine the sound field when a microphone is introduced in the propagation path of a plane wave have been described in the literature.[9–13] However, these studies have been focused on obtaining the free-field correction of the microphone, except Ref. 11, which provided values of the position of the acoustic center of laboratory standard microphones of types LS1 and LS2 determined numerically using the boundary element method (BEM).

The purpose of this paper is to present and examine experimental values of the position of the acoustic center of

laboratory standard microphones based on deviations from the inverse-distance law. The experimental results are supplemented with numerical results obtained using the BEM.

II. DETERMINING THE ACOUSTIC CENTER FROM THE INVERSE-DISTANCE LAW

The discussion may be simplified if the microphones are regarded as axisymmetric sources observed from positions on the axis of symmetry. Under this assumption, the acoustic center must be somewhere on the axis. If the amplitude of the sound pressure is plotted as a function of the distance, a straight line can be fitted over the region of concern. Thus, the position of the acoustic center, $x(k,r)$, can be determined using the following expression:[6]

$$x(k,r) = r + |p(r)| / \frac{\partial |p(r)|}{\partial r}, \qquad (1)$$

where k is the wave number, r is the axial distance from the diaphragm of the microphone, $p(r)$ is the sound pressure as a function of distance, and the rate of change, $\partial |p(r)| / \partial r$, must be estimated by any available means, for example by using least squares fitting.

The rate of change can be determined if measurements of the electrical transfer impedance are made at several distances. This procedure can be used when the characteristics of the air in the environment where the measurements are carried out can be calculated accurately using well defined standard procedures. The sound pressure generated by a microphone used as a sound source decreases as a function of the distance from the acoustic center, r_t, following the inverse-distance law,

$$p(r) = j \frac{\rho f}{2r_t} M_f \cdot i \cdot e^{-\gamma r_t}. \qquad (2)$$

In Eq. (2) ρ is the density of air, M_f is the free-field sensitivity, f is the frequency, i is the current feeding the microphone, and γ is the complex propagation coefficient. This coefficient is defined as $\gamma = jk + \alpha$, where α is the air absorption. Thus, if an ideal receiver that does not disturb the propagating wave is located at a given distance, the output voltage will be inversely proportional to the true acoustic distance.

A realistic implementation of the above procedure must take account of the air absorption and the fact that the receiver will affect the sound field and will have its own acoustic center. In a reciprocity arrangement, the electrical transfer impedance between the microphones contains information about the position of the acoustic center of each microphone; therefore, it can be used for determining the sum of the acoustic centers of the two microphones. The electrical transfer impedance is defined as the ratio of the open-circuit voltage at the terminals of the receiver microphone, u_1, to the current through the terminals of the transmitter microphone, i_2,[4]

$$Z_{e,12} \equiv \frac{u_1}{i_2} = j \frac{\rho f}{2r_t} \cdot M_{f,1} \cdot M_{f,2} \cdot e^{-\gamma \cdot r_t}. \qquad (3)$$

In what follows the position of the acoustic center is defined as positive when the center is placed in front of the microphone diaphragm. Thus, the distance r_t in Eq. (3) is the difference obtained by subtracting the sum of the acoustic centers of the microphones, x_{1+2}, from the physical distance between the diaphragms of the microphones, r. Since only the modulus of the transfer impedance is of concern, it can be assumed that the parameters are independent of the distance. Substituting the true distance by its two components and rearranging terms gives

$$\frac{1}{|Z_{e,12}| e^{\alpha \cdot r_t}} \approx \frac{1}{A}(r - x_{1+2}) \approx mr + b. \qquad (4)$$

Thus, the sum of the acoustic centers, x_{1+2}, can be obtained by dividing the independent term, b, by the slope, m. The slope corresponds to the rate of change defined by Eq. (1). Note that the procedure is based on the following assumptions: (i) The observation distance is long compared to the sum of the acoustic centers. Under typical measurement conditions, the distances range from 250 mm to 500 mm for LS1 microphones, and from 160 mm to 350 mm for LS2 microphones. According to values given in the standard, the acoustic centers are about 9 mm at low frequencies for LS1 microphones, and about 5 mm for LS2 microphones.[4] (ii) The physical properties of the air inside the anechoic chamber can be estimated accurately using standard methods.[4,14] (iii) In the range of distances where the measurements are made, the position of the acoustic center varies very little.[15] The acoustic center determined by means of the above procedure is the average acoustic center at the average distance.

Typically, in a reciprocity measurement, the transfer impedance is measured using three microphones successively coupled in a free field. This yields three sums of acoustic centers of the three microphones. Thus, the position of the acoustic center of each microphone can be obtained by solving the resulting system of equations. The acoustic center of microphone No. 1 is

$$x_1 = \frac{b_{12}/m_{12} + b_{13}/m_{13} - b_{23}/m_{23}}{2}, \qquad (5)$$

where $m_{i,j}$ and $b_{i,j}$ are the slope and the independent term determined for the combination between microphones i and j, respectively. Similar expressions can be obtained for the other microphones.

III. NUMERICAL MODELING

The procedures described above have been applied onto experimental data. However, since there are discrepancies between reported results, some source of validation is needed. No analytical solution of the scattering/radiation problem of the microphone exists, but several numerical formulations have been developed for solving the problem. Any of these formulations can be used for comparison with the experimental results. In this case, an axisymmetric formula-
FIG. 1. Geometry of LS1 and LS2 microphones used in the BEM calculations. Dimensions in mm.

tion of the BEM (Ref. 11) is used for obtaining a numerical estimate of the position of the acoustic center.

This formulation was used by Juhl for determining the position of the acoustic center of laboratory standard microphones. Juhl's purpose was not to analyze the microphone problem in depth, but to validate his formulation with experimental data, and his low frequency approximation was based on the assumption that the movement of the diaphragm follows the first mode of the Bessel function of zero order and can be approximated by a parabolic function at frequencies below the resonance of the microphone. Under this assumption he calculated the position of the acoustic center up to 10 kHz. The assumption of the parabolic movement breaks down at higher frequencies where experimental results show significant deviations from the predicted values.

A modal sum of Bessel functions has been used extensively for describing the movement of the diaphragm.[9,10,12,13,16–18] This has yielded some fairly good approximations in calculations of the free-field correction, but no calculation of the acoustic center based on these results has been made.

In this investigation it has been assumed that the displacement of a diaphragm of radius a under uniform pressure conditions is

$$\eta(r_D) = \left[\frac{J_0(k_D r_D)}{J_0(k_D a)} - 1 \right] \eta_0, \qquad (6)$$

where J_0 is the Bessel function of zero order, η_0 is a constant that defines the amplitude of the movement, k_D is the wave number of the diaphragm, and r_D is the radial coordinate. A constant (pistonlike) displacement distribution has also been examined.

The geometry used in the simulations is shown in Fig. 1. The semi-infinite rod was approximated by a length of 60 cm. This will introduce a small disturbance in the results because of reflections from the back of the rod, but it is expected that the amplitude of this disturbance is negligible. The frequency range used in the calculations was 1 kHz–32 kHz for LS1 microphones and 4 kHz to 50 kHz for LS2 microphones. The size of the smallest element in the axisymmetric mesh was 2.5 mm and 1.5 mm for LS1 and LS2 microphones, respectively. Thus, there were at least four elements per wavelength at the highest frequency. It is well known that BEM solutions for exterior problems can be contaminated by spurious results associated with fictitious eigenfrequencies in the internal domain of the geometry.[19] This is known as the nonuniqueness problem. In the case at hand this problem can occur above about 10 kHz. The nonuniqueness problem has been avoided by adding a random CHIEF point as described in Ref. 19 and further checked by calculating the condition numbers of the BEM matrices[20] and by repeating calculations with small frequency shifts.

IV. EXPERIMENTAL RESULTS

The positions of the acoustic centers of a number of condenser microphones of types LS1 and LS2 have been determined using the linear regression procedure outlined above. Equation (4) gives the sum of the acoustic centers of the two microphones of the measured pair. The individual values are determined using Eq. (5).

The measurements were made using the experimental apparatus described in Ref. 21. The measurement system consists of a homemade reciprocity apparatus which is connected to a Brüel & Kjær PULSE (B&K) analyzer; the receiver and transmitter microphone are connected to the reciprocity apparatus. The environmental conditions are measured and recorded during the measurement of the electrical transfer impedances; temperature and relative humidity are kept at $23° \pm 0.5°$ and $50\% \pm 10\%$, respectively, and the static pressure is 100 kPa±2 kPa. A simplified diagram of the measurement system is shown in Fig. 2. The determination of the acoustic center involves the measurement of the electrical transfer impedance of the three pairs of microphones at four different distances (24, 32, 40, and 48 cm for LS1 microphones, and 16, 20, 24, and 30 cm for LS2 micro-
FIG. 2. Instrumentation used in the experimental determination of the acoustic center of Laboratory Standard Microphones.

FIG. 3. Comparison between "cleaned" (solid line) and "raw" (dashed-dotted line) estimates of the position of the acoustic center for LS1 and LS2 microphones. (a) LS1 microphones (B&K 4160); (b) LS2 microphones (B&K 4180).

phones), at discrete frequencies (from 1 kHz to 30 kHz for LS1 microphones, and from 3 kHz to 50 kHz for LS2 microphones) using stepped sine excitation with a frequency step of 120 Hz. The open-circuit voltage of the receiver microphone and the voltage on the terminals of the reference impedance connected in series with the transmitter microphone are measured using the B&K PULSE analyzer.

After some manipulations carried out onto the measured frequency response (described in Ref. 8), its associated impulse response is obtained by applying an inverse Fourier transform. The frequency step of 120 Hz is fine enough to obtain an impulse response that contains the primary reflections from the walls of the anechoic room and the interference between the microphones. These reflections are eliminated by applying a Tukey time-selective window with a duration of 1.8 ms for LS1 microphones and 1 ms for LS2 microphones. A direct Fourier transform is then applied to the time-windowed impulse response.

Once the influence of extraneous reflections from the walls and second-order interference between microphones have been removed from the measured electrical transfer impedance, the individual acoustic centers can be determined.

A. Effect of the time-selective procedure

Figure 3 shows a comparison between "cleaned" and "raw" estimates of the positions of acoustic centers of LS1 and LS2 microphones. Although the combined effect of cross-talk, interference between the microphones and reflections from the walls can be identified from the periodicity observed in the frequency domain, the identification of such effects is carried out more precisely in the time domain. A more detailed analysis can be found in Refs. 22 and 21. It is also clear that the time-selective procedure effectively removes much of the perturbations from the electrical transfer
impedance and therefore from the estimate of the position of the acoustic center. The ripple observed at the extremes of the frequency range is caused by the time-selective window. Although this has a degrading influence on the estimated acoustic center, it seems to be preferable to the nonpredictable effect of the contaminations present in the raw estimate.

B. Average position of the acoustic center

Figure 4 shows the average acoustic center of LS1 and LS2 microphones (of 12 and 21 microphones, respectively) together with the standardized values.[4] It can be seen that the position of the acoustic center of LS1 microphones more or less follows the standardized values of the acoustic center in most of the frequency range, but above 15 kHz and up to 20 kHz it seems to diverge. The acoustic center reaches a maximum about 26 kHz, and then decreases again. This behavior for LS1 microphones was also observed in one laboratory's measurements in the international comparison,[23] although measurements were made only up to 25 kHz. The same tendency is observed for the LS2 microphones around 47 kHz. A similar behavior at high frequencies was registered for LS2 microphones in Ref. 7.

The frequency where the maximum occurs coincides with the frequency of the second radial resonance of the diaphragm. This suggests that the phenomenon may be related to the actual displacement of the diaphragm. This behavior will be compared with numerical BEM results.
FIG. 4. Average position (solid line) and standard deviation (dashed-dotted line) of the acoustic center of a number of (a) LS1, and (b) LS2 microphones obtained experimentally. For comparison purposes, the standardized values are also included (stars).

FIG. 5. Acoustic center of (a) LS1 and (b) LS2 microphones determined experimentally and numerically using BEM. Solid line, experimental results; dotted line, uniform distribution; dashed line, Bessel distribution.

V. NUMERICAL RESULTS

Figure 5(a) shows the results of the numerical calculations of the position of the acoustic center of LS1 microphones using the axisymmetric BEM formulation. It is interesting to note that the high frequency behavior of the calculated acoustic center resembles the experimental results. At low frequencies the assumed shapes of the displacement yield an acoustic center that follows the experimental estimate, although the uniform displacement distribution gives a slightly smaller value. It can also be seen that the calculated acoustic centers have a maximum at about the same frequency, which is the second radial resonance of the diaphragm. It is interesting to observe that in the frequency range where the peak is observed, it is the uniform distribution that shows the best agreement with the experimental values. This may be caused by the fact that at such high frequencies, the effect of the air film between the diaphragm and the back plate of the microphone begins to dampen the amplitude of the movement of the diaphragm, perhaps heavily, in the middle of the diaphragm, thus flattening the displacement distribution and making it look more like the uniform distribution. A similar behavior is observed in the case of LS2 microphones shown in Fig. 5(b). It should be interesting to have measured values of the actual velocity distribution of the diaphragm.

VI. DISCUSSION

An aspect of interest is the effect of the distance range in which the experimental acoustic centers are determined. This dependence has been demonstrated for some sources,[6] and it

would not be surprising to find a similar behavior in the case of the microphones.[11] Figure 6(a) shows the position of the acoustic center of LSI microphones calculated numerically at different average distances: 240 mm, 480 mm, and 1000 mm. It can be seen that there is a systematic influence of the distance on the position of the acoustic center. It should converge to a value at the largest distances, a far-field acoustic center. At low frequencies (below 1 kHz) the acoustic center converges slowly while above this frequency the convergence is faster.

Although it is very difficult to make reliable measurements of the electrical transfer impedance at large distances between the microphones because the signal to noise ratio is very poor, an experiment was carried out in order to estimate the effect of the distance on the estimated acoustic center. Figure 6(b) shows the experimental acoustic center at average distances of 260 mm and 380 mm. It can be seen that the acoustic center moves away from the microphone when the

average distance is increased. It can be expected that the position of the acoustic center converges to a far-field value as the average distance increases, as observed in the numerical calculations.

The convergence to a far-field acoustic center leads to a discussion about which acoustic center should be used in free-field reciprocity calibration of microphones. An important consequence of the use of the acoustic center determined from modulus measurements is that the resulting free-field sensitivity becomes independent of the calibration distance.

Hence, if small changes in the acoustic center are introduced, this independence is degraded, and this will lead to changes in the free-field sensitivity. A change of 1 mm in the position of the acoustic center will lead to a change of 0.03 dB in sensitivity when the measurements are carried out at an average distance of 300 mm. One possibility would be to use the acoustic center determined experimentally, and to obtain a sensitivity that is valid for the distance range at which the measurements are made. Afterward, a correction could be made in order to obtain a far-field microphone sensitivity.

Because of the poor signal to noise ratio, it is very difficult to determine the position of the acoustic center experimentally at low frequencies and long distances. Additionally, the use of time-windowing will degrade the accuracy of the estimate of the acoustic center position at low frequencies. However, values of the acoustic center in the whole frequency range may be needed. One possible solution is to determine a polynomial approximation of the acoustic center that is obtained from experimental values at mid and high frequencies and from numerical values in the lowest frequency range.

If an accurate prediction of the acoustic centers at high frequencies using BEM is wanted, it is crucial to use a displacement distribution that represents the actual movement. Recent work suggests that a LASER vibrometer may be used to measure the displacement distribution.[24] This shape can subsequently be used to determine the acoustic center at frequencies where the displacement of the membrane is no longer described using simple functions.

Finally, as the position of the acoustic center of an individual microphone is not expected to change unless there is a significant change of the acoustic impedance of the microphone, any convenient choice of a polynomial approximation can be used advantageously instead of determining the experimental values every time. Coefficients of polynomial approximations of the experimental results are shown in Table I. These coefficients are used in the following polynomial:

VII. CONCLUSIONS

The problem of determining the position of the acoustic centers of laboratory standard microphones has been addressed, and the acoustic center of laboratory standard microphones, LS1 and LS2, has been determined from the modulus of the electrical transfer impedance measured at different distances between pairs of microphones.

The position of the acoustic center has also been estimated using an axisymmetrical BEM formulation assuming different velocity distributions of the diaphragm. At low frequencies and up to the resonance frequency of the microphone, the use of simple functions such as the Bessel function yields values that are in good agreement with the experimental values. At higher frequencies the agreement degrades but the numerical results nevertheless confirm the experimental estimates.

There is a good agreement between the standardized and experimental values of the acoustic center in the mid-frequency range. The discrepancies observed at frequencies up to 20 kHz for LS1 microphones, and the need of sensitivity estimates at higher frequencies may point to the need of updating the standard. The experimental results presented in this paper may be regarded as a contribution to this process.

APPENDIX: TABULATED VALUES OF THE POSITION OF THE ACOUSTIC CENTER AND ASSOCIATED UNCERTAINTIES

The uncertainty of the estimate of the position of the acoustic center can be determined by following the ISO/GUM guide for estimating the uncertainty of measurements.[25] Equation (5) is the mathematical model used in the estimation of the uncertainties. The estimated slope and independent term are determined from transfer impedances "cleaned" from the influence of reflections and corrected for the effect of the air absorption. A list of the possible contributors is given below.

1. **Electrical transfer impedance:** The modulus of the electric transfer impedance can be affected by many factors. The most conspicuous are the distance between microphones, the accuracy in the measurement of the voltage ratio, and the environmental conditions. The voltage ratio is measured using a steady state response (SSR) analyzer. This makes it possible to measure the frequency response with a given accuracy using a stepped sine excitation. The measurement is made using two channels in the same input range.
2. **Time-selective technique:** The time-selective technique removes disturbances from the frequency response very effectively, but it also introduces ripples in the extremes of the frequency response. The ripple is caused by the fact that the time-selective window truncates the impulse response at positions where it is not zero. Thus, the ripple is a function of the length and position of the time window.
3. **Microphone sensitivity:** The microphone free-field sensitivity may change slightly as a function of distance, but for the purpose of estimating the uncertainty of the position of the acoustic center of an individual microphone, it can be regarded as constant. However, in the uncertainty of the average position of the acoustic center of a number of microphones, deviations related to the geometry and acoustic impedance should be taken into account.
4. **Air absorption:** The electrical transfer impedance is corrected for the losses induced by air absorption. This

is a function of some basic constants and the environmental conditions and the *physical* distance between the diaphragms of the microphones rather than the distance between acoustic centers. This is due to the fact that the acoustic waves actually propagate between the two diaphragms. The difference between using the physical distance and the acoustic distance is negligible in the frequency range of interest, though.

5. **Least-squares fitting:** The slope and the intercept are estimated using the least squares technique. These estimates have an associated standard error.

These contributors can be added to the model based on Eq. (5). Further simplification can be achieved by assuming that the value and uncertainty of each intercept and slope is the same. Thus, the mathematical model is

$$x_1(f) = \frac{b/m}{2} + R + LS + FF. \tag{A1}$$

The least-squares fitting is made over the electrical transfer impedance measured at different distances. Each electrical transfer impedance is corrected for air absorption, thus $b, m = f\{Z_e, e^{\alpha r}\}$, R is the reproducibility, LS is the contribution from the least-squares fitting, FF is the contribution due to the difference between the far field acoustic center and the acoustic center estimated at short distances between the pair of microphones; this quantity can be estimated experimentally or numerically as described in Sec. VI.

The uncertainty of the "cleaned" electrical transfer impedance measured at each distance can be estimated using a model that includes the effect of the measurement procedure, the time-selective technique, the distance, and the air absorption.

The uncertainty of the total absorption, which depends on the environmental conditions and the distance between the diaphragms of the microphones, can be estimated on the basis of the calculation procedure described in the standard,[4] or the procedure described in a report that harmonized the calculation methodologies of the air properties used in the calibration of microphones.[14] The analytical expressions can be difficult to differentiate, and a simplified procedure based on finite differences[25] has been applied instead. The uncertainty of the temperature, relative humidity, and static pressure is estimated to be 0.5°, 5%, and 50 Pa, respectively.

The inclusion of the reproducibility may result in overestimation of the uncertainty because it may contain the effect of factors already considered in the other contributors. However, as the present model does not include all the possible contributors, it is preferable to have a conservative estimate of the uncertainty of the acoustic center.

The contribution of the least squares fitting can be obtained using the estimate of the standard error. However, in this exercise, the correlation coefficient is always better than 0.99. Therefore, the standard error can be considered negligible. Table II shows the sources of uncertainty. Once the contribution of each element is established, the standard uncertainty of the acoustic center has been estimated using the procedures described in the ISO/GUM.

Table III gives values of the position of the acoustic center and their uncertainty for LS1 microphones at selected frequencies. Table IV lists the corresponding values of the acoustic center and its uncertainty for LS2 microphones.

Techniques have been studied for the detection of buried landmines with acoustic/seismic interrogation signals. Much of this work has involved full wave-field imaging from local measurements of ground motion using noncontact sensors. These offer inherent safety for the system operator and accommodate the need to make measurements over rough ground surfaces. The system requirement is, however, only that a sensor does not intrude on the measurement rather than that it not contact the ground. An experimental investigation was conducted into the feasibility of an array of ground-contacting sensors for use in a seismic landmine-detection system that exploits full wave-field imaging. The main considerations in the design of the array sensor were safety, sensitivity, fidelity, reproducibility, and sensor-to-sensor interaction. A relatively simple and inexpensive sensor was demonstrated in an experimental simulation of a landmine-detection system. The sensor, which is suitable for inclusion in a large planar array that could be used for detection confirmation, exerts a safe normal force at the point of contact and enables detection performance comparable to that which could be achieved using noncontact techniques. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2345911]

I. INTRODUCTION

The use of acoustic/seismic signals to detect buried landmines has been studied for well over 30 years.[1] Some of the system concepts that have been explored involve remotely located arrays of ground-contacting seismic sensors and sources to detect mines using pulse-echo techniques.[2,3] Other system concepts involve local measurement of ground motion at locations, including some directly above buried mines using noncontact sensors.[4,5] For these systems, the motion is induced by either a remote seismic source or direct air-acoustic coupling at the measurement location. Local measurements offer the advantage that the signal scattered by a landmine is not diminished by geometrical spreading, absorption, or scattering from inhomogeneities in the medium before it can be measured. They also permit the entire surface wave-field to be captured so that data can be processed in the domains of both time and two-dimensional space in order to image the target (concepts that involve direct subsurface vibration measurement have also been proposed in the literature, although these have not been developed to a point of experimental testing[6]). Several noncontact sensor types have been found to be effective in systems based on local measurements. These include laser Doppler vibrometers (LDVs),[4,7,8] microwave radar-based vibrometers,[5,9] and ultrasonic vibrometers.[10,11]

The ground-contacting sensors studied here have been considered in the context of a previously investigated seismic landmine-detection technique.[5] This technique employs audio-frequency seismic surface waves. These waves are referred to as Rayleigh waves for the sake of brevity, although they are in fact the lowest order coupled P-SV mode in a vertically heterogeneous medium (i.e., stratified soil). Rayleigh waves interrogate only the near surface layers of soil because they decay exponentially into the medium.[12] These waves are excited by a remotely located source and the full wave-field is measured with a nonintrusive sensor that is scanned to form a synthetic two-dimensional array. The source that is most commonly used is an electrodynamic shaker that is coupled to the ground through a foot designed to preferentially excite Rayleigh waves. Landmine images are formed by post-processing the displacements of the ground's surface measured at many locations. The image processing, which involves spatial and temporal filtering, has been described in previous papers.[5,13]

In previous work, the receiving array has been synthesized using one or two sensors to scan thousands of measurement locations (typically 2500–5000).[5] The most significant drawback to this technique is the slow measurement speed that is forced by the synthesis of the receiving array. An obvious path to improve speed is by replacing the synthetic array with a physical array of sensors. Compatibility with this array requires individual sensors with low cost, small physical size, and low power consumption.

A physical array of sensors should yield time savings that are proportional to the number of elements in the array (*N*) because received signals are simultaneously acquired, and background noise integrated, at many measurement locations. If the array is moved incrementally, movement is *N* times less frequent for the scanning of a predefined area. In a realistic scenario, *N* should be an underestimate for the time

savings that can be realized with a physical array in comparison to a synthetic array of identical sensors. This is because the noise field is accurately sampled in time and space and can therefore be filtered more effectively. Nonseismic noise can be removed more effectively by spatial/temporal filters. Seismic noise that passes these filters should constitute a signal of opportunity.

There are many physical configurations that a field-operable landmine-detection system might take. Recent interest been focused on the development of confirmation systems, which are intended to quickly interrogate a prescribed area that has been identified as a possible landmine location. Here a large physical array of sensors may be used to span an entire region of interest, and the total measurement time should be only that which is required to build a sufficient signal to noise ratio for any individual sensor in the array.

II. ACCELEROMETER-BASED SENSORS

There are many technologies available for measuring surface motion with sensors that contact a surface of interest. These include accelerometers, velocimeters (geophones), seismometers, pressure sensors, and strain sensors. Commercially available accelerometers are an appealing alternative because of their low cost, variety, and ubiquity. Many of these have intrinsic noise densities that are superior to the radar-based sensor used in previous work over most of the frequency range of interest for landmine detection (50–1000 Hz). The radar-based sensor responds to displacement rather than acceleration, so there is a crossover point for signal to noise performance. Many small accelerometers have intrinsic noise density of $10-100$ μg/$\sqrt{\text{Hz}}$ in the frequency range of interest. This compares to 1 nm/$\sqrt{\text{Hz}}$, which was typical of both ultrasonic and radar-based sensors in bench-top testing. Therefore, the crossover for superior noise performance by an accelerometer is in the 50–150 Hz frequency range. Commercially available LDVs advertise intrinsic noise floors of 50 nm s^{-1}/$\sqrt{\text{Hz}}$. Compared to this, the crossover for superior noise performance by small accelerometers is in the 300–3000 Hz range. Soil is an inconsistent reflector for radar, ultrasound, and laser signals. Measurements using these modalities are usually limited by speckle noise rather than the intrinsic noise of noncontact sensors. Because of this, the crossover frequencies for superior noise performance by accelerometers, which are not susceptible to speckle noise, should be lower for practical purposes than they are for bench-top testing conditions.

An accelerometer is only functional if it is in intimate contact with a vibrating surface. The nature of that contact must satisfy conditions similar to noncontact sensors; the contact must not intrude on the vibration of the ground and it must reasonably couple surface motion to the accelerometer. Additionally, this coupling must be reproducible throughout an array of sensors and when an individual sensor is relocated.

There are three ways in which a ground-contacting sensor might intrude unacceptably on the soil surface in a landmine-detection system. First and most obviously, it could require a static biasing force that is sufficient to detonate a buried pressure-fused landmine. Anti-personnel (AP) mines impose a more stringent requirement than anti-tank (AT) mines in this regard. Typically pressure-fused AP mines detonate with contact forces of 20–160 N, although some AP mines may be detonated with applied forces as low as 10 N.[14] AT mines detonate with applied forces that are an order of magnitude higher than this. Second, a sensor may load either the ground or a buried mine to alter the surface motion. This is problematic if it degrades the contrast between landmines and background that can be generated by processing the collected data. Thus, some forms of ground loading may be more acceptable than others. Finally, a sensor may scatter the seismic interrogation signal and alter the signals that are received by other sensors in the array. These requirements generally dictate a sensor such as an accelerometer that is small, lightweight, and rigid.

The suitability of an accelerometer for use as a ground-contacting sensor is obvious. However, there are many suspension and packaging schemes that can be used to couple an accelerometer to the ground, and choosing among these is the more difficult question that was addressed in the design of the sensor. This problem was studied through an analysis involving simple lumped-element models for sensor response. The models were validated and several sensor designs were tested in a series of experiments, both in the laboratory and at a realistic field-test site. All of the sensor designs that were modeled and tested were based on commercially available accelerometers.

III. SENSOR DESIGN

The ground-contacting sensor design under consideration can be described as an accelerometer coupled to the ground's surface with a biasing force acting against a tail mass through a spring (as shown in the inset in Fig. 1). This configuration can be represented as a two degree-of-freedom (2-DOF) system.

The sensor head is modeled as a small mass (m_1) that is attached to the ground through a spring and damper (k_0 and η_0) that represent the reactive and resistive components of the ground's input impedance. Previous experiments have shown that the input reactance of the soil at various field sites is dominantly stiffness-like in the frequency range that is of interest for seismic landmine detection.[5] The stiffness of carefully compacted damp sand, which is a reasonable soil surrogate,[2,3,15–18] has been measured in the laboratory using an impedance head and found to be approximately 1 $\times 10^6$ N/m, with a circular contact area of 2 cm^2 that is typical of the prototype sensors. Although viscous damping was assumed, the frequency dependence of the ground-dominated sensor damping was not known and no physical mechanism was assumed for this process. The measured input resistance of the sand in the experimental model can be reasonably modeled in the frequency range of interest as a viscous damper with 76 N/(m/s) damping for a 2 cm^2 contact area. Laboratory measurements were best fit by a frequency dependence that related loss and displacement by a factor of $\omega^{0.84}$, which is reasonably close to the $\omega^{1.0}$ depen-
FIG. 1. Modeled response of a gravity-biased ground contacting sensor with a 156 g tail mass (A) amplitude and (B) phase. The model is shown in inset. Here the biasing spring $k_2=0$, foam collar $k_1=2.1\times10^3$ N/m, ground $k_0=1\times10^6$ N/m, collar damping $\eta_1=1.6$ N/(m/s), ground damping $\eta_0=76$ N/(m/s), head mass $m_1=5.6$ g, and tail mass $m_2=156$ g.

dence that would be expected for viscous damping. Field measurement data of a sufficient quality to perform a similar inversion for other soil types were not available. The tail mass is modeled as a lumped mass (m_2) that is coupled to the sensor head by means of a second spring (k_1). For some of the sensor designs that were examined, the tail mass was coupled to a backing structure through a third spring (k_2), which was used to provide an adjustable biasing force. In selecting parameters for the sensors, k_2 and m_2 were chosen to be sufficient to isolate the tail mass from motion of a complex supporting structure (an automated positioning system) in order to render the device as a whole insensitive to back-plane motion. An accelerometer is an absolute motion rather than a relative motion sensor, but back-plane motion may be coupled into the ground through the accelerometer and thereby affect accelerometer output. This isolation meant that, although the experiments involved a complex supporting structure, the stationary backing assumed in the model is a reasonable approximation. For all of the sensor prototypes, k_1 was selected to isolate m_2 and to be small in comparison to k_0. In order to minimize intrusion, m_1 was chosen to be as light as possible. The motions of the masses in this model are described by a system of equations as follows:

$$
\begin{bmatrix} k_0 + k_1 - m_1\omega^2 + i\omega\eta_0 + i\omega\eta_1 & -k_1 - i\omega\eta_1 \\ -k_1 - i\omega\eta_1 & k_1 + k_2 - m_2\omega^2 - i\omega\eta_1 \end{bmatrix}
$$
$$
\times \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} (k_0 + i\omega\eta_0)x_0 \\ 0 \end{bmatrix}. \tag{1}
$$

This system has two undamped natural frequencies of oscillation that satisfy the equation[19]

$$
\omega_n^2 = \frac{m_1(k_1+k_2) + m_2(k_0+k_1)}{2m_1m_2}
$$
$$
\pm \sqrt{\left(\frac{m_1(k_1+k_2) + m_2(k_0+k_1)}{4m_1m_2}\right)^2 - \frac{(k_1+k_2)(k_0+k_1) - k_1^2}{m_1m_2}}. \tag{2}
$$

If components are selected such that $k_0 \gg k_1 \gg k_2$ and $m_2 \gg m_1$, the two resonances are effectively decoupled. The first of these occurs at $\omega_{n1} \approx \sqrt{k_1/m_2}$. This is the resonance of the tail mass on the front spring of the sensor. The second resonance, $\omega_{n2} \approx \sqrt{k_0/m_1}$, is the resonance of the accelerometer mass intimately coupled to the ground's stiffness. The tail mass is effectively stationary for $\omega \gg \omega_{n1}$ where $x_2/x_1 \approx (\omega_{n1}/\omega)(k_1m_1/k_0m_2)$ and the dynamic load on the ground is the mass m_1. Under these circumstances $x_1 \approx x_0$ (the requirement for sensor fidelity) provided that $\omega \ll \omega_{n2}$. Thus the operational bandwidth of an undamped sensor would be $\sqrt{(k_1/m_2)} \ll \omega \ll \sqrt{(k_0/m_1)}$.

The values of the parameters of the model were determined by direct measurement with the exception of the sensor damping (η_1), which was assumed to be small but non-negligible so that the lower resonance would have a reasonable quality factor. Figure 1 shows the predicted response of a ground-contacting sensor design based on measured parameters, which are indicated in the figure. The lower frequency resonance is seen to have very little effect on the output variable (x_1). This small effect would be diminished further if η_1 were assumed to be larger, but it is not significant even for $\eta_1=0$. For the selected value $[\eta_1 = 1.6$ N/(m/s)$]$ the quality factor of the lower resonance is 10, which is higher than experimental measurements. The lower resonance frequency for the selected parameters is 18.5 Hz, which is well below the band of interest. The higher resonance, which has a greater impact on the sensor response, occurs at 3 kHz for the selected parameters. The second resonance is heavily damped (the head mass is about twice the mass corresponding to a critically damped system), and therefore has greater effect on the sensor's phase response than on its amplitude response at frequencies of interest. Below 1 kHz, this amounts to less than a 3° phase delay in the sensor response.

Two ground-contacting sensor prototypes that can be modeled by Eq. (1) were designed, built, and tested. These are shown in Fig. 2. The first design [Fig. 2(A)] a spring-biased sensor, was coupled to the backing structure using a long coil spring with a stiffness of 1.3×10^2 N/m. This permitted the normal force on the ground's surface to be easily varied because this biasing force was the sum of the weight of a 40 g tail mass (0.4 N) and the force exerted by the spring's compression. The sensor head weighed 5 g. It was fabricated with a 0.75 g miniature accelerometer (Vibrametrics model VMI9002) encapsulated in rigid foam. The accelerometer sensitivity and noise density were specified by the manufacturer as 100 mV/g and 10 μg/$\sqrt{\text{Hz}}$.

The second sensor [Fig. 2(B)] was a modular gravity-biased sensor. It was completely decoupled from its backing structure $(k_2=0)$. This sensor was placed on the ground so that it was free standing and then lifted and repositioned

2.1×10^3 N/m for the second. In the second design, tubular springs and masses allowed the accelerometers and internal wiring of the sensor to be completely enclosed and weather-proofed.

IV. SENSOR FIDELITY

The fidelity of the ground-contacting sensors described in the previous section was investigated in a series of laboratory experiments using an experimental model filled with damp compacted sand.[20] In the first experiment, surface motion was measured using both a ground contacting sensor (a gravity-biased sensor with a total 156 g tail mass) and a commercial LDV in the same location without the sensor present. The sensor and LDV outputs, corrected for the frequency responses of receiving electronics, were used to generate the transfer function that is plotted in Fig. 3, along with the model prediction for this transfer function. The deviations from the predicted behavior are attributable to several sources, including the calibration of the LDV and the accelerometer that were used, the different areas of the surface that are sampled by each sensor, and the nonlinear elasticity of the sand. Below 1 kHz, the sensor deviates from ideal behavior by less that 20% in amplitude and 10° of phase. Most of the structure above 1 kHz is due to the difference between the footprints of the two sensor types, which made their sensitivities vary for each of the different modes of propagation that were present. This is a complex wavefield that includes several modes of surface-guided and bulk waves in addition to the dominant Rayleigh wave. The model assumes that ground is locally reactive and that both sensors would be equally responsive to all components of the incident signal.

Although the sensor has been modeled as a linear 2-DOF system, sand and soils have shown significant non-

incrementally using a cradle that was not in contact with it during a measurement. The tail mass was a composite made of a 46 cm long 19 mm outer diameter aluminum tube with steel collars attached to it. The long tube permitted the sensor to conform to topography within the array's contact area and the collars allowed for incremental adjustments of the tail mass/biasing force. Each collar was 52 g and the minimum tail mass was 156 g (the mass of the tube with a single collar). The first sensor was one of a kind. The second sensor was built in a quantity of 50 and was designed for use in much larger arrays. The accelerometer for this sensor was selected based primarily on cost and size rather than sensitivity or mass. Here an Analog Devices ADXL103 iMEMs accelerometer was chosen at a cost of less than 1/20th that of the other accelerometers that had been used. This accelerometer had a specified sensitivity and noise density of 1 V/g and 110 μg/$\sqrt{\text{Hz}}$, respectively.

In both sensor designs, the spring represented by k_1 was a section of foam pipe insulation. This permitted the sensor head to move laterally with respect to the tail mass, and to rotate about any axis so that the sensor could be coupled to rough or inclined surfaces and it would not constrain horizontal motion of the ground. This was necessary because the surface motion associated with a Rayleigh wave is elliptical in nature,[12] even though the sensor was only intended to measure its vertical component. The compressive stiffness of the foam springs used in these sensors was measured on a load frame to be 5.4×10^3 N/m for the first design, and

FIG. 4. Accelerations measured from linear scans of a spring-biased sensor away from a seismic source with biasing forces of (A) 1.1 N, (B) 3.6 N, and (C) 11.4 N.

ferences caused by ambient noise. The differences between these plots, which share a common vertical scale, are therefore an indication of nonlinearity. In Fig. 4(A), a 1.1 N biasing force is seen to be sufficient to detect the incident wave and the presence of the buried mine. There are small differences (other than delays) in these waveforms that are indicative of small changes in the sensor's coupling from point to point. In Figs. 4(B) and 4(C), the biasing force is increased to 3.6 N and 11 N, respectively. Here the reproducibility can be seen to improve with the increased biasing force, but the amplitudes of the measured responses change because of the nonlinearity of the sand. For this effect to pose a problem with respect to landmine detection, it would have to degrade the contrast between the mine and the background in addition to reducing the measured response. This is, of course, a function of the algorithm that is used to convert the measured data into an image. Using imaging techniques that have been reported in previous papers, the data shown in Figs. 4(B) and 4(C) will yield nominally identical contrast after processing.[20] With these techniques, the data collected with the 1.1 N biasing force yield a contrast that is degraded by 6–12 dB with regard to the other data sets as a consequence of the reproducibility of the sensor's coupling, rather than the mean fidelity of the measurements. Since this was a synthetic array measurement, the possibility that nonlinearity might adversely affect sensor-to-sensor coupling could not be considered in this analysis.

In another fidelity-related experiment a 20 g sensor head was constructed using a triaxial accelerometer (PCB model W356CA12), with sensitivity and intrinsic noise density comparable to the VMI 9002 accelerometer. This was attached to the spring-biased suspension and used to measure the three components of acceleration on the surface of the damp compacted sand in the experimental model. Figure 5 shows the displacements in the surface normal (Z) and propagation (X) directions that were generated by integration of measurements made 1.5 m from the seismic source. The experiment is configured so that lateral (Y) displacements are negligible in comparison to the other two displacement components. In Fig. 5(A), measurements with a 1.1 N biasing force show that the motion at this location is dominated by two temporally separate pulses. The first of these is characterized by prograde elliptical motion and is consistent with a leaky surface wave (head wave).[24–26] The second arrival is a larger pulse characterized by retrograde elliptical motion that is consistent with a Rayleigh wave. Although a ground truth for this measurement is not available, the measurement is a reasonable match to measurements made with shallow-buried accelerometers in the same model.[23] The measurement indicates that the sensor has not inordinately constrained in-plane motions at the measurement point. In Fig. 5(B) the same measurement is depicted with a 6.2 N biasing force. It is interesting to note here that the nonlinearities apparent in measurements of the surface normal motion do not equally affect both dominant wave types. The motion associated with the leaky wave, which is mediated by compression, is barely altered by the increased biasing force. The

linear behavior.[21–23] In terms of sensor function, this can manifest itself in a modification of the complex stiffness of the ground at the measurement point (k_0 and η_0) as a function of the applied force at that point. To test this, a series of measurements was made using the spring-biased sensor. The biasing force was progressively increased through the compression of the linear coil spring (k_2), while all the dynamic characteristics of the sensor remained unchanged. The data from these measurements are depicted in the waterfall plots shown in Fig. 4. Each plot here represents 101 measurements made 1 cm apart as the sensor is moved away from the seismic source. The positively sloped diagonal connection of the wavefronts of the largest arrivals in these plots represents the incident Rayleigh wave. The enhanced response 50 cm from the source, and backward propagating waves that originate there, are due to a TS50 AP mine that was buried 1 cm below the surface. If the sensor and medium were perfectly linear, each data set would have been identical aside from the dif-

FIG. 5. Hodograms of the displacement measured by a triaxial spring-biased sensor with (A) with a 1.1 N biasing force and (B) with a 6.2 N biasing force.

motion associated with the Rayleigh wave, which is mediated by shear, shows a significant change in both polarity and amplitude at the measurement point.

Although it has not yet been tested experimentally, in-plane displacement information that can be sampled with the ground-contacting sensor, but was not previously available with the radar-based vibrometer, may be exploitable for enhancing the contrast of landmine images. Smith *et al.* have

demonstrated the use of rotational polarity filters to enhance beamforming in a seismic landmine detection system based on pulse echo techniques.[3] Although these techniques have not been extended a full wave-field-imaging seismic system, rotational polarity may offer an additional cue to landmine trigger motion.

V. GROUND COUPLING

As mentioned in the previous section, the reproducibility of ground coupling between sensors and measurement locations appears to be a more significant operational problem than the mean fidelity of measurements. Figure 4 clearly demonstrates that reproducibility is directly related to biasing force; however Figs. 4 and 5 demonstrate that there is a cost in terms of fidelity to arbitrarily increasing this. Although the lost fidelity may not pose a problem for landmine imaging (neglecting a possible effect on mutual scattering), increased biasing force is a potential problem in terms of risk to a system operator. For the data shown in Fig. 3, for example, the largest biasing force that was used (11.4 N) could be sufficient to detonate some types of AP landmines, whereas the smallest allowed a safety factor of at least 10.[14] There is also a cost associated with increasing biasing force in a large array, because the backing structure must support the total load associated with the biasing force. A 1000 sensor array requires a structure with lifting capacity of at least 0.1 ton per N of sensor biasing force. For these practical reasons, it is desirable to achieve reproducible coupling with a minimal biasing force.

In the laboratory model, a variety of contact feet and biasing forces were tested in different sensor designs. A subset of three of these contact feet were tested with several biasing forces in a field experiment to see if one of these permitted acceptable point-to-point reproducibility with a lower biasing force than the others. The three designs that were tested were a flat 1.6 cm diameter disk of Sorbathane™ elastomer, a 90° right-circular polycarbonate cone, and a 60° right-circular polycarbonate cone. The three foot designs were tested at a field site located at a government test facility over a simulated dirt road surface, a gravel-covered roadbed, and a grass-covered surface of comparatively loose dry soil. Data acquired using a 60° conical foot with a 5.6 N biasing force on each these surfaces are depicted in Fig. 6. Each of the data sets shown in this figure represents a linear scan over an area with no known buried targets. It is clear from the figure that a surface wave is sensed for each of the conditions. A common vertical scale normalized by the source's driving current is used for all three plots (the absolute acceleration is irrelevant because a pulse-compression scheme was employed for the measurement[27]). Thus, for a given driving force, which is directly related to drive current for the electrodynamic source, the greatest acceleration response is seen in the gravel roadbed [Fig. 6(B)] and the least response in the grassy area [Fig. 6(C)]. Although the input impedance of the roadbed is higher than the impedance in the grassy area, poor soil consolidation results in more propagation loss and source-coupling nonlinearity in the grass. Similarly, the dirt roadbed [Fig. 6(A)] is a midpoint in
FIG. 6. Windowed waterfall graphs of measured accelerations in a 1 m linear scan away from a seismic at a field site in (A) a dirt roadbed, (B) a gravel roadbed, and (C) a grass-covered area.

FIG. 7. Transfer function of a single ground-contacting sensor in rectangular array/alone (A) amplitude and (B) Phase. Source and sensor locations are shown in inset.

terms of consolidation since it contains finer particles than the grass's sandy soil, and larger rounder particles than the crushed granite base of the gravel roadbed. It is clear from the figure that the soft soil and grass pose a greater reproducibility problem than the rough surface and loose stones of the gravel roadbed. All three of the foot designs were tested with biasing forces down to 1.5 N (the minimum permitted by the hardware configuration). This biasing force proved sufficient in the dirt and gravel roadbeds. Unfortunately, the test range that was used did not include either grass-covered landmine burials or grass-covered regions of sifted soil. Given the history of the site, it is likely that both manmade and natural scatterers (tree roots, rocks, etc.) were present in the grassy area. Thus a direct comparison to the other two carefully controlled soil conditions is difficult.

VI. MUTUAL SCATTERING

Although the ground-contacting sensors were designed to be suitable for large physical arrays, these arrays pose a potential problem as compared to noncontact sensor arrays in that the motions of individual sensors may couple through the ground and impede the function of the array. To thoroughly test coupling effects experimentally would require a very large number of sensors or suitable dynamic surrogates. Because these were not available, limited testing of interaction effects was performed using the sensors that were constructed for the field test.

The mutual scattering experiment involved a rectangular array of 10 sensors in the direction of the source (X), and 3 sensors parallel to the incident wavefronts (Y). The spacing of these elements was 3.4 cm × 10 cm in each direction, respectively. In the experiment, the array was first populated by a single centrally located sensor positioned 1.5 m from the seismic source in the laboratory experimental model. The remaining elements of the array were then populated without disturbing the first sensor. The array's transfer function was constructed as the ratio of the first sensor's response to a seismic incident signal within the array to that sensor's response when the other array locations were empty. This transfer function is plotted in Fig. 7. From the figure, it is apparent that between 150 Hz and 1100 Hz the surrounding
array reduces the output of the sensor slightly ($\lesssim 3$ dB). A small amplification below 150 Hz appears to be indicative of changes in the background noise, which was produced by machinery in adjoining laboratories. The spike at ~1300 Hz is due to a slight downward shift in a spectral null that was caused by interference of the various modes and paths comprising the received signal when the array was populated. The phase of the transfer function shows that there is a delay (linear frequency-phase relationship) between the two measurements. This delay is approximately 14 μs, with the sensor-in-array output leading that of the lone sensor. A plausible explanation for this is that there is a local increase in the shear modulus of the sand around each sensor that is caused by the applied biasing force. This is consistent with the observed reduction in sensor response that results from increasing the biasing force. If this delay is equated with a change in propagation speed over the portion of the array that lies between the sensor and the source (5 sensors spanning 17 cm), it predicts that the array increases the incident signal's mean propagation speed (dominantly the Rayleigh wave speed, although other modes are present) by approximately 1% over its extent. If the problem is viewed as a one-dimensional transmission line, the propagation speed change can only account for a 0.5% amplitude reduction in signal level. More likely explanations for the reduced sensor output observed following the introduction of the array are that it is due to loss in the foam springs of the intervening sensors, or due to shadowing.

VII. LANDMINE IMAGING

The field experiment that was done to evaluate sensor performance involved a linear array of 32 gravity-biased sensors with 156 g tail masses spaced 3.2 cm apart. The array was scanned in 32 steps perpendicular to its alignment to form a semisynthetic 1 m^2 planar array. Figure 8 shows the experimental setup that was used at the field site. The seismic source was oriented both for a broadside and for an
FIG. 8. Configuration of field experiment: (A) photograph of system on simulated dirt roadbed and (B) layout of experiment at field site.

end-fire illumination of the linear array. Although this should have provided insight into mutual scattering effects, the roadbeds at the test site exhibited significant horizontal anisotropy, which was the dominant difference between the two incident signal aspects. There was a horizontal gradient in surface wave speed of the roadbed, which slowed near both shoulders. For all of the measurements, the linear array was located perpendicular to the roadbed. Thus, the end-fire measurements required the source to be located in the low-speed region.

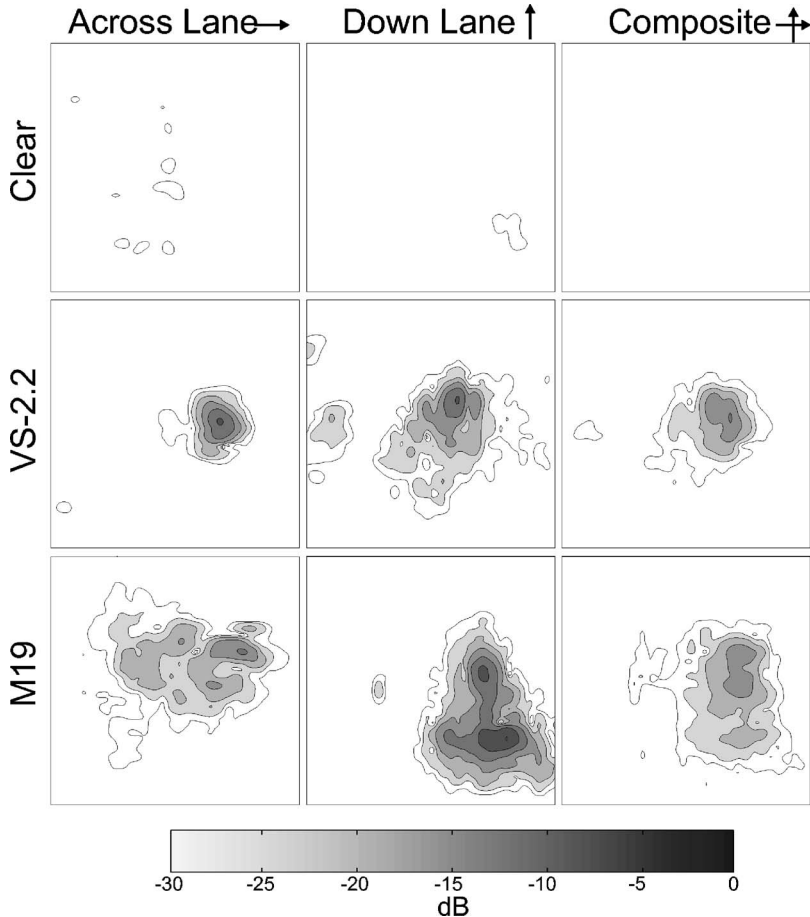
Processed images from the field measurements for various landmine types, road conditions, and propagation directions are depicted in Figs. 9 and 10. Figure 9 contains images formed with data collected in a dirt roadbed, and Fig. 10 shows images from an adjoining gravel roadbed. The targets were all AT landmines or landmine simulants that had been well-weathered in place prior to the experiment to ensure that none of the detections were tied to trenching effects. The array was located to place targets in the approximate center of the scan region, but some of the targets' locations were not well-known and these are offset slightly. Collectively, the images demonstrate sufficient reproducibility and fidelity across the array for the conditions that were examined. This is remarkable given the size of the largest stones on the gravel roadbed, which was comparable to the diameter of the sensor. At many measurement locations, sensors were in contact with a single stone, and sensors frequently sat at steep angles of repose atop these stones. Due to the anisotropy of the roadbeds, there are obvious differences in the images


FIG. 9. Images of AT landmines in a dirt roadbed at the field test site: Rows represent mine types as labeled and columns represent the propagation direction of the interrogation signal with he roadbed as labeled. Color is scaled to the maximum pixel value (M19, down lane).

formed using different source locations in otherwise identical scans. Images formed from incident seismic signals that propagated perpendicular to the road bed (shown in the first columns of Figs. 9 and 10) generally show less background contrast than those that were formed from incident signals propagating parallel to it (shown in the middle columns of the figures).

All of the data were processed with an imaging algorithm that had been developed and refined for use with synthetic array measurements employing a radar-based sensor. The algorithm does not account for the spreading and attenuation of the incident signal and is therefore more sensitive to objects closer to the source. The algorithm may also smear large targets in the direction of the source. Thus, clutter in the original data, regardless of its cause, will produce image clutter that is dependent on its location relative to both the seismic source and the buried target.

In a system designed to search progressively through a region, the deficiencies of the imaging algorithm would need to be accepted or remedied through the use of alternative signal processing techniques. The confirmation-system application that was previously discussed permits this problem to be addressed through a reconfiguration of system hardware. Since the region to be inspected has been prescribed on all sides for the confirmation system, it may be illuminated from any direction or from multiple directions. Each different look direction will result in a shift of the artifact-dominated contributions to the background, while the location of buried objects will be fixed in space. This is apparent in the corresponding pairs of images in the first and second columns of Figs. 9 and 10. It should therefore be possible to improve resolution in the resulting image by combining data from several look directions. This can be done without adding to measurement time by exploiting spread spectrum techniques and simultaneously exciting all of the sources with coded signals.[28,29]

The potential to improve image resolution and contrast with multiple look directions was tested with data collected in the field experiment because the laboratory model is not large enough to permit this sort of experiment. The images shown in the first two columns of Figs. 9 and 10 were combined to form the corresponding images in the third column. The images were combined by taking the square root of the product of corresponding image pixel values. The combined images show better spatial resolution than either of their precedents. The reduction in the overall background ($\sim$3 dB) is not as striking as the reduction of the peak levels measured over some of the landmines. Improved spatial resolution is particularly apparent for the data collected over the SIM30 landmine simulant in the gravel roadbed. Here the combined image clearly outlines the perimeter of the simulant. Any number of data sets collected using different source locations could be integrated in this way, although there are other schemes that can be used to combine these data sets, which may offer advantages over the chosen technique.

VIII. CONCLUSIONS

Ground contacting sensors have been designed, built and tested for use in a seismic landmine-detection system. The sensor design that has been considered is not as easily scanned as noncontacting sensors are, but is suited to the incremental motion of a detection-confirmation system. Its deployment requires that a psychological barrier to touching the ground above a buried mine be overcome. Experimental testing indicates that the current design is capable of meeting reasonable requirements for cost, sensitivity, fidelity, nonintrusion, reproducibility of ground coupling, and large-array compatibility. Measurements that have been conducted with these sensors in both a laboratory model and at a realistic outdoor site reveal that the most significant deviations from ideal behavior are attributable to the nonlinearity of the soil that a sensor contacts.

A general way to enhance the sound absorption capability of polyurethane foam is the use of a nonplanar surface such as the pyramidal surface. The use of the pyramidal surface can greatly enhance the sound absorption of the foam in the mid and high frequency ranges. In this study, a three-dimensional finite element frequency domain acoustical analysis is used to analyze the normal incidence sound absorption of the pyramidal polyurethane foam. Such a numerical method is more efficient than the earlier studies by saving the calculation time on the elements of the incident acoustic field. In the study, the maximum broadband averaged normal incidence sound absorption of the pyramidal polyurethane foam is pursued based on the change of the pyramidal shape. The variation of the pyramidal shape is performed by changing the angle between two sides of a pyramid but keeping the pyramid base and the foam volume the same throughout the study. It is found that the pyramidal polyurethane foam with pyramidal angle of 29° has the highest broadband averaged normal incidence sound absorption in the 100–4k, 500–4k, as well as 2k–4k Hz ranges. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354044]

I. INTRODUCTION

Upon the enhancement of the absorption coefficient in the desired frequency band, foams with complex other than planar surface are usually produced. Conventionally, acoustical properties of foams are numerically analyzed by applying the time-domain porous finite elements coupled with finite elements of an incident acoustic field with which the foam is in contact. The transmission and reflection waves that characterized acoustical properties are then solved. Among these analyses, two major constituent models for describing acoustical properties of foams can be found. First, the foam is seen as an isotropic mixed fluid and the propagation of sound is determined by the empirical power law expressions of air resistance divided by frequency[1] or other physical parameters.[2] In the other aspect, the acoustical properties of the foam are described by the Biot's theory of poroelasticity.[3–5]

Based on the isotropic mixed fluid constituent model, Craggs[6,7] analyzed a one-dimensional, plane or axisymmetric acoustic absorption system for obtaining the absorption coefficient. Easwaran and Munjal[8] predicted the reflection characteristics of rectangular and conical wedges in an impedance tube. Later, Chen *et al.*[9] investigated the absorption coefficient of corrugated porous materials with triangle, semicircle, and convex rectangular surface shapes. There is only one longitudinal wave to be analyzed, if the foam is presumed as an isotropic mixed fluid. To design the acoustical properties of foams, methods that combine the acoustic field with the foam modeling by the Biot's poroelastic theory are more effective. Since, behaviors of two longitudinal waves and one shear wave of the foam can be analyzed. Using the Biot's theory, Kang and Bolton[10] studied the optimal design of axisymmetric foam wedges. Heretofore, the additional acoustic field is needed to perform simulations.

In order to eliminate the use of the incident acoustic field, Tsay and Yeh[11] applied the Biot's theory and used a normal incident impulse pressure excitation to actuate directly on the upper surface of a rigidly backed planar foam. After applying this new approach, the exact acoustic property solutions of planar foams with permeable or impermeable upper surfaces were successfully derived. Later, this approach was extended and the finite element frequency domain acoustical analyses with triangular, four-node quadrilateral, and four-node tetrahedral porous elements were formulated.[12,13] Based on the newly developed finite element frequency domain methods, the acoustical properties of planar polyurethane foams were analyzed. Subsequently, the influence of circumferential edge constraint on the acoustical properties of polyurethane foam samples was examined.

In this study, the three-dimensional finite element frequency domain acoustical analysis with tetrahedral porous elements is applied to analyze the normal incidence sound absorption of the pyramidal polyurethane foams. In the following sections, the three-dimensional finite element frequency domain acoustical analysis and material properties are briefly introduced, and the pursuing of pyramidal shape of the maximum broadband averaged normal incidence sound absorption based on the constraints of constant foam base and constant foam volume is studied.

II. THREE-DIMENSIONAL FINITE ELEMENT FREQUENCY DOMAIN ACOUSTICAL ANALYSIS

A. Finite element model

The acoustical properties of the pyramidal polyurethane foam shown in Fig. 1 with it base fixed on an impermeable rigid plane are investigated in this study. One section of the pyramidal polyurethane foam is presented in Fig. 2. In Fig. 2, L and W are the length and width of the pyramid base, H is the height measured from the base to the tip, H_s is the height of the side edge, θ is the angle between two sides of a pyramid, and $p_0\delta(t)$ is the normal incident impulsive sound pressure loading of amplitude p_0. It is noted that the pyramidal polyurethane foams considered in this study are assumed to be stressed from the initially un-deformed position. Hence, the initial conditions for the foam are $u_i=0$, $U_i=0$, $\dot{u}_i=0$, and $\dot{U}_i=0$ ($i=x,y,z$) at $t=0$. u_i and U_i ($i=x,y,z$) are displacement components of the solid skeleton and the fluid, respectively. The foam is stress free at the initial state, thus, all stresses are zero at $t=0$. According to the Biot's poroelastic theory and the Cartesian coordinates shown, the dynamic equations for the three-dimensional foam problems after Laplace transform with respect to the time variable t can be written in a compact form[13] as

FIG. 3. Four-node tetrahedral porous element.

$$N\nabla^2\bar{u}_i + \nabla[(A+N)\bar{u}_{i,i} + Q\bar{U}_{i,i}]$$
$$- s^2(\rho_{11}\bar{u}_i + \rho_{12}\bar{U}_i) - bs(\bar{u}_i - \bar{U}_i) = 0, \tag{1}$$

$$\nabla(Q\bar{u}_{i,i} + R\bar{U}_{i,i}) - s^2(\rho_{12}\bar{u}_i + \rho_{22}\bar{U}_i) + bs(\bar{u}_i - \bar{U}_i) = 0, \tag{2}$$

where N, A, Q, and R are elastic constants; b is the dissipation coefficient; ρ_{11}, ρ_{22} and ρ_{12} are apparent mass densities. ∇^2 is the Laplacian and ∇ is the gradient. $\bar{u}_i$ and $\bar{U}_i$ are the Laplace transforms of u_i and U_i ($i=x,y,z$). s is the Laplace transform parameter.

In the previous study,[13] the Galerkin finite element method with four-node tetrahedral porous elements was first applied to obtain acoustical properties of the planar polyurethane foam in Laplace domain. Figure 3 shows a four-node tetrahedral porous element. Upon considering three Cartesian coordinate components of displacements of the solid skeleton and of the fluid at each node, the column vector of displacements of a four-node tetrahedral porous element with 24 degrees of freedom was presented as $q=[q_1,\ldots,q_{24}]^T$. In Fig. 3, $P(x,y,z)$ represents an arbitrary point within an element. In terms of a natural coordinate system (ξ,η,ζ), the tetrahedral porous element defined with reference to the Cartesian coordinate system (x,y,z) was transformed into a master element as shown in Fig. 4. $P(x,y,z)$ after the coordinate system transformation was expressed as $P(\xi,\eta,\zeta)$. According to the natural coordinates defined, four Lagrange-type shape functions for the tetrahedral porous element were represented as

FIG. 2. Pyramidal polyurethane foam with its upper surface subjected to a normal incident impulsive sound pressure loading.
FIG. 4. Four-node master element in ξ, η, and ζ space.

$$M_1 = \xi, \; M_2 = \eta, \; M_3 = \zeta, \; M_4 = 1 - \xi - \eta - \zeta. \qquad (3)$$

With the use of the column vector of displacements $\boldsymbol{q}$ and the shape functions defined, the solid skeleton and fluid displacement components were further written in a matrix form as

$$\hat{\boldsymbol{u}} = \boldsymbol{M}\boldsymbol{q}, \qquad (4)$$

where $\hat{\boldsymbol{u}} = [\bar{u}_x, \bar{u}_y, \bar{u}_z, \bar{U}_x, \bar{U}_y, \bar{U}_z]^T$ and $\boldsymbol{M}$ is the shape function matrix, which is shown in Appendix A. Following the Galerkin approach, the equation governing the dynamic behavior of the tetrahedral porous element was derived, which is presented in Appendix B. After the substitution of shape functions [Eq. (3)] and displacement components [Eq. (4)], the dynamic equation of the tetrahedral porous element [Eq. (B1)] was simplified as

$$\sum_{e=1}^{n} [\boldsymbol{K}^{(e)}\boldsymbol{q} - \boldsymbol{F}^{(e)}] = 0, \qquad (5)$$

where $\boldsymbol{K}^{(e)}$ is the stiffness coefficient matrix for the element and $\boldsymbol{F}^{(e)}$ is viewed as the loading vector which contains boundary conditions. A section of the pyramidal polyurethane foam can be analyzed by discretizing it with tetrahedral porous elements. The individual element equations would then be assembled to form the equations for the pyramidal polyurethane foam. After manipulations, the Laplace domain finite element equation for the pyramidal polyurethane foam can be obtained as

$$\boldsymbol{K}^* \boldsymbol{q}^* = \boldsymbol{F}^*, \qquad (6)$$

where $\boldsymbol{K}^*$ is the global stiffness matrix, $\boldsymbol{q}^*$ is the global displacement vector, and $\boldsymbol{F}^*$ is the global loading vector. The Laplace transformed dynamic stiffness $\bar{K}(s)$ evaluated from the top surface of the pyramidal polyurethane foam for normal incidence case can then be defined as $\bar{K}(s) = -p_0 / [(1-\phi)\bar{u}_z + \phi\bar{U}_z]$. Once the Laplace transformed dynamic stiffness $\bar{K}$ is obtained, the Laplace transformed surface acoustic impedance $\bar{Z}$, the reflection coefficient R_0, and the sound absorption coefficient A_0 can be formulated as

$$\bar{Z} = \frac{\bar{K}(s)}{s}, \qquad (7)$$

$$R_0 = \frac{\bar{Z} - Z_{\text{air}}}{\bar{Z} + Z_{\text{air}}} = \frac{\bar{K}(s)/s - Z_{\text{air}}}{\bar{K}(s)/s + Z_{\text{air}}}, \qquad (8)$$

$$A_0 = 1 - |R_0|^2, \qquad (9)$$

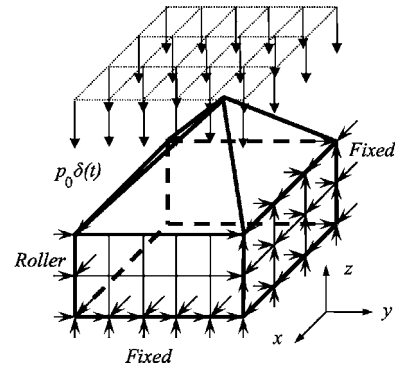
where Z_{air} is the characteristic impedance of air. Frequency response functions of K, Z, R_0, and A_0 can be obtained by replacing the Laplace transform parameter s that appears in Eqs. (7)–(9) by $j\omega$, where ω is the radial frequency.


FIG. 5. Boundary conditions of a pyramidal polyurethane foam.

B. Boundary conditions

As shown in Fig. 5, the amplitude of the normal incident impulsive sound pressure loading applied on the top surface of the pyramidal polyurethane foam is presented as $p = p_0\delta(t)$. If the top surface of the pyramidal polyurethane foam is permeable, the solid skeleton and the fluid of the foam, depending on the porosity, share the pressure loading. Thus, the boundary conditions of the solid skeleton and the fluid on the top surface after the Laplace transform can be described as $\bar{\sigma}_{zz} = -(1-\phi)p_0$ and $\bar{\sigma} = -\phi p_0$, respectively. The base of the pyramidal polyurethane foam is presumed to be fixed on an infinite rigid plane. Hence, the Laplace transformed solid skeleton and fluid displacements are zero on the base of the pyramid.

The side edge surfaces of one section of the pyramidal polyurethane foam can be all set as roller condition for simulating a laterally successively extent pyramidal foam, which is shown on the left-hand side edge surface. The roller condition implies that the node can freely move up and down but not to the sides; hence, the Laplace transformed solid skeleton and fluid displacements normal to the side edge surfaces can all be set as zero. For the case that a side edge surfaces of one section of the pyramidal polyurethane foam is glued to a rigid surface, the side edge restraints can be simulated as fixed, as presented on the right-hand side edge surface. Same as the condition of the pyramid base, fixed condition implies that the solid skeleton and fluid displacements are all zero on the edge surface.

III. MATERIAL PROPERTIES OF POLYURETHANE FOAMS

In order to predict the acoustical frequency response functions of the pyramidal polyurethane foam, the apparent mass densities ρ_{11}, ρ_{12}, ρ_{22}, the dissipation coefficient b, and the elastic constants N, A, Q, R can all relate to the foam constituents, porosity ϕ, tortuosity α_∞, pore cross-section shape correction factor c, and direct current (dc) flow resistivity σ_0. The typical material properties of polyurethane foam saturated with air were discussed in detail in the previous study[11] and are summarized as follows.

Based on the tortuosity, the coupling apparent mass ρ_{12} was represented as $-\phi\rho_f(\alpha_\infty-1)$. Subsequently, the total effective mass of the solid and fluid, ρ_{11} and ρ_{22}, were defined as $(1-\phi)\rho_s-\rho_{12}$ and $\phi\rho_f-\rho_{12}$. ρ_f is the mass density of fluid and ρ_s is the mass density of solid. The Laplace transformed dissipation coefficient $\bar{b}$ defined in the dynamic poroelastic theory was reformulated as

$$\bar{b} = \frac{-\sigma_0}{4}\phi^2\left\{\frac{[m_{r_0}J_1(m_{r_0})]/[J_0(m_{r_0})]}{1-[2J_1(m_{r_0})]/[m_{r_0}J_0(m_{r_0})]}\right\}, \tag{10}$$

where J_0 and J_1 are Bessel functions of the first kind of order zero and one. The dc flow resistivity σ_0 was derived as $(8c\mu\alpha_\infty)/(\phi r_0^2)$. μ is the viscosity of air, r_0 is the radius of the pore, and c is a cross-section shape correction factor. Following the definition of the dc flow resistivity σ_0, the collected material coefficient m_{r_0} appearing in Eq. (10) can be rewritten as $m_{r_0}=c\sqrt{-8s\rho_{22}/(\sigma_0\phi^2)}$. Elastic coefficients of the polyurethane foams, A, Q, and R, were formulated as the combinations of porosity ϕ, the shear modulus of the solid skeleton in vacuum N, the bulk modulus of the solid skeleton K_b, and the bulk modulus of the fluid K_f as

$$A = \frac{(1-\phi)^2}{\phi}K_f + K_b - \frac{2}{3}N, \tag{11}$$

$$Q = (1-\phi)K_f, \tag{12}$$

$$R = \phi K_f. \tag{13}$$

For the air saturated polyurethane foams, N, K_b, and K_f are complex coefficients, and K_b was evaluated by

$$K_b = \frac{2N(1+\nu)}{3(1-2\nu)}, \tag{14}$$

where ν is the Poisson's ratio of the foam. The bulk modulus of air K_f was derived using the equation of state of air and the equation of thermal conduction of air. With the cross-section shape correction factor and tortuosity considered, the Laplace transformed bulk modulus of air $\bar{K}_f$ was formulated as

$$\bar{K}_f = \frac{p_{amb}\gamma}{\gamma-(\gamma-1)\{1-2/Bm_{r_0}[J_1(Bm_{r_0})]/[J_0(Bm_{r_0})]\}}, \tag{15}$$

where p_{amb} is the ambient mean pressure, B is the square root of the Prandtl number, and $\gamma = c_p/c_v$. c_v and c_p are specific heats per unit mass at constant volume and pressure, respectively.

IV. INFLUENCE OF PYRAMIDAL SHAPE ON THE NORMAL INCIDENCE SOUND ABSORPTION OF THE PYRAMIDAL POLYURETHANE FOAM

The normal incidence sound absorption results of the planar polyurethane foam of thickness 0.0508 m examined in the previous study[13] are used as comparators to that of the

TABLE I. Material properties of the polyurethane foam (See Ref. 11).

ϕ	Porosity	0.95
N (10^4 N/m^2)	Shear modulus	$55(1+0.2i)$
ν	Poisson coefficient	0.35
σ_o (N s/m^4)	dc flow resistivity	5500
α_∞	Tortuosity	1.0
ρ_s (kg/m^3)	Density of frame	45.7
c	Shape factor	1.0
h (m)	Thickness of foam	0.0508

pyramidal polyurethane foam as the pyramidal shape modified. The material properties of the planar polyurethane foam are presented in Table I and the normal incidence sound absorption coefficient of the foam is shown in Fig. 6. Figure 6 shows that the normal incidence sound absorption coefficients of the foam samples can be accurately predicted by the three-dimensional finite element frequency domain acoustic analysis (3D FEFDAA) with suitable boundary conditions. The broadband averaged normal incidence sound absorption coefficient of the planar polyurethane foam at $1k$–$4k$ Hz range is around 0.87 and there is a possibility for the enhancement of the sound absorption coefficient of the foam through the change of its surface shape from plane to pyramid.

In the following study, the diameter of 0.0395 m of the foam sample is arbitrary chosen as the width and length of the pyramid base and the dimension of the pyramid base is kept the same throughout the study. The influence of the change of pyramidal shape on the acoustical properties of the foam is studied based on the constraint of constant foam volume of $0.0395 \times 0.0395 \times 0.0508$ m^3 and is performed by
FIG. 6. Normal incidence sound absorption coefficient of the planar polyurethane foam backed with a rigid wall (See Ref. 13) (thickness =0.0508 m, sample diameter=0.0395 m).

TABLE II. Dimensions of pyramidal polyurethane foam models ($W=L$ =0.0395 m, volume=$0.0395 \times 0.0395 \times 0.0508$ m^3=7.9261×10^{-5} m^3).

Model	$\theta°$	H (m)	H_s (m)
1	21	0.1219	$0.3 \times 0.0508=0.0152$
2	24	0.1118	$0.4 \times 0.0508=0.0203$
3	29	0.1016	$0.5 \times 0.0508=0.0254$
4	36	0.0914	$0.6 \times 0.0508=0.0305$

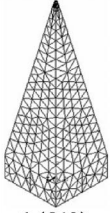
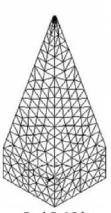
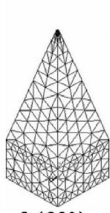
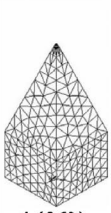
6	66	0.0711	$0.8 \times 0.0508=0.0406$
7	105	0.0610	$0.9 \times 0.0508=0.0457$
8 (Plate)	180	0.0508	$1.0 \times 0.0508=0.0508$

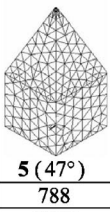
the change of the angle between two sides of a pyramid that is defined in Fig. 2. The dimensions and the model numbers of the pyramidal polyurethane foams examined are presented in Table II and the nodes, elements, and the tetrahedral porous element models of pyramidal foams used in the 3D FEFDAAs are shown in Fig. 7. In the 3D FEFDAAs, the elements are arranged symmetrically to the x and y axes, and the restraints of the nodes on the side edge surfaces of a pyramid section are assumed as rollers for simulating the laterally successively extent pyramidal foam.

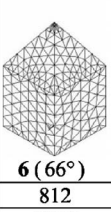
The analyzed results of the normal incidence sound absorption coefficients and the reflection coefficients of the pyramidal polyurethane foams are shown in Figs. 8 and 9, respectively. The analyzed normal incidence sound absorption coefficients and reflection coefficients results clearly show that the change of the upper surface of the foam from plane to pyramid does enhance the normal incidence sound absorption capability of the foam in the mid and high frequency regions ($1k$–$2k$ and $2k$–$4k$ Hz). Furthermore, the reduction of the pyramidal angle gradually increases the normal incidence sound absorption capability of the foam to a certain maximum then decreases its acoustic performance. Figure 10 and Table III show the broadband averaged normal incidence sound absorption coefficients of various pyramidal foams in


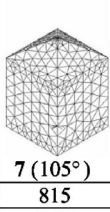












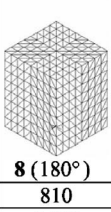


FIG. 7. Nodes, elements, and tetrahedral porous element models of the pyramidal polyurethane foams.

frequency ranges of 100–4k, 500–4k, and 2k–4k Hz. It is found that in all interested frequency ranges, the broadband averaged normal incidence sound absorption coefficients of the third model of the pyramidal foam are higher than that of other models. In the high frequency range (2k–4k Hz), the averaged normal incidence sound absorption coefficient of the third model of the pyramidal foam even reaches the value of 0.98. It is concluded that the third model of the pyramidal foam has the maximum broadband averaged normal incidence sound absorption coefficient among the models analyzed. Through the pyramidal foam analysis, one learned that the change of the surface shape of the foam can reach in different aspect of acoustic enhancement, and the acoustic results of the foam with arbitrary shape can be efficiently analyzed by the 3D FEFDAA.

V. CONCLUSIONS

The 3D FEFDAA, based on the Biot's dynamic poroelasticity theory, for foams with tetrahedral porous elements was introduced in this study. In addition, the use of the analysis for predictions of acoustic properties of pyramidal foams was demonstrated. The normal incidence sound absorption analyses performed in this study lead to the following conclusions.

The analysis developed in this study is more efficient than the earlier studies by saving the calculation time on the elements of the incident acoustic field, and it can be applied to design and predict the acoustic properties of three-dimensional foams such as the pyramidal foams examined in this study. The 3D FEFDAA can accurately predict the acoustic properties of the foams with suitable boundary conditions applied.

In the normal incidence sound absorption analyses of the pyramidal foams, the shape of the pyramid base and the foam volume are kept the same throughout the study. The influence of the change of the pyramidal shape is performed by changing the angle between two sides of a pyramid. It is concluded that the change of the upper surface of the foam from plane to pyramid can greatly enhance the normal incidence sound absorption capability in the mid and high frequency ranges (1k–2k and 2k–4k Hz). By reducing the pyramidal angle, the highest broadband averaged normal incidence sound absorption capability of the pyramidal foam can be pursued. It is found that the pyramidal polyurethane foam with the pyramidal angle of 29° has the highest broadband averaged normal incidence sound absorption coefficients in 100–4k, 500–4k, as well as 2k-4k Hz ranges Through this study, one learned that the change of the surface shape of the foam could reach in different aspect of acoustic enhancement.

M-ary frequency shift keying communications over an underwater acoustic channel: Performance comparison of data with models

Wen-Bin Yang and T. C. Yang
Naval Research Laboratory, Washington DC 20375

The bit error rate (BER) is modeled for *M*-ary frequency-shift-keying (MFSK) signals in a fading channel using different envelope amplitude statistics and compared with frequency-hopping (FH) FSK signaling data collected during the TREX04 experiment, which used Binary FSK (BFSK) for each symbol. The BER data is found to be significantly higher than that of a Rayleigh fading channel and is found to agree with that modeled with a *K*-distribution amplitude fading distribution. Using the parameters of the *K*-distribution, independently measured from the *M*-sequence data collected in the same experiment, the modeled BER as a function of the signal-to-noise ratio (SNR) agrees well with the measured BER within the SNR of the data. This suggests that the BER of FH-FSK signaling can be predicted given some prior channel characterization measurements. [DOI: 10.1121/1.2354463]

I. INTRODUCTION

Underwater acoustic communications are different from radio frequency (RF) communications in many aspects. Most notable are the limited bandwidth available for communications to a distance due to frequency-dependent propagation loss, the long multipath delays that cause intersymbol interference, and the rapid signal fluctuations due to random ocean media. The differences become an important element in the receiver design in order to optimize the communication performance. Likewise, performance modeling and the ability to predict performance depend on knowledge of the channel properties, such as the signal envelope amplitude distributions. Performance predictions for RF communications are generally not applicable to underwater acoustic channels without modifications.

Bit error rate (BER) performance in RF communications has been successfully modeled using the Rayleigh or Rician envelope amplitude distribution.[1–3] In this paper we analyze the BER for frequency-hopping frequency-shift-keying (FH-FSK) signals based on at-sea data collected during the TREX04 experiment. It is found that the BER for underwater acoustic channels is higher than that of a rf channel given the same signal-to-noise (SNR) ratio. The reason is that the envelope amplitude statistics for FSK signals do not follow the Rayleigh or Rician envelope amplitude distribution.

The FSK signaling scheme is referred to as incoherent communications, since detection of the signal symbols is based on the symbol energy only; no phase information is required. It is thus less sensitive to the channel fluctuations and provides a more reliable communication link. FSK signaling is widely used in RF communications due to the (relatively) short multipath delay and the wide bandwidth available. For multipath underwater acoustic communications, the FSK signaling scheme has a disadvantage in that it yields a low data rate; the longer the multipath delay, the slower the rate, since the symbol duration is generally on the order of the multipath spread. Despite this shortcoming, the FSK signal is useful for many applications. One of them is command and control of a remotely operable vehicle, which can tolerate a low data rate but requires a highly reliable acoustic communication link. Note that FH-FSK signaling, using the spread spectrum method, allows multiple users to communicate at the same time (multiaccess communications) with minimum interference between the users, without requiring (precise) time synchronization between the signals. The requirement for multiaccess communications between mobile platforms with variable communication latency provides the motivation to conduct the BER analysis for FH-FSK communications.

For underwater acoustic communications, the rapid medium fluctuations and the long multipath delays of the acoustic signals significantly increase the BER compared with that found in RF communications. How much higher is the BER, and for that matter, how to predict the BER for FSK signals for underwater channels, is the focus of this paper. To calculate the BER for FSK signals, one needs a model of the envelope amplitude probability distribution that fits the data. Previous data analysis by the authors has shown that the envelope amplitude distribution of *M*-ary FSK (MFSK) follows the *K*-distribution.[4] Hence, the *K*-distribution will be included in this paper, along with the Rayleigh and Rician distributions as candidate models for BER predictions. The purpose is to find the model that best fits with the BER data. For this study, FH-FSK data for a single user will be used to avoid interferences caused by multiusers. In this case, FH-FSK signals are treated equivalently as FSK signals (without hopping), assuming that the probability distributions for different frequency components are independent and identically distributed. BER for multiuser communications is beyond the scope of this paper.

II. ENVELOPE AMPLITUDE STATISTICS AND BER MODELING

BER for FSK communications has been modeled (for RF communications) using Rayleigh and Rician distributions. They are two of the models used here for comparisons. In addition, we also calculate the BER using the K-distribution.

An introduction of the K-distribution is in order here. The K-distribution has been used to model monostatic reverberation returns for high-resolution sonar.[5,6] As the sonar time resolution improves, the insonified area for backscattering decreases and the scattered return becomes less Rayleigh-like. The K-distribution is one of the non-Rayleigh distributions, which are characterized by a high-tail distribution; namely, the percentage of its high amplitude distribution is higher than the Rayleigh distribution.

For high frequency sound propagation through a random ocean, recent measurements of the envelope amplitude distribution based on experimental data (M-sequence) have suggested that it is non-Rayleigh like and behaves like the K-distribution.[4] The reason is that the envelope amplitudes of high frequency signals follow a joint probability distribution described by a short-term (short-time scale) probability distribution conditioned on a long-term (long-time scale) probability distribution.[4] The short term fluctuation is presumably caused by the microfine structures in the ocean medium (e.g., turbulence) that have a time scale of seconds or less, whereas the long term fluctuation is caused by the fine structures (e.g., internal waves) that have a time scale of minutes or more. The parameters of the K-distributions were measured using a pseudorandom (M-sequence) signal.[4]

An empirical approach is taken in this paper using three probability distribution functions to fit data. It will be shown that (i) the BER data for FH-FSK signals are better fitted with the K-distribution model than either the Rayleigh or Rician model, and (ii) the parameters of the K-distribution determined from the FH-FSK signals agree well with that deduced previously from the M-sequence data. This implies that one can potentially predict the FH-FSK BER given some prior channel characterization measurements.

In this section, the Rician, Rayleigh, and K-distribution will be briefly reviewed and used to calculate the BER for MFSK signals. The BER predictions are compared with data in the next section.

A. Rician/Rayleigh distribution

Rayleigh and Rician distributions have been used to model a mobile radio channel in which the (narrow band) signal amplitudes (in-phase and quadrature components) are assumed Gaussian distributed. For the Rician distribution, the probability density function for the envelope amplitude z is given by[7]

$$p_z(z) = \frac{z}{\sigma^2} \exp\left(-\frac{z^2 + \mu^2}{2\sigma^2}\right) I_0\left(\frac{\mu z}{\sigma^2}\right), \quad z \geq 0, \tag{1}$$

where z is the amplitude; μ and σ depend upon means and variances of the in-phase and quadrature components, and I_0 is the modified Bessel function of the first kind of zeroth

order. The first and second moments of Z are[7]

$$E\{Z\} = \sqrt{\frac{\pi}{2}} \sigma \cdot \exp(-\overline{K}/2) \cdot [(1 + \overline{K}) \cdot I_0(\overline{K}/2)$$
$$+ \overline{K} \cdot I_1(\overline{K}/2)], \tag{2}$$

$$E\{Z^2\} = 2\sigma^2 + \mu^2 = 2\sigma^2(1 + \overline{K}), \tag{3}$$

where $\overline{K} = \mu^2/2\sigma^2$ is a Rician parameter and is defined as the power ratio of the deterministic (specular) to random (scatter) component of the signal. I_1 is the modified Bessel function of the first kind of first order.

The Rayleigh distribution is a special case of the Rician distribution when $\mu = 0$ (or $\overline{K} = 0$). The Rayleigh distribution is as below.

$$p_z(z) = \frac{z}{\sigma^2} \exp\left(-\frac{z^2}{2\sigma^2}\right), \quad z \geq 0. \tag{4}$$

The first and second moments of the Rayleigh distribution are given by

$$E(Z) = \sqrt{\pi/2} \cdot \sigma \tag{5}$$

and

$$E(Z^2) = 2\sigma^2. \tag{6}$$

B. *K*-distribution

The K-distribution (see the Appendix) is parametrized with a shape parameter v and scale parameter α[5,6]

$$p_z(z) = \frac{4}{\sqrt{\alpha}\Gamma(v)} \left(\frac{z}{\sqrt{\alpha}}\right)^v K_{v-1}\left(\frac{2z}{\sqrt{\alpha}}\right), \quad z \geq 0, \quad \alpha > 0,$$
$$v > 0, \tag{7}$$

where K_{v-1} is the modified Bessel function of the second kind, of order $v-1$, and $\Gamma(v)$ is the Gamma function. The first and second moments of the K-distribution are as below.

$$E(Z) = \frac{\sqrt{\alpha\pi}}{2} \cdot \frac{\Gamma(v + 0.5)}{\Gamma(v)} \tag{8}$$

and

$$E(Z^2) = \alpha v. \tag{9}$$

A special case of the K-distribution is a Rayleigh distribution, which is obtained as $v \to \infty$ with αv remaining as a constant, $\alpha v = 2\sigma^2$.

To compare the characteristics of the various distributions, the amplitude probability distributions for Rayleigh, Rician, and K-distributions are plotted in Fig. 1(a), under the condition that they have the same second moment (the same average signal intensity), i.e., $E(Z^2) = 1$. For the Rayleigh distribution, one has $\sigma = 1/\sqrt{2}$. For the Rician distribution, $\sigma = 1/\sqrt{2(1 + \overline{K})}$, where $\overline{K} = 1$, 3.16, and 10 (corresponding to 0, 5, and 10 dB) are used. For the K-distribution one has $\alpha = 1/v$ with $v = 1$, 2, and 5.

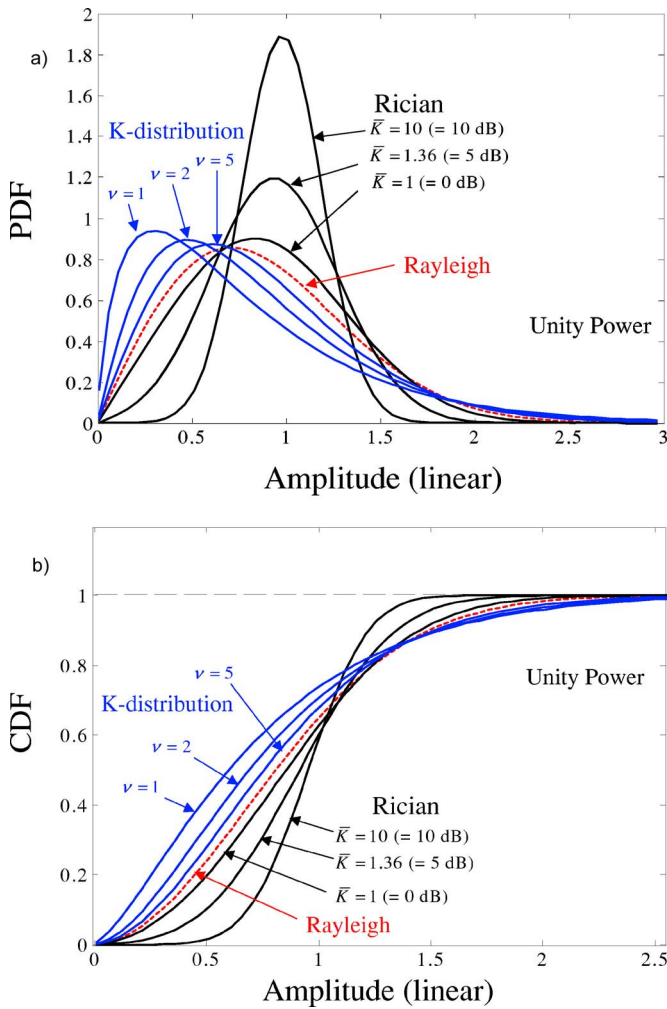
One notes that the mean amplitude of the distribution is the largest for the Rician distribution, followed by the Rayleigh distribution, and the K-distribution. In terms of the


FIG. 1. (Color online) A comparison of Rician/Rayleigh and K-distribution statistics in terms of (a) probability distribution functions and (b) cumulative (probability) density functions.

physical model of the signal, the Rayleigh distribution is described by randomly scattered arrivals. The Rician model describes a signal with a deterministic component plus a random component; hence, the peak distribution has higher amplitudes than the Rayleigh model. The K-distribution has a long tail for the high amplitude distribution. Relative to the high amplitude tail, the "random" component is concentrated at low amplitudes. The different nature of the distributions can be quantitatively summarized using the cumulative density functions (CDF), which are plotted in Fig. 1(b) for the three distributions. One notes also that the K-distribution has the highest CDF for low percentile (e.g., $<30\%$) distributions, followed by the Rayleigh and Rician distribution. For the high percentile (e.g., $>85\%$) distributions, the Rician distribution has the highest CDF, followed by the Rayleigh and K-distributions. These differences in the probability distributions have a direct bearing on the BER, as described later.

C. BER via an energy detector

In this section, the BER for a given SNR for MFSK signals is calculated using an energy detector, which is an incoherent receiver. For the incoherent MFSK, the conditional probability of symbol error under a given received signal amplitude z is[8]

$$p_s(\varepsilon|z) = \frac{1}{M}\sum_{i=2}^{M}(-1)^i\binom{M}{i}\exp\left[-\left(1-\frac{1}{i}\right)\rho\right], \quad (10)$$

where $M=2^q$ (q bits per symbol), σ_N^2 is the variance of Gaussian noise, and $\rho=z^2/2\sigma_N^2$ is the SNR.

Now consider the fact that the signal has a fading distribution. The probability of symbol error is then given by

$$p_s(\varepsilon) = \int_0^\infty p_s(\varepsilon|z)\cdot p_z(z)\cdot dz. \quad (11)$$

The relationship between the probability of symbol error and the probability of bit error for the MFSK signal is given by[3]

$$p_b(\varepsilon) = \frac{M}{2(M-1)}p_s(\varepsilon). \quad (12)$$

The probability of bit error for MFSK over a Rician fading channel can be derived using Eq. (1) and Eqs. (10)–(12). (For a derivation, see, for example, Ref. 9.) The probability of bit error is found to be

$$p_b(\varepsilon) = \frac{1}{2(M-1)}\sum_{i=2}^{M}(-1)^i\binom{M}{i}\frac{\dfrac{1+\overline{K}}{m_\rho}}{\dfrac{1+\overline{K}}{m_\rho}+1-\dfrac{1}{i}}$$

$$\times\exp\left(-\frac{\overline{K}\left(1-\dfrac{1}{i}\right)}{\dfrac{1+\overline{K}}{m_\rho}+1-\dfrac{1}{i}}\right), \quad (13)$$

where $\overline{K}$ is the Rician parameter defined above, and m_ρ denotes the mean signal power over the noise power (mean SNR), which for the Rician distribution is: $m_\rho=E(z^2)/2\sigma_N^2 = \sigma^2(1+\overline{K})/\sigma_N^2$. The mean SNR is related to the SNR per bit by $m_\rho=qE_b/N_0$, where E_b is signal energy per bit and N_0 is power spectrum density of Gaussian noise.[3]

The probability of bit error for the BFSK signal assuming a Rayleigh distribution is obtained by setting $\overline{K}=0$ and $M=2$ in the above equation. One finds

$$p_b(\varepsilon) = (2+m_\rho)^{-1} = (2+E_b/N_0)^{-1}. \quad (14)$$

Assuming, on the other hand, that the amplitude distribution is given by the K-distribution, the probability of bit error for a MFSK signal can be derived using Eq. (7) and Eqs. (10)–(12). The derivation is given in the appendix. One finds

$$p_b(\varepsilon) = \frac{1}{2(M-1)}\sum_{i=2}^{M}(-1)^i\binom{M}{i}\frac{\nu}{\Gamma(\nu)}$$

$$\times\int_0^\infty u^{\nu-1}e^{-u}\frac{1}{\nu+\left(1-\dfrac{1}{i}\right)qu\dfrac{E_b}{N_0}}du. \quad (15)$$

For BPSK, the probability of bit error reduces to

W. Yang and T. C. Yang: Underwater acoustic communications channels
FIG. 2. (Color online) Uncoded bit error rate as a function of the E_b/N_0 for Rayleigh, Rician, and K-distribution fading channels.

$$p_b(\varepsilon) = \frac{v}{\Gamma(v)} \int_0^\infty u^{v-1} e^{-u} \left(2v + u\frac{E_b}{N_0}\right)^{-1} du. \quad (16)$$

The above probability of bit error is evaluated numerically to determine the BER for the BPSK signal. Figure 2 shows the BER as a function of the SNR per bit E_b/N_0, for the Rayleigh, Rician, and K-distributions, with the parameters given above. One notes that the Rician distribution with $\overline{K}=10$ dB has the lowest BER, whereas the K-distribution with $v=1$ has the highest BER. The BER for the Rayleigh distribution lies in between. The reason is that bit errors are normally caused by weak signals (low SNR). As shown in Fig. 1(b), the K-distribution has a higher CDF than the Rayleigh distribution for low percentile amplitudes; hence, it has a higher bit error than the Rayleigh distribution for the same SNR. Likewise, the Rician distribution has a lower CDF than

the Rayleigh distribution for low percentile amplitudes, and hence it has a lower BER than the Rayleigh distribution for the same SNR. It is noted that BER is orders of magnitude different for the three distributions when the SNR increases beyond 10 dB. The difference becomes small when SNR goes below 10 dB, but then the BER is too large to be useful. For BER modeling and prediction, knowledge of the probability distribution will be required.

III. EXPERIMENTAL DATA ANALYSIS AND COMPARISON WITH MODEL

Underwater acoustic communication data were collected during TREX04 experiment, which took place in April 2004 on the continental shelf of New Jersey coast water. Water depth in the experimental area is about 70 meters. The sound speed can be approximated by a constant: 1473 m/s, except near the surface and the bottom, where it increases to 1480–1484 m/s. A vertical line array (VLA) was deployed at a depth of approximately 35 m. It had an aperture of ~2 m and contained 8 hydrophones with uneven spacing. A fixed source was deployed at a depth of ~35 m at a range of 3.4 km. A towed source was deployed at a depth of ~23 m. The source track for the data analyzed below is shown in Fig. 3(a). FH-FSK signals were transmitted from the fixed and towed source to the VLA at different times. The signal uses a bandwidth of 4 kHz. Because of the sound speed profile, the signal travels mainly in the duct.

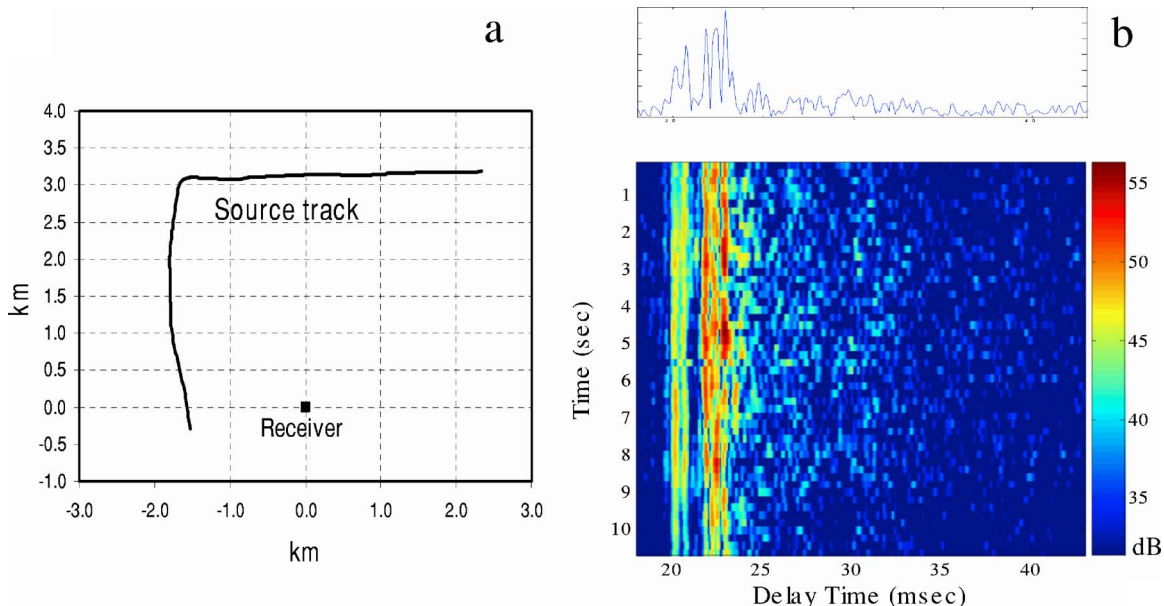
The bit error rates of the FH-FSK signals are analyzed in this section using both the fixed and moving source data. FH-FSK signal have been proposed for underwater acoustic communications.[10,11] Instead of modulating/occupying all frequency bins with bits at all time, the FH-FSK signal occupies only a small group of frequency bins at one time, representing an MFSK symbol, and uses a different frequency group at the next symbol time to represent the next MFSK symbol. Normally, a prescribed sequence of the fre-


FIG. 3. (Color online) (a) Track of the moving source relative to the receiver. (b) Channel impulse response measured using M-sequence data from a fixed source to a fixed receiver.

quency bins as a function of time is used and is referred to as the hopping pattern. The pattern is repeated once it reaches the end. This modulation scheme can support multiple users, each with its own hopping pattern. An FH-FSK signal is described mathematically as

$$s(t) = \sum_i s_i(t) = \sum_i \sqrt{2P} b_i \cos[2\pi f_i(t)t] \cdot W(t - iT), \quad (17)$$

where b_i is the bit sequence as a function of symbol number i, $f_i(t)$ is the hopping frequency as a function of time, occupied by the ith symbol, P is the transmitted power at the ith symbol, T is a symbol period, and $W(t)$ is a rectangular window function representing the symbol duration

$$W(t) = \begin{cases} 1, & if \ 0 \le t < T, \\ 0, & elsewhere. \end{cases} \quad (18)$$

In the TREX04 experiment, the FH-FSK signals used covered a frequency range from 15 to 19 kHz. The hopping pattern uses 13 pairs of frequency bins, one at a time. A pair of frequencies is used to carry bit 1 or 0 (i.e., BFSK modulation for each symbol). The bin size is 80 Hz, but the frequency separation between adjacent bins is 160 Hz to minimize interfrequency interference; the symbol period is $1/80$ s. (This signaling scheme is similar to that used in the WHOI micromodem.) Each data packet transmitted contained 1680 bits lasting about 21.0 s.

As described above, FH-FSK signals were transmitted from a fixed source to the VLA, at a range of 3.4 km, with a received SNR of 26–35 dB. Figure 3(b) shows the channel impulse response function as a function of geotime, measured from the M-sequence data collected during the same experiment. It shows two dominant groups of multipath arrivals separated by $\sim$5 ms time delay, followed by groups of multipath arrivals with weaker amplitudes; the last group of arrivals is $\sim$10 dB down from the first two groups of arrivals. The total multipath spread lasts over $\sim$15 ms. One notes that each symbol, with a duration of $1/80=12.5$ ms, captures most of the multipath energy.

The data were processed with a BFSK energy detector, which compares the energy between a pair of frequencies following the hopping pattern. The received bit is declared 1 or 0 depending on which frequency among the pair has a higher energy.

We have also analyzed FH-FSK data from a towed source to the VLA. The source-receiver range covered 1.73 to 3.70 km. The SNR at the receiver was on the order of 20–27 dB. For the FH-FSK data from a moving source, the data need to be corrected for the Doppler shift first. For a towing speed of 4 knots, the maximum Doppler shift for 17 kHz is around 23 Hz. Since the frequency bin has a width of 80 Hz, about one third of the symbol energy could be shifted outside the frequency bin. One can determine the Doppler shift based on the frequency shift of a pilot tone or the time separation between a pair of pulses measuring the signal dilatation/compression. The latter method is used here. A pair of 0.1 s linear frequency modulated (LFM) signals was placed before and after the FH-FSK signal, with a time separation of approximately 26.9 s between them. The measured time separation between the LFM signals divided by the time
FIG. 4. (Color online) Uncoded bit error rate measured from an hour of data from a fixed-source to a fixed-receiver, and another hour of data from a moving-source to a fixed receiver.

separation of the transmitted LFM signals yields the Doppler ratio. The Doppler shift resolution is inversely proportional to the time separation of the LFM signals; it is on the order $\sim$30 mHz. The data are down- or upshifted using the Doppler shift determined from the Doppler ratio.

To determine the channel effect on the BER, one is interested in the uncoded BER, i.e., the BER in the raw data without using error correction. Figure 4 shows the measured BER as a function of the SNR (E_b/N_0) for both the fixed-fixed transmission and moving-fixed transmission data. Only one receiver is used for this analysis; no significant difference is observed between data on different receivers. Also shown in Fig. 4 is the BER modeled using the Rayleigh distribution and K-distribution. One observes in Fig. 4 that the measured BER is, on average, significantly higher than that based on the Rayleigh fading statistics model. (Consequently, there is no need to include Rician model, which has a lower BER.) It is in fair agreement with the BER calculated using the amplitude fading statistics based on the K-distribution. One finds that the data can be fitted with the K-distribution model using $\nu=1.5$. [Note that the wide spread of the BER for high SNR data is a result of a limited number of data points. The BER at high SNR is usually small. A range of 1–8 bits in error (of 1680) can occur for a small number of data samples. It corresponds to 0.1%–0.5% bit error rate, which shows up as a wide spread in a log plot.]

In a separate study, it was observed that the envelope amplitude distributions for narrowband signals of frequency bandwidth of 80 and 320 Hz follow the K-distribution with $\nu=2.129$ and 1.28, respectively.[4] The envelope amplitude distributions were based on narrow frequency bin components averaged over pseudorandom (M-sequences) signals spread over a 4 kHz bandwidth. The M-sequence data were collected during the same experiment at a slightly different time. The BER curve for $\nu=2.129$ is also shown in Fig. 4. Both values of ν are consistent with the data given the large spread of the data points. One finds that the two different

FIG. 5. (Color online) Uncoded bit error rates evaluated in terms of E_b/N_0 using 10 collected signal packets and 25 different noise data. The E_b/N_0 values are varying by different weighting of the signal and noise data.

FIG. 6. (Color online) A prediction of the uncoded bit error rate for MFSK signals, $M=2$, 4, and 8 based on K-distribution fading statistics measured in TREX04. The uncoded bit error rates are compared with those of a Rayleigh fading channel.

signals (M-sequence and FH-FSK), analyzed with two independent methods, lead to a consistent conclusion about the K-distribution.

The above result can be stated in another way. The BER for FH-FSK signals can be predicted using the measured envelope amplitude distribution function or the K-distribution with v measured from the envelope amplitude fading statistics. The prediction is found in agreement with the measured BER. Although only the frequency-hopped BFSK signals were transmitted during the TREX04 experiment, armed with the above theory, one could predict the BER for (frequency-hopped) QFSK or 8FSK signals for the TREX04 environment. The predictions and practical implications will be covered in the next section.

Figure 4 shows the BER predictions for FH-FSK signals as a function of (decreasing) SNR. To evaluate how good the prediction is against data, noise collected at sea are added to the signal data (ten different packets) to determine the BER for smaller SNR cases. The noise data were collected during the TREX04 experiment when no signal was transmitting within the frequency band. Many (25) segments of noise data collected at a different time and different locations (during the same experiment) were used and added to the 10 packets, from which the BER was determined and then averaged over the data ensembles. The result is plotted in Fig. 5 using both fixed-source and moving-source data. One finds reasonably good agreement between the model predictions (using the K-distribution) and measured BER. Again, note that the BER data is significantly higher than that predicted by the Rayleigh amplitude statistics model.

IV. BER PREDICTIONS FOR HIGHER ORDER MFSK SIGNALS

The previous sections showed that BER can be modeled and predicted for BFSK signals. Good agreement with data was demonstrated. One notes that other types of MFSK signals, particularly QFSK ($M=4$) and 8FSK ($M=8$), are also
of interest; for example, Ref. 11 uses 8FSK for FH-FSK signal transmission. Unfortunately, these signals were not transmitted during the TREX04 experiment, and therefore one cannot conduct a comparison between data and models. Nonetheless, it is of interest (to the communication system designers) to know what kind BER can be expected for this type of signal under the same environment.

To analyze the BER for QFSK and 8FSK, let us assume that the frequency bin size is 80 Hz wide, as was used for BFSK. The symbol duration is $1/80$ s. For BFSK ($M=2$) signal, each symbol consists of two frequency bins. The data rate is 80 symbols/s, or 80 bits/s. It requires a bandwidth of 160 Hz (for each symbol). For the QFSK ($M=4$) signal, each symbol consists of 4 frequency bins. The data rate is 80 symbols/s or 160 bits/s. It requires a bandwidth of 320 Hz (for each symbol). The bandwidth is doubled; so is the data rate. Hence QFSK has the same bandwidth efficiency (bit rate/bandwidth) as BFSK.

For the 8FSK ($M=8$) signal, each symbol consists of 8 frequency bins. The bit rate is now $\log_2(M) \times 80$ $=240$ bits/s, but it requires a bandwidth of 640 Hz (for each symbol). Compared with BFSK, one finds that 8FSK requires eight times the bandwidth, but only increases the bit rate by three times. Continuing the analysis, one can show that for MFSK signaling, the bandwidth efficiency decreases as M increases for $M>4$. On the other hand, one expects that BER will improve as one increases M. Given the envelope amplitude distribution as determined above for underwater acoustic communications, one can calculate the improvement in BER as a function of M.

Assuming the K-distribution with its parameter (v $=2.129$) measured from the TREX 04 data, the BER is calculated using Eq. (15) for QFSK and 8FSK signals. The numerical results are plotted in Fig. 6 to compare with the BER for BFSK. Also shown is the BER using the Rayleigh distribution for comparison, which has been assumed by many system designers. The BER over a Rayleigh channel is given in Eq. (14).

From Fig. 6, one finds that BER is reduced by a factor of $\sim 2/3$ and 3.5/6 for QFSK and 8FSK, respectively, compared with BFSK. The reduction factor is almost independent of the input SNR between 10 to 35 dB. One expects that the

BER will further decrease as M increases. Hence, there is a tradeoff between BER and band efficiency as a function of M. The tradeoff is a system dependent issue, which will not be pursued here. Note, however, that between BFSK and QFSK, QFSK is a better choice since QFSK has the same bandwidth efficiency as BFSK but a lower BER (for the same E_b/N_0) than BFSK.

V. SUMMARY AND CONCLUSIONS

In this paper, the BER of FH-FSK signals were analyzed based on data collected during the TREX04 experiment. The data were transmitted from a fixed source as well as a towed source to a VLA moored to the ocean bottom. The BER data were modeled as a function of input SNR (E_b/N_0), assuming a Rayleigh and K-distribution envelope amplitude statistical distributions for a fading channel. It is found that the measured BER is significantly higher than that modeled by the Rayleigh distribution (hence is also higher than a Rician statistical model with the same E_b/N_0) and can be fitted with the K-distributions. The BER model using a K-distribution fading statistics, based on the model parameters independently estimated from the M-sequence data, yields a reasonable prediction for the BER of the FH-FSK signals. Using the same model, one can also predict the BER for QFSK and 8FSK signals under the same (TREX04) ocean environment.

APPENDIX: MFSK ERROR PROBABILITY OVER A K-DISTRIBUTION FADING CHANNEL

A random variable Z, which has a K-distribution $p_z(z)$, is a product of two independent random variables, X and Y, where X follows a chi distribution with 2ν degrees of freedom and Y follows a Rayleigh distribution in terms of a power ratio α, as given next:

$$p_X(x) = \frac{2x^{2\nu-1}e^{-x^2}}{\Gamma(\nu)} \quad \text{and} \quad p_Y(y) = \frac{2ye^{-y^2/\alpha}}{\alpha}. \quad \text{(A1)}$$

Thus, the K-distribution is given by

$$p_z(z) = \int_0^\infty \frac{1}{|x|} p_Y(z/x) p_X(x) dx$$

$$= \int_0^\infty \frac{1}{x} \left(\frac{2z}{x} \frac{1}{\alpha} e^{-z^2/\alpha x^2} \right) \left(\frac{2}{\Gamma(\nu)} x^{2\nu-1} e^{-x^2} \right) dx$$

$$= \int_0^\infty \frac{4}{\alpha\Gamma(\nu)} z \cdot x^{2\nu-3} e^{-z^2/\alpha x^2} e^{-x^2} dx$$

$$= \frac{4}{\sqrt{\alpha}\Gamma(\nu)} \int_0^\infty \frac{z}{\sqrt{\alpha}} \cdot x^{2\nu-3} e^{-(z/\sqrt{\alpha}x)^2} e^{-x^2} dx$$

$$= \frac{4}{\sqrt{\alpha}\Gamma(\nu)} \left(\frac{z}{\sqrt{\alpha}} \right)^\nu K_{\nu-1}\left(\frac{2z}{\sqrt{\alpha}} \right), \quad z \geq 0, \ \alpha > 0,$$

$$\nu > 0. \quad \text{(A2)}$$

Using the above K-distribution fading statistics $p_z(z)$ and Eqs. (10) and (11), the probability of symbol error is derived as below:

$$p_s(\varepsilon) = \int_0^\infty \frac{1}{M} \sum_{i=2}^M (-1)^i \binom{M}{i} e^{-(1-1/i)z^2/2\sigma_N^2}$$

$$\times \int_0^\infty \frac{4}{\alpha\Gamma(\nu)} z \cdot x^{2\nu-3} e^{-z^2/\alpha x^2} e^{-x^2} dx \, dz$$

$$= \frac{4}{M\alpha\Gamma(\nu)} \sum_{i=2}^M (-1)^i \binom{M}{i} \int_0^\infty e^{-(1-1/i)z^2/2\sigma_N^2}$$

$$\times \int_0^\infty z \cdot x^{2\nu-3} e^{-z^2/\alpha x^2} e^{-x^2} dx \, dz$$

$$= \frac{4}{M\alpha\Gamma(\nu)} \sum_{i=2}^M (-1)^i \binom{M}{i}$$

$$\times \int_0^\infty x^{2\nu-3} e^{-x^2} \cdot \int_0^\infty z \cdot e^{-(1-1/i)z^2/2\sigma_N^2} e^{-z^2/\alpha x^2} dz \, dx$$

$$= \frac{4}{M\alpha\Gamma(\nu)} \sum_{i=2}^M (-1)^i \binom{M}{i}$$

$$\times \int_0^\infty x^{2\nu-3} e^{-x^2} \frac{\alpha\sigma_N^2 x^2}{\alpha(1-1/i)x^2 + 2\sigma_N^2} dx$$

$$= \frac{2\sigma_N^2}{M\Gamma(\nu)} \sum_{i=2}^M (-1)^i \binom{M}{i} \int_0^\infty \frac{u^{\nu-1}e^{-u}}{(1-1/i)\alpha u + 2\sigma_N^2} du, \quad \text{(A3)}$$

where $u = x^2$. In terms of the mean SNR, $m_\rho = E(Z^2)/2\sigma_N^2 = \alpha\nu/2\sigma_N^2$, the probability of symbol error becomes

$$p_s(\varepsilon) = \frac{1}{M} \sum_{i=2}^M (-1)^i \binom{M}{i} \frac{\nu}{\Gamma(\nu)}$$

$$\times \int_0^\infty u^{\nu-1} e^{-u} \frac{1}{\nu + (1-1/i)m_\rho u} du. \quad \text{(A4)}$$

Now using $M = 2^q$ (q bits per symbol) and replacing the mean SNR by the SNR per bit, $m_\rho = qE_b/N_0$, the probability of bit error can be expressed as

$$p_b(\varepsilon) = \frac{M}{2(M-1)} p_s(\varepsilon) = \frac{1}{2(M-1)} \sum_{i=2}^M (-1)^i \binom{M}{i} \frac{\nu}{\Gamma(\nu)}$$

$$\times \int_0^\infty u^{\nu-1} e^{-u} \frac{1}{\nu + \left(1 - \frac{1}{i}\right) qu \frac{E_b}{N_0}} du. \quad \text{(A5)}$$

For the BFSK ($M=2$) case, the BER is given by

$$p_b(\varepsilon) = \frac{\upsilon}{\Gamma(\upsilon)} \int_0^\infty u^{\upsilon-1} e^{-u} \left(2\upsilon + u\frac{E_b}{N_0}\right)^{-1} du. \qquad (A6)$$

As mentioned in Sec. II B, a Rayleigh distribution is a special case of the K-distribution as $\upsilon \to \infty$, with $\alpha\upsilon$ remaining as a constant. This can be shown via

$$p_b(\varepsilon) = \lim_{\upsilon \to \infty} \frac{\upsilon}{\Gamma(\upsilon)} \int_0^\infty u^{\upsilon-1} e^{-u} \left(2\upsilon + u\frac{E_b}{N_0}\right)^{-1} du$$

$$= \lim_{\upsilon \to \infty} \sum_{i=0}^\infty \frac{1}{2\Gamma(\upsilon)} \int_0^\infty u^{\upsilon+i-1} e^{-u} \left(-\frac{E_b}{2\upsilon N_0}\right)^i du$$

$$= \lim_{\upsilon \to \infty} \sum_{i=0}^\infty \frac{1}{2\Gamma(\upsilon)} \left(-\frac{E_b}{2\upsilon N_0}\right)^i \int_0^\infty u^{\upsilon+i-1} e^{-u} du$$

$$= \frac{1}{2} \sum_{i=0}^\infty \lim_{\upsilon \to \infty} \frac{\Gamma(\upsilon+i)}{\upsilon^i \Gamma(\upsilon)} \left(-\frac{E_b}{2N_0}\right)^i = \sum_{i=0}^\infty \frac{1}{2} \left(-\frac{E_b}{2N_0}\right)^i$$

$$= \frac{1}{2 + E_b/N_0}, \qquad (A7)$$

where $\lim_{\upsilon \to \infty}[\Gamma(\upsilon+i)/\upsilon^i\Gamma(\upsilon)] = 1$. Thus, the BFSK BER for a Rayleigh channel is a special case of Eq. (A6).

Laboratoire Roberval FRE-CNRS 2833,
Université de Technologie de Compiègne, Secteur Acoustique, Boîte Postale 20529,
F-60205 Compiègne Cedex, France

This paper presents a methodology for the off-line reproduction of random pressure fields with given spatial correlation characteristics. The simulation method is first presented, together with an outline of the signal processing techniques required. The design of an experimental setup is then detailed in relation with the nature of the simulated pressure fields. Of particular interest is the laboratory synthesis of three different types of partially correlated random excitations: an acoustic diffuse field, a grazing incident plane wave, and a turbulent boundary layer. The corresponding excitations are generated in a semianechoic chamber over a test panel using a near-field array of 16 loudspeakers driven by a set of optimal signals. The loudspeakers are positioned at a suitable distance above a sufficiently dense grid of microphones close to the simulation surface. The mutually correlated drive signals are determined from both the target correlation properties and the acoustic transfer functions measured between the loudspeakers and the microphones. This approach could provide a cost-effective method of reducing the variation of low frequency sound transmission measurements as well as simulating the propeller-induced noise and the boundary layer noise transmitted through aircraft fuselage structures. © *2006 Acoustical Society of America.*

I. INTRODUCTION

The experimental reproduction of random pressure fields in laboratory conditions is a subject of considerable interest within several areas. In building acoustics, the problem of predicting and measuring low frequency sound insulation has become more important recently due to the increasing presence of the noise sources in this frequency range.[1] The characterization of the transmission loss coefficient assumes that the incident sound field is ideally diffuse[2] whereas, in practice, test panels are often tested in a sound transmission suite with two reverberation chambers. At low frequencies, the modal behavior of the rooms influences the measurements of the sound insulation properties of test materials which can vary considerably from one laboratory to the other. This variability has been widely studied experimentally through inter-laboratory comparisons[3,4] as well as through analytical[5–7] and numerical[8,9] investigations. In order to make the measurement of the incident power more reliable at low frequencies, Bravo and Elliott[10] have proposed a novel approach based on the reconstruction of the statistical properties of an acoustic diffuse field over the surface of a test partition using a near-field array of suitably driven loudspeakers. Theoretical results have shown that this approach is efficient in providing a measure of the sound reduction index that only depends on the properties of the panel itself and, at this stage, it would benefit from experimental validations.

In the aeronautical and aerospace industries, there is a timely interest in the laboratory simulation of random loads over components subject to high fluctuating pressure levels. Acoustic progressive wave tube (APWT) facilities are currently used for simulating the dynamic response and the sonic fatigue of aeronautical structures. Adaptive acoustic controllers are developed to generate input power spectral densities (PSD) tailored to field measurements, as those induced by jet noise.[11,12] In particular, a parametric method, the pseudorandom time history simulation, has been widely used to synthesize suitable time-domain signals for the input PSDs.[13] It is based on the time-domain representation of the simulated signals as a sum of a large number of statistically independent harmonics with random phase distributions. The frequency variables of the harmonics are distributed according to a joint density function derived from the specified PSDs. Because of the central limit theorem, it is well suited for the generation of Gaussian random wave forms, but the method may not be computationally efficient for simulating random process with a large number of variables and subsequent improvements have been formulated using the fast Fourier transform.[14] In spite of this, the APWT facilities are not able to reconstruct the detailed spatial correlation patterns associated to the simulated random excitations. Such limitations were found to be critical to simulate the effect of acoustical loadings due to rotating blades over the nacelle surface of a ducted propeller airplane.[15] Under typical flow speed conditions, pressure patterns propagate in spirals at grazing incidence to the fuselage sidewall and the effect of the spatially periodic load on the structure has to be accounted for. Therefore, we found useful to investigate how a

---

[a)]Present address: iTEAM, Universidad Politècnica de Valencia, Camino de Vera s/n, 46022 Valencia, Spain. Electronic mail: tebrama@iteam.upv.es

laboratory system could synthesise propeller-induced noise excitations, readily modeled as a grazing incident plane wave of random phase and amplitude.

The aeronautical industry is also concerned with cabin noise problems and their impact on discomfort and the integrity of the electronic equipment. The noise induced by turbulent boundary layer (TBL) pressure fluctuations developed over the fuselage of well-streamlined aircraft is important during cruise conditions.[16–18] The use of design modifications and noise control measures provides some opportunity for reducing the boundary layer noise in the cabin assuming that a characterization of the TBL-induced noise can be made either from flight tests or low-noise wind tunnel experiments.

Early attempts to understand how TBL-induced responses could be measured made use of reverberant acoustic qualification testing.[19,20] However, for high subsonic Mach numbers, boundary layer turbulence is generally less efficient at exciting the individual panel resonances than a reverberant acoustic field of the same intensity.[21] Alternate approaches propose to use a set of suitably driven actuators to simulate TBL excitations, as initially proposed by Fahy in 1966,[22] or to directly reconstruct the TBL-induced velocity response of a test panel using a limited number of point forces.[23] In order to reconstruct TBL excitations, Fahy observed that it would, in theory, be feasible to generate a spatially decaying correlation function over a test panel using a set of plane waves impinging at continuous random angles within a specific incident range: an equal probability between grazing and normal incidence would reproduce an acoustic diffuse field excitation whereas a probability confined to one incidence angle would generate a progressive plane wave excitation of random amplitude. The spatial decay of the correlation would thus be controlled by the angular bandwidth of the incident waves, although achieving continuous incident range might be questionable using a finite number of acoustic sources. In practice, the use of a near-field array of loudspeakers would require the multichannel discrete simulation of a two-dimensional random sound field over a grid of microphones close to the test surface: the loudspeakers should be driven by optimal time-domain signals to ensure that the statistical properties of the microphones outputs are mostly similar to those from the target random field.

Such an approach can be performed in frequency domain prior to generating the time-domain driving signals. The method consists in factorizing, for each frequency, the specified cross spectral density (CSD) matrix as a product between two matrices which are the Hermitian transform of each other.[13] When driven by a set of uncorrelated white noise signals, these matrices can be considered as shaping filters, the output of which are the simulated spectra in frequency domain. The random wave forms are then generated by calculating the inverse discrete Fourier transform (IDFT) of the complex spectra. The shaping filters can *a priori* be derived from an eigendecomposition or spectral decomposition of the specified CSD matrices. The technique of simulation can also benefit from alternate decompositions such as the Cholesky factorization when the CSD matrix is Hermitian non-negative.[24]

Recently, the multichannel simulation of a TBL excitation over a plane grid of microphones using a near-field array of acoustic sources has been theoretically investigated.[25–27] But, to the best of our knowledge, the experimental reproduction of two-dimensional random processes such as those described in the above using an array of near-field loudspeakers has not yet been achieved. A recent preliminary experiment studied the invertibility of the plant matrix between a set of loudspeakers and microphones housed within an enclosure on top of which is mounted a test panel.[27] It was recommended that the enclosure modal resonances should be heavily damped so that the plant transfer functions can be equalized.

In order to avoid stringent multipaths environments in the area of simulation, a loudspeakers cabinet radiating in "free-field" at a variable height from the test surface is designed.[28] The array of loudspeakers is installed in a nonreactive acoustical environment, a semianechoic chamber, for the near-field generation of prescribed random pressures at a number of microphones positions over the test surface. In particular, we aim to simulate the statistical properties of three types of wall-pressure excitations: an acoustic diffuse field, a grazing plane wave, and a TBL pressure field. The present work first outlines the methodology used for the simulation as well as the signal processing background required for the synthesis experiment. Then a discussion about the design of the experimental facility is detailed in relation with the nature of the simulated pressure fields. The experimental results are presented in a companion paper[29] regarding the physical limitation performances and the practical feasibility of synthesizing these random pressure fields.

II. THEORETICAL BACKGROUND FOR RANDOM PRESSURE FIELD SYNTHESIS

A. The synthesis method

The theoretical formulation for the laboratory reproduction of spatially correlated random pressure fields has been detailed in previous studies for the synthesis of a TBL wall-pressure field[25–27] and for the characterization of low frequency sound transmission between two rooms via a flexible panel.[10] The formulation can be readily extended to the synthesis of any random pressure field with prescribed spatial correlation properties as long as the pressure excitations we aim to reproduce are modeled as random processes stationary both in space and time. The general synthesis method is now briefly summarized.

We consider an array of evenly spaced microphones situated over the panel surface. The microphone outputs provide a measure of the spatial variation of the pressure field, which ideally corresponds to the desired one, $\mathbf{d}$. One assumes that $\mathbf{d}$ can be derived from a set of uncorrelated white noise reference signals, $\mathbf{x}$, via a matrix of shaping filters, $\mathbf{D}$, such that $\mathbf{d} = \mathbf{Dx}$. The CSD matrix between the elements of the desired pressure field can be written as

$$\mathbf{S}_{dd} = E[\mathbf{dd}^H] = \mathbf{DS}_{xx}\mathbf{D}^H = \mathbf{DD}^H, \tag{1}$$

where E denotes the expectation operator, and ^{H} denotes the Hermitian, complex conjugate transpose. The diagonal terms of $\mathbf{S}_{dd}$ correspond to the PSDs of the pressures at the microphones and the off-diagonal terms correspond to the CSDs of the pressures between two microphones. An eigendecomposition of the Hermitian matrix $\mathbf{S}_{dd}$ reads

$$\mathbf{S}_{dd} = \mathbf{Q}\mathbf{\Lambda}\mathbf{Q}^H = \mathbf{Q}\mathbf{\Lambda}^{1/2}(\mathbf{Q}\mathbf{\Lambda}^{1/2})^H, \tag{2}$$

where $\mathbf{Q}$ is the matrix of eigenvectors and $\mathbf{\Lambda}$ is the matrix of real, positive eigenvalues, whose square roots are denoted $\mathbf{\Lambda}^{1/2}$. Equation (2) is equal to Eq. (1) for the following matrix of shaping filters:

$$\mathbf{D} = \mathbf{Q}\mathbf{\Lambda}^{1/2}. \tag{3}$$

A matrix of control filters, $\mathbf{W}$, is determined that generates the optimum input signals to an array of loudspeakers, which drive the sensor outputs, $\mathbf{y}$, to be as close as possible to those due to the desired pressure field, $\mathbf{d}$. The vector of error signals is defined to be

$$\mathbf{e} = \mathbf{d} - \mathbf{y} = (\mathbf{D} - \mathbf{GW})\mathbf{x}, \tag{4}$$

where $\mathbf{G}$ is the matrix of acoustic transfer functions between the near field loudspeakers and the microphones. $\mathbf{W}$ thus minimizes the sum of the mean square error signals, $\mathrm{Tr}[\mathbf{ee}^H]$, where Tr is the trace operator. It can be shown that the optimal least-squares matrix of control filters is given by[30]

$$\mathbf{W}_{\mathrm{opt}} = [\mathbf{G}^H\mathbf{G}]^{-1}\mathbf{G}^H\mathbf{D} = \mathbf{G}^{\dagger}\mathbf{D}, \tag{5}$$

where $\mathbf{G}^{\dagger}$ is the pseudoinverse of $\mathbf{G}$. The calculation of $\mathbf{W}_{\mathrm{opt}}$ requires the knowledge of both the matrices $\mathbf{G}$ and $\mathbf{D}$.

Three models of wall-pressure excitations are now considered: an acoustic diffuse field, a grazing incident plane wave and a TBL. The CSD function between the pressures at two microphones, when subject to a diffuse incident sound field, is known to be of the form[31]

$$S_{dd}(r;\omega) = S_0(\omega)\frac{\sin kr}{kr}, \tag{6}$$

where $S_0(\omega)$ is the power spectral density of the pressure at any single microphone, $k = 2\pi/\lambda$ is the acoustic wave number, λ is the acoustic wavelength, and r is the distance between two microphones. We note that samples of a diffuse pressure field measured at microphones half a wavelength or more apart are uncorrelated.

The CSD function for an incident plane wave with random phase and amplitude is given by

$$S_{dd}(r;\omega) = S_0(\omega)e^{jk(|r_x|\sin\theta_K\sin\phi_L)}e^{jk(|r_y|\sin\theta_K\cos\phi_L)}, \tag{7}$$

where $|r_x|$ is the separation distance in the x direction, $|r_y|$ is the separation distance in the y direction, ϕ_L is the azimuthal incident wave angle, and θ_K is the corresponding polar angle. For a grazing incident plane wave, we have chosen $\theta_K = 90°$ and $\phi_L = 0°$.

The CSD between the pressures at two microphones beneath a TBL is assumed to be that of the Corcos model[32]
FIG. 1. Theoretical correlation as a function of the normalized separation distance between two microphones, respectively, for a diffuse pressure field (solid), a grazing incident plane wave (dashed), and a streamwise TBL pressure field (dash-dotted).

$$S_{dd}(r;\omega) = S_0(\omega)e^{-|r_x|/L_x}e^{-|r_y|/L_y}e^{-j\omega r_y/U_c}, \tag{8}$$

where L_x is the correlation length in the spanwise or x direction, L_y is the correlation length in the streamwise or y direction, and U_c is the convection velocity, which corresponds to $0.6U_\infty$, where U_∞ is the free-stream velocity. As suggested by Corcos, the correlation lengths are assumed to be inversely proportional to frequency, and have the form

$$L_x = \frac{\alpha_x U_c}{\omega}, \tag{9a}$$

$$L_y = \frac{\alpha_y U_c}{\omega}, \tag{9b}$$

where α_x and α_y are empirical constants taken to be, respectively, 1.2 and 8. The convection velocity is assumed to be 135 ms^{-1}, which corresponds to a flow Mach number of 0.66. The empirical Corcos model is well suited to describe the statistics of TBL wall-pressure fluctuations induced by high speed subsonic flows such as in aeronautical applications where the correlation lengths are large. However, it is of limited use to describe the TBL induced by low speed flows such as in marine applications where the correlation lengths are much smaller. Indeed, the short correlation scales involved are poorly resolved due to the finite size of the transducers and the attenuation resulting in the wall-pressure power spectral density should be compensated using a frequency-dependent correction factor.[32] Furthermore, the Corcos model overpredicts by 20 dB or more the spectral levels in the low wave number region. In most low Mach number applications, one may use the more comprehensive model by Chase.[33]

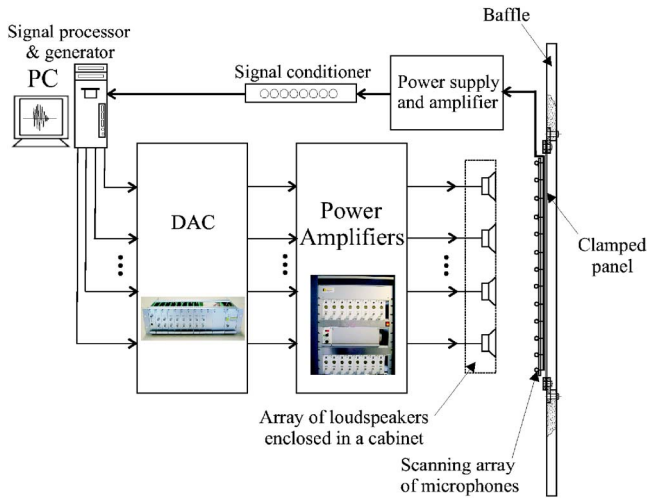
The spatial correlation functions of the three types of excitations are shown in Fig. 1 at a frequency of 1.6 kHz and for a variable distance to a reference microphone. It can be seen that the diffuse pressure field is correlated over an area much larger than the TBL pressure field. It will be shown in


FIG. 2. Experimental setup for the laboratory synthesis of random pressure fields.

a following paper that these differences in the correlation lengths greatly influence the number of loudspeakers required in a synthesis experiment.[29]

B. Signal processing background for the synthesis experiment

The hardware implementation of the loudspeakers array synthesis experiment is first presented, together with an outline of the signal processing techniques required to generate off-line the optimal driving signals.

1. Hardware description

The experimental scheme shown in Fig. 2 consists of a near-field array of loudspeakers driven by a set of optimized signals in order to simulate random pressure fields with prescribed statistical properties over the surface of a panel. The grid of microphones defines the surface of simulation, which is a short distance away from the surface of a test panel.

During the simulation process, the loudspeakers are driven by a set of partially correlated optimal signals which are synthesized by a multichannel arbitrary wave form generator (AWG) system. The AWG system is illustrated by the block diagram shown in Fig. 3. The hardware includes a computer-based signal generator as well as a parallel-oriented array output processor. The signal generator enables the computing of the digital optimal signals $\mathbf{u}_{opt}$ in the frequency domain. It also provides the array output processor with the suitable time-domain signals $\tilde{\mathbf{u}}_{opt}$ by performing on each channel an IDFT of $\mathbf{u}_{opt}$. The length-N elements of the time domain vector $\tilde{\mathbf{u}}_{opt}$ are therefore given by

$$\tilde{u}_{opt,i}(m) = \frac{1}{N}\sum_{l=1}^{N} F_i(l) W_N^{-(l-1)(m-1)}, \quad m = 1, \ldots, N, \quad (10)$$

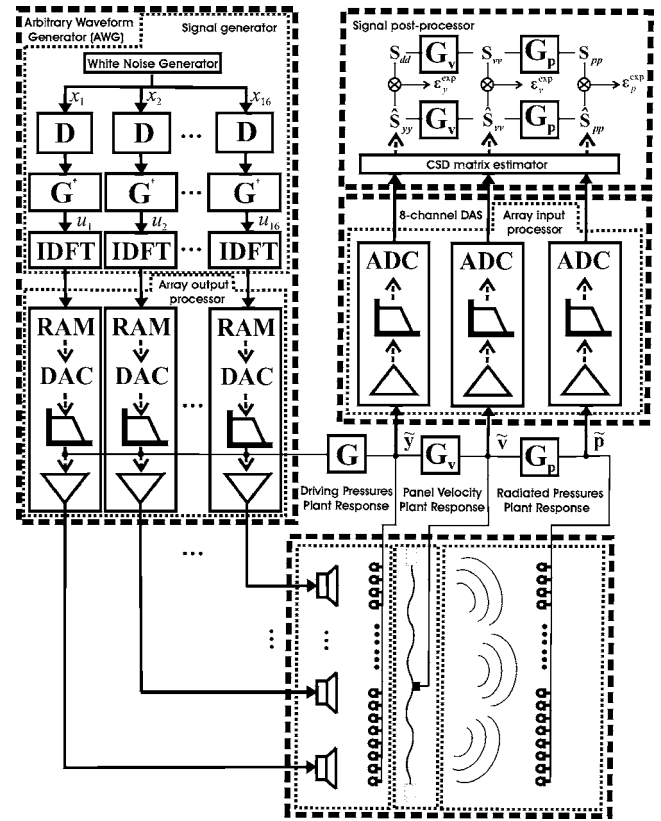
where the index i denotes the ith driving signal and $W_N = e^{-j2\pi/N}$. To assure real time domain signals, the length-$N/2$ elements of the frequency domain vector $\mathbf{u}_{opt}$ must be mirrored with proper symmetry such that, for each i,


FIG. 3. Block diagram of the arbitrary wave form generator and the signal postprocessor that estimates the spatial errors associated to the excitation and to the panel vibroacoustic response.

$$\begin{cases} F_i(l) = u_{opt,i}^*(l), & l = 1, \ldots, N/2, \\ F_i(l) = u_{opt,i}(l - N/2), & l = N/2 + 1, \ldots, N. \end{cases} \quad (11)$$

The digital time-domain signals are then stored in a RAM memory organized as $32k$ words by 8 bits. The maximum number of samples per channel is limited to 32 767. When used in generation mode, a cyclic reading of the binary data can be performed simultaneously on all the memories. A synchronous counter output is also available to trigger the measurements on the real-time signals generation. The data on every channel are then passed through a digital-to-analog converter the output of which are filtered (5th order low-pass) to eliminate the clock residuals (see Fig. 3). The analog drive signals are the inputs to a set of 16 amplifiers delivering up to 50 W root-mean-square (rms) nominal power over 20 Hz–50 kHz bandwidth. The amplifier gain can be monitored on every channel, thus delivering 5, 10, 20, or 50 W rms power with an adjustable output voltage within each power range. A user interface enables to transfer the time samples to the memories, to start or stop the generation and to set up the sampling period of the drive signals (from 20 μs to 1 ms) as well as the cut-off frequency of the low-pass filters (from 2 kHz to 30 kHz).

2. Signal generation and acquisition

Prior to the experimental synthesis, a measurement of the plant matrix $\mathbf{G}$ is required and will be used to calibrate the system. For this purpose, the AWG system is used in

calibration mode and drives the amplifiers with sixteen un-correlated white noise signals with the following CSD matrix between the drive signals, $\mathbf{S}_{uu} = \mathbf{S}_{xx} = \mathbf{I}$. The CSD matrix $\mathbf{S}_{yu}$ between the microphone outputs $\mathbf{y}$ and the drive signals $\mathbf{u}$ allows the determination of the $\mathbf{G}$ matrix

$$\mathbf{S}_{yu} = E[\mathbf{yu}^{\mathrm{H}}] = E[\mathbf{Guu}^{\mathrm{H}}] = \mathbf{G}\mathbf{S}_{uu} = \mathbf{G}. \quad (12)$$

Each element of $\mathbf{G}$ corresponds to the frequency response function between one loudspeaker and one microphone. The frequency responses are estimated from time records of length $N=8192$ samples when collected over a duration $T=2.56$ s. Therefore, 4096 spectral lines were acquired for each frequency response at a sample rate $f_s=3.2$ kHz in order to cover frequencies up to $f_{\max}=N/2T=1.6$ kHz without temporal aliasing. For consistency, the same parameters have been kept for the acquisition of the time-domain microphones output signals, $\widetilde{\mathbf{y}}$, during the synthesis of the random pressure fields, thus setting to $T_A=T=2.56$ s the acquisition time of the synthesized signals at each microphone position.

The duration T_G of the drive signals generated during the synthesis process is set to a value greater than the acquisition time but at the expense of a reduced bandwidth that should cover the broadest frequency range over which the random pressure fields can be simulated. In a previous study it was found that the largest frequency range of simulation over which an acoustic diffuse field could *a priori* be reproduced stays below 1 kHz.[28] Therefore the generation bandwidth could be set up to 1.3 kHz, thus leading to a generation time $T_G=3.15$ s, still greater than T_A. In order to generate drive signals of length $N=8192$ samples over a duration T_G, a sampling period of 385 μs is required. We note that it is still lower than 1 ms, the maximum sampling period set by the memory cards. Also the drive signals are generated only from a single reading of the memories in order to avoid cyclic snapshots that may produce discontinuous time histories at the end sections of each block data.

During the synthesis, the optimal drive signals $\mathbf{u}_{\mathrm{opt}}$ are generated from a set of uncorrelated white noise reference signals $\mathbf{x}$ filtered by the optimal control matrix $\mathbf{W}_{\mathrm{opt}}$, as given by Eq. (5), such that $\mathbf{u}_{\mathrm{opt}}=\mathbf{W}_{\mathrm{opt}}\mathbf{x}$. In practice, the generated optimal signals are calculated off-line and implemented in the signal generator as $\mathbf{u}_{\mathrm{opt}}=\mathbf{G}^{\dagger}\mathbf{d}$. The assumed microphones outputs $\mathbf{d}$ are prefiltered by the inverse matrix $\mathbf{G}^{\dagger}$ in order to compensate for the effects of the plant response. During the simulation process, the target signals $\mathbf{d}$ should be recovered in a least-square sense at the microphones outputs $\mathbf{y}=\mathbf{G}\mathbf{u}_{\mathrm{opt}}$ if the plant response has been correctly equalized by the optimum control filter $\mathbf{W}_{\mathrm{opt}}=\mathbf{G}^{\dagger}\mathbf{D}$. The CSD matrix $\mathbf{S}_{yy}$ between the microphones outputs when subject to a synthesized random pressure field should then approximately match the required CSD matrix $\mathbf{S}_{dd}$. It reads

$$\mathbf{S}_{yy} = E[\mathbf{yy}^{\mathrm{H}}] = \mathbf{G}\mathbf{G}^{\dagger}\mathbf{S}_{dd}(\mathbf{G}\mathbf{G}^{\dagger})^{\mathrm{H}}. \quad (13)$$

The first equality of Eq. (13) is used to estimate the correlation structure between the experimentally synthesized pressures fields. It is obtained from the measured time-domain microphones outputs $\widetilde{\mathbf{y}}$ by means of averaging techniques, according to the Welch's method of smoothed periodo-

grams.[34] This method involves sectioning the length-N record data $\widetilde{\mathbf{y}}$ into M overlapping segments of length L, with D the offset between two consecutive segments so that $N=L+D(M-1)$, and averaging modified periodograms of these segments. An estimation of $\hat{\mathbf{S}}_{yy}$ from time records of length $N=8192$ samples is obtained with a reasonable trade-off between variance and spectral resolution when $\widetilde{\mathbf{y}}$ is subdivided into $M=255$ segments of length $L=2^6=64$ with 50% overlap. Therefore, the spectral density matrix $\mathbf{S}_{yy}$ is estimated as

$$\hat{\mathbf{S}}_{yy}(f_n) = \frac{L}{MN_w} \sum_{m=0}^{M-1} \mathbf{y}_{(m)}^*(f_n)\mathbf{y}_{(m)}^{\mathrm{T}}(f_n), \quad (14)$$

where $\mathbf{y}_{(m)}(f_n)=(1/L)\sum_{l=0}^{L-1}\widetilde{w}(l)\widetilde{\mathbf{y}}(l+mD)e^{-j2\pi lf_n}$ is the discrete Fourier transform (DFT) of the mth block of windowed data and $f_n=nf_s/L$, $n=0,\ldots,L/2$. The DFT of each block data is computed using a fast Fourier transform. $N_w=(1/L)\sum_{l=0}^{L-1}|\widetilde{w}(l)|^2$ is a normalization constant to compensate for the reduction in the average signal power induced by the truncation window $\widetilde{w}$.

III. EXPERIMENTAL FACILITY

The physical design of a loudspeakers array synthesis experiment is first described for the random pressure fields to be simulated over a test section. The modal characteristics of the test section, required to determine the sensitivity of the panel response to the simulated excitations,[29] are subsequently presented.

A. Design of the loudspeaker array synthesis experiment

An experimental device is built that implements the synthesis technique. It consists of a test panel clamped in a baffle and located inside a semianechoic chamber with dimensions 5 m $\times$ 5 m $\times$ 5 m. The desired pressure fields are reconstructed over a grid of electret microphones located in the proximity to the test panel of dimensions $l_x=0.74$ m, $l_y=0.92$ m. The pressures are generated at the microphone positions by a near-field array of loudspeakers mounted on a wooden enclosure of dimensions 1 m $\times$ 1 m $\times$ 0.2 m and centered at a distance h in front of the test section. The operating configuration of the experimental setup is shown in Figs. 2 and 4.

To obtain a characterization of the incident pressure field over a sufficiently dense grid of points, a set of 6-mm closely matched microphone capsules is chosen for their low cost, omnidirectional, and flat response performances in the operating frequency range, i.e., below 1 kHz. A detailed view of the sensor lay-out is presented in Fig. 5. One stainless steel bar is used for accurately positioning the microphones holders, with up to 15 evenly spaced locations along the bar to assess the effects of the number of microphones on the simulation accuracy. The bar acts like a baffle at high frequencies, causing a rise in gain only above 5 kHz. As it can be seen from Figs. 4 and 5, the bar is displaced along the panel length so that a maximum number of $N_x^{\mathrm{mic}} \times N_y^{\mathrm{mic}}=15 \times 18$ microphones positions are uniformly distributed over the
FIG. 4. The operating experimental setup.

FIG. 6. A front view of the loudspeakers cabinet.

panel surface, N_x^{mic} and N_y^{mic} being the number of microphones locations along, respectively, the width and the length of the panel. Due to the finite size of the microphones, the minimum distance between the sensors and the test panel is set to $\delta=0.01$ m.

The desired pressure field is generated by a set of $N_x^{loud} \times N_y^{loud} = 4 \times 4$ woofer loudspeakers of 0.21 m diameter uniformly distributed on the front face of the enclosure, as shown in Fig. 6. N_x^{loud} and N_y^{loud} are the number of loudspeakers along, respectively, the horizontal and vertical dimensions of the face of the enclosure. The number, the position

FIG. 5. A photograph of the microphone array layout.

and the diameter of the drivers were determined as a trade-off between the flatness of their frequency responses over the bandwidth of simulation, i.e., below 1 kHz, and their size limited by the surface of simulation, i.e., the panel dimensions. The loudspeakers cabinet is filled with fiberglass material to limit the internal acoustical coupling between the drivers and to damp the enclosure resonances, this technique being mostly effective above approximately 800 Hz. This uniform arrangement of loudspeakers might not be the most efficient configuration for reproducing a random pressure field with different correlation lengths along the two panel directions such as a TBL pressure field. However, it constitutes a convenient starting point.

The distance h between the array of loudspeakers and the test panel is optimized using a simplified analytical model in which the loudspeakers are modeled as acoustic monopoles radiating in front of a panel clamped in an infinitely rigid baffle. A mean-square error is defined as the ratio of the sum of the mean-square error signals at the microphones outputs to the sum of the mean square desired sensor signals. The minimum value for the normalized mean-square error is shown to be[27]

$$J_e = \frac{\text{Tr}[(\mathbf{I} - \mathbf{G}\mathbf{G}^\dagger)\mathbf{S}_{dd}]}{\text{Tr}[\mathbf{S}_{dd}]}. \tag{15}$$

As illustrated in Fig. 7, the ability of the transducers arrangement to reproduce the three types of random pressure fields is almost independent of the height of the loudspeakers provided it is greater than the loudspeakers separation distance. However, if the array of loudspeakers is too far from the test partition, the matrix of acoustic transfer functions $\mathbf{G}$ becomes ill-conditioned, thus leading to a poor reconstruction of the desired pressure field. Therefore, we have selected a suitable separation distance to the panel equal to the distance between two adjacent loudspeakers in the array, i.e., $h=0.22$ m. From this simplified model we already anticipate that the synthesis of a TBL pressure field will be much more demanding than for the other two types of excitations.

The truncation effects due to the limited aperture of both the loudspeakers and microphones arrays along each of the
FIG. 7. Normalized mean-square error calculated at 120 Hz for the simulation of an acoustic diffuse field (solid), a grazing incident plane wave (dashed), and a TBL pressure field (dash-dotted) over an array of 15×18 microphones, as a function of the distance loudspeakers-microphones normalized by the separation distance between two adjacent loudspeakers.

FIG. 8. The condition number of the acoustic plant matrix measured between the 4×4 loudspeakers and a number of microphones (thin dashed line, 5×6 microphones; thick dashed line, 7×8 microphones; thin solid line, 13×16 microphones; thick solid line, 15×18 microphones).

panel dimensions should be considered. This limitation introduces a cutoff in the angular frequencies of the wave field radiated by the loudspeakers array at each microphone position. The largest angular bandwidth generated by the array is reached at the central microphone position and is given by $B = 2\sin[\tan^{-1}(a/2\tilde{h})]/\lambda$, where $a=1$ m is the aperture of the loudspeakers array and $\tilde{h} = h - \delta = 0.21$ m is the height of the loudspeakers array above the microphone plane. Shannon's sampling theorem defines the spatial resolution of the wave field at the microphone plane as $\delta_m = 1/B$. Assuming that the spatial resolution is limited by the separation distance between two microphones, i.e., $\delta_m = l_x/N_x^{mic} = l_y/N_y^{mic}$, then a synthesis can be carried out with this resolution and without spatial aliasing up to

$$f_{alias} = N_x^{mic} c/\{2 l_x \sin[\tan^{-1}(a/2\tilde{h})]\}, \tag{16}$$

i.e., up to about 3.2 kHz with 13×16 microphones and with a spatial resolution of 0.06 m.

The condition number of the plant matrix **G** plays an important role in order to explore how accurately the least-squares matrix of filters [Eq. (5)] is able to reconstruct the statistical properties of the desired pressure fields in a synthesis experiment. A set of 16×270 acoustic transfer functions has been measured between the loudspeakers and the microphones using an eight-channel LMS CADA-X acquisition system. It can be seen from Fig. 8 that the plant matrix condition number typically decreases as frequency increases. However, the values range well below 10^3, so there is *a priori* no need to use regularisation techniques in order to improve the reconstruction accuracy.[35] The variations with frequency of the plant matrix condition number result from the spectral behavior of all the measured transfer functions that takes into account the structural resonances of the baffled test panel, the semianechoic environment and the radiation properties of the loudspeakers cabinet. Testing on the cabinet alone has shown that the internal enclosure's depth
modes occur above 900 Hz, i.e., within a frequency range for which the dissipative material inside the cavity is effective. Also, the use of 5-cm thick plywood material for the cabinet walls increases the stiffness, mass, and damping of the enclosure, thus reducing the extent to which the cabinet vibrations contribute to the sound radiated. This design leads to a reasonably flat frequency response of the loudspeaker's array up to 1.6 kHz. However, when facing the baffled test section, local maxima are observed in the measured transfer functions. They occur at evenly spaced frequencies, $f_r = cr/2h$, $(r = 1, 2 \ldots)$, where c is the sound speed, and result from a regime of standing waves due to acoustical reflections between the baffled panel and the front face of the loudspeakers enclosure. The first acoustical resonance at 775 Hz dominates the spectrum of a large number of measured transfer functions. As seen from Fig. 8, it locally degrades the plant matrix condition number that still stays below 100 at this frequency. The second acoustical resonance does occur at 1550 Hz, but to a lesser extent.

The influence of the number of microphones on the plant matrix conditioning is also shown in Fig. 8. As expected, the matrix **G** is better conditioned when the density of microphones increases. A density of 7×8 microphones sets a lower limit above which the reproduction of the desired pressure fields should not be significantly improved. However, in a following paper, the results will be presented of pressure fields generated over an array of 13×16 microphones to provide enough spatial resolution on the reconstructed correlation structures.[29]

B. Vibration characteristics of the test section

To delineate error criteria induced by the simulated excitations on the test section, a model of the test panel structural behavior is required. As illustrated in Fig. 9, a modal analysis is performed on the clamped aluminium panel with thickness $h_p = 0.003$ m, with a density $\rho = 2650$ kg/m^3, a Young's modulus of 70.3 GPa, and a Poisson's ratio of 0.35.

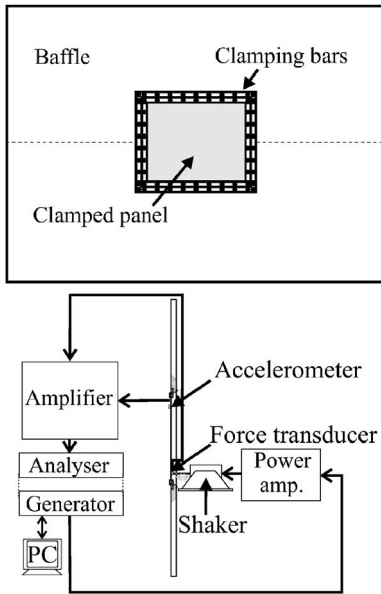
T. Bravo and C. Maury: Random pressure fields synthesis


FIG. 9. Sketch of the experimental setup for modal testing.

FIG. 10. Experimental natural frequencies of the test panel vs the theoretical frequencies. For each frequency, the corresponding theoretical (left) and experimental (right) modal deflection shapes are compared.

The clamped boundary conditions are *a priori* well replicated in our experiment: the upper and lower sides of the panel edges are bolted together to eight stainless steel clamping bars, 0.05 m wide and 0.02 m thick, to prevent any transverse displacement and rotation of the edges. The clamping frame is mounted on a rigid fiberboard baffle.

An analytical solution for the panel response is derived using a classical modal approach. The structural velocity at a point **M** on the panel surface due to a punctual force located at **M′** denotes the transfer mobility function G_v. It can be expressed as a modal summation

$$G_v(\mathbf{M},\mathbf{M}';\omega) = \sum_{m,n=1}^{\infty} a_{mn}(\mathbf{M}';\omega)\psi_{mn}(\mathbf{M}), \qquad (17)$$

where a_{mn} is the complex amplitude of the mnth structural mode with normalized shape function ψ_{mn} and natural frequency ω_{mn}. Expressions are readily found for the normal modes and natural frequencies of a clamped panel.[36]

After substituting Eq. (17) into the variational equations of motion for the panel, one obtains the following expression for the modal amplitudes:

$$a_{mn}(\mathbf{M}';\omega) = -\frac{j\omega\psi_{mn}(\mathbf{M}')}{\rho h_p l_x l_y[(1+j\eta_{mn})\omega_{mn}^2 - \omega^2]}, \qquad (18)$$

where η_{mn} is the modal structural damping loss factor.

In order to validate the panel structural model, "single-point excitation" testing is performed (see Fig. 9).[37] Mobility frequency response functions are measured using a small-sized accelerometer, sequentially positioned at 17×21 points uniformly distributed, respectively, along the width and the length of the panel. A medium-sized electromagnetic driver with a 200 N force rating (sine peak) is attached to the rear part of the panel at a corner point of coordinates (x' =0.12 m, y'=0.17 m), which is not likely to coincide with the nodal lines of many structural modes. The shaker is linked to the panel via a drive rod, very stiff in the excitation direction, with impedance head to measure both force and acceleration at the excitation point.

From Fig. 10, it is clear that the first measured natural modes and frequencies are in good agreement with those calculated. It confirms that the experimental conditions are well modeled assuming a homogeneous panel with clamped edges. The structural damping factors of the panel are extracted by circle-fitting the Nyquist plots of the FRFs in the vicinity of each resonance.[38] After updating the modal damping in the model, a good correlation is obtained between the measured and calculated panel kinetic energies (see Fig. 11). The updated model is used in a following study[29] to assess the effect of the simulated excitations on the panel response through the introduction of spatial errors, $\varepsilon_y^{\exp}$, $\varepsilon_v^{\exp}$, and $\varepsilon_p^{\exp}$, respectively, for the excitation, the panel structural and acoustic responses, and calculated by the signal post-processor between the assumed and synthesized CSDs (see Fig. 3).
FIG. 11. Kinetic energy of the test panel when excited by a punctual force: theory (thick line) and experiment (thin line).

IV. CONCLUSIONS

A framework is presented for the multichannel simulation of spatially correlated random pressure fields with specified statistical properties. We aim to reproduce excitations with given spatial correlation properties such as an acoustic diffuse field, a grazing incident plane wave of random phase and amplitude, and the wall-pressure fluctuations beneath a high speed TBL. Other empirical or theoretical models can be considered for the correlation structure of the pressure field to be synthesized. The synthesis method requires the use of a near-field array of acoustic sources driven by a set of mutually correlated signals so that they reconstruct the spatial correlation structures of the desired pressure fields over a grid of microphones close to the test surface. The drive signals are the outputs of an optimal control filter which is designed off-line, prior to the synthesis experiment. During the synthesis, the drive signals are played out from an arbitrary wave form generator. The spatial correlation structures synthesized over the test section are estimated from measurements of the output microphones signals using averaging techniques. Unlike real-time reconstruction techniques, this approach does not require the causality of the optimal filters which operate on the assumed time histories. The optimal drive signals are obtained from the knowledge of both the target spectral density matrix factorized into a number of statistically uncorrelated components, and the matrix of physical responses between the acoustic sources and the microphones. These two factors *a priori* determine the physical limitation performances of the simulation process.

An experimental setup has been designed in a semi-anechoic chamber for the laboratory synthesis of the spatially correlated random pressure fields over a grid of 13 $\times$ 16 microphones when using a near-field array of 4×4 loudspeakers. It is found that the loudspeakers array, when driven by a set of optimal signals, should equalize for the acoustic transfer paths between the sources and the microphones provided that the height between loudspeakers and microphones is greater than the speakers separation distance. Moreover, the truncation effects due to the limited aperture of both the loudspeakers and microphones arrays sets an upper frequency limit of 3.2 kHz below which a synthesis can be carried out without spatial aliasing and with a resolution of 0.06 m.

At this design step, we anticipate that the synthesis of a TBL pressure field will be much more demanding than for the other two types of excitations. Such differences in the simulation accuracy with respect to the nature of the excitation is analyzed more in detail in a companion paper. In order to achieve the simulation of a TBL over a broader frequency range, further investigations should require a denser as well as a nonuniform arrangement of acoustic sources due to the different spanwise and streamwise correlation lengths involved. Also, refined models of TBL wall-pressure fluctuations should be considered, in particular those avoiding "corners" of equal reduction coherence as well as other models more suitable for low speed flows applications. *A priori*, the very short correlation lengths induced by low speed TBLs may require an unrealistic density of sources which would make the simulation very difficult to achieve. In general, quantitative criteria should be formulated on the number of acoustic sources required for an accurate simulation of each of the three random excitations.

Boîte Postale 20529, F-60205 Compiègne Cedex, France

A previous paper discussed the methodology for the synthesis of partially correlated random pressure fields using a near-field array of loudspeakers. The acoustic sources are optimally driven so that various random excitations are reproduced over a test surface, namely an acoustic diffuse field, a grazing incident plane wave, and turbulent boundary layer fluctuating loads. This paper shows the physical limitation performances and the practical feasibility of synthesizing these random pressure fields in a series of loudspeakers array simulation experiments. Spatial error criteria are proposed on the number of acoustic sources per unit correlation length. They are more representative than mean-square error criteria to quantify the accuracy with which the assumed correlation structures are experimentally reconstructed. Furthermore, structural and acoustic models are formulated to investigate how sensitive is the panel vibroacoustic response to inaccuracies in the synthesized excitations. It is discussed how the direct reproduction of the panel vibroacoustic response with a limited number of loudspeakers should be feasible within the frequency bandwidth for which the modes at resonance well couple with the excitation. © *2006 Acoustical Society of America.*

I. INTRODUCTION

The problem of simulating multivariate and multidimensional random processes with prescribed spectral density characteristics has been extensively addressed in the past decades both theoretically and experimentally for the synthesis of real-world acoustic or vibration environments. A review about the methodologies used to synthesize random pressure fields has been described in a previous work.[1] These methods have been assessed within different areas for the experimental synthesis of partially correlated signals. For example, a parametric approach based on the simulation of pseudorandom time histories has been successfully applied in the automotive industry for the laboratory reproduction of the response of a four-track vehicle to the Gaussian excitation induced by road surface roughness.[2,3] It has also been used for simulating the spatial variation of seismic ground motions recorded over extended areas.[4] More recently, this method has been applied for tailoring in-service environmental vibrations of ground vehicles with non-Gaussian characteristics using shaker testing facilities.[5]

In the frequency domain, an equivalent approach consists in factorizing the spectral density matrix of the target data in order to design shaping filters the output of which are the simulated spectra.[6] It is well adapted for the experimental simulation of multidimensional random fields such as boundary-layer turbulence or acoustic diffuse fields. In particular, a point array forcing experiment (PAFE) has been designed in order to achieve cost-efficient "ground testing" to reproduce turbulent boundary layer (TBL) noise transmis-

sion through aircraft sidewalls.[7] An array of suitably driven shakers was used to reproduce the statistics of the TBL wall-pressure fluctuations over an aluminium panel. The PAFE technique was found to be well suited to simulate resonant forcing of the panel like "rain-on-the-roof" excitation with respect to nonresonant excitations such as those due to a TBL or an acoustic diffuse field. One way of reproducing nonresonant excitations would be to excite the panel by a suitably correlated sound field as it could be generated using a near-field array of loudspeakers. Such an approach builds upon previous theoretical works concerning the synthesis of TBL wall-pressure fluctuations using a number of suitably driven acoustic monopoles.[8,9] Subsequently, an experimental setup has been designed for the laboratory reproduction of spatially correlated random pressure fields with a near-field array of 4×4 loudspeakers.[1,10] Preliminary investigations have shown that this arrangement should *a priori* be able to reproduce the statistics of an acoustic diffuse field and a grazing incident plane wave over a broad frequency range whereas the simulation of TBL loads appears to be restricted to the very low frequency domain.

The present work addresses practical issues for the laboratory synthesis of three random pressure fields, namely an acoustic diffuse field, a grazing acoustic plane wave, and a TBL excitation. The accuracy that can be experimentally achieved for the reconstruction of each kind of excitations is quantified with respect to both energy-based and spatial errors, as explained in Sec. II. In Sec. III, the physical limitations of the simulation performance are assessed and criteria are proposed on the number of sources required for an accurate reconstruction of the excitations. Section IV discusses the experimental results on the off-line synthesis of each of

the three random pressure fields. In Sec. V, results are given on the sensitivity of the panel vibroacoustic response to inaccuracies in the simulated excitations.

II. QUANTIFIERS OF THE SIMULATION ACCURACY

In order to implement the synthesis technique, a possible experimental facility has been designed and constructed for the evaluation of test cases.[1] Briefly, the excitations are reconstructed over a grid of $N_x^{mic} \times N_y^{mic} = 13 \times 16$ microphones evenly distributed, respectively, along the width and the length of a baffled clamped panel located inside a semi-anechoic chamber. The random pressure fields are generated using a near-field array of 4×4 loudspeakers, suitably driven and located at a distance $\tilde{h} = 0.21$ m apart from the grid of microphones which defines the surface of simulation. The height, $\tilde{h}$, between the loudspeakers and the microphones grid was chosen, typically about the separation distance between two adjacent loudspeakers, in order to lower the condition number of the plant response matrix $\mathbf{G}$ between the loudspeakers and the microphones. This number is an indicator of the ill-posedness of the problem associated with the pseudoinversion of $\mathbf{G}$, required for the off-line calculation of the loudspeakers driving signals. Also, given the limited aperture of the loudspeakers array and the spatial resolution set by the microphones separation distance, it has been shown that synthesis can be performed up to about 3.2 kHz without spatial aliasing.[1]

A. The mean-square error

From the knowledge of both the statistical properties for the desired pressure fields, characterized by the spectral density matrix $\mathbf{S}_{dd}$, and the measured transfer functions constitutive of the plant matrix $\mathbf{G}$, a normalized mean-square error is defined to quantify the accuracy of the simulated excitation. It is obtained as the sum of the mean-square error signals at the microphones outputs normalized by the sum of the mean square target sensor signals. Its minimum value is achieved when the loudspeakers are driven by a set of optimal signals. It is given by[9]

$$J_e = \frac{\text{Tr}[(\mathbf{I} - \mathbf{G}\mathbf{G}^\dagger)\mathbf{S}_{dd}]}{\text{Tr}[\mathbf{S}_{dd}]}, \qquad (1)$$

where Tr is the trace operator and $\mathbf{G}^\dagger$ is the pseudoinverse of $\mathbf{G}$.

Another aspect of the simulation is to assess the accuracy with which a reduced set of loudspeakers can approximate the panel acoustic response. A normalized mean-square error, J_p, is defined to quantify the approximation induced on the acoustic response of the panel when subject to the simulated random pressure fields

$$J_p = \frac{\text{Tr}[\mathbf{G}_p\mathbf{S}_{ee}\mathbf{G}_p^H]}{Tr[\mathbf{G}_p\mathbf{S}_{dd}\mathbf{G}_p^H]}, \qquad (2)$$

where H denotes the Hermitian, complex conjugate transpose; $\mathbf{S}_{ee} = [\mathbf{G}\mathbf{G}^\dagger - \mathbf{I}]\mathbf{S}_{dd}[(\mathbf{G}\mathbf{G}^\dagger)^H - \mathbf{I}]$ denotes the spectral density matrix for the error signals at the microphones outputs when the loudspeakers are optimally driven; $\mathbf{G}_p$ is

the transfer impedance matrix the elements of which are calculated from the Green's representation of the acoustic pressure radiated and associated to a given panel velocity distribution [see Eq. (A5)]. The velocity is calculated by the updated model presented in Sec. III B. of Ref. 1.

B. The residual error

Equation (1) is a discrete version of the normalized power spectral density averaged over the microphones locations and associated to the error signals at the microphones outputs. Hence, the mean-square error quantifies the accuracy of the approximation in terms of the incident power associated to the error signals and it is not fully representative of the accuracy with which the correlation structures are reproduced. A quantifier that emphasises the spatial characteristics of the random field statistics is defined as

$$\varepsilon_y^{exp} = \frac{\|\mathbf{C}_{dd} - \hat{\mathbf{C}}_{yy}\|}{\|\mathbf{C}_{dd}\|}, \qquad (3)$$

where $\|\cdot\|$ is the Frobenius norm. It is associated to the residual matrix $\mathbf{C}_{dd} - \hat{\mathbf{C}}_{yy}$ between a specified correlation matrix $\mathbf{C}_{dd}$ and the one estimated from experimental synthesis, $\hat{\mathbf{C}}_{yy}$. A residual error, ε_y, can also be defined with respect to the correlation matrix, $\mathbf{C}_{yy}$, predicted from the measured transfer functions. The normalized spatial correlation matrix, $\hat{\mathbf{C}}_{yy}$, is calculated with respect to a reference signal, $\tilde{y}_{j_0}$, associated to a specific microphone in the array, with entries

$$\hat{C}_{yy}(i,j_0) = \frac{\hat{S}_{yy}(i,j_0)}{\sqrt{\hat{S}_{yy}(i,i)\hat{S}_{yy}(j_0,j_0)}}, \qquad (4)$$

so that $|\hat{C}_{yy}(i,j_0)| \leq 1$ for all $i = 1, \ldots, N_x^{mic} \times N_y^{mic}$. $\hat{S}_{yy}(i,j)$ denotes the cross-spectral density (CSD) function synthesized between the ith and the jth microphone output signals, respectively $\tilde{y}_i$ and $\tilde{y}_j$ for $i,j = 1, \ldots, N_x^{mic} \times N_y^{mic}$. In the following, the reference signal is by default associated to a microphone located at the center of the panel, but it could also be associated to any microphone in the array. Indeed, the CSD functions only depend on the distance between any pair of points for all the microphone locations: they are identically and simultaneously produced with respect to each of the reference microphone which could be at any location in the array. A similar remark also applies to $\mathbf{C}_{yy}$.

We note that the residual error, ε_y (or ε_y^{exp}), sets an upper bound on the relative error due to the differences between the correlation area of the assumed and synthesized random pressure fields, respectively A_d and A_y, such that

$$\varepsilon_y^2 = \frac{A_{d-y}}{A_d} \geq \frac{|A_d - A_y|}{A_d}, \qquad (5)$$

due to the triangle inequality satisfied by the Frobenius norm. A_y is defined in terms of the normalized correlation function C_{yy} as
FIG. 1. Normalized mean-square error for the simulation of an acoustic diffuse field (solid), a grazing plane wave (dashed), and a TBL pressure field (dash-dotted).

$$A_y = \frac{\displaystyle\int\!\!\int_{\infty} |C_{yy}(r_x, r_y; \omega)|^2 dr_x dr_y}{|C_{yy}(0,0;\omega)|^2}, \qquad (6)$$

which can be approximated as $l_x l_y \|\mathbf{C}_{yy}\|^2 / (N_x^{\text{mic}} \times N_y^{\text{mic}})$ after discretization of Eq. (6) over a grid of microphones covering the surface of simulation.

The accuracy with which the spatial correlation structures of the panel response are approximated is quantified by the residual errors, $\varepsilon_\nu^{\exp}$ and $\varepsilon_p^{\exp}$, respectively, associated to the structural and acoustic responses of the panel [see Fig. 3 in Ref. 1]. They are defined as

$$\varepsilon_\alpha^{\exp} = \frac{\|\mathbf{C}_{\alpha\alpha} - \hat{\mathbf{C}}_{\alpha\alpha}\|}{\|\mathbf{C}_{\alpha\alpha}\|}, \qquad \alpha \in \{\nu, p\}, \qquad (7)$$

in terms of the assumed and synthesized spatial correlation matrices, respectively $\mathbf{C}_{\alpha\alpha}$ and $\hat{\mathbf{C}}_{\alpha\alpha}$.

III. PHYSICAL LIMITATIONS OF RANDOM PRESSURE FIELDS SYNTHESIS

An estimate is predicted of the frequency range over which the statistical properties of each kind of target pressure field are reproduced with accuracy by the array of loudspeakers (see Fig. 1). Previous studies[8,9] have shown that a −10 dB mean-square error J_e can be considered as a threshold below which an accurate reproduction of the desired pressure field is achieved. For completeness, comparisons are also made between the assumed and predicted spatial correlation structures, $\mathbf{C}_{dd}$ and $\mathbf{C}_{yy}$, for each of the three random pressure fields to be synthesized (top and middle rows of Figs. 2–4).

It can be seen from Fig. 1 that accurate simulations of an acoustic diffuse field and a grazing incident plane wave can be achieved, respectively, up to about 680 and 550 Hz, when using a near-field array of 4×4 loudspeakers. Over these frequency ranges, the optimal matrix of control filters is able to equalize the acoustic transfer functions measured between the loudspeakers and the microphones. However, another factor limits the performance of the random field synthesis: the number of sources required per correlation length to achieve an accurate reconstruction of each type of excitations over the panel. This factor is shown to be critical for the TBL pressure field statistics.

Empirical energy-based criteria are obtained for an accurate reproduction in terms of the number of sources per

unit correlation length along each of the panel directions, i.e., in terms of $N_x^{\text{loud}} L_x^{\text{cor}}/l_x \times N_y^{\text{loud}} L_y^{\text{cor}}/l_y$, where $N_x^{\text{loud}} \times N_y^{\text{loud}}$, $L_x^{\text{cor}} \times L_y^{\text{cor}}$, and $l_x \times l_y$ are, respectively, the number of sources, the correlation lengths, and the dimensions along each of the panel directions. They are lower bounded by theoretical criteria based on the proper orthogonal decomposition (POD) of the corresponding random processes which leads to the minimum number of uncorrelated components required for the mean-square approximation of each type of excitations. Note that, in order to make the theoretical problem tractable, it is assumed that the total required number of components is equal to the product of the required number of components along each of the panel directions.

A. Acoustic diffuse field

It is deduced from Fig. 1 that 2.7×2.2 acoustic sources per unit acoustic wavelength are required along the panel x and y directions for an accurate reproduction of a diffuse pressure field, thus setting the upper frequency performance of our transducers configuration at 680 Hz. The assumed CSD matrix for an acoustic diffuse field, as given by Eq. (6) in Ref. 1, is associated to a nonrational bandlimited random process. The mean-square values of the POD coefficients, which are also the eigenvalues λ_{mn} of $\mathbf{S}_{dd}$, are given by[11]

$$\lambda_{mn}(k) = \mathrm{R}_{0m}\left(\frac{kl_x}{2},1\right)^2 \mathrm{R}_{0n}\left(\frac{kl_y}{2},1\right)^2, \tag{8}$$

where R_{0m} is known as a radial prolate spheroidal wave function of the first kind and k is the acoustic wave number. The eigenvalues λ_{mn} rapidly decay and approach zero for values of m and n higher than kl_x/π and kl_y/π, respectively. Therefore, for any given k, only a finite number of eigen-

functions or POD components optimally represents the CSD matrix for an acoustic diffuse field. An analytical criterion can thus be determined on the number of uncorrelated components that best reproduce a given acoustic diffuse field over the surface of a test panel. This number scales with the squared frequency and is given by

$$N_{\text{Diff.}} = \frac{(kl_x)(kl_y)}{\pi^2}. \tag{9}$$

The theoretical criterion (9) corresponds to two sources per unit acoustic wavelength. Alternatively, for a given number of sources, $N_{\text{Diff.}}$, this criterion provides an upper frequency limit $f_{\text{Diff.}}$ for the approximation of an acoustic diffuse field

$$f_{\text{Diff.}} = \frac{c}{2}\sqrt{\frac{N_{\text{Diff.}}}{l_x l_y}}, \tag{10}$$

where c is the sound speed. Assuming 16 sources, the criterion (10) predicts a theoretical upper bound of 825 Hz for the approximation of an acoustic diffuse field, which is 17% above the maximum frequency of 680 Hz, obtained from the -10 dB mean-square error criterion.

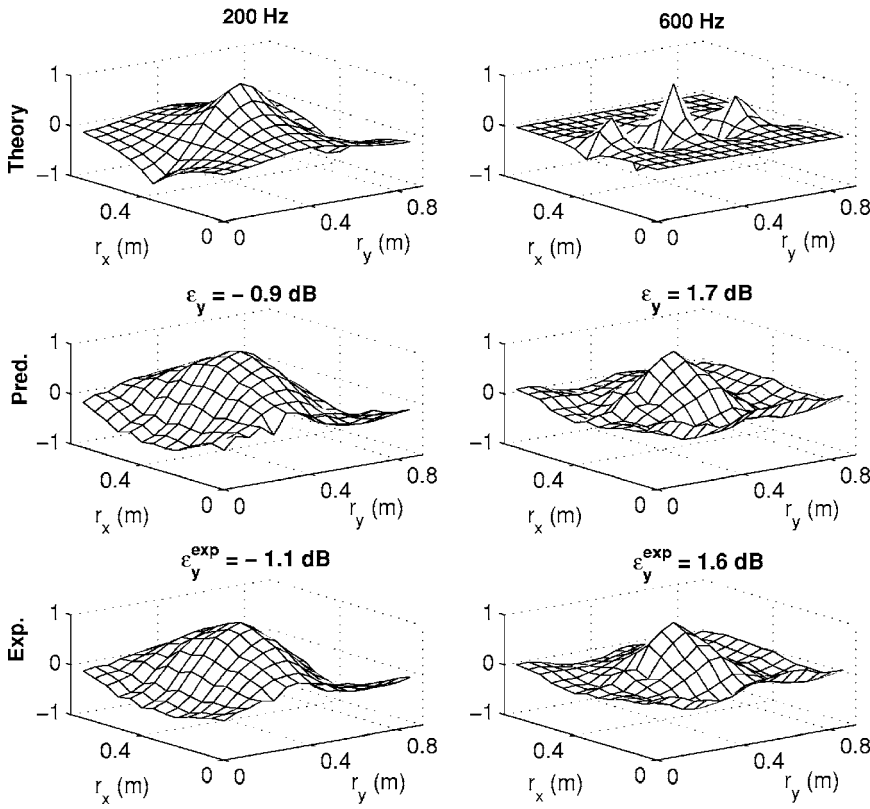
In Fig. 2, we note an excellent reproduction of the diffuse field spatial correlation functions at 480 Hz with a residual error of -9.6 dB. We observe that the assumed and predicted correlation structures stay reasonably similar at 990 Hz, i.e., well above the frequency range of simulation initially determined from the -10 dB threshold, thus suggesting that the energy-based quantifier J_e might lead to rather stringent criteria with respect to the residual error, ε_y.


FIG. 4. Spatial correlation structures at 200 (left) and 600 Hz (right) when perfect reproduction of TBL is assumed (top), that predicted from the measured plant responses (middle), and that experimentally synthesized with 4×4 loudspeakers (bottom).

B. Grazing incident plane wave

The POD decomposition of a periodic homogeneous random field, such as a plane wave of random phase and amplitude [see Eq. (7) in Ref. 1], only requires one independent component, which is a Fourier mode with a wavelength scaling on the spatial period of the correlation function. This satisfies the optimality property of the POD basis functions. For two-dimensional processes, the Fourier mode has the form $e^{2\pi j(x/\Lambda_x + y/\Lambda_y)}$ where $\Lambda_x = \lambda / \sin\theta_K \sin\varphi_L$ and $\Lambda_y = \lambda / \sin\theta_K \cos\varphi_L$ are the traces of the acoustic wavelength λ along each of the panel directions, θ_K and φ_L are the polar and azimuthal incidence angles.

Figure 1 shows that experimental reproduction of a grazing incident plane wave can be attempted up to about 550 Hz which corresponds to 2.7 sources per unit acoustic wavelength along the y direction. More generally, given a frequency range for the simulations, empirical criteria on the number of sources per unit acoustic wavelength required to reproduce a general incident plane wave are found to be

$$N_x^{\mathrm{PW}} \approx 3.4 \left(\frac{kl_x}{2\pi} \right) \sin\theta_K \sin\varphi_L, \tag{11a}$$

$$N_y^{\mathrm{PW}} \approx 2.7 \left(\frac{kl_y}{2\pi} \right) \sin\theta_K \cos\varphi_L. \tag{11b}$$

We note that the theoretical criterion only predicts 0.7 sources per unit acoustic wavelength along the y direction and therefore greatly underestimates the empirical criterion (11b) which mainly reflects the ability of the transducers array to equalize for the acoustical plant response. Further simulations have been achieved when θ_K and φ_L are varied, confirming the validity of the above empirical criteria. In

particular, assuming $\theta_K = 45°$ and $\varphi_L = 0°$, the frequency range of simulation with the loudspeakers array extends up to 700 Hz which is similar to the frequency bandwidth over which an acoustic diffuse field can be well reproduced. The approximate correlation functions shown in Fig. 3 at 300 and 650 Hz correspond, respectively, to −1.1 and −0.8 dB residual error. The comparisons confirm the ability of the loudspeakers configuration to achieve a reasonably good spatial approximation of the grazing incident plane wave over a frequency range wider than the one initially set by the mean-square error criterion, i.e., up to about 550 Hz.

C. TBL pressure field

The CSD matrix for the wall-pressure fluctuations induced by a high speed TBL, as given by the Corcos model [see Eq. (8) in Ref. 1], is associated to a rational nonband-limited random process. The mean-square values, $\lambda_{n,x}$ and $\lambda_{n,y}$, of the POD decomposition of the TBL random processes, along, respectively, the spanwise and the streamwise directions, read

$$\lambda_{n,x} = \frac{(k_c l_x)^2}{(k_c l_x)^2 + [\alpha_x(n-1)\pi]^2}, \quad n = 1, 2, \ldots, \tag{12a}$$

$$\lambda_{n,y} = \frac{(k_c l_y)^2 (1 + \alpha_y^2)}{(k_c l_y)^2 + \alpha_y^2 [(n-1)\pi - k_c l_y]^2}, \quad n = 1, 2, \ldots, \tag{12b}$$

where $k_c = \omega / U_c$ is the convective wave number, U_c is the convection velocity and α_x, α_y are empirical parameters for the Corcos model. The components (12a) and (12b) are calculated as the solutions of a homogeneous differential equa-

tion which, for a rational spectrum, is equivalent to the POD integral eigenvalue problem whose kernel is the random process correlation function.[12] The eigenvalues are monotonically decreasing functions of n and lower bounds can be derived on the number of uncorrelated components, N_x^{TBL} and N_y^{TBL}, that capture the dominant dynamics of the random process. Given a threshold $T(\text{dB}) = 10 \log_{10}(J_e)$ on the average energy captured by the first POD components and after integrating (12a) and (12b) over the component index n, it is found that

$$N_x^{\text{TBL}} = \frac{k_c l_x}{\alpha_x \pi} \tan\left[(1 - 10^{T/10}) \frac{\pi}{2} \right], \tag{13a}$$

$$N_y^{\text{TBL}} = \frac{k_c l_y}{\alpha_y \pi} \left\{ \alpha_y + \tan\left[(1 - 10^{T/10}) \frac{\pi}{2} - 10^{T/10} \tan^{-1}(\alpha_y) \right] \right\}. \tag{13b}$$

Equation (13a) is the limiting criterion on the number of sources required in the spanwise direction since the spanwise correlation length is about eight times shorter than the streamwise correlation length. Given a -10 dB mean-square error, Eq. (13a) predicts 2.1 acoustic sources required per unit spanwise correlation length. With an array of 4×4 sources, it corresponds to upper theoretical frequencies of 92 and 297 Hz for the reproduction of a TBL pressure field induced by a high speed flow, respectively, along the x and y directions.

From Fig. 1, an accurate experimental reproduction of the TBL for high speed flows can only be achieved below about 50 Hz which corresponds to an empirical criterion of 3.7 sources per unit spanwise correlation length. As expected, the -10 dB criterion is lower bounded by the theoretical criterion. Figure 4 shows that the assumed and simulated correlation structures are still quite similar at 200 Hz, i.e., well above the upper frequency range of simulation predicted from the -10 dB criterion in the spanwise direction. From the above criteria, the simulation of TBL excitations induced by low speed flows is found to be very difficult to achieve even at low frequencies, due to the high number of correlation lengths to be synthesized over the panel surface as frequency increases. It would require a much denser array using necessarily smaller acoustic sources with limited performances at low frequencies.

IV. RESULTS ON THE EXPERIMENTAL SYNTHESIS OF THE EXCITATIONS

A. Influence of the loudspeakers configurations

Prior to conducting the synthesis experiments, the practical influence is analyzed of both the number and the location of the loudspeakers on the accuracy with which an acoustic diffuse field is reproduced. The conclusions drawn for the diffuse field case can also be applied to the other types of excitations. The results presented in Fig. 5 correspond to the mean-square error reduction, calculated from the measured transfer functions between a number of loudspeakers and an array of 13×16 microphones. Sets of either 3×3 or 3×4 source array configurations, as subsets of the
FIG. 5. Normalized mean-square error calculated from the measured plant matrix when 3×3 (dotted), 3×4 (thin solid), and 4×4 (thick solid) loudspeakers were used to reproduce an acoustic diffuse field.

4×4 array initially designed for the experiment, have been considered. As expected, the frequency range for an accurate simulation of a random pressure field increases with the number of loudspeakers used within the simulation area. Apart from the number of loudspeakers, the displacement of the sources array from a symmetric position relative to the microphones grid, i.e., the eccentricity, also contributes to degrade the reconstruction accuracy via the plant matrix condition number, but to a lesser extent. This is particularly so for a large number of microphones.

An acoustic diffuse field is experimentally synthesized using the arbitrary wave form generator (AWG) described in Sec. II B of Ref. 1 for each of the source array configurations described above. Figure 6 shows the variations of the corresponding residual error, as given by Eq. (3), when estimated from the synthesized random pressures measured at the microphones positions.[1] It can be seen that the correlation structures are generally better reconstructed as the number of loudspeakers increases and as the geometry of the source
FIG. 6. Normalized residual errors estimated when 3×3 (dotted), 3×4 (thin solid), and 4×4 (thick solid) loudspeakers were used for the experimental synthesis of an acoustic diffuse field.
FIG. 7. Residual errors for the experimental synthesis of random excitations, those predicted from the measured plant responses (diffuse: bold line; plane wave: dotted line; TBL: dash-dotted line) and those experimentally synthesized (diffuse:circles; plane wave: crosses; TBL: diamonds).

array better matches the geometry of the microphone grid. Criteria are now formulated on the number of loudspeakers required per correlation length for an accurate experimental synthesis of the different kinds of random excitations.

B. Experimental synthesis of the random excitations

The statistics of an acoustic diffuse field, a grazing incident plane wave, and TBL wall-pressure fluctuations are experimentally synthesized with an array of 4×4 loudspeakers when optimally driven by the outputs of the AWG. For each kind of excitation, Fig. 7 shows the variations of the residual errors associated to either the experimental synthesis of the random pressures or those predicted from the measured plant response. It is found that the correlation patterns of a diffuse field and a grazing incident plane wave can be accurately reconstructed, respectively, up to about 1 kHz and 650 Hz whereas the spatial statistics of a TBL pressure field can only be synthesized up to about 200 Hz. These frequency ranges for the synthesis correspond to a −1 dB normalized residual error whereas a positive normalized residual error (in logarithmic scale) results in an erroneous reconstruction of the assumed correlation structures.

The results obtained for the experimental synthesis are in good agreement with those predicted from the measured transfer functions and discussed in Sec. III. It shows the robustness of the experimental reconstruction with respect to small changes that necessarily occur between the acoustic transfer functions first measured for the off-line calculation of the optimal drive signals and then equalized by the controller during the synthesis process. Such variations in the plant response are mostly due to inaccuracies in the positioning of the microphones over the surface of simulation as well as electronic and acoustic background noise.

The experimentally reconstructed correlation structures for a diffuse field and a grazing plane wave are shown respectively in Figs. 2 and 3 at frequencies that fall within and towards the upper frequency ranges of simulation. Figure 4 shows results for the experimental synthesis of a TBL exci-

TABLE I. Criteria on the number of acoustic sources required for the synthesis of a number of random pressure fields.

	Criteria on the residual error	Criteria on the mean-square error
Acoustic diffuse field[a]	1.9×1.5	2.7×2.2

[b]Number of acoustic sources per unit spanwise correlation length.

tation at frequencies above the frequency range of simulation. It can be verified that the statistical properties of the random fields are indeed accurately reproduced as long as the residual error is less than −1 dB. Beyond this limit, as a result of an insufficient number of acoustic sources, the amplitudes of the restored correlation structures start to deviate from the assumed statistical properties.

Empirical criteria are summarized in Table I on the number of sources required for an accurate reconstruction of the spatial correlation structures. They can be used as guidelines for further simulations with a denser array of loudspeakers. It can be seen that for all the excitations the residual error criteria are less stringent than those associated to the mean-square error: a −1 dB residual error corresponds to about a −5 dB mean-square error. Indeed, the peak values of the simulated correlation functions mostly contribute to the mean-square errors associated to the power spectral densities of the microphones outputs. Even though the peak values of the simulated correlation structures are underestimated and the −10 dB mean-square error criterion is not yet achieved, a reduced set of loudspeakers is still sufficient to reproduce an approximate correlation structure with the correct correlation area, which is a lower bound for the residual error [see Eq. (5)].

V. RESULTS ON THE PANEL RESPONSE

We now investigate the sensitivity of the panel vibroacoustic response to inaccuracies in the simulated excitations. A representative vibroacoustic model is developed in the Appendix to calculate the CSD matrices associated to the response of the randomly excited panel. This model is used to predict the approximate panel response induced by the random excitations synthesized in the loudspeakers array experiments. We only consider the simulation of an acoustic diffuse field and a TBL pressure field since the conclusions associated to the synthesis of a grazing plane wave are not significantly different from those obtained with a diffuse field, although occurring over a more limited frequency range.

A. Physical limitations

Assuming that the panel acoustic response is sufficiently well reproduced if the mean-square error J_p is less than −10 dB, it can be seen from Fig. 8 that accurate reproduction of the panel acoustic response can be achieved up to about 750 and 120 Hz when subject, respectively, to an acoustic diffuse field and a TBL pressure field. Moreover, a 4×4

FIG. 9. Residual errors associated with the experimental synthesis of a diffuse field (dash-dotted thick), with the induced structural response (dash-dotted thin) and with the induced acoustic response (dotted).

array of suitably driven loudspeakers is able to achieve a rather small mean-square error associated to the panel acoustic response over these frequency ranges whereas little error reductions are achieved for the reproduction of the excitation fields over the same frequency bands. The reason for this is the wave number filtering effect of the panel acoustic response on the random excitation. Indeed, the sound pressure field radiated by the panel is much more spatially coherent than the approximate random excitation field and it can be reconstructed with a fewer number of independent components.

Also we note that the mean-square error induced on the panel response significantly rises at the panel resonances. Indeed, the optimal matrix of control filters only compensates for the acoustic transfer paths between the loudspeakers and the microphones over the simulation surface, but it does not equalize the transfer paths between the loudspeakers and the microphones on the radiating side of the panel, which takes into account the structure resonances. It is anticipated that the error associated to the direct simulation of the panel acoustic response would not exhibit such a resonant behavior, but on the other hand, it would require a preliminary modal analysis of the test panel to determine the optimum matrix of control filters.

B. Experimental results

An acoustic diffuse field is synthesized over the test panel and the residual errors as well as the correlations structures of both the excitation and the induced response are illustrated, respectively, in Figs. 9 and 10. Plots of the same nature are shown in Figs. 11 and 12 when associated to the reproduction of a TBL. For clarity, the correlation structures for the velocity responses in Figs. 10 and 12 have been plotted over a dense set of 26×32 panel elements, but calculations of the residual errors have only been made with 13×16 elemental surfaces.

Figures 9 and 11 indicate that, for both kinds of excitations and up to about 1 kHz, reasonable approximations to

the required spatial acoustic responses can already be achieved with a reduced set of 4×4 loudspeakers. Therefore, the restored correlation structures associated to the panel acoustic responses are generally less sensitive than the excitations to inaccuracies in the synthesis technique. It is also true for the reconstruction of the panel structural response (and near-field acoustic response) but to a lesser extent. We note that these results are less stringent than those based on the mean-square error reduction.

When the response is dominated by resonant modes, a larger residual error reduction is observed in the panel velocity response with respect to the excitation. In this case, the spatial coherence is governed by the resonant mode shapes of the panel and it is weakly sensitive to the approximate nature of the excitation. However, when the panel exhibits a nonresonant behavior, there is a decrease in the spatial coherence of the vibrational field, which therefore shows a greater dependency on imperfections in the simulated excitation. Despite this limitation, the velocity correlation associated to the nonresonant panel response induced at 990 Hz by a synthesized diffuse field is still well restored, with a residual error less than −6 dB (see Fig. 10).

In Fig. 12, the panel structural response to a TBL excitation is dominated at 587 Hz by the resonant mode $(6,1)$ which is weakly excited due to moderate coupling with the inaccurate TBL correlation pattern. This explains the slightly irregular shape observed for the assumed structural response. According to the criteria formulated in Table I, a minimum number of 12×12 loudspeakers would be required for an accurate synthesis of the TBL excitation up to this frequency and clearly, the loudspeakers array used in the experiment is not dense enough to reconstruct the required excitation. Despite this strong limitation, it can be seen that the panel velocity response is quite similar to the assumed one, as well as the acoustic response, with a residual error less than −9 dB. In this case, the resonant mode $(6,1)$ is highly excited and well couples with the inaccurate structure of the simulated TBL.

Theory   **Experiment, $\varepsilon_y^{exp} = -1.7$ dB**

$\varepsilon_v^{exp} = -6.4$ dB

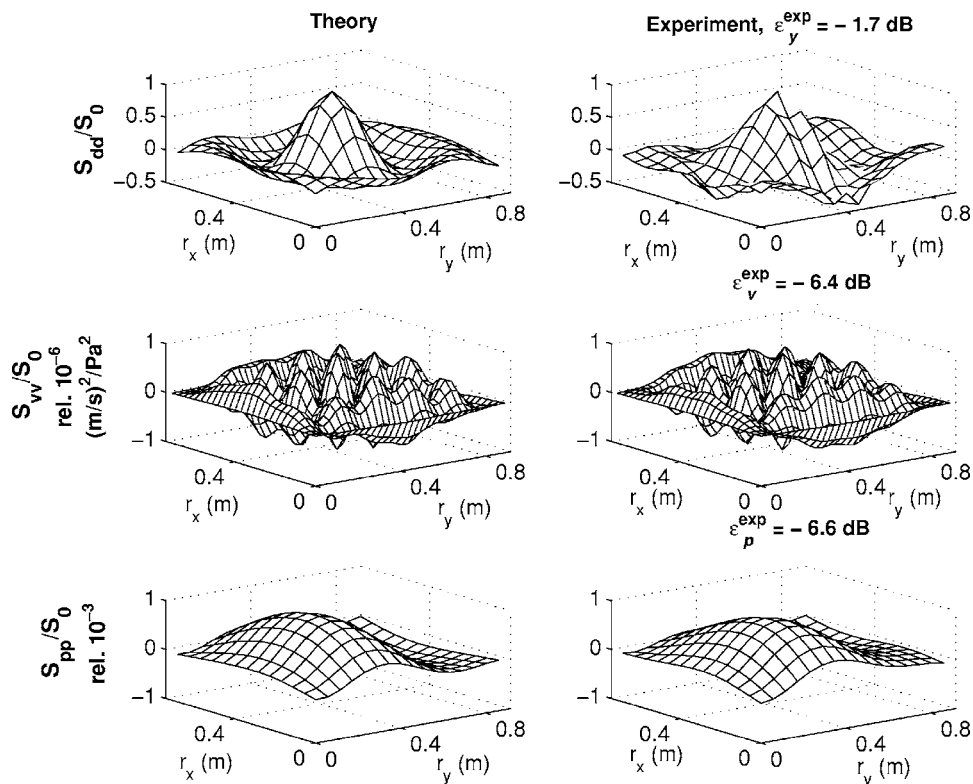
$\varepsilon_p^{exp} = -6.6$ dB


FIG. 10. Spatial correlation structures at 990 Hz associated with the excitation (top) and with the induced structural and acoustic responses (respectively, middle and bottom), when perfect reproduction of a diffuse field is assumed (left) and when it is experimentally synthesized with 4×4 loudspeakers (right).

In Fig. 13, the spectra of the panel kinetic energy are plotted for either a diffuse or a TBL excitation [see Eq. (A9)]. Figure 14 shows the corresponding sound power radiated by the panel [see Eq. (A10)]. In each case, the response spectra are calculated per unit point-power spectral density of the excitations and are therefore associated to the same mean-square wall-pressure value. We observe from the assumed responses that the panel is more efficiently excited by an acoustic diffuse field than by a TBL. At a given frequency, an acoustic diffuse field is correlated over an area greater than the area associated to a TBL excitation, and so it better couples with the panel modes than a TBL.[13]

When comparing the assumed and experimentally simu-

FIG. 11. Residual errors associated with the experimental reconstruction of the TBL pressure field (dash-dotted thick), with the induced structural response (dash-dotted thin) and with the induced acoustic response (dotted).

lated responses, it can be seen that the loudspeakers array is able to reconstruct the spectra induced by a diffuse field excitation up to about 1 kHz. However, the response spectra induced by the simulated TBL progressively deviate from the desired spectra beyond 300 Hz. This is due to the limited number of loudspeakers used in the experiment. In particular, the 4×4 array of loudspeakers cannot synthesize random fields correlated over an area lower than about 40% of the panel area. This lower frequency is reached at about 1 kHz for a synthesized diffuse field whereas it is already achieved at about 300 Hz for a simulated TBL [see Figs. 10 and 12]. Beyond these frequencies, the simulated excitations couple in a similar way with the panel modes and the response spectra induced by the reconstructed random fields tend to become very similar to each other.

VI. CONCLUSIONS

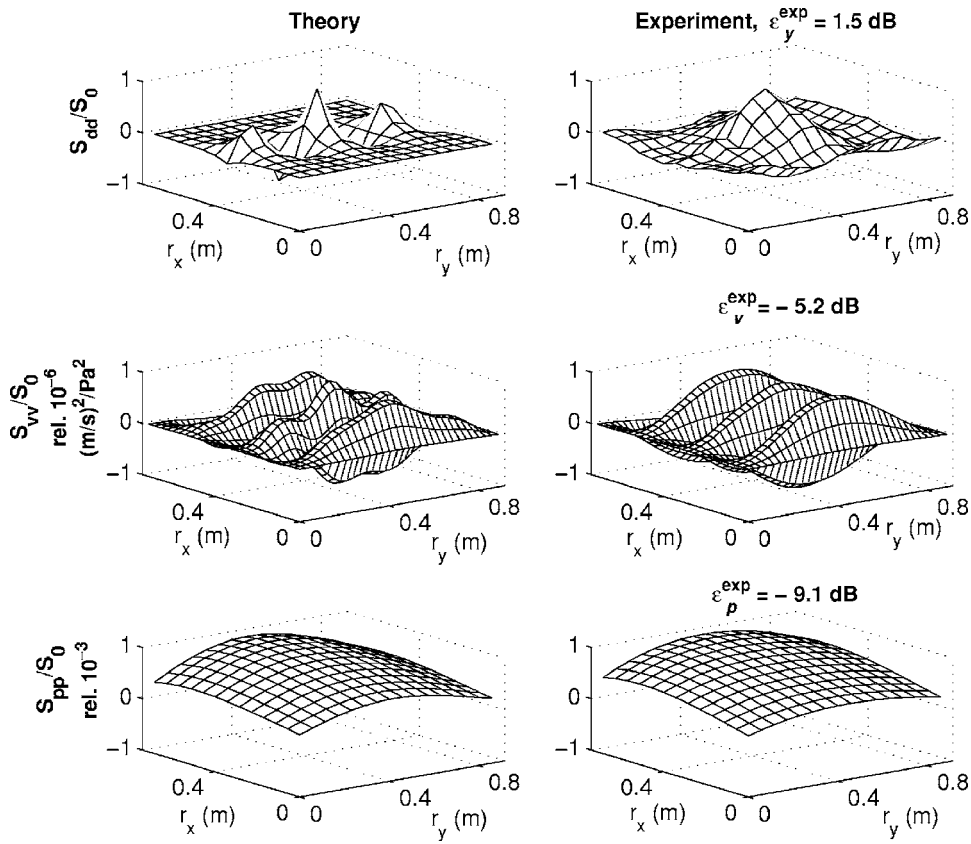
The present paper has shown the practical feasibility of synthesizing various types of random pressure fields with given statistical properties when using a reduced number of suitably driven near-field acoustic sources. The experimental technique based on the off-line calculation of the optimal drive signals and their subsequent synthesis by an arbitrary wave form generator has proved to be successful for reconstructing the spatial statistics of an acoustic diffuse field and a grazing incident plane wave, respectively, up to about 1 kHz and 650 Hz, both in terms of physical performance and robustness. However, it was found that the spatial statistics of TBL wall-pressure fields induced by high speed flows can be synthesized with an acceptable accuracy, only up to about 200 Hz, mainly due to an insufficient number of sources per unit correlation length. The spatial criteria that


FIG. 12. Spatial correlation structures at 587 Hz associated with the excitation (top) and with the panel structural and acoustic responses (respectively, middle and bottom), when perfect reproduction of a TBL is assumed (left) and when it is experimentally synthesized with 4×4 loudspeakers (right).

have been formulated on the required number of loudspeakers are found to be less stringent than the mean-square error criteria which are related to the incident power of the signals synthesized at the microphones outputs.

From this latter energy-based criterion, it is found that the experimental synthesis of an acoustic diffuse field would require at most 2.7 acoustic sources per unit acoustic wavelength which is close to the theoretical lower bound of two sources per unit acoustic wavelength. An excellent reproduction of an acoustic diffuse field could thus be experimentally achieved up to 680 Hz in a semianechoic environment. Fur-

ther work should investigate how the loudspeakers array would perform in a reverberant transmission suite below the Schroeder frequency. The simulation performances may be worsened by the nonminimum phase behavior of the plant transfer matrix to equalize.

At most 3.4 sources per unit trace of the acoustic wavelength are required to simulate experimentally the spatial correlation structure of an incident plane wave of random phase and amplitude. It corresponds to an upper frequency limit of 550 Hz which covers the frequency range above which acoustic progressive wave tubes are able to simulate wideband wall-pressure fluctuations equivalent, in power

spectral density, to jet-induced or propeller-induced excitations. However, very stringent high intensity as well as thermal issues have to be addressed before the experimental rig could be used for fatigue testing purposes.

The simulation of a TBL pressure field with an array of 4×4 uniformly distributed loudspeakers appears to be limited to the very low frequency range and to high speed flows due to the rapid decay of the spanwise correlation length as the frequency increases. Experimental simulation of the TBL correlation structure would require about 3.7 acoustic sources per unit spanwise correlation length. A greater number of loudspeakers as well as a denser distribution along the spanwise direction would contribute to enlarge the frequency range of simulation. However, given that the surface of simulation would be representative of an aircraft skin panel typically of dimensions $0.23 \text{ m} \times 0.25 \text{ m}$, this would require loudspeakers of smaller size with necessarily limited performances at low frequencies. A solution would be to directly simulate the vibroacoustic response of a tensioned skin panel using the experimental rig designed in this work. Good performances are expected since the small size of the test section together with the tensioning effect should enhance the wave number filtering capabilities of the panel and therefore limit the number of sources required.

Most of the physical limitations observed for the simulation of each of the three pressure fields could be overcome through the direct simulation of the panel vibroacoustic response. We have found that imperfections in the reproduction technique have little influence on the panel acoustic response, especially at or near resonances. From a physical point of view, direct simulation could *a priori* be feasible within the frequency bandwidth for which both resonant and coincident modes dominate the panel vibroacoustic response. In particular, the direct reconstruction of the panel response induced by a TBL should be feasible over the hydrodynamic coincidence area, i.e., over the frequency range for which the spacewise variations of the resonant modes are mostly coincident with those of the forcing field. Future work could be directed towards the experimental implementation of such simulation techniques.

ACKNOWLEDGMENTS

APPENDIX: THE VIBROACOUSTIC MODEL

The statistics of the panel velocity response are described by a spectral density function, $S_{\nu\nu}$, between two points $\mathbf{M}$ and $\mathbf{M}'$ located over the test panel of surface Σ. $S_{\nu\nu}$ is expressed in terms of the spectral density of the excitation simulated over the panel, S_{yy}, as

$$S_{\nu\nu}(\mathbf{M},\mathbf{M}';\omega) = B_\omega^{\mathbf{M},\mathbf{M}'}(G_\nu, G_\nu), \qquad (A1)$$

where B_ω is a bilinear form defined as

$$B_\omega^{\mathbf{M},\mathbf{M}'}(u,v) = \int\int_\Sigma \int\int_\Sigma u(\mathbf{M},\mathbf{M}'';\omega)S_{yy}(\mathbf{M}'' - \mathbf{M}''';\omega)$$
$$\times v^*(\mathbf{M}',\mathbf{M}''';\omega)d^2\mathbf{M}''d^2\mathbf{M}''', \qquad (A2)$$

and $G_\nu(\mathbf{M},\mathbf{M}'';\omega)$ is the panel velocity response at a point $\mathbf{M}$ due to a unit point force excitation acting at the point $\mathbf{M}''$, or transfer mobility function. The transfer function G_ν is decomposed as a series of the normal modes of the test panel. This model has been updated in order to be representative of the panel kinetic energy up to 1 kHz, i.e., over the frequency range of simulation.[1] The power spectral density of the panel's kinetic energy is defined as

$$S_{E_c}(\omega) = \frac{\rho h}{2} \int\int_\Sigma S_{\nu\nu}(\mathbf{M},\mathbf{M};\omega)d^2\mathbf{M}, \qquad (A3)$$

where ρ is the panel density, h_p is the panel thickness, and $S_{\nu\nu}$ is obtained from (A1).

An integral representation of the sound pressure field radiated by the panel enables to express the statistical properties, S_{pp}, associated to the acoustic response between two points $\mathbf{P}$ and $\mathbf{P}'$ at two microphones locations, in terms of the spectral density of the excitation reproduced over the panel, S_{yy}, as

$$S_{pp}(\mathbf{P},\mathbf{P}';\omega) = B_\omega^{\mathbf{P},\mathbf{P}'}(G_p, G_p), \qquad (A4)$$

with

$$G_p(\mathbf{P},\mathbf{M}'';\omega) = j\rho_0\omega \int\int_\Sigma G_\nu(\mathbf{M},\mathbf{M}'';\omega)$$
$$\times \frac{e^{-jk|\mathbf{P}-\mathbf{M}|}}{2\pi|\mathbf{P}-\mathbf{M}|}d^2\mathbf{M}. \qquad (A5)$$

G_p is the pressure field radiated at a point $\mathbf{M}$ when the panel is excited by a harmonic point force located at a point $\mathbf{M}''$ on Σ. ρ_0 is the density of the air and k is the acoustic wave number.

The power spectral density of the sound power radiated by the panel is defined as

$$S_\pi(\omega) = \frac{1}{2}\Re\left[\int\int_\Sigma S_{p\nu}(\mathbf{M},\mathbf{M};\omega)d^2\mathbf{M}\right], \qquad (A6)$$

where the cross-spectral density function $S_{p\nu}$ is given by $S_{p\nu}(\mathbf{P},\mathbf{M}';\omega) = B_\omega^{\mathbf{P},\mathbf{M}'}(G_p, G_\nu)$.

The discretized version of the integrals (A1) and (A4) enables to express the CSD matrices of the panel vibrating and acoustic responses, respectively, $\mathbf{S}_{\nu\nu}$ and $\mathbf{S}_{pp}$, in terms of the CSD matrix of the excitation, $\mathbf{S}_{yy}$, as follows:

$$\mathbf{S}_{\nu\nu} = \mathbf{G}_\nu \mathbf{S}_{yy} \mathbf{G}_\nu^H, \qquad (A7)$$

$$\mathbf{S}_{pp} = \mathbf{G}_p \mathbf{S}_{yy} \mathbf{G}_p^H, \qquad (A8)$$

where $\mathbf{G}_\nu$ and $\mathbf{G}_p$ are the plant response matrices whose elements are, respectively, generated by G_ν and G_p. The CSD matrix (A8) is calculated between the far-field pressures ra-

diated by the panel and measured over a plane grid of 13 × 16 microphones positioned one acoustic wavelength apart from the radiating surface.

After discretizing the integrals (A3) and (A6), one obtains the following expressions for the spectra of both the kinetic energy and the sound power radiated by the panel:

$$S_{E_c}(\omega) = \frac{\rho h_p s}{2} \text{Tr}[\mathbf{S}_{\nu\nu}], \tag{A9}$$

$$S_{\pi}(\omega) = \text{Tr}[\mathbf{S}_{\nu\nu}\mathbf{R}], \tag{A10}$$

where s is the area of each panel element and $\mathbf{R}$ is the radiation resistance matrix with entries $\mathbf{R}_{\{i,j\}} = (\rho_0 \omega s^2 k/4\pi)$ sinc(kr_{ij}), r_{ij} is the distance between the midpoints of the ith and jth panel elements.

Acoustic source detection and localization based on wavefield decomposition using circular microphone arrays

Heinz Teutsch[a)] and Walter Kellermann[b)]

Multimedia Communications and Signal Processing, University of Erlangen-Nuremberg, Cauerstr. 7, 91058 Erlangen, Germany

This paper is concerned with the problem of detecting and localizing multiple wideband acoustic sources by applying the notion of wavefield decomposition using circular microphone arrays optionally mounted into cylindrical baffles. The decomposed wavefield representation is used to serve as a basis for so-called modal array signal processing algorithms, which have the significant advantage over classical array signal processing algorithms that they inherently support multiple wideband acoustic sources. A rigorous derivation of modal array signal processing algorithms for source detection and localization, as well as performance evaluations, by means of measurements using an actual real-time capable implementation are presented. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2346089]

I. INTRODUCTION

In this paper, the problem of extracting information contained in an acoustic space, such as the wavefields or parameters describing the acoustic sources, is addressed. Since acoustic wavefields are processes spread out in space and time, it follows quite naturally that these tasks are predominantly performed by evaluating the signals captured by a number of spatially distinct microphones, i.e., microphone arrays. A standard and widely applied vehicle for evaluating the microphone array signals is built upon classical array signal processing techniques.[1,2] Hereby, the term "classical" is used to denote signal processing algorithms that are applied directly to the individual microphones comprising the array. In contrast, the algorithms presented in this paper are applied to signals that are obtained by transforming the microphone signals into a domain defined by the eigensolutions of the acoustic wave equation.

This paper deals with the extraction of the desired source signals from the observed wavefield by means of beamforming and beamsteering techniques.[3] Also, the wavefield parameters, i.e., the number and location of possibly multiple simultaneously active wideband acoustic sources, are of interest for, e.g., acoustic surveillance and for applications based on beamforming as a preprocessing step. While the localization of a *single* desired acoustic source has been the subject of research for several decades—mainly by estimating the time difference of arrival (TDOA) between microphone pairs[4–6]—the problem of estimating the number and positions of *multiple* acoustic sources using nonheuristic methods has only been investigated very recently.[7–12] Motivated by this observation, this paper introduces algorithms that fundamentally support the detection and location of multiple wideband acoustic sources.

The algorithms presented here are not solely based on the foundations of classical array signal processing but also on the principles of wave propagation and wave scattering offered by classical acoustics. Algorithms for parameter estimation solely based on "classical array signal processing" often suffer from a narrowband assumption underlying the signal model. This assumption limits these algorithms' applicability when wideband signals, such as speech, are present in the wavefield under observation. The popular ESPRIT algorithm for source localization tasks is an example of a method that relies on a narrowband assumption.[13] It will be subsequently shown that by also considering methods described by "classical acoustics," algorithms can be derived that are inherently wideband; hence, allowing for more general application. The possibility to formulate parameter estimation algorithms that inherently allow for wideband source models is a previously unknown result of the fusion between classical array signal processing and methods of classical acoustics.

Moreover, it will be shown that acoustic source localization, based on these novel methods, has the potential to unambiguously detect and localize multiple simultaneously active wideband sources in the array's full field of view, i.e. all possible azimuthal angles of arrival.

In this paper, the physics of wave propagation in two-dimensional space is considered for application to localization and detection of multiple wideband acoustic sources. Two-dimensional wavefields can be used as reasonable models for propagating acoustic sound fields in closed rooms, where ceiling and floor reflections are sufficiently attenuated. A natural way of analyzing a two-dimensional wavefield is to decompose it into an orthogonal set of eigenfunctions of the acoustic wave equation in cylindrical coordinates. It will be subsequently shown that this decomposition into so-called "eigenbeams" (EBs) (Ref. 14) can be obtained by circular apertures mounted into a rigid cylindrical baffle, as indicated in Fig. 1.

FIG. 1. Geometric model.

The remainder of this paper is organized as follows. Section II briefly reviews acoustic wavefields created by cylindrical radiators, and the wavefield's modification due to the presence of cylindrical scatterers. The wavefield decomposition process utilizing continuous circular apertures, as well as circular microphone arrays, is outlined in Sec. III. Waveform and parameter estimation techniques employing the EBs, as obtained from the wavefield decomposition process, are developed in Sec. IV. In particular, a novel formulation of the popular ESPRIT algorithm, which allows for the localization of multiple wideband acoustic sources, is presented in Sec. IV B. An acoustic source detection procedure based on EBs is derived in Sec. IV C. Performance evaluations of both algorithms are presented in Sec. V and conclusions are drawn in Sec. VI.

II. ACOUSTIC WAVEFIELDS IN CYLINDRICAL COORDINATES

Assuming linearity of the transmitting medium and steady-state conditions governing all particle interactions, the homogeneous Helmholtz equation describing acoustic wavefields with respect to pressure P in cylindrical coordinates, (r, ϕ, z), can be written as,[15]

$$\nabla^2 P(r, \phi, z) + k^2 P(r, \phi, z) = 0, \qquad (1)$$

where the Laplace operator is given by

$$\nabla^2 = \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \phi^2} + \frac{\partial^2}{\partial z^2}. \qquad (2)$$

Note that the frequency-dependence in terms of the wave number $k = 2\pi f/c$, where f is the frequency and c is the speed of sound, has been omitted for notational convenience.

For *interior* problems, i.e., where all sources are located outside of the cylindrical surface under consideration, the general steady-state solution of the Helmholtz equation, Eq. (1) is[16]

$$P(r, \phi, z) = \frac{1}{2\pi}\sum_{n=-\infty}^{\infty} e^{jn\phi}\int_{-\infty}^{\infty} A_n(k_z)e^{jk_z z}J_n(k_r r)dk_z, \qquad (3)$$

where

$$k_r = \sqrt{k^2 - k_z^2} \qquad (4)$$

are the radial components, and k_z are the z-dependent components of the wave vector $\boldsymbol{k}$, and $k = \|\boldsymbol{k}\|$. $J_n(\cdot)$ denotes the nth-order Bessel function. Note that the integral in Eq. (3) is a Fourier integral. Therefore, the quantity $A_n(k_z)$ can be interpreted as Fourier coefficients. The geometric arrangement for an interior problem is shown in Fig. 1, where the source "S" is located outside the cylindrical boundary at $r = R$.

For *exterior* problems, i.e., where all sources are located inside the cylindrical surface under consideration, the general steady-state solution of the Helmholtz equation in cylindrical coordinates is[16]

$$P(r, \phi, z) = \frac{1}{2\pi}\sum_{n=-\infty}^{\infty} e^{jn\phi}\int_{-\infty}^{\infty} B_n(k_z)e^{jk_z z}H_n(k_r r)dk_z, \qquad (5)$$

where $H_n(\cdot) \triangleq H_n^{(1)}(\cdot)$ denotes the nth-order Hankel function of the first kind and $B_n(k_z)$ are the appropriate Fourier coefficients. A vibrating cylindrical structure, such as the one indicated in Fig. 1, can be considered as an exterior problem.

For simplicity, only normal wave incidence with respect to the z axis is considered in the following discussions, i.e., $\vartheta = \pi/2$, cf. Fig. 1. Assuming further, for now, that $\varphi = 0$, then the pressure due to a single far-field source for $\theta = \pi/2$ and $L \to \infty$ can be written as[17]

$$P_\infty(kr, \phi) = \sum_{n=-\infty}^{\infty} j^n C_n(kr)e^{jn\phi}. \qquad (6)$$

Depending on the applicable boundary conditions,[16,18] it follows that

$$C_n(kr) \triangleq \begin{cases} J_n(kr), & \text{unbaffled} \\ J_n(kr) - \dfrac{J_n'(kR)}{H_n'(kR)}H_n(kr), & \text{baffled-1} \\ J_n(kr) - \dfrac{J_n(kR)}{H_n(kR)}H_n(kr), & \text{baffled-2,} \end{cases} \qquad (7)$$

where the prime associated with the Bessel and Hankel functions denotes the derivative with respect to the argument. Hereby, "unbaffled" means that the circular aperture is not mounted into a cylindrical baffle. "Baffled-1" denotes a circular aperture mounted into an acoustically rigid cylindrical baffle of infinite length, i.e., a rigid scatterer. Here, the acoustic impedance of the baffle is much higher than the acoustic impedance of the transmitting medium resulting in the observation that a large portion of the acoustic energy is reflected without a phase change. "Baffled-2" denotes a circular aperture mounted into a acoustically soft, or pressure-release, cylindrical baffle. In this case, the acoustic impedance of the baffle is much smaller than the acoustic impedance of the transmitting medium resulting in the observation that a large part of the acoustic energy is reflected with a phase change of π.

An important result to be noted here is that the pressure on the *surface* of an infinite-length cylindrical scatterer at $z=0$ follows with $r=R$ from Eq. (6) as

$$P_\infty(kR,\phi) = \sum_{n=-\infty}^{\infty} j^n C_n(kR)e^{jn\phi}. \qquad (8)$$

In the following, only rigid cylindrical baffles are considered, i.e., the "baffled-1" case. The extension of the results to soft cylindrical baffles, i.e., the "baffled-2" case, is straightforward.

Of course, infinite-length cylindrical scatterers are only of theoretical interest. In practice, finite-length cylindrical scatterers need to be considered. Neglecting the boundary conditions at the endcaps, it can be shown that the pressure on the surface of a finite-length rigid cylindrical scatterer, as depicted in Fig. 1 at $z=0$ due to normal plane wave incidence, can be expressed as[17]

$$P_L(kR,\phi) = \sum_{n=-\infty}^{\infty} j^n \left[J_n(kR) - \left(\frac{kL}{\pi} J_n'(kR) \right. \right.$$
$$\left. \left. \times \int_{-\infty}^{\infty} \frac{H_n(\sqrt{k^2-k_z^2}R)\mathrm{sinc}(k_z L)}{\sqrt{k^2-k_z^2}H_n'(\sqrt{k^2-k_z^2}R)}dk_z \right) \right] e^{jn\phi}, \qquad (9)$$

where $\mathrm{sinc}(k_z L) = \sin(k_z L)/(k_z L)$. Note that since[19]

$$\lim_{L\to\infty} \frac{L}{\pi} \mathrm{sinc}(k_z L) = \delta(k_z), \qquad (10)$$

where $\delta(\cdot)$ denotes the Dirac distribution, it follows immediately that

$$\lim_{L\to\infty} P_L(kR,\phi) = P_\infty(kR,\phi), \qquad (11)$$

in the "baffled-1" case.

III. WAVEFIELD DECOMPOSITION

This section details the wavefield decomposition process obtained by circular apertures. For simplicity, the theoretical construct of a continuous circular aperture is considered first. Then, sampled circular apertures, i.e., circular microphone arrays are utilized for the decomposition process. Both apertures are optionally mounted into a rigid cylindrical baffle as indicated in Fig. 1.

A. Continuous circular apertures

A quantity of considerable interest for the following discussion is the response of a circular aperture due to a plane-wave impinging from $(\vartheta = \pi/2, \varphi)$ emitted by a source "S" which is located in the far-field of the aperture, cf. Fig. 1. Both infinite-length rigid cylindrical scatterers, as well as finite-length cylindrical scatterers, are discussed next.

1. Infinite-length cylindrical scatterer

The total response of a circular aperture mounted into an infinite-length rigid cylindrical scatterer can be obtained by applying a spatial Fourier transform[16] to the total incident pressure measured at the circular aperture, Eq. (8), after weighting the aperture by a frequency-dependent function $w(k,\phi)$. Physically, this means that all contributions of the plane wave on the aperture are weighted and integrated to yield the total response of the aperture. Therefore, the response can be expressed as

$$F_m(kR,\varphi) \triangleq \frac{1}{2\pi} \int_0^{2\pi} w(k,\phi)P_\infty(kR,\phi-\varphi)e^{-jm\phi}d\phi, \qquad (12)$$

and can be interpreted as the mth-Fourier series coefficient of the weighted pressure distribution along the aperture. The weighting function can be chosen arbitrarily, although here it will be set to $w(k,\phi)=1$, resulting in an omnidirectionally sensitive aperture. Note that, when spatial sampling of the continuous aperture is considered in Sec. III B, this choice corresponds to employing omnidirectional microphones. With Eq. (8), Eq. (12) becomes

$$F_m(kR,\varphi) = \frac{1}{2\pi} \int_0^{2\pi} \sum_{n=-\infty}^{\infty} j^n C_n(kR)e^{jn(\phi-\varphi)}e^{-jm\phi}d\phi. \qquad (13)$$

By applying the orthonormality property of the exponential function, Eq. (13) can be simplified to finally yield

$$F_m(kR,\varphi) = j^m C_m(kR)e^{-jm\varphi}, \qquad (14)$$

and with $n \triangleq m$,

$$F_n(kR,\varphi) = j^n C_n(kR)e^{-jn\varphi}. \qquad (15)$$

Note that the expression in Eq. (15) can be found as atomic components in the solutions of the Helmholtz equation, cf. Eq. (3) and Eq. (5). Therefore, Eq. (15) represents an eigensolution of the Helmholtz equation in cylindrical coordinates. The symbol $F_n(kR,\varphi)$ is sometimes also referred to as a mode, circular harmonic, or EB of order n.[14] It is obvious from Eq. (15) that these EBs exhibit a response whose frequency-dependent component, $C_n(kR)$, is decoupled from the direction-dependent component, $e^{-jn\varphi}$. Figure 2 shows the normalized frequency-dependent so-called *modal* magnitude response of the first four eigenbeams, $20\log|F_n(kR,\varphi)|$, $n=0,1,2$, and 3. Several properties of the magnitude response are of particular interest here. First, for $n>0$, all eigenbeams exhibit a highpasslike characteristic, with a slope of about $6n$ dB/octave up to the normalized frequency $kR \approx n$. This, in turn, means that a decomposed wavefield, at very small kR, only has the zero-order (omnidirectional) component of considerable strength. As kR increases, more and more eigenbeams are gaining in strength. Second, for an unbaffled aperture, all eigenbeams show periodic zeros in the magnitude response which correspond to the zeros of the respective Bessel functions $J_n(\cdot)$. As a consequence, signals that carry components in the vicinity of the zeros in the magnitude responses cannot be completely identified. By mounting the aperture into a rigid cylindrical baffle, the zeros in the magnitude response disappear, cf. Fig. 2(b). This can be explained by the fact that the Bessel function and the second term in Eq. (7) do not share any common zeros. An additional very interesting property of baffled apertures can be deduced by closely examining and comparing Figs.
(a) unbaffled aperture
(b) infinite-length rigid cylindrical aperture

FIG. 2. Modal magnitude response of a continuous circular aperture.

2(a) and 2(b). For small kR and $n>0$, the magnitude response due to the presence of a rigid baffle obviously lies a few dB above the response of the unbaffled circular aperture. This effect can be interpreted as a *virtual increase of the modal aperture* due to the presence of the scatterer. This effect is examined further in the following. Expressing the relative magnitude response between the response of a circular aperture, mounted into a rigid cylindrical baffle and an unbaffled circular aperture, gives for $\varphi=0$

$$\Delta F_n(kR) \triangleq \frac{J_n(kR) - J_n'(kR)H_n(kR)/H_n'(kR)}{J_n(kR)}$$

$$= \frac{2j}{\pi kR J_n(kR)H_n'(kR)}, \tag{16}$$

where—in the last step—a Wronskian relationship[20] has been used. Since the virtual aperture increase is only effective for small kR, the small argument approximations $(kR \ll n)^{16}$

$$J_n(kR) \approx \frac{(kR)^n}{2^n n!} \tag{17}$$

$$H_n'(kR) \approx \frac{jn!}{\pi \epsilon_n} \left(\frac{2}{kR} \right)^{n+1}, \tag{18}$$

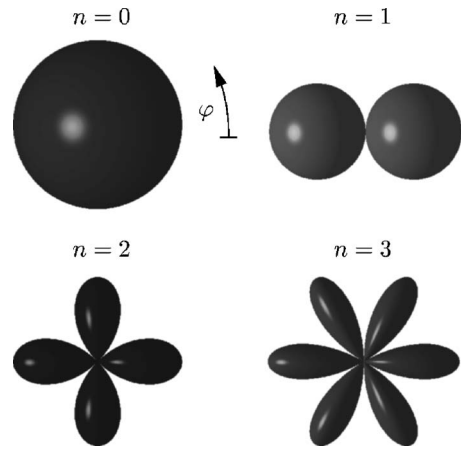
where


FIG. 3. Normalized azimuthal response of the EBs with respect to φ for $n=0,1,2,$ and 3.

$$\epsilon_n = \begin{cases} 1, & n=0 \\ 2, & n>0 \end{cases} \tag{19}$$

applied to Eq. (16) yields

$$\Delta F_n(kR) \approx \epsilon_n. \tag{20}$$

It therefore follows from Eq. (20) that for all $n>0$, the rigid scatterer increases the response of the circular aperture by $20 \log_{10}(2)=6.02$ dB. For quantifying the modal aperture increase, one has to equate the magnitude response of the aperture with the larger radius, $\widetilde{R}$, to the one of "normal" radius, R, multiplied by ϵ_n, i.e., $|J_n(k\widetilde{R})| = \epsilon_n |J_n(kR)|$. With Eq. (17), it follows that the effective modal aperture for $kR \ll n$ increases by a factor of $\Delta R \triangleq \widetilde{R}/R = \sqrt[n]{\epsilon_n}$.

Figure 3 shows the azimuth-dependent component of the EBs, i.e., $e^{-jn\varphi}$. For visualization, $|\text{Re}\{e^{-jn\varphi}\}| = |\cos(n\varphi)|$ is plotted. As can be seen, the eigenbeams correspond to multipoles, i.e., monopole, dipole, quadrupole, etc. Note that these multipoles are mutually *orthonormal*.

2. Finite-length cylindrical scatterer

Applying the same line of arguments as for the infinite-length rigid scatterer, the EBs associated with a finite-length rigid scatterer follow from Eq. (9) as

$$G_n(kR, \varphi) = j^n \left[J_n(kR) - \frac{kL}{\pi} J_n'(kR) \right.$$

$$\left. \times \int_{-\infty}^{\infty} \frac{H_n(\sqrt{k^2 - k_z^2}R)\text{sinc}(k_z L)}{\sqrt{k^2 - k_z^2} H_n'(\sqrt{k^2 - k_z^2}R)} dk_z \right] e^{-jn\varphi}. \tag{21}$$

It can be observed that the azimuth-dependent response is not a function of the scatterer's length. The frequency-dependent response, however, undergoes moderate modifications as the length of the scatterer changes. As an example, Fig. 4 shows the modal magnitude response of a continuous circular aperture mounted into a finite-length rigid cylindrical baffle for $L/R=\{0, 0.1, 1.4, \infty\}$. Note that $L/R=0$ corresponds to an unbaffled aperture, while $L/R=\infty$ corresponds to an aperture mounted into an infinite-length rigid

(a) $n = 0$

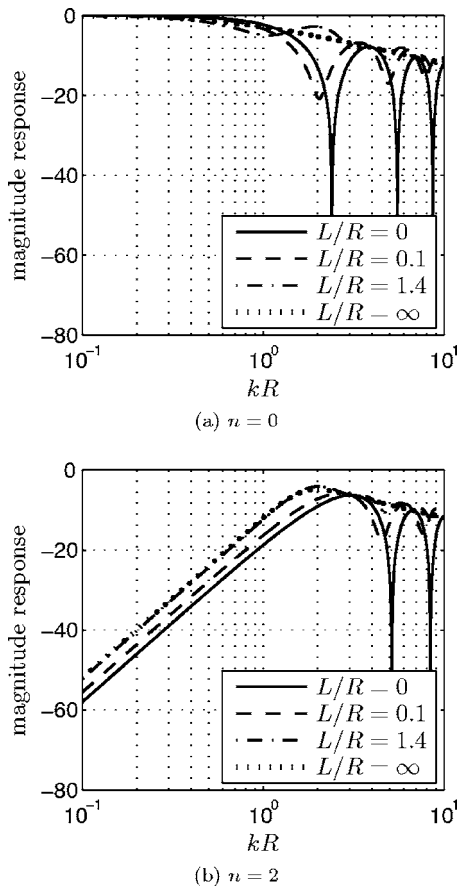
(b) $n = 2$


FIG. 4. Modal magnitude response of a continuous circular aperture mounted into a finite-length rigid cylindrical baffle.

cylindrical scatterer, cf. Fig. 2(b). Note also that $L/R = 1.4$ corresponds to the geometry of the experimental system used for performance evaluations, see Fig. 10 in Sec. V. It can be concluded that even a relatively short cylindrical scatterer is capable of combating the zeros in the frequency response resulting from unbaffled circular apertures. Therefore, continuing further derivations based on an infinite-length rigid cylindrical scatterer seems justified.

B. Circularly symmetric microphone arrays

Up until this point, the discussion exclusively dealt with continuous circular apertures. For real-world applications, however, the continuous aperture needs to be sampled at discrete points in space, i.e., by microphones. In this section, it is assumed that this sampling is performed by ideal omnidirectional microphones. It is further assumed that one wishes to decompose an impinging wavefield into EBs up to a finite order $\mathcal{N}$. Note that in Figs. 2 and 3, $\mathcal{N} = 3$. Following the same reasoning as for the sampling theorem of one-dimensional time-domain signals,[21] a minimum of

$$M \geq 2\mathcal{N}, \tag{22}$$

microphones are necessary for this task.[1] Equality in Eq. (22) denotes the special case of *critical sampling*, which can only be employed when it is ensured that the sensors do not sample the zero crossings of the cosine function, which

would result in a zero-valued output. This sampling theorem can easily be verified by noting that when considering EBs up to order $\mathcal{N}$ eigenbeams, $2\mathcal{N}+1$ Fourier coefficients of the *truncated* Fourier series describing the total wavefield at the circular aperture [cf. Eqs. (8) and (9), where the symbol "∞" is to be replaced by "$\mathcal{N}$"] need to be identified by at least $2\mathcal{N}+1$ samples.

It can be shown[22] that the sampled eigenbeams can be expressed as

$$F_n^s(kR,\varphi) = j^n C_n(kR)e^{-jn\varphi} + \sum_{q=1}^{\infty} j^{Mq-n} C_{Mq-n}(kR)e^{j(Mq-n)\varphi}$$

$$+ \sum_{q=1}^{\infty} j^{Mq+n} C_{Mq+n}(kR)e^{-j(Mq+n)\varphi}, \tag{23}$$

where the superscript "s" indicates the sampling operation applied to the continuous circular aperture. The first term in Eq. (23) is equivalent to the eigenbeam obtained by continuous circular apertures, cf. Eq. (15). The remaining terms are residuals due to the sampling operation. Sampling a continuous circular aperture, therefore, results not only in an EB of order n but also, inseparably superimposed, in EBs of order $n \geq M/2$. In analogy to the error occurring due to sampling of one-dimensional time-domain signals, this distortion is denoted as *modal aliasing*. However, there is one significant difference between one-dimensional time-domain signals and two- or three-dimensional space-time signals. Time-domain signals can be bandlimited in an effective way before application of any type of digital signal processing. This can be achieved by applying analog low-pass filters of sufficiently high order. Therefore, a strict rule can be formulated which quantifies how aliasing can be avoided. This rule is the well-known Nyquist criterion. It is very difficult, if not impossible, to perform effective band-limitation for space-time signals before the application of digital signal processing algorithms, since high-order spatial lowpass filters do not seem to exist. Hence, there is no strict rule guaranteeing an error-free sampling operation. As a consequence, modal aliasing cannot be entirely avoided. However, by judiciously choosing the number of microphones, M, and the maximum spatial frequency, kR, spatial aliasing can be controlled. As an example, Fig. 5 shows the eigenbeam of order $n = 2$ obtained by a continuous baffled circular aperture and a baffled circular microphone array comprising $M = 10$ sensors. Note that Fig. 5(a) can be seen as a combination of Figs. 3 and 2(b) for order $n = 2$. Modal aliasing is clearly visible in Fig. 5(b) for kR greater than about 5, but virtually absent for $kR < 4$.

Evaluation of Eq. (23) shows that the effect of modal aliasing increases with increasing order and decreases with increasing number of sensors. Since no strict aliasing criterion can be specified, a design procedure may include a maximum amount of error to be introduced due to modal aliasing by selecting an appropriate amount of sensors and frequency range of operation. The frequency range of operation has to be restricted since the incoming wavefield is, in general, not bandlimited.

IV. APPLICATIONS OF MODAL ARRAY SIGNAL PROCESSING

In this section, the EBs as derived in Sec. III are used as a basis for a novel concept in array signal processing applied to waveform and parameter estimation tasks, here denoted as *modal* array signal processing. In particular, Sec. IV A briefly discusses the application of modal array signal processing to beamforming, which results in the so-called eigen-beamformer (EBF).[14,23] Sections IV B and IV C detail the application of EBs to acoustic source localization and source detection problems, respectively.

A. Beamforming: EBF

Beamformers using EBs obtained by spherical apertures and arrays have been introduced previously by using the notion of a modal beamformer.[14,23] This section shows how the paradigm of eigenbeamforming can be applied to continuous circular apertures. It is assumed that a planar wavefield has been decomposed into eigenbeams in the sense of Sec. III A 1 and that all processing is applied in the modal domain. In the context of beamforming, these EBs, or multipoles, can be used as building blocks for more complicated beampatterns as shown next.

In general, any square-integrable function on a circle can be expanded into a series of circular harmonics, or eigenbeams. In particular, any desired beampattern, $F^d(kR, \phi)$, with look direction—or rotation angle—$\varphi_s \in \{0 \ldots 2\pi\}$, can be written as a Fourier transform pair as,
FIG. 6. Example of an EBF for $\mathcal{N}=3$.

$$F^d(kR, \phi, \varphi_s) = \sum_{n=-\infty}^{\infty} F_n^d(kR)e^{jn(\phi-\varphi_s)}, \qquad (24)$$

$$F_n^d(kR) = \frac{1}{2\pi} \int_0^{2\pi} F^d(kR, \phi, \varphi_s)e^{-jn(\phi-\varphi_s)}. \qquad (25)$$

Truncating the series to the $\mathcal{N}$th harmonic, *any* beampattern of order up to and including $\mathcal{N}$ can be synthesized. Letting $\phi=\varphi$ and considering a finite number of EBs, i.e., $\mathcal{N}+1$, for real-valued $F^d(kR, \varphi, \varphi_s)$, Eq. (24) can also be written as

$$F^d(kR, \varphi, \varphi_s) = \sum_{n=0}^{\mathcal{N}} \epsilon_n F_n^d(kR)\cos[n(\varphi - \varphi_s)], \qquad (26)$$

where ϵ_n is defined in Eq. (19). Assume one desires to design a frequency-independent third-order hypercardioid pattern for $\varphi_s=0$, i.e.,

$$F^d(\varphi) = \sum_{n=0}^{3} a_n\cos(n\varphi), \qquad (27)$$

where for cylindrically isotropic wavefields[24]

$$\boldsymbol{a} \triangleq [a_0\ a_1\ a_2\ a_3]^T = \frac{1}{7}[1\ 2\ 2\ 2]^T. \qquad (28)$$

Then, since the desired pattern is real valued, it can be readily verified—by comparing Eqs. (26) and (27)—that the EBF structure in Fig. 6 is obtained, where

$$V_n(kR) \triangleq F_n^d(kR) = \frac{1}{j^n C_n(kR)}, \quad n = 0,1,2,3. \qquad (29)$$

It can be deduced that $V_n(kR)$ basically defines a filter for equalizing the magnitude response of the individual eigenbeams, $F_n(kR, \varphi)$, which in turn results in a frequency-independent beampattern, $F^d(\varphi)$. Note that the resulting pattern can be easily rotated by considering a rotation $\varphi_s \neq 0$ in Eq. (26). Note also that, in this section, only continuous circular apertures were considered. An extension to circular microphone arrays is straightforward.

B. Source localization: EB-ESPRIT

Most source localization algorithms for wideband acoustic sources are based on an evaluation of the TDOA between microphone pairs.[4–6] The problem here is that the underlying signal model only allows for a single source to be active at any given time in space.

In this section, a method is derived for *multiple* wideband acoustic source localization based on a popular subspace-based algorithm, namely ESPRIT.[1,13] However, the classical ESPRIT algorithm applied to individual sensor signals, i.e., processing done in *sensor space*, requires the signals to be emitted by narrowband sources. It will be subsequently shown that by applying the notion of EBs to the classical ESPRIT algorithm, an inherently frequency-independent localization method, i.e., EB-ESPRIT, can be devised which does not suffer from this limitation. As a result, EB-ESPRIT performs all processing in so-called *modal space*.

Let $\mathcal{L}$ far-field sources impinge on the circular aperture shown in Fig. 1. Prior to the application of the ESPRIT algorithm, the frequency dependence of the individual EBs must be compensated for, so that

$$\tilde{F}_n(\varphi) \triangleq V_n(kR)F_n(kR,\varphi) \approx e^{-jn\varphi}, \tag{30}$$

where the approximation indicates the assumption that $F_n^s(kR,\varphi) \approx F_n(kR,\varphi)$, i.e., the error due to the sampling operation is assumed to be sufficiently small. Then, the modal array response, i.e., the time-domain output of the discrete spatial Fourier transform (DFT) along the aperture, at time-instance t can be written as

$$y(t) = As(t) + n(t), \tag{31}$$

where

$$A = [F(\varphi_1)| \ldots |F(\varphi_{\mathcal{L}})], \tag{32}$$

is a *frequency-independent* modal array matrix with

$$F(\varphi_\ell) = [\tilde{F}_{-\mathcal{N}}(\varphi_\ell), \ldots, \tilde{F}_{\mathcal{N}}(\varphi_\ell)]^T, \quad \ell = 1,2,\ldots,\mathcal{L}, \tag{33}$$

and where the source vector is defined as $s(t) = [s_1(t),\ldots,s_{\mathcal{L}}(t)]^T n(t)$ denotes the noise vector and $(\cdot)^T$ denotes transposition. The noise field is assumed to be independent of the source signals. Therefore, a total of $Q = 2\mathcal{N}+1$ eigenbeams can be used for further processing.

Dropping the explicit time dependence in the following for notational convenience, the covariance matrix of the modal array response is

$$R_{yy} = E\{yy^H\}, \tag{34}$$

where $E\{\cdot\}$ denotes the expectation operator and $(\cdot)^H$ is the Hermitian operator. Assuming equal power of and statistical orthogonality between the Gaussian and spatially white-noise contributions to each eigenbeam, Eq. (34) can be expressed as

$$R_{yy} = AR_{ss}A^H + \sigma^2\tilde{I}, \tag{35}$$

where R_{ss} is the signal covariance matrix, $\tilde{I}$ denotes the identity matrix, and σ^2 is the noise variance. Let $\xi_l, l = 1,2,\ldots,Q$, denote the lth eigenvector of the covariance matrix R_{yy}. Then, it can be shown[1] that the $\mathcal{L}$ largest eigenvalues, corresponding to the $\mathcal{L}$ signal sources, form the so-called signal subspace E_S as,
FIG. 7. Transition from sensor space to modal space for $\mathcal{N}=2$ and displacement $d_s=1$.

$$E_S \triangleq [\xi_1|\xi_2| \ldots |\xi_{\mathcal{L}}], \tag{36}$$

and that they are linear combinations of the modal array vectors of A. This observation is of central importance for all subspace-based source localization algorithms. Based on the definition of the signal subspace, it can be shown that it is possible to localize up to $\mathcal{L}=Q-1$ simultaneously impinging sources,[1,17] leaving only one eigenvector for the noise subspace with dimension one.

Now, the standard sensor-space ESPRIT[13] can be directly applied to the "modal-space" after replacing the notion of an individual microphone of a standard linear microphone array by an individual eigenbeam of order n, see Fig. 7. It is assumed that the first element in the original sensor space (modal space) array is the first element in the first subarray (modal subarray), and that the (d_s+1)th element in the original array is the first element in the second subarray. Note that d_s, therefore, does *not* correspond to a physical shift in either array configuration. The motivation for this transition can be justified by realizing that the modal array matrix A in Eq. (32) is Vandermonde-type, just like the array matrix of a linear array.[1] A significant difference, however, is the fact that A is now *frequency independent*.

Following the sensor-space ESPRIT algorithm,[13] two overlapping modal subarrays of length $\tilde{M}$ and displacement d_s, cf. Fig. 7, are chosen, whose subarray (modal subarray) matrices satisfy the invariance relation:

$$A_2 = A_1\Phi, \tag{37}$$

where

$$\Phi = \text{diag}\{e^{-jd_s\cdot\varphi_1}, \ldots, e^{-jd_s\cdot\varphi_{\mathcal{L}}}\}, \tag{38}$$

and

$$A_1 = [K|0] A, \tag{39}$$

$$A_2 = [0|K] A, \tag{40}$$

where K is an $\tilde{M} \times \tilde{M}$ identity matrix and 0 is a $\tilde{M} \times d_s$ zero matrix, e.g., 4×1 in Fig. 7. Since the columns of A span the signal subspace, E_S, it holds that

$$E_S = AT, \tag{41}$$

where T is a nonsingular matrix. Therefore, the subspaces of the two subarrays can be defined as

$$E_{S_1} = A_1T, \tag{42}$$

and

$$E_{S_2} = A_2T = A_1\Phi T. \tag{43}$$

By combining Eqs. (42) and (43), one obtains

$$E_{S_2} = E_{S_1}\mathbf{\Psi}, \tag{44}$$

where

$$\mathbf{\Psi} = T^{-1}\mathbf{\Phi}T. \tag{45}$$

$\mathbf{\Psi}$ can then be obtained from Eq. (44) by applying a standard least-squares or total least-squares solver.[25] By realizing that the eigenvalues of $\mathbf{\Psi}$ are the diagonal elements of $\mathbf{\Phi}$, the locations of the sources can be estimated. Note, that in a real system, all equalities in Eqs. (41)–(43) must be replaced by approximate equalities since they must be estimated from the observed covariance matrix, $\hat{R}_{yy}$, which is subject to measurement errors.

Note also, although not shown here, that for a single source an algorithm can be formulated that does not require the frequency compensation used in Eq. (30).[17] This fact has the advantage that uncorrelated noise does not get amplified at low frequencies by low-passlike equalization filters exhibiting a slope of about $6n$ dB/octave, cf. Fig 2.

The fact that individual microphones can be replaced by individual EBs is of central importance in the derivation of EB-ESPRIT. It can be shown[17] that this idea can also be applied to other subspace-based source localization algorithms, such as unitary-ESPRIT,[26] which is basically a real-valued formulation of ESPRIT, and the popular MUSIC algorithm.[27] By applying a temporal Fourier transform to all signals introduced in this section, a frequency-domain formulation of the EB-ESPRIT algorithm can be readily obtained. The performance of EB-ESPRIT in the time-domain is discussed in Sec. V. Note that though offering an improved computational efficiency, EB-ESPRIT—in the frequency-domain—yields equivalent performance compared to the time-domain implementation.

C. Source detection: EB-DETECT

All subspace-based source localization techniques require the number of currently active sources as *a priori* information, cf. Eq. (36). This section describes a detection algorithm for circular apertures which is based on the wavefield decomposition process outlined in Sec. III. In this context, it is important to note that the decomposition of a wavefield into EBs is performed with respect to the aperture's perimeter. It can therefore be observed that, after applying this transformation, one obtains a single virtual receiver exhibiting multiple spatial selectivity characteristics, i.e., the EBs of order n, simultaneously. As mentioned earlier, $n=0$ corresponds to an omnidirectional spatial characteristic, $n=1$ corresponds to a dipole spatial characteristic, and so on.

First, the unbaffled circular aperture is considered. Then, it is explained how to modify the algorithm when baffled circular apertures are employed. It is assumed that the effect of modal aliasing can be neglected due to proper array design, i.e., $F_n^s(kR,\varphi) \approx F_n(kR,\varphi)$.

Let $\mathcal{L}$ plane waves, with unity amplitude, impinge on an unbaffled circular aperture. Then, due to the superposition principle, it follows in modal space that

$$P(kR,\phi,\boldsymbol{\varphi}) = \sum_{\ell=1}^{\mathcal{L}} e^{jkR\cos(\phi-\varphi_\ell)} = \sum_{\ell=1}^{\mathcal{L}}\sum_{n=-\infty}^{\infty} j^n J_n(kR)e^{jn(\phi-\varphi_\ell)}, \tag{46}$$

where $\boldsymbol{\varphi}$ denotes the angular dependency due to the directions of arrival (DOAs) of all $\mathcal{L}$ impinging plane waves, $\boldsymbol{\varphi} = [\varphi_1,\varphi_2,\ldots,\varphi_{\mathcal{L}}]^T$. As a result, it now follows for the EBs corresponding to *multiple* plane waves that, cf. Eq. (15),

$$F_n(kR,\boldsymbol{\varphi}) = \sum_{\ell=1}^{\mathcal{L}} j^n J_n(kR)e^{-jn\varphi_\ell}. \tag{47}$$

As a first step for deriving an algorithm that estimates the number of acoustic wideband sources, a wavefield *synthesis* operation that superimposes the limited number of eigenbeams is considered. This synthesis operation can be seen as an order-limited inverse spatial Fourier series expansion with respect to $\phi=\phi_0$ cf. Eq. (24), which gives with Eq. (47)

$$P(kR,\phi_0,\boldsymbol{\varphi}) = \sum_{n=-\mathcal{N}}^{\mathcal{N}} F_n(kR,\boldsymbol{\varphi})e^{jn\phi_0} + \mathcal{E}_{\text{trunc}}(kR,\phi_0,\boldsymbol{\varphi}), \tag{48}$$

where

$$\mathcal{E}_{\text{trunc}}(kR,\phi_0,\boldsymbol{\varphi}) = \sum_{|n|>\mathcal{N}} F_n(kR,\boldsymbol{\varphi})e^{jn\phi_0} \tag{49}$$

is the error term due to the truncation of the infinite number of eigenbeams to a finite number.

For the sake of simplicity, the truncation error, $\mathcal{E}_{\text{trunc}}(kR,\phi_0,\boldsymbol{\varphi})$ is assumed to be sufficiently small in the frequency range of interest here. Then, Eq. (48) with Eq. (46) and $\phi_0=0$ can be expressed as

$$P(kR,0,\boldsymbol{\varphi}) = \sum_{\ell=1}^{\mathcal{L}} e^{jkR\cos\varphi_\ell} \approx \sum_{n=-\mathcal{N}}^{\mathcal{N}} F_n(kR,\boldsymbol{\varphi}). \tag{50}$$

The transformation of Eq. (50) into the time domain gives the *modal impulse response*

$$p(t,\boldsymbol{\tau}) = \sum_{\ell=1}^{\mathcal{L}} \delta(t-\tau_\ell), \tag{51}$$

where the symbol $\boldsymbol{\tau}$ combines the delays of all $\mathcal{L}$ impinging plane waves, $\boldsymbol{\tau} = [\tau_1,\tau_2,\ldots,\tau_{\mathcal{L}}]^T$ and, where

$$\tau_\ell = \frac{R}{c}\cos\varphi_\ell, \quad \ell = 1,2,\ldots,\mathcal{L}, \tag{52}$$

is a delay caused by the ℓth-plane wave with respect to $\phi_0=0$ on the aperture.

A rule for the system detection problem for wave fronts, propagating in free field can now be derived by observing that the number of Dirac impulses in Eq. (51), corresponds to the number of sources in the impinging wavefield.

Since the targeted application of EB-DETECT involves natural speech signals recorded in real acoustic environments, it follows quite naturally that the actual detection algorithm should be based on an adaptive identification of the
FIG. 8. Equivalent system identification problem.

modal impulse response, $p(t, \boldsymbol{\tau})$, from a block of observed data. In order to transform this task into a classical system identification problem,[28] a reference signal is required. This signal should be independent of the direction with respect to the incoming plane waves as well as of the number of sources. A suitable choice is the zeroth-order EB since it exhibits an omnidirectional spatial characteristic. This signal can be found in Eq. (47) for $n=0$. For the purpose of system identification, the frequency dependence of the zeroth-order harmonic needs to be equalized. The modified reference signal is, therefore,

$$\widetilde{F}_0(kR) \triangleq \frac{F_0(kR)}{J_0(kR)} = \mathcal{L}, \tag{53}$$

which in the time domain equals

$$\widetilde{f}_0(t) = \mathcal{L} \cdot \delta(t). \tag{54}$$

A schematic of the resulting system identification problem is shown in Fig. 8, where the filter $h_1(t)$ is simply a delay that compensates for the delay introduced by the adaptive filter $h_2(t)$, which should be identical to a delayed version of $p(t, \boldsymbol{\tau})$ after convergence.

In practice, this system identification procedure can be performed by applying any adaptive filtering technique such as least mean-squares-based or recursive least-squares-based algorithms.[28]

Figure 9(a) depicts the discretized modal impulse responses $p(t=\nu T, \boldsymbol{\tau})$, where ν is an integer and T is the sampling interval, and $\widetilde{f}_0(t=\nu T)$ for a single bandlimited plane-wave incident on a continuous aperture in free field for $\varphi = \varphi_1 = \pi/6$. The parameters are chosen as $R=0.04$ m, $\mathcal{N}=5$, $f_s=1/T=48$ kHz, and $c=340$ m/s, where f_s denotes the sampling frequency. The sensor signals were bandlimited to $f_{max}=7$ kHz, which corresponds to $(kR)_{max} \approx 5.2$.

Also shown are two vertical lines that represent the maximum delays $\tau_{max} = \pm R/c$, cf. Eq. (52), that need to be considered in this detection scheme. This observation is of some importance since it is expected that moderately reverberant environments only have a limited negative impact on the estimation of the modal impulse response in this very narrow section of the impulse response. Therefore, even though the signal model is based on a free-field model, moderate reverberation should not seriously affect the performance of the algorithm.

In Fig. 9(b), two simultaneously impinging plane waves are considered. The parameters chosen were the same ones that were used to produce Fig. 9(a); the difference being that $\boldsymbol{\varphi} = [\pi/6, 2\pi/3]^T$, i.e., $\varphi_1 = \pi/6$ and $\varphi_2 = 2\pi/3$, indicating si-
(a) single plane-wave, $\varphi = \pi/6$
(b) two plane-waves, $\varphi_1 = \pi/6, \varphi_2 = 2\pi/3$

FIG. 9. Normalized modal impulse responses of the omnidirectional component, omni, and the plane wave component due to $\mathcal{L}$ plane waves, pw($\mathcal{L}$).

multaneously arriving wave fronts. Two distinct peaks in the modal impulse response appear, which correspond to the two sources.

However, as can be deduced from the cosine term in Eq. (52), the two sources cannot be located arbitrarily along the circle. For instance, a plane wave impinging from $\varphi_1 = \pi/6$ cannot be distinguished from a second plane wave impinging from $\varphi_2 = 5\pi/6$, since they cause an identical delay in Eq. (52). This ambiguity problem can be alleviated by also performing the wavefield-synthesis operation in Eq. (48) with respect to $\phi_0 \neq 0$, e.g., $\phi_0 = \pi/2$, and use both detection results for an overall estimate. Any value $\phi_0 \neq 0$ is equivalent to rotating the individual EBs by ϕ_0; thereby resolving the ambiguity problem.

Note that the method presented above cannot be directly applied to baffled apertures without modifications. A wavefield due to a superposition of $\mathcal{L}$ plane waves on a circular aperture mounted into a rigid cylindrical baffle is, cf. Eq. (8)

$$P(kR, \phi, \boldsymbol{\varphi}) = \sum_{\ell=1}^{\mathcal{L}} \sum_{n=-\infty}^{\infty} j^n \left[J_n(kR) \right.$$
$$\left. - \frac{J_n'(kR)H_n(kR)}{H_n'(kR)} \right] e^{jn(\phi-\varphi_\ell)}. \tag{55}$$

Applying the decomposition into EBs as described in Sec. III, yields

$$F_n(kR, \varphi) = \sum_{\ell=1}^{\mathcal{L}} j^n \left[J_n(kR) - \frac{J_n'(kR) H_n(kR)}{H_n'(kR)} \right] e^{-jn\varphi_\ell}. \quad (56)$$

A finite sum of these eigenbeams does not yield an estimate for the superposition of plane waves at the perimeter of the aperture. In contrast to unbaffled circular apertures, the EBs derived from baffled apertures not only represent a wavefield containing plane waves, but also an additional component corresponding to the scattered wave on the surface of the rigid cylinder. Therefore, the superimposed eigenbeams do not correspond to individual peaks in the time domain. Rather, additional peaks occur due to the scattered wavefield. This fact turns the detection task into a very difficult problem. One possibility to overcome this problem is to "undo" the wave scattering effect by a filtering operation. Note that the scattered wavefield only appears in the frequency-dependent component of the eigenbeams, whereas the angular-dependent component remains unaffected. By defining the modified EB of a baffled circular aperture as

$$\widetilde{F}_n(kR, \varphi) \triangleq \frac{F_n(kR, \varphi)}{\left[J_n(kR) - \dfrac{J_n'(kR) H_n(kR)}{H_n'(kR)} \right]} J_n(kR), \quad (57)$$

and choosing

$$\widetilde{F}_0(kR, \varphi) = \frac{F_0(kR, \varphi)}{\left[J_0(kR) - \dfrac{J_0'(kR) H_0(kR)}{H_0'(kR)} \right]} = \mathcal{L}, \quad (58)$$

the same algorithm as presented above for unbaffled circular apertures can then be directly transferred to the baffled circular aperture scenario. Note that the term in the denominator of Eqs. (57) and (58) defines a filter in the frequency domain equalizing the modal frequency response of an nth-order eigenbeam.

Note that by restricting oneself to the employment of *unbaffled* circular microphone arrays, the task of source detection as described in this section can also be accomplished by simply evaluating the relative time differences of plane-wave arrival between two microphones along the circular aperture.[6] The detection scheme based on two individual microphone fails, however, in the case of *baffled* circular microphone arrays since the effect of scattering depends on the plane waves' DOA. Therefore, this effect cannot be compensated for in sensor space by a digital filtering operation, while compensation is possible in modal space.

A few words on resolution capacity are in order, i.e., the question on how close the plane waves can be located along the circle with respect to each other. As can be seen in Fig. 9 and Eq. (52), the maximum delay that needs to be taken into consideration for the detection algorithm depends on the radius of the aperture as well as on the sampling frequency. In the example shown above, where $R=0.04$ m, $c=340$ m/s, and $f_s=48$ kHz, the maximum delay with respect to the peak corresponding to the omnidirectional term is only about ± 6 samples. This, of course, limits the minimum angular distance between the two plane waves, as the two peaks merge into one and can, therefore, not be resolved if the spatial separation is small. For a real system, it is very difficult, if
FIG. 10. Ten-sensor circular microphone array mounted into a rigid cylindrical baffle (dimensions in centimeters).

not impossible, to formulate criteria of general validity on the minimum spacing between the two sources since the accuracy of the identification of the modal impulse responses, depends on the sampling frequency, the frequency range of operation, which is limited due to the effects of wavefield truncation, aperture sampling, and the position of the two sources due to the properties of the cosine function. Note that resolution capacity also largely depends on the properties of the measured acoustic field itself.

V. SYSTEM EVALUATION

The algorithms derived in the preceding sections have been validated by both simulations as well as by measurements performed with an actual circular microphone array, with radius $R=0.04$ m, mounted into a finite-length rigid cylindrical baffle, see Fig. 10. A one Euro coin is placed on top of the array to stress its compact size. Ten calibrated omnidirectional 0.25 in. electret capsules were utilized.

Due to space limitations, the performance evaluations by means of simulations are omitted here. The interested reader is referred to Ref. 17 for a detailed description of the simulation results. In this paper, only performance evaluations obtained by measurements in real acoustic environments are presented in order to stress the fact that the algorithms as described in the previous sections are applicable to real-world scenarios.

The first set of measurements pertains to the array's ability to extract the EBs from a planar wavefield, cf. Sec. III. For this purpose, the array was placed into a low-reverberation chamber. Impulse responses were measured from a fixed loudspeaker position to the array which was constantly rotated by using a stepper motor. The wavefield was then decomposed by applying a spatial DFT to the recorded wavefield along the circular microphone array. As an example, the thus decomposed EB of order $n=2$ due to a sampled circular aperture is reproduced in Fig. 11. It can be directly compared with the simulated second-order EB pre-
FIG. 11. Measured EB of order $n=2$.

(a) mean estimation error

(b) estimator variance

FIG. 13. Measured DOA estimation performance of EB-ESPRIT for $\mathcal{L}=2$.

sented in Sec. III B, see Fig. 5(b). Striking similarities suggest satisfactory agreement with the theory and that the realized finite-length cylindrical baffle is a sufficient approximation of the infinite-length cylindrical baffle considered in Sec. III B.

EB-ESPRIT, cf. Sec. IV B, and EB-DETECT, cf. Sec. IV C, were evaluated in a real moderately reverberated room of size 5.8×5.9 m, exhibiting a reverberation time of about $T_{60}=250$ ms. The array shown in Fig. 10 was placed at the center of a 48-element circular loudspeaker array of 1.5 m radius,[29,30] thereby offering the possibility to simulate 48 source positions in the full field of view of the microphone array.

The performance of EB-ESPRIT due to a *single* speech signal successively applied to all 48 loudspeakers is shown in one superimposed graph in Fig. 12. Here, EB-ESPRIT was evaluated in the time domain, where 100 ms of data was combined into one block. The recorded wavefield, containing a speech signal, was decomposed up to order $\mathcal{N}=3$ and the operating bandwidth was chosen to cover the frequencies from 300 Hz to 3000 Hz. Note that by considering this frequency range, near-field effects can be neglected and plane-wave propagation can be assumed for this particular setup.[17] As can be seen, the maximum error in the estimated azimuth angle, i.e., $\varphi - \hat{\varphi}$, is always less than $3°$ suggesting a highly accurate estimation of the DOA of the impinging plane-wave. Note that no speech activity detector has been employed and that the larger variances around Block Nos. 10

FIG. 12. Measured DOA estimation performance of EB-ESPRIT for $\mathcal{L}=1$.

and 40 are due to speech pauses present in the signal.

The next set of evaluations examines the performance of EB-ESPRIT due to *two simultaneously* impinging plane waves, see Fig. 13. In this case, however, two uncorrelated white-noise signals were chosen since EB-ESPRIT, as with all subspace-based methods, requires the number of active sources in each signal block as *a priori* information. Although this parameter can be obtained via the EB-DETECT algorithm, is kept fixed here in order to avoid possible errors introduced by EB-DETECT. For the purpose of evaluating EB-ESPRIT for two sources, one signal is kept fixed at Loudspeaker No. "1", while the other one is successively fed to one of the other 47 loudspeakers. Additional cylindrically isotropic noise[24] of varying levels is applied in order to test the algorithm's robustness against noise. Figure 13(a) reproduces the mean estimation error in degrees while Fig. 13(b) shows the estimator variance in dB of EB-ESPRIT applied to the source played back by Loudspeaker No. "1". As can be seen, low mean estimation error combined with low estimation variance can be obtained a signal-to-noise ratio (SNR) greater than 0 dB, where "sufficient" spatial distance between the two active loudspeakers is maintained. It is apparent that if the two signals are closely spaced or if the SNR is too low, the performance deteriorates. The counterintuitive effect that for very closely spaced sources the performance seems to improve can be explained as follows. If the two sources are too closely spaced, the algorithm considers them to be a single source. The estimated source position lies right in between the true source positions, with rather remarkable accuracy. The position estimates pertaining to the second
FIG. 14. System excitation signals for EB-DETECT.

FIG. 16. Snapshots of the real-time DOA estimation implementation using EB-ESPRIT for $\mathcal{L} > 1$.

source exhibit comparable performance and are therefore not reproduced here.

The final set of performance evaluations pertains to the EB-DETECT algorithm. As detailed earlier, the goal here is to estimate the number of currently active signals in a wavefield as an input parameter for EB-ESPRIT. Here, the two excitation signals are the speech signals shown in Fig. 14. The male speech signal is reproduced by Loudspeaker No. "5", i.e., $\varphi_1 \approx \pi/6$, while the female speech signal is played back by Loudspeaker No. "17", i.e., $\varphi_2 \approx 2\pi/3$. The signals are recorded by the baffled circular microphone array shown in Fig. 10. The data samples are combined into data blocks of 250 ms length. The maximum wavefield decomposition order is $\mathcal{N} = 5$ and $(kR)_{max} \approx 5.2$. The performance of EB-DETECT is shown in Fig. 15. This figure, in essence, presents a birds-eye view of the adaptively estimated modal impulse response of the plane wave, cf. "pw" Fig. 9, as it progresses in time. The two parallel horizontal white lines bound the region of the modal impulse response that has to be taken into account for the detection purpose, cf. Fig. 9. In combination with Fig. 14, peaks corresponding to regions of a single active speech signal as well as regions of simultaneously active speech signals can be identified, thus allowing for an estimation of the number of active sources in a wavefield. Spurious peaks not corresponding to either source can be removed by appropriate postprocessing due to their small relative amplitudes.

FIG. 15. Performance of EB-DETECT, where $\varphi = [\pi/6, 2\pi/3]^T$.

VI. CONCLUSIONS

In this paper, a decomposition of wavefields by circular apertures has been described. The obtained components have been coined as EBs. It has been shown that a relatively short acoustically rigid cylinder can be approximated reasonably well by an infinitely long rigid cylindrical scatterer with satisfactory accuracy. One of the central messages of this paper is that traditional subspace-based direction finding algorithms, which suffer from narrowband assumptions regarding the source signals, can be directly derived in the modal domain, thereby allowing for the localization of multiple simultaneously active acoustic wideband signals. Also, a method based on modal synthesis has been described for estimating the number of active sources in a wavefield. All methods have been validated by measurements made with a compact-sized realization of a circular microphone array mounted into an acoustically rigid cylindrical baffle. It is important to note that all algorithms presented here are real-time capable. In fact, a real-time capable EB-ESPRIT system has been realized. Figure 16 depicts screenshots of a real-time demonstrator operating on up to five simultaneously active wideband noise sources using the 48-element loudspeaker array. Note that the derivation of all algorithms presented in this paper are based on the assumption of free-field propagation. Although satisfactory performance has been shown for moderately reverberated environments, future developments—which should explicitly model reverberation—promise improved performance for highly reverberated environments.

Adaptive focusing for transcranial ultrasound imaging using dual arrays

F. Vignon, J. F. Aubry,[a] M. Tanter, A. Margoum, and M. Fink

Laboratoire Ondes et Acoustique, ESPCI, Université Paris VII, C.N.R.S U.M.R.7587,
10 rue Vauquelin, 75231 Paris Cedex 05, France

Ultrasonic brain imaging remains difficult and limited because of the strong aberrating effects of the skull (absorption, diffusion and refraction of ultrasounds): high resolution transcranial imaging would require adaptive focusing techniques in order to correct the defocusing effect of the skull. In this paper, a noninvasive brain imaging device is presented. It is made of two identical linear arrays of 128 transducers located on each side of the skull. It is possible to separate the respective influence of the two bone windows on the path of an ultrasonic wave propagating from one array to the other, and thus estimate at each frequency the attenuation and phase shift locally induced by each bone window. The information obtained on attenuation and phase is used to correct the wave fronts that have to be sent through the skull in order to obtain a good focusing inside the skull. Compared to uncorrected wave fronts, the spatial shift of the focal spot is corrected, the width of the focal spot is reduced, and the sidelobes level is decreased up to 17 dB. Transcranial images of a phantom are presented and exhibit the improvement in image quality provided by this new noninvasive adaptive focusing method. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354073]

I. INTRODUCTION

Transcranial ultrasonic brain imaging on adults is currently limited by the strong aberrating effect of the skull bone. In order to obtain a good ultrasound image, it is necessary to focus ultrasound beams in the area under investigation: the thinner the focal spot, the better the image resolution; the lower the sidelobes[1] level, the better the contrast. White *et al.*[1] first investigated the defocusing effect of the skull that prevents one from obtaining good ultrasound images of the brain: the skull bone is absorbing the ultrasonic wave and the speed of sound is not homogeneous inside the skull, so that the phase of the wave front is locally shifted.

As the speed of sound and absorption inside the skull are spatially dependent[1,2] and are *a priori* unknown, it is necessary to use adaptive methods to focus through the skull. Phillips *et al.*[3] and Miller Jones[4] first suggested to apply a time-shift compensation in order to correct the phase distortions induced by the skull. However, this approach is limited by a major drawback: in the limited frequency range available for transcranial brain imaging (1.5–3 MHz), the thickness of the skull bone induce a strong aberration that cannot be reduced to a simple time-delay law. In such strongly aberrating configurations, Fink *et al.*[5] demonstrated that time reversal of ultrasonic waves is much more effective. However, it does not totally correct the skull aberrations because of ultrasonic absorption in the bone that breaks time reversal symmetry of the wave equation.[6] A first improvement of this technique consisted in applying an amplitude compensation of time reversed signals before emission.[6,7] This gain compensation acts as an optimal correction technique for absorption effects as long as dissipation remains spatially located in a very thin absorbing layer. Although this first refinement improves the focusing quality, this assumption of thin absorbing layer is not valid in many areas of the skull bone. In the continuity of the works done by Ebbini *et al.*,[8–11] a more general approach proposed by Tanter *et al.*[12] allowed us to reach the optimal focusing by building a complete inverse filter of the transcranial propagation both in space and time domains. This spatiotemporal inverse filter (the STIF method) can be computed from the experimental measurement of the impulse responses relying on the array to a set of receivers in the focal area. The STIF technique was applied to transcranial focusing by Aubry *et al.*, who demonstrated that a perfect correction of skull aberrations could be achieved.[13] Recently, a faster and more robust extension of this technique based on the concept of iterative time reversal between two arrays was introduced by Montaldo *et al.*[14] However, these methods based on the STIF concept are totally unrealistic in practical configurations as they require the presence of a second array of transducers in the focal area (inside the brain!) and thus cannot be used for medical imaging.

In the current study, a new adaptive strategy overcoming this major drawback is proposed. The second array is no longer located inside the brain but is moved outside the head. A similar setup was proposed two decades ago by Phillips *et al.*[3] and Miller Jones[4] for noninvasive time-shift correction: they proposed to use one single transducer on one side of the head emitting impulses that were recorded and processed by an array located on the other side of the head. This paper can thus be seen as an extension of the work done by Philips *et al.* in the 1980s concerning the noninvasive approach and the work done by Tanter *et al.* in the past ten years concerning the aberration correction.

FIG. 1. (a) Picture of the experimental setup. Two half skulls can be placed alternatively or together between two arrays of transducers. (b) Schematic representation of the experimental set, corresponding to (a), along with an illustration of the physical meaning of the matrices $\mathbf{H}_1(\omega)$ (used in Secs. III and IV), $\mathbf{H}(\omega)$, and $\mathbf{H}_2(\omega)$ (used in Sec. IV).

Thanks to the use of these dual arrays surrounding the patient head (Fig. 1), a noninvasive extension of the STIF technique is proposed and tested. This adaptive focusing procedure is achieved in two steps: the STIF technique is first applied between both arrays and permits one to focus optimally through the whole head from one array to each transducer of the second one. In a second step, the aberrations induced by the skull area located close to the second array are estimated and used to migrate the focal spots inside the brain. In the following, this new strategy will be referred to as the Migrated STIF technique.

The paper is organized as follows: in Sec. II, the defocusing effect of the skull is quantitatively evaluated. In Sec. III, the STIF technique is briefly reintroduced and its potential for spatial focusing through the skull is evaluated. The noninvasive extension of the STIF method is presented in Sec. IV. The experimental validation of this Migrated STIF method (M-STIF) is shown in Sec. V. A single focusing experiment is first analyzed, then the M-STIF method is validated for spatial focusing through different specimens of human skulls. Finally, image quality enhancement is demonstrated on *ex vivo* transcranial images of phantoms.

II. DEFOCUSING EFFECT OF THE SKULL BONE

The experimental setup presented in Fig. 1 is used throughout this study: a sagitally cut human skull is located between two identical linear arrays of 128 ultrasonic trans-
(a)
(b)

FIG. 2. Evaluation of the defocusing effect of the skull. (a) A cylindrical wave front and the resulting spatiotemporal focusing through a skull wall. Bright zones correspond to high pressures, dark zones to low ones. (b) Lateral scans of the temporal maxima of the pressure in focal plane, in dB. Black curve: focusing a cylindrical wave front through water (reference experiment), gray dotted curve: focusing through the skull.

ducers. The whole setup is immersed in water. All skull samples used in this study have been cleaned from organic matter and degassed.

The central frequency of the transducers is 1.5 MHz, with a 50% bandwidth. Each element is connected to its own Input/Output fully programmable electronic channel. The array pitch is 0.5 mm so that the lateral aperture of each array is 6.4 cm. The distance between the arrays is of the order of 15 cm. The elevation dimension of the transducers is 1.2 cm (twelve times the mean wavelength in water).

In this section only one half of the skull is placed between the arrays, as illustrated in Fig. 2(a). The defocusing effect of the skull is experimentally evaluated by emitting a cylindrical law with array 1 in order to focus on the central element of array 2. This cylindrical law and the spatiotemporal acoustic field consequently recorded by array 2 in the focal plane are presented in Fig. 2(a). In order to get a quantitative idea of the spatial focusing quality, the temporal maximum of the acoustic pressure received in focal plane is scanned along the x direction of Fig. 2(a) and its spatial variations are plotted in decibels in Fig. 2(b) (gray dotted curve). In Fig. 2(b) is also plotted as a reference the directivity pattern of the focal spot obtained by emitting a cylin-

drical wave front from array 1 to array 2 in a homogeneous medium (black curve). When focusing the cylindrical law through the skull, the maximum pressure amplitude is laterally shifted 1 mm to the left of the targeted point, the main lobe is two times wider (5 vs 2.5 mm) and the sidelobe level is more than 20 dB higher than in the homogeneous medium. Such alterations of the focusing pattern will respectively induce distortion, resolution, and contrast losses on transcranial ultrasound images.

III. THE (INVASIVE) SPATIOTEMPORAL INVERSE FILTER

A complete description of the STIF theory has been done by Tanter et al.,[12] and detailed experiments of invasive transcranial focusing with the STIF method can be found in Ref. 13. In the following, the invasive STIF technique and formalism are briefly reintroduced, in order to better understand the noninvasive implementation of the Migrated STIF technique.

A. The propagation operator $H_1(\omega)$

Wave propagation from the $N=128$ elements of the imaging array (array 1) to a set of N control points embedded in the medium to image can be described in a matrix formalism. The control points are materialized by a second array of transducers placed in front of array 1 in focal plane, as array 2 in Fig. 2(a). For each pair (control transducer j of array 2, emitting transducer i of array 1), the Green's function $h_{ji}(t)$ is experimentally acquired. It corresponds to the signal received on the jth transducer of array 2 when a temporal Dirac function is emitted from the ith transducer of array 1. This signal includes all the propagation effects through the considered medium as well as the acousto-electric responses of both transducers. Now let $e_i(t)$, $1 \leq i \leq N$ be the input signal on the ith transducer. As the effects of the propagation in the medium are supposed linear, the output signal $f_j(t)$, $1 \leq j \leq N$, received on the jth control point is

$$f_j(t) = \sum_{i=1}^{N} h_{ij}(t) * e_i(t),\tag{1}$$

where the asterisk (*) represents the temporal convolution operator.

This relation is written more easily in the Fourier domain where convolutions become multiplications. Fourier transforming (1) leads to

$$f_j(\omega) = \sum_{i=1}^{N} h_{ij}(\omega) e_i(\omega).\tag{2}$$

N equations similar to Eq. (2) can be written for the N control points and summed up into a single matrix relation:

$$F(\omega) = \mathbf{H}(\omega) E(\omega),\tag{3}$$

where $E(\omega) = {}^t[e_1(\omega), e_2(\omega), \ldots, e_N(\omega)]$ is the emission vector that contains in position i the Fourier transform of the signal emitted from transducer i of array 1; $F(\omega) = {}^t[f_1(\omega), f_2(\omega), \ldots, f_N(\omega)]$ is the focused vector that contains in position j the Fourier transform of the signal re-

ceived on control transducer j of array 2. The transfer matrix $\mathbf{H}(\omega) = \{h_{ji}(\omega)\}_{1 \leq i \leq N, 1 \leq j \leq N}$ describes the propagation through the skull from array 1 to array2 for a chosen frequency component and is called the propagator.

B. The spatiotemporal inverse filter (STIF)

By inverting the matrix relation (3) at each frequency within the bandwidth of the transducers, one can compute the Fourier components $E(\omega)$ of the signals to emit from array 1 in order to focus on any desired target vector $S(\omega)$ on array 2. For instance, in order to focus on a temporal Dirac on the j_0^{th} control point, $S(\omega)$ is set as

$$S_{j0}(\omega) = 1, S_{j \neq j0}(\omega) = 0.\tag{4}$$

The emission signals are then given by

$$E(\omega) = \hat{\mathbf{H}}(\omega)^{-1} S(\omega),\tag{5}$$

where $\hat{\mathbf{H}}(\omega)^{-1}$ is the pseudo-inverse of $\mathbf{H}(\omega)$, regularized by singular value decomposition.[12] The inversion is performed at each frequency within the bandwidth of the transducers. The temporal signals $\{e_i(t)\}_{1 \leq i \leq N}$ to be emitted from array 1 to focus on S on array 2 are finally calculated by an inverse Fourier transform of $E(\omega)$.

Emission signals calculated by STIF in order to adaptively focus through a skull wall are shown in Fig. 3(a) along with the corresponding acoustic field recorded on the receiver array in focal plane. The spatiotemporal emission signals are complicated and nonintuitive but they are able to interfere constructively at the desired focal spot location and destructively in any other position, restoring a focusing quality as good as the one obtained by focusing a cylindrical law through water as can be seen in the lateral focusing patterns presented in Fig. 3(b). The STIF method thus proves that there exists a set of emission signals able to focus through the skull with a focusing pattern close to the one obtained in a homogeneous medium. However it requires the presence of acoustic transducers in the focal region for the acquisition of the propagator: this technique is invasive and is not applicable as is for in vivo imaging.

The noninvasive adaptation of the STIF focusing technique for transcranial imaging is presented in the following.

IV. THE MIGRATED SPATIOTEMPORAL INVERSE FILTER

A. Experimental setup and introduction of the formalism

The experimental setup has to be noninvasive: as shown in Fig. 1 the two arrays (array 1: the imaging array and array 2: the control array) are now located on each side of the full skull. Array 1 will be used later to image the right half of the brain. By switching the role of arrays 1 and 2, array 2 could be used to image the other half of the brain.

For a mathematical description of the method three propagators must be introduced. First, the global propagator $\mathbf{H}(\omega)$ through the entire skull from array 1 to array 2, which can be acquired experimentally noninvasively. Second, $\mathbf{H}_1(\omega)$, which corresponds to the propagator from array 1 to

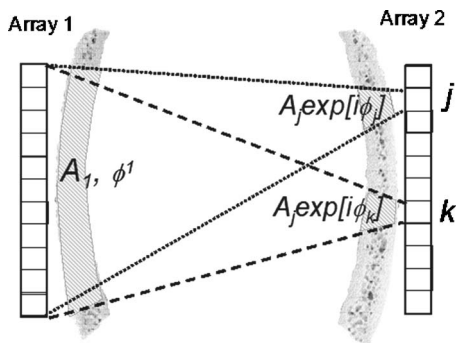
a fictive array 2′ inside the skull stuck to the skull bone window in front of array 2, and then $\mathbf{H}_2(\omega)$, which corresponds to the propagator from the fictive array 2′ to array 2. The whole formalism is illustrated in Fig. 1(b).


FIG. 4. Schematization of the principle used to estimate the phase and amplitude factors. When a beam propagates from one transducer j or k of array 2 to array 1 or in the reverse sense, it crosses only a small portion of the second skull wall that depends on the emitting transducer. As the beam gets larger during its propagation, it always crosses the same portion of the first skull wall that lies in front of the full aperture of array 1, and the phase factor and amplitude shift that it implies thus do not depend on the emitting transducer position of array 2.
(a)
(b)

FIG. 5. Focusing through the skull by the noninvasive migrated STIF. (a) The adaptive focusing wave front calculated by migrated STIF, and the resulting spatiotemporal focusing through the skull. (b) Lateral scan of the temporal maxima of the pressure in focal plane, in dB. Black curve: focusing a cylindrical wave front through water (reference); gray dotted curve: focusing a cylindrical wave front through the skull, and gray dashed curve: focusing the migrated STIF signals through the skull.

The aim now is to deduce from $\mathbf{H}(\omega)$ (the only measurable propagator) an estimation of $\mathbf{H}_1(\omega)$ that could be inverted in order to focus ultrasounds on the plane of the fictive array 2′ virtually inside the brain.

$\mathbf{H}(\omega)$, $\mathbf{H}_1(\omega)$, and $\mathbf{H}_2(\omega)$ are linked by

$$\mathbf{H}(\omega) = \mathbf{H}_2(\omega)\mathbf{H}_1(\omega). \qquad (6)$$

This relation expresses the fact that in order for a wave to propagate from array 1 to 2 [multiplication by $\mathbf{H}(\omega)$] it first has to propagate from array 1 to 2′[multiplication by $\mathbf{H}_1(\omega)$] and then from 2′ to 2 [multiplication by $\mathbf{H}_2(\omega)$].

Instead of trying to directly estimate $\mathbf{H}_1(\omega)$ from information contained in the global propagator $\mathbf{H}(\omega)$, it is proposed here to first estimate $\mathbf{H}_2(\omega)$ by a diagonal propagator $\widetilde{\mathbf{H}}_2(\omega)$ and then invert it in order to deduce an estimator $\widetilde{\mathbf{H}}_1(\omega)$ of $\mathbf{H}_1(\omega)$:
FIG. 6. (a) Lateral scans of the focal spots obtained at each of the 128 focal points by focusing the cylindrical wave fronts through water, in dB. The lateral pressure scan obtained in focal plane when focusing on the jth transducer of array 2 corresponds to the jth column of the represented matrix, the bright zones corresponding to high pressures and the dark zones to low pressures. (b) The lateral scans of the focal spots focusing cylindrical wave fronts through the first skull wall. (c) Focusing of the migrated STIF signals through the first skull wall.

$$\widetilde{\mathbf{H}}_1(\omega)\widetilde{\mathbf{H}}_2(\omega)^{-1}\mathbf{H}(\omega). \tag{7}$$

This indirect method allows us to keep in the estimator $\widetilde{\mathbf{H}}_1(\omega)$ the information on the near field of array 1 that is contained in $\mathbf{H}(\omega)$.

Reducing $\mathbf{H}_2(\omega)$ to a diagonal propagator physically corresponds to the assumption that the skull wall is infinitely thin, and located close to array 2. $\widetilde{\mathbf{H}}_2(\omega)$ is then written as a diagonal propagator in which element (j,j) is an amplitude and phase factor describing the acoustical effects of the small portion of skull bone in front of the jth element of array 2:

$$\widetilde{h}_{2ij}(\omega) = 0 \quad for \ i \neq j,$$

$$\widetilde{h}_{2jj}(\omega) = A_j(\omega)\exp(i\phi_j(\omega)). \tag{8}$$

$A_j(\omega)$ and $\phi_j(\omega)$ are the amplitude and phase factors by which is affected an ultrasound beam that crosses the portion of skull wall in front of transducer j of array 2. Those factors are obtained by the analysis of the propagator through the entire skull $\mathbf{H}(\omega)$ as explained in the following section.

B. Estimation of the amplitude and phase factors induced by the second skull wall

1. Estimation of the amplitude factor

Concerning the amplitude, the influence of the portion of skull located in front of transducer j of array 2 can be modeled by an amplitude factor $A_j(\omega)$ which multiplies the Fourier component ω of the field crossing this local area of the skull. This amplitude factor is estimated as follows. A signal of normalized amplitude 1 is first emitted by transducer j of array 2. The transmitted wave is received on array 1, time-reversed, and sent back by all elements of array 1 to array 2. The amplitude $A_j^{TR}(\omega)$ of the Fourier component at frequency ω of the signal then received on receiver j of array 2 is proportional to the square of $A_j(\omega)$ as the wave has crossed the skull bone twice during the round trip:

$$A_j^{TR}(\omega) = A^1(\omega)^2 A_j(\omega)^2. \tag{9}$$

The proportionality factor $A^1(\omega)^2$ characterizes the global absorption induced by the whole first skull bone window in front of array 1 (it is squared because the wave crosses the first half skull two times during the round trip) and is assumed not to depend, or very slightly, on j. Indeed, when shooting from or focusing on different transducers j and k of array 2, the beam crosses two different small portions of the skull wall in front of array 2 and thus is affected by two different amplitude factors $A_j(\omega)$ and $A_k(\omega)$, while it is af

FIG. 7. Estimation of the focal spot parameters as a function of the lateral position in focal plane, when focusing a cylindrical wave front through water (reference experiment, black curves), focusing a cylindrical law through the skull (gray dotted curves), focusing the M-STIF signals through the skull (gray dashed curves). (a) –6 dB width of the focal spot; (b) lateral shift of the focal spot, (c) contrast loss with respect to the reference.

fected by the whole surface of the skull in front of array 1 experiencing nearly the same amplitude factor $A^1(\omega)$, as evidenced by the dotted and dashed lines in Fig. 4.

As only the relative amplitude factors induced by different parts of the second skull wall are needed, the proportionality factor $A^1(\omega)^2$ due to the crossing of the first skull wall is of no importance. The estimator $\widetilde{A}_j(\omega)$ of the amplitude $A_j(\omega)$ corresponding to the portion of second skull wall located in front of transducer j of array 2 can be taken as the square root of the amplitude of the received signals after this time-reversal process:

$$\widetilde{A}_j(\omega) = [A_j^{TR}(\omega)]^{1/2}. \tag{10}$$

2. Estimation of the phase factor

The phase shift $\phi_j(\omega)$ affecting the Fourier component ω of a wave crossing the portion of skull in front of transducer j of array 2 is estimated as follows. The cylindrical wave front that would converge on transducer j of array 2 in the absence of the skull is sent from array 1. The phase $\psi_j(\omega)$ of the signal received on transducer j after crossing the full skull is extracted at each frequency. This phase differs from $\phi_j(\omega)$ by an additional phase factor $\phi^1(\omega)$ that comes from the crossing of the first half of the skull:

$$\psi_j(\omega) = \phi^1(\omega) + \phi_j(\omega). \tag{11}$$

However the additional phase factor $\phi^1(\omega)$ does not, or very slightly, depend on the position j of the second array we are focusing on. Indeed, when focusing on two different transducers j and k of the second array the beam crosses two different small portions of the skull wall in front of array 2 and thus is affected by two different phase shifts $\phi_j(\omega)$ and $\phi_k(\omega)$, while it is affected by the whole surface of the skull in front of array 1 experiencing nearly the same phase shift $\phi^1(\omega)$, as evidenced by the dotted and dashed lines in Fig. 4. As only the relative phase shifts induced by different parts of the second skull are needed, the additional constant $\phi^1(\omega)$ is of no importance and a phase shift estimator $\widetilde{\phi}_j(\omega)$ for the phase shift $\phi_j(\omega)$ can be taken as

$$\widetilde{\phi}_j(\omega) = \psi_j(\omega). \tag{12}$$

C. Noninvasive focusing

Once $A_j(\omega)$ and $\phi_j(\omega)$ $(1 \leq j \leq 128)$ are estimated, $\widetilde{\mathbf{H}}_2(\omega)$ is constructed as indicated in Eq. (8), replacing $A_j(\omega)$ and $\phi_j(\omega)$ by their estimators $\widetilde{A}_j(\omega)$ and $\widetilde{\phi}_j(\omega)$. The estimated propagator $\widetilde{\mathbf{H}}_1(\omega)$ approaching $\mathbf{H}_1(\omega)$ is then given by inversion of $\widetilde{\mathbf{H}}_2(\omega)$ as indicated in Eq. (7).

$\widetilde{\mathbf{H}}_1(\omega)$ has been derived totally noninvasively through the analysis of signals that cross the full skull. It can now be pseudo-inversed to calculate the STIF signals to focus through the first skull wall. Those noninvasive migrated STIF signals $E_{M\text{-STIF}}(\omega)$ are thus given by

$$E_{M\text{-STIF}}(\omega) = \widetilde{\hat{\mathbf{H}}}(\omega)^{-1} S(\omega). \tag{13}$$

TABLE II. Lateral shift of the focal spot with the cylindrical law through the skull and M-STIF technique through the skull for all eight experiments. Also indicated is its mean value and standard deviation over the eight experiments.

	Exp. 1	Exp. 2	Exp. 3	Exp. 4	Exp. 5	Exp. 6	Exp. 7	Exp. 8	Mean	S.D.
Cylindrical	1	1.5	1	1.5	3	0.5	0	0	**1.1**	1.0
M-STIF	0.5	0.5	0.5	0	0	0	2	0	**0.4**	0.7

The temporal emission signals are finally computed via an inverse Fourier transform.

Finally, from the knowledge of this set of emission vectors focusing in the brain close to the inner part of the skull close to array 2, other focal depths can be reached by simply assuming that the speed of sound is constant inside the brain: simple delays can be applied to the original M-STIF signals that can be used to steer the beams deeper inside the brain.

V. RESULTS

A. Analysis of a single experiment

Concretely, the experimental sequence is the following: the propagator $H(\omega)$ is first acquired through the entire skull, then the migrated STIF (M-STIF) emission signals are calculated as described in the previous section. Then in order to test quality of the M-STIF technique, the focusing pattern is scanned by simply removing the portion of skull bone in front of array 2 without moving the portion of skull bone in front of array 1. The M-STIF signals are emitted from array 1 and the corresponding field in the focal plane is recorded by array 2. The M-STIF spatiotemporal signals set to focus on the central position and the corresponding spatiotemporal field received in focal plane are presented in Fig. 5(a). The lateral directivity pattern of the acoustic amplitude received in the focal plane obtained with the M-STIF technique through the first skull wall is plotted in Fig. 5(b) in a decibel scale (dashed gray curve). It is compared to the reference lateral focusing (focusing a cylindrical wave front through water, black curve) and to the distorted noncorrected focusing (cylindrical wave front through the first skull wall, dotted gray curve). The M-STIF technique corrects the lateral shift of the focal spot induced by the skull bone, narrows the main lobe, and the sidelobe level is reduced up to 17 dB lower than without any correction being performed. This is a significant improvement although the sidelobe level is still 5.5 dB higher than in the reference experiment: the focusing quality that could be obtained through water is not reached because of the imperfect estimation of the propagator $H_1(\omega)$. Assuming the diagonality of the propagator $H_2(\omega)$ through the second skull wall leads to a nonoptimal estimation of $H_1(\omega)$. However, an iterative process could be applied in

order to refine the modeling of $H_2(\omega)$ by introducing a band diagonal matrix instead of a diagonal matrix. This work is currently under investigation.

The migrated STIF technique can be used to focus on any point in the focal plane: being able to focus on different positions in the focal area is essential for imaging. In order to validate this experimentally, the M-STIF technique is now used to focus on any of the 128 transducers of array 2. Each focal spot is scanned in order to check the lateral focusing quality for all focusing locations. The focal spots are presented in Fig. 6: on each of the matrices presented in Fig. 6, the ith column is the lateral focusing pattern when focusing on the ith transducer of array 2 (white corresponds to the highest pressures and black to the lowest pressures). For instance the 64th column of the matrices presented in Fig. 6 corresponds to the pressure curves in Fig. 5(b). The compensation of the spatial shift of the focal spot, the narrowing of the main lobe, and a decrease in the sidelobe level are achieved for each focusing position when using the M-STIF technique. Figures 6(c) and 7 show that the correction reached when using the M-STIF technique to focus through the skull is most efficient when focusing at central positions in the focal plane. In this experiment the focusing quality gets worse when focusing on abscisses $x > 20$ mm. Indeed, because of the curvature of the skull, in this region the transducers of array 2 can be as far as 1 cm away from the second skull wall thus damaging the estimation of $H_2(\omega)$. The estimation of the M-STIF emission signals to focus on these positions is thus less valid.

B. Validation of the M-STIF technique on different skull specimen

The same experiment has been repeated using different skulls, focusing through different parts of the first skull wall, in order to test the robustness of the method.

Eight focusing experiments have been performed through different areas of three different degassed and cleaned skulls. For each experiment, focusing was performed on 128 positions in focal plane. The focusing by migrated STIF through the first skull wall is compared to the one obtained with a prefocused cylindrical wave front through

water (reference focusing) and the one obtained with a cylindrical wave front through the skull (denoted as cylindrical focusing). The characteristics of the lateral focusing are reported when focusing at the central position in focal plane. Three parameters have been measured:

(1) The −6 dB width of the main lobe of the focal spot.
(2) The lateral shift of the main lobe of the focal spot.
(3) The contrast loss with respect to the reference focusing. For the cylindrical focusing through the skull it is the maximum difference, in decibels, of the sidelobe level between the cylindrical focusing through the skull and the reference focusing. For the M-STIF focusing pattern it corresponds to the difference between the M-STIF sidelobe through the skull and the reference sidelobe at the position of this maximum difference [see Fig. 5(b)].

Experiments 1–3 are performed on a first adult skull, experiments 4–6 are performed on a second adult skull specimen, experiments 7 and 8 are performed on a child's skull (12 years old). On each skull different experiments have been done because different relatively planar areas of the skull adequate for performing the M-STIF technique have been encountered. Those planar areas are always located close to the temple. Because the radius of curvature of the child's skull is smaller it is more difficult to find a planar area on this skull that covers the full aperture of the array. The application of the M-STIF technique is thus most difficult when using the child's skull.

The results are summarized in Table I for the −6 dB width, Table II for the lateral shift, and Table III for the contrast loss, for all eight experiments. In all experiments, the lateral width of the focal spot is smaller with the M-STIF method than with the cylindrical focusing through the skull. In all experiments except the seventh one the M-STIF method corrects partially or totally the lateral shift of the focal spot, and in all experiments the M-STIF method sig-
FIG. 9. (a) Reference: image of the wires with cylindrical wave fronts and without the skull (conventional imaging in water). (b) Transcranial image of the wires with the cylindrical wave fronts (conventional focusing). (c) Transcranial image of the wires with the migrated STIF technique.

nificantly reduces the sidelobe level with respect to the side-lobe level of the cylindrical focusing through skull. On average the –6 dB width of the focal spot is lowered by 32%: from 4.9 mm with the cylindrical focusing through the skull to 3.3 mm with the M-STIF through the skull (2.6 mm on average for the reference experiments). The lateral shift of the focal spot is reduced by 63%: from 1.1 to 0.4 mm. Finally, the contrast loss with respect to the reference is lowered by 65%: from 15.1 dB with the cylindrical focusing through the skull to 5.3 dB with the M-STIF method.

In all cases the M-STIF method provides a better lateral focusing quality through the skull than the uncorrected cylindrical wave fronts, and on average the focusing quality reached with the M-STIF method is closer to the reference focusing quality than to the cylindrical focusing quality.

It is worth to say here that experiment 1 corresponds to experiment analyzed in Sec. V A. Tables I–III, show that it is representative of the average results one can obtain applying the M-STIF method on different skulls.

C. Evaluation of the image quality improvement with the migrated STIF method

In order to evaluate the image quality enhancement with the migrated STIF technique, transcranial images of a homemade phantom have been performed *ex vivo*. The phantom is made of a set of nine aluminum wires (0.8 mm diameter) perpendicular to the propagation plane. Those wires are distributed along two axes in order to test axial and lateral focusing quality, and immersed in water (Fig. 8). They have been imaged using cylindrical wave fronts in the absence of the skull [reference image, Fig. 9(a)], using cylindrical wave fronts through the first skull wall [Fig. 9(b)] and using the M-STIF technique through the skull [Fig. 9(c)]. The corrected image exhibits a good enhancement compared to the uncorrected image. In particular, in the uncorrected image [Fig. 9(b)], the shape of the wires is not well rendered, wires 5,6,7 are not resolved and the distortion (the lateral shift of the focal spots) is so strong that wire 1 gets out of the image. The M-STIF image [Fig. 9(c)] resolves wires 5–7, gets wire 1 back into the imaged area, and renders better the shape of the wires. Visually, the general view is much better with M-STIF than with no correction at all.

VI. CONCLUSION

The recent introduction of the STIF for transcranial focusing demonstrated the existence of a set of signals that is able to focus through a human skull with the same quality as conventional prefocused cylindrical signals through a homogeneous medium. The computation of this set of signals required an invasive experimental setup. This technique has been extended in this paper to noninvasive spatiotemporal inverse filter. Thanks to a dual array setup, the optimal set

focusing signals that would be given by the STIF technique can be approached noninvasively. This noninvasive extension of the STIF technique has been termed the Migrated STIF technique because focal spots obtained by STIF outside the head in a first step are migrated inside the brain in a second step. It has been shown that the migrated STIF lowers the -6 dB width of the focal spot by 32%, the lateral shift of the focal spot by 63%, and the contrast loss with respect to the reference by 65% on average. The benefit of such corrections on image quality has been confirmed on transcranial *ex vivo* images of test phantoms.

Applications of precise, adaptive, noninvasive focusing of ultrasounds go well beyond structural imaging. Quantitative blood flow measurements inside the brain can be envisioned with the same approach and could be particularly interesting for the diagnosis of stroke.

Gaussian beams and Legendre polynomials as invariants of the time reversal operator for a large rigid cylinder

Alexandre Aubry,[a] Julien de Rosny,[b] Jean-Gabriel Minonzio,
Claire Prada, and Mathias Fink
Laboratoire Ondes et Acoustique, ESPCI, Université Denis Diderot (Paris VII), CNRS (UMR 7587),
10 rue Vauquelin, 75005 Paris, France

The DORT method (French acronym for decomposition of the time reversal operator) is an active remote sensing technique using an array of antennas for the detection and localization of scatterers. This method is based on the singular value decomposition of the interelement response matrix. In this paper an analytical expression of the singular vectors due to the reflection from a large rigid cylinder is provided. Depending on the array aperture, two asymptotic regimes are described. It is shown that the singular vectors correspond to Hermite-Gaussian modes for large apertures and Legendre polynomials for small ones. Using perturbation theory, the corresponding singular values are deduced. Theoretical predictions are in good agreement with experimental results. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2357700]

I. INTRODUCTION

Acoustical backscattering detection is widely used in many different areas such as medical imaging, nondestructive evaluation, or underwater acoustics. Thanks to technological progresses, arrays made of hundreds of transceivers are built. Consequently, the interest for developing new signal processing techniques is growing fast to make the most of the rich spatial diversity of the collected data. A few years ago an original approach, called the DORT method (French acronym for decomposition of the time reversal operator), was implemented in order to optimize the use of such arrays. The method consists in the singular value decomposition (SVD) of the array response matrix, $\mathbf{K}(\omega)$. Elements of this matrix correspond to the backscattering responses at one frequency ω between all pairs of transducers. The SVD of $\mathbf{K}(\omega)$ provides a set of singular vectors weighted by singular values. The singular vectors of $\mathbf{K}(\omega)$ are the invariants of the time reversal operator $[\mathbf{K}^{\dagger}(\omega)\mathbf{K}(\omega)]$. The SVD is written $\mathbf{K} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\dagger}$, where $\mathbf{\Sigma}$ is a diagonal matrix containing the real positive singular values σ_n. $\mathbf{U}$ and $\mathbf{V}$ are unitary matrices containing the normalized singular vectors $\mathbf{U}_n$ and $\mathbf{V}_n$.

DORT has shown its efficiency in detecting and separating the responses of several scatterers in homogeneous or heterogeneous media.[1] It was applied to the detection of flaws in nondestructive testing,[2] medical acoustics,[3] target detection and identification in underwater acoustics,[4–6] and electromagnetism.[7,8] From the DORT analysis, it is then possible to achieve time reversal imaging thanks to backpropagation algorithms[2,6,9] and also selective focusing.[4,5,8] However, before applying the DORT method to the inverse problem such as target detection and characterization, the direct problem should be investigated. It consists in determining analytically singular vectors and values correspond-

ing to a given target. Until now, almost all such works only address the detection of objects small with respect to the wavelength. For pointlike scatterers, it has been shown that there are only four significant singular values (three for a 2-D configuration) associated to each scatterer[10,11] in acoustics and up to six in electromagnetism.[12]

The case of bigger scatterers has been much less investigated. Chambers[13] extends the analysis of Chambers and Gautesen[10] for a bigger sphere ($ka > 1$, where k is the wave number and a the sphere radius) but singular values and vectors are obtained only numerically. Zhao[14] finds an analytic expression for the first two singular vectors and values in the case of a flat target. His analysis is based on the parabolic approximation of the Green function.

In this study, the DORT method is applied to two different configurations involving a large rigid cylinder. The first configuration corresponds to a "well-resolved" (WR) cylinder, for which the square root product $\sqrt{\lambda a}$ is bigger than the array resolution cell $\lambda F/D$, where λ is the wavelength, F is the distance between the array and the cylinder, and D is the array width. For the second configuration, the cylinder is "poorly resolved" (PR) because its radius a is smaller than the resolution cell ($a < \lambda F/D$). Both models can also be applied to an elastic target if the specular echo dominates the elastic wave radiation such as creeping waves, circumferential waves, etc.

First, experimental singular vectors and values obtained from the two configurations are presented in Sec. II. In Sec. III, these results are compared to those obtained with numerical computations based on a modal decomposition of the scattered wave field. In the next two sections, two asymptotic models explaining the behavior of the singular vectors are proposed. The WR model is deduced from Gaussian beam theory developed in optics. Under the paraxial approximation, the singular vectors are well fitted by Hermite-Gaussian modes. The beam width is established from the ray transfer matrix. In Sec. V, a PR model is proposed and comes from

FIG. 1. Experimental setup.

the Taylor expansion of the backscattering matrix. When this expansion is valid, the singular vectors correspond to Legendre polynomials. The validity ranges of the two models are discussed in Sec. VI.

II. EXPERIMENT

A. Setup

Two experimental configurations have been studied. In both cases a linear array of 124 tranducers is used. Each transducer is 0.387 mm wide and the array pitch is 0.417 mm. Hence the size of the array D equals 53 mm. The central frequency is 3 MHz with 60% bandwidth. The central wavelength λ is about 0.5 mm long. As the transducers are high and parallel to the cylinder axis, the wave propagation is almost two-dimensional. The two configurations differ in the distance F between the array and the cylinder, and the cylinder radius a.

A DORT experiment begins with measuring the interelement matrix of an active array of N transducers (see Fig. 1). A pulse is emitted from transducer i. The back-scattered wave is then recorded with the N transducers of the same array. The operation is repeated for the N emitting transducers. The response from transducer i to transducer j is written $k_{ij}(t)$. The $N \times N$ array response matrix $\mathbf{K}(\omega)$ is the Fourier
FIG. 2. The eight largest singular values at the central frequency (3 MHz) σ_n of the WR cylinder obtained from experimental data ($\bigcirc$), a cylindrical shell model (Sec. III) without transducer directivity ($\times$) and with transducer directivity ($\bullet$), and a model based on the transducer directivity and the Hermite-Gaussian modes ($\diamond$) [Eq. (20)].

transform of the N^2 impulse responses $k_{ij}(t)$ at the frequency ω. The SVD of the array response matrix $\mathbf{K}$ is then calculated with Matlab.

B. Well-resolved cylinder

The first set of experimental data has been obtained by Komilikis et al. (See Figs. 2 and 3).[15] The reflector consists of a steel 0.5-mm-thick 10-mm-radius air-filled cylinder. The distance F equals 70 mm (Fig. 1). The modulus of the corresponding experimental singular vectors $\mathbf{V}_n$ are presented in Fig. 3. In such a hollow cylinder, circumferential waves (Lamb waves) can propagate. However, the radiation of these waves is weak compared to the specular echo. This is why the singular vectors associated with Lamb waves only appear for rank higher than 8.[15] The analysis of this contribution is provided by Prada and Fink.[16]
FIG. 3. The eight singular vectors $\mathbf{V}_n$ at the central frequency (3 MHz) of the WR cylinder associated to the eight largest singular values obtained from experimental data ($\bigcirc$), a cylindrical shell model (continuous line) described in Sec. III, and Hermite-Gaussian modes (dashed line) determined in Sec. IV.
FIG. 4. The seven largest singular values σ_n at the central frequency (3 MHz) of the PR cylinder obtained from experimental data (○), a cylindrical shell model (Sec. III) without transducer directivity (×) and with transducer directivity (●), and a model based on Legendre polynomials (◇) [Eq. (25)].

C. Poorly resolved cylinder

The cylinder radius is much smaller ($a=1.5$ mm) in the second configuration. Its thickness e equals 0.5 mm. Moreover, the cylinder is farther from the array ($F=200$ mm). The seven largest singular values are plotted in Fig. 4. The modulus of singular vectors $\mathbf{V}_n$ corresponding to the six largest singular values are presented in Fig. 5.

III. NUMERICAL CALCULATION OF THE SINGULAR DECOMPOSITION

In order to confirm the experimental results, the backscattering matrix $\mathbf{K}$ has also been numerically computed from an elastic model. At one frequency, the general expression of a pressure field P_{sca} emitted by an isotropic 2D source and scattered by a cylindrical object is given by[17,18]

$$P_{sca}(\mathbf{r}_1, \mathbf{r}_2) = \frac{P_0}{4i} \sum_{l=0}^{\infty} b_l \epsilon_l H_l^{(1)}(k_0 \|\mathbf{r}_1\|) H_l^{(1)}(k_0 \|\mathbf{r}_2\|) \cos(l\theta),$$

(1)

where k_0 is the wave number in water, $H_l^{(1)}$ is the Hankel function of first kind, and P_0 is the incident wave amplitude. $\mathbf{r}_1$ and $\mathbf{r}_2$ are respectively the position of the source and the
FIG. 6. Schematic view of the quantities that are involved in Eq. (1).

receiver with respect to the center of the object O. θ is the angle between $\mathbf{r}_1$ and $\mathbf{r}_2$ (Fig. 6). $\epsilon_n=1$ when $n=0$ and 2 otherwise. In the case of an elastic cylindrical shell, b_l coefficients are given in Refs. 19 and 20. They depend on the outer and inner radius, the longitudinal and transverse wave speeds, the density of the shell, and finally on the inner and outer fluids.

First, the transducers of the array have been considered as omnidirectional, i.e., $K_{i,j}=P_{sca}(\mathbf{r}_i, \mathbf{r}_j)$ where $\mathbf{r}_i$ and $\mathbf{r}_j$ are the positions of the center of the ith and jth transducers on the array. The singular vectors of $\mathbf{K}$ fit the experimental ones (Figs. 3 and 5) correctly. The experimental and numerical singular values differ significantly for the WR cylinder (see Fig. 2). In such a case, the transducer directivity cannot be neglected. The transducer directivity has been taken into account by convolving P_{sca} with the aperture function of the array transducers in emission and in reception. The aperture function is assumed to be a square of width e. The interelement matrix that includes the directivity effect is written

$$K_{i,j} = \int_{-e/2}^{e/2} \int_{-e/2}^{e/2} P_{sca}(\mathbf{r}_i - \mathbf{x}_1, \mathbf{r}_j - \mathbf{x}_2) d\mathbf{x}_1 \, d\mathbf{x}_2.$$

(2)

The integrations over $\mathbf{x}_1$ and $\mathbf{x}_2$ are performed along a line that is parallel to the array. In the experiment, $e=1.5\lambda$. e is larger than the array pitch because mechanical coupling between neighbor transducers has to be taken into account in the effective aperture.

The singular values obtained considering directivity are plotted in Figs. 2 and 4. The directivity has an effect only in the case of the WR cylinder: At 70 mm, the 20° array aper-
FIG. 5. The six singular vectors $\mathbf{V}_n$ at the central frequency (3 MHz) of the PR cylinder associated to the six largest singular values obtained from experimental data (○), a cylindrical shell model described in Sec. III (continuous line), and Legendre polynomials (dashed line) as in (24).
FIG. 7. Schematic top view of the experiment.

ture is comparable to transducer directivity. But at a distance of 200 mm, the angular aperture of the array is three times smaller and the directivity can be neglected.

Although this numerical computation gives exact numerical results, there is no simple analytical expression. Indeed, as the size of the object is large compared to the wavelength, more than 130 terms in the sum contribute to the scattered pressure P_{sca}. Nevertheless, the dominant singular vectors exhibit quite a simple shape for the two configurations. The next two sections show that depending on the value of a and $\sqrt{\lambda a}$ compared to the array resolution $\lambda F/D$, they correspond to Hermite-Gaussian modes or Legendre polynomials.

IV. WELL RESOLVED CYLINDERS: THE HERMITE-GAUSSIAN MODES

A. SVD of continuous fields

A continuous and infinite array is first considered to obtain an analytical expression for the singular vectors and values. This continuous array is at distance F from the edge of the cylinder of radius a (Fig. 7). In the paraxial approximation, the pressure field $\phi'(x')$ on the tangent of the cylinder is given by the Fresnel transformation of the pressure field $\phi(x)$ on the plane of the linear array. With the system being approximately 2D, the field on the tangent becomes

$$\phi'(x') = \int \mathcal{H}_F(x',x)\phi(x)dx \equiv \mathcal{H}_F \times \phi. \qquad (3)$$

$\mathcal{H}_F$ is the kernel of the Fresnel transformation and it is given by

$$\mathcal{H}_F(x',x) = -j\sqrt{\frac{k}{2\pi F}}e^{jkF}e^{j(k/2F)(x-x')^2}, \qquad (4)$$

where k is the wave number and F the distance between the two planes. Using the kernel formalism, the field backscattered toward the array can be worked out. The propagation is composed of three steps: the propagation from the array to the cylinder, the reflection from the cylinder, and then the back propagation from the cylinder to the array. In terms of kernel transformation, the backscattered field ϕ_s is written

$$\phi_s = \mathcal{H}_F \times \mathcal{R}_a \times \mathcal{H}_F \times \phi = \mathcal{K} \times \phi, \qquad (5)$$

where the kernel $\mathcal{R}_a$ describes the specular reflection of the wave from the surface of the cylinder of radius a. The field backscattered towards the array comes from wave reflections on cylinder surface elements located at $x' \ll a$. The parabolic

surface assumption for the cylinder can thus be made. As the cylinder is rigid, only the specular reflection is considered and $\mathcal{R}_a$ is given by

$$\mathcal{R}_a(x_1,x_2) = \mathcal{C}\delta(x_1 - x_2)\exp(-jkx_1^2/a), \qquad (6)$$

where $\mathcal{C}$ is a reflection coefficient of the cylinder and $\exp(-jkx_1^2/a)$ represents the phase delay applied to the backscattered wave field just after reflection due to the cylinder curvature. Thus $\mathcal{H}_F \times \mathcal{R}_a \times \mathcal{H}_F$ represents the scattering kernel $\mathcal{K}$. Performing the SVD means finding the set of singular functions $u_n(x_1)$ and $v_n(x_2)$ associated to the singular value σ_n such as $\mathcal{K}(x_1,x_2) = \Sigma_n u_n(x_1)\sigma_n v_n^*(x_2)$. As the propagation medium is reciprocal, the backscattering kernel is symmetrical, i.e., $\mathcal{K}(x_1,x_2) = \mathcal{K}(x_2,x_1)$. Assuming that the singular values are not degenerated, the reciprocity principle states that $u_n(x) = e^{j\psi}v_n^*(x)$ where ψ is an arbitrary phase. Here, for simplicity, ψ is chosen equal to 0. Finally, the functions v_n verify

$$\sigma_n v_n^* = \mathcal{H}_F \times \mathcal{R}_a \times \mathcal{H}_F \times v_n. \qquad (7)$$

B. Hermite-Gaussian modes and complex radius of curvature

The approach to solve (7) is very similar to the one used to compute the modes of a laser resonator.[21] Indeed, in laser mode theory, the modes of a cavity made of two spherical mirrors are the Gaussian beams that are invariant after reflection from the two mirrors. The Gaussian beams are well adapted to this problem because the wavefronts are parabolic, which corresponds to the parabolic approximations of spherical surfaces. In a 2D problem, the Hermite-Gaussian modes expression is

$$v_n(x) = \sqrt{\frac{2}{\pi w^2}}\xi_{n-1}^H\left(\frac{\sqrt{2}x}{w}\right)\exp\left(-\frac{jkx^2}{2q}\right), \qquad (8)$$

where ξ_n^H are Hermite polynomials and q is the complex radius of curvature (CRC) of the beam at position x. The CRC q is linked to the width w and the radius of curvature of the beam R through the relation

$$\frac{1}{q} = \frac{1}{R} - j\frac{\lambda}{\pi w^2}. \qquad (9)$$

The CRC q is determined from ray transfer matrices,[21] which provide concise and useful representations of both the geometrical propagation of paraxial rays and the propagation with diffraction of Gaussian beams. Hence a simple transformation f changes CRC q_{in} into q_{out} using the expression

$$q_{out} = \frac{Aq_{in} + B}{Cq_{in} + D} \equiv [f] \cdot q, \qquad (10)$$

where A, B, C, and D are the four coefficients of the ray transfer matrix associated with f transformation. The ray transfer matrices, h_F and r_a, corresponding respectively to a propagation over a distance F and the reflection from a cylinder of radius a, are given in Table I.

TABLE I. Ray transfer matrix representation of two Gaussian beam transformations: propagation over a distance F (h_F) and reflection from a cylinder of radius (r_a).

Transformation	h_F	r_a
$\begin{pmatrix} A & B \\ C & D \end{pmatrix}$	$\begin{pmatrix} 1 & F \\ 0 & 1 \end{pmatrix}$	$\begin{pmatrix} 1 & 0 \\ 2/a & 1 \end{pmatrix}$

C. Determination of the singular complex radius of curvature

The conjugate of the phase that appears on the left-hand side of Eq. (7) means that the Gaussian beam width does not change but the radius of curvature is of opposite sign. Consequently, for a beam of CRC q, the CRC of the conjugate beam is written $-q^*$. Finally, the ray transfer matrix formulation of Eq. (7) is

$$-q^* = [h_F] \cdot [r_a] \cdot [h_F] \cdot q. \tag{11}$$

Multiplying the two sides of the last equation by $[h_{-F}]$ and using the property $-([h_{-F}] \cdot q)^* = [h_F] \cdot (-q)^*$ (see Appendix B) it follows that

$$-([h_F] \cdot q)^* = [r_a] \cdot [h_F] \cdot q. \tag{12}$$

Introducing the CRC on the cylinder $q' = [h_F] \cdot q$, the following expression is obtained:

$$-q'^* = [r_a] \cdot q'. \tag{13}$$

Equation (13) implies both wave phase and amplitude remain unchanged after reflection from the cylinder, despite the inversion of the propagation direction. Hence, working out the singular vectors on the array is equivalent to working out the invariants by a reflection from the cylinder. As shown in Appendix C, (13) implies that the beam phase matches the shape of the cylinder. In other words, the CRC at the position of the cylinder is given by

$$\frac{1}{q'} = \frac{-1}{a} - j\frac{\lambda}{\pi w'^2}. \tag{14}$$

There is not yet a condition on the width w'. From the relation $q' = [h_F] \cdot q$, i.e., $q = [h_{-F}] \cdot q'$ the beam width at the array is deduced

$$w^2 = w'^2(1 + F/a)^2 + \frac{\lambda^2 F^2}{\pi^2 w'^2}. \tag{15}$$

The square of the singular value is proportional to the energy of the signal that is backscattered within the array aperture. Under the paraxial approximation, the assumption that all the energy is reflected back to the array can be made. Consequently $\sigma_n = 1$ for every singular vector because energy is conserved. In fact, the degeneracy of $\mathcal{K}$ is broken by considering the effect of the transducers' directivity and the array aperture. Taking into account these two effects implies that the invariants may differ from Gaussian modes. However, the directivity and aperture effects can be considered as small perturbations. From perturbation theory, the first order of the singular vectors is given by the singular vectors of the unperturbed system [here $v_n(x)$] while the perturbed singular values are given by

$$\sigma_n = \int_{-D/2}^{D/2} v_n(x)[\mathcal{K}_d \times v_n(x)]dx, \tag{16}$$

where D is the length of the linear array and $\mathcal{K}_d$ is the backscattering kernel that takes into account the directivity of the transducers. Indeed, Gaussian beams of large width are more sensitive to the finite size of the array. Moreover, they involve larger incident angles on the cylinder, which means that the effect of transducer directivity is stronger. As a result, the maximization of singular values leads to the minimization of the Gaussian mode width w. At the minimum w, dw^2/dw'^2 is null. Using (15) yields

$$w'^2 = \frac{\lambda F a}{\pi(F + a)}. \tag{17}$$

From this value, the width and radius of curvature on the array can be deduced:

$$w^2 = 2F\left(1 + \frac{F}{a}\right)\frac{\lambda}{\pi}, \tag{18}$$

$$R = \frac{-2F(1 + F/a)}{1 + 2F/a}. \tag{19}$$

So, the Gaussian beam at the array is uniquely determined.

D. Determination of singular values

Now the dependence of the singular values with respect to the order of Hermite-Gaussian mode n is investigated. The complete computation of σ_n is performed in Appendix D. Assuming small array elements of effective width e, it follows that

$$\sigma_n \propto \int_{-D/2}^{D/2} |v_n(x)\text{sinc}(\pi e/\lambda R)|^2 \, dx. \tag{20}$$

This equation confirms that the order of the Hermito-Gaussian mode corresponds to the order of the singular vector.

In summary, the singular functions of $\mathcal{K}$ are Hermite-Gaussian modes of width and radius of curvature respectively given by (18) and (19). Assuming small size transducers, the singular values are given by (20).

E. Validity of the approximation

There are two requirements on the Gaussian beams to properly fit at least the first singular function. First, the beam width at the cylinder position should be smaller than the cylinder radius ($w' < a$) to carry out the local approximation of a parabolic shape. Second, in order to observe the complete Gaussian beam on the array, the Gaussian width at the array position should be smaller than the array size ($w < D$). From (17) and (18), it follows that

$$\lambda < a \tag{21}$$

and

Aubry *et al.*: Gaussian and Legendre invariants

$$\lambda F/D < \sqrt{a\lambda}. \tag{22}$$

If these conditions are fulfilled, singular vectors correspond to Hermite-Gaussian modes.

V. POORLY RESOLVED CYLINDERS: THE LEGENDRE POLYNOMIALS

A. Legendre polynomials as singular vectors

The b_l coefficients in (1) are null when l becomes larger than ka. Consequently, the $\cos(l\theta)$ terms are monotonic when $ka\theta < 1$. Since the value of θ is bounded by D/F, the backscattered field smoothly depends on emitting/receiving positions on the array when $\lambda F/D < a$. If this last condition is fulfilled, the backscattered pressure field can be expressed with the following Taylor expansion,

$$P_{sca}(x_1,x_2) = e^{ik(r_1+r_2)} \sum_{n_1,n_2} \frac{\partial_{x_1}^{n_1}\partial_{x_2}^{n_2}\hat{P}_{sca}(0,0)}{n_1!n_2!} x_1^{n_1}x_2^{n_2}, \tag{23}$$

where $P_{sca}(x_1,x_2) = e^{ik(r_1+r_2)}\hat{P}_{sca}(x_1,x_2)$, $r_1^2 = F^2 + x_1^2$, and $r_2^2 = F^2 + x_2^2$. In Appendix A, it is shown that if the Taylor coefficients decrease sufficiently rapidly, the eigenfunctions are given by

$$v_n(x) \approx e^{ikr}\widetilde{\mathcal{L}}_{n-1}(x), \tag{24}$$

and the singular values by

$$\sigma_n \approx D\left(\frac{D}{2F}\right)^{2n}\frac{(2n+1)^2}{(2n+1)!!^2}\partial_{\chi_1}^n\partial_{\chi_2}^n Q(0,0), \tag{25}$$

where $\widetilde{\mathcal{L}}_n$ is the normalized Legendre polynomial of order n (see Ref. 22) and $Q(\chi_1,\chi_2) = \hat{P}_{sca}(\chi_1 F, \chi_2 F)$. Therefore the singular functions v_n are proportional to the Legendre polynomials $\widetilde{\mathcal{L}}_{n-1}$ of order $n-1$. When $F \gg D$, this result is in agreement with Zhao's ones.[14] Zhao works out the first two singular vectors and values from a Taylor expansion of the backscattered field from a flat target. Zhao's model seems to work for a larger range of distances F, but its analysis is restricted to the first two singular vectors and values. The Legendre polynomials model is less accurate but provides the whole basis of singular vectors.

B. Validity of the approximation

In order to observe the Legendre polynomials as singular vectors, the Taylor coefficients should decrease as the indexes increase. This usually happens when the function is sufficiently monotonic and smooth. For the cylinder, the backscattered field on the array slowly fluctuates when $\lambda F/D$ is small compared to the cylinder radius a. However, for more complex scatterers (resonant scatterers for instance), different criteria that involve parameters other than the typical size of the scatterer may have to be introduced. In such PR regime, the singular values decrease very quickly with n. The first obvious consequence is the difficulty to measure them experimentally. The second consequence is the extreme sensitivity of the singular values to a small mismatch between the experimental and theoretical singular vectors. For instance, one can assume a weak coupling between the first

and the sixth theoretical singular vectors. The sixth experimental singular vector is for instance given by $\widetilde{\mathcal{L}}_5 + \widetilde{\mathcal{L}}_0/10$. The singular value equals now $\beta_{0,0} + \beta_{5,5}/100 + \beta_{1,5}/10 + \beta_{5,1}/10$, but $\beta_{0,0}$ is $(F/D)^5$ larger than $\beta_{5,5}$, consequently the sixth singular value can be completely modified (β coefficients are given in Appendix A). Hence in the PR approximation, even if the singular vectors seem to be well-fitted by Legendre polynomials, a small mismatch between theoretical and experimental singular vectors implies a strong deviation of singular values from the theoretical prediction given in (25).

VI. DISCUSSION

In the experiment, the array is discrete and the SVD is applied to the response matrix $\mathbf{K}$. The singular vectors $\mathbf{V}_n$ correspond to singular functions v_n given by (8) and (24) evaluated at each transducer position x_j:

$$\mathbf{V}_n = [v_n(x_1) \quad v_n(x_2) \quad \cdots \quad v_n(x_N)]. \tag{26}$$

The comparison between analytical, experimental, and numerical singular vectors and values are shown in Figs. 2 and 3 for the WR cylinder and Figs. 4 and 5 for the PR one.

A. Well-resolved cylinder

Numerical calculations of the singular vectors give the same results with or without considering transducer directivity and are in a good agreement with experiment (Fig. 3). On the contrary, the singular values depend mainly on the directivity of the transducers (Fig. 2), so the use of the perturbation theory is judicious. An excellent agreement between numerical calculation considering transducer directivity, Hermite-Gaussian modes, and experiment is found for the first five singular values and vectors (Figs. 2 and 3).

A numerical simulation considering omnidirectional transducers shows that for $n \geq 6$, the singular values decrease because of the finite size of the array. In a similar way, for $n \geq 6$, the mismatch between the Hermite-Gaussian modes is especially noticeable on the edges of the array. So, beyond this order, the finite size of the array cannot be considered as a small perturbation and the singular vectors are not simply given by Hermite-Gaussian modes. The typical position of the last maximum of a Hermite-Gaussian mode of order n is $w\sqrt{(2n-1)/2}$ where w is given by (19). Here $w = 11.6$ mm, thus the last maximum of the Hermite-Gaussian mode reaches the edge of the array when $n = 9$, which is roughly in agreement with the observed value 6. Above this order, the Hermite-Gaussian modes no longer correspond to the singular vectors. This criterion gives a qualitative limit for the analytical model.

This model assumes a specular echo. Strictly speaking, it could only be applied to rigid cylinders. However, in the case of elastic targets, if the specular energy is superior to elastic wave radiation, Gaussian beam theory can still be applied. The specular energy lost due to elastic waves can be modeled by introducing a reflection coefficient $\mathcal{C} < 1$ in (6).

B. Poorly resolved cylinder

The Legendre polynomials fit the first five singular vectors (Fig. 5) quite well. Beyond that, the singular vectors do not show coherent structure. They are dominated by experimental uncertainties such as electronic noise or sensitivity fluctuations between the transducers of the array. For the same reason the experimental singular values seem to reach a −60-dB plateau for $n > 5$. The mismatch between the experimental/numerical/theoretical singular values is significant (Fig. 4). As explained before, the singular values are extremely sensitive to a small deviation of the singular vectors. Nevertheless (25) is useful to provide an overall trend. It has been checked numerically that σ_n decreases as $(D/2F)^{2n}$ with the distance between the array and the transducer. Chambers and Gautesen's numerical results confirm the role played by Legendre polynomials in a more complex configuration.[10] The first seven singular vectors are computed for a bubble and a rubber sphere with radius comparable to or larger than the wavelength. In both cases, the singular vectors look like Legendre polynomials. Hence the correspondence between Legendre polynomials and singular vectors seems to be a more general concept than the restricted quasi-two-dimensional configuration. This model does not assume that the cylinder is rigid. The results may thus be generalized to soft targets, contrary to the Gaussian beam model.

VII. CONCLUSION

In this article, the singular value decomposition of the backscattering matrix for a rigid cylinder large with respect to the wavelength has been studied. On one hand, when the array size is small ($\lambda F/D > a$), Legendre polynomials fit the singular vectors well. These Legendre polynomials spread out all over the array. Only the singular values depend on the cylinder's physical parameters. On the other hand, when the array is large ($\lambda F/D < \sqrt{\lambda a}$), Hermite-Gaussian modes are a good approximation of the singular vectors. The width of modes depends on the cylinder radius while the singular values are mostly sensitive to the array directivity. Hence a direct application of this study would be the determination of the cylinder radius from the singular vector behavior in the case of a well-resolved cylinder. The methodology used here to compute the singular vectors of the specular echo that is reflected by a large cylinder could easily be generalized to many other large objects with paraboliclike surface.

APPENDIX A: TAYLOR EXPANSION AND LEGENDRE FUNCTIONS

The Taylor expansion of the backscattered pressure field is written

$$\hat{P}_{sca}(x_1,x_2) = \sum_{n_1,n_2} \frac{\partial_{x_1}^{n_1}\partial_{x_2}^{n_2}\hat{P}_{sca}(0,0)}{n_1!n_2!}x_1^{n_1}x_2^{n_2}, \tag{A1}$$

where $\hat{P}_{sca}(x_1,x_2)$ is the backscattered pressure field on a linear array. x_1 and x_2 are respectively the positions of the emitter and the receiver. The distance between the array and the target F is taken into account by introducing a function Q_{sca} such that $Q_{sca}(\chi_1,\chi_2) = \hat{P}_{sca}(\chi_1 F,\chi_2 F)$. Moreover the positions x_1 and x_2 are normalized by half the size of the array (D). It follows that

$$\hat{P}_{sca}(x_1,x_2) = \sum_{n_1,n_2} \left(\frac{D}{2F}\right)^{n_1+n_2}\frac{\partial_{\chi_1}^{n_1}\partial_{\chi_2}^{n_2}Q(0,0)}{n_1!n_2!}\left(\frac{2x_1}{D}\right)^n\left(\frac{2x_2}{D}\right)^n. \tag{A2}$$

An nth power can be expressed in terms of Legendre polynomials[22]

$$x^n = \sum_{l=n,n-2,n-4,\ldots} \frac{(2l+1)n!}{2^{(n-l)/2}[(n-l)/2]!(l+n+1)!!}\mathcal{L}_1(x), \tag{A3}$$

where $\mathcal{L}_l$ is the lth-order Legendre function. The normalized Legendre function ($\tilde{\mathcal{L}}_l$) is introduced. It is defined by

$$\tilde{\mathcal{L}}_l(x) = \sqrt{\frac{2l+1}{D}}\mathcal{L}_l\left(\frac{2x}{D}\right). \tag{A4}$$

Due to the Legendre polynomial properties, the normalized Legendre polynomials define a orthonormal basis ($\int_{-D/2}^{D/2}\tilde{\mathcal{L}}_l\tilde{\mathcal{L}}_l'(x)\,dx = \delta_{l,l'}$, where δ is the Kronecker symbol).

Combining (A2)–(A4), it follows that

$$\hat{P}_{sca}(x_1,x_2) = \sum_{l_1,l_2} \tilde{\mathcal{L}}_{l_1}(x_1)\tilde{\mathcal{L}}_{l_2}(x_2)\beta_{l_1,l_2}, \tag{A5}$$

where

$$\beta_{l_1,l_2} = D\sum_{n_1=l_1,l_1+2,\ldots}\sum_{n_2=l_2,l_2+2,\ldots}\left(\frac{D}{2F}\right)^{n_1+n_2}\partial_{\chi_1}^{n_1}\partial_{\chi_2}^{n_2}Q(0,0)\alpha_{n_1}^{l_1}\alpha_{n_2}^{l_2}. \tag{A6}$$

Coefficients α_n^l are defined as follows:

$$\alpha_n^l = \frac{\sqrt{2l+1}}{2^{(n-l)/2}([n-l]/2)!(l+n+1)!!}. \tag{A7}$$

Assuming that the array aperture is very small, ($D/F \ll 1$), only the first term in (A6) is kept ($l_1 = n_1$ and $l_2 = n_2$). Now β_{l_1,l_2} is approximated by

$$\beta_{l_1,l_2} \approx D\left(\frac{D}{2F}\right)^{l_1+l_2}\frac{(2l_1+1)(2l_2+1)}{(2l_1+1)!!(2l_2+1)!!}\partial_{\chi_1}^{l_1}\partial_{\chi_2}^{l_2}Q(0,0). \tag{A8}$$

Here a qualitative argument is proposed to justify that the Legendre polynomials are the singular functions. The "matrix" made of the β_{n_1,n_2} coefficients is dominated by the $\beta_{0,0}$ element (zeroth order in D/F). Considering only this element, the singular value is given by $\beta_{0,0}$ and the singular vector is $\tilde{\mathcal{L}}_0$. The second singular function can be deduced

from the previous matrix where the first column and the first line are removed because of the orthogonality between the singular functions. Now this new matrix is dominated by $\beta_{1,1}$ element (second order in D/F). Again the singular value is given by $\beta_{1,1}$ and the singular function by $\tilde{\mathcal{L}}_1$. The same argument can be used to work out all the singular values and functions. Finally, the singular vectors are given by

$$v_n(x) \approx e^{ikr}\tilde{\mathcal{L}}_n(x), \tag{A9}$$

and the singular values by

$$\sigma_n \approx D\left(\frac{D}{2F}\right)^{2n}\frac{(2n+1)^2}{(2n+1)!!^2}\partial_{\chi_1}^n\partial_{\chi_2}^n Q(0,0). \tag{A10}$$

APPENDIX B: TRANSLATION OF CONJUGATE GAUSSIAN BEAMS

Here it is shown that the translation by a distance F of a phase conjugate CRC q is equal to the phase conjugate of translated CRC q by a distance $-F$. Indeed,

$$[h_F]\cdot(-q^*) = -q^* + F = -(q^* - F) = -(q - F)^*$$
$$= -([h_{-F}]\cdot q)^*. \tag{B1}$$

The last equation corresponds well to the initial statement.

APPENDIX C: COMPLEX RADIUS OF CURVATURE REFLECTION

The time-reversal invariance of the Gaussian beam after reflection from a cylinder of radius a is written

$$-q'^* = [r_a]\cdot q', \tag{C1}$$

where q' is the CRC of the Gaussian beam. Using the matrix elements of the reflection transformation (see Table I), it follows that

$$-q'^* = \frac{q'}{2q'/a+1}. \tag{C2}$$

This relation is easier to interpret in terms of inverse of CRC:

$$\mathrm{Re}\left(\frac{1}{q'}\right) = -\frac{1}{a}. \tag{C3}$$

The last equation implies that the radius of curvature of the beam equals $-a$ at the position of the cylinder. Note that the reflection invariance does not set a condition on the beam width.

APPENDIX D: PHASE CONJUGATE INVARIANT

The finite size of the transducer acts as a low-pass filter in emission and in reception that eliminates the high spatial frequencies. Formally, the directivity is taken into account by introducing a smoothing function $W(x/e)$, where W is the square function[23] and e is the effective size of one transducer on the array. The perturbed kernel $\mathcal{K}_p$ is written

$$\mathcal{K}_p = \mathcal{D}\times\mathcal{K}\times\mathcal{D}, \tag{D1}$$

where $\mathcal{D}$ is the directivity function ($\mathcal{D}(x,x') = W[(x-x')/e]$). When v_n is emitted by the array, the backscattered field

$S(x) = \mathcal{K}_p\times v_n(x)$ is then recorded on the array. $S(x)$ is not proportional to v_n^* due to the transducer directivity. Using the convolution operator $\otimes$, $S(x)$ becomes

$$S(x) = \{[\mathcal{H}_F(x)\otimes W(x/e)\otimes v_n(x)]\cdot r_a(x)\}\otimes\mathcal{H}_F(x)$$
$$\otimes W(x/e), \tag{D2}$$

where $\mathcal{H}_F(x)\equiv\mathcal{H}_F(x,0)$ and $\mathcal{R}_a(x,x')\equiv\delta(x-x')r_a(x)$. Introducing the field on the cylinder $v_n'(x)$, it follows that

$$S(x)\propto\{[W(x/e)\otimes v_n'(x)]\cdot r_a(x)\}\otimes\mathcal{H}_F(x)\otimes W(x/e). \tag{D3}$$

To proceed further, e is assumed to be small. More precisely one can show that if $e\ll\sqrt{\lambda a/4\pi}$, the last equation can be approximated by

$$S(x)\propto W(x/e)\otimes[v_n'(x)r_a(x)]\otimes\mathcal{H}_F(x)\otimes W(x/e). \tag{D4}$$

$v_n'(x)$ has been chosen such that $v_n'(x)r_a(x) = v_n'^*(x)$ because it is invariant under reflection from the cylinder. Using this property, it follows that

$$S(x)\propto W(x/e)\otimes v_n'^*(x)\otimes\mathcal{H}_F(x)\otimes W(x/e). \tag{D5}$$

Introducing the conjugate field on the array, the expression is simplified:

$$S(x)\propto W(x/e)\otimes v_n^*(x)\otimes W(x/e). \tag{D6}$$

$v_n(x)$ is a normalized function, so the perturbed singular value is given by

$$\sigma_n = \int_{D/2}^{D/2}S(x)v_n(x)dx \tag{D7}$$

$$= \int_{D/2}^{D/2}|W(x/e)\otimes v_n(x)|^2\,dx. \tag{D8}$$

The finite aperture size D is taken into account at the integration boundaries. The expression can be simplified when $e\ll\sqrt{D\lambda/2\pi}$ and it finally follows that

$$\sigma_n\propto\int|v_n(x)\mathrm{sinc}(\pi e/\lambda R)|^2\,dx. \tag{D9}$$

A method is introduced for using a pair of vertical line transducer arrays (VLAs) to produce time-reversal (TR) foci at any location in a range-independent shallow-ocean waveguide without the need for a probe source. Modal theory suggests that the acoustic response sampled between a pair of VLAs separated by a range R can be repeatedly iterated to estimate the acoustic response at ranges that are integer multiples of R. When combined with the frequency-based variable-range-TR method, the process results in a virtual sampling of the acoustic response over long distances that can be applied to both passive and active shallow-ocean acoustic imaging. Here, the technique is applied to active time-reversal focusing. Array geometry effects are explored and simulation and experimental results are presented. © *2006 Acoustical Society of America.*
[DOI: 10.1121/1.2355538]

I. INTRODUCTION

The ability of time reversal (TR) to generate high-resolution acoustic focusing in the shallow ocean makes it an attractive candidate for active and passive sonar and communications applications as well as matched-field processing techniques.[1,2] The major limitation of current TR methods is that they require an acoustic probe source at the desired focal location. This work discusses a method for using a pair of vertical line transducer arrays (VLAs) to produce TR foci at distant ranges at any depth in the water column without the need for a probe source.

By Green's theorem, the acoustic response over a closed surface completely determines the response throughout the enclosed volume. In an experimental context, a dense sampling of the point-to-point acoustic response between a pair of vertical transducer arrays separated in range can be used to uniquely determine the response throughout the intervening volume. In the case of a range-independent, static propagation medium, the point-to-point acoustic response is reciprocal and independent of absolute position, depending only on the source and receiver depths and on their relative range separation (throughout the remainder of this paper, the relative range separation between the VLAs is referred to as the iteration range). Modal theory suggests that the point-to-point acoustic response between a pair of VLAs can be iterated to estimate the acoustic response at integer multiples of the iteration range. According to Huygen's principle, the re-

sponse on one array due to the other can be decomposed into wavelets that govern the phase evolution of the field over the iteration range. Iterating the response function is equivalent to evolving the response phase over integer multiples of the iteration range. The iterated response estimates can be used to generate a TR focus at integer multiples of the iteration range at any sampled depth.

In a mathematical context, time reversal is applied as a cross correlation between the sampled VLA field (due to a point source for example) and the Green's function (as a function of range and depth) summed over the array elements. The iteration process, on the other hand, is mathematically applied as a cross convolution of the sampled point-to-point pressure response (between the array pair) summed over one of the arrays. Whereas the correlation process (phase conjugation of the source field) brings the field back into focus back at the source origin, convolution propagates the field further down range. As the convolution is a multiplicative process, repeated iteration can lead to undesirable narrowing of the frequency spectrum.

The virtual sampling generated by the iteration process, termed sampled response iteration (SRI), is limited to integer multiples of the iteration range. Applying the theory of acoustic field invariants in a range-independent waveguide,[3] SRI can be combined with variable-range TR (Ref. 4) to extend the method to intervening ranges, i.e., nonintegral multiples of the iteration range.

Section II presents a development of the theory of the iteration method and accompanying simulation results. A discussion of the experimental setup in Sec. II A is followed in Sec. II B by a theoretical development. Section II B 1 introduces the modal acoustic model. The theory of the iteration method is developed in Sec. II B 2. The theoretical discus-

FIG. 1. Experimental setup. The point-to-point acoustic pressure response sampled between transducer arrays V^α (closed circles) and V^β (open circles) is propagated to generate virtual sampling at integer multiples of the array separation, R. The virtual sampling locations are indicated with gray closed and open circles. Time-reversing the virtual field corresponding to one of the virtual samples results in a TR focus that is measured by a third array, V^γ (closed circles).

sion addresses the iteration technique as well as associated bandwidth equalization issues. The effects of array geometry are considered in Sec. II B 3. In Sec. II B 4 the iteration method is extended to the entire waveguide in combination with variable-range TR. Results from ultrasonic experiments in a laboratory waveguide are presented in Sec. III. Section IV gives a summary and concluding remarks.

II. THEORY AND SIMULATION OF THE SAMPLED RESPONSE ITERATION (SRI) PROCEDURE

A. Experimental setup

The range-independent, azimuthally symmetric experimental geometry for which the SRI procedure is designed is schematically represented in Fig. 1. A pair of parallel, vertical-geometry transducer element arrays, labeled V^α (closed circles) and V^β (open circles), are located a distance R apart, where R is the iteration range. A cylindrical coordinate system is chosen such that the origin ($r=0$) coincides with V^α. The point-to-point acoustic response, sampled between all transducer elements of the array pair, is iterated to generate response function estimates at successive intervals of the iteration range. The net result is that the point-to-point response is virtually sampled in range with R as the range sampling interval. The gray closed and open circles of Fig. 1 represent points at which the field is virtually sampled. By applying a frequency shift to the iterated fields, it is possible to extend the virtual sampling to intervening ranges. For the purposes of time reversal, the set of virtual samples represents an ensemble of fields from virtual sources. Time reversal (phase conjugation) and transmission of a chosen virtual source field results in an acoustic focus at the location of the virtual source. In order to simplify the analysis, the arrays are always labeled such that V^α corresponds to the TR field transmission array. As seen in Fig. 1, a third array, labeled V^γ, is used to sample the resulting TR field.

B. Theoretical discussion

After summarizing the relevant modal theory, this section introduces the range iteration method. Array geometry and bandwidth effects are addressed. Finally, the SRI method is combined with the variable-range TR method of Ref. 4. The theoretical analysis is illustrated with simulation results.

1. The modal point-to-point pressure response

The elements of arrays V^α and V^β are labeled by the indices a and b, respectively. The ath element of array V^α is at depth $z=z_a$ and likewise for V^β. The arrays are separated by a distance R. Array V^α comprises a total of A elements while array V^β comprises B elements. Applying the convolution theorem, the ω angular frequency component of the acoustic pressure response at element a on V^α due to a source at element b on V^β is written as the product

$$P_{ab}(R,\omega) = G_{ab}(R,\omega)S(\omega), \tag{1}$$

where $G_{ab}(R,\omega)$ represents the point-to-point Green's function between elements a and b, and $S(\omega)$ represents the ω component of the Fourier decomposition of the time-domain source signal.

The Green's function in terms of modal depth functions, $\phi_m(z,\omega)$, and associated modal wave numbers, $k_m(\omega)$, is written[5]

$$G_{ab}(R,\omega) = \frac{e^{-i(\pi/4)}}{\rho(z_b)\sqrt{8\pi R}} \sum_{m=1}^{M} \frac{\phi_m(z_a,\omega)\phi_m(z_b,\omega)}{\sqrt{k_m(\omega)}} e^{-ik_m(\omega)R},$$
$$\tag{2}$$

with associated closure and orthogonality relations,

$$\sum_{m=1}^{\infty} \frac{\phi_m(z,\omega)\phi_m(z',\omega)}{\rho(z')} = \delta(z-z') \tag{3}$$

$$\int_0^D \frac{\phi_m(z,\omega)\phi_n(z,\omega)}{\rho(z)} dz = \delta_{mn}. \tag{4}$$

Here, $z=0$ corresponds to the water surface and $z=D$ is the depth spanned by the modal depth functions, while $\rho(z)$ represents the depth-dependent mass density.

2. SRI theory

a. The singly iterated field. Convolution of a signal by the Green's function generates a forward propagation through the medium in positive time. This suggests the possibility of virtually propagating the pressure response between a pair of arrays to further ranges through iterative convolution. To demonstrate, suppose the pressure response on array pair V^α/V^β has been determined through measurement [Eq. (1)]. Taking the pressure response, $P_{ba'}(R,\omega)$, on V^β due to the source at element a' on V^α as a collection of source fields (invoking reciprocity to switch the indices), the propagation operation is defined as the cross convolution of each source field by the full point-to-point pressure response, $P_{ab}(R,\omega)$, summed over the elements of V^β (note that $[P_{ba'}]$ is a vector over the elements of V^β while $[P_{ba}]$ is a two-dimensional matrix over the elements of both arrays). Using Eqs. (1) and (2), the resulting virtually propagated field, $\hat{P}(\omega)$, is

$$\hat{P}_{aa'}(\omega) = \sum_{b=1}^{B} P_{ab}(R,\omega) P_{ba'}(R,\omega) \Delta z_b$$

$$= \frac{e^{-i\pi/2} S^2(\omega)}{8\pi\rho(z_{a'})} \sum_{m,n=1}^{M,M} \frac{\phi_m(z_a,\omega)\phi_n(z_{a'},\omega)}{\sqrt{k_m(\omega)R}\sqrt{k_n(\omega)R}}$$

$$\times e^{-i(k_m(\omega)+k_n(\omega))R} \left(\sum_{b=1}^{B} \frac{\phi_m(z_b,\omega)\phi_n(z_b,\omega)}{\rho(z_b)} \Delta z_b \right).$$

(5)

The quantity Δz_b represents the interelement spacing associated with the transducer element at $z = z_b$. Applying the mode orthogonality relation of Eq. (4) to the term in parentheses in the limit where V^β densely samples most of the water column, Eq. (5) simplifies to

$$\hat{P}_{aa'}(\omega) \approx \frac{e^{-i\pi/2} S^2(\omega)}{8\pi\rho(z_{a'})} \sum_{m=1}^{M} \frac{\phi_m(z_a,\omega)\phi_m(z_{a'},\omega)}{k_m(\omega)R} e^{-i2k_m(\omega)R}$$

$$\approx e^{-i\pi/4} S(\omega) \left(\sqrt{\frac{1}{4\pi R}} \right) P_{aa'}(2R,\omega).$$

(6)

Orthogonality condition (4) is valid for every mode for which the array geometry samples at two points per period (in depth) over the entire effective span of the mode. Typically, an array sampling interval equal to or less than half the characteristic acoustic wavelength of the water column is sufficient to adequately sample all the modes.

Ignoring for the moment the factor in Eq. (6), $e^{-i\pi/4} S(\omega)(\sqrt{1/4\pi R})$, the virtual propagation result closely approximates the frequency response between array V^α and a second virtual array at range $2R$. Effectively, the procedure has propagated the field an additional range increment R. In the case of a single iteration, the virtual array is of the same geometric configuration as V^α. As will be shown, the geometry of the final virtual array alternates between the geometries V^α or V^β with each iteration.

Although the iteration procedure preserves the relative phases of the modal components, it produces errors associated with cylindrical spreading. As a result, in deriving the approximation of Eq. (6), a factor of $1/\sqrt{k_m(\omega)}$ has been neglected for each modal component in proceeding from the first line to the second line. This is justifiable because the modal wave numbers typically do not differ significantly. For example, under realistic shallow-ocean conditions, the modal wave numbers differ at most by a factor of 2 between the highest and lowest order modes. Indeed, the experimental success of the iteration method validates the theoretical assumption that the mode dependence of the cylindrical spreading factor is negligible.

In both simulation and experiment, the collection of virtual responses can be time-reversed and broadcast from array V^α to produce an acoustic focus at all sampled depths at range $2R$. Repeated iteration results in the virtual responses at multiple integers of R.

b. The multiply iterated field. Ignoring for the moment the practical considerations involved with deploying a pair of parallel, full-spanning, densely sampling arrays, this result implies that the field can be virtually sampled over long ranges without any knowledge of the environment by simply iterating this procedure. To demonstrate this, it is convenient to identify the acoustic response between the arrays as a matrix,

$$\mathbf{P} \equiv [P_{ab}(R,\omega)].$$

(7)

For simplicity, the explicit dependence on R and ω is suppressed in the matrix notation.

In order to be as general as possible, the iteration method is developed for the case of arrays of differing geometries comprising different numbers of elements ($A \neq B$). In this case $\mathbf{P}$ is not a square matrix. Depending on the implementation and number of iterations, the iterated, virtually sampled field, $\hat{\mathbf{P}}$, may be an $A \times A$, $A \times B$, $B \times A$, or $B \times B$ matrix. In what follows, the iteration procedure is developed to yield virtually sampled fields that facilitate TR imaging from array V^α, i.e., the final virtually sampled response always has A components.

The multiply iterated virtually propagated response is given as

$$\hat{\mathbf{P}}_{\mathbf{N}} = \mathbf{Q}_{\mathbf{N}} \mathbf{Q}_{\mathbf{0}},$$

(8)

where $\mathbf{Q}_{\mathbf{0}}$ is the starter field, N is the number of applied iterations, and $\mathbf{Q}_{\mathbf{N}}$ is the iterated field. The starter field is defined

$$\mathbf{Q}_{\mathbf{0}} = \begin{cases} [P_{a'b}(\omega)]^T & N = \{1,3,5,\dots\} \\ [P_{ab'}(\omega)] & N = \{2,4,6,\dots\}, \end{cases}$$

(9)

where a' and b' denote the virtual source depth on V^α or V^β, respectively, depending on which array is appropriate, and the superscript $(^T)$ denotes the transpose operation. In this analysis, subscripts appearing with the prime notation $(')$ indicate the virtual source element location. The iterated field is a product of matrices

$$\mathbf{Q}_{\mathbf{N}} \equiv \left[\prod_{n=1}^{N} \mathbf{\Gamma}^{(-\mathbf{1}^{\mathbf{N-n}})} \right],$$

(10)

where $\mathbf{\Gamma}$ represents the appropriate form of the acoustic response

$$\mathbf{\Gamma}^1 \equiv A(\omega) \mathbf{P} \mathbf{\Delta}_{\mathbf{z}}^{\beta}$$

$$\mathbf{\Gamma}^{-1} \equiv A(\omega) \mathbf{P}^{\mathbf{T}} \mathbf{\Delta}_{\mathbf{z}}^{\alpha}.$$

(11)

These expressions are generalized to include a normalization factor, $A(\omega)$, whose meaning is addressed in Sec. IIB2c. Diagonal matrices $\mathbf{\Delta}_{\mathbf{z}}^{\alpha}$ and $\mathbf{\Delta}_{\mathbf{z}}^{\beta}$ are included to account for the discretization of the array depth sampling,

$$\mathbf{\Delta}_{\mathbf{z}}^{\alpha} = \begin{bmatrix} \Delta z_1 & 0 & \cdots & 0 \\ 0 & \Delta z_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \Delta z_A \end{bmatrix},$$

(12)
FIG. 2. Schematic of the iteration procedure for two iterations generalized to arrays of differing geometry. Elements of V^α and V^β are indicated by closed and open circles, respectively. Larger circles denote actual array elements while smaller circles mark virtual sample locations. The pressure field sampled by V^α due to a source at a chosen element depth on V^β (indicated by the black lines) is chosen as the starter field. Bear in mind V^α is the origin of the iterated field. The array V^β, from which the starter field originates, is drawn to the left of V^α in order to clarify the procedure. Two iterations of the point-to-point array pressure response (gray lines) are applied to propagate the starter field in range.

$$\boldsymbol{\Delta_z^\beta} = \begin{bmatrix} \Delta z_1 & 0 & \cdots & 0 \\ 0 & \Delta z_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \Delta z_B \end{bmatrix}.$$

They represent the interelement depth spacings of arrays V^α and V^β, respectively. In the case where the depth sampling is dense, knowledge of the interelement depth spacings is not essential. When the field is densely sampled, deviations of the depth sampling from uniformity result in manageable deviations from orthogonality between the modes. Incorporation of the interelement depth spacings serves to enhance the performance of the iteration method. If the spacings are not known, $\boldsymbol{\Delta_z^\alpha}$ and $\boldsymbol{\Delta_z^\beta}$ are simply unit matrices.

At this point it is instructive to consider an example. Using Eqs. (9)–(13) to explicitly expand the iteration algorithm for $N=2$ yields

$$\hat{\mathbf{P}}_2 = \mathbf{Q}_2 \mathbf{Q}_0 = [\boldsymbol{\Gamma}^1 \boldsymbol{\Gamma}^{-1}][P_{ab'}(\omega)]$$

$$= A^2(\omega)[\mathbf{P}\boldsymbol{\Delta_z^\beta}\mathbf{P^T}\boldsymbol{\Delta_z^\alpha}][P_{ab'}(\omega)]$$

$$\approx A^2(\omega)e^{-i\pi/2}\left(S(\omega)\sqrt{\frac{1}{4\pi R}}\right)^2 [P_{ab'}(3R,\omega)]. \quad (13)$$

The process is shown schematically in Fig. 2. As with Eqs. (6) and (14), a factor of $1/\sqrt{k_m(\omega)}$ has been neglected for each modal component in writing the third line above. This is justified in the case of multiple iterations due to the presence of modal attenuation in any realistic waveguide. With each iteration the effect of the cylindrical spreading error, through the $1/\sqrt{k_m(\omega)R}$ factor, is counteracted by the effect of the exponential decrease resulting from modal attenuation. The net result is that with each iteration the high-order modes tend to attenuate more strongly than the low-order modes.

c. Bandwidth equalization. Because the source signal is embedded in the sampled pressure field, any structure in the source frequency power spectrum will tend to compound with each iteration. As shown in Eqs. (6) and (14), the N-iterated source spectrum is proportional to $S^N(\omega)$. For ex-

ample, in the case of a Gaussian modulated pulse, repeated iteration leads to a reduction of bandwidth. Assuming the source signal is known, such a loss of bandwidth can be overcome by defining the normalization constant of Eqs. (12) and (14) in accordance with the source signal spectrum,

$$A(\omega) = \frac{\sqrt{4\pi R}}{|S(\omega)|}. \quad (14)$$

Including the term in the numerator, this frequency equalization scheme simultaneously compensates for the range dependence of the cylindrical spreading. Due to the term in the denominator, this equalization scheme may prove problematic in the case where the source signal spectrum approaches zero within the bandwidth. Additionally, repeated equalization is subject to limitations associated with noise.

3. The influence of array geometry

The effects of array geometry on TR focusing in an ocean waveguide have been demonstrated.[6,7] Namely, undersampling in depth, both in terms of the sampling interval and the total aperture, leads to reduced focusing performance. Because array geometry effects are compounded with each iteration, TR imaging applications based on the SRI method are even more sensitive to array geometry than standard TR imaging techniques. This section considers three aspects of array geometry that affect the imaging performance of the SRI method: total array aperture, array depth sampling rate, and array tilt. Each aspect is considered separately in order to isolate its individual effects. The following four cases are consider: (1) full-spanning, densely sampling vertical arrays; (2) partial-spanning, densely sampling vertical arrays; (3) full-spanning, sparsely sampling vertical arrays; and (4) full-spanning, densely sampling tilted arrays.

a. Full-spanning, densely sampling vertical array geometries. It has already been demonstrated theoretically that for a full-spanning, densely sampling array [one for which Eq. (4) holds true], iteration results in an accurate approximation of the true pressure response at an equivalent range, particularly with respect to the phase. This is verified in Fig. 3. As the goal is to perform TR focusing, Fig. 3 shows a simulated comparison of TR focusing between an SRI result and the standard modal model for the case of full-spanning, densely sampling arrays. The top panel shows the spatial component of the time-reversed virtual pressure field resulting from eight iterations of the simulated pressure field between the array pair. Eight iterations of the iteration range, $R=500$ m, corresponds to a virtual source at 4.5 km. The simulation is for a narrow-band source at a depth of 45 m. The lower panel shows the TR focus over the same range achieved using the standard modal model for a true source at the same location. Even after eight iterations, there is good agreement between the SRI result and the TR benchmark. It is noted here that all simulation results presented in this paper are carried out for identical simulated Pekeris waveguide propagation media for which the modal components are calculated using the KRAKEN mode model including modal attenuation.[8] The water depth is 100 m, with bottom parameters of sound

Walker *et al.*: Acoustic focusing in shallow water
FIG. 3. Comparison of the spatial components of simulated SRI and modal model benchmark time-reversed fields for the case of full-spanning, densely sampling arrays located 500 m apart. The top panel shows the result after eight iterations of the field while the bottom panel is the benchmark result for the modeled field for a source at 4.5 km. The water depth is 100 m and the source depth is 45 m. The depth aperture and element spacing interval of array $V^\alpha(V^\beta)$ are given by $\Delta z_\alpha(\Delta z_\beta)$ and $dz_\alpha(dz_\beta)$, respectively. The source signal carrier frequency is given by f_c.

FIG. 5. Simulated time-domain time-reversed pressure fields corresponding to the array geometries of Fig. 4. All TR results correspond to the TR field measured over a receive array (V^γ of Fig. 1) located at range $r = 4.5$km. The dashed line indicates the expected focal depth. (a) TR result for the benchmark field of Fig. 4(a). (b) TR result for the full-spanning, densely sampled field of Fig. 4(b). (c) TR result for the partial-spanning, densely sampled case of Fig. 4(c). (d) TR result for the full-spanning, sparsely sampled field of Fig. 4(d). (e) TR result for the cleaned full-spanning, sparsely sampled field of Fig. 4(e). (f) TR result for the compensated tilted array case of Fig. 4(f).

speed and density given by $c_b = 1800$ m/s and $\rho_b = 1800$ kg/m³, respectively.

In order to better demonstrate and understand the effects of array geometry, it is useful to consider the time-domain fields. Figure 4 shows a comparison of simulated time-domain fields on arrays of various geometries due to a broadband source at 4.5 km. While panel (a) shows the field from a true source, panels (b)–(f) show iterated fields from virtual sources corresponding to eight iterations of the SRI method. All SRI simulation results are frequency equalized in accor-

FIG. 4. Simulated time-domain pressure fields sampled on arrays of varying geometries from a broadband point source at 4.5 km. All SRI results are for eight iterations of the sampled point-to-point pressure response between arrays separated by 500 m. The source signal is characterized by a Gaussian modulated 200-Hz bandwidth pulse at a carrier frequency of $f_c = 300$ Hz. (a) Benchmark result generated from the modal model for a full-spanning, densely sampling array. (b) SRI result for a pair of full-spanning, densely sampling arrays. (c) Iteration result for the case of partial-spanning, densely sampling arrays. Arrays V^α and V^β spanned 90% and 80% of the water column, respectively. (d) SRI result for full-spanning, sparsely sampling arrays. The sampling interval of the arrays is equivalent to the acoustic wavelength at the carrier frequency in water, $dz = 5$ m. (e) Iteration result for full-spanning, sparsely sampling arrays, cleaned to remove aliased high-order modal components. (f) SRI result for tilted full-spanning, densely sampling arrays compensated to remove the tilt.

dance with the normalization introduced in Eqs. (12) and (15) in order to suppress iterative bandwidth effects.

As a benchmark for comparison, Fig. 4(a) shows the field from a true source, sampled over a full-spanning, densely sampling array. The SRI result for a pair of full-spanning, densely sampling arrays shown in Fig. 4(b) is in good agreement with the true field, particularly with respect to the low-order modal components (the early arrivals). In accordance with the increasing difference in propagating wave number among the higher order modes, the relative weightings of the high-order modal components (late arrivals) are more sensitive to the extra factor of $1/\sqrt{k_m(\omega)}$. Compounding this error over many iterations has resulted in the slight, but observable, difference among the high-order modal components of the iterated field as compared to the benchmark. This effect is moderated by the inclusion of attenuation in the simulation. The time-domain TR results for the SRI full-spanning, densely sampling case, shown in Fig. 5(b), are also in good agreement with the benchmark TR result of Fig. 5(a). To clarify, time reversal is applied by multiplying the phase-conjugated iterated (or benchmark) field by the modal model response from a given range.

b. Partial-spanning, densely sampling vertical array geometries. The case of partial-spanning, densely sampling arrays is addressed in Figs. 4(c) and 5(c). Figure 4(c) shows the time-domain virtually sampled pressure field after eight iterations generated using a 90% spanning array for V^α and an 80% spanning array for V^β. Deviation from the benchmark result [Fig. 4(a)] is apparent over all modal components. This result is expected as partial coverage of the water column results in deviations from orthogonality between all modal components. The resulting TR field in Fig. 5(c) exhibits significant degradation of both the temporal and spatial resolution.

c. Full-spanning, sparsely sampling vertical array geometries. In the case of full-spanning, sparsely sampling ar-

rays, it is possible that orthogonality may exist differentially among the sampled modal components. While the low-order modes may be well sampled in depth, the high-order modes may not. Figure 4(d) shows the compounded effects arising from iterating a sparsely sampled field. The sampling interval of both arrays is equivalent to the wavelength at the carrier frequency, $dz=\lambda_c=5$ m. While there is good agreement among the low-order modal components in comparison to the benchmark, there is an obvious deviation between the high-order modal components. The TR result of Fig. 5(d) displays the characteristic aliasing errors associated with undersampling. One solution for dealing with undersampling errors is to clean the aliased, high-order components from the signal prior to time reversal. Due to the temporal dispersion of the modes, as shown in Fig. 4(e), the high-order components are easily isolated and removed in the time domain. As demonstrated in Fig. 5(e), cleaning the sparsely sampled signal results in a significant improvement in TR focal resolution.

d. Full-spanning, densely sampling tilted array geometries. The final aspect of array geometry considered is array tilt. In the context of this paper, array tilt refers to deviations from vertical aspect among the array elements. In contrast to standard TR, where array tilt has no effect on imaging performance, the SRI method is highly sensitive to tilt. Relative range offsets among the array elements generate phase errors that are amplified by the iteration process. Even a small deviation from verticality of either of the arrays can lead to a drastic degradation of the imaging performance after only a few iterations.

One straightforward way to compensate for array tilt phase errors is to add time delays to the pressure response matrix elements,

$$P_{ab}(R,\omega) \rightarrow P_{ab}(R,\omega)e^{i\omega(\Delta t_a + \Delta t_b)}. \tag{15}$$

In order to do this, the relative range offsets of the array elements must be independently known, either through direct or inferred measurement. Denoting as Δr_a (Δr_b) the range offset of element a (b) with respect to a given reference element, the time delay compensation on element a (b) is given as $\Delta t_a = \Delta r_a / c_s$ ($\Delta t_b = \Delta r_b / c_s$), where c_s is a sound speed characterizing acoustic propagation in the waveguide. Applied in this manner, this form for the time delay can be thought of as an angular beamform operation. Because the group speeds of the low-order modes are more densely packed than those of the higher order modes, choosing a sound speed from among the group speeds of the lowest modes results in the best compensation for the greatest number of modes. Additionally, because they are more highly attenuated, high-order modal contributions tend to be less significant. To a good approximation in a Pekeris waveguide the mode 1 group speed can be estimated by the sound speed of the water column. If the sound speed varies with depth, it is useful to average over depth.

Array tilt simulation results are presented in Figs. 4(f) and 5(f). In this case, array V^α remains vertical while array V^β has been given a characteristic curved tilt profile consistent with a strong current along the ocean bottom. The tilt profile, shown in Fig. 6, has a maximum element range offset
FIG. 6. Array tilt schematic. Dots indicate locations of array elements of V^β relative to the deepest element.

of nearly 10 m (in a 100-m waveguide), or 2 acoustic wavelengths. Iterating the sampled field in this geometry quickly leads to large errors and is not shown. However, applying the tilt compensation method outlined above (assuming a characteristic group speed $c_s=1500$ m/s) to the sampled field under the assumption that the relative array positions (Δr_b) are perfectly known leads to the result shown in Fig. 4(f). As expected, there is good agreement between the low-order modal components (for which the assumed group speed is a good approximation) of the SRI and benchmark fields. The mismatch between the assumed characteristic group speed and the group speeds of the high-order modes leads to small, but observable, accumulated errors among the later arrivals (higher order modal components).

To make the analysis more realistic, the assumption of perfect knowledge of the relative element positions on the tilted array is relaxed. Applying a random uncertainty between −30 and 30 cm to each element range offset (of the tilted array) leads to little observable difference in the SRI time-reversed field (not shown), indicating that small random deviations from perpendicularity are tolerable.
FIG. 7. Schematic of the coverage of the waveguide resulting from combining the SRI method with variable-range TR generalized to the case of arrays of differing geometry. Closed and open circles indicate the element depths of arrays V^α and V^β, respectively. These points represent the ensemble of virtual samples generated by the iteration process. The shaded gray areas indicate the regions of the waveguide to which TR focusing can be achieved when the SRI method is combined with variable-range TR.

4. Combining SRI with variable-range TR

Waveguide invariant theory predicts that interference among modal components leads to a regular pattern of the acoustic intensity as a function of range and frequency.[9–11] One important proven application of invariant theory is range shifting. Reference 4 describes a set of at-sea experiments where the TR focus from a TR mirror was successfully translated in range from the source location by applying a frequency shift to the original received signal on the TR mirror. It was found that applying a frequency shift, $\Delta\omega$, to the frequency domain acoustic field sampled on a vertical array from an acoustic point source at range r_0 leads to a TR focus at the translated range

$$r' \approx r_0\left(1 + \frac{1}{\beta}\frac{\Delta\omega}{\omega}\right), \tag{16}$$

where β denotes the waveguide invariant. Due to the frequency dependence of the depth-dependent amplitudes of the modal components of the acoustic field, the focal resolution of variable-range TR is expected to degrade as the fractional frequency shift, $|\Delta\omega/\omega|$, increases. Empirical evidence suggests that variable-range TR focusing is effective for absolute fractional frequency shifts less than 10%,[4] $|\Delta\omega/\omega| < 0.1$.

By applying variable-range TR to the virtually sampled iterated field, it is possible to extend the TR focusing capability of the SRI technique to include all points of the waveguide. Recall that iteration of the sampled point-to-point acoustic pressure response leads to an ensemble of virtual sources at integer multiples of the iteration range. Placing a conservative restriction on the fractional frequency shift of the carrier frequency, $|\Delta\omega/\omega|_{max}=0.05$, it is possible to generate a high-resolution TR focus at all ranges and depths of the waveguide after eight iterations of the sampled field (assuming $\beta \approx 1$). This can be seen by substituting $|\Delta\omega/\omega|_{max}=0.05$ and $\beta=1$ into Eq. (17) for positive and negative range shifts of ranges corresponding to eight and nine iterations, respectively,

$$9R(1 + 0.05) \approx 10R(0.95).$$

The imaging capability of variable-range TR applied to SRI is schematically presented in Fig. 7. The diagram has been generalized to the case of arrays of differing geometry.
FIG. 8. Comparison of the spatial components of simulated SRI and modal model benchmark range-shifted time-reversed fields for the case of full-spanning, densely sampling arrays. The top panel shows the result for the virtual source at 4.5 km corresponding to eight iterations of the field while the bottom panel is the benchmark result for the modeled field for a source at 4.5 km. In both cases a fractional frequency shift of $\Delta\omega/\omega=+0.05$ has been applied, resulting in the perceived range shift of the fields. The expected range shift, Δr, for a $\beta=1$ waveguide is indicated. The water depth is 100 m and the source depth is 45 m. The depth aperture and element spacing interval of array $V^\alpha(V^\beta)$ are given by $\Delta z_\alpha(\Delta z_\beta)$ and $dz_\alpha(dz_\beta)$, respectively. The source signal carrier frequency (before applying the frequency shift) is indicated by f_c.

Using the iterated virtually sampled field alone, TR foci can be generated at the ensemble of points indicated by the open and closed circles. The closed and open circles correspond to the array element depths of V^α and V^β, respectively. Notice the points span the array depths at multiple integer intervals of the iteration range. Combining SRI with variable-range TR, it is possible to focus at all ranges indicated by the shaded regions at the sampled depths of the corresponding arrays.

Figure 8 shows a simulated variable-range TR result for the case of full-spanning, densely sampling arrays. The top panel shows the spatial component of the time-reversed virtual pressure field resulting from eight iterations. A +5% fractional frequency shift has been applied, resulting in a positive range shift of the TR focus. For the purposes of comparison, the variable-range TR iteration result is accompanied by the variable-range TR result for the standard modal model for the same range and fractional frequency shift (bottom panel). The initial range of the source in both cases (virtual source in the former and real source in the latter) is 4.5 km. The realized focal range shift, $\Delta r \approx 225$ m, is consistent with the expected range shift for a $\beta=1$ waveguide. Figure 9 shows the time-domain range-shifted TR focus (at $r=4.725$ km) corresponding to the simulation of Fig. 8. The resolution of the SRI result [Fig. 9(a)] is comparable to the standard model benchmark result [Fig. 9(b)].

III. EXPERIMENTAL RESULTS

This section presents results of an experimental study of the SRI method. The experiment was conducted under controlled laboratory conditions in a small-scale range-independent waveguide at ultrasonic frequencies. As illustrated in Fig. 1, the point-to-point acoustic response sampled
FIG. 9. Simulated time-domain range-shifted time-reversed pressure fields. Each TR result corresponds to the TR field measured over a receive array (V^γ of Fig. 1) located at $r=4.725$ km. (a) Range-shifted SRI result. (b) Range-shifted benchmark result. The time axes indicate the delay with respect to the arrival time of the non-range-shifted TR focus at $r=4.5$ km. The dashed line indicates the expected focal depth.

between a pair of VLAs, V^α and V^β, separated by iteration range R, was iterated to generate a virtual sampling of the point-to-point response at successive integer multiples of the iteration range. The virtually sampled response was then time-reversed with the aim of generating TR foci at the virtually sampled points. A third VLA, V^γ, was positioned down range to measure the time-reversed fields.

A. Setup

The experiment was designed to model the shallow ocean at small scales. The waveguide comprised well-mixed fresh water over a uniform steel bottom maintained at a constant depth over the extent of the waveguide. The working length of the waveguide was roughly 1 m. The water depth was $D=26.5$ mm, resulting in far-field scaling ($R/D \gg 1$). All point-to-point pressure response measurements were sampled using a $\Delta f=1.5$ MHz bandwidth Gaussian modulated source signal at carrier frequency of $f_c=1.5$ MHz. The acoustic wavelength in the water at the carrier frequency was approximately 1 mm, $\lambda_c \approx 1$ mm.

Each VLA, V^α and V^β, consisted of 50 evenly spaced linearly arranged transducer elements spanning 24.5 mm. The element spacing was 0.5 mm ($\approx \lambda_c/2$). Due to the small scale of the setup, it was not possible to determine the array tilt *a priori*. Rather, the tilt was deduced from the performance of the TR results. It was determined that a tilt of 0° for V_α and 0.5° for V_β yielded the optimal TR imaging performance. It is emphasized that the optimization for array tilt is a by-product of the small experimental dimensions. At the larger scales characterizing shallow-ocean applications, the tilt is directly measurable. The iteration range separating the VLAs was $R=82.8$ mm. The VLA used to measure the TR fields, V^γ has identical geometry to V^α.

B. Results

Figure 10 shows the measured SRI TR foci generated from several virtually sampled fields. Panels (a) and (b) are the fields for two different virtual source depths at a range of $r=5R=414$ mm, corresponding to four iterations of the sampled response function. In each case, the dashed lines indicate the expected focal depth. For comparison, the mea-
FIG. 10. Experimental time-domain time-reversed pressure fields measured over a receive array (V^γ of Fig. 1) at the indicated ranges. In all cases, the dashed line indicates depth of the source from which the TR field originated (real or virtual). Panels (a) and (b) show the TR foci produced by iterated fields (four iterations) corresponding to virtual sources at $r=414$ mm$=5R$. Panel (c) is the TR result for a real source at the same range. Similarly (d) and (e) show the TR foci produced by iterated fields (nine iterations) corresponding to virtual sources at $r=828$ mm$=10R$ with panel (f) giving the TR result for a real source at the same range. Panel (g) corresponds to panel (e). In this case, array tilt was not accounted for. The source signal bandwidth and carrier frequency were $f_c=1.5$ MHz and $\Delta f=1.5$ MHz, respectively.

sured TR focus due to a real source at the same range, $r=414$ mm, is included in panel (c). Similarly, panels (d) and (e) show SRI TR focus results due to virtual sources at $r=10R=828$ mm (nine iterations). Again, the measured TR focus due to a real source at the same range is presented in panel (f) for comparison. The experimental SRI TR result in panel (g) resulted from application of the iteration procedure without accounting for array tilt. The tilt was relatively small, accounting for a total maximum absolute interelement range displacement of $|\Delta r_b|_{max}=0.2$ mm$\approx \lambda_c/5$. After nine iterations, however, even such a small tilt results in a significant degradation of imaging performance. Noting that the temporal extent of the TR foci remained constant over many iterations, it is encouraging that the frequency equalization scheme of the iteration procedure resulted in negligible iterative bandwidth loss. In experimental applications, it is important to consider the frequency response of the transducer devices. As it is embedded in the sampled point-to-point pressure response, the transducer response will be propagated with each iteration.[12] Ideally, transducer responses could be measured and accounted for in the equalization scheme. Similar experimental results were achieved at all depths spanned by the VLAs out to nine iterations. The usable working range limited the experiment to nine iterations. The results suggest that the virtual field could have been propagated out further.

The SRI method was combined with the variable-range-TR method of Ref. 4 to shift the TR focus from integer multiples of the iteration range to intermediate ranges. As mentioned, it is possible to range shift the TR focus to all intermediate ranges after eight iterations in a $\beta=1$ waveguide assuming a conservative 5% range shift maximum. Figure 11 shows an experimental range-shifted TR focus re-
FIG. 11. Experimental time-domain range-shifted TR focus measured with a receive array (V^γ of Fig. 1) at $r = 801$ mm. The time axis indicates the delay with respect to the arrival time of the non-range-shifted TR focus at $r = 828$ mm (nine iterations). The dashed line indicates the expected focal depth.

sult. In this case a fractional frequency shift of $\Delta\omega/\omega = -3.33\%$ ($\Delta f = -4.884 \times 10^4$ Hz) has been applied to the iterated field that produced the TR focus at $r = 10R = 828$ mm (nine iterations) shown in Fig. 10(e). Figure 11 shows the time-domain field at the expected range-shifted focus range, $r = 801$ mm (assuming a $\beta = 1$ waveguide). Similar experimental range-shifted TR focus results were achieved at all sampled intermediate ranges and depths between $r = 744$ mm (eight iterations) and $r = 828$ mm (nine iterations).

IV. SUMMARY AND DISCUSSION

A method for using a pair of vertical transducer arrays to ensonify a spatially compact region at any location of a shallow, range-independent ocean waveguide has been presented. The method termed sampled response iteration (SRI), is fully self-adaptive, requiring no *a priori* knowledge of the environment other than that the medium is range independent and static. Furthermore, in contrast to existing time-reversal (TR) focusing methods, the technique does not require a down-range source.

Denoting the initial sampling range separating the arrays as the iteration range, the sampled point-to-point acoustic pressure response between the arrays has been multiply iterated to generate accurate estimates of the point-to-point acoustic response projected over the arrays at integer multiples of the iteration range. In both simulation and experiment, the procedure resulted in a virtually sampled acoustic field that was time-reversed to produce high-intensity, high-resolution acoustic focusing at any of the virtually sampled locations. The SRI method has been combined with the variable-range-time-reversal technique proposed by Song *et al.*[4] to demonstrate the potential to produce time-reversal foci at ranges other than the virtually sampled ranges. The SRI method has proven effective experimentally under controlled laboratory conditions out to nine iterations.

As the process is iterative, array geometry effects assume great importance. Any deficiencies in the sampling geometry of the arrays compound with each iteration. The method is effective over many iterations for full water column spanning geometries, even in the case of sparse array sampling. In the case where one or both of the arrays are partially spanning, the effectiveness of the iteration procedure is limited to fewer iterations, with the limit depending on the extent of the array coverage. Of particular importance

is the issue of array tilt. For the iteration procedure to be effective, array tilt must be compensated for, requiring that the arrays be equipped with tilt measurement devices. So long as the arrays can be rendered vertical on average, small uncertainties in tilt compensation are tolerable.

Because the iteration invokes range invariance, the analysis presented in this paper has been limited to range-independent applications. However, there is reason to suspect that the method may be extendable to weakly range-dependent environments, suggesting a possible avenue of future study. The SRI method has potential as both a passive and active sonar application. As a passive sonar application, SRI is a natural candidate for matched-field signal processing (MFP) methods. For example, a pair of low-power arrays separated by a short-range interval could be used to self-adaptively generate replica fields at long ranges. Because the arrays are low power, they would remain undetectable by long-range targets. It may be possible to make the method completely passive using the ambient noise field. As demonstrated by Roux *et al.*,[13] cross correlation of the ambient noise acoustic field over the array elements leads to the array pressure response between the elements. The signal from any source, then, could be cross correlated and iterated to determine the source location. As an active sonar application, the demonstrated ability of SRI, when combined with time reversal, to ensonify spatially compact regions of the shallow ocean makes it a promising candidate for directed sonar. Additionally, as it is a method for generating a large virtual range aperture, the SRI method may prove useful as a mode extraction application. Of particular interest is the potential for extracting the lowest order modes requiring the greatest range aperture.

Distortion product otoacoustic emissions (DPOAEs) are low-level acoustic signals, the detection of which involves extraction from a background of noise. Boege and Janssen [J. Acoust. Soc. Am. **111**, 1810–1818 (2002)] described a method for modeling the presence and growth of these responses. While improving growth function parameter estimation, this technique excludes a significant fraction of the data (especially low-level responses), and relies on ad hoc model fit acceptance criteria. The statistical difficulties associated with these limitations are described, and a weighted segmented linear regression model that avoids them is proposed. A simple test is presented for the presence of DPOAE growth. This technique is compared to that of Boege and Janssen in a dataset of 9 556 input/output (I/O) functions collected over 4 years on 866 ears from 379 construction apprentices and 63 age-matched controls. Comparisons are made on the entire dataset and within audiometric hearing loss categories. Segmented regression avoids the statistical pitfalls of the previous method, allows estimation of the threshold and slope of auditory response on a far greater number of I/O functions, and improves estimation of these parameters in this dataset. The potential for this method to yield more sensitive metrics of hearing function and compromise is discussed. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2258871]

I. INTRODUCTION

First reported by Kemp (1978), otoacoustic emissions (OAEs) reflect acoustic energy produced by cochlear outer hair cells, either spontaneously or in response to an external stimulus. The distortion product OAE (DPOAE) has generated considerable interest as a sensitive and frequency-specific indicator of outer hair cell function (Brownell, 1990; Stypulkowski, 1990; Kujawa *et al.*, 1992, 1994; Avan and Bonfils, 2005). DPOAEs are produced by simultaneously presenting two pure tones at frequencies f1 and f2 and intensities L1 and L2 to the ear. In normally functioning human ears, this yields a family of distortion components. Under many stimulus conditions, the most robust of these, and thus the most commonly monitored, corresponds to the frequency 2f1−f2. Stimulus parameters that affect the level, or strength, of the DPOAE include the intensity, the level difference (L1−L2), and the frequency ratio (f2/f1) of the two pure-tone stimuli used to produce it (e.g., Brown *et al.*, 1992; Whitehead *et al.*, 1995a, 1995b; Moulin, 2000).

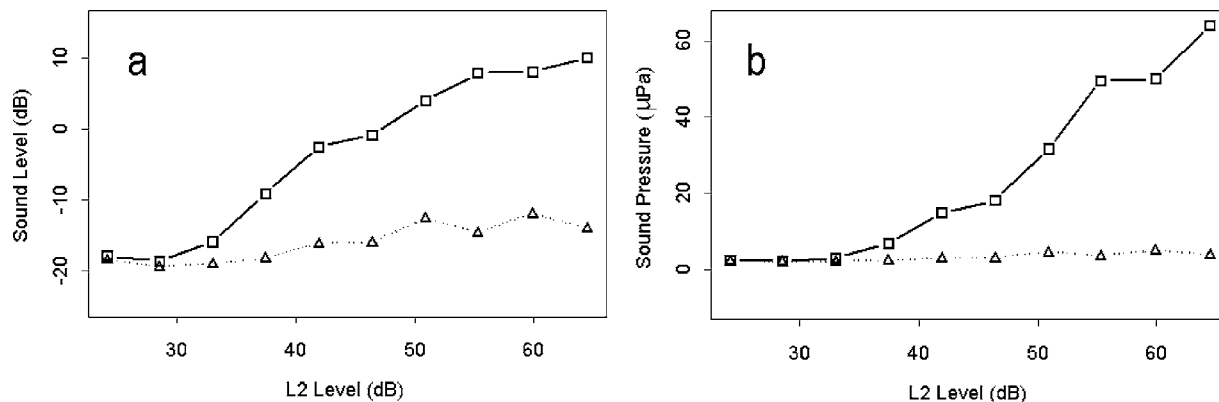
At the ear canal site of their detection, DPOAEs are present in a background of noise, and may be easily identified as responses only if their levels exceed those of other frequency components present in the surrounding canal spectrum. Since both the emission and the noise floor are measured with error, not all OAE measurements with a positive signal to noise ratio (SNR) represent actual emissions, nor is the reverse true. Rather, the SNR is positively related to the probability that an OAE measurement represents an actual emission (Kimberley *et al.*, 1997). Nonetheless, a SNR criterion approach is commonly used to identify valid DPOAE responses (Vinck *et al.*, 1996; Boege and Janssen, 2002; Gorga *et al.*, 2003; Oswald and Janssen, 2003). In other words, the level of the noise floor is treated like a fixed limit of detection. Since, however, noise floor level varies with frequency, and depends heavily upon the environment, equipment, and protocol used in testing, as well as the physiologic noise created by the individual being tested, the noise floor behaves like a random variable. The statistical implications of this with respect to growth function modeling are explored in detail below. Although measurement-based stopping rules may be used in an effort to reduce the noise floor level (e.g., Gorga *et al.*, 2003), they do not eliminate the effect of variability across subjects and testing conditions.


FIG. 1. Sample I/O function (f2/f1 = 1.22, L1−L2 = 10 dB) from a subject with normal hearing, plotted both in dB (a) and in μPa (b). These units are related as follows: $P = 20 \times 10^{L/20}$, where L is the level in dB and P is pressure in μPa. In this example, the DP emission (□) diverges from the noise floor (△) at an L2 level of around 33 dB, indicating the approximate beginning of the growth function.

Such rules also induce an association between DPOAE level and noise floor, raising other statistical concerns discussed below.

Several cross-sectional studies have found correlation between DPOAE level at a single f1 primary stimulus level (usually between 60 and 75 dB) and standard audiometric thresholds, both among normal and hearing-impaired ears (Avan and Bonfils, 1993; Gaskill and Brown, 1993; Kimberley *et al.*, 1994; Gorga *et al.*, 1997; Lind, 1998). Additionally, data collected longitudinally in both animals and humans suggest that declines in DPOAE strength may correlate with future, as well as concurrent hearing loss (Littman *et al.*, 1998; Stavroulaki *et al.*, 2001; Lucertini *et al.*, 2002). Indeed, some reports have described shifts in DPOAEs that precede behavioral threshold shifts in ears with presumed cochlear insult from ototoxic drugs (Littman *et al.*, 1998) and noise (Lonsbury-Martin and McCoy, 1992; Seixas *et al.*, 2005; Sallustio, 1998). Such findings suggest that DPOAEs may provide early warning of future sensory hearing loss. These preclinical changes will likely be first evident for low-level responses (Kujawa *et al.*, 1992, 1997; Mills *et al.*, 1993). As a result, methods which reliably extract low-level responses from their surrounding background of noise should yield the most sensitive metrics of compromise.

The difficulties encountered by current DPOAE extraction methods are depicted in Fig. 1. DPOAE response growth is plotted as a function of increasing stimulus level over a range capturing its fluctuation, eventual emergence from the noise floor, and roughly linear growth. At higher levels, DPOAE growth often becomes nonmonotonic, as cochlear active processes saturate (Kimberley *et al.*, 1997). At lower levels, DPOAE level is dominated by the noise floor, making it unclear to what extent, if any, the measured value represents an emission.

Although several methods for modeling and summarizing the growth function have been developed in the past decade (Nelson and Zhou, 1996; Vinck *et al.*, 1996; Kimberley *et al.*, 1997; Boege and Janssen, 2002; Oswald and Janssen, 2003; Gorga *et al.*, 2003; Neely *et al.*, 2003; Shaffer *et al.*, 2003), much recent work has been based upon the method of Boege and Janssen (2002). They proposed a simple linear regression model to describe the relationship

between L2 and DPOAE pressure. The x intercept of this line is interpreted as an extrapolated DP threshold (L_{edpt}), or the theoretical minimum L2 needed to elicit a cochlear response. This method offers the advantage over fixed SNR-based criterion methods that it is flexible enough to obtain ear-specific point estimates and standard error estimates of growth function parameters. By using the information contained from multiple DPOAE responses, it reduces the impact of DPOAE measurement error on parameter estimation. The parameter of primary interest (L_{edpt}) has shown modest correlation with audiometric thresholds, suggesting that this model may permit estimation of pure-tone thresholds from DPOAE data.

More recently, Oswald and Janssen (2003) refined this method by upweighting points in proportion to their SNR and downweighting points at the upper end of the I/O function, where outer hair cell saturation can cause departures from linearity in the growth function. Under the same set of data inclusion and model acceptance criteria, this weighted regression led to more model fits being accepted, thereby allowing threshold and slope estimation in a greater number of I/O functions. Gorga *et al.* (2003) showed improved model performance with some changes to the model acceptance criteria, and when I/O functions were recorded over a broader intensity range.

All of these variations on the L_{edpt} method of Boege and Janssen involve the exclusion of all DPOAE measurements that fail to achieve a SNR of at least 6 dB. As discussed, the SNR is related to the probability that a measured value at the emission frequency reflects an actual auditory response. One set of results estimated this probability for SNRs of 3 and 6 dB at 0.82 and 0.95, respectively (Kimberley *et al.*, 1997). Although no published studies have validated these estimates over a range of OAE testing conditions, they nonetheless imply that application of this 6 dB threshold involves the exclusion of valid data. Furthermore, points excluded by this SNR-based criterion are preferentially located in the low-level portion of the I/O function, eliminating values that may provide important insights regarding cochlear functional status, and excluding valid and highly influential data points from the analysis of the growth function. In the presence of measurement-based stopping rules, this method encounters

further statistical difficulties in that points are excluded based on the value of a variable (noise floor) that is correlated with the dependent variable (DPOAE level). Such informative missingness is known to yield biased regression parameter estimates (Seber and Lee, 2003). A method that avoids these pitfalls and makes more efficient use of the information contained in low-level responses, and is therefore more sensitive to cochlear compromise, is therefore desired.

The L_{edpt} method also applies criteria that accept as valid only those model fits in which the slope and Pearson correlation coefficient between DPOAE pressure and L2 are sufficiently large, and the standard error of L_{edpt} is sufficiently small. Since the Pearson correlation coefficient is highly sensitive to outliers, it may not be a reliable measure of association when so few points (typically 3–10) are modeled. Furthermore, although this method sets a lower bound for the growth function slope estimate, it does not offer any formal test for the presence of a growth function, which may limit its ability to reliably distinguish those cases in which a true response is present from those in which it is not. When growth function parameter estimation is of primary interest, a modeling technique that explicitly estimates the onset of the growth function and specifically tests for its presence without relying on ad hoc selection criteria would be preferred.

In this paper, we present a segmented regression model for the analysis of I/O function data collected from a large cohort of normal and noise-damaged ears. Segmented regression describes a class of models in which the relationship between the outcome and the predictors changes abruptly at a threshold value of one of the predictors (Muggeo, 2003; Hinkley, 1971), and has many applications in the biomedical literature, especially in describing dose-response relationships (Ipp *et al.*, 1990; Berman *et al.*, 1996; Kuchenhoff and Ulm, 1997; Pastor and Guallar, 1998; Luwel *et al.*, 2001; Monti *et al.*, 1980; Pires *et al.*, 2002; Slate and Turnbull, 2000; Teeter *et al.*, 1985). The model presented here assumes that, at near-threshold levels of the DPOAE, its pressure fluctuates randomly about a mean, whereas for stimulus (L2) levels above this point there is a positive linear relationship between the two. Including this changepoint as a parameter in the model allows for direct estimation of ear-specific growth function parameters without the need for data exclusions. By including all low-level responses in the analysis, this method may be more sensitive to preclinical changes in cochlear function. Just as linear regression reduces the impact of DPOAE measurement error in the L_{edpt} method, segmented regression mitigates the increased error associated with low-level responses by "borrowing information" from the entire I/O function. We discuss differences between parameter estimates derived from a purely model-based approach to those obtained after exclusion of some subset of the data. We describe a simple method for using segmented regression results to test for the presence of a growth function. Finally, we compare the parameter estimates obtained by segmented regression and by the L_{edpt} method of Boege and Janssen (2002), both over the entire dataset and within audiometric subgroups.

TABLE I. Description of the study population. * Normal hearing at baseline is determined by standard audiometry. Hearing is considered normal if the mean of the audiometric thresholds recorded at 2, 3, and 4 kHz is no greater than 20 dB HL.

Mean (SD) age	27.3 (6.9)	27.3 (4.1)	27.3 (6.6)
Ears	741	125	866
% Normal Baseline Hearing*	83.1%	96.0%	85.0%

II. METHODS

A. General

As part of a longitudinal study on the effect of occupational noise exposure on various hearing outcomes, audiometric information was collected over 4 years for a group of apprentices in various construction trades and graduate student controls of similar age. All lived in the Seattle area. All subjects underwent otoscopy, tympanometry, pure-tone threshold audiometry, and detailed DPOAE evaluation. Tests were conducted by CAOHC-certified audiometric technicians and audiologists; all results were reviewed by an audiologist (see Seixas *et al.*, 2004, 2005 for details).

B. DPOAE dataset

A total of 10 589 I/O functions at f2=2, 3, 4, and 6 kHz were collected over 4 years on 907 ears in 454 subjects. DPOAEs were measured using a commercially-available system (Bio-Logic Scout® AuDX) in a quiet room (levels generally less than 70 dBA), verified by periodic sound-level monitoring. Each I/O function was comprised of 10 points, corresponding to target L1 intensities of 35−80 dB in 5 dB steps, with f2/f1=1.22 and the target L1−L2 difference =10 dB. Noise floors were sampled at ±50 Hz of the 2f1−f2 frequency.

All I/O functions were excluded where testing irregularities led to a change of probe and/or technician during the testing session. Also excluded were all I/O functions recorded on ears with nonintact tympanic membranes or in which tympanometry indicated middle ear pressures more negative than −100 daPa. Individual DP responses were excluded where the achieved L1−L2 difference deviated from the target setting of 10 dB by more than 2 dB. Finally, 16 I/O functions were removed because fewer than 5 points remained after the other exclusions. The final dataset comprised 95 489 DP emissions from 9 556 I/O functions on 866 ears in 442 subjects. The number of study visits for each subject ranged from 1 to 4, with a mean of 2.8. The study population is described briefly in Table I.

For 9 157 of these I/O functions, corresponding audiometric thresholds were also recorded. Pure tone air conduction behavioral threshold testing was conducted in a mobile, acoustically-treated audiometric test van by CAHOC-certified audiology technicians (Washington Audiology, Inc., Seattle, WA). Background noise levels in the test van were monitored throughout each testing session using a Quest Bioacoustics Monitor. The test environment met OSHA re-

quirements for audiometric test facilities (OSHA, 1983) during all tests, and was in most cases compliant with the more stringent ANSI standard (S3.1-1991) recommended by the National Hearing Conservation Association for audiometric test facilities (NHCA, 1996). Audiometry was conducted on up to six subjects at a time using a Tremetrics RA300 audiometer with TDH-39 headphones. Thresholds were measured in increments of 5 dB.

C. L_{edpt} modeling

A complete description of this method for modeling the I/O function parameters is available in Boege and Janssen (2002). Briefly, it involves three key steps. First, only those DPOAE measurements with an SNR of at least 6 dB are included in the analysis. Second, a simple linear regression of DPOAE pressure against input signal intensity (L2) is fit to those I/O functions with at least 3 remaining points. Finally, those I/O functions in which a linear growth function is present are identified by the following model acceptance criteria: $r^2 \geq 0.8$, standard error of x intercept < 10 dB, slope $\geq 0.2 \, \mu$Pa/dB. Oswald and Janssen (2003) refined this method by applying a weighting scheme designed to downweight points at the extremes of the I/O function, where deviations from linearity often occur.

A weighting scheme similar to that used by Oswald and Janssen (2003) was adopted for the present analysis. Two considerations went into its development. First, since DPOAE pressure is an exponential function of the original data, a mean-variance relationship is present. To avoid any gross violation of the constant variance assumption of the regression model, an inverse-variance weighting scheme was applied in which the DPOAE pressure at each frequency and intensity is assigned a weight inversely proportional to its variance. A mixed effects model was used to estimate this variance from these longitudinal study data (Goldman, 2005; Seixas *et al.*, 2005). This scheme downweights measurements at the high end of the intensity range, where outer hair cell saturation is most likely to cause the growth function to deviate from linearity. Since the goal of this model is to fit the linear portion of the growth function, this inverse-variance weighting scheme has the additional benefit of downweighting those points for which the linear model may be incorrect.

Secondly, a SNR-based weighting scheme was explored. A logistic weighting function was built with its center at 6 dB, and with a shape such that measurements with a SNR of 0 dB are given half the weight of those with a SNR of 6 dB. This resulted in a function that is approximately linear for SNR values from -10 to $+15$ dB, which covers almost all DPOAE measurements in this dataset. All analyses were conducted with the inverse-variance weights alone and with a scaled product of the inverse-variance and SNR-based weights. Since the results of the two schemes were very similar (Goldman, 2005), only the results using the scaled-product weighting scheme are reported.

D. Segmented regression modeling

The segmented regression model proposed for fitting I/O function data consists of a flat line at low L2 levels, an unknown changepoint, and an increasing line at higher L2 levels, corresponding to the growth function. A major difference from the L_{edpt} method is that no DPOAE measurements are excluded from the analysis. This restricted two-segmented linear regression model may be represented as follows:

TABLE III. Breakdown of the number (percentage) of I/O functions included in the segmented regression analysis under each of the inclusion criteria. For algorithm convergence, percentages are out of the entire dataset. For the other criteria, percentages are out of the number remaining after application of the previous criterion.

Inclusion criterion	Frequency				Total
	2 kHz	3 kHz	4 kHz	6 kHz	
Algorithm convergence					
Singular gradient matrix	172 (7.3%)	172 (7.2%)	167 (7.0%)	140 (5.9%)	651 (6.8%)
Step size reduced below min.	76 (3.2%)	96 (4.0%)	163 (6.8%)	105 (4.4%)	440 (4.6%)
Max. No. iterations exceeded	1 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	1 (0.0%)
Success	2122 (89.5%)	2131 (88.8%)	2067 (86.2%)	2144 (89.7%)	8464 (88.6%)
Growth function presence (by significant F test)	2062 (97.2%)	2092 (98.2%)	2044 (98.9%)	2050 (95.6%)	8248 (97.4%)
x intercept estimable (by t test on slope estimate)	2002 (97.1%)	2039 (97.5%)	2005 (98.1%)	1970 (96.1%)	8016 (97.2%)

$$E(Y|X = x) = \alpha + \beta(x - \tau)_+,$$

where

$$(x - \tau)_+ = \begin{cases} 0 & \text{if } x < \tau, \\ x - \tau & \text{if } x \geq \tau, \end{cases}$$

and τ is the change point. This equation may be solved via nonlinear least squares using the SPLUS package **nls**. A generalization of standard linear regression, **nls** fits the model

$$y_i = f(\theta, x_i') + \varepsilon_i,$$

where $f(\cdot)$ is not necessarily linear, the parameter vector θ is typically not of the same dimension as the vector of predictors x_i', and all ε_i are independent $N(0, \sigma^2)$ variables. Parameter estimates for this model are found when the sum of squared residuals (RSS)

$$S(\theta) = \sum (y_i - f(\theta, x_i'))^2$$

is minimized. This is done by setting the partial derivatives with respect to θ

$$\frac{\partial S(\theta)}{\partial \theta} = -2 \sum (y_i - f(\theta, x_i')) \frac{\partial f(\theta, x_i')}{\partial \theta}$$

equal to 0. The resulting estimating equations must be solved by numerical optimization, which is accomplished in **nls** using the Gauss-Newton algorithm to step through the parameter space between iterations. The algorithm iteratively fits the model, declaring convergence when the parameter estimates become stable to within a small multiple of their standard error (Bates and Watts, 1988; Chambers and Hastie, 1998). The estimated covariance matrix of the parameter vector is

$$\hat{V}(\hat{\theta}) = s^2 (F'F)^{-1},$$

where s^2 is the estimated least squares error variance and $F = \partial f(\theta, x_i')/\partial \theta$, sometimes called the gradient matrix. For this study, the parameter vector θ consisted of the y intercept (α), the slope of the growth function (β), and the x intercept ($x_{int} = \tau - \alpha/\beta$). The model was parameterized in terms of x_{int} rather than τ to permit direct comparison with the L_{edpt} method, which does not estimate a change point, or starting point of the growth function. It should also be noted that the scaled-product weighting scheme was applied in both the L_{edpt} and segmented regression analyses.

The numerical optimization algorithm may encounter any of several problems, each of which can prevent conver-

TABLE IV. Comparison of the number of I/O functions included in the analysis using the L_{edpt} and segmented regression methods.

		Segmented regression		
		Included	Excluded	Total

	Excluded	2798	1271	4069 (42.6%)
	Total	8016 (83.9%)	1540 (16.1%)	9556

gence at the minimum of the RSS. First, in the case of a true minimum that is either very peaky or that yields $\hat{\tau}$ near a boundary of the range of the data, the algorithm may fail to converge, instead moving in miniscule step sizes around the minimum until the step size determined by the algorithm is reduced below the minimum allowed and an error is returned. A less frequent problem occurs when the iterations proceed slowly towards the true minimum, but fail to converge within some predetermined maximum number of iterations. Finally, if the model is inappropriate for the data (or sometimes if initial parameter values are poorly chosen), the gradient matrix will become singular after some number of iterations, leaving the estimating equations without a unique solution. This last error may occur in the presence of extremely noisy data, or when $\hat{\tau}$ converges towards a value outside the range of the data. In this paper, segmented regression model fits are called successful only if no errors were encountered.

The procedure for testing for the presence of a growth function and the validity of inference on its parameters consisted of two parts. First, the absence of a growth function indicates nonresponsiveness of the ear over the range of stimulus intensities presented to it. DPOAE measurements from such an I/O function are therefore said to represent background noise, and are thus adequately summarized as variability around a mean (Lonsbury-Martin and Martin, 1990; Kimberley *et al.*, 1997). This suggests that the weighted F statistic

$$F_0 = \frac{\sum w_i(\hat{y}_i - \bar{y})^2/2}{\sum w_i(\hat{y}_i - y_i)^2/(n-3)},$$

where $\hat{y}_i$ is the fitted value from the segmented regression model and w_i is the weight assigned to the ith DPOAE measurement, may be used to test for the presence of a growth function (Seber and Lee, 2003). Significant evidence of
FIG. 2. Examples of successful L_{edpt} model fits, showing DP emissions included ($\square$) and excluded ($\blacksquare$) from the analysis.
FIG. 3. Examples of L_{edpt} model fits that failed to meet the inclusion criteria, showing DP emissions included (□) and excluded (■) from the analysis.

the presence of a growth function (i.e., that the data are better fit by segmented regression than by a horizontal line at the mean) was declared if the null hypothesis in this F test was rejected at $\alpha < 0.05$.

The second part of the testing procedure addresses the difficulties of performing inference on the x intercept from a linear regression, which is the DPOAE threshold in this analysis. The simple linear regression equation $E[Y|X=x] = \alpha + \beta x$ gives an x intercept estimate of $-\hat{\alpha}/\hat{\beta}$, for which the delta method is often used to estimate the variance as follows:

$$\text{var}\left(\frac{-\hat{\alpha}}{\hat{\beta}}\right) \approx \frac{E[\hat{\alpha}]^2}{E[\hat{\beta}]^2}\left[\frac{\text{var}(\hat{\alpha})}{E[\hat{a}]^2} + \frac{\text{var}(\hat{\alpha})}{E[\hat{\beta}]^2} - \frac{2\,\text{cov}(\hat{\alpha},\hat{\beta})}{E[\hat{\alpha}]E[\hat{\beta}]}\right]$$

(Cox, 1990). This variance estimate is invalid, however, when $\beta = 0$, since in this case the true confidence interval for $-\alpha/\beta$ occupies either the whole real line or the outside of a standard interval (Fieller, 1954; Scheffe, 1970; Young et al., 1997). Inference on the x intercept is valid only when H_0: $\beta = 0$ is rejected; in other words, when the t statistic $|\hat{\beta}/s\hat{e}(\hat{\beta})|$ exceeds some critical value $t_{df,\alpha}$. Accordingly, the x intercept was declared to be estimable only if $\hat{\beta}/s\hat{e}(\hat{\beta}) > 1.90$ (corresponding to the one-sided critical value $t_{7,0.05}$). Note that this t test is based on the segmented regression parameter estimates, and is therefore only meaningful once the F test described above has been rejected.

III. RESULTS

A. Assessment and comparison of model fits

DPOAE thresholds could be estimated from 5 487 I/O functions under the L_{edpt} model and selection criteria, whereas 8 016 I/O functions were included for analysis under the segmented regression method. There was somewhat

more variation across frequencies in the number of I/O functions included under the L_{edpt} model than under segmented regression (see Table II for details).

A breakdown of the number of I/O functions excluded by each inclusion criterion in the segmented regression analysis is shown in Table III. For none of the criteria was there substantial variation across frequencies in the percentage excluded. Overall, the **nls** algorithm encountered an error in 11.4% of I/O functions. Of those remaining, 2.6% did not show significant evidence of a growth function. The x intercept inference criterion rejected 2.8% of those which met the other inclusion criteria.

Table IV compares the inclusion of I/O functions in the analysis by the two modeling techniques. Overall, the two techniques were in agreement regarding inclusion or exclusion of 67.9% of the I/O functions in this dataset. Among those included in the segmented regression analysis, 34.9% were excluded from the L_{edpt} analysis. Of those included in the L_{edpt} analysis, only 4.9% were excluded by segmented regression.

Examples of L_{edpt} model fits that met the inclusion criteria are shown in Fig. 2, and examples of those excluded by these criteria are shown in Fig. 3. Hollow squares depict points included in the analysis, whereas filled in squares show those excluded. Almost all I/O functions that were successfully fit showed clear visual evidence of a growth function. In some cases, however, points that do not appear to be part of the growth function were fit by the line, leading to a smaller slope estimate than the apparent relationship [e.g., Figs. 2(b) and 2(c)]. Many I/O functions excluded by the L_{edpt} criteria also appeared to have growth functions, as in all of the examples in Fig. 3.

Successful segmented regression model fits that met all inclusion criteria are shown in Fig. 4. In general, the model fit appeared to be quite appropriate for these I/O functions. Deviations from linearity, however, were noted at the highest
FIG. 4. Examples of successful segmented regression model fits.
FIG. 5. Examples of segmented regression model fits in which the step size was reduced below the minimum allowed, thereby producing an error.

L2 intensities [e.g., Figs. 4(b) and 4(c)], possibly due to outer hair cell saturation. In another deviation from the model assumptions, some functions showed evidence of a slightly positive slope in the nongrowth region [e.g., Fig. 4(a)].

Examples of functions for which the step size was reduced below the minimum allowed are shown in Fig. 5. Figure 5(c) shows growth with no inflection point, suggesting that this entire I/O function is a growth function, and therefore not appropriately modeled by segmented regression. Other functions, such as in Fig. 5(a), showed so little evidence of growth that the algorithm was unable to declare convergence at any one estimate of the inflection point. This error was also encountered in a few functions for which segmented regression appears to be a reasonable model, but in which a decline in DPOAE pressure was observed at the highest intensities [e.g., Fig. 5(b)]. The functions for which a singular gradient matrix was encountered, shown in Fig. 6, tend to exhibit either growth throughout [e.g., Fig. 6(b)] or no growth whatsoever [e.g., Fig. 6(c)]. A small number show some other irregular pattern [e.g., Fig. 6(a)].

Model fits in which the algorithm successfully converged, but which failed the F test for significant deviation from a simple mean model almost always occurred in I/O functions that have some large deviation from a horizontal line early in the nongrowth portion of the I/O function. Since the inverse-variance weighting scheme upweights points at the lowest intensities, such deviations contributed disproportionately to the sum of squared residuals. Model fits that met the convergence and F test inclusion criteria but not the x intercept inference criterion occurred in I/O functions that showed either very little growth ($\hat{\beta}$ very close to 0), or substantial deviation from the model assumptions of a flat line in the nongrowth portion and of linear growth thereafter [$s\hat{e}(\hat{\beta})$ very large].

A residual plot of the successful L_{edpt} model fits is shown in Fig. 7(a). The standardized residuals plotted on the y axis are the scaled difference between measured DPOAE pressure and that predicted by the L_{edpt} model. Black points were included in the L_{edpt} analysis, whereas gray points were excluded. While most of the excluded points are clustered below $\hat{x}_{int}$, there are many spread out in the region above $\hat{x}_{int}$, all of which have large negative residuals. Residuals at the low end of the I/O function are too large to be shown on this plot. This is because the L_{edpt} model, were it extrapolated below $\hat{x}_{int}$, would predict a large negative DPOAE pressure in this part of the I/O function, which is obviously impossible. The thick solid line represents a local smooth function fit to the residuals from all points included in the L_{edpt} analysis, and the thin solid lines represent the 95% confidence interval of this fit. Since any DPOAE pressure measurement must be positive, all residuals are necessarily positive at $\hat{x}_{int}$ (denoted by the vertical dashed line). Residuals decrease rapidly in the first 5 dB above $\hat{x}_{int}$, and beyond that point a sigmoid residual structure is apparent, suggesting that the linear fit may not completely describe the functional form. The widening of the confidence bands at the high end of the I/O function also suggests, however, that the residual structure in this region is less certain.

Figure 7(b) shows a residual plot of the segmented regression model fits that met all inclusion criteria. Below $\hat{x}_{int}$, a residual positive relationship in the data suggests that DP response may not be entirely independent of L2 intensity prior to the growth function. In the vicinity of $\hat{x}_{int}$, the sigmoidal residual structure is far subtler than that seen for the L_{edpt} model fits. The relationship is nearly flat from 5 dB below to 25 dB above $\hat{x}_{int}$, with a residual mean slightly above 0. At $\hat{x}_{int} + 25$ dB, a negative residual relationship appears in the data. This may be due to outer hair cell saturation causing DP response to level off or decrease at the high end of the I/O function. Although similar to that seen in the residuals from the L_{edpt} model fits, this decrease begins earlier and has somewhat narrower confidence intervals, prob-
FIG. 6. Examples of segmented regression model fits in which a singular gradient matrix was encountered, thereby producing an error.
FIG. 7. Standardized residuals for all successful fits using (a) L_{edpt} and (b) segmented regression, plotted against L2$-\hat{x}_{int}$. ably because many of the smallest DP responses at the high end of the I/O function were excluded from the L_{edpt} analysis.

B. Comparison of parameter estimates

Summary descriptions of the parameter estimates from the L_{edpt} and segmented regression analyses are given in Table V. In the subset of 5 218 I/O functions which meet the inclusion criteria for both methods, $\hat{x}_{int}$ was 7–8 dB higher at 6 kHz than at the other frequencies, $\hat{\beta}$ was 0.5–0.6 μPa/dB higher at 2 kHz than at 3 or 6 kHz, $s\hat{e}(\hat{x}_{int})$ was lowest at 6 kHz, and $\hat{\beta}$ was lowest at 4 kHz. For both the x intercept and slope, segmented regression appears to yield somewhat larger parameter and standard error estimates than the L_{edpt} method. This also holds true in the comparison of all parameter estimates, although the differences are slightly larger for the point estimates, and much larger for the standard error estimates. These differences do not vary by frequency except that, among slope estimates, they are much smaller at 4 kHz than at the other frequencies. Figure 8 provides a graphical comparison of the parameter estimates obtained under seg-

mented regression and L_{edpt} modeling in the matched subset of 5 218 I/O functions. There is moderately high correlation between them, with a large majority of parameter estimates higher under the segmented regression model.

C. Audiometric subgroups

For 9 157 (95.8%) of the 9 556 I/O functions in this dataset, standard audiometric testing was also performed at the same test visit. Threshold data appeared to be missing at random, as it was equally likely to be missing at each of the four frequencies, and I/O function parameters were similar between those for which audiometric testing was performed and those for which it was not. As shown in Table VI, the percentage of thresholds greater than 20 dB HL in this dataset increased with frequency, especially at 4 and 6 kHz, a frequency region commonly compromised in noise-exposed human ears (NIOSH, 1998; Seixas et al., 2004, 2005). Table VI also shows that, under either method, ears excluded from the analysis were more likely to have elevated behavioral thresholds (exceeding 20 dB HL) than those included. For both methods, the percentage difference between

TABLE V. Mean of growth function parameter point and standard error estimates. The left column summarizes all estimates included in the analysis. The right column summarizes parameter estimates for those 5 218 I/O functions that met the inclusion criteria for both methods.

those included in and excluded from the I/O function analysis was greatest at 4 and 6 kHz. Although segmented regression excludes far fewer ears than L_{edpt} overall, a greater fraction of those excluded by segmented regression had elevated behavioral thresholds than of those excluded by the L_{edpt} method. In other words, exclusion by segmented regression was more closely associated with poor hearing than was exclusion by L_{edpt}. This difference was greatest at 6 kHz, where 61.7% of ears excluded under segmented regression had depressed function, as compared to 37.1% of ears excluded from the L_{edpt} analysis.

For 5 012 of the 5 218 DPOAE I/O functions included in both analyses, standard audiometric thresholds were available. Parameter estimates for these I/O functions are broken down by frequency and by audiometric category in Table VII. At 3, 4, and 6 kHz, slope estimates for both methods decrease with increasing thresholds. At all frequencies, x intercept estimates for both methods increase with increasing thresholds, although for both methods at 6 kHz those in the two highest threshold categories are too close to be distinguishable. For both parameters, segmented regression yields larger estimates than the L_{edpt} method at all frequencies and in all audiometric subgroups. Among slope estimates, this difference is substantially greater at all frequencies among ears with audiometric thresholds ≤ 10 dB HL than among those with higher thresholds.

IV. DISCUSSION

Under the segmented regression method presented here, parameter estimates are available for over 46% more I/O functions in the sample dataset than under the L_{edpt} method proposed by Boege and Janssen (2002). This novel approach performs formal statistical hypothesis tests for the presence of a growth function, as well as for whether valid inference can be made on the x intercept of the fitted line. In doing so, it avoids the statistical pitfalls that accompany the use of ad hoc inclusion criteria in the L_{edpt} method. The L_{edpt} method excludes not only a large number of DPOAEs which are highly likely to be valid from the analysis of individual I/O functions, but also entire I/O functions from the grouped analysis based on criteria that are not designed to perform reliably across datasets. Since this method does not apply any x intercept inference criterion, some of the standard error estimates of L_{edpt} that are used as acceptance criteria are likely to be invalid (see Methods for summary). In the present analysis, 3.6% of included L_{edpt} fits fail the x intercept inference criterion applied in the segmented regression analysis.

Some I/O functions were included in the segmented regression analysis where $\hat{\beta}$ was only slightly greater than zero. Table V indicates, however, that segmented regression growth function slope estimates were larger for those I/O

TABLE VI. Percentages of ears with audiometric threshold exceeding 20 dB HL among those included and excluded from the L_{edpt} and segmented regression I/O function analyses, as well as among the overall dataset of 9 157 I/O functions for which audiometric data were available.

Frequency	Overall	L_{edpt}		Segmented regression	
		Included	Excluded	Included	Excluded

functions excluded from the L_{edpt} analysis than for those included. This suggests that the inclusion criteria for segmented regression were not simply less restrictive than those for the L_{edpt} method, but that the L_{edpt} method fails to identify a large percentage of growth functions in this dataset. Furthermore, within the set of I/O functions included in the L_{edpt} analysis, slope estimates were much smaller among those excluded by segmented regression than among those included. In other words, weaker DP responses are seen among the 269 I/O functions included only by the L_{edpt} method, whereas stronger DP responses are seen among the 2 798 I/O functions included only by segmented regression. It appears, then, that segmented regression more properly distinguishes those I/O functions that show significant evidence of auditory response from those that do not.

In the subset analysis of 5 218 I/O functions included in both analyses, segmented regression gives larger growth function parameter estimates and standard errors than the L_{edpt} method. Since there is no gold standard for defining and estimating the x intercept for DPOAE I/O functions, and since the DPOAE threshold cannot be directly measured (a background sound pressure level of 0 μPa is impossible to achieve), it is difficult to assess which model produces more appropriate parameter estimates. Since the two estimation methods are not typically based on the same set of data points, formal goodness-of-fit tests between these methods are not available. Nonetheless, the fit of each of these models in this dataset may be assessed in the residual plots in Fig. 7. While the residual structure evident in both suggests that neither model has the functional form of the data specified entirely correctly, it is far less pronounced for segmented regression, especially in the immediate vicinity of $\hat{x}_{int}$. For L_{edpt} model fits, the strongest evidence of a residual relationship in the data is seen in this area. In other words, the model breaks down most dramatically in the area most sensitive to cochlear compromise.

The residual plots call into question some of the segmented regression modeling assumptions. In the nongrowth region (below $\hat{x}_{int}$), a positive linear relationship remains in the data. One possible explanation for this lies in the sampling algorithm used by the DPOAE system. The measurement-based stopping rules used by this algorithm induced a relationship between the measured levels of the DP response and of the noise floor. The noise floor may increase slightly as L2 increases, since one component of the noise floor is the noise made by the testing equipment itself. Therefore, a modest positive slope in an I/O function may result primarily from the equipment settings, rather than from any actual auditory response. The residual structure below $\hat{x}_{int}$ would also be present if the true relationship between L2 and DP pressure were a smooth curve rather than the broken stick modeled here, as is likely. As a result of these issues, in testing for the presence of a growth function, the null hypothesis of a flat I/O function appears to be too strong, and may have led to incorrect inclusion of some I/O functions in this analysis.

The residual plots from both sets of model fits show a negative relationship remaining beyond about $\hat{x}_{int}+25$ dB. The residual structure in the data above $\hat{x}_{int}$ suggests that the growth function is not so much linear as sigmoidal, consistent with the saturating nonlinearity of the normal cochlear response described previously by others (see Robles and Ruggero, 2001 for review). The possibility of fitting a logistic function was briefly explored, but there were inadequate data at the high end of each I/O function with which to estimate either the L2 intensity at saturation onset or the upper limit of the DP response.

Despite this evidence of some segmented regression model misspecification, the residual plots shows a much better fit to the data (smaller deviations from the horizontal line) for this model than for the L_{edpt} model. This is especially true over the range $[\hat{x}_{int}, \hat{x}_{int}+25]$, which covers the majority of the growth function, including its onset. It therefore appears better suited to estimate growth function parameters.

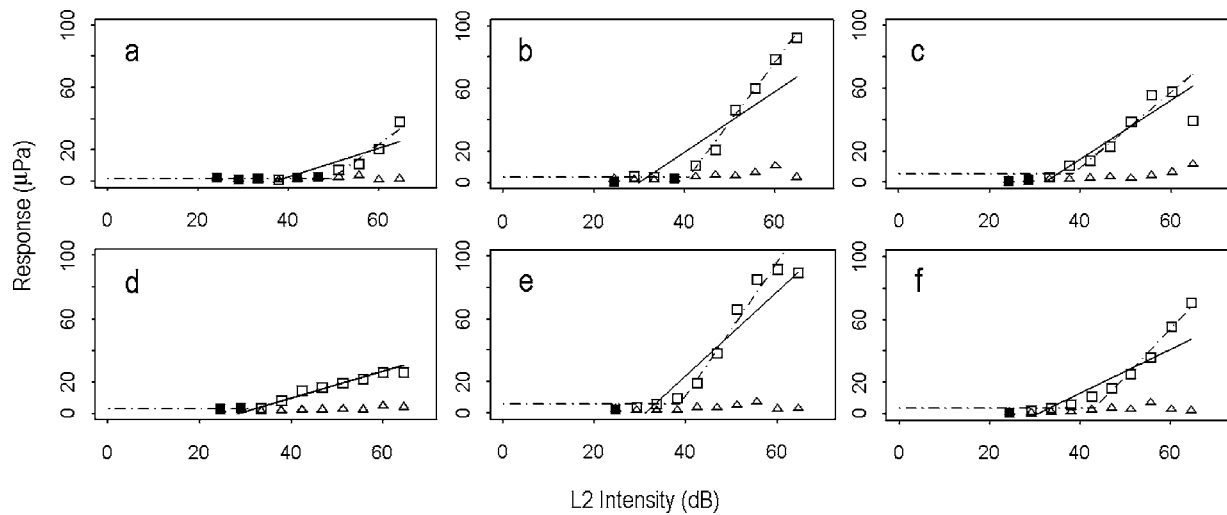
Among I/O functions successfully fit by both methods, segmented regression assigned a median of 6 DP emissions to the growth function, whereas the L_{edpt} model was fit to a


FIG. 9. Comparison of sample L_{edpt} (—) and segmented regression (—··—) fits to DPOAE data. Emissions included (□) and excluded (■) from the L_{edpt} analysis are shown, as well as the noise floor (△).

median of 7 DP emissions. This difference arises from the fact that the L_{edpt} model incorrectly assumes that all points that meet the SNR criterion are part of the growth function and therefore lie on the same line. The effect of this assumption is illustrated in the random sample of I/O functions successfully fit by both models that is plotted in Fig. 9. In Figs. 9(a), 9(b), and 9(f), it is especially apparent that the L_{edpt} method does not properly distinguish between the nongrowth and growth regions of the I/O function, leading to underestimates of both growth function parameters.

Although the segmented regression model presented here provides improved growth function estimation in this dataset, it is unclear how generalizable this result is to other DPOAE datasets. The strength of a DPOAE, and hence the shape of an I/O function, depends on the paradigm used to generate it (Whitehead *et al.*, 1995a, 1995b; see Kimberley *et al.*, 1997 for review). Whereas all published applications of the L_{edpt} method have used DPOAE data generated by a scissor paradigm, the paradigm used to generate this dataset specified a fixed L1−L2 difference of 10 dB. Nonetheless, the comparison of segmented regression and L_{edpt} model fits presented here is applicable to all I/O functions with the features (nongrowth region at low L2 levels, linear growth on the pressure scale at high L2 levels) described by Boege and Janssen (2002).

Whether or not this particular method is validated in other DPOAE datasets, future work in this area should be built upon formal statistical procedures of the sort employed here. Key components of such a procedure include the use of all points in an I/O function and the capability of testing for the presence of a growth function. To the extent that low-level responses contain information about cochlear compromise, the analysis of any set of DPOAE responses benefits from exploitation of this information.

The segmented regression model failed to converge for 11.4% of I/O functions in this dataset, although some of these clearly contained a growth function. In some of these cases, the growth function appeared to comprise the entire I/O function, meaning that data were not collected at suffi-

ciently low L2 levels to observe growth function onset. A simple linear regression may be fit in this case, and tested against H_0: $\beta = 0$ for significant evidence of growth. If, however, the nongrowth portion of the curve were allowed to have positive slope, as proposed above, it is unclear how one would choose H_0 in a test for the presence of a growth function. A preferable direction for future work might involve the collection of data at lower L2 levels to ensure that the nongrowth region has been captured, fitting both simple linear regression and segmented regression to the I/O function, then applying a likelihood ratio test for the changepoint. This procedure would explicitly test for the presence of a growth function without allowing positive slope in the nongrowth region, and its properties have been explored at length in the literature (Feder, 1975; Gallant, 1975; Kim and Cai, 1993; Zhan *et al.*, 1996).

Segmented regression also encountered errors in cases where there was clear growth in DP response followed by a sharp decline at the highest L2 levels. Such extreme nonlinearities clearly require a more flexible I/O function model. Although we explored the possibility of extending this model to allow for a nongrowth region at the highest L2 levels, there were insufficient data in this region to fit such a model. Future work to extend this model to one that estimates the beginning and end of the growth function and tests for the presence of both change points would be desirable, although this will require a richer set of DPOAEs collected over a wider range of L2 levels.

It is also worth noting that improvements in DPOAE measurement techniques may reduce these modeling difficulties. DPOAEs are known to consist of a mixture of reflection and distortion sources, the interaction of which increases the variability in these measurements (Shera and Guinan, 1999; Kalluri and Shera, 2001; Shera, 2004). Shera (2004) has suggested that unmixing these components may substantially reduce the variability in DPOAE measurements. To the extent that this variability currently leads to large deviations from linearity in the growth function, such an approach may im-

Goldman *et al.*: Otoacoustic emission input/output function modeling

prove the ability of segmented regression to detect DPOAE growth, and the sensitivity of the growth function parameter estimates to cochlear changes.

Although previous work with the L_{edpt} method demonstrated fair correlation between extrapolated DPOAE and pure-tone thresholds, similar results would not necessarily be expected in this analysis, since our DPOAEs were not elicited under the scissor paradigm. Also, since audiometric thresholds were measured in 5 dB increments in this study, the analysis of their association with DPOAE thresholds was limited to summaries of the I/O function analyses by audiometric categories. This analysis suggests important differences between the two sets of parameter estimates.

First, at 6 kHz, ears excluded from the segmented regression analysis were far more likely to have depressed function than those excluded under the L_{edpt} model. In this dataset partially comprised of noise-exposed ears, many ears with elevated audiometric thresholds at 6 kHz also showed little or no evidence of a 6 kHz growth function. Although both methods exclude I/O functions from many audiometrically normal ears, these findings are consistent with the hypothesis that exclusions are more likely to be due to the absence of a growth function in segmented regression than in the L_{edpt} analysis. It would nonetheless be desirable to refine this segmented regression procedure such that all I/O functions may be fit and properly tested for the presence of a growth function.

Second, although average parameter estimates from segmented regression exceed those from L_{edpt} in all subgroups in Table VII, this difference is greatest among those ears with audiometric thresholds ≤ 10 dB HL. Segmented regression parameter estimates vary somewhat more across audiometric categories than do those obtained by the L_{edpt} method. This suggests that segmented regression parameter estimates may be more highly correlated with audiometric threshold, although this study was not specifically designed to address this question. One possible explanation for this observation is that subjects with the best hearing may be especially likely to have a DP response with a SNR ≥ 6 dB in the nongrowth portion of the I/O function, in which case L_{edpt} would be especially prone to I/O function parameter underestimation in these subjects.

It would be of great interest if the I/O function parameters, either individually or in combination, were found to reliably predict hearing function and/or future hearing loss. Future work is needed to examine this question more closely, especially in a dataset using the scissor paradigm, as well as to compare the parameters obtained from the L_{edpt} and segmented regression models, in terms of both how well they correlate with other hearing-related outcomes and how well they generalize across levels of hearing function.

V. CONCLUSION

Segmented linear regression represents an improvement over the L_{edpt} method in that it avoids the pitfalls of data-driven exclusions and outcome-based inclusion criteria that are prone to incorrect inference, and makes better use of the information contained in low-level responses. Based on a comparison of model fits, in this dataset of 9 556 I/O functions it appears to provide a more accurate and more complete description of the relationship between DP pressure and L2 intensity, and appears to be more reliable in determining the growth function. Segmented regression also has the advantage of being able to estimate the point of growth function onset, which may be useful as a hearing threshold metric that lies within the range of the data, rather than the extrapolated thresholds examined in this study. Evidence of both model misspecification and misclassification of I/O functions according to the presence of a growth function suggests that more work is needed. It would be desirable to explore whether threshold estimation may be substantially improved by increasing the density and range of intensities in the I/O function, as this would provide not only a richer dataset, but also the possibility of developing models that address nonlinearities in the growth function. Finally, although there is some suggestion that segmented regression parameter estimates covary with audiometric thresholds more than do those obtained from the L_{edpt} model, more work is clearly needed to compare these methods in terms of how well the parameter estimates of each correlate with standard audiometric measures.

Development and the role of internal noise in detection and discrimination thresholds with narrow band stimuli

Emily Buss,[a] Joseph W. Hall III, and John H. Grose
Department of Otolaryngology/Head and Neck Surgery, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27599

The experiments reported here examine the role of internal noise in the detection of a tone in narrow band noise and intensity discrimination for narrow band stimuli in school-aged children as compared to adults. Experiment 1 used 20-Hz wide bands of Gaussian and low-fluctuation noise centered at 500 Hz to assess the role of stimulus fluctuation in detection of a 500-Hz pure tone. Additional conditions tested whether performance was based on level and/or level-independent cues. Children's thresholds were elevated with respect to adults, and whereas adults benefited from the reduced fluctuation of low-fluctuation noise, children did not. Results from both groups were consistent with the use of a level cue. Experiment 2 estimated intensity increment thresholds for a narrow band Gaussian noise or a pure tone, either with or without a presentation-by-presentation level rove, an additional source of level variability. Stimulus variability was found to have a larger effect on performance of adults as compared to children, a rather counterintuitive finding if one thinks of children as more prone to informational masking introduced by stimulus variability. Both tone-in-noise and intensity discrimination data were consistent with the hypothesis that children's performance is limited by greater levels of internal noise. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354024]

I. INTRODUCTION

In many psychoacoustic paradigms, performance of young children is poor in comparison to the performance of adults. This has been found for relatively complex listening tasks, such as speech recognition under challenging listening conditions (e.g., Elliot, 1979; Nábelek and Robinson, 1982) and informational masking (Allen and Wightman, 1995; Hall *et al.*, 2005; Oh *et al.*, 2001; Wightman *et al.*, 2003). It has also been demonstrated for relatively simple tasks, such as the detection of a tone in quiet or in masking noise (Allen and Wightman, 1994; Fior, 1972; Maxon and Hochberg, 1982), frequency discrimination (Jensen and Neff, 1993; Maxon and Hochberg, 1982), and intensity discrimination (Fior, 1972; Maxon and Hochberg, 1982; see also Jensen and Neff, 1993). Although the time course of these developmental effects varies with paradigm and experimental conditions, there is at least some evidence of improvement out to 10–12 years of age in very simple psychoacoustic tasks (e.g., Maxon and Hochberg, 1982). A satisfactory explanation of these prolonged developmental effects for relatively simple psychoacoustic paradigms has proven elusive.

Previous research has considered a range of factors that might explain threshold elevation in children, including poor frequency selectivity, reduced motivation or inattention, and inefficient listening strategies. While any of these factors could contribute to the effects observed under some conditions, none seems to account for all effects observed. For example, Schneider *et al.* (1990) estimated critical bands and argued that the somewhat wider critical bands of infants and young children were not nearly wide enough to account for the elevation in masked thresholds observed. Motivation and inattention have been argued to be unlikely candidates based on relatively small effects of changing the task reward structure and the relative stability of thresholds over time for a given listener (for a review, see Schneider *et al.*, 1989). While listening strategy almost certainly plays a role in the performance of young children under some listening conditions, Willihnganz *et al.* (1997) provide evidence that it cannot account for all of the developmental effects observed, even under complex listening conditions. In that study, perceptual weights characterizing performance of adults and young school-aged children in a masked intensity discrimination paradigm were estimated; the pattern of weights did not suggest that children were using a particularly inefficient strategy when compared to adults, despite the finding of elevated thresholds for the younger listeners.

Schneider and colleagues (1989, 1992) suggest that increased internal noise might account for a wide range of developmental differences. While the phrase *internal noise* is sometimes used in a very broad sense, describing any of a number of inaccuracies that might account for deviations from optimal performance, the hypothesis proposed was more specific. In this case, internal noise was defined in terms of variability in the neural representation of intensity. Further, it was reasoned that increased internal noise would result in shallower psychometric functions in a masked detection task because energy at the output of the auditory filter centered on the signal would be more variable. Schneider *et al.* (1989) tested this hypothesis by estimating percent correct for the detection of a tone masked by a 1/3 octave band

of noise; psychometric functions from group data failed to show compelling evidence that children's psychometric functions are shallower than those of adults. However, other studies (e.g., Allen and Wightman, 1994; Olsho *et al.*, 1988) have estimated psychometric functions based on *individual* listeners' data and have found an increase in slope with age, as would be expected if internal noise played a role in the elevated masked detection thresholds of the child listeners.

Internal noise has been very useful in helping to account for various psychoacoustical data of adult listeners, including intensity discrimination (Jesteadt *et al.*, 2003). Although the hypothesis that developmental differences in threshold sensitivity can be accounted for in terms of differences in internal noise is attractive, it has not been widely applied to studies of the developmental effects observed in simple psychoacoustic tasks. Our main purpose in the present study was to test the hypothesis that developmental effects observed with a simple psychoacoustic task in school-aged children can be explained, at least in part, in terms of internal noise.

One general strategy that has been used previously to study internal noise in adult listeners is to observe the effects of manipulating the variability of some physical parameter of the stimulus, such as intensity, and observing the effects on listener performance (Jesteadt *et al.*, 2003; Spiegel and Green, 1981). In this approach, the magnitude of change in performance due to changes in the variability of the physical parameter is used to draw inferences about the neural variability (or internal noise) associated with the detection process. One type of variability commonly introduced in psychophysical paradigms is that of level rove, whereby a random intensity is selected prior to each presentation interval from a restricted range (cf. Jesteadt *et al.*, 2003). Another source of variability is the within-interval fluctuation of a stimulus (Spiegel and Green, 1981), such as that characterizing random noise samples. Both experiments reported here use the general approach of assessing performance in the face of stimulus variability and making inferences about the magnitude of internal noise based on susceptibility to external noise.

Narrow band Gaussian noise is characterized by relatively prominent amplitude fluctuation dictated by its bandwidth, as well as the relative magnitudes and phases of the constituent components. In this context, the addition of a pure tone signal produces a number of effects that could potentially be used as detection cues: the overall level of the stimulus is increased, but there are also changes in envelope statistics, temporal fine-structure regularity, and, possibly, spectral shape. Level-independent cues can be shown to support the detection of a tone in bandpass Gaussian noise under conditions where level is an unreliable cue (Richards, 1992; Kidd *et al.*, 1989; Richards and Nekrich, 1993), such as in the presence of an intensity rove, and may be combined with a level cue under more typical (nonroved) conditions (Richards, 2001). The cues available for a tone in "low-fluctuation noise," characterized by a relatively flat temporal envelope, are somewhat different from those available in Gaussian noise. Notably, adding a pure tone to a narrow band Gaussian

noise tends to flatten the amplitude envelope of the stimulus, while adding a tone to a narrow band low-fluctuation noise can increase envelope fluctuation.

In adult listeners detection thresholds for a pure tone added to a low-fluctuation masker tend to be lower than those for a pure tone added to a comparable bandpass Gaussian noise masker (Hall *et al.*, 1998; Hartmann and Pumplin, 1988; Kohlrausch *et al.*, 1997; Eddins and Barber, 1998; but also see Eddins, 2001). At least two possibilities have been suggested to account for this finding. Kohlrausch *et al.* (1997) suggested that the change in envelope statistics with the addition of a tonal signal is responsible. Eddins (2001) offered an alternative suggestion that the short-term stability of low-fluctuation noise maskers facilitate the detection of an increment in intensity. This interpretation was supported by data on intensity discrimination; thresholds for low-fluctuation noise were lower than those for Gaussian noise, even when the signal interval was associated with a change in level and no change in the envelope statistics. This interpretation is also consistent with the views of Bos and deBoer (1966), who argued that both intensity discrimination and masked tone detection are limited at narrow bandwidths (10–40 Hz) by inherent stimulus fluctuations.

As mentioned at the outset, intensity discrimination has been shown in some studies to be elevated in school-aged children. Thus, children might be poorer than adults in detecting a signal in noise because of relatively poor ability to utilize the associated level cue. It is less clear how well children make use of level-invariant cues for a tone added to narrow band noise. Allen *et al.* (1998) examined the types of cues used by children in a tone-in-noise detection task for a 400-Hz wide masker centered at 1 kHz. Preschool aged children were able to use level-invariant cues, such as temporal changes in the masker with the addition of a signal. It was also noted that at the detection threshold of children, multiple cues associated with the signal would be present in the physical stimulus: it was hypothesized that children may not be good at integrating the different cues available or switching between cues.

Very little is known about the effect of stimulus variability on young school-aged children in tone detection or intensity discrimination with narrow band stimuli other than tones. Preliminary data collected in our lab in the course of a binaural experiment, however, suggested that children 5–9 years of age might perform quite differently from adults in the face of stimulus variability. In that study (Buss *et al.*, 2003), diotic thresholds for a 500-Hz tone in a 20-Hz wide narrow band of noise centered on 500 Hz were measured for both Gaussian and low-fluctuation noise. While adults showed the expected masker effect, with lower thresholds in low-fluctuation noise, children had very similar thresholds in low-fluctuation and Gaussian noise, suggesting that they may not be able to take advantage of the cues available in low-fluctuation noise. Experiment 1 pursued this preliminary finding by estimating monaural pure-tone detection thresholds in both Gaussian noise and low-fluctuation noise. Additional conditions measured sensitivity to either level cues or level-independent cues present in the tone-in-noise task in order to confirm that any age effects obtained with a tone in

noise were related to level (and not level-independent) cues. Experiment 2 used stimuli with high or low degrees of inherent fluctuation and examined the effects of additional variability introduced by level rove on intensity discrimination, a paradigm closely resembling that used in adults by Jesteadt *et al.* (2003) to estimate internal noise.

II. EXPERIMENT 1: ENVELOPE FLUCTUATION AND MONAURAL CUES FOR MASKED TONE DETECTION

The purpose of Experiment 1 was to test the prediction that if internal noise is the limiting factor in children's detection of a tone in narrow band noise, then they should not benefit from reduced masker fluctuation to the same extent as adults, for whom external noise plays more of a role in performance. In other words, elevated levels of internal noise could result in a failure of children to make effective use of the more stable level cues in low-fluctuation as compared to Gaussian noise. Because this logic rests on the assumption that listeners are using a level cue to perform the task, and because multiple cues are available for these stimulus conditions, additional conditions were run in which level and level-independent cues were assessed separately. Results of these additional conditions will be interpreted in terms of the cues most likely to underlie performance in the tone-in-noise conditions. Further, if children have difficulties integrating multiple cues in the basic conditions, as suggested by the results of Allen *et al.* (1998), then these blocks of stimuli characterized by reduced cues (e.g., just level) should give a more accurate indication of the child listeners' abilities to make use of level and level-independent cues.

A. Methods

1. Listeners

A group of 8 children participated, including 6 males and 2 females, aged 5.0 to 10.5 yr (mean=7.3 yr). The adult group was comprised of 10 listeners, 2 males and 8 females, aged 18.0 to 48.0 yr (mean=28.4 yr). All listeners had pure tone thresholds equal to or better than 15 dB HL for octave frequencies 250 to 8000 Hz (ANSI, 1996). None of the listeners reported a history of ear problems. A history of ear disease, including chronic otitis media (OM), or an active case of OM at the time of testing were considered grounds for exclusion from the study. Data for one additional 7-years-old child listener were excluded from the study due to excessive variability in performance. Thresholds for this child varied by more than 25 dB in one condition in a single session: this variability was attributed to fatigue and inattention rather than to learning because thresholds increased (worsened) over the course of the session.

2. Stimuli

The Gaussian masker was a 20-Hz wide band of noise centered on 500 Hz. The low-fluctuation noise was generated following a procedure described by Kohlrausch *et al.* (1997). First, a 20-Hz wide band of Gaussian noise centered on 500 Hz was generated; the sample was divided by its Hilbert envelope in the time domain and then restricted to the origi-

nal 20-Hz spectral region via multiplication in the frequency domain, a procedure that was repeated 10 times for each sample. This process resulted in a masker with a relatively flat temporal envelope. Quantifying envelope fluctuation as the ratio between the standard deviation and the mean of the envelope (V), the low-fluctuation and Gaussian noise maskers are characterized by $V=-24.1$ and $V=-5.6$ dB, respectively. In terms of the modulation depth (m) for sinusoidal amplitude modulation, these values are comparable to $m=0.09$ and $m=0.74$, respectively (see Kohlrausch *et al.*, 1997). Maskers were scaled to a digital amplitude associated with 65 dB SPL and presented for 409-ms, including 50-ms $\cos^2$ ramps. The signal was a 500-Hz pure tone, 309 ms in duration. When present, the signal was ramped on and off using 50-ms $\cos^2$ ramps, with onset occurring 100-ms after onset of the masker, and the signal level was adjusted by way of a scalar. Stimuli were generated digitally in MATLAB and played out via two channels of a DAC (TDT, RP2) at approximately 12.2 kHz. The resultant streams were routed through a headphone buffer (TDT, HB7) to the left earphone of a pair of circumaural earphones (Sennheiser, HD 265).

Maskers were generated using arrays of 2^{13} points. The effect of truncating these arrays to the number of points associated with 409 ms (4993 points) and imposing ramps introduced some variability around the 65-dB mean masker level. This effect was estimated based on 100 samples, generated following the procedures described above, with the level for each sample calculated based on the steady portion of the stimulus (i.e., excluding ramps). For Gaussian noise stimuli, 50% of the samples were within ±0.5 dB of 65 dB SPL, 75% were within ±1 dB, and 90% were within ±1.5 dB. For low-fluctuation noise stimuli, 90% of the samples were within ±0.5 dB of 65 dB SPL. The effects of this source of stimulus variability will be revisited below.

For the purposes of stimulus generation, the 409-ms masker was divided into two portions: the *fringe* and the *core*. The *fringe* portion of the masker was 150-ms in duration, including 50-ms $\cos^2$ onset and offset ramps. The *core* portion of the masker received the same gating as the pure tone signal: that is, it was 309-ms in duration, including 50-ms $\cos^2$ ramps. The *fringe* offset and the *core* onset masker ramps overlapped in time, such that the masker sounded continuous when the two portions were played together. Dividing the masker in this way allowed the independent manipulation of the *core* portion of the masker in conditions where cues were limited to either just level or just envelope. The primary motivation for the use of a masker fringe was to allow comparison with tone-in-noise data collected using an asynchronous onset. The implications for adopting the *core/fringe* stimulus configuration in the present study are considered further in the discussion section.

In the *all-cues* condition, the 500-Hz pure-tone signal was simply added to the masker with no further adjustment made to the *core* portion of the masker. This condition is referred to as the *all-cues* condition because the addition of the signal introduces both level and level-independent cues. In a second condition, the signal was an increment in intensity of the *core* portion of the masker. In this case, waveform amplitude of the *core* portion of the masker was adjusted

according to the increment that *would have been obtained* by the addition of a pure tone signal at the associated signal level. This was computed with the formula $10 \log(10^{65/10} + 10^{\text{Sig Lev}/10})$, where Sig/Lev is the level of the simulated pure-tone signal, in dB. As such, thresholds in this condition can be directly compared to those obtained in the *all-cues* condition. This condition is referred to as the *level-only* condition because the signal consists of an increment in the level in the core portion of the masker and is not associated with level-independent cues, such as a change in envelope statistics within that portion of the masker. In the final condition, a pure tone signal was added to the masker, but the sum (signal+core) was scaled down to counteract any resultant change in level. In this *no-level* condition there was a change in the stimulus envelope with the addition of the signal, but no change in the overall level. Other possible cues in the *no-level* condition include the regularity of zero-crossings and spectral shape, although the latter was unlikely to be a viable detection cue for such a narrow bandwidth.

Maximum values for *no-level* tracks were imposed because of the nonmonotonicity of some of the temporal stimulus features thought to provide possible cues. For example, the temporal envelope of a low-fluctuation noise masker alone is relatively flat. With the addition of a tone, envelope variability increases with increases in signal level up to a point, but beyond that point variability begins to drop, as the stimulus envelope becomes dominated by the pure-tone signal. Based on these considerations, and calculations of possible level-invariant cues (i.e., average envelope slope, envelope max/min ratio, and periodicity of zero crossings), it was decided to impose a track ceiling value of 65 dB SPL for low-fluctuation noise, the approximate signal level associated with the most prominent level-invariant cues. A ceiling of 90 dB SPL was set for the *no-level* Gaussian noise masker stimuli; while level-invariant cues were monotonic for this masker type, it was reasoned that failure to make use of these cues with a 90 dB signal would not likely change in the face of further increases in signal strength. A threshold estimate was judged to be at ceiling if the threshold estimation track hit ceiling three or more times during a run, and an average data point for a given condition was judged to be unmeasurable if two or more threshold estimates were at ceiling.

To summarize, there were six conditions in total, illustrated in Fig. 1. In this figure, an example Gaussian noise sample is shown in the left panel and an example low-fluctuation noise sample in the right. The repeated gray waveform is the masker alone and the associated black lines indicate the envelope of a signal-plus-masker, with both signal and masker presented at a level of 65 dB SPL. At the top of each panel are indications of the temporal placement (and overlap) of the *fringe* and *core* portions of the stimuli. In the *all-cues* condition the signal was a pure tone gated with the ramps defining the *core* portion of the stimulus; interactions between signal and masker produced both level and envelope cues. In the *level-only* conditions the signal consists of an increment in masker level, defined as the increment that would have been produced if a pure tone signal had been added. In these conditions there was no change in envelope statistics over the course of the signal presentation to cue the
FIG. 1. Example stimuli from Experiment 1 are shown, with Gaussian noise (left panel) and low-fluctuation noise (right panel), and signal conditions indicated in the left margin. The top row in each panel shows the segments of the stimulus identified as the *fringe* and core portions. The next row, labeled *all cues*, shows a standard stimulus (in gray) and the envelope of that standard summed with a 65-dB SPL pure tone signal (black line). The final two rows show standard and signal-plus-standard for the comparable *level-only* and *no-level* conditions. For illustrative purposes a single random sample was selected for all three signal conditions within each panel; in the experiment a new random sample was generated prior to each presentation.

presence of the signal other than those at the boundary of the *fringe* and *core* segments. In the *no-level* conditions the overall level of the *core* portion of the stimulus was scaled back after addition of the signal such that a change in envelope statistics over the course of the signal presentation cued the presence of the signal, but there was no increase in level.

3. Procedures

Threshold estimates were obtained using a 3-alternative forced-choice procedure and a 3-down 1-up tracking rule, estimating 79% correct on the psychometric function (Levitt, 1971). Initial signal level adjustments were made in steps of 4 dB, and level adjustments were reduced to 2 dB after the second track reversal. Each track continued for a total of six reversals, and the final threshold estimate was the mean level at the last four reversals. Listening intervals were marked visually via animation on a computer screen. Over the course of a track a cartoon picture was unmasked, in the style of a jigsaw puzzle, with one piece revealed following each correct response. No visual feedback was provided, following an incorrect response. At the end of the track the cartoon was fully revealed and performed a two-second animation. All listeners used this interface.

On the first visit to the lab, child listeners were randomly assigned to one of two groups. One group ran a block of the *all-cues* and a block of the *level-only* condition for each masker type. The other group ran a block of the *all-cues* and a block of the *no-level* condition for each masker type. On the second visit to the lab, child listeners performed a second block of the *all-cues* condition and a block of the reduced-cue condition they had not previously listened to (either *level-only* or *no-level*) for each masker type. Within a visit, the order of the four blocks (2 signal conditions × 2 masker types) was randomized. Adult listeners followed the same sequence of blocks, but were able to complete more than four blocks in a visit. Each visit lasted no longer than one hour, with frequent breaks. A block of trials consisted of three threshold estimates, with a fourth if the span in initial estimates was 3 dB or more. All estimates for a listener were averaged to produce the final thresholds reported below.

Prior to each block, the experimenter described the detection cue associated with that condition. For the *level-only* condition, listeners were asked to select the loudest interval. In the *no-level* condition, the signal was described as the "more wobbly" sound for low-fluctuation noise and the "smoother, or less wobbly" sound for Gaussian noise. In the *all-cues* condition, instructions were to listen to loudness and/or degree of fluctuation. In all cases, use of visual feedback to optimize performance was encouraged.

B. Results

The *all-cues* condition was performed twice by each listener for each masker type. This was done in part to assess the stability of this very important baseline condition. To that end the first and the second replicate thresholds were compared for evidence of improvement.[1] One-tailed, paired *t* tests revealed no improvement between the first and second replication for Gaussian ($t_{16}=-1.16$, $p=0.13$) or low-fluctuation noise ($t_{16}=0.90$, $p=0.19$). Tests with just child and just adult data similarly resulted in no significant difference between the first and second block of thresholds ($\alpha=0.05$). Subsequent analyses incorporating *all-cues* data were performed based on the first set of estimates obtained, although results are qualitatively identical when analyses are performed on the mean of all (six to eight) threshold estimates in the *all-cues* condition.

Figure 2 shows the mean thresholds for each group (bars) and individual listeners' thresholds (circles) obtained with Gaussian noise (top) and low-fluctuation noise (bottom). Individuals' thresholds are ordered by listener age, youngest (left) to oldest (right) within group. Open bars and open circles indicate adult data, and hatched bars and filled circles indicate child data. In the *all-cues* condition, mean thresholds for adults were 68.2 and 62.5 dB SPL for Gaussian and low-fluctuation noise, respectively. This difference of 5.7 dB was significantly greater than zero in a paired *t* test ($t_9=5.09$, $p<0.001$, two-tailed). This result is comparable to the 5-dB effect reported by Hall *et al.* (1998) for 10-Hz wide noise bands centered at 500 Hz. In contrast, for children the mean thresholds were 69.9 and 70.4 dB in Gaussian and low-fluctuation noise. The masker effect of
FIG. 2. The mean thresholds from Experiment 1 are plotted for Gaussian noise (top panel) and low-fluctuation noise (bottom panel). Bar markings indicate mean data from adults (□) and children (⊠), and the circles associated with each bar show individual data. Stimulus conditions are indicated along the abscissa. The ratios at the right of each panel indicate the proportion of listeners contributing to each mean in the *no-level* conditions: individuals' data were omitted from the average if they were deemed to be indistinguishable from ceiling performance.

only 0.5 dB was not significant ($t_7=0.105$, $p=0.92$, two-tailed). This result closely replicates results for analogous diotic stimuli collected in the course of a binaural study (Buss *et al.*, 2003).[2] The +5 dB S/N ratio at threshold for the Gaussian noise masker can be compared with the results of Hall *et al.* (1997). In one condition of that study, thresholds were estimated for the detection of a 500-Hz pure tone masked by a 20-Hz wide band of noise centered on 500 Hz. The masker was 600 ms in duration, and the signal was 400 ms, with signal onset occurring 200 ms after masker onset. The average threshold for school-aged listeners in that study (ranging from 5–11 yrs) was +3.4 dB S/N, comparable to the +5 dB S/N observed here.

The second set of bars in each panel of Fig. 2 shows thresholds in the *level-only* condition. In all cases these thresholds are quite similar to those in the corresponding *all-cues* condition. A repeated-measures ANOVA was performed to assess this relationship. There was one between-subjects factor (AGE: child, adult) and two within-subject factors (CUE: *all-cues*, *level-only*; MASKER: Gaussian, low-fluctuation). There was a significant main effect of AGE ($F_{1,16}=16.23$, $p<0.001$) and a significant main effect of MASKER ($F_{1,16}=40.42$, $p<0.0005$). The interaction between AGE and MASKER was significant ($F_{1,16}=27.77$, $p<0.0005$). There was no main effect of CUE ($F_{1,16}=1.56$, $p=0.23$) and no interactions between CUE and the other factors. This confirms that the *level-only* and *all-cues* thresholds were not statistically different. Thus, there was a significant masker effect in the *level-only* condition for adults, but no significant effect for children.

The right-most set of bars in each panel of Fig. 2 shows results of the *no-level* condition. Only those data points deemed to be measurable were included in the average, so these results tend to underestimate thresholds by way of ex-

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Buss *et al.*: Development and internal noise   2781

cluding large values at ceiling. The proportion of data points included in each mean is indicated at the base of each bar or in place of a bar. For the Gaussian noise masker, none of the children obtained a threshold below the ceiling value of 90 dB SPL. All but one of the adults performed below the ceiling, but thresholds in this condition were elevated more than 10 dB relative to the *all-cues* condition. These results suggest that cues other than level (e.g., envelope) probably played little or no role in performance in the *all-cues* condition with Gaussian noise. For low-fluctuation noise, 3/8 of children and 8/10 of adults produced a threshold estimate below the ceiling of 65 dB SPL. In all cases where a measurable threshold was obtained, the resultant threshold was near 62 dB, similar to average adult *all-cue* threshold and 8 dB better than average child *all-cue* threshold. The three children who performed below ceiling in the *no-level* condition attained thresholds approximately 5 dB lower than their thresholds in the associated *all-cue* condition. This suggests that these listeners failed to make use of level-independent cues present in the *all-cue* condition.

C. Discussion

Experiment 1 showed that adults were more sensitive at detecting a tone added to a low-fluctuation masker as compared to a Gaussian noise masker, and children showed no such masker effect. While children's detection thresholds did not vary as a function of masker type, it seems reasonable to assume that children were able to perceive a difference between Gaussian and low-fluctuation noise stimuli. A 20-Hz wide band of Gaussian noise has an equivalent AM rate of approximately 13 Hz (Rice, 1953). Based on the temporal modulation transfer function (TMTF) data of Hall and Grose (1994), at a modulation rate of near 13 Hz, AM of the Gaussian noise (with $m=0.74$) should be clearly perceptible for all child listeners, while modulation for the low-fluctuation stimuli (with $m=0.09$) would be expected to fall below the modulation detection threshold. This suggests that child listeners in Experiment 1 should be able to perceive the difference between the envelope fluctuation of Gaussian and low-fluctuation noise, and yet these perceptible differences did not affect the performance. There are no published AM discrimination data that permit the assessment of the relative sensitivity to AM in children and adults, another factor that could bear on the absence of a masker effect in the current dataset.

It is possible that children might have particularly elevated thresholds for a tone masked by a low-fluctuation noise when compared to adults because of increased cue complexity. If the cues allowing adults to achieve lower thresholds with low-fluctuation noise are more subtle or complex than those present in the Gaussian noise case, and if children are not as adept as adults at combining or switching between cues available in low-fluctuation noise, then low-fluctuation noise thresholds in children would not benefit from these additional subtle or complex cues. This hypothesis is similar to that proposed by Allen *et al.* (1998) to account for tone-in-noise masking results obtained with preschool-aged children. The fact that 3 out of 8 child listen-

ers attained lower thresholds in the *no-level* than the *all-cues* conditions is consistent with this view.

Results of the reduced-cue conditions suggest that an increment in level may be the primary cue underlying thresholds for a tone added to a narrow band of noise for most listeners, both children and adults. Level-invariant cues in isolation were associated with elevated or unmeasureable thresholds for the Gaussian noise masker, and so almost certainly played no material role in detection for the *all-cues* Gaussian condition. The level-invariant cues associated with the low-fluctuation masker support a relatively good performance for some adult listeners, comparable to that seen in the *all-cues* condition. The failure of many listeners to attain a threshold below the ceiling value of 65 dB SPL, however, suggests that this cue is not viable for all adult listeners and fewer than half of the child listeners. These observations are consistent with the conclusion that performance in the *all-cues* condition can be most parsimoniously explained in terms of the change in level across intervals associate with the addition of a signal. This does not imply that child observers are not able to make use of level-invariant cues, in general. Indeed, Allen *et al.* (1998) showed that preschool listeners are able to make use of level-invariant cues in the detection of a tone in bandpass noise spanning 800–1200 Hz. The assertion is just that the *present* results are likely based on level.

One aspect of the current paradigm that varies from the one employed by Allen *et al.* (1998) is the use of a leading *fringe*. It has been shown that asynchronous onset can aid in sound source segregation (Bregman, 1990), and that school-aged children can make use of gating cues in an informational masking paradigm (Hall *et al.*, 2005). Based on these findings it is plausible that delaying the onset of the signal portion of the stimulus could have the benefit of improving signal detection by virtue of improved segregation. A second factor of interest is the role of memory in this paradigm. The presence of a fringe prior to signal presentation offers the opportunity for the subject to make a within-interval comparison of the *fringe* and *core* segments of the stimulus. Because no across-interval comparison is necessary for this strategy, the availability of such a cue could improve the performance of child listeners. Alternatively, asynchronous onset could introduce added complexity and make the task more difficult for child listeners just by virtue of increasing the number and quick succession of different stimulus features. This is unlikely in light of the results of Hall *et al.* (1997), however. That study measured thresholds for school-aged and adult listeners for stimuli comparable to those in the *all-cues* condition. No difference was observed between a condition in which a narrow band masker was played continuously and a gated condition, where the masker was gated on 200 ms prior to the signal and both the signal and masker were gated off synchronously. This result argues against the idea that increased task complexity associated with the fringe could have elevated thresholds in the present study, at least for Gaussian noise conditions. One motivation for Experiment 2 was to test the fidelity with which level cues can be used under conditions of synchronous onset to determine

whether the results of Experiment 1 would generalize to other stimulus conditions.

One interesting result of Experiment 1 is the significant MASKER $\times$ AGE interaction in the *level-only* condition. As in the *all-cues* condition, thresholds in the *level-only* condition varied across masker for adults but not for children: adults' thresholds in the *level-only* condition were 4.1 dB lower for low-fluctuation than Gaussian noise, while for children the difference was a (nonsignificant) 1.0 dB. The advantage for intensity discrimination in low-fluctuation as compared to Gaussian noise obtained for adults was noted by Eddins (2001). In that study adults discriminated level across interval for 50-Hz wide bands of noise, and average thresholds were 3.2 dB lower for low noise than Gaussian noise. Eddins speculated that the reason for the different intensity discrimination thresholds across stimulus types was the stability of the short-term level cue. However, if the performance of children is limited by internal noise rather than external noise, as hypothesized in the Introduction, then children would not be able to benefit from this reduction in external noise. Results of Experiment 1 provide preliminary support for this hypothesis.

III. EXPERIMENT 2: THE EFFECT OF STIMULUS VARIABILITY ON INTENSITY DISCRIMINATION

Whereas the paradigm of Experiment 1 examined the effects of inherent stimulus fluctuation on the use of level cues in adults and children, Experiment 2 incorporates level rove as an additional source of stimulus variability. Roving the level of the stimuli on an interval-by-interval basis introduces external noise that would be expected to elevate thresholds to the extent that external noise (as opposed to internal noise) imposes limits on performance. Similar to the approach taken in Experiment 1, the hypothesis of Experiment 2 is that children's intensity discrimination thresholds should be less severely elevated by level rove than those of adults. This result would be expected if the performance of children is limited by internal noise to a greater extent than that of adults.

To that end, Experiment 2 addresses the role of both within-interval and across-interval stimulus variability in intensity discrimination of adults and children. Thresholds for detecting an across-interval increment in intensity were estimated for a narrow band Gaussian masker and for a pure tone, characterized by pronounced variability and very steady within-interval intensity, respectively. An additional manipulation imposed a random level rove to each stimulus presentation, which has the consequence of increasing the variability of the intensity cue.

A. Methods

1. Listeners

A group of 15 children participated, including 10 males and 5 females, ages 5.0 to 10.5 yr (mean=7.9 yr). The adult group was comprised of 12 listeners, 3 males and 9 females, ages 17.1 to 50.0 yr (mean=29.2 yr). Exclusion criteria and audiometric status were the same as those described for Experiment 1. Two additional child listeners (5 and 7 yr) were excused due to excessive variability in threshold estimates; these listeners consistently provided a 10+ dB spread in thresholds within condition. Two of the child listeners and two of the adult listeners had previously participated in Experiment 1.

2. Stimuli

Stimulus generation was similar to that described for Experiment 1. Stimuli were either 20-Hz wide bands of Gaussian noise centered on 500-Hz or 500-Hz pure tones, ramped on and off with 50-ms $\cos^2$ ramps and 409-ms in duration (including ramps). Noise samples were generated in the time domain, converted to the frequency domain for filtering by way of multiplication with a boxcar function, converted to the time domain, truncated to 409 ms and ramped with 50-ms $\cos^2$ functions. Pure tones were generated in the time domain, truncated and ramped. Like the *level-only* condition of Experiment 1, the standard interval stimulus was 65 dB SPL and the signal was an increment in the level, produced by adding a scaled copy of the standard. In contrast to Experiment 1, such increments spanned the entire (409-ms) stimulus duration. In an additional manipulation, the standard presented in each interval was roved in level, according to a random draw from a uniform distribution ±6 dB. The level of the "scaled copy" (producing the level increment in the signal interval) was not roved in these conditions.

The condition in which the tonal standard was roved in level will be referred to as a *tone roved*, and the condition with no rove will be referred to as the *tone-steady* condition. Analogous conditions with Gaussian noise stimuli will be referred to as *Gnoise-roved* and *Gnoise-steady*, respectively.

3. Procedures

As in Experiment 1, listeners performed a 3-alternative forced-choice track with visual indications of the listening intervals and positive feedback following a correct response. Instructions were to select the loudest of the three intervals. The signal level was adjusted in a 3-down, 1-up procedure, with 4 dB steps at the outset and 2 dB after the first 2 reversals. As above, thresholds are reported *as if* the signal was added to the masker in random phase, to facilitate comparison of these results with the tone-in-noise results of Experiment 1. The four conditions were run in blocks, with blocks visited in random order. Three threshold estimates were obtained in each block, with a fourth collected in cases when the initial three spanned a range of 3 dB or more. Listening sessions lasted no more than 1 hour, with frequent breaks. In most cases child listeners were able to complete all four conditions in this time period, although in several cases more than one test session was required. All adult listeners completed the study in a single 1 h session.

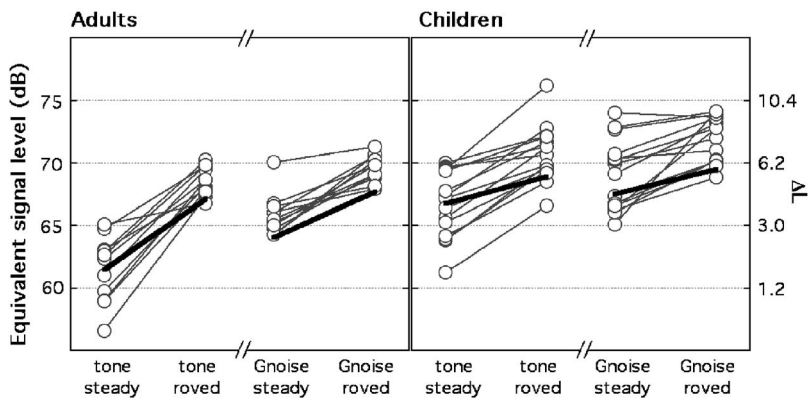
Thresholds in this experiment were highly variable, particularly in the child group. Effects of this variability were counteracted by the following procedure for identifying outliers. The difference between the maximum and the minimum threshold in a block of estimates was computed. If that value was 6 dB or greater, the set was visually examined for


FIG. 3. Individual data from Experiment 2 are shown in units of dB *as if* the signal had been added in random phase. The ordinate labels at the right show associated units of ΔL. Panels show results for adults (left panel) and children (right panel), with stimulus conditions indicated along the abscissa. Dark lines indicate fits to the data.

outliers, defined as a single threshold estimate that is at least 4 dB greater than or less than all the other estimates in that condition. If an outlier was identified, it was removed from the mean. Following this procedure, fewer than 5% of the child data and 2.5% of the adult data were culled from the results presented below.[3]

B. Results

Thresholds for each listener in each condition are indicated with open circles in Fig. 3, with data for adults in the left panel and those for children in the right panel. The labels on the abscissa indicate the associated stimulus condition. The left ordinate indicates signal level at threshold in dB and the right ordinate shows associated units of ΔL, to facilitate a comparison with published intensity discrimination data. Average thresholds in the *Gnoise-steady* condition are 65.8 dB for adults and 68.9 for children. These values are within 2.5 dB of those observed in comparable conditions in Experiment 1. The inclusion of stimulus rove increased these thresholds by 3.7 for adults and by 3.1 dB for children. Average thresholds in the *tone-steady* condition are 61.5 for adults and 66.7 for children. The inclusion of rove increased these thresholds by 7.0 and 4.0 dB for the adults and children, respectively. Thus, the effect of rove was larger for the pure tone than for the noise stimulus, and the effect of rove for the pure-tone stimulus was larger for adults than for children. Comparing *tone-steady* and *Gnoise-steady* conditions, the effect of stimulus type was 4.3 dB for adults and 2.2 dB for children. Thus, increases in threshold associated with introduction of stimulus variability, either rove or inherent (within interval) fluctuation, were larger for adults than children when using the *tone-steady* condition as a baseline.

A repeated-measures ANOVA was performed on data in units of dB[4] to assess the significance of these effects. There was one between-subjects factor (AGE: adult, child) and two within-subject factors (ROVE: steady, roved; STIM: Gaussian noise, tone). There were significant main effects of AGE $(F_{1,25}=24.97, p<0.0001)$, ROVE $(F_{1,25}=187.98, p<0.0001)$ and STIM $(F_{1,25}=53.88, p<0.0001)$. The two-way interaction between ROVE and STIM was significant $(F_{1,25}=19.93, p<0.001)$, reflecting a larger effect of rove for the tone as compared to Gaussian noise. The ROVE$\times$AGE effect $(F_{1,25}=7.89, p<0.01)$ reflects greater susceptibility to the rove of adults as compared to children. The STIM $\times$AGE interaction failed to reach significance $(F_{1,25}$

$=2.14, p=0.16)$. The significant three-way interaction $(F_{1,25}=6.12, p<0.05)$ is consistent with the observation that the largest rove effect is associated with the *tone-steady* data of adults.

Comparing the results of the *all-cues* condition of Experiment 1 to those of the no-rove conditions of Experiment 2 indicates analogous effects of stimulus fluctuation. In Experiment 1, thresholds of adult listeners dropped (improved) by 5.7 dB, comparing Gaussian with low-fluctuation noise conditions. In Experiment 2 a drop of 4.3 dB is observed comparing the *Gnoise-steady* and *tone-steady* conditions. For child listeners, improvements in threshold were smaller than those observed in adults, with values of 0.5 and 2.3 dB, respectively. These results suggest that the *fringe/core* stimulus configuration of Experiment 1 was not of great consequence to the interaction between age and effects of stimulus fluctuation.

C. Discussion

The results of Experiment 2 suggest that stimulus variability had less of an effect on the results of child than adult listeners, consistent with the hypothesis that child listeners are operating under conditions of elevated internal noise. One relatively uninteresting source of error in child listeners' performance is confusion regarding the signal cue. As noted by Jesteadt *et al.* (2003), feedback can often be misleading in roved intensity discrimination. Under such conditions the stimulus in the "signal" interval can, in fact, be the least intense; this occurs when the "signal" interval is associated with a low value of rove and/or the "no-signal" intervals are associated with a high value of rove. It is plausible that children could be more prone to confusion in the face of spurious feedback than adults. There are several considerations suggesting that this probably did not play a substantial role in the results obtained here, however. First, both adults and children performed the experiment using an interface where correct responses were rewarded by the unmasking of one piece of a "puzzle." Following an incorrect response there was no such unmasking. Listeners were not informed explicitly about this reward structure, and it seems likely that positive feedback (unmasking of a piece) would be more salient than negative feedback (nothing happening). As such, the listener would not receive salient feedback that an unselected and less intense stimulus was in fact the signal. Second, if spurious feedback causes more confusion in children than

adults, then one might expect to see a larger effect of rove for children than adults. In fact, the opposite result was observed, with child listeners' data more closely resembling that of adults in the roved conditions. Finally, there is a good correspondence in the pattern of results obtained in Experiments 1 and 2. In Experiment 1, external variability was manipulated by way of stimuli with large and small fluctuations over time, but no interval-by-interval rove (and hence no spurious feedback). As such, the most parsimonious explanation of the results of Experiment 2 would not rely on confusion associated with rove. If the elevated thresholds of the child listeners are due to some factor that is not specific to the current paradigm, then, the challenge is how to characterize that error and identify its source.

One way to summarize the findings of Experiment 2 is to note that the largest effect of stimulus variability is observed in cases where the baseline sensitivity was quite good (e.g., adult, *tone-steady* data). This observation prompted an attempt to model these results in terms of the combined effects of internal and external noise. In classic treatments of internal noise, sensitivity (d') is defined in terms of the mean difference in signal and no-signal cues (Δ) divided by the standard deviation of those underlying cue distributions (σ). The value of σ can be decomposed into internal noise (σ_i) and external noise (σ_e), resulting in the equation

$$d' = \Delta / \sqrt{(\sigma_e^2 + \sigma_i^2)}. \tag{1}$$

Jesteadt *et al.* (2003) provide a modern treatment of this classical approach. While there is some debate regarding the appropriate units in which to perform these calculations, following Jesteadt *et al.*, calculations reported here were performed in units of ΔL, and internal and external variability was assumed to add in dB.

The 3-down 1-up tracking procedure used in Experiment 2 estimates 79% correct, associated with a d' of 1.61 for a 3-alternative forced-choice task. Assuming that thresholds in the *tone-steady* condition are dominated by internal noise (i.e., $\sigma_e \approx 0$), the value of internal noise can be estimated as $\sigma_i = \Delta / 1.61$. For adults' mean data, this produces an estimate of internal noise of $\sigma_i = 0.99$ comparable to that reported for the adult listeners of Jesteadt *et al.* (2003). For children, the estimate of internal noise was considerably larger, with $\sigma_i = 2.46$.

For the remaining stimulus conditions, external noise is greater than zero, due to rove and/or small differences in level that arose because stimuli were equalized based on a longer sample than the one presented. Procedures for estimating thresholds based on these sources of variability are discussed in Appendix A. Predicted values of ΔL appear as dark lines in Fig. 3. These estimates capture the general trends in the data, most notably the biggest effects of external noise seen when comparing adult *tone-steady* to *tone-roved* conditions. Predicted thresholds in the *tone-steady* condition are quite close to the mean observed thresholds in each group; this is a consequence of the fact that values of σ_i were fitted based on these thresholds. Predicted thresholds in other conditions tend to underpredict performance by 1.4–2.4 dB. In adult data, predicted thresholds fall 3+ standard errors of the mean below the mean in all three condi-

tions characterized by high external noise. A similar pattern is observed in the data of child listeners, with the caveat that increased variance across individuals, reduces the magnitude of differences relative to estimates of the standard error. The underprediction of thresholds in cases of elevated values of σ_e is consistent with the findings of Eddins (2001), who showed that intensity discrimination is impaired for fluctuating (Gaussian noise) as compared to relatively stable (low-fluctuation noise) stimuli, even though overall stimulus level was stable in both cases. The fact that both rove and inherent fluctuation are associated with higher-than-expected thresholds in the current dataset suggests that these results are probably not due to the effects of amplitude modulation on loudness (e.g., Zhang and Zeng, 1997). Regardless of the source, this effect is roughly comparable in adult and child listeners' data, with an average mismatch of 1.7 and 1.9 dB between the prediction and mean threshold, respectively.

These discrepancies aside, the results shown in Fig. 3 suggest that the differential effects of stimulus variability across subject groups are broadly consistent with a very simple model of the combination of internal and external noise. By this account, children are less susceptible to the effects of stimulus variability because their rather large internal noise has a dominant effect on the internal representation of the cue. Similar logic can be used to account (at least in part) for the pattern of results obtained in the *all-cues and level-only* conditions of Experiment 1. In these data, adults' thresholds were more affected by the degree of inherent masker fluctuation (Gaussian versus low-fluctuation noise) than were the children's thresholds. This result is consistent with the argument that the lower levels of internal noise of adults make them more susceptible to the disruptive effects of external noise (i.e., stimulus variability).

While this approach is reasonably successful in characterizing the general trends in processing errors of child as compared to adult observers, it does not identify the source of that error. The foundation of the approach taken here (and in Jesteadt *et al.*, 2003) rests on the assumption that the source of noise reflects the physiological limitations associated with the encoding of the cues underlying performance. Self-generated noise, such as that produced by breathing or shifting position, could introduce noise that is not specific to the auditory system and might well be better characterized as "external" from the point of view of auditory processing. Further, the model proposed here assumes that the cues underlying performance are submitted to an optimal detector to generate a response, a process that is well characterized by signal detection theory. Evidence that children behave according to the rules of signal detection theory is scant, however. In the classic model, for example, the psychometric function has a well-defined shape determined by the internal noise distribution. It is possible that child listeners may change strategy or lose motivation under conditions of increased task difficulty, rather than consistently following a well-specified strategy, a result that could be reflected in an oddly shaped psychometric function. If the expectations of the classic model are met, however, the larger estimate of internal noise in child listeners predicts a shallower psychometric function for intensity discrimination. Buss *et al.*: Development and internal noise   2785
FIG. 4. Individual data of child listeners in the *tone-steady* condition are plotted as a function of age. Consistent with units used to compute internal noise, data are plotted in units of ΔL, with ±2 std around the mean adult threshold indicated as the shaded region.

underway will address the degree to which internal noise in child listeners, as estimated here, is consistent with the principals of signal detection theory.

Whereas it is not uncommon to consider internal noise as a qualitative factor in children's psychophysical data, it is not commonly quantified, as it was for these data. One exception is a study by Allen and Nelles (1996). That study estimated internal noise in adults and children for a frequency discrimination task and reported that internal noise was elevated for young children and reached levels comparable to that observed in adults by age 7. Because internal noise for the results of Experiment 2 was estimated based on ΔL in the *tone-steady* condition (that is, $\Delta L/1.61$), the effects of age on estimates of internal noise can be assessed directly based on those data. Figure 4 shows ΔL for individual child listeners in the *tone-steady* condition plotted as a function of age, with ±2 standard deviations around the mean adult threshold indicated in the shaded region. Here 10 out of the 15 child listeners fall above the 95% confidence interval for the adult performance. Those who fell within the confidence interval were, on average, older than the mean of the child group (8.8 yr as compared to 7.9 yr, respectively), consistent with the hypothesis that performance improves over this age range. A regression analysis failed to identify a significant age effect, however ($F_{1,13}=1.79$, $p=0.20$). A post-hoc power analysis indicates that if these data are representative of the population, it would be necessary to run approximately 55 listeners to obtain a significant correlation using a one-tailed criterion of $\alpha=0.05$, with a power of 0.8 (Cohen, 1988). A line fit to the resulting data would be quite poor at describing the time course of development in detail, however, with many more listeners necessary to reliably estimate the age at which the average performance becomes adult-like. These observations are qualitatively consistent with the individual differences previously noted in intensity discrimination in children (e.g., Jensen and Neff, 1993). It is difficult to assess whether the *tone-steady* thresholds reported here are consistent with the literature on intensity discrimination in school aged children given the variability both across studies and within the current dataset, but the present results are more consistent with the suggestion that development extends out to 10 yr of age (e.g., Fior and Bolzonello, 1987) than the suggestion that intensity discrimination may be adult-like in most children by age 5 yr (e.g., Jensen and Neff, 1993).

IV. SUMMARY AND CONCLUSIONS

In Experiment 1 thresholds for a tone-in-noise detection task were different for children and adults. Not only were thresholds elevated for children, but adults benefited more from stimulus features of low-fluctuation noise than children. Results of reduced-cue conditions revealed that both children and adults performed similarly with just level cues and with tone-in-noise conditions, which also provided level-invariant cues. Most adults could make use of level-invariant cues, but most of the children were at a ceiling on these tasks. While this result leaves open the possibility that some adults could have made use of multiple cues in a simple tone in noise task, performance with just the level cue was not significantly different from the case where all cues were present, suggesting that level-invariant cues likely contributed little to performance. There was an interaction between the stimulus type and the listener group for both conditions, where the level served as a cue to the presence of a signal; that is, adults performed better in the low-fluctuation than the Gaussian noise, while children showed no effect of stimulus type. This result led to the somewhat counterintuitive hypothesis tested in Experiment 2 that children are less susceptible to the effects of external stimulus variability than are adults.

Experiment 2 estimated intensity discrimination for a tonal standard and a Gaussian noise standard, with and without an interval-by-interval level rove applied to that standard. As predicted, data from child listeners showed less evidence of threshold elevation in response to stimulus variability. The general form of the data was fitted with a simple model of performance as a function of internal and external noise. The estimate of internal noise for children was a factor of 2.5 times greater than that estimated for adults, and the effect of this greater internal noise was to temper the effects of external noise on the performance of child listeners.

While the definition of internal noise has traditionally been quite broad, encompassing variability due to transduction noise, memory, criteria, and attention—in short, any variability not accounted for by external variability—the proposal tested here is more specific, namely that the neural representation of intensity is more variable in children than adults. The conclusion that poorer performance and greater internal noise, either described qualitatively (as in Exp 1) or modeled quantitatively (as in Exp 2), can account for an age effect is important to the interpretation of the result because it does not require that we think of development in terms of the maturation of multiple specialized processing abilities. Rather, a refinement in the auditory ability may appear to emerge at different ages simply by virtue of their sensitivity to one or a small set of variables underlying internal noise. More work is needed to assess the extent to which child listeners adhere to the assumptions underlying the simple signal detection model fitted here.

APPENDIX A: ESTIMATING THRESHOLD BASED ON INTERNAL AND EXTERNAL NOISE

Thresholds in the conditions other than the *tone-steady* condition are substantially affected by stimulus variability, quantified as σ_e in Eq. (1). Implicit in this equation is the assumption that the noise is normally distributed around the mean, such that σ_e represents the standard deviation of a Gaussian distribution. The noise associated with stimulus fluctuation in the Gaussian noise stimuli was approximately normally distributed, with a slight skew (third moment) of −0.68, when represented in dB. The noise introduced by the rove, however, was clearly not normal, being based on a uniform distribution applied to the standard.

Rather than approximating external noise as normally distributed and predicting thresholds with Eq. (1), a MATLAB routine was written to generate cue distributions associated with the stimuli used here. At each of a range of signal levels, 5000 samples of signal present and 5000 samples of no-signal stimuli were generated using the same procedures as employed in Experiment 2. Independent samples of Gaussian-distributed internal noise were then added to each estimate of signal level in each array, based on estimates of σ_i computed above. Pairs of signal-present and no-signal samples were subtracted, for a total of 5000 values of cue difference. The distribution of these differences was then used to estimate d', according to the formula

$$d' = \sqrt{2}\Delta/\sigma_{\text{diff}}, \tag{A1}$$

where Δ is the signal level associated with the signal-present array and σ_{diff} is the standard deviation of the cue difference array. The scalar ($\sqrt{2}$) is introduced because the standard deviation of the difference between two distributions is $\sqrt{2}$ times the standard deviation of each contributing distribution, assuming they are of equal variance. In this way the d' associated with each signal level was computed. A total of 5 signal levels were used, spaced at 0.5 dB intervals and chosen adaptively to bracket the final estimate. The relationship between d' and signal level was well characterized in terms of a least-squares line fit, and this fitted line was used to estimate the signal level associated with $d' = 1.61$.

This process was repeated 8 times: 4 levels of external variability (*tone-steady, tone-roved, Gnoise-steady, and Gnoise-roved*) × two groups (child and adult, with $\sigma_i = 2.45$ and $\sigma_i = 0.99$, respectively). To give an indication of the reliability of these procedures, threshold estimates in the *tone-steady* condition computed using this procedure were within 0.1 dB of those computed analytically. Threshold predictions are indicated with dark lines in Fig. 3.

[1] Due to time constraints, one child listener did not repeat the *all-cues* condition, so his data are not represented in this analysis.
[2] Buss *et al.* (2003) ran 13 child listeners, two of whom also participated in Experiment 1.

[3] Elimination of these data points did not change the general conclusions of the experiment. Repeating the statistics with outlier data included produced the same pattern of significance as reported in Sec. III B.
[4] The primary consideration in selection of units for intensity discrimination, apart from ease of comparison with other data, was compliance with assumptions regarding the variance across the dataset. For the ANOVA, Box's Test of equality of covariance was not significant ($p=0.10$) for data represented in dB SPL. Units of ΔL were less consistent with assumptions of normal and uniform variance: in that case Box's Test was significant ($p<0.05$), indicating that the covariance matrices were not equal across groups. This result motivated the use of dB SPL units in the statistical tests reported here.

Frequency and amplitude discrimination thresholds along the kinesthetic to cutaneous continuum were evaluated on the left index fingerpad using a multifinger tactual display. Target stimuli were presented either in isolation (no-masker condition) or in the presence of masking stimuli (one- or two-masker conditions). Six reference target signals in the frequency range 2–300 Hz (two each from low-, medium-, and high-frequency regions) and at an amplitude of either 20 or 35 dB sensation levels (SL) were used. In the no-masker condition, the range of frequency Weber fraction was 0.13–0.38 and 0.14–0.28, and the range of amplitude discrimination threshold was 1.82–2.98 dB and 1.65–2.71 dB, at 20 and 35 dB SL, respectively. In the masking conditions, average frequency Weber fractions rose to 0.60 and 0.46, and average amplitude thresholds rose to 3.63 and 3.72 dB, at 20 and 35 dB SL, respectively. In general, thresholds were largest in the two-masker condition and lowest in the no-masker condition. Although the frequency and amplitude thresholds generally increased in the presence of masking stimuli, there was some indication of channel independence for low- and high-frequency target stimuli. The implications of the results for tactual communication of speech are discussed. © *2006 Acoustical Society of America.*

I. INTRODUCTION

The present study is motivated by issues related to the development of artificial aids designed for the communication of acoustic signals through the sense of touch for persons with profound hearing impairment. A multifinger tactual display capable of simultaneously stimulating the thumb, index, and middle fingers, the TACTUATOR, has been developed recently to broaden the spectrum of tactual stimulation from the tactile/cutaneous region (small-amplitude high-frequency vibrations) that is commonly used by most artificial tactile aids to the kinesthetic region (large-amplitude low-frequency movements) (Tan and Rabinowitz, 1996). The idea of presenting movement signals in addition to vibrations in a tactual communication aid was inspired by a means of natural tactual speech communication called the Tadoma method where a deaf-and-blind receiver places one hand or both hands on the face of a talker and monitors the tactual signals (e.g., laryngeal vibration, mouth opening, lip movements, air flow at the lips, etc.) associated with the articulatory process (Reed *et al.*, 1985). One hypothesis for the success of the Tadoma method is that Tadoma users have access to a rich set of signals including both cutaneous and kinesthetic stimulation. The TACTUATOR is uniquely suited for evaluating such a hypothesis because unlike other tactual displays (such as a minishaker) that can generate signals at very low frequencies but can only do so at near-threshold intensity levels, the TACTUATOR is capable of delivering slow motions at a peak-to-peak displacement of up to 25 mm.

Previous research conducted with the TACTUATOR shows high-information transmission capability with stimulus sets composed of kinesthetic movements, cutaneous vibrations, signals with intermediate frequencies, and their combinations. For example, a static information transfer (IT) of 6.5 bits and a dynamic IT rate of 12 bits/sec were achieved in one study (Tan *et al.*, 1999) and an IT rate of 21.9 bits/sec was reported in another (Tan *et al.*, 2003). These static IT and dynamic IT rates are among the highest reported for any artificial tactual display and are comparable to those of the natural Tadoma method used by deaf-and-blind individuals for speech communication (Reed and Durlach, 1998).

A subsequent study using the TACTUATOR evaluated temporal onset-order discrimination with a 50-Hz sinusoidal signal delivered to the thumb and a 250-Hz sinusoidal vibration to the index finger (Yuan, Reed, and Durlach, 2005a). The average temporal onset-order threshold was found to be 34 msec. The same authors then used amplitude envelope information from two spectral regions of speech to transmit consonant voicing information through the TACTUATOR (Yuan, Reed, and Durlach, 2005b). The amplitude envelope of the high-frequency band was used to modulate a 250-Hz vibration at the index finger and the amplitude envelope of

---

the low-frequency band was used to modulate a 50-Hz vibration at the thumb. Results indicated that noise-masked normal-hearing subjects were highly successful in discriminating voiced from unvoiced sounds at the segmental level and that the display provided a substantial benefit to lip-reading alone in closed-set consonant identification tasks. Results of sentence recognition tasks, however, revealed that the tactual cues were not beneficial for lip reading. This lack of benefit may have reflected the user's inability to integrate tactual and visual cues and therefore may have been the result of insufficient training.

Recently, a 2-DOF (degree of freedom) controller has been developed for the TACTUATOR that preserves the relative intensities of the spectral components of input waveforms in terms of perceived intensity (Israr, Meckl, and Tan, 2004). Consider the case where the input signal to the TACTUATOR contains two spectral components at 50 and 250 Hz at equal voltage levels. The 2-DOF controller compensates for both the frequency response of the TACTUATOR hardware and the difference in human detection threshold at the respective frequencies such that the two signal components are perceived at roughly the same sensation levels (SL). With this controller, a low-pass filtered broadband acoustical speech signal can be directly applied as the input to the TACTUATOR to transmit, for example, pitch information. The use of such an encoding scheme for speech obviously requires that the user be able to discern variations in frequency and/or amplitude in the presence of other masking signals occurring before, after, or simultaneously with the target. In order for speech signals to be transmitted successfully through the TACTUATOR, it is important to characterize frequency and amplitude discrimination thresholds associated with the use of the TACTUATOR in the presence of masking stimuli delivered to the same or neighboring digits of the hand.

Previous studies have examined frequency and amplitude discrimination thresholds through the tactual sense. Frequency discrimination thresholds, typically expressed in the form of Weber fractions (WFs), computed as $(\Delta F)_0 / F_{ref}$ where $(\Delta F)_0$ is the frequency discrimination threshold in hertz and F_{ref} the reference frequency, have been found to be in the range 0.02 to 0.72 on fingertips, forearm, thenar eminence, and sternum using sinusoidal or pulselike waveforms over a frequency range of 1 to 512 Hz and an amplitude range of 14 to 35 dB SL (Franzen and Nordmark, 1975; Globe and Hollins, 1994; Goff, 1967; Horch, 1991; Knudsen, 1928; LaMotte and Mountcastle, 1975; Rinker, Craig, and Bernstein, 1998; Rothenberg et al., 1977). Variability in the size of frequency WFs across studies has been attributed to differences in experimental conditions, methodology, and stimulus artifacts (Bensmaia et al., 2005; Hnath-Chisolm and Medwetsky, 1988; Rothenberg et al. 1977; Verrillo and Gescheider, 1992).

Amplitude discrimination thresholds are typically expressed in decibels in amplitude change. Previous studies of just-noticeable-differences (JNDs) in intensity for tactile stimulation have employed a variety of experimental methods (continuous versus gated methods, pulses versus pure sinusoids, forced-choice method versus method of adjustment, method of limits versus adaptive procedures) using

stimuli that varied in frequency, amplitude, body site, and contact area. Amplitude-discrimination thresholds in $(\Delta A)_0$ have been reported in the range of roughly 0.4 to 6 dB; for example, 0.8 dB (Geldard, 1957), 1.5–2.5 dB (Craig, 1972), 1.5–6 dB (Craig, 1974), 0.4–2 dB (Fucci, Small, and Petrosino, 1982), 0.5–4 dB (Gescheider et al., 1990), 0.8–5 dB (Gescheider, Zwislocki, and Rasmussen, 1996), 0.8–3 dB (Globe and Hollins, 1993), and 0.8–1.5 dB (Rinker et al., 1998). Despite differences in experimental conditions, it is generally agreed that amplitude-discrimination thresholds tend to decrease with an increase in stimulus intensity when the intensity is close to detection threshold, and then stay constant when stimulus intensity is above 14 to 20 dB SL (see, for example, Craig, 1972; Craig, 1974; Gescheider et al., 1990).

Despite all existing data, there have been relatively few studies concerned with the masking properties of kinesthetic signals on vibrations and vice versa, presumably because, until very recently, no displays existed that could deliver signals over a wide range of frequencies that spanned the kinesthetic-cutaneous continuum.[1] The TACTUATOR provides a unique opportunity for studying frequency and amplitude discrimination thresholds using both kinesthetic and cutaneous signals in the presence of masking stimuli. In an earlier study, experiments were conducted to examine the temporal masking properties for recognition of tactual stimulation patterns using forward masking, backward masking, and sandwiched masking (in which the target was presented between two maskers) paradigms (Tan et al., 2003). In the present study, frequency and amplitude discrimination experiments were performed in the presence of masking stimuli that occurred *simultaneously* with the target. The results from the present and previous studies will shed light on the design of multidimensional tactual signals for speech communication.

II. METHODS

A. Apparatus

The experimental apparatus (the TACTUATORII[2]) consists of three independent, point-contact (with a contact area of approximately 70 mm²), one-degree-of-freedom actuators interfaced individually with the fingerpads of the thumb, the index finger, and the middle finger [Fig. 1(a)]. The motion trajectory for the thumb is perpendicular to that of the index and middle fingers, thereby maintaining an approximately natural hand configuration with the wrist resting in its neutral position. The range of motion for each digit is about 25 mm. All motions begin and end with each of the three digits at the middle of its respective range of motion. Each digit can thus be moved either outward (extension) or inward (flexion).

Each actuator utilizes a disk-drive head-positioning motor augmented with angular position feedback from a precision rotary variable differential transformer that has a response bandwidth (−3 dB) of 1 kHz and a theoretically unlimited resolution[3] due to electromagnetic coupling [Fig. 1(b)]. The overall system performance is well suited for the present study for several reasons. First, each movement channel has a *continuous* frequency response from dc to 300 Hz (the disk-drive motor ceases to move beyond about
FIG. 1. The TACTUATOR. (a) Schematic drawing illustrating finger placement on the TACTUATOR and the motion trajectories of the thumb, index, and middle fingers. (b) Photograph of one of the three motor assemblies with its components labeled. The participant rests the fingerpad on the rod labeled "finger interface" in (b).

400 Hz). Therefore, stimulation can be delivered in the kinesthetic (i.e., low-frequency gross motion) and cutaneous (i.e., high-frequency vibration) ranges as well as in the mid-frequency range. Stimuli with any desired spectral components can be realized within the frequency range of dc to 300 Hz. Second, across the frequency range of dc to 300 Hz, amplitude of 0 dB SL to at least 47 dB SL can be achieved at each frequency.[4] This stimulus range is well matched to the dynamic range of tactual perception in that stimulation levels exceeding 50–55 dB SL tend to induce discomfort and fatigue (Verrillo and Gescheider, 1992). Third, measurements with single and multiple frequency inputs at various amplitude levels indicate that each channel is highly linear, harmonic distortion is low, and interchannel crosstalk is small. These characteristics permit high-fidelity delivery of waveforms of arbitrary frequency content and stimulation level (e.g., a 20 dB SL high-frequency vibration superimposed on a 35 dB SL low-frequency motion) simultaneously to all fingers. Fourth, "loading" a movement channel (i.e., resting a finger lightly on the actuator's moving bar) does not significantly alter the intended stimuli. Selected measurements indicate that loading reduces the magnitude of stimulation by an average of 1.5 dB at 2 Hz, 2.7 dB at 20 Hz, and 0.1 dB at 200 Hz. These minor alterations due to loading do not pose a significant problem for the experiments reported here because the stimuli are generally strong (i.e., at least 20 dB SL).

Real-time positional control is provided by a digital 2-DOF controller implemented on a floating-point digital signal processing (DSP) system with 16-bit analog-to-digital and digital-to-analog converters. The controller shapes the frequency response of the closed-loop TACTUATORII assembly to that of the human detection-threshold function, thus preserving the relative amplitude of spectral components in terms of their perceived intensity by human observers. The current system can therefore be driven with a broadband signal (up to 300 Hz) while preserving the relative intensity of different spectral components in terms of the relative sensation levels delivered by the TACTUATORII (Israr et al., 2004). The nominal threshold function values for six target frequencies are shown in Table I (see last column). These thresholds are averages of measurements obtained by Israr et al. (2004) on three experienced observers.

B. Participants

Four participants (2 females and 2 males; age 21 to 28 years old; average age 24 years old) took part in the experiments. S1 was highly experienced with the TACTUATORII device. S2 and S4 had not felt the device prior to the present study. S1 and S3 were research staff and had previous experience in other haptic perception experiments. S2 and S4, who had no prior experience with psychophysical experiments, were paid on an hourly basis. None of the participants reported any known tactual impairments of their hands.

C. Stimuli

The present study employed a stimulus set applied only to the left index finger. The duration of each stimulus was fixed at 250 msec throughout the experiments. The independent stimulus attributes were frequency and amplitude of sinusoidal signals. The entire frequency range of the TACTUATORII (0–300 Hz) was divided into three regions (low, medium, and high) as in previous studies with the TACTUATOR device (Tan et al., 1999; Tan et al., 2003). Two target frequencies were tested in each frequency region at two amplitudes of 20 and 35 dB SL (sensation level; decibels above nominal detection threshold at the same frequency). A 250-ms Hanning window (with 25-ms rise and fall time) was used so that each stimulus began and ended in the middle of the finger's range of motion. All stimuli started in the finger extension direction. A complete list of the test stimuli is provided in Table I. Also shown are the nominal detection threshold levels measured from three participants (one of whom was S1) in our previous study (Israr et al., 2004) from which signal amplitudes in decibels SL are derived for the present study. The sensation levels reported in Table I are

TABLE I. Listing of stimuli used in the frequency and amplitude discrimination experiments.

Frequency Region	Frequency (Hz)	Amplitude (dB SL)	Nominal Detection Threshold (dB re 1 μm peak)
Low	2	20 & 35	38
	4	20 & 35	34
Medium	15	20 & 35	25
	30	20 & 35	16
High	80	20 & 35	−8
	200	20 & 35	−18

nominal and representative, but not individualized for each participant (see the Appendix).

Different perceptual attributes are associated with the stimuli within each region. The 2- and 4-Hz low-frequency signals are perceived as movements that extend the index finger and bring it back to its resting position. The 15- and 30-Hz mid-frequency signals give rise to a mixed flutter/rough sensation. The 80- and 200-Hz high-frequency signals are perceived as smooth and penetrating vibrations. Within each of the three frequency regions, the two test stimuli can be easily discriminated in isolation.

1. Stimuli for Frequency Discrimination

For frequency discrimination, the participant was presented with either the *reference* frequency F_{ref}, or the *test* frequency $F_{\text{ref}}+\Delta F$, where ΔF was a variable frequency increment. Each F_{ref} was presented with either $A_1=20$ dB SL or $A_2=35$ dB SL. During an experimental run, the same amplitude (in sensation level) was used for F_{ref} and $F_{\text{ref}}+\Delta F$. The *target* stimuli (F_{ref} or $F_{\text{ref}}+\Delta F$) were presented either in isolation (no-masker condition $C1$) or in the presence of a *masker* that occurred simultaneously with the target (one-masker conditions $C2$ and $C3$, and two-masker condition $C4$). $C1$ served as a baseline condition against which the effect of masking stimuli could be measured. For $C2$, a single masker was selected from the lower one of the two frequency regions of which F_{ref} was not a member. For $C3$, a single masker was selected from the other (i.e., higher) frequency region that did not include F_{ref}. For example, if $F_{\text{ref}} =2$ Hz, then the masker in $C2$ was selected from the mid-frequency region, and the masker in $C3$ from the high-frequency region. For $C4$, two maskers were selected, one from each of the two frequency regions that did not include the target F_{ref}. In any of the masking conditions ($C2–C4$), the frequency of the masker was selected randomly from ten values linearly spaced between the two frequency values listed for that frequency region as shown in Table I. For example, the frequency of a masker in the mid-frequency region assumed values in the range of 15 to 30 Hz. The amplitude of the masker was also selected at random on each trial. In order that the intensity of the masker did not overwhelm the perception of the target signal, the masker amplitude for a target presented at $A_1=20$ dB SL was randomly selected from ten levels linearly spaced between 10 and 20 dB SL. The masker amplitude for a target presented at $A_2=35$ dB SL was randomly selected from ten levels between 20 and 35 dB SL. For any of the masking conditions, the masker frequency and amplitude were randomly selected on each presentation.

2. Stimuli for Amplitude Discrimination

The stimuli for amplitude discrimination were very similar to those used in frequency discrimination. The participant was presented with either the *reference* amplitude A_{ref}, or the *test* amplitude $A_{\text{ref}}+\Delta A$, where ΔA was a variable amplitude increment. During an experimental run, the same frequency was used for A_{ref} and $A_{\text{ref}}+\Delta A$. Two values of A_{ref} were tested: 20 and 35 dB SL. Six values of frequency were employed in the amplitude-discrimination tests consisting of two values from each of the three frequency regions as listed in Table I. As described above for the frequency discrimination experiment, the target stimuli were presented either in isolation ($C1$) or in the presence of masking stimuli ($C2–C4$). The amplitude-discrimination experiments also employed randomized values of masker frequency and amplitude on each presentation using the procedure described above for the frequency-discrimination experiments.

D. Procedures

The same experimental procedure was used in both the frequency and amplitude discrimination experiments. A three-interval forced-choice (3IFC) paradigm with a one-up three-down adaptive procedure (Leek, 2001; Levitt, 1971) was used. On each trial, the participant received three stimulus presentations. One randomly selected interval contained the test stimulus ($F_{\text{ref}}+\Delta F$ or $A_{\text{ref}}+\Delta A$) while the remaining two intervals contained the reference stimulus (F_{ref} or A_{ref}). During the masking conditions ($C2–C4$), the frequency and amplitude of the masker were randomly selected for each of the three intervals. The participant's task was to indicate the "odd" interval that contained $F_{\text{ref}}+\Delta F$ or $A_{\text{ref}}+\Delta A$ by pressing "1", "2", or "3" on the keyboard. The initial value of ΔF or ΔA was selected to be sufficiently above the expected discrimination threshold. The value of ΔF (or ΔA) changed by 2/3 octave (or 4 dB) initially (for faster convergence), and then by 1/6 octave (or 1 dB) after the first three reversals (for better resolution of threshold estimate). The experimental run terminated after 12 reversals at the smaller step size, which typically took 60–80 trials. After each experimental run, a plot of ΔF or ΔA as a function of trial number was generated. If it appeared that the stimulus frequency (or amplitude) did not converge, the participant was asked to repeat the same run again. Each run lasted about 4–6 min. Participants typically completed four experimental runs (one reference stimulus with all four conditions $C1–C4$) in one session.

For frequency discrimination, there were 12 possible reference signals (3 frequency regions × 2 frequencies per region × 2 amplitudes per frequency). The order of the reference signals was randomized for each participant. Given each reference signal, however, the four conditions $C1–C4$ were always tested in the same order as follows. The no-masker condition $C1$ was tested first, followed by either one of the one-masker conditions $C2$ or $C3$ (randomly chosen for each reference stimulus), then the remaining $C2$ or $C3$ that had not been tested yet, and finally the two-masker condition $C4$. Participants were required to complete all four conditions associated with one reference stimulus in one session. Assuming that a typical adaptive run terminated after 70 trials, each participant completed a total of 3360 trials (12 references × 4 conditions per reference × 70 trials per condition) for the frequency discrimination experiment. For amplitude discrimination, there were also 12 possible reference signals. Again, the order with which the reference signals were presented was randomized, and participants always went through $C1–C4$ in the same order for each reference
FIG. 2. Experimental setup. The apparatus was placed to the left of the participant's torso in a wooden box. The participant sat in front of the computer screen and placed the left index finger on the finger rest of the TACTUATORII as shown in the inset. The left elbow was supported by the arm rest. The participant wore earmuffs and ear plugs.

signal as in the frequency discrimination experiment.[5] Data were collected on a total of 48 conditions in both the frequency and the amplitude discrimination experiments. Thus, each participant completed a total of 96 experimental runs which required roughly 6,720 trials.

During the experiments, the TACTUATORII was placed to the left of the participant's torso as shown in Fig. 2. It was covered by a padded wooden box that served as an armrest for the participant's left forearm. The top of the box had an opening that allowed the participant to place the left index finger on the "fingerpad interface" rod as shown in Figs. 1(b) and 2. Earmuff (Twin-Cup type, H10A, NRR 29, Peltor, Sweden) and pink noise (presented at roughly 80 dB SPL) were used to eliminate possible auditory cues. No correct-answer feedback was provided during the experiments.

Training was provided before each run. During training, the participant could click on the appropriate buttons on a computer screen to feel the reference (F_{ref} or A_{ref}) or the test stimulus ($F_{ref}+\Delta F$ or $A_{ref}+\Delta A$). For the masking conditions $C2-C4$, the participant could either feel the target stimulus (reference or test signal) in isolation or in the presence of a masker (as would be the case during the actual experiment). The participant could terminate the training whenever she/he was ready. Training typically lasted only a few minutes. Data collection followed immediately after the training.

E. Data analysis

From the six pairs of peaks and valleys of stimulus intensities (ΔF or ΔA) obtained during the last 12 reversals at the smaller step size, six estimates of thresholds were obtained by averaging each peak-valley pair. The frequency and amplitude detection thresholds, $(\Delta F)_0$ in hertz and $(\Delta A)_0$ in decibels, respectively, were then estimated by averaging the six threshold estimates. The corresponding standard errors were also obtained from the six threshold estimates. The threshold so obtained corresponds to the 79.4-percentile

point on the psychometric function (Levitt, 1971), and a d' value of 1.63 assuming no response bias (Hacker and Ratcliff, 1979).

III. RESULTS

A. Frequency discrimination thresholds

Under the no-masker baseline condition ($C1$), the frequency discrimination threshold, $(\Delta F)_0$ in hertz, increased with the reference frequency F_{ref}. The linear regression model was $(\Delta F)_0=0.13\cdot F_{ref}+2.7$ ($r^2=0.7142$) at 20 dB SL, and $(\Delta F)_0=0.15\cdot F_{ref}+0.7$ ($r^2=0.8415$) at 35 dB SL. The average Weber fractions, WF=$(\Delta F)_0/F_{ref}$, are shown for each condition (in four separate panels) in Fig. 3 for 20 dB SL and in Fig. 4 for 35 dB SL. A visual inspection of both Figs. 3 and 4 revealed large interparticipant differences (particularly for the three masking conditions $C2-C4$), confirmed by a four-way (participant, frequency, amplitude, condition) analysis-of-variance (ANOVA) ($p<0.0001$). The Scheffe *post hoc* multirange test indicated two participant groups: $S1$ and $S3$ (experienced, with lower thresholds), and $S2$ and $S4$ (inexperienced, with higher thresholds). Despite the significant differences among participants, however, all participants' data displayed similar trends along frequency, amplitude, and masking conditions. Therefore, we discuss the general trends demonstrated by the pooled data and point out individual exceptions when they are significant.

The frequency WFs from the no-masker condition [$C1$; see Figs. 3(a) and 4(a)] averaged 0.25 and 0.18 at 20 and 35 dB SL, respectively. A two-way (amplitude, frequency) ANOVA showed that both frequency and amplitude were significant ($p<0.001$). Specifically, the WFs were significantly lower at 35 dB SL than at 20 dB SL, and they generally decreased as F_{ref} increased. The interaction term was also significant ($p<0.001$) indicating mixed trends along frequency and amplitude. For low-frequency targets ($F_{ref}=2$ and 4 Hz), the WFs were significantly lower at 35 dB SL than at 20 dB SL. For targets at $F_{ref}=200$ Hz, however, the opposite trend was observed. The trends were mixed for targets at $F_{ref}=15$, 30, and 80 Hz.

When frequency WFs from all conditions ($C1-C4$; see Figs. 3 and 4) were considered, it was found that the average WF at 35 dB SL (mean = 0.39) was significantly lower than that at 20 dB SL (mean = 0.52) by a four-way (participant, frequency, amplitude, condition) ANOVA ($p<0.001$). As expected, the WFs for the no-masker condition ($C1$) were no greater than those for the one-masker conditions ($C2$ or $C3$), which in turn were no greater than those for the two-masker condition ($C4$), as confirmed by the four-way ANOVA ($p<0.001$). The average WFs decreased significantly in the order $C4$, $C2$, $C3$, and $C1$ (average WFs were 0.70, 0.49, 0.40, and 0.22, respectively). All the interaction terms of the four-way ANOVA were significant ($p<0.001$) implying mixed trends along frequency, amplitude, and masking conditions.

To visualize the masking effects ($C2-C4$), the average frequency WFs for $C1$ were subtracted from the corresponding WFs for $C2-C4$. The differences are shown in Fig. 5 for stimuli presented at (a) 20 dB SL and (b) 35 dB SL, respec-
FIG. 3. Frequency discrimination Weber fractions $(\Delta F)_0 / F_{ref}$ for the four participants as a function of reference frequency F_{ref} at 20 dB SL. Panel (a) shows the thresholds in the no-masker condition C1. Panels (b), (c), and (d) show thresholds for the one- and two-masker conditions C2, C3, and C4, respectively. Shown are individual participant's data (open symbols), the average (dashed lines), and standard errors.

tively. An asterisk indicates that the corresponding data column is significantly different from 0 ($p < 0.05$). A four-way ANOVA analysis (participant, frequency, amplitude, condition) applied to the data in Fig. 5 showed that there were more masking effects at 20 dB SL than at 35 dB SL ($p < 0.001$). All interaction terms were again significant ($p < 0.001$). The WFs for low-frequency targets ($F_{ref} = 2$ and 4 Hz) increased in the presence of mid-frequency maskers ($C2-C1$), but the WFs for mid-frequency targets ($F_{ref} = 15$ and 30 Hz) were generally not affected by low-frequency maskers ($C2-C1$). The WFs for low-frequency targets were not affected by high-frequency maskers ($C3-C1$), yet the WFs for high-frequency targets ($F_{ref} = 80$ and 200 Hz) were affected by low-frequency maskers ($C2-C1$). The interference between mid-frequency and high-frequency targets/maskers appeared to depend on both frequency and amplitude.

B. Amplitude discrimination thresholds

The average amplitude thresholds $(\Delta A)_0$ in dB are plotted against reference frequency (F_{ref}) for all four masking conditions ($C1-C4$) in Fig. 6 for 20 dB SL and Fig. 7 for 35 dB SL. Each of the four panels presents amplitude thresholds for one of the four conditions. Similar to the results of frequency discrimination experiments, interparticipant variability was observed in these results. A four-way ANOVA (participant, frequency, amplitude, condition) confirmed a significant interparticipant difference ($p < 0.0001$). A Scheffe *post hoc* multirange test indicated that lower thresholds were obtained for participants $S1$ and $S3$ (experienced), and higher thresholds were obtained for participants $S2$ and $S4$ (inexperienced). Despite the significant differences among participants, however, all participants displayed similar trends along frequency, amplitude, and background conditions. Therefore, we discuss the general trends demonstrated by the pooled data and point out individual exceptions when they are significant.

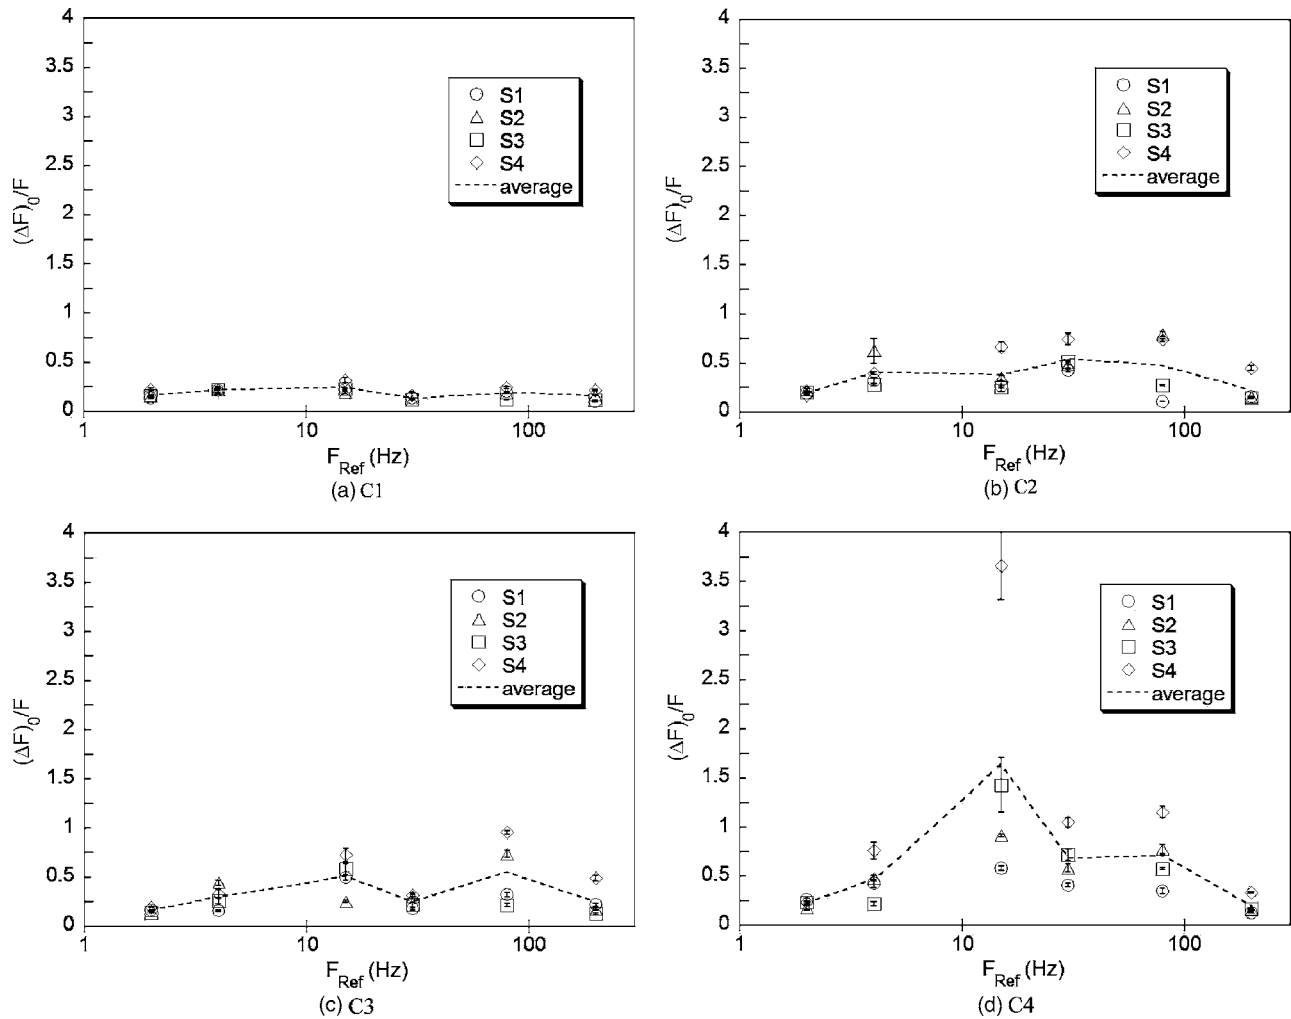
The amplitude discrimination thresholds in the no-masker condition [$C1$; see Figs. 6(a) and 7(a)] averaged 2.5 dB and 2.17 dB at 20 and 35 dB SL, respectively. A two-way ANOVA (frequency, amplitude) of the data showed that both frequency and amplitude were significant (p


FIG. 4. Frequency discrimination Weber fractions $(\Delta F)_0/F_{ref}$ for the four participants as a function of reference frequency F_{ref} at 35 dB SL. Panel (a) shows the thresholds in the no-masker condition C1. Panels (b), (c), and (d) show thresholds for the one- and two-masker conditions C2, C3, and C4, respectively. Shown are individual participant's data (open symbols), the average (dashed lines), and standard errors.

<0.001). The interaction term was also significant (p <0.001) indicating mixed trends along frequency and amplitude. Unlike frequency discrimination data that exhibited a scattered pattern, an orderly transition of amplitude discrimination thresholds from low- to high-frequency regions was observed at both amplitude levels [see Figs. 6(a) and 7(a)]. A Scheffe multirange test at the two amplitudes (20 and 35 dB SL) separated the target frequencies into two groups. The thresholds for the low-to-mid-frequency group (F_{ref}=2, 4, and 15 Hz) were found to be significantly higher than those for the mid-to-high-frequency group (F_{ref}=30, 80, and 200 Hz) at 20 dB SL, and the opposite was true at 35 dB SL. The analysis also showed that the thresholds for the low-to-mid-frequency group were significantly lower at 35 dB SL than at 20 dB SL, but the thresholds for the mid-to-high-frequency group were similar at the two amplitude levels.

Unlike the results obtained in the frequency discrimination experiments, the average amplitude discrimination thresholds (see Figs. 6 and 7) were not significantly different at the two amplitude levels, as indicated by a four-way (participant, frequency, amplitude, condition) ANOVA (p >0.05). Similar to the frequency discrimination thresholds,

masking stimuli had a significant effect on amplitude discrimination ($p<0.001$). The average amplitude discrimination threshold was significantly different in all test conditions ($C1-C4$) and differed in the same order as in the frequency discrimination experiment (4.08 dB for $C4$, 3.60 dB for $C2$, 3.35 dB for $C3$, and 2.33 dB for $C1$). As expected, the amplitude thresholds for the no-masker condition ($C1$) never exceeded those for the one-masker condition ($C2$ or $C3$), which in turn were smaller than those for the two-masker condition ($C4$).

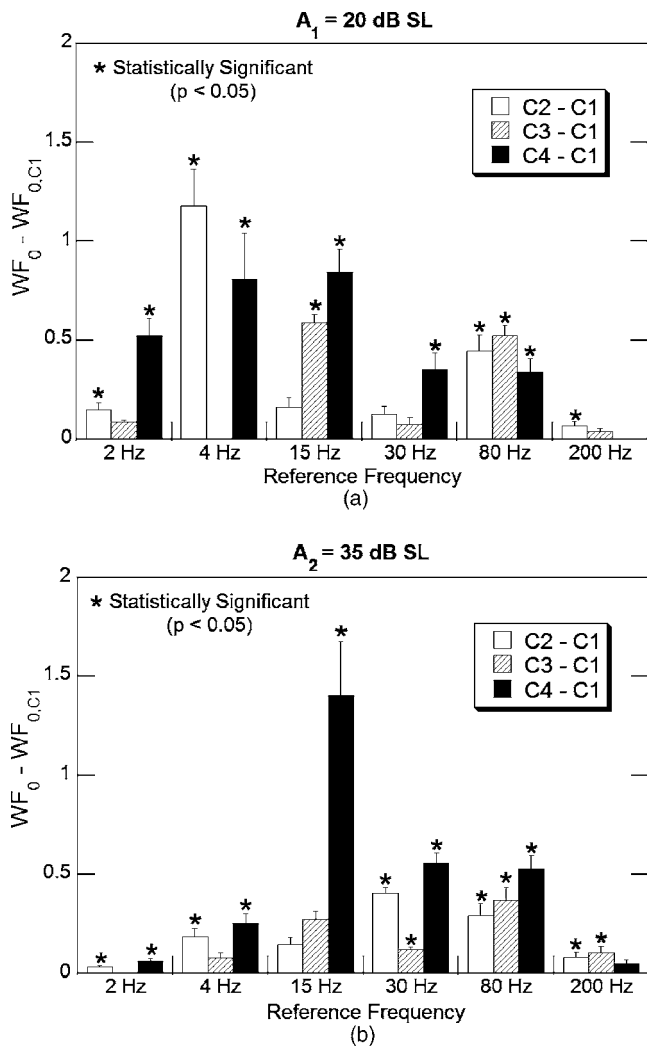
Changes in the amplitude discrimination thresholds due to masking are shown in Fig. 8. The average $(\Delta A)_0$ for $C1$ is subtracted from those for $C2-C4$ at the same reference frequency and the differences are plotted as bar graphs. The statistical significance ($p<0.05$) of the difference in $(\Delta A)_0$ is indicated by an asterisk. The masking effects were slightly more pronounced at 35 dB SL than at 20 dB SL ($p<0.01$). For both the low-frequency targets (F_{ref}=2 and 4 Hz) and the mid-frequency targets (F_{ref}=15 and 30 Hz), the effect of high-frequency maskers ($C3-C1$) was generally smaller than that in the other one-masker conditions ($C2-C1$). For


FIG. 5. Increase in frequency Weber fractions under the one- and two-masker conditions (C2–C4) for stimuli presented at (a) 20 dB SL and (b) 35 dB SL. WF_0 is the Weber fraction for the one- and two-masker conditions (C2–C4) and $WF_{0,C1}$ is the Weber fraction for the no-masker condition (C1). Differences are shown in a bar graph for each reference frequency. An asterisk indicates statistical significance ($p < 0.05$). Also shown are the standard errors.

the high-frequency targets ($F_{ref} = 80$ and 200 Hz), all the masking conditions affected the amplitude thresholds except for the 200-Hz targets at 20 dB SL for which the one-masker conditions ($C2 - C1$ and $C3 - C1$) did not significantly increase the amplitude threshold.

IV. DISCUSSION

The present study measured frequency and amplitude discrimination thresholds in the absence and presence of masking stimuli over a wide range of frequencies. In this section, we first compare our results from the no-masker condition to those in the literature, and then summarize the general effects of masking on frequency and amplitude discrimination thresholds. We also discuss the implications of our results in the context of tactile speech communication.

The frequency WFs in the no-masker condition (0.13–0.38 and 0.14–0.28 at 20 and 35 dB SL, respectively) are comparable to those reported by Goff (1967) (0.20–0.55 and

0.18–0.38 at 20 and 35 dB SL, respectively) and Rothenberg et al. (1977) (0.15–0.30 at 14 dB SL). The current data, however, do not show an increasing trend in WF with frequency as was apparent in the data of Goff (1967) and Rothenberg et al. (1977), although Rothenberg et al. (1977) did comment that some of their participants achieved very low WFs at high frequencies (0.05 and 0.03 at 150 and 200 Hz, respectively). As far as signal amplitude is concerned, the frequency WFs from the present study generally confirm the expected trend that WFs decrease with an increase in signal amplitude, presumably due to an increased signal-to-noise ratio in afferent signals at higher signal amplitudes (see Goff, 1967; LaMotte and Mountcastle, 1975). The one exception from the present study was that the frequency WFs for 200-Hz targets were significantly lower at 20 dB SL than at 35 dB SL. According to the psychophysical model proposed by Bolanowski Jr., et al. (1988); Gescheider et al., (2002); and Gescheider, Bolanowski, and Verrillo (2004), only the P channels respond to 200-Hz targets at 20 dB SL, and both the P and NP II channels are sensitive to 200-Hz targets at 35 dB SL. Our results at 200 Hz are consistent with previous studies that reported better tactual performance with high-frequency targets at intensities that activated only the P channels (Bensmaia et al., 2005; Horch, 1991; Summers et al., 1997). It is therefore possible that the activation of the NP II channels at 35 dB SL can somehow elevate frequency discrimination thresholds, although an explanation for such a phenomenon has yet to be discovered (although see Bensmaia et al., 2005; Bensmaia and Hollins, 2000; Summers et al., 1997; Verrillo and Gescheider, 1992).

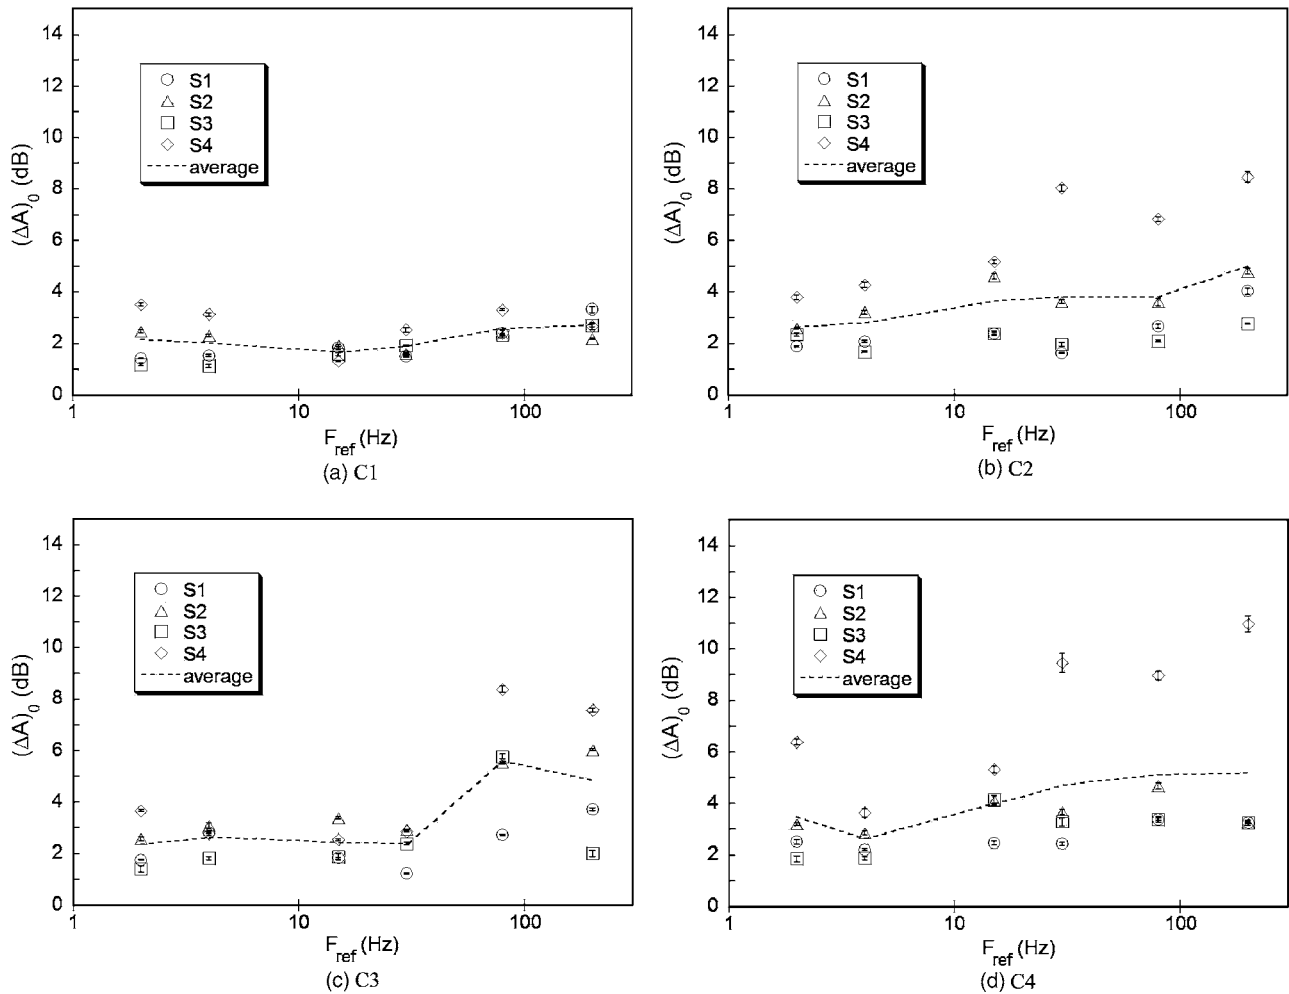
The amplitude-discrimination thresholds obtained from the no-masker condition of the present study are similar to those reported in previous studies and vary with reference frequency and amplitude. The trend exhibited by the data depended on whether the target frequency was in the low-to-medium (2, 4, and 15 Hz) or medium-to-high (30, 80, and 200 Hz) regions. The amplitude discrimination thresholds in the lower frequency region were significantly higher at 20 dB SL than at 35 dB SL. This is consistent with the trend reported by Rinker et al. (1998) in that amplitude discrimination thresholds of 1-Hz waveforms decreased from roughly 1.3 to 0.8 dB as the waveform amplitude increased from 6.3 to 19.2 mm (a change of approximately 10 dB). The amplitude discrimination thresholds in the higher-frequency region did not change with amplitude in the present study. Several earlier studies have also reported that amplitude discrimination thresholds remained constant at amplitude levels above about 15 dB SL for mid- and high-frequency reference signals (Craig, 1972; Fucci et al., 1982; Gescheider et al., 1990; Knudsen, 1928; LaMotte and Mountcastle, 1975).

Although overall trends in the data were similar across participants, individual differences in threshold values were noted, particular for the masked conditions ($C2 - C4$). For frequency discrimination, no one subject stands out as consistently exhibiting the highest values of WF [e.g., see panel (d) of Fig. 4]; for amplitude discrimination, on the other hand, the performance of S4 is consistently worse than that of the other three participants [e.g., see panels (b) and (d) of

$A_1 = 20$ dB SL
FIG. 6. Amplitude discrimination thresholds $(\Delta A)_0$ in decibels for the four participants as a function of reference frequency F_{ref} at 20 dB SL. Panel (a) shows the thresholds in the no-masker condition C1. Panels (b), (c), and (d) show thresholds for the one- and two-masker conditions C2, C3, and C4, respectively. Shown are individual participant's data (open symbols), the average (dashed lines), and standard errors.

Fig. 7]. One issue that could have potentially contributed to the significant interparticipant differences observed in the present study was the use of nominal detection threshold values for estimating the sensation levels of tactual signals. As mentioned earlier, the detection thresholds used in the present study were representative of three participants in Israr *et al.* (2004). Post detection thresholds of three participants in the present study showed that measured detection thresholds were within 6 dB from the nominal detection thresholds except for high-frequency targets where the thresholds varied up to 13 dB from the nominal detection thresholds (see the Appendix). From existing data in the literature, it appears that a small variation in the sensation level of tactual signals should not have a strong effect on discrimination thresholds. For example, Horch (1991) showed that the capability of humans to discriminate vibrations between 168 and 226 Hz did not change when the amplitude of the stimulus was varied from −4.6 dB to 3 dB relative to the reference. LaMotte and Mountcastle (1975) also demonstrated that frequency discrimination thresholds obtained at 30 Hz with roving amplitudes (24–36 dB SL) were identical

to those evaluated with equal subjective intensities, for both humans and monkeys. Therefore, the significant interparticipant differences were likely due to other factors such as familiarity with the experimental apparatus and training, and is not uncommon in psychophysical studies involving threshold testing (see, for example, Brisben, Hsiao, and Johnson, 1999). Previous studies have shown that training can lead to improved tactile discrimination performance, especially with new participants (Hnath-Chisolm and Medwetsky, 1988; Horch, 1991).

The detrimental effects of masking stimuli on frequency and amplitude discrimination found in the present study are consistent with similar findings from numerous earlier studies (Craig, 1972, 1974; Gescheider *et al.*, 1990; Gescheider, Verrillo, and Van Doren, 1982; Verrillo and Gescheider, 1992). In general, compared to the thresholds obtained in the no-masker condition, discrimination thresholds increased more under the two-masker condition (C4) than under the one-masker conditions (C2 and C3), and masking effects decreased as the frequency separation between the target and the maskers increased. The latter is consistent with findings


$A_2 = 35$ dB SL

FIG. 7. Amplitude discrimination thresholds $(\Delta A)_0$ in decibels for the four participants as a function of reference frequency F_{ref} at 35 dB SL. Panel (a) shows the thresholds in the no-masker condition C1. Panels (b), (c), and (d) show thresholds for the one- and two- masker conditions C2, C3, and C4, respectively. from other studies (Gescheider *et al.*, 2004; Hollins *et al.*, 1990; Summers *et al.*, 2005; Tan *et al.*, 1999, 2003). From the point of view of developing coding schemes for transmitting speech through a tactual display, one of the most important findings of the present study is that the discrimination of low-frequency targets is hardly affected by high-frequency maskers, and vice versa.

No definite model of frequency and amplitude discrimination is available, presumably due to the complex mechanisms underlying mechanical touch. Bolanowski Jr., *et al.* (1988) proposed a four-channel psychophysical model for the mechanical nature of touch in the dynamic range of about dc−400 Hz and 0−55 dB SL. According to this model for the glabrous skin of the thenar eminence, the detection thresholds of mechanoreceptors are contributed by four neural channels (NP I, NP II, NP III, and P) that partially overlap in their absolute sensitivity. In addition, each channel exhibits its own temporal and spatial characteristics (Verrillo and Gescheider, 1992). A similar psychophysical model was obtained at the fingertip by the same research group (Gescheider *et al.*, 2002, 2004). It is likely that suprathreshold stimuli activate more than a single channel (if not all four channels) as frequency and amplitude vary. The reference

and masker stimuli of the present study covers approximate the entire dynamic range of useful mechanical touch, in that the low-frequency targets are sensed by the NP I and NP III channels and also activate receptors for kinesthetic sensations at larger amplitudes, and the 200-Hz targets are sensed by the P channels as well as the NP II channels at higher amplitudes. Our results contribute to future studies of a model for frequency and amplitude discrimination in the presence of masking stimuli.

The present study was a continuation of our effort to use the tactual sense as a channel for speech communication. Despite decades of intense research efforts, performance with artificial hearing aids is still shadowed by that of natural methods such as the Tadoma method. Inspired by the Tadoma method, the TACTUATOR was developed to deliver both high-frequency low-amplitude vibrations and low-frequency high-amplitude movements to enrich the amount of speech information that can be transmitted through the tactual sense. Building on the author's previous studies using the TACTUATOR, the present study focused on user's ability to detect small variations in frequency or amplitude in the presence of a broadband speech signal. In this context, the main conclusions to be drawn from the present study are that low-

and high-frequency tactual signals do not interfere with each other, that experience with the apparatus or task improved discrimination performance, and that tactual discrimination thresholds appear to be too large for encoding more than a few speech features. The relative independence of the low- and high-frequency tactual channels will be exploited in the near future to improve the transmission of one speech cue: place of articulation. Previous studies on tactile aids were able to provide manner and voicing distinctions, but failed to transmit the place of articulation cue (Bernstein *et al.*, 1991; Carney *et al.*, 1993; Clements, Braida, and Durlach, 1982, 1988; Weisenberger, Craig, and Abbott, 1991; Weisenberger and Percy, 1995). Place of articulation is well correlated with the frequency values of the first two formats *F*1 and *F*2 and their transitions (see, for example, Ainsworth, 1968; Ali, Van der Spiegel, and Mueller, 2001a, 2001b; Jongman and Miller, 1991; Jongman, Wayland, and Wong, 2000; Sharf and Hemeyer, 1972; Stevens and Klatt, 1974). Based on the frequency and amplitude discrimination thresholds found in the present

200	−18	−22	−9	−12

study, the human hand does not have the resolution required for discriminating changes in high-frequency vibrations in the *F*1 and *F*2 region. A direct presentation of vibration signals associated with *F*1 and *F*2 is therefore expected to lead to poor speech reception performance. We will use a low-frequency motional signal to supplement the *F*1 and *F*2 vibrations. The direction (extension versus flexion of a finger) and the extent of the motional signals will be used to indicate to a user whether the formats increase or decrease and how fast they are changing. We hope to demonstrate that the strategy of redundantly encoding place of articulation cues via the simultaneous use of low- and high-frequency signals will eventually contribute toward improved speech transmission through the sense of touch.

ACKNOWLEDGMENTS

APPENDIX

To check the validity of the threshold levels shown in Table I, detection thresholds for *S*1, *S*2, and *S*3 were measured after the main experiments and are presented in Table II. S4 was no longer available for the additional testing.

[1]There exists another device that can display both high-frequency vibrations and low-frequency motions with appreciable amplitude (Eberhardt *et al.*, 1994). However, it either operates closed loop under 20 Hz or open loop above 100 Hz, but does not deliver signals in the frequency range 20–100 Hz.
[2]The first TACTUATOR was developed at MIT (Tan and Rabinowitz, 1996). A second device, the TACTUATORII, was then developed at Purdue University with essentially the same hardware, but a new two degrees-of-freedom controller (Israr *et al.*, 2004).
[3]The actual noise level of the sensor (due to mechanical and electrical noises) can be found in Fig. 8 of Tan and Rabinowitz (1996).
[4]To estimate the displacements associated with the sensation levels discussed in this paragraph, please see Table I for the detection thresholds at six frequencies tested in the present study.
[5]To examine training effects, participants *S*1 and *S*2 completed two runs of experimental conditions. For both subjects, frequency-discrimination thresholds improved in the second run. In the amplitude discrimination experiments, thresholds for *S*1 were not significantly different across the two runs, while those of *S*2 were better in the first run. The better of the two runs was used in the final data analyses. Because of the mixed training trends observed here, *S*3 and *S*4 completed only one set of runs.

The mean matters: Effects of statistically defined nonspeech spectral distributions on speech categorization

Lori L. Holt[a)]

Department of Psychology and the Center for the Neural Basis of Cognition, Carnegie Mellon University, 5000 Forbes Avenue, Pittsburgh, Pennsylvania 15213

Adjacent speech, and even nonspeech, contexts influence phonetic categorization. Four experiments investigated how preceding sequences of sine-wave tones influence phonetic categorization. This experimental paradigm provides a means of investigating the statistical regularities of acoustic events that influence online speech categorization and, reciprocally, reveals regularities of the sound environment tracked by auditory processing. The tones comprising the sequences were drawn from distributions sampling different acoustic frequencies. Results indicate that whereas the mean of the distributions predicts contrastive shifts in speech categorization, variability of the distributions has little effect. Moreover, speech categorization is influenced by the global mean of the tone sequence, without significant influence of local statistical regularities within the tone sequence. Further arguing that the effect is strongly related to the average spectrum of the sequence, notched noise spectral complements of the tone sequences produce a complementary effect on speech categorization. Lastly, these effects are modulated by the number of tones in the acoustic history and the overall duration of the sequence, but not by the density with which the distribution defining the sequence is sampled. Results are discussed in light of stimulus-specific adaptation to statistical regularity in the acoustic input and a speculative link to talker normalization is postulated. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354071]

I. INTRODUCTION

The fluency of speech communication makes it a rarity for any particular speech sound to be present without context. Many studies have confirmed that the nature of adjacent context greatly influences how speech is categorized (for a review, Repp, 1982). For example, following /al/, listeners identify speech targets more often as "ga" than "da" whereas, following /ar/, the same speech targets are more often identified as "da" (Mann, 1980). Lotto *et al.* (1997) found that Japanese quail (*Coturnix coturnix japonica*) trained to peck a key in response to /ga/ or /da/ exhibit context-dependent responses when /al/ or /ar/ precede novel test tokens along a /ga/ to /da/ series. Quail trained to peck to /ga/ respond more vigorously when /al/ precedes novel test syllables. Thus, it appears that context-dependent response to speech is not species specific, implicating instead rather general auditory processing.

Results with human adult listeners support this possibility. When nonspeech sine wave tone contexts with spectra modeling the third-formant (F3) offset frequency of /al/ and /ar/ precede /ga/ to /da/ targets, context-dependent speech categorization shifts are observed that mirror the effects produced by /al/ and /ar/ speech contexts. Other studies have verified the generality of this finding (for a brief review, see Lotto and Holt, 2006). Nonspeech context effects on speech categorization have been observed with nonspeech analogs of consonant contexts affecting categorization of consonants (Fowler *et al.*, 2000; Lotto *et al.*, 2003; Lotto and Kluender,

1998) and vowels (Holt *et al.*, 2000). Nonspeech models of vowel contexts also influence consonant targets (Coady *et al.*, 2003; Holt, 1999). Steady-state and frequency-modulated sine-wave tones, single formant harmonic stimuli, and band-pass noise have each been effective as nonspeech contexts in shifting speech categorization. Moreover, the interactions of speech and nonspeech signals are reciprocal; speech precursors also influence perception of nonspeech targets (Stephens and Holt, 2003). Finally, like observed context dependencies among speech contexts and targets, later-occurring nonspeech contexts influence perception of preceding speech (Wade and Holt, 2005a). Language-independent auditory processes may also contribute to compensation for phonological assimilation (Gow, 2003; Mitterer *et al.*, 2006).

Thus, there is mounting evidence that speech is perceived relative to the characteristics of neighboring sounds, whether speech or nonspeech, and therefore without respect to whether the signals originate from a vocal-tract source (see also Holt, 1999; Lotto and Kluender, 1998). When nonspeech contexts possess spectra similar to the speech contexts they model, they are effective in producing effects of context on speech categorization. This perceptual pattern has been described as spectral contrast in that higher-frequency context stimuli (e.g., /al/ or the nonspeech tones that model it) shift perception toward lower frequency targets (i.e., /ga/; Lotto and Kluender, 1998). It does not appear that speech-specific information is necessary to elicit context-dependent phonetic categorization. Rather, the body of evidence suggests a role for more general perceptual mechanisms. These

---

a)Electronic mail: lholt@andrew.cmu.edu

studies thus serve as an example of how studies of context effects on phonetic categorization can be informative about speech processing.

Reciprocally, the generality of phonetic context effects suggests it may be possible to use context-dependent phonetic categorization as a means of understanding auditory processing, generally speaking. Using listeners' context-dependent phonetic categorization as an index, it is possible to investigate how different signals interact in auditory processing. In this way, phonetic categorization can serve as a platform from which to address general perceptual questions via manipulation and control of the context stimuli. The present experiments exploit this possibility.

A. Auditory sensitivity to acoustic distributions

It is now quite well established that auditory processing is sensitive to a variety of regularities within the acoustic environment. Human adult (Saffran *et al.*, 1996), infant (Saffran *et al.*, 1996), and nonhuman (Hauser *et al.*, 2001) listeners are able to use transitional probabilities to segment running speech streams as well as streams of nonspeech acoustic elements (Saffran *et al.*, 1999). Adult and infant listeners appear to be sensitive to frequency distributions of phonetic exemplars (Maye *et al.*, 2002). Video-game players are able to extract higher-dimensional acoustic cues in aid of auditory categorization in the course of game play (Wade and Holt, 2005b). In each of these cases, experienced regularity in the acoustic input shapes subsequent auditory perception, including phonetic perception. However, within the environment, there are an infinite number of statistics that might be tracked by perceptual systems. Therefore, it is of much interest to understand the perceptual and cognitive constraints that may be imposed upon the processing of regularity from the perceptual world and the learning that may result from it. Because novel nonspeech acoustic contexts can be so readily defined in entirely statistical terms, their influence on phonetic categorization affords an opportunity to carefully manipulate and control the regularity in the acoustic environment and to observe the effects of this regularity on speech processing. The present experiments make use of the effect of nonspeech contexts on phonetic categorization as a means by which to investigate the bounds of perceptual sensitivity to statistical regularity in the input in an effort to zero in on the regularities in acoustic context that are important for online speech perception.

For example, is auditory processing sensitive only to interactions among temporally adjacent acoustic events as in the examples above (Lotto and Kluender, 1998; Holt *et al.*, 2000)? Or, rather, is it also responsive to distributional regularities among multiple acoustic events that unfold across time? Taking a hint from speech processing, there is some long-standing evidence that may be characteristic of such sensitivity. In a classic study, Ladefoged and Broadbent (1957) manipulated the formant frequencies of a sentence preceding a target word that could be perceived as *bit*, *bet*, *bat*, or *but*. These manipulations to the precursor sentence affected the way listeners categorized the final target word, producing context effects such that the target word was iden-

tified differently as the formant frequencies of the preceding sentence changed. The spectral manipulations to the formant frequencies of the precursor sentence created a perceived change in voice characteristics, making it sound like different speakers uttered the sentence. Accordingly, these results have been interpreted as an instance of perceptual normalization for speaker characteristics (e.g., Repp, 1982). However, the overall distributions of spectral energy in the precursor sentence also shifted as the formant frequencies were manipulated. Thus, the effect of precursor on identification of the final word might be described also as an effect of varying distributions of spectral energy on perception of the final word. If listeners are sensitive to the long-term regularity of the spectral distributions of acoustic energy, it may affect phonetic categorization.

There is some evidence that supports this latter possibility. Watkins and Makin (1994) conducted a series of studies similar to those of Ladefoged and Broadbent (1957), demonstrating that the effect of preceding sentence on speech categorization persists even when the context sentence is played backwards and even when it is replaced by noise that matches the long-term spectra of the context sentence. These results are consistent with findings on perceptual compensation for spectral distortion in transmission channels (Darwin *et al.*, 1989; Kiefte and Kluender, 2001; Watkins, 1991; Watkins and Makin, 1996) in which categorization of a speech target is shifted by filtering the context sentence. The target sound is heard as if it were filtered with the inverse of the filter shape applied to the context. They are also consistent with recent reports of the effects of context on perceptual normalization of lexical tone (Francis *et al.*, 2006). In all of these experiments, perception of the target sound appears to be relative to and contrastive with context. This is precisely the pattern of perception required for producing the effects observed by Ladefoged and Broadbent and presumed to relate to speaker normalization.

Extending the principle that context-dependent phonetic categorization may be a useful index of the types of acoustic information of significance in auditory processing and, taking a cue from the influential findings of Ladefoged and Broadbent (1957), Holt (2005) tested explicitly whether listeners are sensitive to statistically defined distributions of acoustic energy. Like the Ladefoged and Broadbent (1957) study, these experiments manipulated the spectral distribution of energy across sentence-length precursors. However, the spectral distributions were sampled not with shifted formant frequencies, but with purely nonspeech sine wave tones. As such, there was no information for any particular speaker or vocal source or any information about speech whatsoever. The question of interest was whether phonetic categorization of speech syllable targets shifts as a function of the characteristics of the spectral distributions sampled by the sequences of sine wave tones. If so, it would suggest that auditory processing is sensitive to statistical distributions of acoustic energy that unfold across time and that, moreover, this sensitivity can play a role in phonetic categorization—perhaps accounting for some of the perceptual shifts that have been attributed to speaker normalization processes.

In these experiments, 22 70-ms sine-wave tones were

FIG. 1. Stimulus structure and results of experiment 1. (a) Schematic illustration of the experiment 1 stimulus structure based on the paradigm of Holt (2005); (b) a representive stimulus spectrogram from each of the eight (2 Mean × 4 Variability) conditions; (c) listeners' average "ga" categorization responses to the /ga/ to /da/ series stimuli in the context of preceding high and low mean acoustic histories with 1 tone at the mean frequency, 3 tones sampling 100 Hz around the mean frequency, 7 tones sampling 300 Hz around the mean frequency, or 21 tones sampling 1000 Hz around the mean frequency; and (d) average "ga" categorization responses collapsed across the target stimulus series as a function of the distribution characteristics of the acoustic history precursors.

presented sequentially across 2.2 s. These tones were followed by a speech target stimulus drawn from a series ranging perceptually from /ga/ to /da/. Figure 1(a) depicts the construction of the stimuli. Twenty-one tones formed an "acoustic history" that preceded the speech targets. The frequencies of these tones were drawn from distributions that differentially sampled the acoustic spectrum such that spectral distribution characteristics differentiated conditions. A low mean condition with an 1800-Hz mean sampled 1300–2300 Hz. A high mean condition with a 2800-Hz mean sampled 2300–3300 Hz. These distribution means modeled the spectral characteristics of the tones Lotto and Kluender (1998) found to be effective in shifting listeners' /ga/-/da/ speech categorization responses. Within the acoustic history distributions, tones were equally probable (presented once per stimulus) and were sampled in 50-Hz steps. The tones of the acoustic histories were presented sequentially;

30 ms of silence separated tones. The sequence of tones comprising the acoustic history was reordered on each trial of the experiment; thus, each trial was a unique stimulus and idiosyncrasies of particular tone orderings could not account for any observed effects on phonetic categorization. Finally, each acoustic history ended in a 2300-Hz standard tone that was found, in a pilot experiment, to have no effect on labeling the /ga/ to /da/ targets (Holt, 2005). This prevented any observed context effects from originating from adjacent interactions of acoustic stimuli such as those described by Lotto and Kluender (1998).

Holt (2005, 2006) reports that these statistically defined acoustic contexts exert a strong contrastive influence on phonetic categorization. Sequences of tones drawn from the high mean acoustic history distribution result in more "ga" responses (i.e., the target characterized by greater low-frequency energy) whereas the same speech targets are more often labeled as "da" when preceded by tone sequences drawn from the low mean distribution. Further studies demonstrate that the influence of the acoustic histories does not depend on temporal adjacency with the speech target. Even when the acoustic histories are separated from the speech targets by 1.3 s of silence or by 13 repetitions of the standard tone (across 1.3 s), the acoustic histories elicit a context effect on speech categorization (Holt, 2005). For these effects to emerge, the auditory system must exhibit sensitivity to the distributional characteristics of acoustic events emerging across time. The precise characteristics of the sequences varied on a trial-by-trial basis; the distribution characterizes the influence of the acoustic histories on speech categorization. The implication of these studies is that the auditory system may "tune" or calibrate its response to spectral characteristics of the acoustic environment such that speech processing is thoroughly context dependent and relative to the distribution of acoustic energy present across some preceding temporal window, even if the energy across that window is nonspeech.[1]

The Holt (2005) results implicate the distribution mean as an important determiner of the influence of statistical regularity on auditory perceptual processing. However, it is not yet known the extent to which other distribution characteristics play a role. The present experiments extend the principle of using phonetic context effects as an empirical index of auditory processing to examine the kinds of distributional information to which listeners exhibit sensitivity in online speech processing. Experiment 1 investigates whether listeners are sensitive to distribution variance by examining whether phonetic context effects produced by the acoustic history distribution means are modulated also by the variability of the distributions across the spectrum. Experiment 2 seeks to understand what information contributes to the overall distribution, specifically whether the auditory system exhibits sensitivity to local as well as global regularities in acoustic history distributions. The results of each of the first two experiments underscore the significance of the mean of the distribution of spectral energy in predicting effects on phonetic categorization. Therefore, experiment 3 explicitly tests the consequent hypothesis that spectral complements of the acoustic histories should produce a complementary effect

FIG. 2. Spectrograms of five representative speech target stimuli along the nine-step series.

on phonetic categorization. Finally, in two parts, experiment 4 attempts to tease apart how much information the auditory system requires to exhibit sensitivity to a distribution and whether the sampling density and/or duration of this information modulates its effect on phonetic categorization. Each of the experiments manipulates the distribution characteristics of the nonspeech acoustic history precursors on phonetic categorization to attempt to understand the boundaries of and constraints on online auditory processing of statistical regularity in the acoustic environment. The experiments address multiple questions of how distribution characteristics of context stimuli influence phonetic categorization. They are bound together in that their results converge on the conclusion that the mean of the distribution of preceding acoustic energy matters in auditory processing. Statistical regularity in the acoustic environment is tracked and employed in evaluating incoming acoustic signals; acoustic signals appear to be perceived relationally and contrastively with respect to the distribution mean of preceding acoustic energy. For each of the observed effects, listeners' speech categorization is robustly influenced by the mean of the acoustic history distribution of nonspeech sounds that precede the speech target.

II. EXPERIMENT 1

In investigating which types of acoustic regularity are important for speech processing, distribution variability is an obvious candidate. The results reported by Holt (2005) hint that distribution variability may be important in modulating the context effects on speech categorization produced by acoustic histories. In addition to the high (2800 Hz) and low (1800 Hz) mean experimental conditions, Holt (2005) tested two control conditions with middle mean acoustic history means of 2300 Hz preceding the speech targets. The two control conditions differed from one another only in the variability of the distributions from which the tones composing them were drawn. One condition sampled a frequency distribution equivalent to the 1000-Hz ranges sampled by the high and low mean experimental conditions. The other sampled the joint range of the high and low mean conditions taken together, 2000 Hz. Therefore, the variability of the distributions distinguished the two control conditions. Holt reported a small, statistically insignificant shift in speech categorization as a function of the distribution variability such that there were somewhat more "ga" responses when the middle mean acoustic histories had greater distribution variability. It is unclear whether this shift was perceptually meaningful as it was considerably smaller than the shifts observed as a

function of distribution mean. Therefore, experiment 1 explicitly manipulates the variability of the sound distributions over a greater frequency range and across the experimental high and low mean conditions to explicitly test whether acoustic history distribution variability influences speech categorization.

A. Methods

1. Participants

Ten volunteers from Carnegie Mellon University participated for course credit or a small payment. All listeners reported normal hearing and were monolingual native English speakers.

2. Stimuli

Stimulus design is illustrated in Fig. 1(a). For each stimulus an acoustic history composed of 22 sine-wave tones [21-tone acoustic history plus standard tone at 2300 Hz, as in the Holt (2005) experiments] preceded a 50-ms silent interval and a speech target drawn from a stimulus series varying perceptually from /ga/ to /da/.

a. Speech targets. The nine speech target stimuli were identical to those reported in earlier studies (Holt, 2005, 2006; Wade and Holt, 2005a). The stimuli were derived from natural /ga/ and /da/ recordings from a monolingual male native English speaker (Computer Speech Laboratory, Kay Elemetrics, Lincoln Park, NJ; 20-kHz sampling rate, 16-bit resolution). Multiple natural productions of the syllables were recorded and, from this set, one /ga/ and one /da/ token were selected that were nearly identical in spectral and temporal properties except for the onset frequencies of F2 and F3. LPC analysis was performed on each of these tokens and a nine-step series of filters was created to span these endpoints (Analysis-Synthesis Laboratory, Kay Elemetrics) such that the onset frequencies of F2 and F3 varied approximately linearly between /g/ and /d/ endpoints. These filters were excited by the LPC residual of the original /ga/ production to create an acoustic series spanning the natural /ga/ and /da/ endpoints in approximately equal steps. The series was judged by the experimenter to shift between natural-sounding /ga/ and /da/ tokens and this impression was confirmed by regular shifts in phonetic categorization across the series by participants in previous studies (Holt, 2005, 2006; Wade and Holt, 2005a). Each stimulus was 589 ms in duration. These speech series members served as categorization targets. Figure 2 shows spectrograms for five series members. Note that creating stimuli using LPC analysis in this way provides the advantage of very natural-sounding tokens, but sound-source separation may be imperfect. The percep-

tual results from previous experiments using these stimuli proved quite clear, so this potential concern is allayed for the present stimulus set.

b. Nonspeech acoustic histories. The tone sequences making up the acoustic histories were created in the same manner as described by Holt (2005), but the distribution variability was explicitly manipulated across conditions. Eight acoustic history distributions defined eight experiment conditions. These distributions were defined by two means, low (1800 Hz) and high (2800 Hz), equivalent to those of Holt (2005). Each of these distribution means was paired with four variability manipulations: 21 unique tone frequencies sampling 1000 Hz in 50-Hz steps; 7 unique tone frequencies sampling 300 Hz in 50-Hz steps (repeated three times each for 21 total tones); 3 unique tone frequencies sampling 100 Hz in 50-Hz steps (repeated seven times each for 21 total tones); or 1 tone at the mean frequency repeated 21 times. For each stimulus, the 21 tones sampling the acoustic history distribution were followed by a 2300-Hz standard tone.

Tones comprising the acoustic histories were synthesized with 16-bit resolution and sampled at 10 kHz using MATLAB (Mathworks, Inc.). Each tone was 70 ms with 5-ms linear onset/offset amplitude ramps. Each tone was followed by 30 ms of silence. As in previous experiments, the order of the tones making up the acoustic history sequence was randomized on a trial-by-trial basis to minimize effects elicited by any particular tone ordering (except, of course, in the case of the 1-tone condition). Consequently, for the 21-, 7-, and 3-tone conditions, each trial was unique; acoustic histories within a condition were distinctive in surface acoustic characteristics, but were statistically consistent with other stimuli drawn from the acoustic history distribution defining the condition. Thus, any influence of the acoustic histories on speech categorization is indicative of listeners' sensitivity to the long-term spectral distribution of the acoustic history and not merely to the simple acoustic characteristics of any particular segment of the acoustic history. Target speech stimuli were digitally down-sampled to 10 kHz from their recording rate of 20 kHz and tones and speech tokens were digitally matched to the rms energy of the /da/ endpoint of the target speech series. A 50-ms silent interval separated the acoustic history plus standard tone sequence and the speech target. Figure 1(a) provides a schematic illustration of stimulus construction and Fig. 1(b) shows a representative stimulus from each condition.

Except for the 1-tone variability conditions, the speech targets were paired with ten unique acoustic histories sampled from the distribution defining the condition to create ten unique repetitions. Stimuli from the conditions with 1-tone variability were repeated ten times each in the experiment. In all, there were 720 stimuli (2 means, 4 variabilities, 9 speech targets, 10 repetitions).

3. Procedure

Seated in individual sound-attenuated booths, listeners categorized the speech target of each stimulus by pressing electronic buttons labeled "ga" and "da." Listeners heard stimuli from each of the eight conditions (720 stimuli) mixed across a single session; each listener responded to stimuli from each condition.

Acoustic presentation was under the control of Tucker Davis Technologies System II hardware; stimuli were converted from digital to analog, low-pass filtered at 4.8 kHz, amplified, and presented diotically over linear headphones (Beyer DT-150) at approximately 70 dB SPL(A).

B. Results

Figure 1(c) illustrates listeners' average categorization responses as a function of the acoustic history distribution mean and variability. Figure 1(d) shows the means of the conditions, collapsed across the speech target stimulus series. A 2×4 (mean $\times$ variability) repeated measures ANOVA of the percent "ga" responses averaged across the speech target stimulus series revealed a robust effect of acoustic history distribution mean on speech categorization, $F(1,9)=29.86$, $p<0.0001$, $\eta_p^2=0.768$. Replicating Holt (2005, 2006), listeners more often identified the speech targets as "ga" when the targets were preceded by high mean acoustic histories. However, there was no effect of acoustic history distribution variability on speech categorization, $F(3,27)=1.10$, $p=0.365$, $\eta_p^2=0.109$. There also was no difference in the effect of acoustic history means across variability conditions, as indicated by the lack of an interaction between acoustic history distribution mean and variability, $F<1$. Condition means are presented in Table I.

Although auditory processing shows sensitivity to the mean of a sequence of tones drawn from a spectral distribution, changes in the variability of the distribution did not influence the magnitude of the effect of acoustic histories on speech categorization. It appears that the auditory system does not track the variability of the acoustic distribution as it unfolds or, if it does, it does not play a significant role in producing spectral contrast between contexts and speech targets in this paradigm. It remains possible, of course, that distribution variability may be found to play a significant role in other aspects of speech processing. It has already been implicated, for example, in phonetic category learning in human infants (Maye *et al.*, 2002) and a nonhuman avian species (Kluender *et al.*, 1998). Here, there is considerable evidence for sensitivity to the mean of the distribution, but the variability of the distribution matters remarkably little. The perceptual effect of acoustic histories on speech categorization was statistically indistinguishable whether a single tone at the mean frequency was repeated 21 times or whether 21 unique tones sampling a range of 1000 Hz with the same mean preceded the speech target.

It is interesting to note that this lack of an influence of distribution variability on phonetic context can be differentiated from context effects in visual perception of color. Much like speech, color is perceived relationally; the perceived color at a point in a visual scene depends upon its own characteristics as well as those of the surrounding areas of the scene. Simultaneous color contrast refers to the pattern of perception that arises when changes in the overall brightness or hue of the surround shifts the perceived brightness or hue

TABLE I. Summary statistics for individual conditions.

of the target object in a complementary, contrastive manner (da Vinci, 1492; Chevreul, 1845; Helmholtz, 1866). Brown and MacLeod (1997) report that changing the variance of the colors in a test spot's surround while holding the mean constant induces a contrastive shift in the perceived contrast and saturation of the test spot's color. Thus, as in the auditory case considered in this report, the distribution of visual context influences visual perception. However, in the case of simultaneous visual contrast, distribution variance appears to have a larger role than is observed in the present auditory example.

III. EXPERIMENT 2

Experiment 1 provides further evidence that the auditory system is sensitive to the spectral distribution of context sounds preceding a speech target, particularly the mean. In investigating the processes responsible for such effects, it is of interest whether the entire sequence of the acoustic history is weighted equivalently in its influence on subsequent perception. There are examples of context effects in speech categorization for which temporally adjacent context elicits a more robust effect on speech categorization than does more temporally remote context. For example, whereas the rate of presentation of a precursor sentence influences speech categorization, the segment of the sentence temporally adjacent to the speech target is most influential in target speech syllable identification (e.g., Summerfield, 1975; Newman and Sawusch, 1996).

Experiment 2 addresses this issue in the present paradigm by introducing "meta-statistics" such that the acoustic

history precursors possess both local and global regularities. Previous results demonstrate that higher-frequency acoustic histories shift /ga/-/da/ categorization toward more "ga" responses whereas lower-mean acoustic histories shift categorization toward "da." Holt (2005) showed, as well, that acoustic histories with an intermediate mean (2300 Hz) equivalent to the standard-tone frequency produce a categorization function that is significantly different from those of the high or low mean acoustic histories and lies approximately mid-way between the high and low mean categorization functions.

The present experiment exploits these findings by dividing the 21-tone acoustic history into three sequential 7-tone segments, each with its own local distribution mean. Each of the three segments was synthesized to possess tones sampled from a low-frequency distribution (mean=1800 Hz), a high-frequency distribution (mean=2800 Hz), and an intermediate-frequency distribution (mean=2300 Hz); the order of these three subcomponents of the acoustic history was randomized across conditions, resulting in six distinct orderings each possessing a global mean (across the full 21 tones comprising the entire acoustic history) of 2300 Hz. Whereas in experiment 1 the ordering of the tones making up the acoustic histories was randomized on a trial-by-trial basis to eliminate the potential for local acoustic influences, the present stimulus structure explicitly creates local regularities in the three subcomponents of the acoustic history. A consequence of this is that the 7 tones immediately preceding the speech target varied across conditions, too, making it possible to assess whether, as seems to be the case with rate effects on speech categorization (Summerfield, 1975; Newman and Sawusch, 1996), temporally local information elicits a greater context effect on the speech targets. Most broadly, the question of interest is whether perceptual processing is sensitive to these local statistics or whether the global characteristics of the sequence of tones drive context-dependent speech categorization. To assess this, the effect of these conditions is compared to homogeneous conditions with only global regularities, akin to those of experiment 1 and previous experiments (Holt, 2005, 2006).

A. Methods

1. Participants

Ten volunteers who had not participated in experiments of this kind were recruited from Carnegie Mellon University. They participated for course credit or a small payment. All listeners reported normal hearing and were monolingual native English speakers.

2. Stimuli

Figure 3(a) illustrates the stimulus structure of experiment 2 stimuli. Three conditions were defined by statistically homogeneous acoustic histories, with a global mean but no consistent local regularities. Twenty-one tones sampling a distribution with a high (condition HHH, mean=2800 Hz), middle (condition MMM, mean=2300 Hz), or low (condition LLL, mean=1800 Hz) mean were randomly ordered on a trial-by-trial basis; thus, stimuli in these conditions were
FIG. 3. Stimulus structure and results of experiment 2. (a) Schematic illustration of the experiment 2 stimulus structure; (b) listeners' average "ga" categorization responses to the /ga/ to /da/ series stimuli in the context of preceding acoustic histories. In the top left panel, the thick, solid lines depict speech categorization in the context of the homogeneous acoustic history conditions for which there was only global regularity. In the top right panel, the dashed lines illustrate categorization in the context of the hetergeneous acoustic histories with an intermediate global mean of 2300 Hz and local regularities within 7-tone subelements. The bottom left panel combines the data from the two former graphs. The bottom right panel shows the data as a function of the frequency of the distribution mean of the final subsequence immediately preceding the speech target; and (c) average "ga" categorization responses collapsed across the target stimulus series as a function of the distribution characteristics of the acoustic history precursors.

created identically to those of the most variable distributions in experiment 1, sampling 1000 Hz in 50-Hz steps and possessing only global distribution regularity.

Six conditions possessing local statistical regularity in addition to the global regularity were also created. The acoustic histories of each of these conditions had a global mean of 2300 Hz, equivalent to the middle mean condition of Holt (2005) and the MMM condition of the current experiment. However, unlike previous experiments, these acoustic histories also possessed local regularities in each of three consecutive groups of 7 tones. These local regularities were formed by assigning each of the high, middle, and low distribution means to one of the three 7-tone subsequences of the acoustic history. Thus, averaged across the entire 21 tones, the global mean was always 2300 Hz. However, local regularity existed in each of the subunits of the acoustic history. Exhaustively ordering the high, middle, and low means

across these three subunits yielded six conditions (LMH, LHM, HLM, HML, MLH, MHL). Each of the 7-tone subsequences sampled frequencies around the distribution mean in 50-Hz steps. Therefore, each of the subcomponents of the acoustic history sampled a range of 300 Hz; the global range was 1650–2950 Hz or 1300 Hz. Given the results of experiment 1, this difference in distribution variability from the homogeneous condition was not expected to significantly influence the results. Within a subunit, the 7 tones were randomly ordered on each trial.

To reduce the overall number of observations necessary to test the nine acoustic history conditions, only consonant stimuli 3–7 along the /ga/ to /da/ series were used in experiment 2. Holt (2005) found that this limited range of speech targets, spanning the more ambiguous members of the consonant series, was sufficient to observe effects of acoustic history contexts on speech categorization. Overall, there were 450 stimuli presented in a single experiment session (9 acoustic history conditions, 5 speech target stimuli, 10 repetitions). In all other respects, stimuli were created as in experiment 1.

3. Procedure

The procedure and apparatus were identical to those of the previous experiment. Listeners heard stimuli from each of the nine conditions mixed across a single experiment session. On each trial, listeners responded whether the speech syllable was "ga" or "da."

B. Results

For clarity, the top panels of Fig. 3(b) show separately the categorization functions for the homogeneous conditions possessing only global acoustic regularity and the heterogeneous conditions with local and global regularity. The data are plotted together in the bottom left panel of Fig. 3(b). Condition means can be found in Table I.

A repeated-measures ANOVA was conducted across the nine distribution conditions as a function of the percent "ga" responses averaged across the target stimulus series. This analysis revealed an overall main effect of the acoustic history distribution, $F(8,72)=21.40$, $p<0.0001$, $\eta_p^2=0.704$. Planned Bonferroni-corrected pairwise comparisons revealed that there was a significant difference in listeners' categorization of the consonants preceded by the homogeneous high mean (HHH) and low mean (LLL) conditions, $F(1,9)=137.98$, $p<0.0001$, $\eta_p^2=0.939$. In addition, phonetic categorization was significantly different in the context of the homogeneous middle mean (MMM) condition versus the high (HHH), $F(1,9)=94.02$, $p<0.0001$, $\eta_p^2=0.913$, and the low (LLL), $F(1,9)=23.824$, $p=0.001$, $\eta_p^2=0.726$, homogeneous conditions.

The relationship of speech categorization across the heterogeneous conditions possessing both global and local statistics is of specific interest in the present studies. A repeated-measures ANOVA of the percent "ga" responses across target stimuli for the six heterogeneous conditions with global middle means, but varying local means, revealed no significant main effect of the acoustic histories, $F(5,45)=2.12$, p

$=0.08$, $\eta_p^2=0.191$, although there was a trend in this direction. Investigating this trend more fully among the heterogeneous conditions reveals that only the HLM condition was significantly different from the homogeneous MMM condition (with which heterogeneous conditions shared a global mean). It appears that listeners more often identified consonants following the HLM condition acoustic histories as "ga" than in other conditions with a 2300-Hz global mean, $F(1,9)=30.77$, $p<0.0001$, $\eta_p^2=0.774$. Nonetheless, speech categorization in the context of HLM acoustic histories, albeit distinguishable from the other global intermediate-mean conditions, was significantly different than the HHH condition, $F(1,9)=23.143$, $p=0.001$, $\eta_p^2=0.720$, and the LLL condition, $F(1,9)=50.799$, $p<0.0001$, $\eta_p^2=0.849$. Figure 3(c) illustrates the condition means for each of the nine experiment conditions.

Interpreting these results, it appears that manipulating the local statistics of the acoustic histories has little effect on speech categorization. Despite the presence of local regularities, the global mean dominated the context effect on speech categorization. Irrespective of which local subcomponent to which they belonged, the tones were equal-amplitude sinewaves. Given the overall similarity of the stimuli, grouping at the global level may have been more coherent than that at the local levels, resulting in a bias toward global effects. There thus remains an interesting open question of whether auditory group plays a role in how auditory processing tracks distribution regularity. A straightforward means of beginning to address this possibility in future behavioral work would be to increase the differentiation of the local elements by introducing local changes in amplitude or timbre, for example, to determine whether local regularity exerts more of an influence on defining the distribution when auditory grouping cues are facilitative of it.

Another issue of importance in this experiment was whether local regularities temporally adjacent to the speech targets elicited a greater influence on speech categorization, as has been reported for effects of preceding sentence rate on phonetic categorization (Summerfield, 1975; Newman and Sawusch, 1996). This possibility was investigated with a repeated-measures ANOVA of the percent "ga" responses across the target syllable series as a function of the mean of the final segment of the six heterogeneous conditions. Conditions with a final high mean segment (LMH/MLH) were compared against those possessing a final low mean segment (HML/MHL) and a final middle mean segment (LHM/HLM). The results of this analysis support what is clear from the plot in the bottom right panel of Fig. 3(b). There was no main effect of final segment mean, $F<1$. Phonetic categorization responses could not be predicted from the immediately preceding local regularity alone. Thus, these findings depart from the results of Summerfield (1975) and Newman and Sawusch (1996) for effects of preceding speech on phonetic categorization of temporal contrasts (e.g., /ba/ vs /wa/). Further studies will be needed to determine whether these different patterns of results arise because of differences in temporal versus spectrally based context effects in phonetic categorization, or whether differences in processing speech versus nonspeech contexts may be responsible. Acoustic his-

tories that vary in global temporal characteristics have been found to influence listeners' categorization of following /ba/ vs /wa/ speech targets in a temporally contrastive manner [i.e., slower acoustic histories result in more /ba/ responses, the alternative with a faster formant frequency transition rate (Wade and Holt, 2005c)]. However, it is not yet known whether listeners may be sensitive to local rate regularities in such contexts. Note, as well, that this result is not incompatible with Lotto and Kluender's (1998) finding that adjacent nonspeech tones shift /ga/-/da/ categorization as a function of tone frequency. In the present experiments, the acoustic histories of the present experiment were separated from the speech syllable by a constant mid-frequency standard tone.

IV. EXPERIMENT 3

The first two experiments underscore the relative importance of the global mean of the acoustic history distribution in predicting phonetic context effects. The average spectrum across a somewhat extended temporal window appears to tune processing of incoming acoustic information contrastively with respect to the distribution mean. If this interpretation of the results is correct, then reversing the average energy present in the acoustic history spectra should reverse the influence of context on speech categorization. To be more specific, acoustic histories that *lack* energy at precisely the frequencies where energy is present in the tone-based acoustic histories should produce a context effect on speech categorization in the opposite direction. A complementary spectrum should produce a complementary context effect. This prediction was investigated in experiment 3 by comparing the effects of context for tone acoustic histories and spectral complement acoustic histories created with white noise from which notches were filtered such that acoustic energy existed at all frequencies *except* those sampling the acoustic history distributions.

A. Methods

1. Participants

Ten volunteers who had not participated in experiments of this kind were recruited from Carnegie Mellon University and participated for course credit or a small payment. All listeners reported normal hearing and were monolingual native English speakers.

2. Stimuli

Two sets of acoustic histories were prepared. One set was created from sine-wave tones as described by Holt (2005) and as created for experiments 1 and 2, with high (2800 Hz) and low (1800 Hz) mean distributions sampled by 21 tones with unique frequencies spanning 1000 Hz in 50-Hz steps. As in previous experiments, the order of the acoustic history tones was randomized on a trial-by-trial basis to minimize effects elicited by any particular tone ordering. The final, standard, tone was always 2300 Hz [see Fig. 4(a)]. The speech targets were paired with ten unique acoustic histories sampled from the distribution defining the high and low mean conditions to create ten unique repetitions of each stimulus pairing.
FIG. 4. Stimulus structure and results of experiment 3. (a) Schematic illustration of the experiment 3 stimulus structure; (b) example spectrograms illustrating a high mean and a low mean stimulus token from the notched noise and tone acoustic histories of experiment 3. Note that the tone acoustic histories possess energy where the notched noise acoustic histories lack energy. (c) The left panel illustrates listeners' average "ga" categorization responses to the /ga/ to /da/ stimulus series as a function of the tone acoustic history contexts. The right panel shows the same listeners' responses to the same speech stimuli preceded by notched noise acoustic history contexts. (d) Average "ga" categorization responses collapsed across the target stimulus series as a function of the distribution characteristics of the acoustic history precursors.

A matched set of notched noise acoustic histories was also created. Stimulus for stimulus, the frequencies and orderings of the tone acoustic histories were matched. However, the spectra for the notched noise acoustic histories were created as spectral complements to the tone acoustic histories. This was achieved by beginning with a white noise stimulus possessing spectral energy across all frequencies. From this 2200-ms white noise stimulus, notches (70-ms, 100-Hz-bandwidth spectral regions with acoustic energy greatly reduced) were produced by digitally band-stop filtering the white noise in sequential time slices (Matlab, Mathworks; sixth-order elliptical filter, with 3-dB peak-to-peak ripple and a minimum stop-band attenuation of 50 dB). Notch center frequencies were equivalent to tone frequencies in the tone acoustic histories. As a result, these notched-noise

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Lori L. Holt: Characteristics of context dependence   2809

stimuli were spectral complements to the tone acoustic histories in that they lacked acoustic energy precisely where the tone acoustic histories possessed energy. In other ways, stimulus creation was as described for the previous experiments. Example stimuli are pictured in Fig. 4(b). In all, there were 360 stimuli (2 means, 2 types of acoustic history, 9 speech target stimuli, 10 repetitions).

3. Procedure

Seated in individual sound-attenuated booths, listeners categorized the speech target of each stimulus by pressing electronic buttons labeled "ga" and "da." Listeners completed two blocks in a single session; the order of the blocks was counterbalanced. In one block, the notched noise contexts preceded the speech targets. In the other block, participants heard the same speech targets preceded by tone acoustic histories. Thus, each listener responded to stimuli from each condition.

B. Results
