Figure 4(c) depicts listeners' average categorization responses as a function of the acoustic history type (tone versus notched-noise) and acoustic history distribution mean (high versus low). Figure 4(d) illustrates the condition means, collapsed across the speech target series stimuli. Condition means can be found in Table I. A repeated measures ANOVA of the percent "ga" responses across the speech target series reveals what the graphs illustrate: both the tone acoustic histories, $F(1,9)=19.46$, $p=0.002$, $\eta_p^2=0.684$, and the notched noise acoustic histories, $F(1,9)=5.72$, $p=0.04$, $\eta_p^2=0.388$, had a significant effect on speech categorization. Of note, however, is the direction of these context effects. A direct prediction of spectral contrast is that notched-noise spectral complements of tonal acoustic histories (created such that where there was energy in the tone acoustic histories there as a corresponding lack of energy in the notched noise) should produce the *opposite* effect of context on speech categorization. This prediction is cleanly supported by the present data. As reported in previous studies (Holt, 2005, 2006) and experiments 1 and 2, the tone acoustic histories shifted speech categorization contrastively. Speech targets preceded by acoustic histories sampled from a higher-frequency spectral distribution were more often categorized as "ga," the lower-frequency alternative, than the same stimuli preceded by tone acoustic histories sampling a lower-frequency spectral distribution. The notched noise acoustic histories produced results that similarly follow from the distributions of spectral energy. The notched noise acoustic histories labeled "high" had notches modeling the frequencies of the "high" tone acoustic histories (and lacked acoustic energy around the high mean, 2800 Hz). As a result, they possessed relatively *less* high-frequency energy than the "low" notched noise stimuli. Listeners' categorization responses followed this spectral reversal. Listeners more often categorized consonants preceded by "low" notched noise acoustic histories as "ga" relative to the same consonants preceded by "high" notched noise acoustic histories. Again, greater high-frequency energy in the precursor stimulus led

to speech categorization functions contrastively shifted toward lower-frequency spectral energy and vice versa. These results therefore substantiate the claim that the average spectrum of acoustic energy preceding a speech target has a significant spectrally contrastive influence on speech categorization.

A further analysis was conducted to examine whether the size of the context effect produced by the notched noise versus tone acoustic histories differed. Participants' percent "ga" categorization responses were submitted to a 2×2 (context type $\times$ acoustic history mean) repeated measures ANOVA of the percent "ga" responses across the speech target series. The analysis revealed that there was no main effect of whether the acoustic history was created from tones or notched noise, $F<1$, indicating no overall shift in speech categorization across context types. As would be expected from the analyses above, there was a significant influence of the acoustic history distribution mean, $F(1,9)=28.38$, $p=0.0005$, $\eta_p^2=0.759$. Of note, there was no context type by acoustic history distribution mean interaction, $F(1,9)=2.92$, $p=0.122$, $\eta_p^2=0.245$. Context effects produced by the notched noise versus the tone acoustic histories were statistically equivalent, indicating that the size of the context effects produced by the tone and notched-noise acoustic histories were statistically equivalent in magnitude, albeit complementary. Caution, however, should be taken in interpreting the importance of this null interaction. The principal finding of experiment 3 is that spectrally complementary acoustic histories produce a complementary effect on phonetic categorization. The effect is predicted from the average spectrum of the preceding nonspeech context.

V. EXPERIMENT 4

From the results so far, we can conclude that the mean matters in auditory context effects. In the face of considerable variability or no variability, with local or only global regularity, and with tones or notched noise, the global mean spectra of the acoustic history distribution predicts the effect on speech categorization. Moreover, the effects are "statistical" in the sense that acoustic characteristics that vary trial-by-trial do not drive them. Rather, they are related to *distributional* characteristics of the context. Distributions, however, must be sampled; the greater the number of events drawn from a distribution, the better the estimate of that underlying distribution parameter such as the mean.

Does the auditory system treat distributional information in this way? Are the distributional context effects elicited by acoustic histories more robust when the distributions are better sampled with more events across time or with finer sampling of frequency within the spectral range? Table I illustrates that the experiments reported thus far have investigated acoustic histories sampled by an equivalent number of tones. In this scheme, the duration of the acoustic history has been constant as has been the number of tones sampling the distribution. To return to the original aim of the present studies to investigate the bounds of sensitivity to distribution regularity in auditory processing, experiment 4 investigates whether sampling the acoustic history with
FIG. 5. Stimulus structure and results of Experiment 4a. (a) Schematic illustration of the experiment 4a stimulus structure; (b) example spectrograms illustrating a high mean stimulus token from each experiment 4a condition. Low mean conditions (not illustrated) follow the same pattern across conditions. (c) Listeners' average "ga" categorization responses to the /ga/ to /da/ series stimuli in the context of preceding high and low mean acoustic histories are plotted for each of the seven conditions of Experiment 4a. The bar graph in the lower right corner illustrates the same data collapsed across speech target stimulus.

greater density across frequency (experiment 4a) or more events across time (experiment 4b) modulates the influence of the distribution mean on phonetic categorization. In experiment 4a, the number of tones composing the acoustic histories is manipulated while the range of frequencies sampled is constant at 1000 Hz. As a result, the density with which the distribution is sampled varies (as reflected by the step-size between tones comprising the distribution). If three tones with unique frequencies sample a 1000-Hz range, then the sampling frequency of these tones must be greater (500 Hz) than the sampling frequency of 26 unique tones that sample a 1000-Hz range (40 Hz) when distribution mean is held constant. Due to the multiple dimensions defining the acoustic history distribution in the spectral and temporal domains, this scheme necessarily covaried acoustic history duration and frequency sampling density, thus confounding firm conclusions as to the source of any observed effects.

Therefore, a second study was run with additional controls. Experiment 4b examines speech categorization in the context of acoustic histories that vary in the sampling of events across time by varying the number of tones comprising the acoustic histories (from 3 to 21 tones), with the sampling density across frequency held constant. Jointly, these experiments examine whether the distributional effects of auditory context observed on phonetic categorization are subject to manipulations of distribution sampling in the frequency and time domains.

A. Method

1. Participants

Ten volunteers who had not participated in experiments of this kind were recruited from Carnegie Mellon University and participated for course credit or a small payment. All listeners reported normal hearing and were monolingual native English speakers.

2. Stimuli

a. Experiment 4a. Stimuli were created in the manner of experiment 1, with the overall structure following the pattern schematized in Fig. 5. In experiment 4a the number of tones in the sequence composing an acoustic history was manipulated across seven conditions such that high and low spectral distributions were sampled with 3, 5, 6, 9, 11, 21, or 26 tones. The 21-tone condition was created in the same way as acoustic histories of experiments 1–3, with tones sampled at 50-Hz intervals. The range of variability of tones was held constant at 1000 Hz across conditions, so the frequency distance between tones composing an acoustic history varied (3 tones, 500 Hz; 5 tones, 250 Hz; 6 tones, 200 Hz; 9 tones, 125 Hz; 11 tones, 100 Hz; 21 tones, 50 Hz; 26 tones, 40 Hz). Table I provides a summary. The 2300-Hz standard tone served as the final tone in each sequence. Each stimulus was repeated ten times for a total of 1260 stimuli (7 sampling density conditions × 2 acoustic history means × 9 speech target stimuli × 10 repetitions) in the experiment.

Overall, the present stimuli differed from those of the previous experiments in three ways: (1) the number of tones in the acoustic history varied from 3 to 26; (2) tone duration was held constant, so overall duration of the acoustic histories varied with the number of tones (from 300 to 2600 Hz); and (3) the overall range of frequencies sampled was held constant at 1000 Hz, so the density of frequency sampling across this 1000 Hz varied with the number of tones composing the acoustic history (40–500 Hz, from 26 to 3 tones).

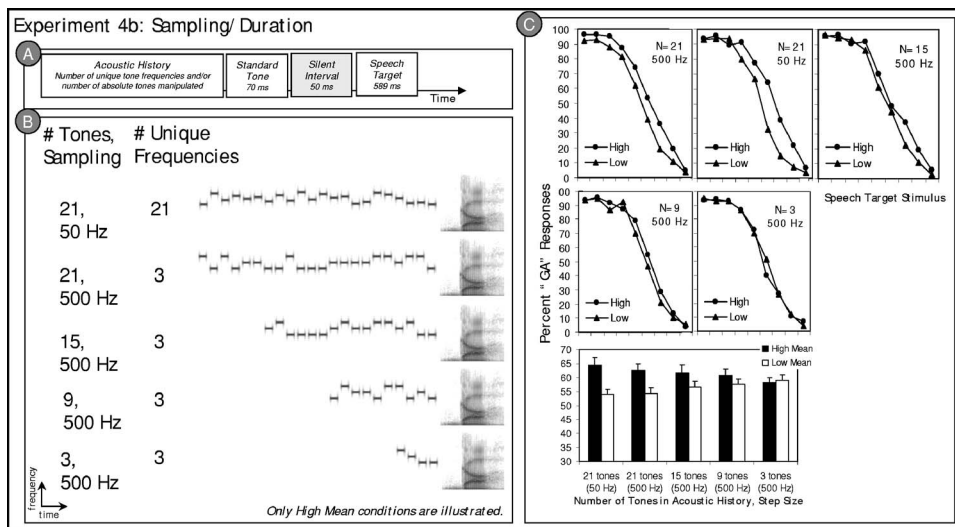
b. Experiment 4b. Holding the overall range of the distribution and the tone duration constant in experiment 4a meant that the density of frequency sampling across the 1000-Hz range and the overall duration of the acoustic histories varied simultaneously. Therefore, it is not possible to know definitively the source of any observed effects of the acoustic histories of experiment 4a. To address this concern, an additional set of acoustic histories was created for experiment 4b. In these stimuli, the distribution sampling density was held constant at 500 Hz; tones in the experiment were sampled from the distributions in 500-Hz steps. Three unique tones with frequencies sampling the low mean (1300, 1800, 2300 Hz) distribution or the high mean (2300, 2800, 3300 Hz) distribution served as the basis for each of the


FIG. 6. Stimulus structure and results of Experiment 4b. (a) Schematic illustration of the experiment 4b stimulus structure; (b) example spectrograms illustrating a high mean stimulus token from each experiment 4b condition. Low mean conditions (not illustrated) follow the same pattern across conditions. (c) Listeners' average "ga" categorization responses to the /ga/ to /da/ series stimuli in the context of preceding high and low mean acoustic histories are plotted for each of the five conditions of experiment 4b. The bar graph in the lower right corner illustrates the same data collapsed across speech target stimulus.

acoustic histories. These three tones were repeated one, three, five, or seven times to create acoustic histories composed of 3, 9, 15, or 21 tones. The order of the tones was randomized on a trial-by-trial basis. There were 900 total stimuli (5 conditions × 2 acoustic history means × 9 speech target stimuli × 10 repetitions). In other ways, stimuli were created as described for experiment 1; representative stimuli are shown in Fig. 6.

The experiment 4b stimuli had a constant sampling of frequency (1000 Hz in 500-Hz steps), but the duration (300–2600 ms) varied with the number of tones composing the acoustic histories (3 to 26 tones). For comparison and as a control condition, an additional pair of high and low mean acoustic history conditions was created with 21 tones sampling 1000 Hz in 50-Hz steps, as in experiments 1–3. Overall, comparing the results of experiments 4a and 4b, it is possible to begin to understand whether distribution regularity is related to the density with which the acoustic spectrum is sampled or the absolute duration of the acoustic history.

3. Procedure

Seated in individual sound-attenuated booths, listeners categorized the speech target of each stimulus by pressing electronic buttons labeled "ga" and "da." Listeners responded to stimuli from each condition mixed across an experimental session on each of two consecutive days.

B. Results

The results of experiment 4a are plotted in Fig. 5 and were investigated with a 7 × 2 (number of tones × acoustic history mean) repeated measures ANOVA of the percent "ga" responses averaged across the target speech series. As was the case in experiments 1–3, there was a robust main effect of acoustic history distribution mean on speech categorization, $F(1,9)=90.04$, $p<0.0001$, $\eta_p^2=0.909$, with listeners responding "ga" more often in the context of preceding high mean acoustic histories. There was no main effect of the number of tones in the acoustic histories, $F(6,54)=1.89$, $p=0.10$, $\eta_p^2=0.174$, indicating that there was no overall categorization shift as a function of the number of tones composing the acoustic history. Of interest, there was an interac-

tion, $F(6,54)=10.44$, $p<0.0001$, $\eta_p^2=0.537$, indicating that the size of the context effect elicited by the acoustic history mean varied as a function of the number of tones composing the acoustic history. The magnitude of the effect of the acoustic history mean on speech categorization decreased with the number of tones composing the distribution. Table I provides condition means.

Thus, it appears that the effect of the preceding spectral distribution on speech categorization may be modulated by the acoustic history duration or the number of events composing it. However, to satisfy the multiple constraints on stimuli in experiment 4, the number of tones composing the acoustic histories across conditions necessarily covaried with the sampling of the range of spectral distribution. Therefore, it is impossible to know the source of the interaction of acoustic history distribution mean with the number of tones composing the acoustic histories. The number of acoustic events, the overall acoustic history duration, and the density with which the acoustic history was sampled varied across the conditions so the source of the interaction cannot be inferred from experiment 4a alone.

To investigate this further, experiment 4b examined the effect of acoustic histories for which the number of tones varied across conditions but the mean of the distribution and density with which the acoustic histories were sampled were held constant. Acoustic histories with 3, 9, 15, or 21 tones sampled at 500-Hz intervals and a 21-tone acoustic history sampled at 50 Hz, as in previous experiments, served as contexts. The interesting comparisons come among the perceptual consequences of the four conditions sampled at 500 Hz, for which the number of tones varied while sampling interval was held constant, and between the two 21-tone conditions for which sampling frequency varied while the number of tones was constant.

A 4 × 2 (sampling interval × acoustic history mean) repeated measures ANOVA of the percent "ga" responses across the speech target series comparing the conditions for which sampling density was constant revealed no overall effect of the number of tones, $F<1$, but a significant effect of the acoustic history distribution mean, $F(1,13)=6.23$, $p=0.02$, $\eta_p^2=0.324$. The interaction between the number of

tones and the acoustic history distribution mean was also significant, $F(3,39)=8.53$, $p=0.0002$, $\eta_p^2=0.396$, indicating that the size of the context effect varied with the number of tones composing the acoustic history. With fewer tones, the effect of the distribution means was smaller. Table I provides condition means. Figure 6 plots the results.

An additional 2×2 (sampling density $\times$ acoustic history mean) repeated measures ANOVA of the percent "ga" responses across the target series, comparing just the conditions for which sampling interval varied (50 vs 500 Hz) while the number of tones (21) remained constant, revealed no significant overall effect of condition, $F<1$, but the expected effect of acoustic history distribution mean, $F(1,13)=20.157$, $p=0.001$, $\eta_p^2=0.608$. Of special interest, there was no interaction of acoustic history distribution mean with the sampling density of the tones, $F(1,13)=1.896$, $p=0.192$, $\eta_p^2=0.127$. Thus, the context effect was the same magnitude for 21-tone acoustic histories with high and low distribution means, whether the 21 tones sampled 21 unique frequencies in 50-Hz steps across 1000 Hz or whether they sampled just three frequencies in 500-Hz steps across the 1000-Hz range. When the acoustic history distribution mean and number of tones was held constant, there was no effect of sampling density.

The change in the magnitude of the context effects observed for experiment 4a therefore appears to be the result of the distribution mean and the duration of the acoustic history, or the number of events composing the acoustic history, rather than the density with which the distribution was sampled in the frequency domain. The longer acoustic histories produced larger effects of context on speech categorization, the direction of which was predicted by the distribution mean for all conditions. Again, as in the previous experiments, the mean of the distribution plays the dominant role in driving the effects of context observed on speech categorization.

VI. GENERAL DISCUSSION

Like perception in other modalities, auditory perception is relational in the sense that context is critical in interpreting information for object identity. From the lowest-level cochlear interactions to higher-order cortical processing, the auditory neural code is significantly affected by context sounds. Nonetheless, not all characteristics of context are effective in influencing perception. As a result, understanding the characteristics of context that have a perceptual effect can be informative of the types of information that interact in perceptual processing. The present studies find that nonlinguistic acoustic sounds as simple as tones and notched white noise are sufficient to influence speech categorization. This implicates rather general perceptual processes in the categorization of speech (Diehl *et al.*, 2004; Holt and Lotto, 2002; Lotto and Kluender, 1998).

Holt (2005) introduced an "acoustic history" paradigm for studying the effects of statistical distributions of nonspeech context sounds on speech perception and demonstrated that manipulating the spectral mean of a distribution sampled by a sequence of tones of varying frequencies pro-

duces robust spectrally contrastive context effects on speech categorization. The present series of experiments exploited the acoustic history paradigm to zero in on the statistical distribution characteristics that influence online speech categorization. Experiment 1 found that whereas the mean of the acoustic history distributions serves to shift speech categorization contrastively, the variability of the distributions has little effect. Whether the acoustic history distribution was sampled by 21 tones with unique frequencies spanning a 1000-Hz range or a single tone at the mean frequency of that range repeated 21 times, the effect on speech categorization was robust and statistically equivalent. Experiment 2 demonstrated that local statistical regularity existing within the global regularity did not have much of an effect on speech categorization. Listeners' speech target identification was influenced by the global mean of the acoustic history, without significant influence of the local regularity. Experiment 3 provided additional evidence that the average spectrum of the acoustic histories drives the observed context effects; spectral complements of the acoustic histories produced an opposite effect on speech categorization. The spectrum thus predicts the direction of the context effects. Finally, experiment 4 highlighted how distribution sampling influences the effect of the spectral distribution mean on speech perception. The number of tones composing the acoustic history was influential; as the number of tones and the overall duration of the acoustic history decreased, so too did the effect of the acoustic history mean on speech categorization. The sampling density of the distribution in the frequency domain was not essential, however. Whether the frequency range was sampled with tones differing by 500 or 50 Hz, the effect of the acoustic histories on speech categorization was the same so long as the number of tones and duration of the acoustic history were constant; longer acoustic histories produced more robust context effects. Moreover, the context effects observed across all of the experiments strongly support the claim by Holt (2005) that the mean of a distribution of context sounds influences speech categorization. Table I provides a verification of the robust nature of the influence of acoustic history contexts on speech categorization. Across conditions and experiments, this finding was replicated 18 times.

On the whole, the present experiments provide converging evidence for auditory sensitivity to spectral distributions of sound and of perceptual consequences of this sensitivity in processing other sounds. There are three primary characteristics of these data that must be understood. The first is that nonspeech contexts are effective in shifting speech categorization at all. The second is the contrastive nature of the results, such that lower frequency contexts shift speech categorization toward higher-frequency alternatives and higher-frequency contexts shift speech categorization toward lower-frequency alternatives. These first two characteristics are supported thoroughly by other studies of nonspeech contexts on speech categorization. The context effects produced by the acoustic histories mirror the contrastive effects reported for single, temporally adjacent nonspeech contexts (Holt, 1999; Holt *et al.*, 2000; Lotto and Kluender, 1998), although with longer time courses (Holt, 2005). The third characteris-

tic of importance was hinted at in the studies of Holt (2005), but is firmly supported by the present studies: the mean matters. The influence of the distributionally defined nonspeech acoustic history contexts was driven by the mean of the distribution across experiments. At a broad, algorithmic level a general auditory perceptual mechanism that accentuates change such that, in response to regularity in the acoustic input, the system responds best to novelty, would accommodate these three primary characteristics of the results.

A. Stimulus-specific adaptation and spectral contrast

Neuronal adaptation, the decline over time of neuron responses to sensory stimuli, serves this algorithmic requirement. It is a ubiquitous characteristic of neural processing in sensory areas and, in the auditory system, neuronal adaptation exists at multiple levels. Auditory nerve neurons are able to follow very fast acoustic presentation rates of up to hundreds of presentations per second (Greenwood and Joris, 1996), but at the level of the auditory thalamus (medial geniculate body, MGB) neurons adapt at rates of tens of presentations per second (Creutzfeldt et al., 1980). Cortical neurons in primary auditory cortex (A1) adapt even when stimulus presentation is at a rate of only a few stimuli per second (Condon and Weinberger, 1991; Creutzfeldt et al., 1980; Miller et al., 2002). Thus, neurons show somewhat weak, fast adaptation at the periphery, but adaptation becomes progressively stronger, with longer time constants along the ascending auditory pathway.

Adaptation is often thought of simply as a fatigue of the neural response and, in fact, it can be manifested in this way (Carandini, 2000). In past work examining the contrastive nature of nonspeech context effects on speech, we had hypothesized that peripheral adaptation of this sort might be responsible for the effects of single temporally adjacent speech and nonspeech context stimuli on speech categorization (Holt et al., 2000). Subsequent research, however, revealed context effects of nonspeech even when the nonspeech signals were presented to the ear opposite that of the speech target and across silent intervals incompatible with solely peripheral processing (Lotto et al., 2003; Holt and Lotto, 2002).

A fairly recent series of studies has provided strong evidence that the auditory system, like the visual system (Dragoi et al., 2000; Movshon and Lennie, 1979; Saul and Cynader, 1989), exhibits another form of adaptation—known as *stimulus-specific adaptation* (SSA)—that may better account for spectrally contrastive context effects. This stimulus-specific adaptation has been shown to occur with long adaptation sequences (Condon and Weinberger, 1991; Dragoi et al., 2000; Movshon and Lennie, 1979; Saul and Cynader, 1989) and also with pairs of stimuli (Malone and Semple, 2001; Malone et al., 2002; Müller et al., 1999). Thus, SSA can occur rapidly (on the time scale of a single stimulus) or evolve more slowly over multiple stimulus presentations. Visual neurons, for example, adapt to the statistical distribution of input stimuli. This pattern of SSA has been shown to maximize information transmission in the visual network and

is closely related to principles of optimal neural coding (Fairhall et al., 2001).

Ulanovsky and colleagues (Ulanovsky et al., 2003, 2004) have recently described SSA in primary auditory cortex (A1) and have suggested that a central role of A1 may be to respond to regularity in the long-term statistics of auditory signals by depressing neuron response to regularity in the acoustic input and, relatedly, to detect auditory novelty with enhanced neuronal response. At the algorithmic level, SSA is perhaps better suited than adaptation-by-fatigue to relate to context-dependent auditory processing of the sort investigated here. Ulanovsky et al. have provided explicit evidence that SSA creates *enhancement* of neural responses to rare stimuli, and thus to acoustic change and the *stimulus specificity* of the neural adaptation and enhancement. The effects are therefore sensitive to distributions of energy evolving across time and elicit adaptation and the consequent enhancement that would be expected to produce contrastive patterns of perception like those observed in the present results.

The experimental paradigm of Ulanovsky et al. (2003) can be considered to be a single-neuron version of mismatch negativity (Näätänen et al., 1978), an important auditory event-related potential (ERP) whereby sequences of common acoustic stimuli are presented with rare deviant stimuli occasionally embedded in an "oddball" design. The MMN is the difference in the ERP for the deviant versus the standard, with an enhanced response to the deviant. The MMN can reflect deviation in stimple acoustic properties like absolute frequency or duration, or complex regularities in acoustic input that evolve across time. Given that the perceptual system must have some accounting of what is standard in order to respond more robustly to a deviant, many have interpreted the existence of the MMN as indicative of auditory sensory memory (see Näätänen et al., 2001). Employing a standard/deviant "oddball" stimulus presentation paradigm in studying single-neuron responses in A1, Ulanovsky et al. report an enhanced response of individual auditory cortical neurons to acoustic novelty. Specifically, a particular tone frequency serving as an infrequent deviant in a series of tones is responded to more robustly by A1 neurons than is the same tone frequency when it serves as a frequent, repeating standard. These data provide evidence that primary auditory cortex tracks statistical regularity in the input signal across rather extended temporal windows and modulates its responsiveness in reaction to this regularity. The relative adaptation to common input characteristics coupled with the enhanced response to novelty serves to exaggerate acoustic change in the neural code. The coding strategy of the auditory system is thus matched to the stimulus statistics over time (see also Fairhall et al., 2001).

Of course, these physiological studies were not conducted with the acoustic history paradigm of the present experiments in mind and so direct comparisons should be made with much caution. However, these studies do demonstrate the sensitivity of auditory cortex to distribution characteristics of acoustic context that unfolds across time. With this caveat in mind, there is a way in which SSA may account for the robust effect of distribution mean in influencing phonetic

Lori L. Holt: Characteristics of context dependence

categorization in the present experiments. In addition to studying A1 neuron response to distributions of stimuli that varied in their regularity, Ulanovsky *et al.* (2004) examined the response of A1 neurons to equally probable, equal-amplitude tones with 20 different frequencies. This stimulus ensemble was thus quite similar to the acoustic histories of the present experiments. Ulanovsky *et al.* report that the responses of the A1 neurons to frequencies at the center of the stimulus frequency range adapted the most and there was relative *enhancement* of responses at the eccentric frequencies furthest away from the center of the frequency range. This response pattern created a U-shape in the neural tuning curves, with maximal adaptation at the central frequencies and enhancement at the edges. This response pattern emerged due to relatively simple properties of SSA. Adaptation strength is negatively correlated with the frequency difference between the present stimulus and that of the stimulus from the preceding trial (Brosch and Schreiner, 1997; Ulanovsky *et al.*, 2004) and, on average, central frequencies have smaller frequency differences from the preceding trials compared to eccentric frequencies. As a result, adaptation is greatest for central frequencies and, significantly, the response of the neuron to the eccentric frequencies is enhanced. This pattern of neural coding meets the algorithmic requirements necessary to explain the importance of the distribution mean in predicting the patterns of perception observed in the present experiments. The possibility that such a mechanism is consistent with the robust perceptual effects of distribution regularity on phonetic categorization is intriguing, but should not be over-interpreted without further explicit behavioral and physiological investigations.

B. Implications for speech processing

It is rather unexpected that a simple sequence of tones something like a tune should influence speech perception. However, considered in light of the natural soundscape in which we have evolved, the results of the present studies need not be entirely surprising. Sounds in the natural world rarely appear in isolation; rather, they are intermixed with common and rare acoustic events that change on multiple time scales (Nelken *et al.*, 1999). Added to this complexity is the fact that sounds exist for mere moments. Thus, there are significant demands from the environment for fast, online adaptation to regularity as well as sensitivity to longer-term regularity in the acoustic input. Perceptual processing does not provide a passive, veridical representation of the acoustic environment; instead it provides a means of rapidly extracting information relevant to behavior in the present circumstances. So, too, when the acoustic signal is speech. From this perspective, the context in which a signal occurs is critical to its perception. Sensitivity to regularity and concomitant detection of change appears to be characteristic of auditory processing and may provide us with insights about behaviorally relevant questions in speech processing.

As an example, it has long been observed that listeners perceive vowel categories dependent on the spectral characteristics of a precursor sentence (Ladefoged and Broadbent, 1957) such that they appear to normalize perception for different talkers or accents. Many models suggest a speech-specific translation from the surface acoustic variability to a more canonical representation [see Repp (1982) for a review]. The nonlinguistic nature of the context effects elicited by the acoustic histories, coupled with their sentence-level time course, suggests the possibility such "normalization" may arise when spectral regularities in the acoustic environment produce contrastive effects on auditory processing and, concomitantly, speech categorization. The present results specifically suggest that sensitivity to the average spectrum of a particular speaker's speech may help to resolve ambiguities in speech categorization later in an utterance through rather general auditory perceptual mechanisms not specific to speech, but nonetheless operating at a rather high level of auditory processing sensitive to statistical regularities unfolding across sentence-length time courses. This, of course, does not deny the importance of longer-term learning and generalization to familiar voices that is known to occur in speech processing (e.g., Johnson and Mullennix, 1997). However, it provides a means of reconsidering one of the classic issues in speech perception: how do listeners maintain perceptual constancy despite the considerable acoustic variability present in the speech signal? The "lack of invariance" between acoustics and speech categories has long been taken as evidence of the special status of speech perception relative to auditory perception in general (see Repp, 1982). Considering the effects of nonspeech contexts on speech categorization and the general perceptual mechanisms that might relate to them casts doubt on whether this supposition is necessary. Rather, the present data would argue, it is necessary to consider the fact that the problem of perceptual constancy in the presence of variable contexts is a very general problem faced by all perceptual systems, whatever the signal. Given the strong evidence of nonspeech context effects on speech categorization (Coady *et al.*, 2003; Fowler *et al.*, 2000; Holt, 1999; Holt and Kluender, 2000; Holt *et al.*, 2000; Holt, 2005; Lotto *et al.*, 2003; Lotto and Kluender, 1998) and the demonstration that a nonhuman species exhibits "phonetic" context effects (Lotto *et al.*, 1997), it appears that speech communication makes use of general characteristics of perceptual processing to maintain perceptual constancy in the face of variability. The present results highlight that this may be accomplished by an adaptive tendency of the auditory perceptual system to seek regularity in acoustic input and exaggerate change relative to the regularity. Specifically, in the case of distributional regularity in the acoustic environment, the average frequency across time appears to be influential in auditory processing.

On the influence of interaural differences on temporal perception of masked noise bursts

In this research, the influence of interaural differences on temporal positioning of the perceived onset of a dichotic broadband noise target in a diotic broadband noise masker was explored. Interaural time or level differences, a combination of these differences, and filtering with head-related transfer functions were applied to broadband noise bursts, to establish lateralization in quiet at center and right positions in the lateral plane. While applying these interaural differences, the subjects' ability to accurately align the noise's onset to the meter of a regular series of diotic reference onsets was investigated for various signal-to-noise ratios. At high target sensation levels, mean onset positions were close to physical isochrony and no systematic differences in temporal positioning due to different interaural cues were observed. At low target sensation levels, positioning accuracy decreased with a decreasing signal-to-noise ratio, and dichotic targets were positioned less accurately than diotic targets. This reduced temporal positioning accuracy could not be attributed to differences in detectability of the targets just above the threshold, nor to a reduction of effective target bandwidth of dichotic broadband targets. From these results, the reduced accuracy of temporal perception in binaural unmasking conditions may be seen as a consequence of temporal integration in binaural processing. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2345913]

I. INTRODUCTION

Fast increases in intensity of signal components, i.e., onsets, are grouped by the human hearing system if they have a level above the detection threshold and occur simultaneously in several spectral regions. Such synchronous onsets are likely to emanate from the same physical source, and are combined to form a perceptual stream or auditory object (Bregman, 1990). The detection of these onsets is, therefore, deemed key to the organization of auditory objects from an acoustic scene.

The perceptual moment of occurrence, i.e., the *perceived* onset, of a sound depends on transient behavior of the auditory system (Schütte, 1978; Zwicker and Fastl, 1999, pp. 271–275). The perceived onset is a function of the sound's duration and its temporal envelope, and may be defined as the moment at which a certain percentage of the maximum of the transient is reached. For a sound with an abrupt onset, the shorter the sound's duration, the stronger its perceived onset is associated with its physical onset.

Directional cues also support and enhance perceptual streaming, although the grouping of signal components is not *initiated* by common interaural time differences only (Hill, 1994; Culling and Summerfield, 1995; Darwin and Hukin, 1999). Interaural differences in time and intensity enable the localization of sound sources, and make the human auditory system more robust in detecting and segregating sounds from

and within complex acoustic scenes. Much of this ability is due to a spatial release from masking, commonly referred to as the *binaural masking level difference*, which is computed as the difference in the detection threshold between a specific binaural condition and a monaural or diotic reference condition. Differences in location of concurrent sound sources provide physical parameters to support differentiation between sounds in *cocktail-party* conditions, in which separating spectrally overlapping signal components would otherwise be difficult. In the present study we investigated whether directional cues of a sound have an influence on perception of a sound's onset, and consequentially may influence the organization of auditory objects.

The most extensively researched phenomenon with regard to interaural differences and the perception of onsets is the *precedence effect*, i.e., the observation that localization of a sound in reverberant environments is mainly determined by the interaural cues of the first-arriving direct sound with decreased influence of later-arriving reflections (Wallach *et al.*, 1949; Litovsky *et al.*, 1999). From measuring the just-noticeable differences in interaural time and intensity of Gaussian noise bursts of less than 5 ms in continuous low-pass filtered noise, the precedence effect can be seen as a result of a temporary degradation of interaural sensitivity between approximately 0.5 and 10 ms after the immediate onset of a sound (Zurek, 1980).

The influence of a signal's sensation level on the precedence effect was investigated by Goverts *et al.* (2000). Using a 2.4-kHz low-pass filtered 5-ms noise burst with fixed but

[a]Electronic mail: armin.kohlrausch@philips.com

ambiguous lateralization cues, they changed the sensation level either by modifying the signal level in silence or adding a noise masker. The onset dominance for lateral perception of the stimulus declined at sensation levels below about 30-40 dB and disappeared completely at 3 dB. Thus, the audibility of a signal's onset influences processing of its directional information.

Conversely, an effect of directional information on temporal perception was established (van Noorden, 1975). The dichotic presentation of an alternating tone sequence of 40-ms tones at 100-ms interonset intervals that, in diotic presentation, yielded a single perceptual stream, resulted in two separate perceptual streams in which the temporal coherence of the original tone sequence was lost. This finding indicated a difference between within-stream and across-stream temporal judgments, induced by directional information, that may influence the perception of a sound's onset.

Furthermore, the effects of directional information on temporal perception may be expected in masking conditions. Binaural unmasking of the target at low signal-to-noise ratios depends on the detection of a change in the interaural correlation (Durlach *et al.*, 1986). This processing requires temporal integration, as it is the change of interaural differences over time and the inconsistency of interaural time differences across frequency that allow the detection of decorrelation. The slow temporal response of the binaural hearing system to changing directional cues, the so-called *binaural sluggishness*, was shown to play a role in binaural detection (Kollmeier and Gilkey, 1990). Directional cues that improve detection through a spatial release from masking may, therefore, oppose the binaural detection of a decorrelating sound's onset.

Our aim in the research presented here was to investigate the influence of interaural differences on onset perception. The question was addressed whether the availability of different directional information for two sounds changes the temporal perception of a sound's onset, compared to a situation without any difference in directional information between two sounds.

II. EXPERIMENT 1

This experiment was defined to measure whether specific differences in interaural parameters between an existing and a newly emerging broadband noise influence the temporal perception of the new noise's onset.

A. Method

1. Procedure

To determine a sound's perceived onset, an experimental procedure was adapted from speech perception research, based on the perceptual center location (Marcus, 1976; Pompino-Marschall, 1989). The perceptual center procedure comprises judging the temporal position of a target sound, and/or moving a target sound along the time axis of a stimulus, relative to isochronous reference sounds in the stimulus, in order to find the desired temporal alignment or perceptual center. These perceptual centers are related to the acoustic
FIG. 1. Example of an acoustic stimulus for the temporal onset positioning experiment. In quiet or against a stationary masker (as depicted here by the cross-hatched area), a randomly positioned target's onset (in white) was to be temporally aligned to the meter of a regular series of reference onsets (in black), to yield the dependent variable adjusted onset position, quantified as the deviation (Δt) from physical isochrony (dashed line at 0 ms).

makeup of a stimulus. In speech sounds, for example, they are determined both by the vowel onset and the duration of preceding consonants (Marcus, 1976).

Because perceptually regular patterns have regular perceptual centers, perceptual isochrony can be achieved with physically isochronous onsets of equal-duration reference and target sounds with identical temporal envelopes. In other words, for perceptually identical (or at least very similar) sounds, the perception of a target sound's onset can be inferred from the accuracy of positioning it to reference sound onsets. A systematic shift from physical isochrony may then be associated to manipulations of the target sound's physical properties. A monotonic relationship between temporal positioning accuracy and the underlying dimension of onset perception is assumed.

The stimulus structure consisted of a regular series of five clearly audible marker pulses of which the third marker pulse was omitted, both in quiet and against a stationary masker. The subjects' task was to temporally align the target's onset, initially positioned randomly around the onset position of the missing third marker pulse, to the meter of the marker pulse onsets (see Fig. 1 for a graphical representation of a stimulus). The time difference between the adjusted temporal position of the target's onset from physical isochrony at the temporal center between onsets of marker pulse two and four was recorded, and served as a quantitative measure for positioning performance. From these measures, temporal positioning bias and accuracy of differently processed targets could be obtained.

The step size for timing adjustments was set to 5 ms, which is roughly the size of the just-noticeable difference in perceptual center changes (cf. Marcus, 1976; Schütte, 1976). The initial random temporal displacements were equally distributed between −125 and 125 ms in steps of 5 ms. The temporal positions the subjects could adjust were limited to the range between −450 and 450 ms around physical isochrony.

Subjects controlled the experiment from a computer keyboard. After an initial playback of the stimulus with a randomly positioned target, the target position could be adjusted by pressing **f** (for 'forward') or **b** (for 'backward') the number of times the target was to be shifted by the step size. Confirmation by pressing **Enter** would start playback of the stimulus with the target at the new temporal position. This procedure could be repeated until subjects were satisfied

with the target onset's fit to the meter of the reference onsets. The final time instant of the target's onset on the time line of the stimulus was then recorded as its perceived moment of occurrence. Feedback was provided after each condition in the form of a graph, representing the followed track from the initial temporal displacement to the final temporal position set. A within-subject experimental design with counterbalanced complete randomization was applied. All conditions were randomly presented twice to each subject, and obtained results were averaged across subjects.

The experiment was conducted in an acoustically isolated listening room at the Philips Research Laboratories in Eindhoven, using a computer running MATLAB software to digitally generate stimuli and automate the experiment and data collection. Digital stimuli were converted to analog signals by a Marantz CDA-94 two-channel 16-bit digital-to-analog converter at a sampling rate of 44.1 kHz, and presented to subjects over Beyer Dynamic DT990 Pro headphones.

2. Stimuli

Three sounds were used: a continuous masker with a level of 70 dB SPL, a number of 50-ms marker pulses with a level of 76 dB SPL, and a 50-ms target with a level of 70 dB SPL. All sounds were broadband noises with independent Gaussian probability distributions, covering the frequency range up to 22.05 kHz, only limited by the frequency response of the headphones. No ramps were applied to the sounds, so they had abrupt onsets and offsets. The masker and the marker pulses were presented diotically, i.e., identically at both ears, to establish lateralization in the center.

The target was presented with different interaural parameters to yield lateralization in quiet at two different positions: one in the center (diotic conditions) and one to the far right (dichotic conditions). This was achieved by the controlled manipulation of interaural time differences, interaural level differences, or by filtering using head-related transfer functions. The following six lateralization conditions were presented: two diotic reference conditions, [C] and [0], and four dichotic conditions, [ITD], [ILD], [ITLD], and [90].

The [C] condition comprised an unprocessed target, identical at both ears. In the [ITD] condition, a time delay was set at 29 samples at 44.1 kHz in the left channel, approximating a 660-μs lag at the left ear. In the [ILD] condition, an interaural level difference was set at 18 dB: target level +9 dB at the right ear, and target level −9 dB at the left ear. The [ITLD] condition combined interaural differences of the [ITD] and [ILD] condition. The diotic [0] and dichotic [90] conditions were computed from head-related impulse responses at 0° and 90° of the HEAD acoustics HMS II artificial head (Blauert *et al.*, 1998).

3. Subjects

Eleven male subjects participated voluntarily in the experiment. All subjects had previous experience in listening tests and reported normal hearing. Training was thought not to be required, because the procedure allowed the subjects to

TABLE I. Mean values and, in brackets, standard deviations of the adjusted temporal onset positions (in ms), for each lateralization condition in quiet and in a noise masker.

	[C]	[ITD]	[ILD]	[ITLD]	[0]	[90]
In quiet	−3.2	−6.2	−9.3	−6.0	−4.3	−5.0
	(7.6)	(12.2)	(9.6)	(11.2)	(11.9)	(11.7)
In noise	2.0	−0.9	8.4	5.0	−0.5	1.1
	(13.0)	(14.5)	(14.6)	(14.1)	(11.8)	(14.1)
Mean	−0.6	−3.5	−0.5	−0.5	−2.4	−1.9

adjust the stimuli for as long as necessary to reach a high confidence level about the temporal onset position before continuing with the next condition.

B. Results

All 22 adjustments (2 adjustments for 11 subjects) for each condition (6 lateralizations at 2 target sensation levels) were pooled, and scanned for severe outliers (onset positions at more than 3 times the interquartile range of the pooled data). Here 2 severe outliers out of the 264 adjustments were removed from the results. Table I shows the mean and standard deviations of the adjusted temporal onset positions. The columns display the six lateralization conditions; the rows indicate the conditions in quiet and in noise.

Table I shows that mean onset positions for all lateralization conditions, both in quiet and in noise, were generally close to physical isochrony and had grand means just below zero. The 95%-confidence intervals of the mean onset positions for each lateralization condition in quiet and in noise revealed that all four dichotic conditions in quiet and the [ILD] condition in noise had means significantly different from physical isochrony.

Because the primary interest was in the temporal positioning *accuracy*, the standard deviations of the adjusted onset positions were used for further analysis. Standard deviations were roughly between 8 and 12 ms in quiet, and between 12 and 15 ms in noise, suggesting an influence of adding the noise masker. A statistical analysis of the difference between variances was performed using paired comparisons by the F ratio, using a 5% level of significance and Bonferroni correction for multiple comparisons. The paired comparisons showed that the introduction of the noise masker significantly reduced temporal positioning accuracy from the condition in quiet only in the [C] conditions ($F_{(21,21)}=2.94$, $p=0.018$). Both in quiet and in noise, results for all six conditions were statistically identical.

C. Discussion

Statistically significant biases from physical isochrony were observed for all four dichotic conditions in quiet. This finding may suggest an effect of lateralization cues. Due to different perceived locations, two independent perceptual streams for markers and target may have been formed in which temporal coherence was compromised, i.e., across-stream judgments of temporal position were worse than within-stream judgments (cf. van Noorden, 1975). However, while these biases were found to be *statistically* relevant,

based on the derived *standard error of the mean*, they were considered to be *perceptually* irrelevant because their differences from physical isochrony were smaller than the *standard deviations* of their underlying distributions. In terms of a d' analysis, all these bias values were below a d' value of one, as was the d' value of the [ILD] condition in noise. Therefore, a systematic bias in temporal positioning for any of the lateralization conditions was not supported by these data. Thus, if the target indeed formed a separate perceptual stream on the basis of different lateralization cues, temporal perception of its onset remained unaffected in the procedure used.

Standard deviations indicated similar temporal positioning accuracy in quiet and in the presence of the noise masker, regardless of interaural differences. An overall comparison of diotic versus dichotic conditions did not reveal a systematic influence of interaural differences on temporal positioning accuracy. In the case of the [C] condition, the unprocessed target was most similar to the diotic markers, so finding the most accurate temporal positioning in quiet here may not be surprising.

With these results in quiet, a baseline for temporal positioning performance was established. The following experiment examined temporal positioning performance at low target sensation levels, where lateralization ability by onset cues was shown to break down (Goverts *et al.*, 2000).

III. EXPERIMENT 2A

This experiment was defined to measure masked threshold levels of diotic and dichotic broadband noise targets in a diotic broadband noise masker, which were needed as reference data for the next temporal positioning experiment at equal target sensation levels.

A. Method

1. Procedure

A three-interval, three-alternative forced-choice procedure with adaptive level adjustment was used in a within-subject experimental design with counterbalanced complete randomization, to measure the individual detection threshold levels for various target conditions. The subjects' task was to identify the interval containing the target. Feedback was provided after each trial. The masker level was 70 dB SPL throughout the experiment, as was the initial target level. The target level was adjusted according to a two-down one-up rule, to track the 70.7%-correct response level (Levitt, 1971). To increase efficiency of the procedure, the initial step size of 8 dB was halved after every second reversal, and was kept constant once it had reached 1 dB. After eight reversals at the 1-dB step size, the median of these eight levels was calculated to estimate threshold. Each condition was repeated four times for each subject. The same equipment and facility were used as in the previous experiment.

2. Stimuli

Two sounds were used: a long-duration masker and a short target. Both target and masker sounds consisted of broadband noise, with independent Gaussian probability dis-
FIG. 2. Mean and standard deviations of the masked threshold levels (in dB, as spectral power ratio between target and masker) for each lateralization condition, based on data of 11 subjects with 4 measurements each. The lower threshold levels of the dichotic conditions ([ITD], [ILD], [ITLD], and [90]) compared to their reference diotic conditions ([C] and [0]) reflect the binaural masking level difference from the application of interaural differences on the target.

tributions, covering the frequency range up to 22.05 kHz, only limited by the frequency response of the headphones. No ramps were applied to the sounds, so they had abrupt onsets and offsets.

The masker had a duration of 400 ms, a level of 70 dB SPL, and was presented diotically. The three masker intervals were separated by 100 ms of silence. The 50-ms noise target was added to the temporal center of one of the maskers. Noise masker waveforms were identical in all intervals within a trial.

The noise target was set at two positions in the lateral plane, one in the center (diotic conditions) and one to the far right (dichotic conditions), by the same manipulations of interaural time differences, interaural level differences, combination of interaural time and level differences, and head-related transfer functions, as described for experiment 1.

3. Subjects

The same 11 subjects participated in this experiment. Again training was thought not to be required, as the procedure allowed straightforward selection of one interval being different from the other two (if detection occurred), without depending on the ability to consistently label the difference.

B. Results

Results of all subjects were pooled, because the between-subject variability (standard deviations across the mean values of the subjects) was similar to the within-subject variability. Figure 2 displays the mean and standard deviation of the masked threshold levels for each lateralization condition, based on data of 11 subjects with 4 measurements each. Threshold levels are expressed in dB as signal-to-overall-noise spectral power ratio between target and masker.

Mean masked threshold levels for the dichotic conditions ([ITD], [ILD], [ITLD], and [90]) were considerably lower than for both diotic reference conditions ([C] and [0]). Compared to the [C] condition, the threshold level for the [ITD] condition was about 9 dB lower, and for the [ILD] condition about 14 dB lower. There were clear differences in the effects of manipulating ITD and ILD; although both cue manipulations caused the target to be lateralized to the far right, thresholds were about 4 dB lower in the [ILD] condition than in the [ITD] condition. In the [ITLD] condition, with both interaural time and level differences present, the threshold was about 1 dB lower than in the [ILD] condition, the condition with the lowest thresholds for the separate lateralization cues. Target presentations with head-related transfer functions yielded a threshold about 3 dB lower in the [0] condition compared to the [C] condition. The average difference in threshold level of about 11 dB between the [0] and [90] conditions was smaller than the difference of about 15 dB between the [C] and the [ITLD] conditions.

C. Discussion

The [C] condition without any interaural time or level differences had the highest detection threshold. Because the signal was identical in both ears, with a bandwidth identical to the masker, detection had to occur on the basis of temporal-profile cues, i.e., an increase in level for the period of the target being present. The calculated level increase of adding a 66.5-dB noise target to a 70-dB noise masker is 1.6 dB. This value is in line with other measured increment-detection thresholds of about 2 dB for 40-ms and 60-ms spectrally matching broadband noises (Heinz and Formby, 1999).

As expected, targets with interaural differences were detected at lower levels. Thresholds for dichotic conditions with only a 660-μs interaural time difference on the target ([ITD]) were 9 dB lower than for the diotic reference condition ([C]). For these stimuli, the cue for detection was likely the interaural decorrelation caused by the addition of the target to the masker (i.e., a change in the perceived width of the masker), rather than a monaural change as in the [C] condition. Binaural interaction for detection of decorrelation needed to be present to account for the 9-dB reduction in detection threshold.

Applying interaural level differences to the target ([ILD]) shifted the detection threshold by about −14 dB. Because of the imposed interaural level differences in the target, the signal-to-noise ratio in the right ear was 9 dB larger than for a diotic target. However, the threshold was 14 dB lower, showing an additional 5-dB shift of the threshold that could not be attributed to the signal-to-noise ratio at the better ear. Again, binaural interaction for the detection of decorrelation needed to be present to account for the additional 5-dB reduction in threshold beyond any better-ear effect. The same was then true for the combination of interaural time and level differences ([ITLD]), which yielded a shift in detection threshold of about 15 dB.

In order to evaluate binaural detection cues, the change in interaural correlation ($\Delta\rho$) for the [ILD] and [ITD] conditions was computed using the formulas from van de Par and Kohlrausch (1995). For the [ILD] condition, this change is by definition constant across the whole frequency range, regardless of the signal bandwidth. For the mean threshold of −17.4 dB, $\Delta\rho$ amounted to 0.05. For the lowest and highest individual threshold values, $\Delta\rho$ amounted to 0.029 and 0.075, respectively. The present authors are unaware of any comparable data on $\Delta\rho$ sensitivity for broadband noise signals of a similar bandwidth as used in the current experiment. The data of Gabriel and Colburn (1981) for detecting a change in correlation for a reference correlation of one showed an increase of $\Delta\rho$ with increasing noise bandwidth. For a noise of 4.5 kHz width, the threshold $\Delta\rho$ values of the two observers amounted to 0.02 and 0.03, about a factor 2 lower than the present results. This remaining factor may be explained by the shorter duration of the signals used in the current experiment (50 ms), compared to the 300-ms signals used in Gabriel and Colburn (1981). Koehnke *et al.* (1986) obtained data for $\Delta\rho$ thresholds of 1/3-octave-wide diotic noise bands centered at 500 and 4000 Hz. The mean values of $\Delta\rho$ were 0.022 and 0.092, respectively. There was considerable intersubject variability in their data, leading to a range from 0.006 to 0.075 for $\Delta\rho$ at 500 Hz, which covers nicely the range found for the broadband experiments in the current data.

The analysis of the [ITD] data in terms of $\Delta\rho$ was more complicated, because for a fixed signal level $\Delta\rho$ depends on the frequency. Therefore, the analysis was performed for critical-band-wide noise at various frequencies. The mean threshold value of −13.0 dB led to the following values of $\Delta\rho$ at 200, 500, and 800 Hz: 0.016, 0.071, and 0.095. The value did further increase toward higher frequencies, but these will be ignored due to the loss of phase locking which will start somewhere around 1 kHz, and the fact that the change in *envelope* correlation, which is the only cue at high frequencies, is much smaller than the change in waveform correlation (van de Par and Kohlrausch, 1995). The values of $\Delta\rho$ in individual low-frequency filters were of similar magnitude as for the [ILD] data, and were close to the values found in the literature. This analysis of the thresholds in terms of $\Delta\rho$ was also supported by the high correlation between individual data for [ITD] and [ILD] conditions, with a correlation coefficient of 0.93. Thus, it can be concluded that detection of the dichotic targets was mediated by changes in the interaural correlation.

In the case of applying head-related transfer functions to the target, i.e., filtering with a *frequency dependent* filter, signal-to-noise ratios were no longer the same in all auditory filters. In the [0] condition, the threshold for detection was about 3 dB lower than in the [C] condition, suggesting a release from masking as an effect of this filtering that introduced considerable amplification and attenuation in different frequency regions of the target sound. For instance, at 1, 3, 5, and above 10 kHz there were peaks in the frequency spectrum of 3 dB or more, relative to the specified level, which may account for the 3-dB reduction in detection threshold.

The detection threshold of the [90] condition was measured to be about −17 dB relative to the 70-dB noise masker, indicating a masking level difference between [0] and [90]

conditions of about 11 dB. Relative level increases of the target in this condition were approximately 8 dB at 1, 7, and roughly between 10 and 16 kHz. A better-ear effect, therefore, could not completely explain this shift in threshold, and again binaural interaction for the detection of decorrelation needed to be present to account for the 11-dB reduction in threshold.

The difference in threshold between the [ITLD] condition and its reference [C] condition was about 15 dB, between the [90] condition and its reference [0] condition about 11 dB. These threshold differences concur with the maximum release from masking (10–15 dB) for out-of-phase tones in diotic broadband noise ($N_0 S_\pi$) at signal frequencies below 500 Hz (cf. Durlach and Colburn, 1978).

IV. EXPERIMENT 2B

This experiment was defined to measure whether specific differences in interaural parameters between an existing and an added broadband noise influence the ability to temporally position the perceived onset of the new noise at low target sensation levels.

A. Method

The same temporal positioning procedure as in experiment 1 was used. The only difference was a systematic variation of the target level.

The same three sounds were used: a continuous diotic masker with a level of 70 dB SPL, a number of 50-ms diotic marker pulses with a level of 76 dB SPL, and a 50-ms target with the same six lateralization conditions as in previous experiments, at various sensation levels. Seven different sensation levels were applied to the noise target: from 0 through 6 dB relative to detection thresholds of the noise target, as measured for each lateralization condition and subject in the previous experiment. By choosing target levels relative to the threshold for each lateralization condition and subject, target sensation levels were equal in all lateralization conditions and data could be compared between conditions and subjects.

The same 11 subjects participated in this experiment.

B. Results

The 22 adjustments (2 adjustments for 11 subjects) for each condition (6 lateralizations at 7 target sensation levels) were pooled, and scanned for severe outliers. Here 11 severe outliers out of the 924 adjustments were removed from the results. Table II shows the mean and standard deviations of the adjusted temporal onset positions. The columns display the six lateralization conditions, the rows display target sensation levels 0 through 6 dB.

Table II shows that onset positions for both diotic conditions were distributed rather symmetrically around physical isochrony, with grand means just above zero, whereas onset positions of all 4 dichotic conditions had negative grand means (i.e., their onsets were positioned earlier than physical isochrony) of about −10 ms. The 95%-confidence intervals of the mean onset positions for each lateralization condition and target sensation level revealed 4 of the 42 con-

ditions to have means significantly different from physical isochrony. Three conditions indicated a bias of about −28 ms ([ITD] at 2 dB, [ILD] at 0 dB, and [ITLD] at 0 dB) and one of about −9 ms ([ILD] at 4 dB).

Because interest was in temporal positioning *accuracy*, the standard deviations were used for further analysis. Figure 3 gives a graphical overview of standard deviations for the six lateralization conditions. The abscissa shows target sensation level (in dB) relative to the detection threshold in the 70-dB noise masker, and the ordinate shows standard deviation (in ms). The six lines connecting different symbols represent results for each lateralization condition. The dashed line at 74 ms represents the calculated standard deviation of the random distribution of initial onset positions (between −125 and 125 ms), i.e., the line to which the standard devia-
FIG. 3. Standard deviations of the adjusted temporal onset positions (ordinate) versus the target sensation level (abscissa), for six different lateralization conditions. Target sensation levels are relative to the detection threshold in the 70-dB noise masker. The dashed line at 74 ms represents the calculated standard deviation of the random distribution of initial onset positions.

tions would converge if no temporal adjustments were made.

As can be seen on the right side in Fig. 3, standard deviations were lowest at the highest target sensation levels. With a decrease in signal-to-noise ratio between target and noise masker, standard deviations systematically increased for all lateralization conditions. However, standard deviations for dichotic conditions with interaural differences (filled markers) increased faster than those of diotic conditions without interaural differences (open markers). At the detection threshold (0 dB), results had some intrinsic randomness due to the 70.7%-correct level of the procedure followed to establish detection thresholds. Differences in standard deviation between diotic and dichotic conditions were therefore best observed at target sensation levels of 2 through 5 dB. Please keep in mind that results of the dichotic conditions at equal target sensation levels were obtained at much lower *absolute* target levels than in the diotic conditions, reflecting the binaural masking level difference.

A statistical analysis of the difference between variances was performed using the same paired comparisons by the F ratio as in experiment 1. When comparing variances at each target sensation level from 2 through 5 dB, 19 out of 32 comparisons showed significant differences in distributions of adjusted onset positions between the two diotic conditions and the four dichotic conditions ($F_{(19/20/21,20/21)} \geq 3.33$, $p \leq 0.009$). In the same 2 through 5 dB range, the two diotic conditions were statistically identical at each target sensation level, as were the four dichotic conditions.

C. Discussion

Mean differences from physical isochrony, as seen in Table II, were all smaller than their corresponding standard deviations of the underlying distributions, indicating the absence of a perceptually relevant bias in temporal positioning for any of the lateralization conditions. These standard deviations increased toward detection threshold, indicating that temporal positioning accuracy deteriorated when it became increasingly difficult to detect the noise target in the noise masker, regardless of interaural differences. This general deterioration may be due to the transient behavior of the auditory system, in which a lower signal-to-noise ratio results in shallower transients and a consequential disassociation of the perceived onset with the physical onset (cf. Schütte, 1978).

When comparing standard deviations at each target sensation level, significant differences between diotic and dichotic conditions at target sensation levels 2 through 5 dB were found in the paired comparisons of the data shown in Fig. 3. At these target sensation levels, results of the four dichotic conditions (filled symbols) showed worse temporal positioning accuracy than their diotic reference counterparts (open symbols). Results of the two diotic conditions were similar, as were results of the four dichotic conditions. By maintaining equal sensation levels, these findings led to the conclusion that there was an effect of interaural differences on temporal positioning accuracy at low sensation levels.

Three explanations for this influence of interaural differences on temporal positioning accuracy are possible. First, binaural unmasking of the target at low signal-to-noise ratios

TABLE III. Slopes of the psychometric functions fitted to the threshold detection data (in % correct/dB), at the 70.7%-correct level, for each lateralization condition.

	[C]	[ITD]	[ILD]	[ITLD]	[0]	[90]
Slope	16.1	13.6	12.9	12.4	18.4	10.7

depends on detecting interaural decorrelation. The temporal integration required to process the decorrelation of a dichotic target in a binaural unmasking condition, i.e., binaural sluggishness, may then yield more ambiguous and insufficient temporal cues to accurately position the target's onset.

Second, it may be caused by differences in detectability of the noise target at low sensation levels, just above the detection threshold. If there are differences in the slopes of the psychometric functions of the lateralization conditions at the threshold level, this would mean that in lateralization conditions with steeper slopes, (onset) detection at a specific target level just above threshold is more successful, i.e., it occurs at a higher percentage correct of the psychometric function, than in conditions with shallower slopes.

In order to check whether the difference in temporal positioning accuracy between diotic and dichotic listening conditions was attributable to detectability of the target at low sensation levels, psychometric functions were reconstructed for each lateralization condition from adaptive procedure data of the threshold detection experiment. Individual detection data were first transposed in level to have the same 0-dB target level at the 70.7%-correct point, and then pooled across subjects. A Weibull function was fitted to the data, and slopes at the 70.7%-correct level were calculated. Table III shows the slopes of the psychometric functions at the 70.7%-correct level for each lateralization condition.

From earlier research on the relation between the detectability and the energy of a signal for various interaural phase conditions (e.g. Egan *et al.*, 1969), the shapes of the psychometric function were expected to be comparable, except for an attenuation constant reflecting the binaural masking level difference. However, as can be seen in Table III, slopes at the 70.7%-correct level of both diotic conditions were somewhat steeper (16.4 and 18.4%/dB) than those of the dichotic conditions (13.6, 12.9, 12.4, and 10.7%/dB), meaning that in diotic conditions detection at a fixed level just above the detection threshold was slightly easier than in dichotic conditions. These differences between diotic and dichotic condition slopes (at a maximum ratio of about two, between the [0] and [90] conditions) were, nonetheless, too small to conclusively account for differences between diotic and dichotic conditions in temporal positioning accuracy. At target sensation levels of 2 through 5 dB, the percentage correct at these levels was well above 90% in all six lateralization conditions. So, despite the fact that the slopes of the constructed psychometric functions were different, it was concluded that the differences in the temporal positioning accuracy between diotic and dichotic conditions were not simply an issue of detectability.

When comparing slopes of the dichotic conditions with slope data from previous research (cf. Durlach *et al.*, 1986),

values of the broadband signals here (between 10 and 14%/dB) were considerably higher than those of tonal and narrowband signals in noise maskers (between 3 and 8%/dB in the vicinity of the 75%-correct level). It has been argued before (Hicks and Buus, 2000), that psychometric functions for signals covering several auditory filters are steeper than those for signals covering only one auditory filter, like pure-tone signals, and the obtained results seem to support this expectation. In this light, one may also speculate that steeper slopes in the diotic conditions, compared to the dichotic conditions, were a result of a larger number of excited filters in the former conditions, which brings us to the third possible explanation for the difference in positioning accuracy.

Third, the influence of interaural differences on temporal positioning accuracy may be the consequence of a bandwidth effect. It is known that localization based on fine-structure ITDs only operates in the frequency region below approximately 1.5 kHz. For higher frequencies, the phase of the signal at the two ears cannot be compared anymore, and fine-structure information of the input waveform is gradually lost. Furthermore, sensitivity to changes in the interaural correlation decreases above about 1.5 kHz, when correlation changes are no longer detected via the waveform correlation, but only via the envelope correlation (Koehnke *et al.*, 1986; van de Par and Kohlrausch, 1995). It can therefore be assumed that, in the dichotic target conditions applying interaural time differences, high-frequency parts of the broadband target do not contribute much, and low-frequency parts are dominant in detection and lateralization. Because detection in the other dichotic conditions is also mediated by changes in correlation, it may be concluded that only a small part of the broadband lateralized target contributed to detection just above threshold, in contrast to the diotic condition, in which high-frequency channels contribute to detection as well. The hypothesis is that also in temporal positioning at low sensation levels the effective target bandwidth differs between diotic and dichotic conditions, and that temporal positioning becomes more difficult when the target bandwidth is reduced. If this assumption is correct, it is expected that temporal positioning accuracy in a diotic condition at low sensation levels decreases if the target bandwidth is reduced by low-pass filtering. When the target bandwidth in the diotic condition matches the presumed effective bandwidth in a dichotic condition, the accuracy in these conditions should agree. Furthermore, positioning accuracy in the dichotic condition should not be affected by low-pass filtering, because the removed high-frequency parts did not contribute to positioning the broadband target's onset. To investigate a possible target bandwidth effect, the experiments described in the sections before were repeated with low-pass filtered noise targets.

V. EXPERIMENT 3A

This experiment was defined to measure detection thresholds of diotic and dichotic low-pass filtered noise targets in a diotic broadband noise masker, which were needed
FIG. 4. Mean and standard deviations of the masked threshold levels (in dB, as spectral power ratio between the low-frequency parts of signal and masker) for three lateralization conditions and three target bandwidths, based on data of nine subjects with four measurements each.

as reference data for the next temporal positioning experiment with different target bandwidths at equal sensation levels.

A. Method

The same three-alternative forced-choice procedure with adaptive level adjustment was used to establish individual detection thresholds of low-pass filtered noise targets. Measurements were limited to the [C], [ITD], and [ILD] conditions.

Two different low-pass filtered noise targets were realized by filtering a broadband noise target generated at 70 dB SPL by performing a Fast Fourier Transform, zeroing all signal content above 1.5 kHz or above 750 Hz and applying an inverse Fast Fourier Transform. Target duration was again 50 ms, without on- and offset ramps, but the onset was limited in steepness by the spectral filtering.

This experiment employed a subset of 9 of the 11 subjects from the previous experiments.

B. Results

Results for all subjects were pooled. Figure 4 gives an overview of the mean and standard deviation of the masked threshold levels for each lateralization condition and target bandwidth, based on the data of nine subjects with four measurements each. Threshold levels are expressed in dB as the spectral power ratio between the low-frequency parts of the signal and masker. Displayed are thresholds for the [C], [ITD], and [ILD] conditions for broadband target conditions from the previous threshold detection experiment for the nine subjects involved in the current experiment, and 1500-Hz and 750-Hz low-pass filtered target conditions.

The mean masked thresholds for the low-pass filtered [C] condition were 2.2 dB (1500-Hz low-pass filtered) and 3.5 dB (750-Hz low-pass filtered) higher than for their corresponding broadband condition. Differences for the two di-

chotic conditions were smaller: mean thresholds for the low-pass filtered [ITD] condition were 0.2 dB (1500-Hz low-pass filtered) and 0.7 dB (750-Hz low-pass filtered) lower than for the broadband [ITD] condition, mean thresholds for the low-pass filtered [ILD] conditions were equal to (1500-Hz low-pass filtered) and 0.5 dB lower (750-Hz low-pass filtered) than for the broadband [ILD] condition.

Analysis of variance on the mean thresholds indicated, next to significant differences between lateralization conditions ($F_{(2,72)} = 1437.95$, $p < 0.001$) and between target bandwidths ($F_{(2,72)} = 3.63$, $p = 0.031$), a significant interaction between the lateralization condition and target bandwidth ($F_{(4,72)} = 9.68$, $p < 0.001$). Tukey HSD post-hoc comparisons showed significant differences between all three lateralization conditions, and significant differences between the broadband target condition and the 1500-Hz low-pass filtered target condition. When comparing target bandwidths for each lateralization condition, significant differences were found between the broadband target condition and both low-pass filtered target conditions in the [C] condition.

C. Discussion

Analogous to the previous detection threshold experiment, the noise target in the diotic [C] condition was detected by an increase in the overall level during its presence. The main difference with the previous experiment was that, because of the 1500-Hz and 750-Hz low-pass filtering, also a spectral cue for detection was introduced. Based on earlier experiments about spectral integration (Green, 1958), a theoretical threshold increase of about 1.5 dB for each halving of the number of stimulated auditory filters would be expected when thresholds are expressed as power density. The three target bandwidths used in the current experiment matched about 42 ERB, 19 ERB, and 14 ERB. Thus, the increases observed here agree with the earlier findings cited above.

The detection for the two dichotic conditions was not influenced by the low-pass filtering of the target. This finding suggests that high-frequency parts of the broadband noise target did not contribute to detection in the [ITD] conditions, and is in line with the well-established decrease in BMLD above about 500–700 Hz. Also in the [ILD] condition, low-pass filtering of the noise target did not have a statistically significant effect on the required level for detection. This lack of influence of the high-frequency component may, on a first view, be surprising because interaural level differences were identical in all excited auditory filters. However, detection of the target depended, in addition to level differences, also on changes in the interaural correlation from combining the target and masker. At high frequencies above about 1.5 kHz, only changes in the envelope correlation were available for the binaural analysis. It has been shown by van de Par and Kohlrausch (1995) that for a given target-to-masker ratio, changes in the envelope correlation for Gaussian signals are much smaller than changes in the waveform correlation. Therefore, also in the [ILD] condition, high-frequency channels contributed much less to target detectability than low-frequency channels.

In summary, these detection data support the hypothesis that the "effective" target bandwidth at low sensation levels was indeed much narrower for dichotic targets than for diotic targets.

VI. EXPERIMENT 3B

This experiment was defined to investigate a potential influence of the target bandwidth on temporal onset positioning of broadband noises at low target sensation levels, due to the supposed dominance of the low-frequency region in lateralization and in binaural unmasking.

A. Method

The temporal positioning procedure was repeated for the 1500-Hz and 750-Hz low-pass filtered noise targets, at target sensation levels relative to the new detection thresholds. All experimental settings remained the same as in the previous experiments.

The same noise masker and marker pulses were used: a continuous diotic masker with a level of 70 dB SPL and a number of 50-ms diotic marker pulses with a level of 76 dB SPL, but this time in combination with 50-ms, 1500-Hz, and 750-Hz low-pass filtered targets. The same three lateralization conditions as in the previous experiment were applied to the targets. The noise target was presented at five sensation levels: from 0 through 3 dB relative to detection thresholds of the low-pass filtered noise targets, as measured for each condition and subject, and at 70 dB SPL in quiet.

The same subset of nine subjects participated in the experiment.

B. Results

All 18 adjustments (two adjustments for nine subjects) for each condition (three lateralizations and two bandwidths at five target sensation levels) were pooled, and scanned for severe outliers. Here 8 severe outliers out of the 810 adjustments were removed from the results. Temporal positioning performance of the 1500-Hz and 750-Hz low-pass filtered noise target is shown in Table IV, as are results of the broadband condition from previous experiments for the nine subjects involved in the current experiment. Displayed for each condition are the mean and standard deviation of the adjusted temporal onset positions. The different rows indicate target sensation levels relative to the detection threshold in the noise masker for that particular lateralization condition (0 through 3 dB), and the condition in quiet.

Grand means as shown in Table IV showed that in the diotic conditions both low-pass filtered targets were positioned about 5 ms later than physical isochrony, while in dichotic conditions they were positioned about 5 to 15 ms earlier than physical isochrony. Furthermore, with only one exception, low-pass filtered targets were on average positioned about 5 to 10 ms later than their corresponding broadband targets, in all three lateralization conditions.

The 95%-confidence intervals of the mean onset positions for each lateralization condition, target bandwidth, and target sensation level revealed 8 out of 45 conditions to have means significantly different from physical isochrony. With

TABLE IV. Mean values and, in brackets, standard deviations of the adjusted temporal onset positions (in ms), for each lateralization condition, bandwidth, and sensation level.

one exception, however, standard deviations of the mean onset positions of these eight conditions were larger than their difference from physical isochrony. These biases were considered to be perceptually irrelevant, and a systematic bias from physical isochrony for any of the three lateralization conditions was not supported by this data.

As before, standard deviations were taken for further analysis. Figure 5 gives a graphical overview of standard deviations for the three lateralization conditions, for broadband data from previous experiments for subjects involved in the current experiment, and both low-pass filtered target conditions. Low-pass filtered target conditions showed similar patterns of generally increasing standard deviations with a decrease in the signal-to-noise ratio as did the broadband target conditions. For target sensation levels above 0 dB, all diotic conditions had lower standard deviations than in both dichotic conditions, with the exception of the 750-Hz low-pass filtered [ILD] condition at 1 dB.
FIG. 5. Standard deviations of the adjusted temporal onset position (ordinate) versus target sensation level (abscissa) for broadband, 1500-Hz and 750-Hz low-pass filtered targets in [C], [ITD], and [ILD] conditions. Target sensation levels are relative to the detection threshold in the 70-dB noise masker. The dashed line at 74 ms represents the calculated standard deviation of the random distribution of initial onset positions.

Paired comparisons by the F ratio were again performed to statistically analyze the difference between variances at sensation levels 1 through 3 dB. When comparing performance between the three target bandwidths in the diotic conditions, only one out of nine comparisons showed a significant difference in temporal positioning accuracy (between both low-pass filtered target conditions at 1 dB, $F_{(15,17)}=4.17$, $p=0.008$). Here 9 out of 12 comparisons between the diotic and their corresponding dichotic low-pass filtered target conditions did not show significant differences. Furthermore, temporal positioning accuracy for all target bandwidths of the dichotic conditions was found to be statistically identical.

C. Discussion

As argued, evidence for a target bandwidth effect should be reflected in two observations: first, a decrease in temporal positioning accuracy at equal low target sensation levels in the diotic condition due to the low-pass filtering, potentially matching the performance of the two broadband dichotic conditions if the effective bandwidth is similar, and second, no effect of low-pass filtering on temporal positioning accuracy in both dichotic conditions.

The first prediction was not supported by the data. Although overall narrowband data in the [C] condition were higher than broadband data, these differences were not significant at the three highest target sensation levels in the masker (1 through 3 dB), where the bandwidth influenced was expected to be seen most clearly. The higher narrowband data did, though, result in the disappearance of significant differences between diotic and dichotic conditions. As for the second prediction, the data showed no significant differences in temporal positioning accuracy between the broadband and both narrowband dichotic conditions, as expected.

From finding no effect of low-pass filtering the target in the diotic conditions, it was concluded that a reduction of the effective target bandwidth could not account for the differences in temporal positioning between diotic and dichotic target conditions at low target sensation levels, which were observed in the broadband condition.

Therefore, the most likely explanation for the observed

differences between diotic and dichotic conditions in temporal onset positioning accuracy at low sensation levels is a systematic influence of binaural processing on perception of a sound's onset. This would mean that in the analysis of a spatial auditory scene, for which a precise temporal analysis of onsets is required (e.g., in speech perception), the advantages in signal detectability from the BMLD are opposed by a reduction in temporal resolution due to the sluggishness of processing binaural detection cues.

VII. GENERAL DISCUSSION

An onset can be detected at the moment a certain level of energy, or change in energy, in one or more frequency parts is reached to make it emerge from its acoustic background, and the new sound can actually be perceived. Though this is certainly true for monaural listening, in binaural listening it is more complex. Current experiments not only showed the expected influence of interaural differences on masked thresholds, but also revealed an influence of interaural differences on the perception of a sound's onset at low sensation levels. Differences in directional cues between an acoustic background and an emerging sound provided detection advantages over having identical directional information, at the cost of a reduction of temporal accuracy in binaural unmasking conditions due to binaural sluggishness. The detection threshold is direction dependent, and so is temporal resolution for perception near this detection threshold.

Onset cues that are known to lead to a strong onset effect, resulting in good localization ability (cf. Zurek, 1993), were already shown to be weakened by a decrease in sensation level and to be ineffective for lateralization at a 3 dB sensation level (Goverts *et al.*, 2000). Here it was argued that temporal perception of dichotic onsets itself was degraded at low sensation levels when compared to the perception of diotic onsets at equal sensation levels. This degradation could not be attributed to differences in detectability just above the threshold. Neither could it be attributed to a reduction of effective target bandwidth of dichotic broadband sounds. The decreasing ability to perceive the onset of a lateralized sound at decreasing signal-to-noise ratios may be seen as a systematic effect of binaural unmasking. At low sensation levels, where unmasking of the target occurs by detecting a change in interaural correlation, the required temporal integration for processing binaural information may yield more ambiguous cues with regard to determining the exact target onset than at high sensation levels.

The difference between diotic and dichotic conditions in perceiving a sound's onset suggests that realization of an auditory object (i.e., the detection of an onset and consequential buildup of a new perceptual stream) in binaural unmasking conditions is influenced by the processing of binaural cues. Although an influence of interaural differences on temporal positioning a perceived onset was established here, the results did not provide further insight in how binaural processing and auditory object formation interact. For instance, localization based on interaural differences can still be independent of, and a parallel process to auditory object formation, as suggested by Woods and Colburn (1992).

VIII. CONCLUSION

Onsets influence binaural processing of interaural differences, and interaural differences influence detection. The aim of the current experiments was to investigate the influence of interaural differences on temporal perception of onsets, a perception that is deemed key to the organization of auditory objects from an acoustic scene. The question was addressed whether the availability of different directional information for two sounds changes perception of an onset, compared to a situation without any difference in directional information between the two sounds.

As expected, binaural cues of interaural time differences, interaural level differences and head-related transfer functions improved the detection of a broadband Gaussian noise target within a continuous broadband Gaussian noise masker. The accuracy of temporally aligning a noise target's onset to the regular meter of reference onsets was influenced by the target's sensation level and directional information. With a decrease in sensation level, the ability to temporally position the target's onset accurately was decreased as a consequence of the transient behavior of the human auditory system. At equal low sensation levels, this temporal positioning accuracy decreased faster in dichotic conditions than in diotic conditions. This reduced temporal accuracy in binaural unmasking conditions is seen as a consequence of binaural processing.

This study evaluates the relative contributions of envelope and fine structure cues in both temporal and spectral domains to Mandarin tone recognition in quiet and in noise. Four sets of stimuli were created. Noise-excited vocoder speech was used to evaluate the temporal envelope. Frequency modulation was then added to evaluate the temporal fine structure. Whispered speech was used to evaluate the spectral envelope. Finally, equal-amplitude harmonics were used to evaluate the spectral fine structure. Results showed that normal-hearing listeners achieved nearly perfect tone recognition with either spectral or temporal fine structure in quiet, but only 70%–80% correct with the envelope cues. With the temporal envelope, 32 spectral bands were needed to achieve performance similar to that obtained with the original stimuli, but only four bands were necessary with the additional temporal fine structure. Envelope cues were more susceptible to noise than fine structure cues, with the envelope cues producing significantly lower performance in noise. These findings suggest that tonal pattern recognition is a robust process that can make use of both spectral and temporal cues. Unlike speech recognition, the fine structure is more important than the envelope for tone recognition in both temporal and spectral domains, particularly in noise. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2346009]

I. INTRODUCTION

Acoustic characteristics and their importance for tone recognition have been demonstrated in many tonal languages, including Cantonese (Gandour, 1984), Mandarin (Liang, 1963; Lin, 1988; Whalen and Xu, 1992), and Thai (Abramson, 1978). Results have shown that lexical tones in these languages are distinguished primarily by the change in fundamental frequency (F0) during phonation, although other acoustic properties, such as syllable duration and amplitude contour, also convey tonal information (Whalen and Xu, 1992; Fu *et al.*, 1998; Fu and Zeng, 2000).

Liang (1963) systematically studied the role of spectral cues in Mandarin tone recognition by low- and high-pass filtering the speech stimuli with different cutoff frequencies. He reported that perfect tone recognition can be achieved either with the presence of F0 information with low-pass filtering at 300 Hz or with the harmonic structure with high-pass filtering at 300 Hz. However, in another experimental condition where he only preserved the first formant frequency (300–1200 Hz), performance was still maintained at the 83% level, suggesting the use of formant information in voice pitch perception. Because F0 could still be extracted from harmonics in the first formant frequency range, Liang

also used whispered speech, which contained neither F0 nor harmonic fine structure, to evaluate the contribution of formant information to voice pitch perception. He found that Mandarin tone recognition could be achieved with 60%–80% accuracy (see also Jensen, 1958). Other studies (e.g., Miller, 1961; Howie, 1976), however, showed that tonal contrast was not well preserved with whispered speech. Miller (1961) reported only approximately 40% correct tone recognition in Vietnamese.

In addition to the F0, other information such as temporal envelope was shown to contribute to tone recognition in Mandarin (Fu *et al.*, 1998; Fu and Zeng, 2000; Xu *et al.*, 2002; Whalen and Xu, 1992). Most studies on temporal cues for Mandarin tone recognition concentrated mainly on the envelope cues (e.g., Lin, 1988; Whalen and Xu, 1992; and Fu *et al.*, 1998; Fu and Zeng, 2000; Xu *et al.*, 2002). For Mandarin speech, the amplitude contour cues refer to the slow changes in amplitude and such cues were shown to co-vary with the change of F0 over time in Mandarin. The periodicity cue refers to the fluctuation at a rate, which is directly related to the change in fundamental frequency. Systematically manipulating the amount of the temporal envelope cues, Fu and Zeng (2000) showed that while the duration cues play a minor role in identifying tones, the amplitude contour and periodicity cues contributed significantly to Mandarin tone recognition. Using the noise vocoder processing algorithm described in (Shannon *et al.* 1995), Fu and co-workers (1998) reported that 60%–80% correct tone

recognition in quiet can be achieved, independent of the number of frequency bands. With the amplitude contour cue alone, tone recognition was at 65% correct in the 1-band condition. The additional periodicity cue, however, improved the tone recognition by 10–20 percentage points. The reliance on periodicity cues for tone recognition was also demonstrated by Xu *et al.* (2002), where they reported a trade-off between the amount of spectral information (number of frequency bands) and the low-pass cutoff frequency of temporal envelope extraction. As the low-pass cutoff frequency increased, the number of frequency bands required to achieve the similar tone recognition performance decreased. Xu *et al.* (2002) also created frequency-modulated (FM) pulse trains with F0 contours that mimicked the Mandarin tone contours while eliminating the temporal envelope cue. They reported that without the temporal envelope and duration cues, recognition of vocoder processed FM patterns was poor.

A recent study by Xu and Pfingst (2003) investigated the relative contribution of temporal envelope and fine structure (Hilbert definition) to Mandarin tone recognition. Using the chimearic processing algorithm developed by Smith *et al.* (2002), Xu and co-workers further supported the differential contribution of temporal envelope and fine structure to speech and pitch perception (Smith *et al.*, 2002; Nie *et al.*, 2005). Smith *et al.* found that the temporal envelope cues are sufficient to support speech recognition in quiet, but temporal fine structure is needed for pitch perception. Xu *et al.* (2003) claimed that pitch perception is the common basis for both lexical tone perception and melody recognition by showing that while Mandarin word recognition was determined by the temporal envelope cues, tone recognition was consistent with the temporal fine structure of the chimearized stimuli, with an average of 90.8%, 89.5%, and 84.5% correct for the 4-, 8-, and 16-band conditions, respectively.

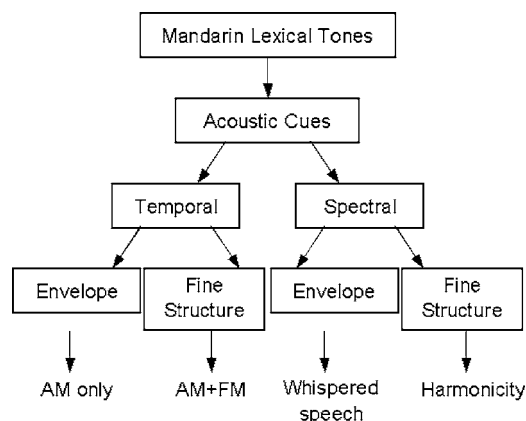
The main goal of this study was to systematically investigate the relative contribution of envelope and fine structure cues to voice pitch perception. First, we extended previous studies by examining the envelope and fine structure cues necessary for tone recognition in both temporal and spectral domains. Second, we evaluated the four acoustic cues for Mandarin tone recognition in both quiet and in noise conditions. To our knowledge, no studies have been done on whether reliable Mandarin tone recognition can be achieved in the presence of noise. There are reasons to believe that the effect of noise on tone recognition differs with the type of cue. The terms temporal envelope and fine structure have been defined loosely in the literature. From the speech perception point of view, Rosen (1992) divided temporal envelope cues into three categories, depending on the rate of amplitude fluctuation: (1) envelope (2–50 Hz); (2) periodicity (50–500 Hz), and (3) fine structure (500–10 000 Hz). However, the formal mathematical definition, based on the Hilbert transform (Hilbert, 1912), the temporal fine structure is defined as the instantaneous phase information of the signal. In the present study, the temporal envelope cues were defined as follows: duration and amplitude contours (amplitude fluctuation between 2–50 Hz) and periodicity cues (50–500 Hz). The temporal fine structure was defined as the instantaneous phase information in the signals provided by


FIG. 1. A block diagram depicts the acoustic cues in the spectral and temporal domains which were evaluated for Mandarin tone recognition.

the Hilbert transform (Hilbert, 1912). As for spectral cues, spectral envelope was defined as the general shape of the spectrum, a smooth curve that passes though the peaks of the spectrum (Hartmann, 1997). For speech stimuli, the spectral envelope represents the filtering properties (or the resonance) in the vocal tract, such as the formant structure of a speech signal. Spectral fine structure, which was also considered as the spectral details, was defined as the detailed frequency components in the power spectrum. The term "spectral fine structure" has been widely used to refer to the spectral details in the power spectrum and we will continue to use this term in this paper. For speech signal, the spectral fine structure represents the source information, which has a harmonic structure for a voiced source and noise structure for an unvoiced source. It should be noted that there are differences between temporal fine structure and spectral fine structure. Consider a simple case of a sinusoidally amplitude-modulated stimulus with a 1000 Hz carrier modulated at a 40 Hz rate; the temporal fine structure is the 1000 Hz carrier of the amplitude-modulated signal, but the power spectrum is composed of three components at 960, 1000, and 1040 Hz.

Figure 1 outlines the four types of acoustic cues that were examined in the study and the stimuli that were used to deliver this information for each experimental condition. We divided the acoustic information into envelope and fine structure in both the temporal and spectral domain. First, for temporal envelope cues, we used the noise vocoder type of processing (Shannon *et al.*, 1995) to manipulate the relative distribution of temporal and spectral information in the speech stimuli. The amount of the temporal envelope information was manipulated by changing the cutoff frequency of the envelope extraction filters, i.e., 50 or 500 Hz in the present study. Previous studies demonstrated that temporal envelope cues contributed significantly to tone recognition in quiet. We hypothesized that the envelope information alone would not be sufficient for tone recognition in noise, due to the nonsaliency of amplitude modulation for pitch perception and also the reduced detectability of amplitude modulation in noise. Second, speech stimuli processed with a novel algorithm developed by Nie *et al.* (2005) were used to assess the importance of temporal fine structure for Mandarin tone recognition. Unlike the noise vocoder processing, which pro-

vided only the amplitude modulation, Nie *et al.* derived additional slowly-varying frequency modulations around the center frequency of each analysis filter and amplitude modulated them with the extracted temporal envelope. We hypothesized that the additional frequency modulation in the speech signal would produce better Mandarin tone recognition. Third, to present only the spectral envelope information in the absence of harmonicity cues, two sets of stimuli were created: naturally recorded whispered speech and synthesized whispered speech using a Linear Predictive Coding (LPC) technique. Lastly, the contribution of spectral fine structure to Mandarin tone recognition was evaluated using stimuli that were the residue of a 14-order LPC processing. While the spectral envelope was presumably flat in this set of stimuli, harmonicity cues were preserved. Based on previous psychophysical findings, we hypothesized that robust voice pitch perception can be determined by the harmonicity cues alone and that spectral envelope cues without the harmonic structure only convey limited voice pitch information.

II. MANDARIN TONE RECOGNITION WITH TEMPORAL ENVELOPE CUES

A. Methods

1. Subjects

Five native Mandarin speakers (S1–S5) participated in the experiment. All of them were females, with ages ranging from 22 to 33. All subjects had normal hearing sensitivity below 20 dB HL at octave frequencies between 125 and 8000 Hz bilaterally.

2. Stimuli

The test material included 100 Mandarin words consisting of 25 syllables with four lexical tones for each syllable (Wei *et al.*, 2004). The original stimuli were recorded from one adult male and one adult female Beijing Mandarin speaker, resulting in a total of 200 words for each test condition. Recording was carried out in a double-walled sound-treated booth and the stimuli were digitally recorded through a preamplifier to the computer at a sampling rate of 22 050 Hz using COOL EDIT PRO (2.0) software. All stimulus waveforms were then adjusted to the same root-mean-squared (rms) amplitude.

Speech-shaped noise was used for the noise conditions. Two samples of speech-shaped noise were created, one for the male speaker and one for the female speaker, by summing the speech tokens (100 words) from either the male or female speaker and then processing them using the 10-order LPC to extract the long-term spectrum of the summed stimuli. While the rms amplitude of speech waveforms was fixed, the rms of the noise waveform varied to achieve the desired signal-to-noise ratios (−10, −5, 0, +5, and +10 dB) tested in this experiment.

The original speech stimuli, combined with the original speech-shaped noise in the noise conditions (male noise combined with the male speech tokens, and female noise with the female speech tokens), were subjected to further processing to contain either temporal envelope cues alone or additional coarse spectral cues via a cochlear implant simu-

lation program similar to that used in Shannon *et al.* (1995). The original broadband (80–8800 Hz) stimuli were first pre-emphasized by a first-order high-pass Butterworth filter at 1200 Hz. The pre-emphasized stimuli were then divided into 1 or 8 frequency bands using sixth-order elliptical bandpass filters. The cutoff frequencies of each band were determined by approximating equal cochlear distance for each band according to the Greenwood map (1990). The corner frequencies for the 1-band processing condition were 80 and 8800 Hz and for the 8-band processing condition were 80, 220, 440, 780, 1300, 2100, 3500, 5500, and 8800 Hz. The temporal envelope was then extracted from each analysis band using two different methods: (1) Hilbert transformation followed by low-pass (LP) filtering (elliptical IIR filters) at 50 or 500 Hz (−6 dB/octave) to smooth out the envelope, or (2) full-wave rectification followed by low-pass filtering (elliptical IIR filters) with cutoff frequency at 500 Hz (−6 dB/octave). While the periodicity cues were preserved in the temporal envelope with the 500 Hz cutoff frequency, it was reduced in the 50 Hz cutoff condition. This envelope signal was then used to modulate white noise, which was then bandpass filtered with the same analysis filters used on the original signal. Stimuli were resynthesized by summing these envelope-modulated narrow-band signals. Note that the temporal envelope fine structure (Rosen's definition) could be preserved in the lower frequency bands with the full-wave rectified envelope but not in the Hilbert envelope.

3. Procedure

All tests were performed in a double-walled sound-treated booth and the stimuli were presented to the listeners monaurally through TDH-49 headphones. The target original and processed speech were presented at a fixed level of approximately 65 dBA. All subjects were first presented with a block of original stimuli followed by four blocks of stimuli processed with the Hilbert envelope (2 spectral conditions ×2 LP cutoffs). Stimuli with higher numbers of frequency bands and higher LP cutoffs were tested first. The most difficult condition (i.e., one-band with 50 Hz LP cutoff) was tested last. Each block of stimuli consisted of one quiet and five different noise conditions. Within each block, the quiet condition was presented first followed by the noise conditions from the highest SNR (10 dB) to the lowest SNR (−10 dB). Therefore, the better performance in the higher SNR conditions compared to the lower SNRs cannot be due to the learning effect. To investigate the effect of the temporal envelope extraction techniques on Mandarin tone recognition, subjects were then further tested with two extra sets of processed stimuli (1-band and 8-band) which contained the envelopes that were extracted using the full-wave rectification and low-pass filtering technique.

The experiment was conducted using a four-alternative, forced-choice procedure, in which four Chinese characters with the same syllable and the tonal marking for each character ("−" for Tone 1, "/" for Tone 2, "∨" for Tone 3, and "\" for Tone 4) were displayed on a computer screen for each trial. The 200 words in the test battery were presented randomly in each experimental condition and subjects were
FIG. 2. Average tone recognition scores as a function of signal to noise ratio. Panel (a) shows the tone recognition performance with the Hilbert envelope. Dashed line (- - -) indicates performance with original stimuli. Square symbols represent the 1-band conditions and the circles represent the 8-band conditions. Open symbols indicate the 500-Hz LP conditions and the closed symbols indicate the 50-Hz LP conditions. Panel (b) shows the tone recognition performance with the full-wave rectified envelope in the 8-band (circles) and 1-band (squares) conditions. The vertical bars represent the standard error of the mean.

asked to choose the Chinese characters on the screen that corresponded to the tone they heard. Visual feedback was given after each response.

B. Results

Figure 2(a) shows the average percent correct tone recognition scores as a function of SNR for the original stimuli (dashed line) and for the four processed conditions with the Hilbert envelope (squares: 1-band conditions; circles: 8-band conditions; solid symbols: 50-Hz LP cutoff; open symbols: 500-Hz LP cutoff). On average, tone recognition with original stimuli was maintained at 99%–100% correct from quiet to −5 dB SNR. Performance decreased by 23 percentage points when the SNR was further reduced to −10 dB. Tone recognition was significantly poorer in all of the processed conditions compared to the original stimuli in quiet and at all noise levels ($p < 0.001$).

A three-way repeated-measures ANOVA was performed to examine the following three factors: noise, spectral details (1-vs 8-bands), and temporal details (50- vs 500-Hz LP cutoff). Unlike the original condition in which performance plateaued at −5 dB SNR, tone recognition performance for the four processed conditions increased monotonically as a function of SNR ($p < 0.001$) from nearly chance at −10 dB SNR for all conditions to 86%, 81%, 71%, and 58% correct in quiet for the 8-band 500-Hz LP, 1-band 500-Hz LP, 8-band 50-Hz LP, and 1-band 5-Hz LP conditions, respectively. Significant interactions were observed between the temporal and spectral details [$F(5,20)=15.0, p<0.01$], the temporal details and SNRs [$F(5,20)=13.7, p<0.01$], and spectral details and SNRs [$F(5,20)=8.5, p<0.01$], indicating that the relative importance of temporal and spectral cues for tone recognition differed in quiet and in noise. In general, tone recognition performance improved with 8 frequency bands compared to a single band [50-Hz LP: $F(1,4)=129.1, p<0.001$; 500-Hz LP: $F(1,4)=43.1, p<0.01$]. The presence of periodicity cues also contributed significantly to tone recognition independent of the amount of spectral details [1-band: $F(1,4)=151.8, p<0.001$; 8-band: $F(1,4)=583.1$,

$p<0.001$]. When both the periodicity and spectral cues were available (8-band 500-Hz LP), tone recognition performance was superior to the other three conditions in both quiet and noise (except for the −10 dB SNR), but was the worst when both cues were absent (1-band 50-Hz LP). With either the periodicity (1-band 500-Hz LP) or spectral (8-band 50-Hz) cue, the pattern of performance differed in quiet and in noise. In quiet, the 1-band 500-Hz LP condition produced significantly better tone recognition than the 8-band 50-Hz LP condition [$F(1,4)=47.6, p<0.01$], but was worse in the 0 dB [$F(1,4)=14.4, p<0.05$], and −5 dB [$F(1,4)=8.3, p<0.05$] SNR conditions.

Figure 2(b) depicts the average tone recognition with full-wave rectified envelopes. Compared to the results in Fig. 2(a) with the 500-Hz LP conditions, we can see that tone recognition performance with Hilbert envelopes and full-wave rectified envelopes was essentially identical in both quiet and noise [1-band: $F(1,4)=0.2, p>0.05$; 8-band: $F(1,4)=1.0, p>0.05$], suggesting that listeners were unable to use the envelope fine-structure to perceive voice pitch. In general, the difference between Hilbert and full-wave rectified envelopes was less than 4 percentage points in quiet and at all SNRs for both the 1-band and the 8-band conditions.

III. MANDARIN TONE RECOGNITION WITH SLOWLY-VARYING AMPLITUDE AND FREQUENCY MODULATIONS

A. Methods

1. Subjects

Four additional normal-hearing native Mandarin speakers (S6–S9) participated in this experiment. They were three females and one male, with age ranging from 26 to 41 years. All subjects passed the hearing screening at 20 dB HL at frequencies between 125 and 8000 Hz bilaterally.

2. Stimuli

The recorded Mandarin speech tokens from both the male and female speakers in Experiment 1 were used in this

experiment. The original stimuli were processed in two different ways to extract the slowly-varying temporal envelope (amplitude modulation) alone or the amplitude modulation with additional slowly-varying frequency modulation information.

To produce stimuli with amplitude modulation (AM) cues alone, the signal processing scheme in Experiment 1 was used to extract the Hilbert envelope from 1 to 32 frequency bands in one-octave steps, which produced 1, 2, 4, 8, 16, and 32 subbands. The extracted temporal envelopes were then low-pass filtered at 500 Hz to preserve the periodicity cues in the original speech stimuli.

In addition to the amplitude modulation (AM) information, frequency modulation (FM) was extracted using the algorithm (Frequency-Amplitude-Modulation-Encoding Algorithm) developed by Nie *et al.* (2005) (see also Vongphoe and Zeng, 2005; Stickney *et al.*, 2005 for the description of this algorithm). In this algorithm, the slowly-varying AM was extracted in a similar manner as in the noise vocoder (Shannon *et al.*, 1995) described above. The slowly-varying FM was extracted by first removing each analysis band's center frequency through phase-orthogonal demodulators as used in phase vocoders (Flanagan and Golden, 1966). Two low-pass filters were then used to restrict the FM bandwidth and the FM rate. The bandwidth of the FM was restricted to 500 Hz or the bandwidth of the analysis bands whichever was less, and the FM rate was fixed at 400 Hz. To resynthesize, the slowly-varying FM signal from each subband was used to frequency modulate a sinusoid with a frequency equal to the center frequency of the subband and then the AM signal was used to amplitude modulate the frequency modulated sinusoid. The resynthesized AM and FM signals from each band were summed to recover the original signal. Unlike the fine-structure mathematically defined by the Hilbert transform, in which the obtained instantaneous frequency varies rapidly and over a broad range, the FM encoded using this technique is slowly-varying up to 400 Hz and band-limited to 500-Hz or to the critical bandwidth of the analysis bands.

3. Procedure

Presentation of the stimuli and the experimental setup were identical to those described in Experiment 1. All subjects were presented with a block of original stimuli first, followed by six blocks of AM+FM stimuli, and finally were tested with six blocks of AM-only stimuli. The six blocks within each processed condition (AM-only or AM+FM) corresponded to the six different number of frequency bands conditions from 1 to 32 bands and the blocks were presented in order from highest (32 bands) to lowest number of frequency bands (1 band). Similar to Experiment 1, each block of stimuli consisted of the quiet and different noise conditions and the subjects were presented with the quiet stimuli first followed by the noise conditions from the highest SNR to the lowest SNR. Five noise SNR conditions (−10, −5, 0, +5, +10 dB) were tested for AM-only processed stimuli whereas an additional SNR (−15 dB) was tested for both the original and the AM+FM processed stimuli.

B. Results

Figure 3 shows an average tone recognition performance with the original stimuli [the dashed line in top-left panel of Fig. 3(a)], the AM+FM stimuli (open triangles), and the AM stimuli (filled circles). Similar to the results revealed in Experiment 1, the average tone recognition for the four subjects in this experiment with the original stimuli increased from the chance level performance at −15 dB SNR to 73% correct at −10 dB SNR and then plateaued at 99% correct at −5 dB SNR. Figure 3(a) shows the tone recognition performance as a function of SNR with each panel representing a different number of frequency bands. First note that in the 1-band AM-only condition, tone recognition performance decreased monotonically from 79% correct in quiet to 51% at 0 dB SNR and approached the chance level at −5 dB SNR. While tone recognition was essentially identical between the 1-band and 2-band conditions, tone recognition performance improved significantly as the number of frequency bands further increased in quiet [$F(5,15)=25.6$, $p<0.005$] and at all noise levels [10 dB:$F(5,15)=35.5$, $p<0.005$; 5 dB: $F(5,15)=20.2$, $p<0.05$; 0 dB:$F(5,15)=38.0$, $p<0.005$; −5 dB:$F(5,15)=31.3$, $p<0.005$; −10 dB:$F(5,15)=20.8$, $p<0.05$].This finding is consistent with that reported in Experiment 1. Detailed spectral information, as much as 32 frequency bands, was required to produce tone recognition performance close to the original stimuli. Tone recognition with 32 bands decreased from 99% correct in quiet to 62% at −5 dB SNR and finally to 38% at−10 dB SNR. However, the performance difference between the original and the 32-band AM-only stimuli was significant from −10 to 5 dB SNRs [−10 dB:$F(1,3)=376.4, p<0.001$;−5 dB:$F(1,3)$ $=189.6, p<0.005$; 0 dB:$F(1,3)=177.0, p<0.005$; 5 dB: $F(1,3)=49.0, p<0.01$]. The difference was 5, 15, 38, and 36 percentage points for 5, 0, −5, and −10 dB SNRs, respectively. In contrast, with additional FM, only 4 bands were necessary to achieve performance similarly to the original stimuli for both quiet and noise conditions. Significant performance difference between the 4-band AM+FM and the original stimuli was only 2 percentage points at 0 dB SNR [$F(1,3)=49.0, p<0.01$], 13 percentage points at −5 dB SNR [$F(1,3)=35.4, p=0.01$], and 18 percentage points at −10 dB SNR [$F(1,3)=161.5, p=0.001$].

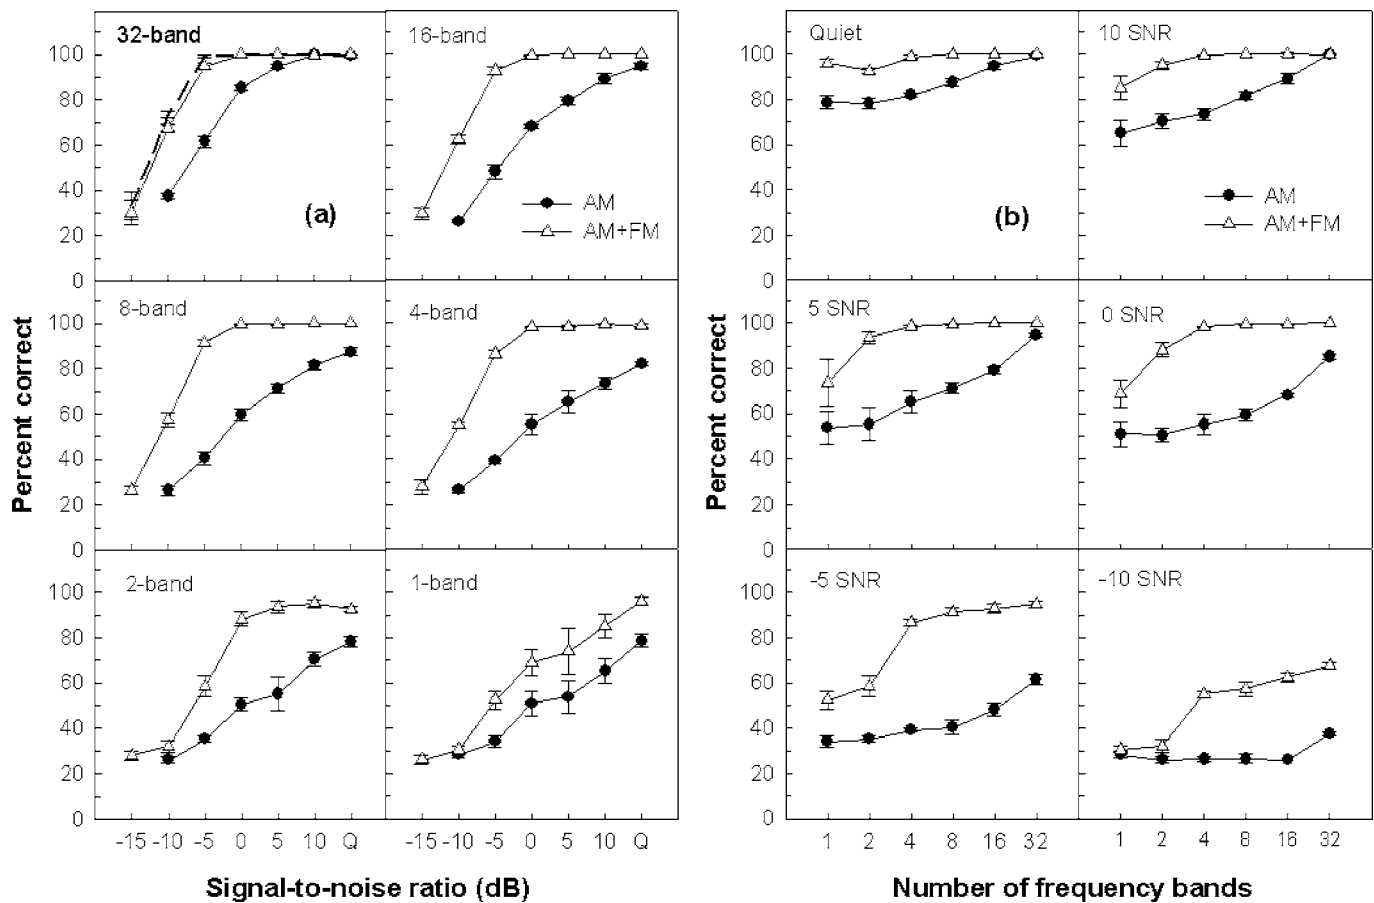
The difference between the AM+FM and the AM-only conditions was also significant ($p<0.05$) in quiet and at all SNRs independent of the number of frequency bands. For a better visual comparison, the same set of data is replotted in Fig. 3(b) in which average scores are shown as a function of number of frequency bands with each panel representing the different SNR conditions. In general, averaged across different numbers of frequency bands, the differences between AM-only and AM+FM conditions increased from 11 to 36 percentage points as the amount of noise increased from the quiet condition to the −5 dB SNR condition. It is noted that performance with 32 frequency bands in the AM-only condition resembles that observed with two bands in the AM+FM condition, suggesting the contribution of FM cues.


FIG. 3. Average tone recognition with original stimuli [dashed lines in panel (a)], AM alone (solid circles), and AM+FM (open triangles). Panel (a) shows recognition scores as a function of signal-to-noise ratio with individual panels indicating different number of frequency bands. Panel (b) shows the same set of data, but is plotted as a function of number of frequency bands. Individual panels represent different signal-to-noise ratio conditions. The vertical bars represent the standard error of the mean.

IV. MANDARIN TONE RECOGNITION WITH SPECTRAL ENVELOPE CUES

A. Methods

1. Subjects

The same five normal-hearing native Mandarin speakers (S1–S5) that participated in Experiment 1 also participated in this experiment.

2. Stimuli

The same Mandarin word list from Experiment 1 was used in this experiment. Three sets of stimuli were created to evaluate the contribution of spectral envelope and the harmonicity cues to Mandarin tone recognition. Two of the sets, which contained the spectral envelope cues were (1) naturally recorded whispered speech and (2) synthesized whispered speech.

Natural whispered speech was recorded from the same male and female speakers used in Experiment 1, resulting in a total of 200 whispered speech tokens. The recording procedures were identical to those described in Experiment 1. All speech waveforms were adjusted to have equal rms amplitude. Note that the amplitude contour patterns in the whispered speech were similar to those observed in their phonated counterparts. While the harmonic structure of the

phonated speech is replaced by a noise source due to the opening of the vocal folds, the filtering properties (or resonance) of the vocal tract are preserved. In other words, whispered speech contained the formant structures that are similar to its phonated counterparts (von Helmholtz, 1863; Thomas, 1969; Hingashikawa and Minifie, 1999).

Synthesized whispered speech was created by extracting the spectral envelope of the original phonated speech recorded in Experiment 1, using a 14-order LPC technique. Signal processing was performed on every 10-ms time window with a 5-ms overlap. The extracted spectral envelope was then used to modulate with white noise.

To evaluate the contribution of spectral fine structure (i.e., harmonicity cues) to tone recognition, another set of stimuli which contained only the F0 and the harmonics of the original phonated speech was created. The F0 and harmonics of the original phonated speech were extracted as the by-product of the 14-order LPC processing, which was used for creating the synthesized whispered speech. With this processing, the F0, the harmonic, and the phase spectrum of the original stimuli were preserved, but the spectral envelope was flat with no identifiable formant peaks.

3. Procedure

Presentation of the stimuli and the experimental setup were identical to those described in Experiment 1. All sub-
FIG. 4. Mean tone recognition scores with spectral envelope and harmonicity cues. Tone recognition scores with original stimuli (dashed line) from Experiment 1 are replotted in this figure for comparison. Solid circle and triangle symbols represent the natural whispered speech and synthesized whispered speech using the LPC technique, respectively. Open squares represent stimuli with only harmonicity cues. The vertical bars represent the standard error of the mean.

jects were presented with a block of original stimuli first, followed by three blocks of experimental stimuli (natural whispered speech, synthesized whispered speech, and speech with only harmonicity cues). Each block of stimuli consisted of the quiet and five different noise conditions and the subjects were presented with the quiet stimuli first followed by the noise conditions from the highest SNR to the lowest SNR. The noise used for the whispered speech was created by summing all the whispered speech tokens from the male speaker or the female speaker (see noise generating procedures in experiment 1). As for the other two conditions, phonated target speech underwent LPC processing before mixed with noise.

B. Results

Figure 4 shows the average tone recognition scores for the natural whispered speech (circles), synthesized whispered speech (triangles), and speech stimuli with harmonicity cues alone (squares). Mean recognition scores with original stimuli from Experiment 1 are included to facilitate comparison. First note that tone recognition performance with harmonicity cues alone was essentially identical to that with original stimuli at all SNR conditions ($p > 0.05$). Second, tone recognition scores with primarily spectral envelope cues (both natural and synthesized whispered speech) were significantly poorer ($p < 0.0001$) than those obtained with harmonicity cues alone in quiet and at all SNRs. Tone recognition with spectral envelope cues increased monotonically as the SNR increased from chance level performance at −10 dB SNR to 72% and 67% correct in quiet for the natural whispered and synthesized whispered speech, respectively. Third, post-hoc pairwise comparisons with Bonferroni correction revealed that subjects performed similarly ($p > 0.05$) between the natural whispered speech and synthesized whispered speech, except in the quiet condition [$F(1,4)=32.7, p=0.005$] where the natural whispered speech

produced about 5 percentage points better recognition than the synthesized speech.

V. DISCUSSION

A. Comparison with previous studies

Consistent with previous studies (e.g., Fu *et al.*, 1998; Xu *et al.*, 2002), listeners in our study were able to use solely the slowly-varying temporal envelope information, i.e., the amplitude contours and durational cues, to identify the tonal patterns with accuracy of about 60% in the absence of any spectral contents (1-band 50-Hz LP) in quiet. Tone recognition was further improved with additional periodicity cues (1-band 500-Hz LP) by about 20 percentage points. The present results are also in agreement with previous studies of the effect of the number of bands on tone recognition. Both the present and previous results found that tone recognition was essentially the same between one and two frequency bands but improved as the number of frequency bands was increased to 4–8 bands. Using the more challenging stimuli of monosyllabic words with equal durations, Xu *et al.* (2002) found that tone recognition continued to improve up to 12 bands, the highest number of bands tested in their study. In our study, we found further improvement up to 32 bands, with such improvement being particularly apparent in noise.

Xu *et al.* (2002) also reported the existence of a trade-off between temporal and spectral cues for Mandarin tone recognition in quiet. They showed that subjects can achieve a similar tone recognition performance using either a small number of frequency bands combined with a higher temporal envelope cutoff frequency, or a larger number of bands, but with a low envelope cutoff frequency. Here, we observed another relationship—a complementary contribution between temporal periodicity cues and spectral cues for tone recognition between quiet and noise conditions. Note that while the 1-band 500-Hz LP condition produced better tone recognition performance than in the 8-band 50-Hz LP condition in quiet, a reverse pattern was observed in noise. This complementary contribution between periodicity cues and spectral cues suggests that periodicity cues are more important than coarse spectral cues for Mandarin tone recognition in quiet, but they are more susceptible to noise compared to spectral cues.

B. Relative contribution of envelope and fine structure cues to tone recognition

Our study demonstrated that pitch perception was dominated by fine structure rather than the envelope cues. Although tone recognition can be achieved by all four cues in quiet, fine structure cues play a more important role than the envelope cues in noise. In quiet, spectral or temporal envelope cues alone produced relatively low (70%–80% correct) tone recognition performance, but almost perfect performance was observed with spectral or temporal fine structure cues. The difference in performance between envelope and fine structure cues is even greater in noise. From −10 to 10 dB SNR, while tone recognition was still maintained at almost perfect performance level with spectral or temporal fine structure cues, it was 30–60 percentage points lower

with spectral or temporal envelope cues, suggesting that envelope cues are less salient and are more susceptible to noise in voice pitch perception. It should be noted that spectral cues are available in the lower numbers of bands conditions in our AM+FM stimuli and they could be used by our normal-hearing subjects to perceive pitch. Nevertheless, the improved tone recognition in noise with higher numbers of bands (i.e., 16- and 32-bands) is likely to be attributed to the fine timing information within as well as across bands.

The importance of fine structure cues for Mandarin tone recognition is consistent with previous psychophysical findings on pitch perception with pure tones and complex tones. Pitch of a harmonic complex can be extracted based on the place cue (Goldstein, 1973; Terhardt, 1974), or the timing cue (Licklider, 1951; Schouten *et al.*, 1962), or both (Oxenham *et al.*, 2004). Salient pitch percepts can be elicited on the basis of fundamental frequency and the lower resolved harmonics (Ritsma, 1967). Thus, it was not surprising that Mandarin tone recognition was much improved with harmonicity cues compared to spectral envelope cues alone.

In contrast to the fine structures, the saliency of the pitch provided by the temporal envelopes is rather weak, as demonstrated in previous findings on melody recognition with sinusoidally amplitude-modulated noise (Burns and Viemeister, 1981) and modulation frequency discrimination for amplitude-modulated stimuli (Formby, 1985; Grant *et al.*, 1998). The susceptibility of temporal envelope cues to noise in tone recognition could be attributed to the low salience of temporal envelope pitch and the reduced detectability of amplitude modulation in noise.

C. Contribution of formant frequencies to tone recognition

1. Processed speech with temporal envelope cues

Although we have established the role of coarse spectral cues for Mandarin tone recognition, the type of spectral information in this processed speech that enabled the enhancement of tone recognition has not yet been determined. The most important type of spectral information is the F0 and the harmonics. In our recorded speech, the F0 variation patterns were consistent with those reported previously. An acoustical analysis of the F0 of the recorded stimuli was conducted using the correlation algorithm of the TFR™ software.[1] For the male speech, the average F0 of Tone 1 was 174 Hz, the F0 of Tone 2 rose from 113 to 193 Hz, Tone 3 initially fell from 114 to 87 Hz, then rose to 147 Hz, and Tone 4 fell from 189 to 85 Hz. The female speech exhibited similar pitch contours, but with a higher F0 for all tones. In the 8-band AM-only processed speech, the F0 differences among the four tones may not be well represented, due to the fact that the low harmonics were not resolved by the low-frequency analysis filters. Therefore, it was unlikely that better tone recognition with 8-band processing was due to the better encoding of the F0 and the harmonics in the original speech stimuli.

Another type of spectral cue present in speech is the formant structures. Unlike the harmonics, formant information of speech could be coarsely represented in the 8-band

processed stimuli and in turn, vowel recognition performance could be achieved with at least 80% accuracy in quiet (Friesen *et al.*, 2001). However, how is this formant information able to convey differences in Mandarin tones for the same syllable? A careful examination of the formant frequencies of the original recorded single-vowel syllables (/ma/, /pʰɔ/, /kʰɛ/, /ɕi/, /du/, /dʐy/) from the male speaker[2] measured by both the TFR™ software and by a speech synthesis and analysis program PRAAT (Boersma and Weenink, 2005) revealed that:

(1) Formant structures are different for different lexical tones of the same syllable. This finding is supported by the recent articulatory and acoustic data reported in Erickson *et al.* (2004). Using an electromagnetic articulatograph, Erickson and co-workers demonstrated that the jaw and tongue position were significantly more retracted for Tone 3 than for Tone 1 for the vowel /a/, resulting in a higher F1 frequency for Tone 3.
(2) The patterns of difference in formants among tones are not the same for all syllables. In our measurement, F1 frequency was higher for Tone 3 than for Tone 1 for the low vowel, but the pattern of difference was inverted for high and mid vowels. The difference in F1 between Tone 1 and Tone 3 was as large as 100 Hz, particularly for the high vowels. The second formant (F2), however, was consistently higher for Tone 1 than Tone 3 in all vowels, and the difference reached 200 Hz for the back vowels.
(3) Even with a single vowel, the formant frequencies changed considerably over time and the patterns of change differed for different tones. The interesting finding was that the direction of formant changes did not covary with the F0.

The above findings suggest that there may be a possible coupling between the source (vocal folds vibration) and the filter (vocal track configuration) in the articulatory system. This is different from the speech production mechanism proposed in the tradition source-filter theory (Fant, 1960). The source-filter model assumed a linear system in which there was disassociation between the source and the filter.

The considerable difference between F1s among the four lexical tones and the changing frequency of the formants over time for each tone could be represented in an 8-band processed condition. Also, one cannot rule out the possibility that the excitation patterns arising from different filters, due to the overlapping of the filters, may provide additional non-pitch cues for tone recognition. Since the F1 differences among the tones were larger for some vowels (e.g., high vowels) than for others (e.g., mid vowels), it would be of interest to see how tone recognition performance with processed stimuli differed with different syllables. Such information, however, was not recorded in our result matrix during our experiment. Further examination of the effects of vowels on tone recognition is needed.

2. Whispered speech

The contribution of formant frequencies to tone recognition was further supported by our findings with whispered

speech stimuli. Previous studies on whispered speech demonstrated that listeners can (1) match the pitch of whispered vowels to some standard frequency using only the formant frequency information [F1: von Helmholtz (1863); F2: Thomas (1969); F1 and F2: Hingashikawa and Minifie (1999)]; (2) identify speaker's sex with approximately 70%–80% correct performance (Lass *et al.*, 1976; Tartter, 1991); and (3) achieve 60%–80% correct tone recognition in other languages, including Norwegian, Swedish, Slovenian, and Mandarin Chinese (Jensen, 1958). In particular, our results are consistent with Jensen's findings, in which listeners can achieve about 60%–70% correct for whispered speech in quiet. Although most of the studies on whispered speech suggested the contribution of formant information to voice pitch perception, a study by Remez *et al.* (1997) on sinewave speech did not show this relationship. Remez *et al.* (1997) used three sinusoids tracking the lowest three formants of a natural speech and found that normal-hearing listeners could correctly identify the both the speech and speaker. However, they found that the formant (F1 and F2) differences between speakers and the error patterns for speaker identification were poorly correlated, suggesting that listeners did not rely on formant information to identify speakers. They concluded that listeners might be able to use other linguistic features, such as idiolect, dialect, or style differences to identify the talkers. The disagreement between sinewave speech and the whispered speech remains determined.

Acoustical analyses on whispered Mandarin speech were conducted and results showed that the differences of F1 and F2 among the four tones were similar between the whispered speech and their phonated counterparts[3]. These findings were also evidenced in a recent study by Li and Xu (2005). Similar to the phonated speech, both the durational and amplitude contour cues are also available in whispered speech. One might claim that the significant Mandarin tone recognition performance with whispered speech could be attributed to solely the contribution of the temporal envelope cues. However, we argued that the durational and amplitude contour cues alone could not account for relatively high levels of tone recognition in both quiet and noise. The 1-band 50-Hz LP condition yielded a performance level at about 58% in quiet, 14 percentage points lower than the whispered speech and the difference between whispered speech and 1-band 50-Hz LP speech was as large as 21 percentage points at 5 and 0 dB SNR (see Fig. 5). The differences in F1 and F2 among the four tones could be better detected by normal-hearing listeners in the whispered speech compared to the 8-band processed speech. Surprisingly, tone recognition performance was essentially the same between the 8-band 50-Hz LP condition and the whispered speech in both quiet and in noise (see Fig. 5). In addition to the percent correct scores, the error patterns between the 8-band processed and natural whispered speech were similar. These findings suggest that (1) listeners used the same cues to perform the task in both conditions, and (2) well-defined formant information, as in whispered speech, was not necessary for Mandarin tone recognition.

The further improvement beyond 8 frequency bands, i.e., the 16- and 32-band conditions in Experiment 2, may be
FIG. 5. Mean tone recognition scores for original (dashed line), natural whispered speech (solid diamonds), processed stimuli with 8-band 50-Hz LP (solid triangles), 1-band 50-Hz LP (open squares), and stimuli with harmonicity cues alone (open circles). The vertical bars represent the standard error of the mean.

attributed to the resolvability of the harmonics. Qin and Oxenham (2005) investigated the F0 discrimination limen (F0DL) for a harmonic complex processed by a noise vocoder similarly to Shannon *et al.* (1995). The F0DLs were found similar from 1 to 8 frequency bands and improved considerably in the 24- and 40-band conditions. They concluded that the better F0DLs with the higher number of frequency bands were associated with the spectral cues, and the poorer F0DLs with fewer number of frequency bands were the result of non-salient pitch associated with the envelope cues.

D. Implication for cochlear-implant design

Except for the analog processing strategy, current cochlear implant processing provides only the temporal envelope information from several frequency bands. Both temporal and spectral fine structures are not explicitly encoded in these processing schemes. A study by Wei *et al.* (2004) on Mandarin tone recognition in cochlear-implant listeners measured performance as a function of number of electrodes. They revealed that implant listeners performed only at average 57% correct with a range of 25%–71% correct when listening with a 20-electrode map, considerably lower than the normal-hearing performance even at the 1-band AM-only conditions observed in the present study. Although, the appropriateness of using standard noise-band vocoders as an acoustic model for pitch perception in cochlear implants is being questioned (Laneau *et al.*, 2006), we would still expect implant listeners to be able to perform better than the 1-band AM-only condition given the potential limitation on envelope-periodicity pitch cues in the vocoder. The inability of cochlear-implant listeners to perceive lexical tones was also documented in other languages. Ciocca *et al.* (2002) studied a group of early-deafened Cantonese-speaking cochlear-implant children. They reported that very few of their cochlear implantees performed above the chance level in a two-alternative choice tone identification task.

Improving current cochlear-implant performance in pitch perception can be accomplished by better encoding the temporal and/or spectral fine structures. The present study on Mandarin tone recognition with additional slowly-varying frequency modulation showed significant improvement in Mandarin tone recognition even with a fewer number of frequency bands and also in noisy conditions. One potential problem of adding temporal fine-structure in cochlear implants is that the timing information may not be mapped at the right place along the cochlea in electric hearing, which in turn would still not elicit the salient pitch necessary for voice pitch and music perception. Oxenham *et al.* (2004), using transposed stimuli that resembled the low-frequency pure tones, showed that frequency discrimination with the transposed tones, presented at a higher-frequency place, were considerably poorer than for the pure tones.

Pitch perception in cochlear implants can also be improved with better frequency-to-electrode mapping and/or increasing the number of functional channels. Our results, together with Qin and Oxenham (2005), showed that tone recognition and F0 discrimination improved as increasing the number of frequency bands.

VI. CONCLUSIONS

Mandarin tone recognition was measured in a group of normal-hearing listeners with the goal to understand the underlying mechanisms for voice pitch perception. Four types of speech stimuli were created to evaluate the relative contributions of temporal and spectral envelope and fine structure cues to tone recognition. The main findings are:

(1) Listeners can achieve nearly perfect tone recognition performance with spectral or temporal fine structure cues alone in quiet, but only 70%–80% correct with the envelope cues alone. In noise, the performance difference between fine structure and envelope cues can range from 30 to 60 percentage points from −10 to 10 dB SNR.
(2) While envelope cues, either in the spectral or temporal domain, are sufficient for speech recognition in quiet, fine structure is critical for voice pitch perception in noise.
(3) There exists a complementary contribution of temporal and spectral envelope cues to tone recognition. While the 1-band 500-Hz LP condition produced better tone recognition than the 8-band 50-Hz LP condition in quiet, a reverse pattern was observed in noise. This suggests that temporal envelope cues are susceptible to noise, but spectral cues are more resistant to noise.
(4) Differences in formant frequencies were observed among the four tones for the same vowel in Mandarin speech, suggesting a potential coupling between F0 and formant frequencies.

Aerodynamically and acoustically driven modes of vibration in a physical model of the vocal folds

Zhaoyan Zhang, Juergen Neubauer, and David A. Berry

UCLA School of Medicine, 31-24 Rehabilitation Center, 1000 Veteran Avenue, Los Angeles, California 90095-1794

In a single-layered, isotropic, physical model of the vocal folds, distinct phonation types were identified based on the medial surface dynamics of the vocal fold. For acoustically driven phonation, a single, in-phase, x-10 like eigenmode captured the essential dynamics, and coupled with one of the acoustic resonances of the subglottal tract. Thus, the fundamental frequency appeared to be determined primarily by a subglottal acoustic resonance. In contrast, aerodynamically driven phonation did not naturally appear in the single-layered model, but was facilitated by the introduction of a vertical constraint. For this phonation type, fundamental frequency was relatively independent of the acoustic resonances, and two eigenmodes were required to capture the essential dynamics of the vocal fold, including an out-of-phase x-11 like eigenmode and an in-phase x-10 like eigenmode, as described in earlier theoretical work. The two eigenmodes entrained to the same frequency, and were decoupled from subglottal acoustic resonances. With this independence from the acoustic resonances, vocal fold dynamics appeared to be determined primarily by near-field, fluid-structure interactions. © *2006 Acoustical Society of America.*

I. INTRODUCTION

A primary prerequisite for self-sustained oscillation of the vocal folds is that the net transfer of energy from the airflow to the tissue be sufficient to overcome frictional forces (Ishizaka and Matsudaira, 1972; Stevens, 1977; Broad, 1979; Titze, 1988). In order for this transfer of energy to occur, the tissue velocity must be approximately in-phase with the driving forces. Titze (1988) argued that this condition may be facilitated by (1) an inertive vocal tract, (2) the superposition of two or more lower-order eigenmodes which propagate a mucosal wave up the medial surface of the vocal fold, or (3) some combination of the previous two conditions.

For a one-mass model, or any model which does *not* propagate a mucosal wave, it has been shown that self-sustained oscillations can only be achieved when the vocal folds entrain with one of the acoustic resonances of the *vocal tract*, a condition which is facilitated by an *inertive supraglottal tract* (Flanagan and Landgraf, 1968; Ishizaka and Flanagan, 1972; Titze, 1988). Alternately, it has been shown that self-sustained oscillations of a one-mass model may also be achieved when the vocal folds entrain with one of the acoustic resonances of the *subglottal tract*, a condition which is facilitated by a *compliant subglottal tract* (Fletcher, 1993; Zhang *et al.*, 2006). Because of the strong dependence on the acoustic resonances of the vocal system, we refer to such vibrations as *acoustically driven modes of phonation.* As a rule, such modes of phonation are *undesirable* for voice and speech because they tend to be plagued by frequency jumps and involuntary voice breaks, as the vocal folds entrain to distinct acoustic resonances of sub- or supraglottal tracts.

In contrast, the two-mass model (Ishizaka and Flanagan, 1972), or any model which propagates a mucosal wave, tends to oscillate independently of the acoustic resonances. Instead, its dynamics are governed primarily by a near-field fluid-structure interaction. We refer to such vibrations as *aerodynamically driven* modes of phonation. In this mode of phonation, two or more eigenmodes of the vocal fold tissues (Fig. 1) entrain or phase lock so as to create favorable aerodynamic conditions for phonation. Usually the strongest eigenmode creates an alternating convergent/divergent glottis near the top of the glottal airway [Fig. 1(c)], which makes it intimately associated with the glottal aerodynamics, e.g., a convergent glottis is associated with a relatively high intraglottal pressure, and a divergent glottis is associated with a relatively low intraglottal pressure (Titze, 1988). In the literature, this eigenmode has been referred to as an *x*-11 mode [which according to the nomenclature of Titze and Strong (1975), Berry *et al.* (1994), Berry and Titze (1996) is in the form of x-$n_y n_z$, where x refers to a medial-lateral mode of vibration, and n_y and n_z represent the number of half-wavelengths in the anterior-posterior and inferior-superior directions, respectively]. The second mode, usually capturing an in-phase medial-lateral motion of a rectangular glottis near the top of the glottal airway [Fig. 1(b)], governs the net lateral tissue velocity in this region, and modulates the glottal airflow. In the literature, this eigenmode has been referred to as an *x*-10 mode. Using the method of empirical eigenfunctions (EEFs), Berry *et al.* (1994) investigated the details of this theory with regard to a finite element model of vocal fold vibration. In that investigation, the tissue dynamics were explained by two dominant eigenmodes. The two eigenmodes exhibited a 1:1 entrainment or phase locking such that the intraglottal pressure (governed by an *x*-11-like mode)
FIG. 1. The three lowest-order eigenmodes of a two-dimensional vocal foldlike structure: (a) eigenmode 1, analogous to the z-10 mode; (b) eigenmode 2, analogous to the x-10 mode, describes in-phase motion along the vertical extent of the medial surface; (c) eigenmode 3, analogous to the x-11 mode, describes out-of-phase motion along the vertical extent of the medial surface. Left and right folds are shown to give an indication of the glottal geometry produced by the corresponding mode. Upper and lower frames indicate extreme positions of eigenmodes, spaced 180° apart in a vibratory cycle. Solid lines indicate equilibrium positions.

FIG. 2. (a) Schematic of the experimental setup, and (b) the hemimodel configuration.

was in phase with the net lateral tissue velocity (governed by an x-10-like mode), thus facilitating energy transfer from the airflow to the tissue.

More recently, Thomson *et al.* (2005) examined these same concepts in the laboratory using a physical model of vocal fold vibration, and a numerical simulation. Based on the results of the numerical simulation (which was driven by an imposed unsteady subglottal pressure as measured from the physical model), they investigated aerodynamic energy transfer mechanisms. In particular, they reported further substantiation of "the hypothesis that a cyclic variation of the orifice profile from a convergent to a divergent shape leads to a temporal asymmetry in the average wall pressure, which is the key factor for the achievement of self-sustained oscillation." However, using the same physical model with a slightly lower Young's modulus, Zhang *et al.* (2006) showed that the physical model usually exhibited self-oscillation *only when entrained to the acoustic resonances of the subglottal tract*, suggesting that the model exhibited *acoustically driven* rather than *aerodynamically driven* modes of phonation. Indeed, Thomson *et al.* (2005) disclosed that the vibration frequency observed in their study was near the half-wavelength resonance of the subglottal tube. Thus, for aerodynamically driven modes of phonation, it would appear that energy transfer mechanisms remain relatively unexplored in the physical model.

Using the physical model of Thomson *et al.* (2005), the purpose of the present study was to (1) attempt to induce aerodynamically driven phonation in the physical model, and (2) to distinguish *aerodynamically driven* and *acoustically driven* modes of phonation based on the medial surface dynamics of the physical model, over a range of subglottal pressures and tracheal lengths. Historically, a variety of studies have suggested that acoustically-driven modes of phonation are analogous to one-mass models of vocal fold vibration (Flanagan and Landgraf, 1968; Ishizaka and Flanagan, 1972; Titze, 1988; Fletcher, 1993), and that aerodynamically-driven modes of phonation are analogous to any tissue model which propagates a mucosal wave, usually through the superposition of two or more, lower-order eigenmodes (Titze and Strong, 1975; Titze, 1988; Berry *et al.*, 1994; Berry,
2001; Doellinger *et al.* 2005a, 2005b). Consequently, we hypothesize that aerodynamically and acoustically driven modes of phonation may be distinguished based on the medial surface dynamics of the vocal fold, and by their degree of dependence on the acoustic resonances of the vocal system. In particular, we will seek to substantiate and elucidate this hypothesis with quantitative, experimental data from the physical model.

II. METHOD

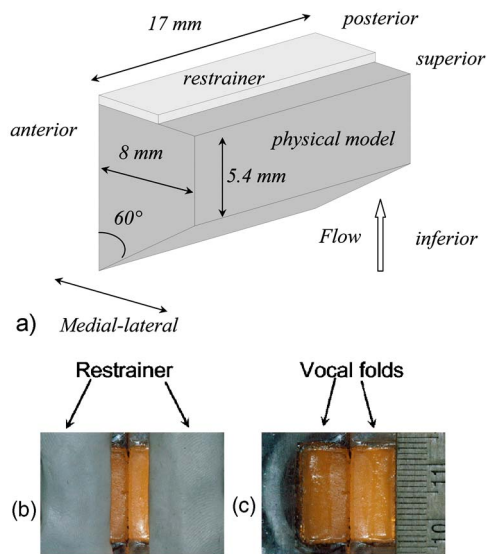
A physical replica of the human vocal system [Fig. 2(a)] was constructed using a rubber model of the vocal folds and a uniform (PVC) tracheal tube (2.54-cm inner diameter) connected upstream to an expansion chamber, simulating the subglottal system. The rubber model was a single-layered, cover-only, isotropic, physical model of the vocal folds (Thomson *et al.*, 2005; Zhang *et al.*, 2006). Using a mold, it was created with a two-component liquid polymer solution mixed with a liquid flexibilizer solution. For additional details regarding the fabrication and dynamical properties of the physical model, please see the original papers. Each vocal fold model measured approximately 1 cm in the superior-inferior direction, 1.7 cm in the anterior-posterior direction, and 0.8 cm in the medial-lateral direction [Fig. 3(a)]. The inferior side of each vocal fold had an entrance convergence angle of approximately 60° measured from the inferior-superior axis, yielding an inferior-superior vocal fold thickness of approximately 5.4 mm. Using a 5544 Instron Testing System, the stress-strain relationship of the artificial vocal fold tissue was measured to be nearly linear in the strain range of 0–20 %. Using the stress-strain data, the Young's modulus was calculated to be approximately 11 kPa across this range. The density was 997 kg/m³. The vocal folds were glued into a rectangular groove on the medial surface of two


FIG. 3. (a) A sketch of the physical model of the vocal fold, and a superior view of the model both (b) with, and (c) without restrainers.

acrylic plates. The medial surfaces of the two folds were positioned to be in contact so that the glottis was closed when no airflow was applied.

Different lengths of the PVC tracheal tube were used in this study, ranging from 11 to 120 cm. No efforts were made to smooth the transition from the tracheal tube to the physical model, although such an abrupt transition may have generated undesired perturbations in the airflow. The geometry of the transition region was kept unchanged so that its effects remained constant during the course of the experiments. The expansion chamber had an inner cross-sectional area of 23.5×25.4 cm and was 50.8-cm long. The inside of the expansion chamber was lined with a 2.54-cm-thick layer of fiberglass. Cross-sectional area data of the subglottal airway (Ishizaka et al., 1976) have shown that the cross-sectional area function from the trachea and the primary bronchi to the lungs increases abruptly by 10–100 times over a distance of about 6 cm. In this setup, the cross-sectional area from the pseudotrachea section to the expansion chamber increased by a factor of about 117. The expansion chamber was connected to the air flow supply through a 15.2-m-long rubber hose, reducing possible flow noise from the air supply. The acoustic characteristics of the expansion chamber and the flow supply were evaluated using the two-microphone method in a separate study (Zhang et al., 2006) and were found to be similar to an ideal open-ended termination of the tracheal tube for frequencies above approximately 50 Hz. Admittedly, this subglottal system does not exactly reproduce the human subglottal system, particularly the lossy compliance of the lungs. However, the relative simplicity of the system and its acoustical similarity to the human lungs yielded a reliable, controllable model of the subglottal acoustic system, which was essential for the present study.

A hemi-model procedure was used to investigate the medial surface dynamics of the vocal fold model, a technique which has been previously implemented for a variety of other laboratory experiments, including other physical mod-

els of the folds (Titze et al., 1995; Chan et al., 1997), excised larynx experiments (Jiang and Titze, 1993; Berry et al., 2001; Doellinger et al., 2005b), and the in vivo canine laryngeal model (Doellinger et al., 2005a). Figure 2(b) shows a schematic of the hemi-model setup. In this experimental configuration, one of the vocal fold plates was removed and replaced by a glass prism. The prism provided two distinct views of the medial surface of the vocal fold, which was imaged using a high-speed digital camera (Fastcam-Ultima APX, Photron Unlimited, Inc.). A frame rate of 2000 Hz was used with a spatial resolution of 1024×1024 pixels per image. Prior to imaging, graphite powder was sprinkled on the medial surface of the vocal fold to form random dot patterns. In the post-processing stage, such patterns facilitated cross-correlation analysis to compute the medial surface dynamics.

In particular, time-series cross-correlation analysis was performed on the medial surface images using the image-processing package DaVis (LaVision Inc.). A multipass algorithm was used in the cross-correlation analysis. Initial estimates of the displacements were made using a relatively large interrogation window. Next, these estimates were used as input for subsequent analyses which used smaller interrogation window sizes. For each camera view, the correlation analysis yielded the medial surface displacements in image coordinates. Using an appropriate mapping, the three-dimensional, physical coordinates of the displacements were derived from the two sets of image coordinates. The mapping function was determined through means of a calibration process (Hartley and Zisserman, 2000), using a calibration target with known three-dimensional coordinates.

In this case, the calibration target (LaVision Inc., Type no. 2.5) was 25×25 mm with a 2-mm spacing between calibration points in the inferior-superior and anterior-posterior directions, and 0.5-mm spacing between calibration points in the medial-lateral direction. Due to the periodic motion of the medial surface, the correlation analysis was performed with respect to the first frame. Therefore, a Langragian displacement field was obtained as a function of the reference coordinates in the first frame. Ultimately, displacements were computed over a total medial surface area of 16×16 mm, with a grid spacing of 0.22×0.22 mm in the inferior-superior and anterior-posterior directions, respectively. In contrast to previous methods of tracking vocal fold displacements which were semiautomatic (Berry et al., 2001; Doellinger et al., 2005b), the present technique was fully automated.

The subglottal pressure in the tracheal tube was monitored using a probe microphone (B&K 4182), which was mounted flush with the inner wall of the tracheal tube, 5-cm upstream from the vocal fold plates. A pressure tap was also mounted flush with the inner wall of the tracheal tube, 2-cm upstream from the vocal fold plates. The time-averaged transglottal pressure was measured using a pressure transducer (Baratron type 220D). Because no vocal tract was used in this study, the subglottal pressure was equivalent to the transglottal pressure. The volumetric flow rate through the orifice was measured using a precision mass-flow meter (MKS type 558A) at the inlet to the setup. During the experiments, the flow rate was increased from zero to a certain
FIG. 4. Sound pressure power spectra as a function of increasing and decreasing subglottal pressure in the hemimodel configuration for: (a) a tracheal tube of length 17.1 cm, without restrainer; (b) a tracheal tube of length 17.1 cm, with restrainer; (c) a tracheal tube of length 60 cm, without restrainer; (d) a tracheal tube of length 60 cm, with restrainer.

maximum value in discrete increments, and then decreased back to zero in discrete decrements (Zhang *et al.*, 2006). At each step, measurement was delayed for an interval of about 4–5 s after the flow rate change, allowing the flow field to stabilize. Sound pressure inside the subglottal tube, flow rate, and subglottal pressure were recorded for a 2-s period. Analog-to-digital conversion of the output signals was performed using a United Electronic Industries Powerdaq board, with 16 bit resolution over a ±10 V measurement range at a sampling rate of 50 kHz.

III. RESULTS

In a companion paper (Zhang *et al.*, 2006), the vibrations of the physical model were studied as a function of tracheal length and subglottal pressure. In that study, the tracheal length was varied from 11 to 325 cm, and subglottal pressure was varied between 0 and 6 kPa. Despite the desire to generate both aerodynamically and acoustically driven modes of vibration, over the range of parameters investigated (0–6 kPa for the subglottal pressure and 11–325 cm for the tracheal length), only acoustically driven modes of vibration were produced by the model, i.e., phonation only occurred when the phonation frequency entrained with one of the subglottal acoustic resonances, and showed little variation with subglottal pressure. Furthermore, as a function of tracheal length, the vocal folds exhibited bifurcations or abrupt jumps to distinct subglottal resonances. Finally, the acoustically driven modes did not occur for typical human tracheal lengths (i.e., approximately 17 cm). Instead, such modes appeared only for tracheal lengths of 30 cm or more. It was also noted that the acoustically driven modes of vibration exhibited significant vertical (inferior-superior) vibrations similar to the eigenmode in Fig. 1(a), a vibration pattern which easily coupled with the subglottal acoustics.

Thus, over the original range of parameters investigated, aerodynamically driven modes of vibration were not observed. In this study, in a further effort to induce aerodynamically driven phonation, several physical constraints

were applied to the vocal fold model to reduce the large vertical vibrations characteristic of the acoustically driven modes of phonation, and thereby reduce source-tract coupling. Indeed, it was hoped that the restriction of the large vertical vibrations would suppress the vertical motion and facilitate the emergence of an *x*-11 eigenmode and mucosal wave propagation, and thereby promote an aerodynamically driven mode of phonation (Titze, 1988). The following constraint produced the desired effect: rubber restrainers were laterally positioned over the superior surface of the vocal fold model [Figs. 3(a) and 3(b)]. The thickness of the restrainers was chosen so that the restrainers were thin enough to avoid disturbance of the near-field flow (approximately 2.5 mm), yet stiff enough to restrain the vertical motion of the vocal fold body. The lateral-medial extent to which the restrainers covered the vocal fold was adjustable. The lateral distance of the uncovered superior portion of the vocal fold roughly approximated the effective lateral depth of vibration of the physical model.

Experiments were conducted on both full and hemi-model configurations. Both configurations produced qualitatively similar vibration patterns. The vibration frequencies between configurations generally differed by a few hertz. Also, phonation threshold pressures were slightly higher (0.1–0.2 kPa) in the hemimodel than in the full model. However, as expected, the threshold airflow in the hemimodel was about half that of the full model. Because of our focus on medial surface dynamics, only results from the hemimodel experiments are discussed below.

A. Phonation frequency

Figures 4(a) and 4(b) compare the power spectra of the subglottal acoustic pressure as a function of the mean subglottal pressure for cases with and without restrainers, for a tracheal tube length of 17.1 cm, which is a typical estimate of the length of the human trachea (Flanagan, 1958; Ishizaka *et al.*, 1976). The subglottal resonance for this tracheal length could be measured directly as dominant energy peaks in the

acoustic power spectra before onset, or estimated from linear acoustic theory using the measured reflection factor of the subglottal system in Sec. II. In this case, the first subglottal resonance occurred around 350 Hz. The power spectra for an unrestrained fold are shown in Fig. 4(a), and the power spectra for a restrained fold are shown in Fig. 4(b). Note that, during the experiments, the mean subglottal pressure was first increased to a maximum value and then decreased back to zero. For the unrestrained fold, phonation did not occur. In this case, two broad horizontal lines can be seen in Fig. 4(a), which correspond to broadband flow noise around the subglottal acoustic resonance of approximately 350 Hz, and the would-be phonation frequency of approximately 210 Hz (small-amplitude vibrations were observed at this latter frequency at higher subglottal pressures than those originally investigated in this study [up to about 7 kPa]). Figure 4(b) shows the restrained case with an effective lateral depth of vibration of 2.2 mm (compared with an effective lateral depth of vibration of 8.0 mm when no restrainer was applied). Phonation onset occurred at a subglottal pressure of approximately 2 kPa. After onset, phonation frequency appeared to vary continuously as a function of subglottal pressure. Although close to the acoustic resonance, the fundamental frequency clearly exhibited variations which were independent of the subglottal resonance.

Figures 4(c) and 4(d) show the acoustic power spectra for unrestrained and restrained folds, respectively, when a longer tracheal tube of approximately 60 cm was utilized. The first subglottal resonance was about 134 Hz. Without the application of the restrainer, phonation was observed. The vocal fold entrained to a subglottal acoustic resonance, and the fundamental frequency exhibited weak dependence on the subglottal pressure [Fig. 4(c)]. Clearly, the physical model vibrated in an acoustically driven mode. However, with the restrainer (with an effective lateral depth of vibration of 5.4 mm), the physical model vibrated independently of the subglottal acoustic resonance (about 134 Hz), and appeared to vary continuously as a function of subglottal pressure in the range of 200–250 Hz, as shown in Fig. 4(d).

Shown in Fig. 5 are the medial surface trajectories of one coronal slice of the medial surface, midway between anterior and posterior extremes of the same physical model with and without restrainers. Without restrainers, large vertical vibrations were observed in the acoustically driven mode of vibration. However, this vertical motion was suppressed when restrainers were applied. Note that lip vibrations in brass instruments exhibit similar vibratory phenomena. For example, the unrestrained vibrations observed in this study roughly correspond to the "swinging door" motion of the vibrating lips, and the vertically restrained vibrations roughly correspond to the "sliding door" motion (Adachi and Sato, 1996; Copley and Strong, 1996).

The fact that the physical model vibrated independently of the subglottal acoustic resonances illustrates that the restrained physical model vibrated in the aerodynamically driven modes of vibration. This suggests that the application of vertical constraints may facilitate the excitation of aerodynamically driven modes of vibration, perhaps by enhancing the near-field fluid-structure energy transfer. The results
FIG. 5. Anterior view of medial surface trajectories for one coronal slice of the medial surface of the vocal fold, midway between anterior and posterior extremes, for cases with (left) and without (right) restrainers. Because the vibrational amplitudes from the case with restrainers were relatively small, they have been amplified by a factor of three. For a clearer illustration, only trajectories from every fifth grid point are shown along the inferior-superior length. The tracheal tube length was 60 cm.

also suggest that the suppression of vertical motion reduced the coupling of the tissue vibrations with the subglottal acoustics.

B. Spatiotemporal analysis

Figure 6 is a spatiotemporal representation of the medial-lateral component of motion for one coronal slice of the medial surface of the vocal fold model, midway between anterior and posterior extremes. For each subplot, the x axis corresponds to time and the y axis corresponds to the inferior-superior direction. The superior edge of the vocal

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Zhang *et al.*: Modes of vibration   2845

fold model was at about −4.5 mm and −3 mm in the superior-inferior direction for the aerodynamically driven mode and acoustically driven mode, respectively. For both modes of phonation, displacement amplitudes were greatest near the superior edge of the vocal fold. However, the vibration patterns were quite distinct. For the acoustically driven mode of phonation [Fig. 6(b)], a traveling wave was initiated about 10-mm below the superior edge, and traveled superiorly with time until it reached the superior edge of the vocal fold, where it exhibited its greatest amplitudes.

In contrast, for the aerodynamically driven mode of phonation [Fig. 6(a)], a forward or superiorly traveling wave and a backward or inferiorly traveling wave were initiated at about 5-mm below the superior surface. Although the backward-traveling wave had smaller amplitudes than the forward-traveling wave, it constituted a characteristic feature of the overall wave structure. The forward traveling wave proceeded until it reached the superior edge of the fold. The more complicated wave structure associated with the aerodynamic mode of phonation was further confirmed through means of a principal component analysis (PCA), as discussed below.

C. Empirical eigenfunctions

Empirical eigenfunctions (EEFs) were extracted from the three-dimensional displacement field of the entire medial surface of the vocal fold using the method of principal components analysis (PCA) (Berry *et al.*, 1994). Prior to analysis, the mean component of the displacement data was calculated and subtracted from the displacement data. Using the method of PCA, the three-dimensional displacement data over the medial surface $D(x,y,z,t)$ was decomposed into a linear combination of empirical eigenfunctions

$$D(x,y,z,t) = \sum_{k=1}^{N} \sigma_k \Phi_k(t) \Psi_k(x,y,z), \qquad (1)$$

where the normalized scalar function $\Phi_k(t)$ and normalized vector function $\Psi_k(x,y,z)$ were the kth temporal and spatial empirical eigenfunctions, σ_k was the modal scaling factor, and N was the total number of time samples. The temporal eigenfunctions may be also thought of as the temporal coefficients of the spatial eigenfunctions. The total energy associated with the vibration was given by

$$E_{tot} = \left\langle \int |D(x,y,z,t)|^2 dx dy dz \right\rangle_t = \sum_{k=1}^{N} \sigma_k^2, \qquad (2)$$

where the angle brackets denoted a time average. The relative weight of the contribution of each eigenfunction toward the total energy (or percentage variance) can be calculated as the ratio of corresponding σ_k^2 and the total energy E_{tot}.

Figure 7 shows the first two temporal eigenfunctions for both modes of phonation. The percentage variance (or relative weight) of the displacement data captured by the first four EEFs, and the vibration frequencies of the temporal eigenfunctions, are shown in Table I. The temporal eigenfunctions of the first four EEFs were harmonic functions with a dominant single-frequency component, with the first
FIG. 7. The first two temporal empirical eigenfunctions for aerodynamically driven (top) and acoustically driven (bottom) modes of phonation. The tracheal tube length was 60 cm. —— : first temporal eigenfunction; – – – : second temporal eigenfunction.

two EEFs entrained to the fundamental frequency and the next two EEFs entrained to the second harmonic.

For both modes of phonation, Fig. 8 shows the normalized, medial-lateral component of the first two spatial eigenfunctions. From a coronal aspect, Fig. 9 illustrates medial-lateral and inferior-superior components of these same eigenfunctions, for one coronal slice of the medial surface, midway between anterior and posterior extremes. For the acoustically driven mode of phonation, considerable vertical motion was present (see Fig. 5), which was captured by the first eigenfunction (see Fig. 9). The medial-lateral component of the first eigenfunction was similar to an x-10 eigenmode (Titze and Strong, 1975; Berry *et al.*, 1994; Berry and Titze, 1996), in which the medial-lateral motion near the top of the glottal airway was in phase. This eigenfunction captured 85% of the variance of the medial surface displacements. Although the second eigenfunction was similar to an x-11 eigenmode and alternately shaped a convergent/divergent glottis (Titze and Strong, 1975; Berry *et al.*, 1994; Berry and Titze, 1996), this eigenfunction captured only 11.1% of the variance, and was approximately 7.6 times less energetic than the first eigenfunction. Other higher-order eigenfunctions captured 1.5% or less of the variance of the medial surface displacements. Therefore, in an acoustically driven mode of phonation, the vocal fold oscillations were captured primarily by one eigenfunction, with the medial-

lateral component corresponding to an x-10 mode and the inferior-superior component corresponding to a z-10 mode.

In contrast, for the aerodynamically driven mode of phonation, the medial surface displacements were more complex, capturing two relatively strong eigenfunctions. The first eigenfunction (Figs. 8 and 9) was similar to an x-11 eigenmode (alternately shaping a convergent/divergent glottis) and captured 65% of the variance of the medial surface displacements. However, near the top of the glottal airway, the second eigenfunction was similar to an x-10 mode, and captured 31% of the variance of the medial surface displacements. Thus, for this aerodynamically driven mode of phonation, at least two eigenfunctions were required to reconstruct the primary dynamics of the vocal fold. Moreover, the two eigenfunctions entrained to the same frequency, which was independent of the subglottal acoustic resonance. This superposition of two eigenfunctions in the aerodynamically driven mode of phonation, with a phase difference determined by the temporal eigenfunctions, generated a traveling wave along the medial surface. This may explain the more complicated wave structure shown in Fig. 6(a), as compared to Fig. 6(b). Indeed, for the acoustically driven mode of phonation, only one eigenfunction was required to capture the essential dynamics of the vocal fold, resulting in a less-complicated wave structure, and a necessary dependence on and coupling with a nearby acoustic resonance.

IV. DISCUSSION

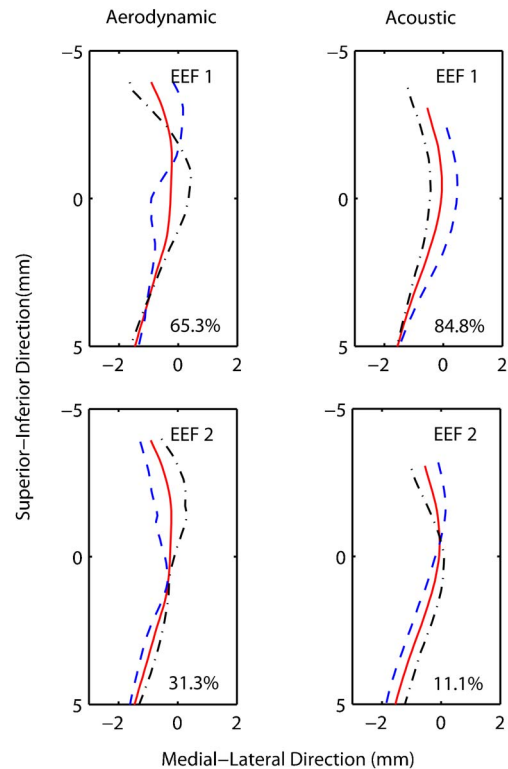
In this study, an attempt was made to distinguish aerodynamically and acoustically driven modes of vibration in a physical model based on the medial surface dynamics of the vocal fold, and the relative independence of the source and the acoustic resonator. The physical model was a single-layered, isotropic model of vocal fold vibration (Thomson *et al.*, 2005). Initially, only acoustically driven modes of phonation were observed in the physical model. For acoustically driven modes of phonation: (1) a single, dominant, x-10 like eigenmode captured the essential dynamics, explaining 85%


FIG. 9. (Color online) Medial-lateral and superior-inferior components of the first two spatial eigenfunctions for one coronal slice of the medial surface of the vocal fold, midway between anterior and posterior extremes, for both aerodynamically driven (left) and acoustically driven (right) modes of phonation. Maximum (dash-dotted) and minimum (dashed) projections of the eigenfunctions are superimposed on the mean surface projection (solid). The tracheal tube length was 60 cm.

of the variance of the medial surface displacements; (2) the eigenfunction always coupled with one of the acoustic resonances of the subglottal tract; and (3) phonation occurred only for relatively long tracheal lengths of 30 cm or more. In contrast, aerodynamically driven modes of phonation were observed only when a physical constraint restricted the vertical vibrations of the folds. For aerodynamically driven modes of phonation: (1) at least two eigenmodes were required to capture the essential dynamics, including an x-11-like eigenmode which explained 65% of the variance of the medial surface displacements, and an x-10-like eigenmode which explained 31% of the variance; (2) the two eigenmodes entrained to the same frequency and were successfully decoupled from subglottal acoustic resonances; and (3) self-oscillation was achieved for typical, human, tracheal lengths of approximately 17 cm.

The idea that human phonation, particularly the singing voice, may be influenced by sub- or supraglottal acoustic resonances is not new to speech science. Indeed, a variety of investigators have proposed an intimate connection between subglottal acoustic resonances and vocal registers (Nadoleczny-Millioud and Zimmerman, 1938; Vennard, 1967; van den Berg, 1968; Large, 1972; Austin and Titze, 1997). Similarly, Mergell and Herzel (1997) showed an example of high-frequency female singing, in which one vocal fold entrained with the first formant frequency, after the two folds had desynchronized due to left-right asymmetries.

Titze (1988) stated, "…the vocal instrument operates with varying degrees of source-resonator coupling. When coupling is weak…the larynx is able to control frequency, intensity, and the glottal source spectrum rather independently. Decoupling preserves constancy of phonation and seems to be desirable." The results of the present investigation demonstrate both weak and strong source-resonator coupling. The acoustically driven mode of phonation corresponds to strong source-resonator coupling, and the aerodynamically driven mode of phonation corresponds to weak source-resonator coupling. Although the physical model (Thomson *et al.*, 2005) had a propensity to vibrate in an acoustically driven mode of phonation, we were able to induce an aerodynamically driven mode of phonation by applying an appropriate vertical restraint. In the normal human condition, epilaryngeal manipulation through means of the ventricular folds may be able to provide a natural vertical restraint on the true vocal folds. Simultaneous contraction and stiffening of the thyroarytenoid muscle may also cause a natural vertical restraint.

In retrospect, after performing the experiment, it was realized the Young's modulus of 11 kPa utilized for the vocal fold model was relatively stiff, especially for the vocal fold cover, which may have discouraged the propagation of the mucosal wave. By lowering the value of the Young's modulus, post-experiment studies revealed a whole continuum of source-resonator coupling possibilities, with the examples in this investigation representing the extremes of both strong source-resonator coupling (e.g., acoustically driven modes of phonation) and weak source-resonator coupling (e.g., aerodynamically driven modes of phonation). Further details regarding the continuum of source-resonator coupling possibilities will be the subject of future work.

While the effectiveness of the vertical constraint in facilitating aerodynamically driven modes of phonation is not fully understood, it has potential applications in the area of phonosurgery which might merit further investigation. For example, despite the existence of a relatively stiff mucosal cover in the current study (both body and cover had a Young's modulus of approximately 11 kPa), a vertical constraint facilitated the emergence of an x-11 eigenmode, and the propagation of a mucosal wave. Whether induced by aging, scarring, or some other means, a stiffened mucosal cover is clinically known to be a major deterrent to mucosal wave propagation. Thus, it may be that the introduction of a vertical constraint through phonosurgical means could have potential benefit for patients with a stiffened vocal fold cover. Similarly, the introduction of a vertical constraint may also facilitate the propagation of a mucosal wave in patients with a relatively lax vocal fold body, such as might be caused by RLN (recurrent laryngeal nerve) paralysis.

Although no supraglottal vocal tracts were included in the current experiments, we would expect the supraglottal vocal tract to exhibit effects similar to that of the subglottal system, especially near phonation onset. Moreover, the inclusion of a supraglottal vocal tract would introduce yet another resonator, further complicating the interactions of the coupled system. This topic will be explored in future studies.

While medial surface dynamics were a useful tool to distinguish aerodynamically and acoustically driven modes of phonation in this study, such dynamics may not be a useful tool to distinguish these modes of phonation in other contexts, since medial surface dynamics are rarely reported. A few exceptions are Berry *et al.* (1994), Berry *et al.* (2001), and Doellinger *et al.*, (2005a, 2005b). In nearly all of these studies, the x-11 eigenmode was the strongest EEF, as might be expected in an aerodynamically driven mode of phonation. However, in Berry *et al.* (2001), the x-10 eigenmode was stronger, which was indicative of strong source-resonator coupling. Indeed, in a related conference proceeding, Berry *et al.* (1999) indicated that they did observe involuntary frequency jumps, which may be another indication of source-tract coupling.

Indeed, a variety of commonly observed vocal phenomena may help to distinguish the degree of source-resonator coupling when access to medial surface dynamics is not available. For example, continuous control of fundamental frequency as a function of vocal fold tension or subglottal pressure may be suggestive of aerodynamic phonation (e.g., independence of source and resonator). On the other hand, involuntary frequency jumps or "voice breaks" may be suggestive of source-resonator coupling. Because such jumps may also be caused by the intrinsic dynamics of the vocal folds (e.g., different eigenmodes within the folds may be excited), voice breaks do not guarantee the existence of source-tract coupling. However, when voice breaks occur, source-tract coupling is highly probable, and must not be ruled out.

V. CONCLUSION

Using a physical model of vocal fold vibration, aerodynamically and acoustically driven modes of vibration were distinguished based on the medial surface dynamics of the vocal fold, and the relative independence of source and acoustic resonator. The single-layered, cover-only, isotropic physical model was dynamically similar to a one-mass model, and its medial-lateral vibration could be described efficiently by an x-10 eigenmode. The physical model had a propensity to vibrate in an acoustically driven mode of phonation, i.e., vocal fold vibration did not occur unless it was coupled to an acoustic resonance of the vocal system. However, an aerodynamically driven mode of phonation could be facilitated by introducing a vertical constraint, and or by lowering the stiffness of the vocal fold. This mode of phonation captured two relatively strong eigenmodes (e.g., x-11 and x-10), exhibited a clear mucosal wave, and was vibrated independently of acoustic resonances. Because of the increased control over fundamental frequency and register, aerodynamically driven modes of phonation are generally deemed preferable to acoustically driven modes of phonation in both speech and singing.

Perception of synthetic vowel exemplars of 4 year old children and estimation of their corresponding vocal tract shapes

Richard S. McGowan

CReSS LLC and Haskins Laboratories, 1 Seaborn Place, Lexington, Massachusetts 02420

Formant scalings for vowel exemplars of American 4 year olds who were imitating adult production were used along with published data of American adult male vowel production to synthesize /ɑ, æ, u, i/. Other vowel exemplars were also synthesized. Adult listeners were asked to categorize these synthetic vowels in a forced choice task. With some exceptions, the formant frequencies preferred for the vowels /ɑ, æ, u, i/ were close to the published data. In order to gain insight on children's articulation during imitation of vowels /ɑ, æ, u, i/, a five-tube model was used in an algorithm to infer vocal tract shape from the first three formant frequencies of the adult productions, the formant frequencies derived for 4 year olds by scaling, and formant frequencies for 4 year olds derived based on the listening experiments. It was found that the rear tube length for the children, in proportionate terms, was nearly always greater than that of the adult. The rear tube length was proportionately twice as long in children compared to adults for the vowel /u/. Tongue root flexibility and the oblique angle between the pharynx and mouth may be more important than pharynx length in determining formant scalings for 4 year old children. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Children generally learn to speak the language that is used in their surroundings. Within the first 2 years, children will have acquired a basic vocabulary that is understandable to many adults in their families. However, the acoustic output of young children's speech cannot completely resemble adults' speech simply because of anatomical differences between adults and young children. One of the most obvious of these differences between children and adults is in vocal tract length, but there are also differences in the relative lengths of the pharynx and mouth (Goldstein, 1980; Kent and Vorperian, 1995; Fitch and Giedd, 1999). Despite anatomical differences, children do learn to speak, and, in particular, they produce vowels that are recognized by adults.

Acoustic studies of vowel production by American men, women, and/or children, such as those of Peterson and Barney (1952), Hillenbrand, Getty, Clark, and Wheeler (1995), and Lee, Potamianos, and Narayanan (1999) have documented the acoustics of vowel production differences between adults and children. A quantitative look at such data indicates that there is more than simple length scaling that must be invoked to account for formant frequency differences between, say, men and children (e.g., Fant, 1975). Some of the differences might be attributed to differences in the pharynx-to-mouth length differences. However, the effect of anatomical differences on articulation is still unclear.

One way to understand the relation between adults' production and children's production of particular utterances is to examine the children's production when they are asked to imitate the speech of adults. Imitation is understood here in the narrow sense of the situation when children are asked to imitate adult phonetic segments in experimental context. Here, we will restrict ourselves to vowel production and ask

the following questions. How do children imitate adult vowels when their anatomies differ? Are there any constraints on children's production of vowels beyond the length differences in fixed vocal tract structures? The answers to these questions will help in understanding how children develop as speakers.

One source of data on children's vowel production when they were asked to imitate adult vowels comes from Kent and Forner (1979). In their experiment, Kent and Forner asked three 4 year old boys and six 4 year old girls to imitate vowels that had been synthesized on a cascade formant (Klatt) synthesizer. Five of these synthetic vowels were modeled on the mean adult male data of Peterson and Barney (1952) for the vowels /i, u, ɑ, æ, ɚ/, and five other vowels were used to fill the vowel space, but they were without specific phonemic identity. These ten stimuli were presented five times each for a total of 50 imitations. Children's formant frequencies from the imitation task were made from spectrograms in a procedure described in their paper (Kent and Forner, 1979). From these measures, an average scale factor (=ratio of child formant frequency to adult formant frequency) for each formant frequency and each vowel can be computed across all ten 4 year olds (see Fig. 10 of Kent and Forner, 1979 for a closely related quantity). Based on these formant scaling factors for 4 year old children and the formant frequencies for adult males provided by Olive, Greenwood, and Coleman (1993), a set of formant frequencies for vowels /ɑ, æ, u, i/ as might be spoken by a 4 year old imitating an adult can be found. It should be noted that the scaling derived from Kent and Forner and the formant frequencies provided by Olive *et al.* (1993) could be affected differently by individual and regional dialect differences.

Listening experiments with adult subjects were used to verify that the formant values for the four year-old children's

vowels derived using the Kent and Forner (1979) and Olive *et al.* (1993) parameters were, indeed, reasonable. Thus, using these data, vowels /ɑ, æ, u, i/ were synthesized, as well as vowels whose formant frequencies were altered from these four vowels. This also served to verify the scaling results of Kent and Forner (1979) when they are applied to a set of published adult formant frequency values of Olive *et al.* (1993).

In order to begin to answer the questions about how children imitate it is necessary to know something about the articulation employed by children to imitate the vowels of adult speech. It is difficult to obtain articulatory measures during speech production in young children. Therefore, our strategy was to infer vocal tract shape from the speech acoustic data of children's vowel production described above. The vocal tract shapes of both children and adult males in the production of vowels /ɑ, æ, u, i/ were inferred using an analysis-by-synthesis procedure that maps formant frequencies to an acoustic tube model of the vocal tract. While vocal tract shapes are not synonymous with articulatory positions, vocal tract shape can be informative as to the articulatory strategy used by children during speech imitation.

Our previous work in inferring vocal tract shape and dimensions from acoustics has been to use analysis-by-synthesis, in which the synthesis is done using an articulatory synthesizer with a model vocal tract. In this previous work, task-dynamic parameters of the model vocal tract were adjusted in a stochastic optimization algorithm, a genetic algorithm, so that the resulting formant frequency trajectories produced by an articulatory synthesizer matched the formant frequencies of the corresponding data vowel (e.g., McGowan, 1994). The closeness of the match for each utterance was judged by the size of sum of the square differences between the model and the data in the first three formant frequencies. The work here will use static formant frequency values to infer static vocal tract tube shapes. There can be problems of ambiguity (i.e., multiple optimal solutions) in such a procedure, so the analysis-by-synthesis procedure was run several times, and, further, the number of allowed vocal tract tube sections was limited. By running a stochastic optimization procedure several times, it can be expected that a variety of optimal solutions will be found. Also, by attending to grosser features of the vocal tract corresponding to the information that the first three formant frequencies provide, it can be assured that the inferences made about the vocal tract shapes are valid.

II. LISTENING EXPERIMENT: METHOD

Vowels /ɑ, æ, u, i/ were synthesized as monophthongal vowels with a cascade (Klatt) formant synthesizer using the formant frequencies shown in Table I. The first three formant frequencies (F1, F2, F3) were derived from the scaling factors for 4 year olds provided by Kent and Forner (1979, Fig. 10) and the formant frequencies for an adult male provided by Olive *et al.* (1993, p. 104). The formant frequencies were measured from sentences containing the words "bottle," "bat," "boot," and "beet" spoken by an adult male from Pittsburgh, Pennsylvania (Olive *et al.*, 1993, p. 8). The formant

TABLE I. The first three formant frequencies, without alteration, used to synthesize KFO condition vowels of a 4 year old. The scaling factors from Kent and Forner (1979) and adult formant frequencies from Olive *et al.* (1993) are in brackets.

	Child F1 (scale, Adult F1)	Child F2 (scale, Adult F2)	Child F3 (scale, Adult F3)
ɑ	1125 Hz (1.5, 750 Hz)	1650 Hz (1.5, 1100 Hz)	4030 Hz (1.55, 2600 Hz)
æ	980 Hz (1.4, 700 Hz)	2475 Hz (1.5, 1650 Hz)	4250 Hz (1.7, 2500 Hz)
u	429 Hz (1.43, 300 Hz)	1080 Hz (1.27, 850 Hz)	4375 Hz (1.75, 2240 Hz)
i	448 Hz (1.6, 280 Hz)	3488 Hz (1.55, 2250 Hz)	4125 Hz (1.5, 2750 Hz)

frequencies from Olive *et al.* (1993) are all within 10% of the mean values for adult males given in Peterson and Barney (1952), which were the values used by Kent and Forner (1979) in their experiments. Further, with the exception of the three formants for /u/ and F2 for /ɑ/, the formant frequencies are within one standard deviation of the mean values given by Lee *et al.* (1999). In the cases of these four formant frequency values, the values of Olive *et al.* (1993) are within 20 Hz of the values given by Peterson and Barney (1952). Because the speech data for the Lee *et al.* (1999) were collected in St. Louis, Missouri and the data of Peterson and Barney (1952) were collected in New Jersey over 40 years previously, these differences can probably be attributed to dialect differences amongst the various studies. With the values of F1, F2, and F3 for the synthetic children's vowels derived from Kent and Forner and from Olive *et al.*, the values F4 and F5 were scaled from 3500 Hz and 4500 Hz using the scaling factor for F3. This was done because of a lack of data for F4 and F5. These synthetic base vowels, /ɑ, æ, u, i/, are called *KFO condition* vowels in this paper. These vowels were intended to be synthetic approximations of vowels produced by 4 year olds imitating adults.

Other vowels were synthesized with the first three formant frequencies of the base vowels altered by −20%, 0%, or 20%, and the fourth and fifth formant frequencies were changed the same amount as the third formant frequency from the values for the base vowels. With all possible combinations of these perturbations there were twenty-seven $=3^3$ different vowel exemplars for each base vowel, including the base vowel itself. All vowels were sampled at a 20 kHz sampling rate. The vowels were 400 ms long with the fundamental frequency gradually decreasing from 240 Hz to 200 Hz throughout that duration. This was on the low side for 4 year old fundamental frequencies [e.g., Eguchi and Hirsh (1969) show a mean fundamental frequency of 286 Hz], but they were within reason and engendered a less ambiguous vowel quality than would have higher fundamental frequencies. Also, after an initial increase in amplitude for the first 20 ms, the voice amplitude decreased while parameters making the voice sound more breathy, such as random noise amplitude, increased with time into the vowel. These parameter settings made the voice quality child-like, as judged by the author.

TABLE II. The mean of the formant frequencies in each vowel category receiving a score of 50%, or greater, of the highest score. The scaling factor from adult male formants and percent difference from the children's KFO condition formant frequencies are shown in Table I in brackets.

	Child F1 (scaling, % diff.)	Child F2 (scaling, % diff.)	Child F3 (scaling, % diff.)
ɑ	1210 Hz (1.61, +7.5%)	1672 Hz (1.52, +1%)	4128 Hz (1.59, +2%)
æ	1087 (1.55, +11%)	2700 (1.64, +9%)	4173 (1.67, −2%)
u	393 (1.31, −8%)	1080 (1.27, 0%)	4421 (1.97, +1%)
i	386 (1.38, −14%)	3541 (1.57, +2%)	4188 (1.52, +2%)

Fifteen adult students who were recruited by advertisement from the University of Connecticut student body participated in a listening experiment with these synthetic vowels. Each subject was seated at a computer terminal and listened to the stimuli over a set of speakers controlled by the computer. The 108 synthetic vowels were presented in randomized lists, in which each token appeared three times. As soon as a stimulus was played, a list of five hVd words (except for one hVti word) appeared on the screen (see the Appendix). The subject was asked to choose the word with the vowel that most closely matched the vowel presented auditorily. Once the choice was made, the subject was asked for the goodness of the match on a scale from one to five. After the subject responded to this choice, he was given the choice to repeat the trial, continue on to the next stimulus, or to exit the experiment. In this way the subject was able to be as certain as possible about his judgments and less likely to attempt to compensate for a perceived poor judgment in listening to a future stimulus.

III. LISTENING EXPERIMENT: RESULTS

For each synthetic vowel, the goodness scores for each category were totaled. For instance, a certain synthetic vowel would sometimes be heard as /i/ and sometimes as /ɪ/, and the goodness scores for this vowel were totaled separately for each of these phonemic categories. Table II shows the average formant frequencies of the synthetic vowels that received scores of 50% (an arbitrary level), or greater, of the maximum goodness score for the phonemic categories of each of the four base vowels. The percents in brackets are the amount these formant frequencies differ from those in Table I. These average formant frequency values specify vowels that are called *listening condition* vowels in this paper.

With some exceptions, listeners favored the formant frequency values for the 4 year olds that were taken to be representative of children's productions according to the Kent and Forner (1979) scalings and the Olive *et al.* (1993) formant frequencies. The percents in brackets indicate that listeners favored more extreme F1 values, or extreme tongue height positions, than those given in the KFO condition. Further, the listeners favored a higher F2, or more fronted tongue, for /æ/.

TABLE III. The number of times a particular vowel, as determined by the KFO condition, is classified into one of five vowel categories with a goodness score of greater than, or equal, to 3.

KFO condition vowel	scores	Listener Choices				
		ɑ	ɔ	ʌ	æ	oʊ
ɑ	**5, 4**	9	7	1	0	0
ɑ	**3**	9	6	2	3	2
		æ	ɛ	ɑ	eɪ	ʌ
æ	**5, 4**	11	4	0	0	0
æ	**3**	0	8	1	0	0
		u	ʊ	oʊ	ʌ	ɑ
u	**5, 4**	10	7	1	0	0
u	**3**	7	2	2	2	0
		i	ɪ	eɪ	ɛ	æ
i	**5, 4**	20	1	2	0	0
i	**3**	11	0	1	1	0

The KFO condition vowels, whose formants are shown in Table I, were examined to find which categories listeners favored. The instances when these vowels received a goodness score of four or five for a particular category were counted, and the instances when these vowels received a goodness score of three were counted separately. Dividing the goodness scores four and five from goodness score three indicates how many times a token was rated as very good or excellent as an exemplar from when it was merely rated as a moderately good exemplar. The total number of times that a KFO condition vowel was rated is 45 (=15 subjects times 3 repetitions). Table III shows these counts for each KFO condition vowel.

Table III accounts for 39 tokens of /ɑ/, 24 tokens of /æ/, 31 tokens of /u/, and 36 tokens /i/, out of 45 tokens each. As indicated by Table III, the four vowels in the KFO condition were acceptable tokens of their target phonemic category in the listening condition. The low vowels /ɑ/ and /æ/ in the KFO condition were often perceived as good examples of slightly higher, neighboring phonemes, that is as /ɔ/ and /ɛ/, respectively. This is consistent with Table II, which indicates that listeners preferred higher first formant frequencies (i.e., a lower vowel) than provided by these vowels in the KFO condition. Also, the KFO condition /u/ was often heard as a good example of /ʊ/, a neighboring lower vowel. This, again, is consistent with Table II: listeners preferred higher vowels (i.e., lower first formant frequencies) for /u/ than provided in the KFO condition. While listeners preferred higher vowels than provided by the KFO condition /i/, they still counted the KFO condition /i/ as an unambiguously good example of that vowel.

IV. VOCAL TRACT DIMENSIONS: METHOD

Children's area functions for the vowels /ɑ, æ, u, i/ were inferred from formant frequency data from two different sources: the KFO condition for 4 year old children (Table I)

and preferences given by adults in the listening experiment (Table II). A five-tube vocal tract model was used, which is justified by the fact that the four adult male vowels could be simulated using as few as four tube sections (Stevens, 1998), thus leaving one extra tube in case the children's vocal tract shapes proved anomalous. Adult male area functions were also inferred for these vowels.

A genetic algorithm was used for each vowel to infer the lengths and areas of the five tubes that could produce the formant frequencies given in Tables I and II. A simple genetic algorithm was used as in previous work in recovering articulatory movement from formant frequencies (e.g., McGowan, 1994), but only static area functions were inferred in the current work. A genetic algorithm is a stochastic optimization technique, in which each variable parameter is coded as a binary number, which is called a gene (Goldberg, 1989). All the genes, each coding a particular parameter, are concatenated to form a chromosome. In this study a gene represented either a tube length or a tube area, for a total of ten genes in a chromosome. For the present study, the fitness of a chromosome was based on the first three formant frequencies produced by the five-tube model specified by the genes of that chromosome. Those three formant frequencies were compared with formant frequency data from one of the conditions in Table I and II and a distance between the model formants and data formants was computed. This distance was related to fitness, so that the smaller the distance, the greater the fitness. The specific form of the relation between distance and fitness is given below.

A simple genetic algorithm starts with a random group, or population, of chromosomes, each coding a different set of parameters. The population is then allowed to progress through generations. For each generation, pairs of chromosomes are selected for possible mating. In the algorithm used in this study, the number of pairs equaled one-half the size of the population. The chromosomes for possible mating are selected according to their fitness, so that the probability of a chromosome being selected in this work was proportionate to its fitness. Each pair of chromosomes selected has a probability of mating. If they do not mate, they are put back into the population unchanged, except for a small probability of mutation, where bits of the chromosome are changed in a process of mutation. Otherwise each of the chromosomes is cut at a randomly selected bit in each chromosome, and the divided strings of bits are swapped to produce new offspring chromosomes. These chromosomes are then subjected to the same small probability of mutation as the unmated pairs of chromosomes. The fitness of each new chromosome is evaluated, and a new generation is thus created. In the algorithm used here, the fittest individual of a generation was always preserved to enter the next generation. The process is stopped after a fixed number of generations. This process is supposed to be analogous to natural selection, and it can be shown to tend to produce chromosomes that are more fit as the number of generations increase (Goldberg, 1989).

In the current study, populations of 240 chromosomes were coded with five bits per tube area with minimum areas of 0.05 cm² and maximum areas of 10 cm², and with five bits per tube length with minimum lengths of 0.5 cm and

maximum lengths of 8.0 cm. These populations were run through 120 generations with fitness proportionate selection. There was a 0.6 chance for two selected chromosomes to mate, where mating entailed cutting a chromosome at a random bit and swapping the cut substrings to produce children chromosomes. There was a 0.005 chance for any bit to mutate from a one to a zero or vice versa. To compute the fitness function, the square-root of the sum over the first three formant frequencies of the square fraction of the differences between the data formant frequency and the inferred formant frequency was computed. The fitness was the exponential of the inverse of this quantity. The genetic algorithms were run five times for each of the sets of three formant frequencies for the four vowels from both Tables I and II for the children, and from Table I for adult males.

V. VOCAL TRACT DIMENSIONS: RESULTS

The vocal tract dimensions that best fit the adult male acoustic data are shown in Fig. 1. For the adults there were often multiple recovered area functions. Also, while the cross-sectional area near the glottis varies from less than 0.5 cm² for /ɑ/ [Fig. 1(a)] to over 3.0 cm² for /i/ [Fig. 1(d)], these areas only represent an average cross-sectional area in the pharyngeal region. For the adult /i/ [Fig. 1(d)], there is some ambiguity in the area of the tube in front of the constriction, because there are compensatory area changes in the rear cavity. For the adult /ɑ/ [Fig. 1(a)] there is a compensatory relation between the length of the rear tube and the total vocal tract length. The most striking ambiguity is for the vowel /æ/ [Fig. 1(b)], where, in the first case, there is a narrow rear tube for about one-third of the total length of the vocal tract with a wide front tube, and in the other case there is a more gradual increase in area from the rear to the front of the vocal tract. Figure 2 shows the spectra for the two adult /æ/s. Because the second formant has most of its energy associated with the longer front tube in the first case, it has greater amplitude than the third formant, which is associated with the rear tube [Fig. 2(a)]. In the second case the third formant has greater amplitude than the second formant when there is a more gradual increase in area [Fig. 2(b)]. Thus more of the second formant energy is associated with the rear and more of the third formant energy is associated with the front of the vocal tract compared to the first case. Accounting for relative formant amplitudes would disambiguate these situations.

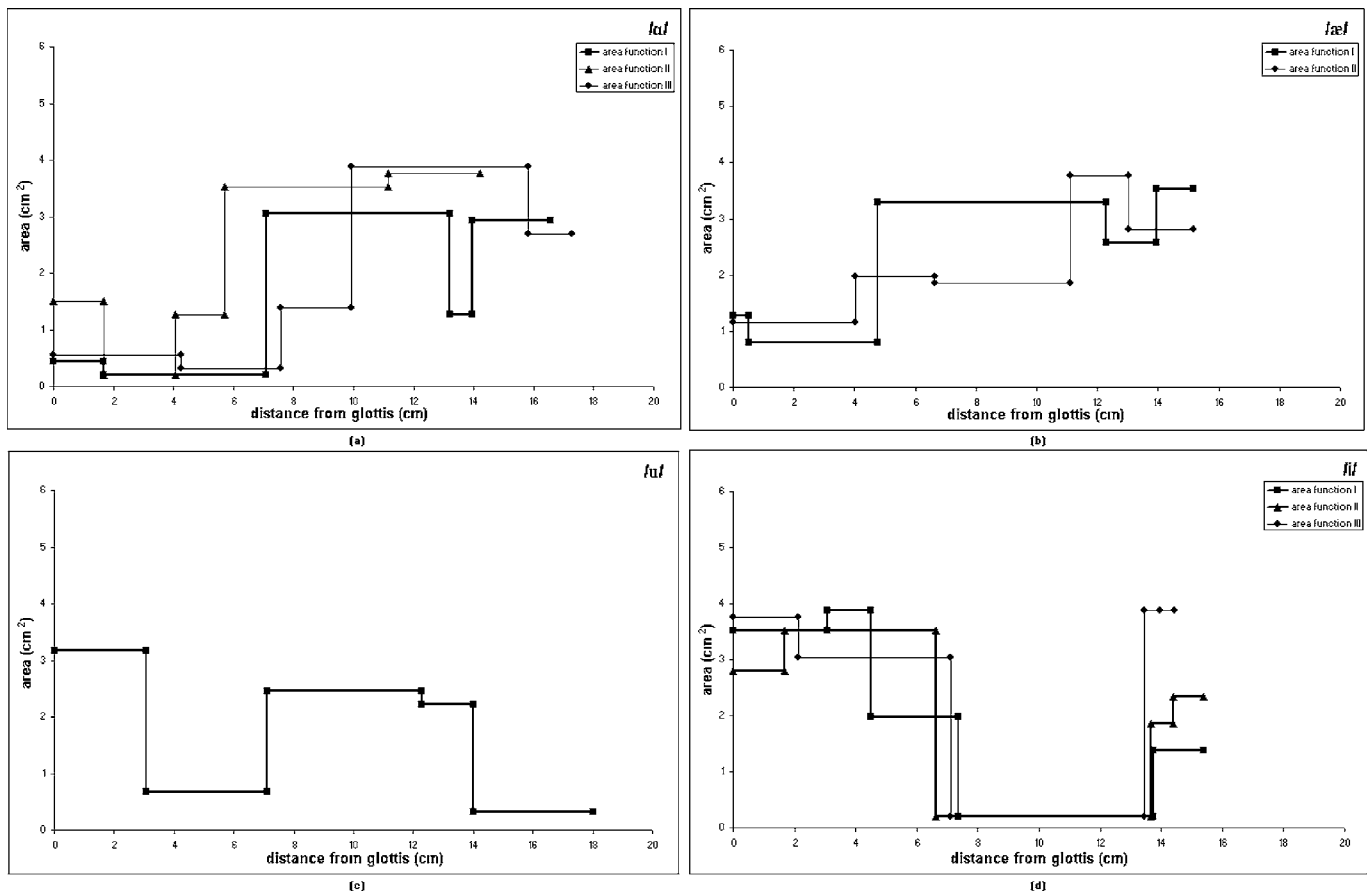
Comparisons of the tube shapes from the adults' production, the children's KFO condition, and the adult listening preferences of children's synthetic vowels show the same general vocal tract shapes (Figs. 1, 3, and 4). Both /æ/ and /ɑ/ have rear constriction tubes, with the one for /ɑ/ more constricted than the one for /æ/ [Figs. 1(a), 1(b), 3(a), 3(b), 4(a), and 4(b)]. In both the KFO and listening conditions, the children's /æ/ had a less, constricted, but longer rear tube than the adult case with a rear tube length about one-third the vocal tract length. The children's /æ/ is more closely related to the second adult case with a more gradually changing area function. However, there were configurations with more constricted, shorter rear tubes for the children's KFO and listen-


FIG. 1. Tube dimensions recovered from adult formant frequency data (a) /ɑ/, (b) /æ/, (c) /u/, and (d) /i/. Different recovered vocal tracts for a single vowel are possible and are denoted by different symbols and line thickness.

ing conditions that did not attain the fitness of the configurations shown in Figs. 3(b) and 4(b), but were nearby in terms of formant frequency fit. Thus there appears to be a similar ambiguity to the adult males in the vowel /æ/ for children. For /u/ there are two cavities separated by a constriction, and there is a constriction at the lips [Figs. 1(c), 3(c), and 4(c)]. For /i/ there is a back cavity with a front constriction [Figs. 1(d), 3(d), and 4(d)].

Beyond the general shapes of the vocal tract tubes there were differences between the children's and adult's vocal tract tubes. A difference that appeared fairly consistently across the four vowels involves the length dimension of the rear tube, whether or not that tube was a constriction or a cavity[1]. Comparisons of these lengths and their ratios with the total recovered vocal tract lengths are shown in Table IV. (Recall that there were multiple tube configurations for the adult data, as shown in Fig. 1.)

All of the rear tube length ratios in the case of the children's vowels in the listening condition were at least as large as the corresponding adult rear tube length ratios. The same is true for the children's vowels, except for /i/, in the KFO condition. Even for /i/ in the KFO condition, the adults' ratios do not exceed the children's ratios by more than 0.06. In the case of /u/, the ratio is on the order twice as large in children compared to the adults. /u/ is the vowel that has the greatest range of the three formant scalings: 1.27–1.75 for the KFO condition (Table I) and 1.27–1.97 for the listening

condition (Table II). For the KFO condition of /u/, the scaling difference was 1.43 for F1 and 1.27 for F2, which is the greatest difference among the vowels for these two formants. Thus, it is not surprising to find substantial differences in the ratios of tube lengths between adults and children. The recovery algorithm indicates that on a proportionate length basis, the children's /u/s are more "fronted" than the adult /u/. Also, this is the vowel of the four with the shortest rear tube length for both children and adults.

It is interesting to compare the rear tube lengths to the location of the velum. In one method of computation using MRI images, Fitch and Giedd (1999) took the distance from the glottis to the free edge of the velum (uvula) as the length of each of their subject's pharynx. The pharyngeal segment, along with four other line segments spanning the rest of the upper vocal tract, was also used to compute the total length of each vocal tract in their study. From their data, the ratio of a 4 year old's pharynx length to total length is between 0.25 and 0.29. For an adult male, this ratio is 0.37. In reference to Table IV, this means that all the children's rear tubes include the uvula, although for /u/ the uvula is very close to the front of the rear tube. For the adult male however, it is possible, according to these analyses, that the rear tube does not include the uvula for /ɑ/ and /æ/, and is wholly contained in the pharynx below the uvula. Further, the rear tube for the adult male /u/ is wholly contained in the pharynx below the uvula.
FIG. 2. Transfer functions for two tube configurations for adult /ae/ (a) short rear tube, and (b) long rear tube.

Because the rear tube in /u/ is a part of the volume element in one of the Helmholtz resonators in a double Helmholtz resonator system (Fant, 1960), it is possible to explore the acoustic ramifications of this geometry. F1 and F2 in /u/ are the resonances of this double Helmholtz resonance system, with the rear tube and the constriction closest to the rear constituting one resonator, the back resonator, and the mouth cavity and lip constriction forming the other Helmholtz resonator, the front resonator. The resonant frequencies of these resonators, if they were uncoupled are denoted $F1_0$ and $F2_0$ here, with the $F1_0$ the lower frequency. When these Helmholtz resonances are coupled, as they are in the vocal tract, the resonance frequencies shift from their uncoupled values to F1 and F2, with $F1 < F1_0$ and $F2 > F2_0$. Estimates of the resonant frequencies of the uncoupled back and front resonators are shown in Table V.

It can be seen that $F1_0$ and $F2_0$ are closer together for both of the children's conditions than for the adult's, both in absolute and relative terms. This corresponds to the fact that in both the production and listening condition for children, the scaling factor for F1 is greater than that for F2, which means that F1 is relatively closer to F2 for both children's conditions than for the adult male. (The proximity of F1 to

F2 is not completely accounted for by the proximity of $F1_0$ and $F2_0$, but also depends on the degree of coupling between the resonators.) Further, while the lower frequency $F1_0$ is associated with the front resonator for the adult and the listening condition for the children, it is associated with the back resonator in the KFO condition for the children.

Based on these results, 4 year old children are able to form vocal tract shapes that are appropriate for the vowels /ɑ, æ, u, i/. However, not all of these vowels are related to the adult versions of these vowels by a simple formant scaling factor. This is most apparent with /u/, and to some extent /æ/, in the data from Kent and Forner (1979). This acoustic pattern appears to be the result of a proportionately longer rear cavity for /u/, and, possibly, a longer rear tube for /æ/ in the child's vocal tract, compared to adults.

VI. SUMMARY AND DISCUSSION

The adult formant frequencies for the vowels /ɑ, æ, u, i/ as given by Olive *et al.* (1993), were scaled to the formant frequencies of 4 year old children imitating adults according to the values given by Kent and Forner (1979). These KFO condition vowels, along with vowels with formant frequencies altered from these values, were synthesized on a cascade formant synthesizer employing a child-like voice quality. Adults were asked to categorize and then to assign goodness scores to these vowels in a forced choice listening task. The average of each formant frequency for each vowel that received at least 50% of the score of the vowel with the largest total score in each phonemic category was computed. The results for the four vowels /ɑ, æ, u, i/ indicated that the formant frequencies of vowel tokens preferred by adult listeners differ little from those computed from adult data and scale factors. The largest differences between the formants in the listening condition and the KFO condition formants were more extreme F1s for all four vowels and the higher F2 for /æ/ in the listening condition. However, the KFO condition vowels, /ɑ, æ, u, i/, were usually perceived as good exemplars of their vowel categories in the listening condition.

Five-tube models were used in an analysis-by-synthesis procedure to infer the lengths and cross-sectional areas of the tubes from the first three formant frequencies. There was some minor ambiguity in the optimum five tubes for the adult male /ɑ/ and /i/. However, there was a more striking two-way ambiguity in the adult male /æ/, which could be differentiated if formant amplitudes had been accounted for along with formant frequencies. While adult males may produce /æ/ in a configuration with a relatively short and constricted rear tube or with an alternative tube with a gradually changing area, the inferred shapes for children show that they may prefer the latter configuration. Informal experimentation shows ambiguity for the mid, front vowel /ɛ/ as well. These observations on low-to-mid front vowels will be pursued in subsequent work, noting here that they are vowels with difficult-to-define constriction locations (e.g., Ladefoged and Maddieson, 1996; p. 284).

In both the listening and KFO conditions, children appear to produce back vowels /ɑ/ and /u/ with a rear tube at least as long, proportionately, as adults. (The rear tube is a

TABLE IV. The length of the recovered rear tube and its ratio with the total vocal tract length. Multiple values appear when there were multiple recovered shapes. Exceptions to when the children's rear tube-to-total length ratio is greater than or equal to the same ratio for adults are shown in italics. (When there was a tube of intermediate area between the rear tube and the third tube from the rear, one half of its length was added to the rear tube length to provide the number in this table.)

	Adult length and ratio	Children (listening) length and ratio	Children (KFO) length and ratio
ɑ	4.89 cm, 0.34	6.13 cm, 0.57	5.89 cm, 0.53
	7.09 cm, 0.43		
	6.28 cm, 0.41		
	8.75 cm, 0.51		
æ	4.75 cm, 0.31	9.06 cm, 0.78	6.19 cm, 0.67
	7.57 cm, 0.50		
u	3.08 cm, 0.17	3.55 cm, 0.30	3.80 cm, 0.35
i	6.62 cm, 0.43	9.30 cm, 0.49	4.51 cm, 0.44
	5.94 cm, 0.39		
	7.11 cm, 0.48		
	6.65 cm, 0.45		
	7.09 cm, 0.49		

constriction for /ɑ/ and an unconstricted cavity for /u/.) In the case of /u/, the difference in proportionate terms can be as large as a factor of 2, and in absolute terms, the rear tube for adults and for children is of similar length. One result of the proportionate difference in rear tube length is the possibility that the natural frequency of the rear Helmholtz resonator in children is less than the frequency of their front Helmholtz resonator, where the opposite is the case for adult's production of a "canonical" /u/.

The following can be offered as one cause for the relatively forward tongue constriction in /u/ for a 4 year old talker. If the child's constriction were moved any further back, it may be that the rear cavity would be so small or totally obliterated, that a double Helmholtz resonance would not be possible. This, in turn, may be due to the limited control and/or flexibility of the tongue body and root, and the fact that the pharynx tube forms an obtuse angle with the mouth cavity, while adult pharynges form right angles with the mouth (Kent and Vorperian, 1995, p.161). (The more obtuse the angle between the pharynx and mouth, the closer the pharynx and mouth are to forming a straight tube, and the more tongue body needs to bend to form the rear cavity and constriction.) Corroborating research on the production of [ɹ] by young children indicates that it is difficult for them to make two simultaneous constrictions with the tongue, and that the rear constriction for [ɹ] may be missing or not par-

TABLE V. Helmholtz resonance frequencies for the uncoupled back and front resonators.

	Adults resonance freq. (Hz)	Children (listening) resonance freq. (Hz)	Children (KFO) resonance freq. (Hz)
Back resonator	723	784	564
Front resonator	357	575	832

ticularly tight (McGowan, Nittrouer, and Manning, 2004). Thus, the child produces an acceptable /u/ with a proportionately longer rear cavity compared to the adult double Helmholtz resonator.

The results presented here are in accord with the finding that simple area function scaling from adult to child is not sufficient to account for the observed vowel formant frequencies. For instance, Nordström (1979) attempted to reproduce children's formant patterns by scaling the tube lengths for adults' area functions according to the ratio of children-to-adults pharyngeal length and mouth length separately. As this did not provide sufficient fit to children's vowels, the cross-sectional areas in the pharyngeal and mouth regions were, themselves, scaled by the squares of these scaling factors. This also did not provide a good fit to children's formant frequencies.

Scaling based on two anatomical dimensions is not sufficient to explain the differences in adults and children in their vowel production. Possible physiologic causes have been posited in this paper for the differences in /u/ production, coupled with an anatomic difference: flexibility of the tongue, control of the tongue body and root, and the oblique angle between the pharynx and the mouth. There are further factors to consider, including the mandible, which is disproportionately smaller for children four years of age (Kent and Vorperian, 1995). There may be other factors that prevent proportionate or encourage disproportionate formant scaling, as in the case of /u/. Further, /æ/ exhibits nonuniform formant scaling, but a physical reason has not been posited here. It is intriguing that, as Maeda and Honda (1994) point out, /u/ and /æ/ are extreme vowels for the styloglossis-genioglossis anterior antagonist pair. Further work should study /æ/ in relation to other relatively open vowels, such as /ɛ/ and /ʊ/.

The findings here do not corroborate the speculation made by Maeda and Honda (1994) that one needs the right angle of the rear pharyngeal wall and the mouth to produce the vowels /ɑ/ and /i/. (It should be born in mind, however, that the present study does not use articulatory constraints.) Table III shows that listeners judged the children's vowels under the KFO condition to be good exemplars of their phonemic categories. Even without a pharynx at right angles to the mouth, the average 4 year old child can produce these vowels in a ways that are perceptually acceptable to adults. In fact, Kent and Forner (1979) show that the vowels /ɑ/ and /i/ are produced with scale factors that are fairly constant across the three formants (Table I). The results here indicate that in order for children to achieve proportionate formant scaling it is important to form constrictions and cavities whose lengths are not far from proportionate to the adults. (A statement that proportionate length is sufficient cannot be made because of differences in the associated cross-sectional areas.) The vowels /ɑ/ and /i/ show that mismatches in the relative positions and sizes of fixed anatomical structures, such as the pharynx and mouth, do not necessarily hinder a child's ability to form such constrictions and cavities. Indeed, in perceptual tests using speech produced by an articulatory synthesizer, Ménard, Schwartz, and Boë (2004) showed that infants can produce all the French vowels. How-

ever, caution should be used in this kind of experiment, because scaling of an adult vocal tract model to simulate a child's vocal tract is not sufficient to ensure that all the important physiological aspects of children's speech are captured.

This research offers no clear strategy that a child may adopt in attempting to imitate an adult's vowels. It is plausible that the child attempts proportionate scaling of tube lengths in certain instances, and when this is impossible, he or she attempts to imitate the general vocal tract shape. It is not possible to say from these data whether children attempt to imitate vocal tract shape or acoustic parameters. This may be impossible in any study that involves only acoustic and/or articulatory data because of the causal relation between the two domains.

ACKNOWLEDGMENTS

APPENDIX

The choices given to the listener when the synthetic vowel was /ɑ/, or a vowel with its formant frequencies up to 20% different, were: "hot," "haughty," "hut," "hat," "how" or /ɑ, ɔ, ʌ, æ, oʊ/.

The choices given to the listener when the synthetic vowel was /æ/, or a vowel with its formant frequencies up to 20% different, were: "had," "head," "hot," "hayed," "hut" or /æ, ɛ, ɑ, eɪ, ʌ/.

The choices given to the listener when the synthetic vowel was /u/, or a vowel with its formant frequencies up to 20% different, were: "whoed," "hood," "hoed," "hut," "hot" or /u, ʊ, oʊ, ʌ, ɑ/.

The choices given to the listener when the synthetic vowel was /i/, or a vowel with its formant frequencies up to 20% different, were: "heed," "hid," "hayed," "head," "had" or /i, ɪ, eɪ, ɛ, æ/.

[1]Rear cavities were defined using the following rules: (1) Rear tubes are constrictions for /ɑ/ and /æ/, and they are cavities for /i/ and /u/, (2) going from rear to front, a constriction (cavity) never ends at a tube whose neighbor to the rear has a greater (lesser) cross-sectional area, (3) cross-sectional area differences of less than 0.5 cm^2 are ignored, (4) going from rear to front a constriction (cavity) ends at the first tube with increased (decreased) area, and (5) if the front neighbor of the tube ending a constriction (cavity) has an even greater (lesser) area, than one-half the length ending the constriction (cavity) is added to the length of the rear tube, otherwise there is no extra length added to the rear tube.

Modeling coupled aerodynamics and vocal fold dynamics using immersed boundary methods

Comer Duncan[a] and Guangnian Zhai[b]
Department of Physics and Astronomy, Bowling Green State University, Bowling Green, Ohio 43403

Ronald Scherer[c]
Department of Communication Disorders, Bowling Green State University, Bowling Green, Ohio 43403

The penalty immersed boundary (PIB) method, originally introduced by Peskin (1972) to model the function of the mammalian heart, is tested as a fluid-structure interaction model of the closely coupled dynamics of the vocal folds and aerodynamics in phonation. Two-dimensional vocal folds are simulated with material properties chosen to result in self-oscillation and volume flows in physiological frequency ranges. Properties of the glottal flow field, including vorticity, are studied in conjunction with the dynamic vocal fold motion. The results of using the PIB method to model self-oscillating vocal folds for the case of 8 cm H_2O as the transglottal pressure gradient are described. The volume flow at 8 cm H_2O, the transglottal pressure, and vortex dynamics associated with the self-oscillating model are shown. Volume flow is also given for 2, 4, and 12 cm H_2O, illustrating the robustness of the model to a range of transglottal pressures. The results indicate that the PIB method applied to modeling phonation has good potential for the study of the interdependence of aerodynamics and vocal fold motion. © *2006 Acoustical Society of America.*

I. INTRODUCTION

Computational modeling of the dynamics of phonation is a challenge from the standpoint of the inherent interdependence of glottal material properties, the motion of the vocal folds, and the complex aerodynamics that develops in the glottis. The main approaches which have been used to date may be generally classified as (1) lumped parameter models using multiple masses (Story and Titze, 1995), (2) finite element based models (Alipour, Berry, and Titze, 2000), and (3) a finite element based biophysical model (Alipour and Titze, 1996; Alipour and Scherer, 2000; Alipour and Scherer, 2004). In the first type of modeling the vocal folds are approximated by a few (two or three) lumped masses which undergo motion transverse to the inflow direction. The focus in this type of model is the dynamics of the lumped masses which model the vocal folds. The aerodynamics is modeled assuming a steady-state based approximation. The second approach has focused on the development of a more sophisticated finite element model of the vocal folds. The emphasis was on the modal properties of the finite element based material model. The aerodynamics was included in a restricted steady-state treatment. In the third approach the aerodynamics was treated using a Navier–Stokes model for the air and the material was treated using a finite element model for the vocal folds. While all three approaches have treated important parts of the system, none other than the biophysical model method of Alipour and co-workers allow the potential complexity of the model to approach the real system. The method presented in this work is a step toward a more complete model with special attention to the closely coupled interactions between air and vocal folds. The approach taken in the present work is unique in its treatment of the interface between the vocal folds and the air. This work demonstrates how emergent biophysical properties of both the air and the vocal fold can result from an intrinsic treatment of the interface.

This work focuses on simulations which utilize the penalty immersed boundary (PIB) method developed by Kim (2003), based on the immersed boundary method originally developed by Peskin (1972) and further elaborated by Peskin and McQueen (1989) for the heart system. The PIB method as applied in this work treats the dynamics of the air and the vocal folds on a more or less equal footing. The emergent complex dynamics of the system comes from the coupled nature of the two interacting subsystems, and the PIB method described in this work shows promise in providing a more intrinsic characterization of the physics of phonation.

In the work reported here, some of the basic features of the PIB method are presented, a description of a simplified two-layer treatment of a two-dimensional model of the material properties of the modeled vocal folds is given, and a summary of the results of simulations of phonation using the combined system are given. Snapshots of the vocal fold dynamics and the aerodynamics generated by the interactions among the subsystems are shown. The 8 cm H_2O case was used throughout because this transglottal pressure is common in human phonation and should result in sustained oscilla-

tions. The results indicate that this simplified two-dimensional model yields interesting interrelations between the closely coupled dynamics of the vocal folds and the aerodynamics.

II. PIB METHOD APPLIED TO MODELS OF PHONATION

The basic idea of this approach to modeling the coupled air-vocal folds system is to approximate the air as a viscous, incompressible fluid in which there is an immersed material boundary, here taken to be the vocal folds. The method handles the coupled system of air and vocal folds as a single, potentially strongly interacting whole. In general, the coupling can involve quite complex motions of both the air and the vocal folds. The dynamics that emerges from this interaction cannot be determined from approximations that assume one or the other of the subsystems dominates. As in the physiological system, in the computational model the behavior must emerge from the complex interplay between the two subsystems. This is a strength of the method that this work utilizes.

A. Summary of the PIB method

The PIB method of Kim and Peskin (Kim, 2003), when applied to modeling the vocal folds and glottal aerodynamics, contains three interrelated subsystems: (a) the air, (b) the immersed material, and (c) the interface between them. The PIB method is in the general class of methods which addresses the interacting systems (air and vocal folds) as a fluid-structure interaction problem. Thus the method must detail its treatment of the interface between the air and vocal folds, which in turn determines how the two subsystems influence each other.

1. The air

The air is assumed to satisfy the Navier–Stokes equations for a viscous, forced, incompressible fluid

$$\rho\frac{\partial u}{\partial t} + \rho u \cdot \nabla u = -\nabla p + \mu\nabla^2 u + f,$$

$$\nabla \cdot u = 0, \tag{1}$$

where ρ, $\mathbf{u}$, p, and μ are, respectively, the density, velocity, pressure, and viscosity of the air. The term $\mathbf{f}$ is the force density (force per unit area in the current two-dimensional model) used in this paper. It is the force density exerted on the air by the vocal folds at the interface between them. This force density is related to the force per unit length $\mathbf{F}$ on the vocal folds at a given point along the interface labeled by s due to internal forces in the material via

$$f(x,t) = \int F(s,t)\delta^{(2)}[x - X(s,t)]ds, \tag{2}$$

where $\delta^{(2)}$ is the two-dimensional Dirac delta function. $\mathbf{X}(s,t)$ represents the position vector of a point on the vocal fold parametrized by s at time t. This provides an important link between the two subsystems. The forced Navier–Stokes
FIG. 1. Eulerian grid for aerodynamics and Lagrangian grids for vocal fold material model. The Eulerian mesh is a fixed Cartesian mesh the nodes are labeled by i, j with $i=1, nx$ and $j=1, ny$. The velocity and pressure fields are stored at the nodes labeled by i, j. The Lagrangian mesh is used to describe the moving particles which constitute the model vocal folds. On the Lagrangian mesh the particles are labeled by their Cartesian coordinates referred to the background Eulerian mesh. The positions for the outer layer of massless particles adjacent to the air are labeled by $X(k)$ with $k=1, n_{\text{particles}}$. The positions of the inner layer of particles which have mass M are labeled by $Y(k)$.

equations are set on a fixed background Eulerian mesh using Cartesian coordinates with mesh of constant spacing h in two dimensions in the present work. Figure 1 illustrates the node-centered storage for the velocity $\mathbf{u}$ and pressure p characterizing the aerodynamics.

2. The vocal fold material

The vocal fold "material" adopted in the present paper requires choosing appropriate models of the internal forces between the immersed material parts. A vocal fold is modeled by a two-layer system of particles, as is shown in Fig. 1. These two sets of particles constitute the outer and inner layers, respectively, of our simplified two-layer material model. The PIB method utilizes both Eulerian and Lagrangian meshes. The Eulerian mesh is a fixed background mesh for the description of the aerodynamic velocity and pressure fields, which are to satisfy the forced Navier–Stokes equations. The Eulerian mesh is Cartesian with a discrete set of nodes which are equally spaced in both the x and y directions. The mesh spacing is h. Eulerian mesh points are indexed using (i,j) with $i=1, nx$ and $j=1, ny$. The velocity and pressure fields are centered at the (i,j) nodes. The Lagrangian mesh consists of two layers of particles. The outer layer of mesh points immediately adjacent to the air consists of massless particles whose positions are described using a vector array $\mathbf{X}(k)$, where k indexes the particles and runs from 1 to $n_{\text{particles}}$. A second Lagrangian mesh consists of massive particles whose positions are described by a vector array $\mathbf{Y}(k)$. The massless and massive particles are adjacent and their motion is governed by the forces exerted on them by surrounding particles. In general, the Lagrangian mesh points do not coincide with the background Eulerian mesh. The force per unit length $\mathbf{F}$ on a given material point in Eq. (2) is the sum of two parts: the force per unit length on the element at $\mathbf{X}(k)$ due to adjacent elements, denoted by $\mathbf{F}_{\text{internal}}$, deter-

mined by the material properties of the vocal folds, and the force $\mathbf{F}_M$ on the massless boundary particle labeled by $\mathbf{X}(k)$ due to a spring connecting it to a particle of mass M residing at $\mathbf{Y}(k)$. The specification of $\mathbf{F}_{\text{internal}}$ and $\mathbf{F}_M$ will be given in the following section.

3. Interface between the air and the vocal fold, and tissue forces

A small portion of the material of the vocal fold is illustrated in Fig. 1 by the two sets of particles. The massless particles move with the interpolated average of the velocity field values of the surrounding air so that the no-slip condition

$$\frac{\partial X}{\partial t}(s,t) = u[X(s,t),t] = \int u(x,t)\delta^{(2)}[x - X(s,t)]dxdy \quad (3)$$

is satisfied. In Eq. (3) the two-dimensional Dirac delta function $\delta^{(2)}$ is used since the current model is two dimensional. Thus in the PIB method, the positions of the outer layer of massless particles is adapted so that they always move with the aerodynamic velocity field interpolated to the instantaneous positions of each massless particle. This provides a useful way in which the outer layer of particles maintain the same velocity as the local air velocity.

The particles of the inner layer possess mass and are moved around subject to a spring force exerted on them via connection with the adjacent massless outer layer markers. This force is modeled by a simple spring force per unit length: $F_M = -K_M(X - Y)$. The spring constant K_M is chosen large enough so that the inner layer tracks the outer layer close enough to maintain the integrity of the two layers throughout the simulation.

The motion of the particle with mass M at $\mathbf{Y}(k)$ in Fig. 1 is governed by the equation of motion

$$M\frac{\partial^2 Y}{\partial t^2} = -F_M. \quad (4)$$

Equations (3) and (4) are discretized using second-order accurate approximations when implemented in the algorithm to update the massless and massive particles in the PIB scheme.

In the present work there are forces exerted on a given outer layer particle due to surrounding outer layer particles plus a force on a given outer layer particle do to the inner layer particle. These consist of

(a) a stretching force per unit length on a particle due to nearest neighboring particles in the outer layer

$$F_{\text{stretch}}(k) = \frac{[\tau(k + 1) * \hat{e}(k + 1/2) - \tau(k) * \hat{e}(k - 1/2)]}{ds},$$

$$\tau(k) = s_{\text{stretch}}(k) * [1(k) - ds],$$

$$1(k) = |X(k) - X(k - 1)|,$$

where $\tau(k)$ is the tension at particle k, $\hat{e}(k+1/2)$ is a unit vector centered between the particles pointing from particle $k-1$ to particle k, and $1(k)$ is the distance between particles $k-1$ and k. The parameter $s_{\text{stretch}}(k)$ is the stretching force constant.

(b) a bending force per unit length

$$F_{\text{bending}}(k) = s_{\text{bending}}(k) * \{\text{curv}[X(k)] - \text{curv}[X_0(k)]\},$$

$$\text{curv}[X(k)] = \frac{[X(k - 1) - 2 * X(k) + X(k + 1)]}{ds^2},$$

where $s_{\text{bending}}(k)$ is the bending force constant, $\text{curv}[X(k)]$ is an approximation to the second derivative of the kth particle position along the boundary and $X_0(k)$ is the initial position of the kth particle.

(c) a fixed-point restorative force per unit length promoting the return of the particle position to its initial state

$$F_{\text{restore}}(k) = - s_{\text{restore}}(k) * [X(k) - Y(k)],$$

where $s_{\text{restore}}(k)$ is the force constant, $X(k)$ is the kth massless particle position, and $Y(k)$ is the position of the inner massive particle.

In addition, there is the spring force per unit length $\mathbf{F}_M(k)$ exerted on the outer layer particle due to the inner layer particle adjacent to it

$$F_M(k) = - s_M(k) * [X(k) - Y(k)],$$

with $s_M(k)$ the spring constant per unit length of the spring connecting the kth massless particle at $X(k)$ to the kth massive particle at $Y(k)$. Due to the fact that these forcing terms F_{stretch}, F_{bending}, F_{restore}, and F_M must have physical dimensions of dyn/cm, it follows that the physical dimensions of the individual forcing constants are as follows: $s_{\text{stretch}}(k)$ has dimensions of dyn/cm, $s_{\text{restore}}(k)$ and $s_M(k)$ have dimensions of dyn/cm^2, while $s_{\text{bending}}(k)$ has dimensions of dyn. The bending constant is a phenomenological model constant which represents the tendency of the vocal fold material to return of its initial configuration, which has been modeled via a dependence on the second derivative of the particle position along the vocal fold interface.

These forces per unit length are illustrated in Figs. 2 and 3. Their vector sum

$$F(k) = F_{\text{stretch}}(k) + F_{\text{bending}}(k) + F_{\text{restore}}(k) + F_M(k)$$

represents the net force per unit length on particle k. This force is spread to the Eulerian grid using the delta-function interpolation characteristic of the PIB method. The force $\mathbf{f}$ resulting from the delta-function spread is what appears on the right hand side of the Navier–Stokes equations, Eq. (1). The nonzero values of this force $\mathbf{f}$ are typically confined to regions in the Eulerian mesh which are near the outer layer. In the PIB method this force $\mathbf{f}$ is the only way that the material layers exert influence directly on the Navier–Stokes based aerodynamics. Figure 4 schematically illustrates a typical initial configuration, showing the two sets of particles which constitute the model vocal folds.

The elastic constants describing the strength of these four kinds of forces and the mass of the inner layer particles determine the material properties. These force constants have been carefully chosen so that the resulting dynamics of the model exhibit behavior approximating known physiological kinematics. In addition we apply a body force upstream over the first few rows of the Eulerian computational domain with values chosen to induce the transglottal pressure gradient of

interest in a given simulation. In Table I the ranges of parameters chosen to characterize the material properties of the simplified two-dimensional model of the vocal fold material are shown. The values of some of the material constants vary over the extent of the model vocal folds. Figure 5 provides
FIG. 3. (Top) Force restoring particle to initial configuration; (bottom) Force exerted by inner layer on outer layer to promote integrity of two layer mode vocal fold.

an example showing how the restoring-to-initial-configuration constant varies over the run of the initial positions of the vocal folds.

In this paper we report on a sequence of simulations with transglottal pressures of 2, 4, 8, and 12 cm H_2O, respectively. All simulations use the same material properties for the two-layer model vocal folds. The initial state of each case was chosen symmetric about the line $x=1$ cm along the y axis. All runs used the same initial adduction of 0.042 cm (minimal glottal diameter) and a parallel configuration of the left and right vocal folds. The initial velocity of the air was chosen to be everywhere zero. The total time simulated was 26.0 ms with a time step of $dt=1.0e-7$ and a sampling of the output every 0.1 ms.

All of the simulations used a fixed Cartesian Eulerian grid of 256×4096 equally spaced points in the x and y directions, respectively. The number of particles which make up the vocal folds depends on the constant Eulerian mesh spacing h in that the distance ds between adjacent particles must be no larger than $h/2$ to prevent leaking of the air

through the boundary. Typically $ds=h/4$ is chosen, as that gives some extra coverage of the vocal folds. This was useful when highly dynamic motions of the vocal folds occurred during the simulations. The Navier–Stokes solver made efficient use of the fast Fourier transform to produce velocity and pressure fields that satisfy the incompressible, forced Navier–Stokes equations. A two-step, formally second order accurate scheme described by McQueen and Peskin (2001) was used.

A single step in time from t^n to $t^{n+1}=t^n+dt$, schematically shown in Fig. 6, is outlined as follows:

(1) given the position of all boundary points and the velocity field at time t^n;
(2) update particle positions $\mathbf{X}(k)$ to time level $t^{n+1/2}$;
(3) compute the force per unit length $\mathbf{F}(\mathbf{k})$ on each vocal fold point k due to adjacent vocal fold points given by $\mathbf{F}_{\text{internal}}[\mathbf{X}(k)]+\mathbf{F}_M(k)$;
(4) spread this force to the Eulerian grid giving the force density exerted on the fluid using Eq. (2);
(5) update the Eulerian fluid velocity and pressure to time $t^{n+1/2}$;
(6) use the no-slip condition Eq. (3) to advance all the vocal fold point positions to time t^{n+1};
(7) use Eq. (1) to solve the forced Navier–Stokes equations to find the velocity and pressure field at time $t^{n+1}=t^n+dt$ and use Eq. (4) to advance the massive points at $\mathbf{Y}(k)$ to t^{n+1}; and
(8) use Eq. (4) to advance the massive points at $\mathbf{Y}(k)$ to t^{n+1}.

The simulations reported in the present work all utilized a background Eulerian mesh of 256×4096 cells, as mentioned above, and used a Lagrangian mesh of 34 036 particles with a fixed time step of $dt=1.0e\text{-}7$ s. One of the

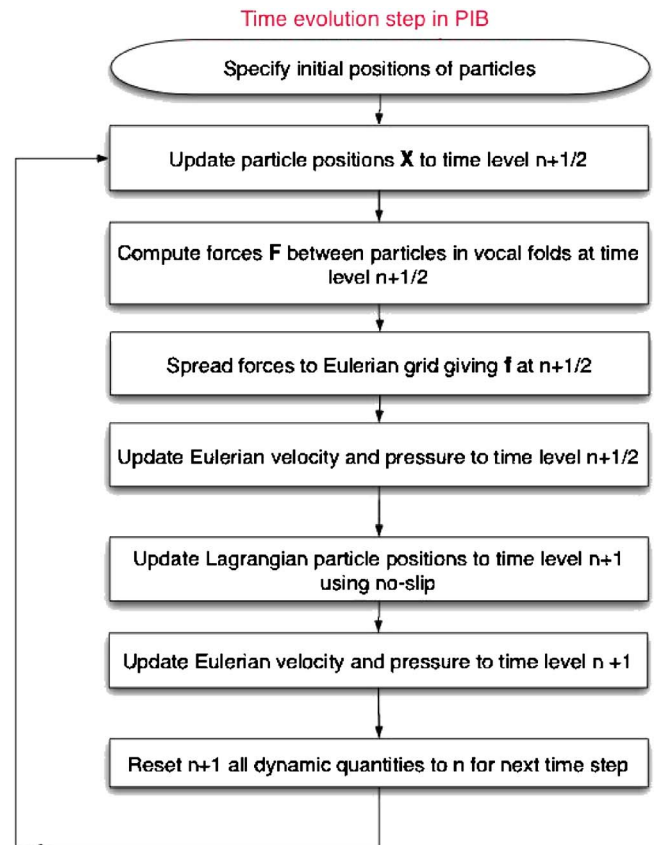
unique features of the PIB method in the present vocal folds modeling is the high resolution that the method provides. This means that very small scale coverage of the dynamics of


FIG. 6. (Color online) Flow chart of a single time step in the PIB method.

the vocal folds is part and parcel of the method. Thus the PIB model provides unprecedented ability to track vocal fold dynamics. The use of 256 cells in the direction transverse to the flow covering a distance of 2 cm provided adequate spatial resolution. The need for a time step of 0.1 μs was induced by the demand of numerical stability of the simulations. Thus the requirements of stability and adequate spatial coverage necessitated rather long run times, typically of the order of one week on a Pentium xeon processor.

III. RESULTS AND DISCUSSION

A. Simulation at 8 cm H$_2$O transglottal pressure

One of the important aspects of any model of phonation is its ability to exhibit self-oscillation under the condition of an appropriately chosen transglottal pressure. To illustrate some of the characteristics which come out of the PIB model, a simulation for a transglottal pressure of 8 cm H$_2$O was performed. The method uses periodic boundary conditions in both the transglottal (y) and the transverse (x) directions, as required by the Navier–Stokes solver used here. In order to induce a pressure gradient across the glottis, a body force of constant magnitude was applied over two rows of the domain near the inlet (near $y=0$). The body force magnitude was chosen so that the resulting transglottal pressure was equivalent to 8 cm H$_2$O. The initial minimal separation between the vocal folds was set to 0.042 cm and the medial vocal fold surfaces were placed in a parallel arrangement at $t=0$.

The simulation gives the positions of the particles representing the vocal folds and the velocity and pressure fields of the air. Given the substantial memory requirements for the simulation, these quantities were written out every 0.1 ms during the simulation. Space limitations of the tools for data analysis (MATLAB) made the spatial and temporal resolution coarser than the resolution simulated. In the presentation here, the spatial data sets have been down-sampled by a factor of 4 in each direction. While the resulting spatial resolution is relatively coarse, the essential aspects of the model are preserved.

1. Volume flow and transglottal pressure dynamics

The properties of the volume flow are important output of the vocal fold dynamics. Given the restriction to two dimensions in the present work, the definition used for the volume flow is given. The volume flow U_0 used in the analysis of the simulation output is defined in general by

$$U_0 = \int \frac{dV}{dt},$$

where dV is the volume swept out in time dt and the integral is over an area perpendicular to the y component of the aerodynamic velocity field. In the present case

$$\frac{dV}{dt} = u_y(x, y_{\text{fixed}}, t^n) * dx * dz.$$
FIG. 7. Volume flow rate vs time for transglottal pressure of 8 cm H$_2$O. The dots represent the values of the volume flow rate at intervals of 0.1 ms.

The integral is over the x direction from one side of the system to the other, covering the range 0, $1x$ in x. The fixed value of y is taken to be well outside the region where the vocal fold dynamics is significant. Here it is taken to be at the y location corresponding to $j=308$, or $y=2.412$ cm. dz is taken to have a unit value. Thus the volume flow rate used in the present work is

$$U_0 = \int_0^{1_x} u_y(x, 308 * h) * dx * dz.$$

The discrete version of the integral used in the present work is

$$U_0 = dz * (dx) * \sum_{i=1}^{nx/4} u_y(i, j_{\text{fixed}}),$$

where dx has been taken to be $4*h$ since the velocity data has been sampled at every fourth spatial point in each direction, as alluded to above. The sum over i from 1 to 64 covers the range in x from 0 to $1_x=2$ cm and $j_{\text{fixed}}=77$ in the sampled data set runs.

Figure 7 presents the volume flow. Given that the data were written out in time increments of 0.1 ms, the volume flow graph contains a total of 260 snapshots over the 26 ms shown. At each snapshot the volume flow was computed along a plane at $y=2.412$ cm downstream from the inlet (0.912 cm from the glottal exit; see Fig. 5).

From the volume flow shown in Fig. 7 it is clear that there is a transitory initial interval of time as the initially quiescent vocal folds begin to move in response to the external pressure gradient. After that the flow exhibits more consistent cyclic behavior. The flow indicates that there is self-oscillatory behavior for this case. There are regions where the vocal folds are nearly closed during which the flow oscillates and goes slightly negative. This behavior is most likely due to a slight backflow introduced near closure. Further investigation is underway to study the subcycle details

Duncan *et al.*: Penalty immersed boundary model of phonation
FIG. 8. Plot of transglottal pressure vs time for 8 cm H_2O.

of the closure process in the present model. It may be advantageous to introduce a collision model in the intervals during near closure.

Much dynamic behavior is going on during the complex interactions between the air and the vocal folds. A sense of the dynamics of the air may be had by observing the transglottal pressure. In the present simulations, the transglottal pressure is the difference between the pressure at $x=1$ cm, $y=0$ (center of the inlet) and $x=1$ cm, $y=2.412$ cm (see Fig. 5). This downstream point was chosen to be representative of a distance at which the flow would be clearly outside of the glottis. Since most of the pressure gradient occurs over this distance, such a difference between the two pressures should give a reasonable estimate of the effective transglottal pressure, and is expected to be a complex function of time. Indeed this is the case, as is shown in Fig. 8. An important aspect of the present PIB method as applied to vocal fold and aerodynamic modeling is that the output dynamics is determined by the detailed interaction and mutual influence of the vocal fold and the air. Such an intrinsic coupling means that the emergent dynamics is a truly cooperative phenomenon. This unique aspect of the PIB method means that it is possible for these closely coupled subsystems to induce dynamics on small spatial and temporal scales unachieved by other methods. The use of very small spatial separations between the particles (of the order of $h/4$, where h is the background Eulerian mesh spacing) provides the PIB model with a capability to model to track tissue response in greater detail than other models.

The complex dynamics of the transglottal pressure show quasi-periodic behavior with a dominant ripple frequency. The first 5 ms exhibits a complex, organized variation of the transglottal pressure that corresponds directly to the volume velocity variations of Fig. 7. Some of this behavior is associated with the initial transitory interval (covering up to 3.2 ms from the perspective of Fig. 7) with the rest continuing until the first indication of a transglottal pressure peak is seen at around 6.7 ms. The transitory interval is the result of the starting conditions and the necessary time interval through which the two-way interaction between the external

transglottal pressure applied and the biomechanical properties of the vocal fold material come to a dynamically consistent compromise. From then on, the behavior is still quite complex, but repetitions of peaking behavior reappear. The high pressure is in the range of 14 000–15 200 dyn/cm^2 (14.3–15.5 cm H_2O). The lowest transglottal pressures dip to around 4700 dyn/cm^2 (4.8 cm H_2O), and the computed mean of the data is 8211 dyn/cm^2 (8.3 cm H_2O).

Several quantitative measures of the combined vocal fold and aerodynamics will now be presented. Figure 9 shows plots of the transglottal pressure (dp), the subglottal pressure ($psubgl$), the supraglottal pressure ($psupragl$), the volume flow (U_0), and the time derivative of the volume flow (dU/dt) for the 8 cm H_2O case.

The combined plot in Fig. 9 demonstrates several correlated aspects of the 8 cm H_2O case, all of which are consistent with real phonation. Considering that the transglottal pressure is the difference between the subglottal and supraglottal pressures, it is of interest to examine these two components separately. Note that when the subglottal pressure has a peaking indication, the supraglottal pressure tends to show a trough. This is consistent with other models and measures of these pressures (e.g., Cranen and Boves, 1985), and is due to the closing glottis generating air pressure increase below the glottis and decrease above relative to reactance of the airways. Also, the numerical value of the subglottal pressure is larger than the supraglottal pressure value. The subglottal pressure has a mean value 7648 dyn/cm^2 (7.8 cm H_2O) whereas the supraglottal pressure has a mean of −563 dyn/cm^2 (−0.6 cm H_2O), with some fluctuations. Finally, the flow derivative achieves its largest absolute values on the down-slope of the flow graph, indicating that inertive loading and vocal fold motion may be contributing to flow skewing (which can be seen in the U_g trace) as expected in human phonation.

It is of interest to compare the time variation of the transglottal pressure with the volume flow in isolation. The resulting plot of both is shown in Fig. 10, where each time series is normalized to its maximum. The peaking of the dynamic transglottal pressure lags the peaking of the volume flow. This lag is to be expected, because the peak pressures are related to the closing of the vocal folds. However, the amount of lag is not constant from period to period. The differences between the peak values of the transglottal pressure and volume flow for the data displayed in Fig. 10 are 1.14, 1.59, 0.91, and 0.796 for each of the four cycles consecutively. The relation between these two quantities and other air flow properties is thus of interest. One important quantity which helps characterize the air flow field throughout the domain outside the vocal folds is the vorticity ω, where

$$\omega = \nabla \times u.$$

In the present two-dimensional model, the only nonzero component of the vorticity is the z component. In fact, our main use of the vorticity is to track its magnitude at various points in the computational domain. To this end, snapshots of contours of the vorticity have been superimposed on the po-
FIG. 9. Combined plots of (top to bottom) flow rate U (cm^3/s), time derivative of flow rate dU/dt (cm^3/s^2), transglottal pressure (dyn/cm^2) supraglottal pressure (dyn/cm^2), and subglottal pressure (dyn/cm^2) for an applied body force equivalent to 8 cm H$_2$O. The arrows in the U_0 graph indicate its maxima and the arrows in the transglottal pressure graph indicate its maxima.

sitions of the vocal folds in Figs. 11–14, at times corresponding to the maxima of the transglottal pressure. We note that the qualitative appearance of the glottal angle (all slightly divergent, with greater divergence with each consecutive cycle), vocal fold positions, and vorticity contours generally indicates that the decreasing flow rate is associated with a somewhat increased magnitude of vorticity. This is not to say that vorticity is not produced at other times during these cycles but that the data show a strong coincident relation

among three aspects: transglottal pressure achieving maxima, largest negative slope (maximum flow declination rate) during the fall of the volume flow, and times of increasing magnitude of vorticity. The dynamic relation between the measures of the vocal fold positions and the aerodynamics indicates that the PIB model produces a complex dynamic system.

2. Study of a single period of volume flow

While the discussion above has focused on the volume flow, transglottal pressure, and vorticity in a preliminary way, vocal fold motion and vorticity for a single cycle of the volume flow will now be considered. The intent is to illustrate in snapshots the vocal fold positions and vorticity contours during the cycle between 13.6 and 18.9 ms. These are shown in Fig. 15. The seven arrows in Fig. 15 correspond, respectively, to the times 14, 15, 16, 17, 17.5, 18, and 18.5 ms during the cycle. At these times the instantaneous vocal fold positions and the contours of the vorticity in the glottal region are shown. As the volume flow rises from near zero to its maximum, the vorticity associated with these vocal fold positions and shapes also changes. At the time of maximum volume flow the vocal folds are near their maximum opening, and the glottal angle is slightly divergent. Also, these figures show the relation between vorticity pro-

duction and the details of the intra-glottal shape. In what follows, the salient features of the selected times shown in Fig. 15 are:

14.0 ms:

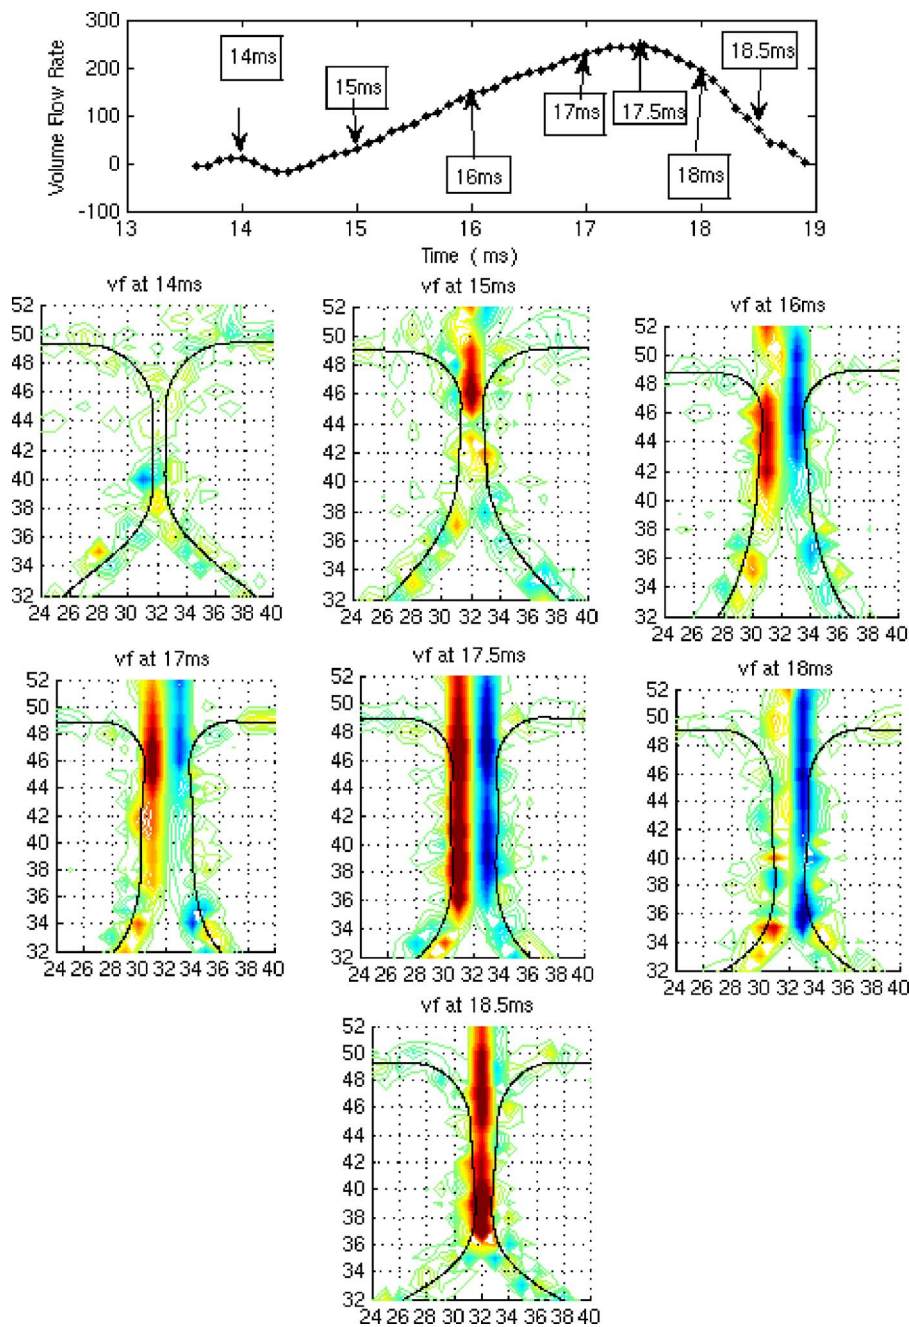
- vocal folds are nearly parallel and near closure,
- vorticity production is minimal,
- volume flow is low,
FIG. 14. (Color online) Vorticity contours and vocal folds positions at t =24.4 ms. Zoomed to cover central part of glottis. Horizontal and vertical indices represent Eulerian grid indices down-sampled by a factor of 4 in each direction.


FIG. 15. (Color online) Single cycle of volume flow rate and selected vocal folds position with instantaneous vorticity contours. At the top of the figure the arrows in the volume flow correspond to times at which the overlay of the vocal fold positions and the vorticity contours: 14, 15, 16, 17, 17.5, 18, and 18.5 ms, respectively.

15.0 ms:

- vocal folds being pushed apart from below by subglottal pressure, with a convergent glottal angle and a narrower opening at the top,
- vorticity production minimal throughout glottis except at glottal outlet where the curvature of the vocal folds is significant, and
- volume flow increasing;

16.0 ms

- vocal folds are increasingly separated, glottis is convergent, and the overall diameter of the opening of the glottis is larger,
- vorticity production is associated with the outlet of the glottis, where the curvature of the vocal folds is significant, and

- volume flow increasing;

17.0 ms:

- vocal folds are near maximum separation, glottal angle is less convergent, with a notable intra-glottal curvature (concavity), indicating intraglottal shape dynamics in progress,
- vorticity production now dominant at the glottal outlet where curvature of glottis is largest, and
- volume flow increasing, as average opening of glottis is larger, but nearing the maximum value;

17.5 ms:

- vocal folds at the glottal outlet have not altered position to changed diameter and curvature substantially, but the inlet of the glottis has larger curvature; glottal angle is slightly divergent, suggesting initial closing phase,

- vorticity production associated strongly with both glottal inlet and glottal outlet regions of large curvature of glottis, and
- volume flow has maximum value;

18.0 ms:

- glottal outlet has not substantially decreased in diameter; glottis more divergent in shape,
- vorticity production associated with curvature at the glottal inlet, as curvature of that region is enhanced at this time, and
- volume flow is decreased since average glottal opening diameter is smaller;

18.5 ms:

- vocal folds moving toward each other near glottal outlet but still relatively open at the glottal outlet region; glottis more divergent with narrow glottal entrance,
- vorticity production associated with curvature of glottal inlet, and
- volume flow is decreased further.

Several general properties of the snapshots can be gleaned:

(1) as the cyle begins, the lower portion of the glottis opens first;

(2) vorticity production is associated with regions of increased curvature (i.e., smaller radii of curvature) and vorticity is largest near the top end of the glottis during the first half of the cycle; and

(3) the dynamic character of the glottal duct makes the relation between a specific point of the glottis and vorticity not an appropriate object of attention, as the glottis is changing so rapidly that the dynamic effects of the glottal wall motion on the aerodynamics are not separable. Further, given that the shape of the glottis is time dependent, it is clear that when vortical motion is in part induced by the curvature of the glottis, this curvature itself is a dynamic quantity. Thus, subsequent to the instantaneous curvature being sufficient to encourage vorticity to be produced locally, the vorticity does not find itself in a static environment. This means that if vorticity is produced, the dynamic nature of the glottal walls affects and is affected by the aerodynamics. In addition, it is of interest to estimate the skewing quotient $\mathbf{Q}_S$ and the open quotient $\mathbf{Q}_O$ (Titze, 1994; Titze and Sundberg, 1992) for the selected single cycle in the simulation. These estimates were made by first obtaining the time $\mathbf{T}_p$ during which the slope of the time derivative of the flow, dU/dt, is positive, the time T_n during which the slope of dU/dt is negative, and the time $\mathbf{T}$ for the single period. From the graph of dU/dt (Fig. 9), $\mathbf{T}_p = 3.0$ ms, $\mathbf{T}_n = 2.3$ ms, and $\mathbf{T} = 5.6$ ms. Based on the present simulation of 8 cmH$_2$O, these data provide the following estimates of the skewing and open quotients: $\mathbf{Q}_S = 1.26$, $\mathbf{Q}_O = 0.95$, values which are indicative of the initial adduction for the present simulations. Also, the value of the time $\mathbf{T}$ for the period yields a rough estimate of a frequency of 178 Hz.

An estimate was made of the maximum subglottal
FIG. 16. Volume flow rate showing selected instants for analysis, labeled A–K. The dots represent the values of the volume flow rate at intervals of 0.1 ms.

power for the subglottal pressure of 8 cm H$_2$O, which is 784 N/m^2, and the maximum volume flow rate of 250 cm^3/s, viz.,

$$\text{Max}(\text{Power}_{\text{subglottal}}) = P_{\text{subglottal}} * U_{0\text{max}} = 0.196 \text{ W}.$$

3. Properties of the aerodynamics and vocal fold motion in regions of near zero volume flow

The volume flow graph in Fig. 7 indicates four time intervals in which the volume flow is near zero. Given the similarity of the short period oscillations in the volume flow during these intervals, the motion of the vocal folds and the attendant vorticity contours during three of these intervals were inspected. One question was, are there similarities in the aerodynamics and closely associated vocal fold dynamics that are common to all three of the intervals shown in Fig. 16?

Three separate sets of sample times, chosen by the local extrema of the volume flow where it approaches zero, are labeled (A, B, C), (D, E, F), and (G, H, I, J, K), respectively, in Fig. 16. A study of the vocal fold positions and the vorticity contours for these sets of points indicates that there is little vorticity associated with them. During these intervals, the vocal folds (and therefore the glottal walls) oscillate with rather small amplitudes, as movies of the dynamics clearly indicate. These small oscillations appear to be the cause of the local flow variations near zero, rather than, for example, resonance effects of the airway. In the simulations, the initially chosen adduction was not expected to permit complete closure. Perhaps some adjustments in one or more of the material constants would affect these "near-closing" oscillations. If the vocal fold material was a bit stiffer in one of the material constants, then the material would not be so flexible as to allow substantial suboscillations as are seen here. This possibility is under investigation and will be reported on in subsequent work.
FIG. 17. Volume flow rate for 2, 4, 8, and 12 cm H_2O. The dots represent the values of the volume flow rate for the separate transglottal pressures at intervals of 0.1 ms.

B. Volume flow for several transglottal pressures

In this section the ability of the PIB model to characterize the effect of varying the transglottal pressure is explored. The main interest is to investigate the sensitivity of the simplified two-dimensional model to the onset of self-oscillation. A second reason is to inquire about how the vocal fold position dynamics and the aerodynamics associated with each different input pressure are qualitatively and quantitatively different below and above a numerically determined threshold. Such information is important to the understanding of the interrelations between the two subsystems.

Transglottal pressure values of 2, 4, and 12 cm H_2O were chosen to study the ability of the PIB model to simulate phonation and suprathreshold behavior. For the different cases, all parameters were fixed as in the 8 cm H_2O case except for the magnitude of the body force to induce the desired pressure gradient in the y direction. Figure 17 shows the volume flow graph for the four runs.

It is seen in Fig. 17 that there is a lack of significant flow modulation for the 2 cm H_2O condition, but obvious modulations for the 4 cm H_2O condition. While an apparent onset of oscillation is observed for the 4 cm H_2O case, it is presently not possible to conclude that the threshold is just above 2 cm H_2O, because intermediate pressure values were not studied, and other adduction and tissue properties should be explored. The point of the present trend in the response of the flow rate to different transglottal pressures is that the PIB model appears robust enough to study threshold behavior realistically.

IV. CONCLUSIONS AND FURTHER WORK

The results of applying the penalty immersed boundary method to a simplified two-dimensional model of the aerodynamics and vocal fold dynamics show that the method can produce physiologically relevant properties. The method allows for an intrinsic treatment of the complexities of the air-vocal fold systems and demonstrates the close connection between the production of the air flow field by the dynamic vocal fold motion. The two subsystems are not separable in the real glottis. The PIB method recognizes this inseparability and adapts to it. This preliminary study of the potential for the PIB method suggests that it should be extended to a broader range of normal phonatory conditions, and eventually to pathologies and other asymmetries of tissue biomechanics, conditions for which the model appears to be well suited. Indeed a long range goal of such modeling is to develop a comprehensive model wherein the intimate connection between the aerodynamics and the vocal fold contour and material properties will likely yield new insights into the relation between glottal structure, its dynamics, and the "output" aerodynamics. One of the challenges of modeling the vocal folds using a fixed Eulerian mesh for the velocity and pressure fields, with the Lagrangian mesh for the vocal fold material moving on that mesh, is to capture all the important physics in the model. Simplified lumped models necessarily leave out the expression of potentially physiologically important effects. Thus the PIB method initially explored in the present work frees the interacting subsystems to produce vocal fold oscillations which potentially more closely represent the real world vocal fold oscillations. It must be mentioned, however, that the present PIB model does not take into account the effects of coupling to the trachea and the pharynx (except to the extent shown in Fig. 6). Further, the influence of the false vocal folds is not included in the present study. Only after coupling to these other important subsystems can the PIB method be said to represent a complete model. Such developments are currently under active study.

As the Reynolds number associated with the flow of air increases, the number of Eulerian mesh points needed in-

creases. Even in two spatial dimensions it thus becomes clear that at some point the computational resources will be severely challenged to provide the needed spatiotemporal resolution. In order to address this problem, a program is under development to implement the immersed boundary methods in the context of parallel adaptive mesh refinement (AMR) technology coupled with a more general Navier–Stokes solver which can accommodate a variety of boundary conditions. Currently under development is a version of the two-dimensional PIB method which uses the infrastructure of methods developed at Lawrence Berkeley Labs (LBL) (Almgren *et al.*, 1998). The LBL computational technology has been developed in part to allow the implementation of a robust class of solvers of the forced Navier–Stokes equations for variable density systems. Underlying the solver is a set of meshes with varying degrees of resolution, with the meshes created as the physics being expressed requires more resolution. The meshes are thus dynamically created and destroyed as the simulation proceeds, giving needed coverage of small scale phenomena while doing so consistent with phenomena at coarser scales. The net result of this approach will be to provide more accurate characterization of the vocal fold-air system and do so in a computationally efficient manner. In addition, this technology has been parallelized. This means that the evolution of the vocal fold system will be accomplished with much enhanced spatial and temporal resolution and carried out on large parallel clusters. This has an important practical payoff: by spreading the computations among a large number of processors, more resolution is obtained than with a simulation bound to just one processor. Such a coupling of parallel AMR with a robust class of Navier–Stokes solvers is expected to yield increased resolution and computational efficiency.

The present PIB model has another simplification which would be removed in subsequent studies. This is that the material model has no viscous tissue forces. While physiological vocal fold tissue possesses viscosity, it was felt that for the initial study the effect of such dissipation would not be included. By not including viscosity of the vocal folds, the model lacks a mechanism whereby the energy is lost in tissue. Including such effects will promote a balance between the losses that the tissue possesses and the input energy from the transglottal pressure gradient. In human phonation, the inclusion of material viscosity will have an effect on the vocal fold dynamics and indirectly an effect on the aerodynamics, due to the closely coupled nature of our model. The inclusion of viscosity is thus planned for the follow-up modeling using the PIB model.

The present work has used a very simple model of the vocal fold material consisting of a two-deep layer of particles with stretching, bending, and fixed point restorative forces between the particles, as well as a stretching force between the outer and inner layers of the material model. While the present work demonstrates the basic viability of such a simplified model of the material, it is clear that further work is needed to make a more realistic model of the vocal folds. Further, it is seen how even with this simplified model of the vocal folds, simulations are obtained which possess volume flows that exhibit many of the properties expected of a viable model of vocal fold dynamics and aerodynamics. Analysis of the 8 cm H_2O case and volume flow graphs for 2, 4, 8, and 12 cm H_2O cases have provided results suggesting a sensitivity of the model to the imposition of given external transglottal pressures.

The development is currently underway of a generalized PIB method which couples to an extended material rather than layers to the interface with the air. Additional models of the material will be supplied in subsequent studies. One advantage that the PIB method approach provides is the option to tune the material parameters to obtain qualitatively and quantitatively different dynamics. This aspect of the PIB model, wherein various "computational vocal fold materials" are designed and their properties explored is just beginning to be exploited. Here the stage has been set for the application of the PIB model to such questions.

Interarticulator programming: Effects of closure duration on lip and tongue coordination in Japanese

Anders Löfqvist[a]

Haskins Laboratories, New Haven, Connecticut 06511 and Department of Logopedics,
Phoniatrics & Audiology Clinical Sciences, Lund, Lund University, Lund, Sweden

This paper examines the coordination of lip and tongue movements in sequences of vowel-bilabial consonant-vowel where the duration of the oral closure for the consonant is varied for linguistic purposes. Native speakers of Japanese served as subjects. The linguistic material consisted of Japanese word pairs that only differed in the duration of the labial consonant, which was either long or short. Recordings were made of lip and tongue movements using a magnetometer system. Results show a robust difference in closure duration between the long and short consonants. The tongue movement from the first to the second vowel had a longer duration in the long than in the short consonants, and its average speed was slower in the long consonant. The size of the tongue movement path between the vowels did not consistently differ between the long and short consonants. The tongue movement almost always started before the oral closure for the consonant, while the onset of the lip movement towards oral closure mostly started before that of the tongue movement. The offset of the tongue movement occurred after the release of the closure, but there was no clear pattern for the long and short consonants. © *2006 Acoustical Society of America.*

I. INTRODUCTION

This paper examines the coordination of lip and tongue movements in sequences of vowel-bilabial consonant-vowel, where the duration of the oral closure for the consonant is varied for linguistic purposes, using speakers of Japanese. An earlier study of American English (Löfqvist and Gracco, 1999) showed that the onset of the tongue movement from the first to the second vowel in such a VCV sequence almost always started before the oral closure for the consonant. In addition, more than 50% of the tongue movement trajectory between the vowels occurred during the oral closure. There was also a weak positive correlation between the magnitude of the tongue movement for the vowels and the interval between tongue movement onset and the onset of the lip closing movement. That is, the tongue started to move earlier than the lips as the tongue trajectory increased.

In Japanese, the ratio of closure duration for long and short consonants is about 2:1 (Beckman, 1982; Han, 1994; Hirata and Whiton, 2005). There is an extensive body of acoustic studies of the Japanese sound system with particular emphasis on the role of the mora for speech timing (e.g., Warner and Arai, 2001). The long consonants in Japanese are sometimes referred to as "geminates," and such a consonant contributes one mora; it is also traditionally assumed that a mora boundary occurs in the long consonant. This paper does not address the general issue of mora timing, however. Its primary focus is on speech motor control, capitalizing on the length distinction in Japanese sound structure to study coordination of lip and tongue movements under two conditions of consonant length. It is thus beyond the scope of this

study to review the many different views of the mora in Japanese. The reader is referred to Vance (1987) and Warner and Arai (2001).

If the duration of the oral closure for the consonant is increased, a speaker can in principle use two strategies for the coordination of the tongue and lip movements, as illustrated in the bottom panel of Fig. 1; the top panel in Fig. 1 shows tongue, jaw, and lip movements between the two vowels in the word /kami/ with a short labial consonant. One strategy would make the same tongue movement trajectory for a long and a short consonant. Such a strategy could have one or two versions, or a combination of them. The onset of the tongue movement might be shifted later relative to the oral closure, so that the tongue movement reached its position for the second vowel at the same point in time for the long and short consonant, pattern 1a in the lower panel of Fig. 1. Alternatively, the onset of the tongue movement could have the same temporal relationship to the consonant closure, pattern 1b in the lower panel of Fig. 1. In this second case, the interval between the offset of the tongue movement and the release of the oral closure for the labial consonant would thus increase for the long consonant. Pattern 1c in the lower panel of Fig. 1 shows a tongue movement trajectory that is shifted both relative to the onset and offset of the labial consonant. A second strategy would be to modify the tongue movement during the long consonant, so that the relative timing between the tongue movement for the vowels and the lip movements for the oral closure of the consonant would be more or less the same for the long and short consonants, pattern 2 in the lower panel of Fig. 1. This would imply making a slower tongue movement trajectory for the long than for the short consonant. The timing between the tongue and lip movements would thus be similar in the two

---

FIG. 1. The top panel shows tongue, jaw, and lip movements between the two vowels in the word /kami/ with a short labial consonant; the gray line is an outline of the hard palate. The bottom panel shows the actual tongue body movement between the two vowels in the word with a short labial consonant and potential tongue movement trajectories in a word with a long consonant. See the text for further explanation.

conditions of consonant length. Experimental evidence for the second strategy has been provided by (Smith, 1992, 1995). Using the x-ray microbeam system (Nadler *et al.*, 1987), she showed that Japanese speakers tended to increase articulatory intervals from the medial consonant to the second vowel in long compared to short consonants.

The present study extends the findings of Smith, using the measurement procedures developed by Löfqvist and Gracco (1999). For example, to analyze temporal patterns of tongue movements, Smith made separate measurements in the vertical and horizontal tongue movements, and also used "target intervals" based on a criterion of minimum movement. In this study, a single measure of tongue movement speed, taking into account both the vertical and horizontal movement components, is used for determining onset and offset of tongue movements. In addition, measurements are made of the duration and magnitude of the tongue movement trajectory, the average speed of the tongue movement between the two vowels, and the coordination of lip and tongue movements. The question addressed is whether these measures differ between words with long and short consonants. The hypothesis, based on the work of Smith, is that the

tongue movement in the words with a long consonant will be slower and of longer duration than in a word with a short consonant, implying that speakers maintain a similar overall phasing between lip and tongue movements in long and short consonants.

II. METHOD

A. Subjects

Five native speakers of Japanese, three male and two female, served as subjects. They reported no speech, language, or hearing problems. They were naive as to the purpose of the study. Before participating in the recording, they read and signed a consent form. (The experimental protocol was approved by the IRB at the Yale University School of Medicine.)

B. Linguistic material

The linguistic material consisted of Japanese words with a sequence of vowel-labial nasal-vowel. These words formed minimal pairs, where the only difference between the pairs was the duration of the labial consonant. The words were designed to require a substantial amount of tongue movement from the first to the second vowel. The following words were used: /kami, kammi/, /kamee, kammee/, /kema, kemma/, /semu, semmu/. The productions of the last word pair turned out to have a very small amount of tongue movement, so they were not analyzed. In addition, to examine tongue movements in symmetrical vowel contexts, the following words were also recorded for three of the subjects: /kama, kamma/, /ʃimi, ʃimmi/. The linguistic material was organized into randomized lists and presented to the subjects in Japanese writing, with the words occurring in a short frame sentence. Fifty repetitions of each word were recorded.

C. Movement recording

The movements of the lips, the tongue, and jaw were recorded using a three-transmitter magnetometer system (Perkell *et al.*, 1992); when proper care is taken during the calibration, the spatial resolution of the system is on the order of 0.5 mm. Receivers were placed on the vermilion border of the upper and lower lip, on three positions of the tongue, referred to as tip, blade, and body, and on the lower incisors at the gum line. Two additional receivers placed on the nose and the upper incisors were used for the correction of head movements. The lip and jaw receivers were attached using Isodent, a dental adhesive, while the tongue receivers were attached using Ketac-Bond, another dental adhesive. Care was taken during each receiver placement to ensure that it was positioned at the midline, with its long axis perpendicular to the sagittal plane. Two receivers attached to a plate were used to record the occlusal plane by having the subject bite on the plate during the recording. All data were subsequently corrected for head movements and rotated to bring the occlusal plane into coincidence with the *x* axis. This rotation was performed to obtain a uniform coordinate system for all subjects (cf. Westbury, 1994).
FIG. 2. (a) Audio and lip aperture signals for the word /kami/, showing the point in the acceleration signal used for defining the onset of the lip closing movement. (b) Audio and tongue body signals for the word /kami/, showing the points used in the speed signal for defining the onset and offset of the tongue movement between the two vowels. The baseline in the bottom panel with the speed signal represents zero speed.

The articulatory movement signals (induced voltages from the receiver coils) were sampled at 500 Hz after low-pass filtering at 200 Hz. The resolution for all signals was 12 bits. After voltage-to-distance conversion, the movement signals were low-pass filtered using a 25-point triangular window with a 3-dB cutoff at 14 Hz; this was done forwards and backwards to maintain phase. A measure of lip aperture was obtained by calculating the vertical difference between the upper and lower lip receivers. To obtain instantaneous velocity of the lip aperture and tongue receivers, the first derivative of the position signals was calculated using a 3-point central difference algorithm. For the lip aperture signal, its acceleration was also calculated from its velocity. For each tongue receiver, its speed $v = \sqrt{(\dot{x}2 + \dot{y}2)}$ was also calculated. The velocity signals were smoothed using the same triangular window. All the signal processing was done using the Haskins Analysis Display and Experiment System (HADES) (Rubin and Löfqvist, 1996). The acoustic signal was pre-emphasized, low-pass filtered at 4.5 kHz, and sampled at 10 kHz.

The onset and release of the oral closure for the nasal consonant were identified in waveform and spectrogram displays of the acoustic signal. They were both identified by a change in the amplitude and the spectral properties.

To define the onset of the closing movement of the lips for the nasal consonant, an algorithmically obtained minimum in the lip aperture acceleration signal just before oral closure was used, following Löfqvist and Gracco (1999); see Fig. 2(a). In the words with asymmetrical vowel contexts, tongue movement onsets and offsets were defined algorithmically in the tongue body speed signal as minima during, or close to, the first and second vowels; see Fig. 2(b). We should note that, at these points in time, the horizontal and vertical velocity of the tongue is usually not zero. The duration of the tongue body movement was measured between its onset and offset. The magnitude of the tongue movement trajectory from the first to the second vowel was obtained by summing the Euclidean distances between successive samples of the tongue body vertical and horizontal receiver positions from movement onset to movement offset. The average speed of the tongue body was obtained by adding the speed of all the individual samples between movement onset and offset and then dividing by the number of samples in the interval. The vertical and horizontal positions of the tongue

body receiver at movement onset and offset were measured to examine if any observed changes in movement magnitude were due to changes in onset position, offset position, or both. Three temporal measurements were made. The first one consisted of the interval between tongue movement onset and oral closure; it provides information about the tongue movement relative to consonant closure. The second one was the interval between tongue movement onset and lip closing movement onset; it examines the coordination between tongue and lip movements. The third one was the interval between tongue movement offset and oral release; it is useful for examining the tongue movement relative to consonant release. The kinematic signals are expressed in a maxilla-based coordinate system. Thus, the tongue body movement includes the contribution of the jaw, which is appropriate when we are interested in the tongue as the end effector.

In the words with symmetrical vowel contexts, no temporal landmarks could be defined in the tongue movement signals. For these words, the movement path of the tongue, and the jaw were measured during the acoustically defined oral closure for the nasal consonant, and also the tongue body and jaw positions at consonant onset and offset. The jaw was included, since it might contribute to the labial closure, and hence to tongue movements, in particular in the words with the open vowel /a/.

To assess differences between the long and short consonants for each subject, T-tests were used. Given the large number of comparisons, a conservative α-level of 0.001 was adopted. Since the variances usually differed between the long and short consonants, as shown by Levene's test, the statistical tests assumed unequal variances, so the degrees of freedom were adjusted (e.g., Winer *et al.*, 1991, p. 67).

III. RESULTS

A. Consonant duration

The duration of the oral closure for the long and short nasal consonants is summarized in Fig. 3. For all speakers, there is a clear and robust difference between the long and short consonants, with the long ones having about twice the duration of the short ones. The statistical analysis showed all the differences to be significant (for /kami, kammi/ $t=$ -20.28, -24.39, -24.83, -18.28, and -17.86, for speakers YK, YM, KN, SO, and TT, respectively; for /kamee, kammee/ $t=-19.88$, -29.19, -40.79, -38.19, and -23.01, and for /kema, kemma/ $t=-19.72$, -28.78, -38.73, -26.32, and -15.67, with $p<0.001$ in all cases).

B. Tongue movements

The first analysis focused on the kinematic properties of the tongue movement from the first to the second vowel.

1. Tongue body movement duration

Figure 4 shows the duration of the tongue body movement from the first to the second vowel. For most subjects and words, the duration is longer in the long than in the short consonant. The two exceptions were for the productions of
FIG. 3. Closure duration of the bilabial nasal consonant (mean and standard deviation).

/kema, kemma/ by speakers SO and TT, where the duration of the movement trajectory was longer for the short consonant, but the difference was not significant in either case (t $=1.27$, and 3.23 for SO and TT, ns). For all the other cases, the difference was significant (for /kami, kammi/ $t=-11.2$, -8.19, -4.2, -12.17, -13.63; for speakers YK, YM, KN, SO,

Average speed of the tongue body movement from the first to the second vowel

FIG. 5. Average speed of the tongue body movement from the first to the second vowel (mean and standard deviation).

2. Average speed of tongue body

Figure 5 shows the average speed of the tongue body movement from the first to the second vowel. Overall, the average speed is slower for the long than the short consonant. With the exception of /kami, kammi/ of speaker YM ($t=3.2$, ns) the difference was statistically significant (for /kami, kammi/ $t=6.39$ 14.91. 7.0, 8.64, for speakers YK, KN, SO, and TT, respectively; for /kamee, kammee/ $t=9.55$, 6.63, 22.12, 10.61, 13.42; and for /kema, kemma/ $t=-6.73$,

and TT, respectively; for /kamee, kammee/ $t=-13.48$, -7.55, -10.34, -17.58, -14.55; and for /kema, kemma/ $t=-9.97$, -4.64, -4.97, for speakers YK, YM, and KN, with $p < 0.001$ in all cases).

Anders Lofqvist: Interarticulator programming

Length of the path of the tongue body movement from the first to the second vowel
FIG. 6. Path of the tongue body movement from the first to the second vowel (mean and standard deviation).

17.56, 12.52, 11.91, 3.84, for speakers YK, YM, KN, SO, and TT, respectively, with $p < 0.001$ in all cases).

3. Magnitude of tongue movement path

Figure 6 shows the path of the tongue body movement from the first to the second vowel. Here, the results differ both within and across speakers. Speaker YK always produced the long consonant with longer movement path, but the difference was only statistically significant for /kami, kammi/ ($t=-5.17$, $p < 0.001$) and /kema, kemma/ ($t=-4.3$, $p < 0.001$) but not for /kamee, kammee/ ($t=-1.98$, ns). Speaker YM made significant differences between all the

word pairs, but in /kami, kammi/ ($t=-7.26$, $p < 0.001$) and /kamee, kammee/ ($t=-5.86$, $p < 0.001$) the path was longer for the long consonant, whereas the opposite pattern was found for /kema, kemma/ ($t=4.49$, $p < 0.001$). Speaker KN consistently produced the short consonant with a longer tongue movement path, but the difference was only significant in two cases ($t=9.38$ and 11.6 for /kami, kammi/ and /kamee, kammee/, respectively, with $p < 0.001$ in both cases, but not for /kema, kemma/ $t=1.97$, ns). Also for speaker SO, the results varied between words. For /kami, kammi/ and /kamee, kammee/ the path was longer for the long than for the short consonant ($t=-8.53$, and -5.29, with $p < 0.001$ in both cases). However, the opposite was found for /kema, kemma/ ($t=14.03$, $p < 0.001$). Finally, speaker TT only showed a significantly longer path for the short consonant in /kema, kemma/ ($t=5.08$, $p < 0.001$), while no difference was found for the other two words ($t=-3.34$, and 2.83, ns, for /kami, kammi/ and /kamee, kammee/, respectively).

The path of the tongue body movement was not influenced by consonant length in a systematic manner across speakers. Whenever an influence was found, it could be due to a difference in onset position, offset position, or both, but there was no consistent pattern across subjects.

In summary, the results for the tongue movement from the first to the second vowel show that it generally had a longer duration for the long than the short consonant. Its average speed was always lower for the long than for the short consonant. The path of the tongue movement showed no consistent influence of consonant length.

C. Interarticulator programming

The next analysis examined the timing between the lip and tongue movements for the labial consonant and the two vowels. Three different measurements were made.

1. Onset of tongue body movement relative to onset of oral closure

Figure 7 summarizes the duration of the interval between tongue movement onset and oral closure for the consonant. Of note here is that, with the exception of only one case, /kammee/ for subject KN, the tongue movement onset always occurs before the closure. Overall there is no clear pattern for the long and short consonants. For /kami, kammi/, only subjects KN and YM showed a reliable difference (KN, $t=11.1$, $p < 0.001$, and YM, $t=12.9$, $p < 0.001$), but they were not in the same direction. The corresponding t values for the other subjects were 1.45, 0.36, and 0.83 for YK, SO, and TT, respectively, all ns. Also for the pair /kamee, kammee/, the results were inconsistent. Subjects YM, KN, and SO had significant differences ($t=11.30$, -10.41, and 3.39, with $p < 0.001$ in all cases), but only speakers YM and SO showed this interval to be longer for the long than for the short interval. Speaker KN produced the long consonant with a tongue movement that started after the closure. The other two speakers, YK and TT, showed no difference ($t=2.75$, and -2.37, ns). In contrast, four of the speakers produced the long consonant in /kema, kemma/ with an earlier start of the tongue movement for the short consonant ($t=-4.45$, -9.74,

(mean and standard deviation).

−17.87, and −17.59 for YM, KN, SO, and TT, respectively,
with $p < 0.001$ in all cases). Speaker YK showed the oppo-
site pattern($t = 5.26$, $p < 0.001$).

2. Onset of tongue body movement relative to onset of lip movement for closure

The results for this interval are shown in Fig. 8. The
overall results suggest that the lips lead, but there is no clear

difference between the long and short consonants. For /kami,
kammi/, speakers YK, YM, and KN showed a significant
difference between the long and short consonants ($t = -2.61$,
3.57, and −11.51, for YK, YM, and KN, respectively, with
$p < 0.001$). However, the difference went in opposite direc-
tions for YK and KN, compared to YM. For the remaining

two speakers, SO and TT, there was no difference ($t=0.92$ and -1.93, ns). For /kame, kammee/, only speakers YK and KN had a reliable difference in this interval between the long and short consonants ($t=-5.59$, and 14.36, $p<0.001$) and here the lips led with a longer time for the long than for the short consonants. For the other speakers, YM, SO, and TT, no difference was found ($t=-0.67$, -1.54, and -2.04, ns). Four of the subjects, YM, KN, SO, and TT showed a longer lead of the lip movement in /kemma/ than in /kema/ ($t=-7.65$, 9.78, -19.6, and -16.64, for YM, KN, SO, and TT, respectively, with $p<0.001$ in all cases). Note that, for the short consonant /kema/, these four subjects started the tongue movement before the lip movement. Subject YK showed a different pattern with the tongue movement leading the lip movement, with a significant longer tongue movement lead for the long consonant ($t=3.49$, $p<0.001$).

3. Offset of tongue body movement relative to oral release

As shown in Fig. 7, the onset of the tongue movement from the first to the second vowel almost always started before the oral closure for the consonants. Its offset tended to occur after the oral release; see Fig. 9. The pattern was, however, quite variable as shown by the standard deviations. Only speakers YK and YM showed a significant difference between the long and short consonants in /kami, kammi/, with the tongue movement offset occurring later for the short consonant ($t=3.19$ and 4.06, $p<0.001$). The remaining three subjects had no difference ($t=0.06$, 2.39, and 1.13, for speakers KN, SO, and TT, respectively). A similar pattern with a later offset for the short than for the long consonants in /kame, kammee/ was found for speakers YK, SO, and TT, but the difference was only significant for SO and TT ($t=5.03$, and 4.35, $p<0.001$), and not for YK ($t=2.54$, ns). The remaining two speakers, YM and KN, showed no difference ($t=0.09$, and -1.28, ns). Finally, for the pair /kema, kemma/, only subjects YK and SO showed a reliably later offset in the short than in the long consonant ($t=5.3$, and 3.59, $p<0.001$). The other subjects showed no difference ($t=0.88$, 1.89, and -0.6, ns, for YM, KN, and TT, respectively).

4. Symmetrical vowel contexts

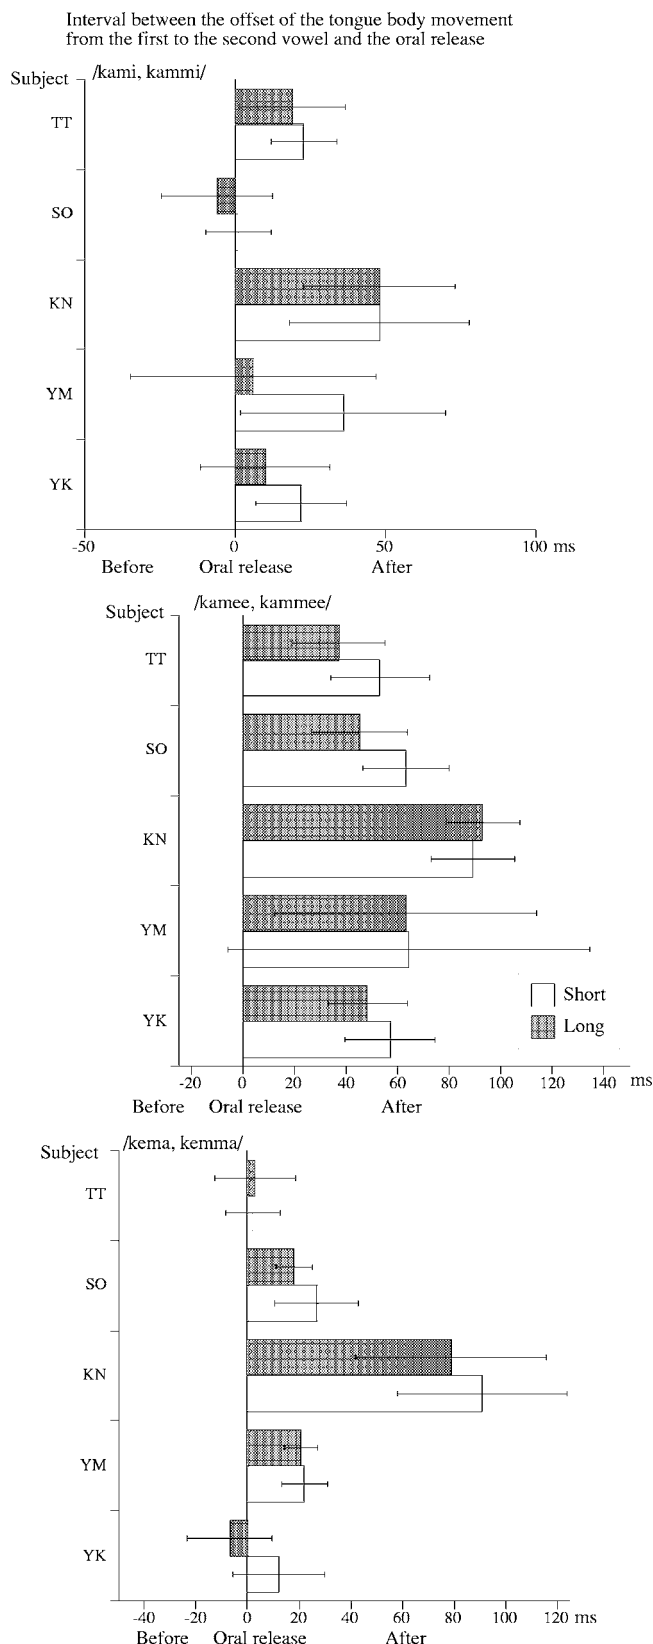
Two word pairs with symmetrical vowel contexts, /kama, kamma/, /ʃimi/, /ʃimmi/, were examined in three of the subjects. The results for tongue body and jaw path lengths during the acoustically defined oral closure are shown in Fig. 10. For the open vowels in /kama, kamma/, the movement path during the oral closure is longer for the long than for the short consonant for both the tongue body and the jaw (tongue body: $t=-12.88$, -5.94, and -11.73, for subjects YK, SO, and TT, with $p<0.001$; jaw $t=-16.8$, -22.78, and -11.58, $p<0.001$). For the high vowels in /ʃimi, ʃimmi/, the path of the tongue body movement is longer during the short than during the long consonant ($t=6.51$, 6.51, and 8.17,


FIG. 9. Interval between the offset of the tongue body movement from the first to the second vowel and the oral release (mean and standard deviation).

$p<0.001$). In contrast, the path of the jaw during the oral closure is longer for the long than for the short consonant, but the difference was only statistically significant for subjects YK and TT ($t=-4.37$, and -6.83, $p<0.001$), but not for

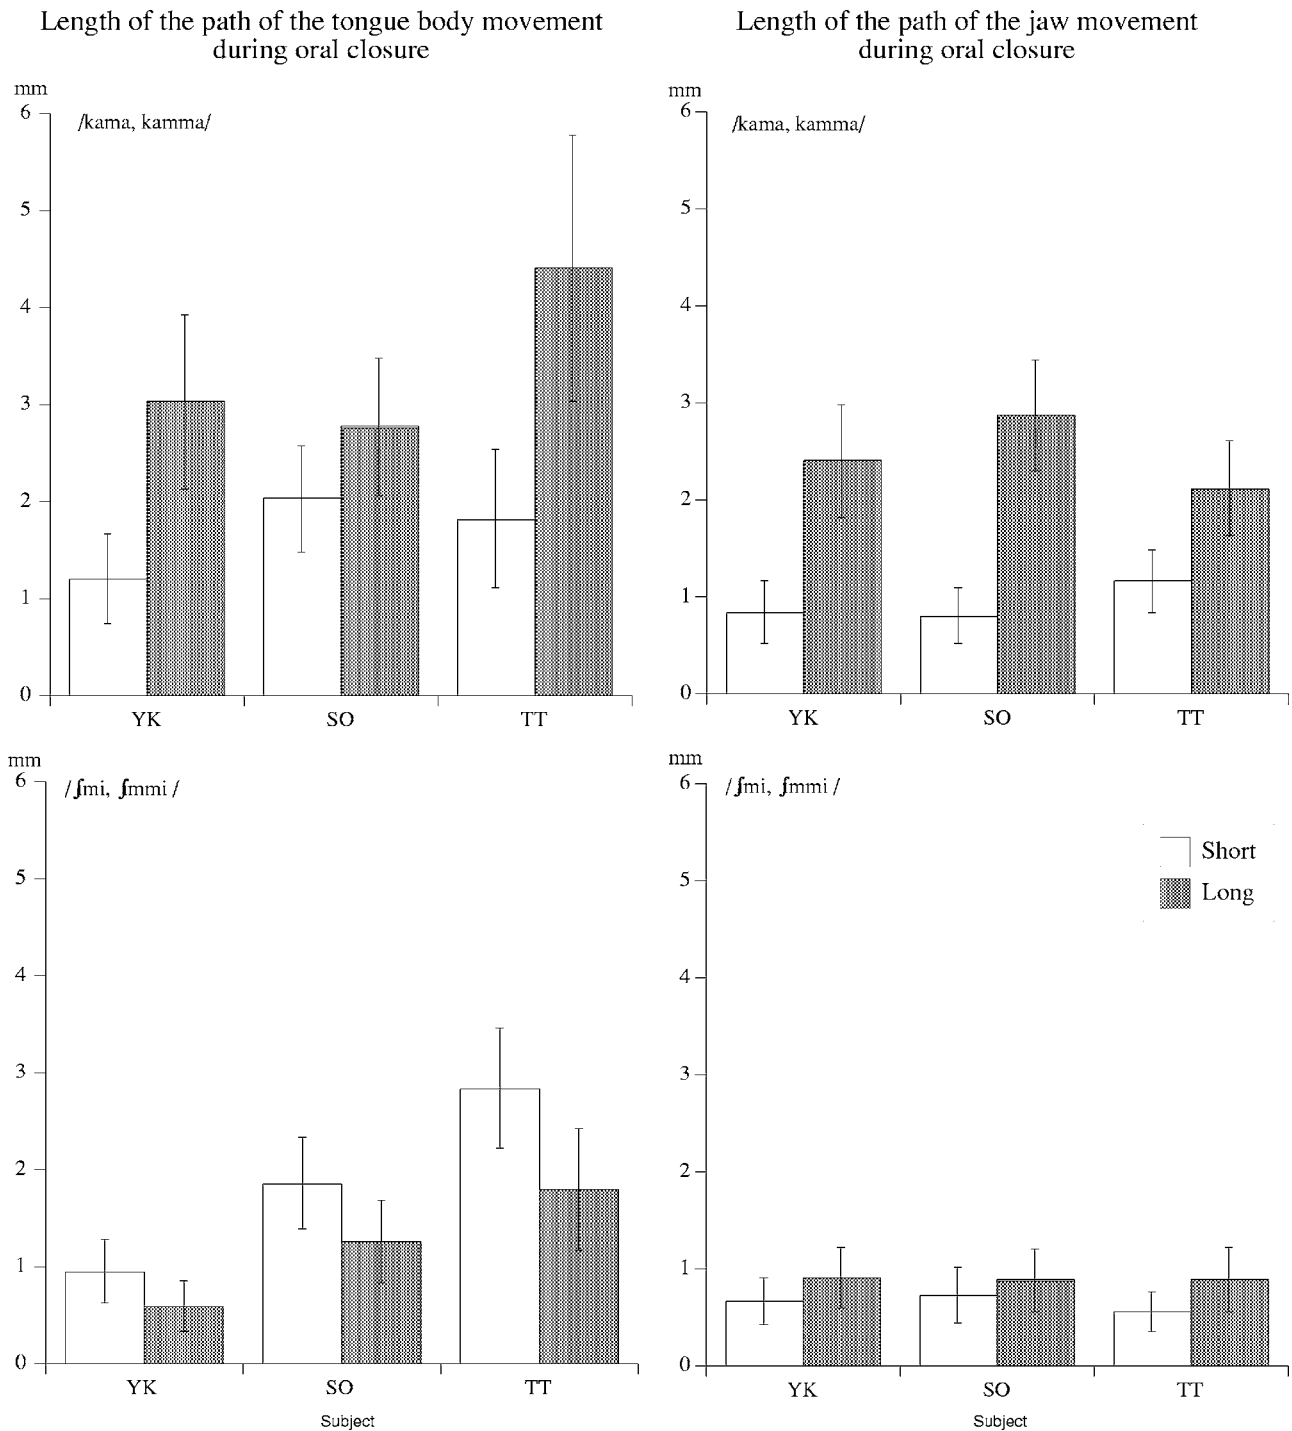

FIG. 10. Paths of the tongue body and jaw movements during the oral closure (mean and standard deviation).

subject SO ($t=-2.55$, ns). The movement of the jaw is made to assist in making the labial closure, which is reflected in the longer movement path of the jaw for the open vowel context /a/ than for the high vowel context /i/. As shown in the lower panels of Fig. 11, the jaw positions at the onset and offset of the nasal consonant do not differ very much in either vowel context. Nor is there any clear pattern within and across subjects for the long and short consonants.

Although the tongue is not rigidly coupled to the jaw, some of its movement is related to that of the jaw. This was particularly the case during the oral closure in the open

vowel context, where the tongue body positions at closure and release were almost identical for subject YK, while the offset position tended to be lower for subjects SO and TT (Fig. 11, upper left panel). In the high vowel context, however, the tongue movement appeared to be more related to coarticulatory influences, since the tongue body had moved forward and upward during the oral closure; the movement magnitude ranged from 0.5 to 1.0 cm in both the horizontal and vertical dimensions (Fig. 11, upper right panel). This movement was most likely made to position to the tongue for the upcoming /t/ in the carrier phrase.

Tongue body and jaw position at consonant onset and offset in symmetrical vowel contexts

For clarity of presentation, the horizontal and vertical scales are different. The dashed lines in the two right panels separate the data points for subjects SO and TT.

IV. DISCUSSION

This study examined the influence of consonant duration on the coordination of lip and tongue movements in VCV sequences with a labial nasal consonant. It was hypothesized that a speaker could use one of two possible strategies of interarticulator programming if the duration of the consonant was increased. In one of them, the tongue movement trajectory would be similar for the long and short consonants; thus, the timing between the lip and tongue movements would change. In the second one, the tongue movement would be modified for the long consonant, resulting in a similar coordination of lip and tongue movements for both the long and short consonants. The present results clearly support the second strategy.

They thus show that speakers of Japanese modify their tongue movements when they produce a sequence of a vowel-bilabial consonant-vowel with a long and a short consonant. In particular, the duration of the tongue movement is increased, while its average speed is reduced in the long consonant. However, the path of the tongue movement did not vary consistently with vowel duration. The onset of the tongue movement started before the oral closure for both the long and short consonants. Similarly, the offset of the tongue movement occurred after the release of the consonant. Thus, the coordination of the tongue movement relative to the onset and release of the oral closure was similar for the long and short consonants. Importantly, all five speakers showed the same modification of tongue movement speed and dura-

tion for the long consonant. These findings are similar to the ones reported by (Smith, 1992, 1995). They thus suggest that the Japanese speakers tend to maintain a similar, but not identical, coordination between the tongue and lip movements across consonant length.

Although all subjects changed the tongue movement between the two vowels, they did not change it in such a way that its duration in the long consonant was about twice the duration of the movement for the short consonant; see Fig. 4. Thus, the duration of the tongue movement did not correlate closely with the duration of the oral closure. The onset and offset of the tongue movement were defined as minima in the speed signal, but as suggested by the large variability in some of the temporal intervals in Figs. 7–9, these points need not be under tight temporal or spatial control. Tongue positions for vowels do not have point targets, but rather regions, that are influenced by phonetic context and speaking rate (e.g., Gay, 1974; Guenther, 1995).

As shown in Fig. 5, all subjects reduced the speed of the tongue body movement between the two vowels in the long consonant, thus maintaining a similar interarticulator timing for the two consonant durations. However, no subject completely stopped the movement of the tongue. This finding could follow from a general principle of motor control, based on a cost minimization, often expressed as a minimum jerk criterion (Flash and Hogan, 1985; Flash, 1987) or as a smoothness constraint (Uno *et al.*, 1989). Thus, speakers avoid excessive accelerations and decelerations of the tongue by keeping it moving.

The present results are generally in agreement with those of Löfqvist and Gracco (1999). As in their study, the onset of the tongue movement very rarely starts after the oral closure. They also found that the tongue started to move earlier than the lips as the tongue trajectory increased (their Fig. 7). A similar analysis of the coordination of tongue and lip movement onsets and tongue movement magnitude in the present results showed the same overall trend for all the speakers, although the correlations were generally less than 0.5. Interestingly, an inspection of Figs. 6 and 8 shows that there is sometimes a relationship between the path of the tongue movement and the interval between tongue movement onset and lip movement onset for the individual speakers. For example, for /kema, kemma/, speakers YM, KN, SO, and TT all had a longer path for the short than for the long consonant. These subjects also had the tongue movement leading the lip movement in producing the short consonant. In addition, speaker YK had a longer movement path for the long consonant, and also an earlier tongue movement onset for the long consonant. Similarly, speaker KN consistently produced a longer path in for the short than for the long consonant (Fig. 6) and also had a shorter interval between tongue and lip movement onsets for the short consonant.

The present results thus show that speakers of American English and Japanese have similar coordination between lip and tongue movements in VCV sequences, and that this is true for both the long and short consonants in Japanese. At the same time, American English and Japanese are described to have stress- and mora timing, respectively, but the inter-

articulator programming of lip and tongue movements appears to be very similar for the two languages.

This raises the issue of whether the prosodic structure of a language will influence patterns of interarticulator timing. The results presented by Smith (1992, 1995) suggest that this may he the case, since speakers of Japanese and Italian, which also has a length contrast, may have different patterns of coordination in VCV sequences when the consonant length differs. Japanese is described as having mora timing, Italian is said to have syllable timing, but how, and if, such a difference will influence speech timing is debatable (e.g., Dauer, 1983; Bertran, 1999). Vatikiotis-Bateson and Kelso (1993) examined lower lip movements in English, French, and Japanese, using reiterant speech. Analyzing movement duration, amplitude, and peak velocity, they found that movement dynamics were qualitatively similar in the three languages but also that there were quantitative differences. Among these were speaking rate, the quantitative relationship between movement amplitude and peak velocity, and movement variability. Since the results presented by Smith for the Italian speakers were not as robust as for the Japanese speakers, it is of interest to further pursue this issue by applying the methodology used in the present study to languages such as Italian and Finnish.

Is fundamental frequency a cue to aspiration in initial stops?

Alexander L. Francis,[a] Valter Ciocca, Virginia Ka Man Wong, and Jess Ka Lam Chan
Department of Speech and Hearing Sciences, University of Hong Kong, Hong Kong

One production and one perception experiment were conducted to investigate the interaction of consonant voicing and fundamental frequency at the onset of voicing (onset f_0) in Cantonese, a tonal language. Consonantal voicing in English can affect onset f_0 up to 100 ms after voicing onset, but existing research provides inconclusive information regarding the effects of voicing on f_0 in tonal languages where f_0 variability is constrained by the demands of the lexical tone system. Previous research on consonantal effects on onset f_0 provides two contrasting theories: These effects may be automatic, resulting from physiological constraints inherent to the speech production mechanism or they may be controlled, produced as part of a process of cue enhancement for the perception of laryngeal contrasts. Results of experiment 1 showed that consonant aspiration affects onset f_0 in Cantonese only within the first 10 ms following voicing onset, comparable to results for other tonal languages. Experiment 2 showed that Cantonese listeners can use differences in onset f_0 to cue perception of the voicing contrast, but the minimum extent of f_0 perturbation necessary for this is greater than is found in Cantonese production, and comparable to that observed in acoustic studies of nontonal languages. These results suggest that consonantal effects on onset f_0 are at least partially controlled by talkers, but that their role in the perception of voicing/aspiration may be a consequence of language independent properties of audition rather than listeners' experience with the phonological contrasts of a specific language.

I. INTRODUCTION

In English, fundamental frequency at the vowel onset (onset f_0) is correlated with the phonological feature of voicing in initial stops, such that the onset f_0 following voiceless stops is higher than after voiced stops (Haggard, Ambler, and Callow, 1970; Hombert, 1978; House and Fairbanks, 1953; Lehiste and Peterson, 1961; Löfqvist, Baer, McGarr, and Seider Story, 1989; Ohde, 1984; Whalen, 1990). It has been argued that this pattern is *intrinsic* to voicing differences, meaning that the onset f_0 is determined by physiological and/or aerodynamic factors related to the relative timing of voicing and oral closure release in a manner that is not (entirely) under the control of the speaker (cf. Hombert, 1978; Ohala, 1978 pp. 25–29). However, the duration of consonant-related f_0 perturbations in English extends farther into the vowel than would be predicted by simple physiological or aerodynamic factors (Hombert, 1978). Because of its longer-than-expected duration, Kingston and Diehl (1994) argued that this effect is an intentional maneuver on the part of English speakers to help cue the perception of voiced consonants.

Further support for the hypothesis that English speakers may intentionally exaggerate consonant-related f_0 perturbations in order to enhance voicing perception is found in tonal languages: Gandour (1974) and Hombert (1977) both determined that voicing-related onset f_0 perturbations were shorter in Thai and Yoruba, respectively, than in nontonal languages, extending approximately 30–50 ms into the vowel. By contrast, onset f_0 perturbations are observed for 100 ms or more in nontonal languages such as English (House and Fairbanks, 1953; Lehiste and Peterson, 1961; Löfqvist, Baer, McGarr, and Seider Story, 1989; Whalen, 1990), French (Hombert, 1978) and Dutch (Löfqvist *et al.* 1989). Thus, it has been argued that tonal language speakers either actively seek to inhibit the extent of an intrinsic effect on f_0 or choose not to manipulate pitch as a voicing cue because they are already using pitch to cue lexical tone contrasts. In either case, the essential point is the same: Pitch is a strong cue for tone categorization but a relatively weak one for consonant identification (Abramson and Lisker, 1985; Haggard, Ambler, and Callow, 1970). Therefore, tone language speakers avoid allowing a consonant-associated f_0 event to affect pitch (and therefore tone) except perhaps very locally within the onset of a syllable (Hombert, 1978, p. 83). If tonal language speakers are able to control the effect of consonant voicing on onset f_0, then this effect must be at least partially controllable, and not purely intrinsic to the production of voicing.

However, one crucial causal link in this chain of reasoning is still missing: It is not clear whether tone language speakers are able to use f_0 as a cue to consonant voicing (or aspiration), let alone whether they actually do so in their native language. It has been shown that f_0 is not always a strong cue to consonant voicing even for speakers of languages that do show considerable correlation between onset f_0 and voice onset time (VOT) in production (Francis and

[a] Author to whom correspondence should be addressed. Department of Speech, Language and Hearing Sciences, Purdue University, Heavilon Hall, 500 Oval Drive, West Lafayette, Indiana 47907. Electronic mail: francisa@purdue.edu

Nusbaum, 2002; Haggard *et al.*, 1970; Whalen, Abramson, Lisker, and Mody, 1990). If f_0 is so critical to tone perception that speakers cannot afford to allow it to vary (much) according to voicing, then perhaps tone language listeners simply disregard this property of the signal when making consonant voicing decisions in the first place. In the present paper we revisit the interaction of consonantal perturbations of f_0 and tone and extend this research into the domain of perception. We ask whether native speakers of Cantonese, a tone language, produce consonants with limited voicing-associated f_0 perturbations like Thai and Yoruba speakers, and, if so, whether they are still able to use onset f_0 as a cue to consonant voicing.

A. Voicing and onset f_0

To some extent, the effects of English stop consonant voicing on onset f_0 are unexpected. Although English stops are often considered to contrast in terms of voicing, this distinction is primarily phonological. The phonetic distinction, especially in syllable-initial position is more properly characterized as one between voiceless unaspirated and voiceless aspirated stops (Keating, 1984; Lisker and Abramson, 1964; Zlatin, 1974). However, English voicing effects on onset f_0 follow a pattern similar to that found in languages that contrast phonetically *voiced* with phonetically *voiceless unaspirated* consonants. That is, English phonologically voiced (phonetically voiceless unaspirated) stops have the same lowering effect on onset f_0 as do French and Dutch phonologically (and phonetically) voiced stops, while both English phonologically voiceless (phonetically voiceless aspirated) and French and Dutch phonologically voiceless (phonetically voiceless unaspirated) stops have a raising effect on onset f_0 (French: Hombert, 1978; Dutch: Löfqvist *et al.* 1989). This type of patterning (among other factors) led Kingston and Diehl (1994) to argue that consonantal effects on onset f_0 are the result of controlled processes related to the *phonological* status of the consonant series (voiced vs voiceless) rather than a result of intrinsic physiological dependencies between the articulatory and/or aerodynamic properties of the production of different degrees of prevoicing or voicing delay.

Like English, syllable-initial stop consonants in Cantonese may be divided into two phonological voicing classes, typically termed *voiceless unaspirated* and *voiceless aspirated* (Bauer and Benedict, 1997; Lisker and Abramson, 1964). In this case, the phonological and phonetic terminologies agree, and this contrast is distinctive and phonemic. For example, /p/ in the word 錶/piu55/ ("watch") and /pʰ/ in the word 飄/pʰiu55/ ("float") are two different phonemes as these two words carry different lexical meanings (see Sec. I B, for information on tone transcription). In terms of voice onset time (VOT), this Cantonese contrast is similar to the voicing contrast of English. For example, both English and Cantonese voiceless unaspirated stops typically have a short-lag VOT (under 30 ms) and a lower amplitude of the postburst aspiration noise, while voiceless aspirated consonants have a long-lag VOT (greater than 30 ms) and higher amplitude aspiration (Clumeck, Barton, Macken, and Huntington, 1981; Lisker and Abramson, 1964). Based on this similarity,

it seems reasonable to expect that Cantonese, like English, should be considered to manifest the distinction between [+voice] and [−voice] consonant classes in terms of two phonetic features, {voiceless unaspirated} and {voiceless aspirated} (cf. Keating, 1984).

If the effect of consonant voicing on onset f_0 in English is primarily intrinsic, resulting from physiological and/or aerodynamic consequences related to laryngeal gestures involved in voicing (delay), then we would expect Cantonese stops to exhibit the same degree of consonantal influence on onset f_0 as in English because both languages exhibit similar patterns of VOT: Voiced (voiceless unaspirated) stops should show a rising or level onset f_0, and voiceless (voiceless aspirated) stops should show a falling onset f_0. On the other hand, if the English pattern of onset f_0 is (at least partly) due to an intentional manipulation of a secondary cue for the purposes of enhancing the perception of a primary cue (e.g. VOT, cf. Kingston and Diehl, 1994) then Cantonese speakers might show little or no effect of consonant voicing on onset f_0, because f_0 manipulations are likely to be preferentially reserved for tonal cues.

B. Cantonese tones and onset f_0

There are six contrastive tones in Hong Kong Cantonese and each tone has a specific contour (direction of f_0 movement: level, rising, or falling) and register (f_0 height: high, mid, or low) (Bauer and Benedict, 1997; Fok Chan, 1974). While it is not possible to speak of a defined standard for Cantonese, the tonal system in Hong Kong Cantonese differs only slightly from systems observed in speakers from other Cantonese-speaking areas where instrumental phonetic research has been conducted (primarily Macau and mainland Guangdong province). The main difference is the absence of a high falling (51) tone in Hong Kong, where it has been replaced by the high level (55) tone. It appears possible that this is the result of a sound change in progress in Cantonese more generally. Although some speakers from other regions have still been observed to produce the high falling tone consistently, the Hong Kong system is commonly considered the norm (see Bauer and Benedict, 1997 for acoustic data and further discussion). Each Cantonese tone can be represented using the Chao (1947) system with numbers from 1 to 5 expressing the talker's pitch range from lowest to highest. Two numbers are used, such that the first number indicates the pitch level at the start of the syllable while the second number indicates the syllable's ending pitch level. According to this system the tones of Cantonese are as follows. high level (HL): 55; high rising (HR): 25; mid level (ML): 33; low rising (LR): 23; low level (LL): 22; low falling (LF): 21. Given the importance of tone contour in Cantonese, and the large number (four) of tones starting at the same pitch level (2), it is possible that the influence of consonants on onset f_0 may be even more constrained than in other tone languages (e.g., Yoruba, with three phonologically level tones, see Hombert, 1977) because listeners may require more precise information about fine details of a syllable's pitch contour in order to make accurate tonal judgments.

C. Aspiration and onset f_0

Cantonese stops are more properly characterized as differing according to aspiration rather than voicing (see also Bauer and Benedict, 1997). The acoustic properties of the following vowel (f_0, frequency of formant transitions, amount of aspiration noise in the vowel) appear to be more salient perceptual cues than either VOT or (the presence or absence of) aspiration noise for the perception of aspiration in Cantonese initial stops. Tsui and Ciocca (2000) manipulated the duration of the VOT interval of naturally produced aspirated and unaspirated CV syllables to create long VOT conditions with or without aspiration noise between the burst release and the onset of voicing. They found that long VOT stimuli (created by introducing a silent interval between the burst and the onset of voicing of unaspirated stops) were perceived as "unaspirated" by native listeners, showing that VOT per se is a weak cue to the perception of (phonological) aspiration. Poon (2000) systematically manipulated aspiration noise (the level of the breathy sounds between the burst release and the onset of voicing), vowel and VOT cues of similar CV syllables in a fully crossed design, and found that stimuli that contained the vowel portion of syllables originally produced with voiceless aspirated stops were always perceived as "aspirated," independent of the level of the aspiration noise in the gap between the burst release and the onset of voicing and VOT duration. In addition, stimuli that contained a vowel taken from an originally unaspirated syllable were only perceived as "aspirated" if (both) VOT was long and aspiration noise was present between the burst and the onset of voicing, indicating that neither of the two cues (VOT and aspiration noise between the burst and the onset of voicing) could on its own override the effect of vowel type (possibly representing some sort of breathiness property or presence of aspiration noise *during* the first pitch periods of the vowel such as that described for Wu dialects by Jianfen and Maddieson, 1992).

As discussed by Löfqvist *et al.* (1989) and Ohde (1984), gestures associated with consonant voicing contrasts (specifically, increased activity of the cricothyroid muscle for voiceless consonants), not aspiration per se, appear to be the primary physiological basis for consonantal effects on onset f_0. Studies of languages that contrast aspiration, e.g., Hindi (Kagaya and Hirose, 1975) and Korean (Kagaya, 1974), support this hypothesis: Onset f_0 is lower following voiceless aspirated stops as compared with voiceless unaspirated stops, but, at least in Hindi, both types of voiceless stops have a higher onset f_0 than either voiced one. If it is the case that Cantonese stops contrast according to aspiration, not voicing, than we might expect both series of stops to induce some degree of raising of onset f_0.

Even in tonal languages aspirated stops seem to cause less of an increase in onset f_0 than do unaspirated stops. For example, Shi (1998) reported that aspirated stops in Wu and Gan Chinese showed a lower onset f_0 when compared to that of corresponding unaspirated stops, but did not mention the duration of the consonant's effect. Xu and Xu (2003) found that, in Mandarin Chinese, aspirated alveolar stops showed a significantly lower onset f_0 (measured at the first glottal pulse) than did corresponding unaspirated stops, but it is not clear how far into the vowel this effect extended. Finally, Gandour (1974) showed that, in Thai, onset f_0 following voiceless aspirated stops is lower than following voiceless unaspirated stops, and the duration of consonantal effect ranges from 10 to 50 ms. Moreover, in Gandour's (1974) study both voiceless unaspirated and voiceless aspirated stops showed a higher onset f_0 than corresponding voiced stops.

The only study found on the interaction of aspiration and f_0 in Cantonese presented evidence that aspirated stops are associated with a higher onset f_0 than unaspirated stops (Zee, 1980), suggesting that Cantonese does indeed pattern with English with respect to the influence of voicing on onset f_0. However, this groundbreaking study was somewhat limited in scope and investigated only the effects of bilabial consonants on the onset f_0 of syllables with High Level tones. Moreover, Zee (1980) computed only a single value for onset f_0 for each syllable, calculated as the mean value of the first 30 ms after voicing onset. Thus, it is not possible to determine from Zee's (1980) data whether the overall duration of the effect of aspiration was longer or shorter than 30 ms. Such averaging might also have obscured the most significant f_0 changes which were shown by Hombert (1977) to occur immediately after voicing onset.

If Cantonese stops do contrast according to aspiration rather than voicing, then we would expect that both voiceless unaspirated and voiceless aspirated stops should exhibit a relatively high onset f_0; that is, f_0 should fall or at least not rise into the vowel; but unaspirated stops should show a higher onset f_0 than aspirated ones.

D. Goals

The first goal of the present study was to investigate the effect of voicing (or aspiration) differences in Cantonese initial stops on the f_0 of the following vowels, and the interaction of this effect with tone height and contour, and consonant place of articulation. For this purpose, the f_0 of vowels preceded by voiceless aspirated and unaspirated stops was measured over the first 100 ms after voicing onset. Based on the results of previous research, it was hypothesized that there would be a significant difference between the onset f_0 following aspirated and unaspirated stops. Two possibilities of directions of f_0 changes at vowel onset were suggested: (1) a rising versus a falling f_0 pattern would be found to distinguish unaspirated from aspirated stops if the consonantal contrast in Cantonese initial stops is similar to that in English and Yoruba as suggested by Hombert (1977), or (2) the f_0 patterns would be falling for both aspirated and unaspirated stops if the consonantal contrast in Cantonese initial stops is more of an aspiration contrast as in languages including Wu, Gan, Mandarin, Korean, and Thai (Gandour, 1974; Kagaya, 1974; Shi, 1998; Xu and Xu, 2003). In all cases it was expected that any effect of aspiration on f_0 in Cantonese would be shorter than the 100 ms (or so) observed in nontonal languages such as English, French, and Dutch. The goal of the second experiment was to determine whether Cantonese listeners are able to identify consonants in initial

position as either aspirated or unaspirated based solely on differences in onset f_0 and, if so, to estimate the necessary duration of the change in onset f_0 for such a contrast to be made.

II. EXPERIMENT 1: PRODUCTION

A. Methods

1. Subjects

Sixteen native speakers of Cantonese (eight women, eight men) reporting no hearing or speaking disability participated in this study. Participants' ages ranged from 20 to 23 years (mean 21.75). Eight participants (four women, four men) were Hong Kong University students in the Department of Speech and Hearing Sciences with some training in acoustic phonetics. The other eight participants (four women, four men) were students from other departments with no acoustic phonetic training.

2. Stimuli

Ten monosyllabic real words with unaspirated or aspirated initial stops were employed as stimuli. They were: /pa55/ "scar," /pʰa55/ "on all fours," /ta55/ "dozen," /tʰa55/ "he," /ka55/ "home," /kʰa55/ "compartment," /pa25/ "target," /pʰa25/ "steak," /pa21/ "father" and /pʰa21/ "climb." All words had consonant vowel (CV) syllable structure with the vowel /a/ (approximately as in "father" in English) to control for possible effects of intrinsic vowel f_0 (cf. Diehl and Kluender, 1989; Peterson and Barney, 1952). Only real words were used to avoid the difficulty of eliciting nonsense syllables from speakers of a language with lexicographic orthography.

These stimuli can be divided conceptually into two overlapping sets. One set contained /pa55/ and /pʰa55/, /ta55/ and /tʰa55/, and /ka55/ and /kʰa55/. All of the tokens in this set had a high level (55) tone, thus eliminating the possibility of a tone-by-consonant interaction. This set of stimuli was used to investigate the role of place of articulation (bilabial, alveolar, and velar) in determining the effect of consonant aspiration on onset f_0. The second set consisted of /pa55/, /pʰa55/, /pa25/, /pʰa25/, /pa21/, and /pʰa21/. This set of stimuli was designed to investigate the interaction of tone with the effect of aspiration on onset f_0. Due to the constraint of using only real words, it was not possible to generate a complete set of both aspirated and unaspirated CV syllables at a single place of articulation differing according to all six possible Cantonese lexical tones. However, in the present set of stimuli all three tone contours of Cantonese (rising, falling, and level) and both the highest and lowest registers were represented.

3. Procedure

The Chinese character representing each stimulus word was written on a file card with one character per card. Recordings were made with participants seated comfortably in a single-walled sound-shielded booth. Prior to recording, participants read a set of written instructions, and were then familiarized with all of the stimuli used in the experiment. For familiarization, each stimulus card was presented, and

participants were asked to pronounce the target in a carrier phrase with a speaking rate similar to conversational speech. The semantically neutral carrier phrase, /ŋɔ23 wui23 tɔk22 _ _ pɛi35 lɛi23 tʰɛŋ55/ "I will read _ _ for you to hear," was used for both familiarization and recording to encourage a natural production of each stimulus. The results of this study should be expected to generalize to both isolated productions and fluent speech since the absolute f_0 level and contour of syllables in isolation and in carrier phrase context (Ohde, 1984), and in fluent reading (Umeda, 1981) were found to be comparable. Although absolute f_0 values may be affected by coarticulation (Xu, 1994), these effects were held constant since the syllable /tɔk22/ always preceded the target syllable. This preceding syllable has a low level (22) tone, so coarticulatory effects (if present) should cause a uniform lowering of f_0 at the onset of the target syllable across all target syllables (aspirated and unaspirated).

For recording, each of the ten target stimuli was written on five separate file cards for a total of 50 cards (5 repetitions of each of 10 words). All cards were presented to participants individually in randomized order, subject to the constraint that two cards with the same token could not be presented in immediate succession.

Participants were asked to read aloud each word as it was revealed by the experimenter (the third author). Approximately 1–2 production errors were observed for each talker over the course of the 50 target stimuli. After hearing a speech error, the experimenter would immediately produce the target word correctly, and ask the participants to repeat the utterance with that stimulus embedded again. There was no obvious difference between speakers' spontaneously correct productions and those following such prompting. Recording took a total of 15–20 min per talker.

All speech samples were recorded using a Shure Beta 87 microphone and a TASCAM DA-30MKII DAT tape recorder. The microphone was mounted on a boom stand and placed approximately 15 cm in front of the talker's mouth in the horizontal plane. The recorded stimuli were low-passed filtered at 22 kHz and sampled at 44.1 kHz using a Power Macintosh 7200/120AV computer equipped with a DigiDesign Audiomedia II sound card and stored in AIFF format for further analysis.

4. Analysis

Acoustic waveforms, spectrograms, and f_0 plots were obtained using Macquirer 4.9.9 (Macquirer, 1999). For analysis, spectrograms were produced with the Macquirer default wide-band filter setting (172 Hz for male talkers and 344 Hz for female talkers). Fundamental frequency was computed using the default method based on a 35 ms cepstral analysis window. In cases in which the Macquirer algorithm for calculating f_0 was unable to resolve a value at the designated time, f_0 was calculated manually from the acoustic waveform as the reciprocal of the respective glottal period at that time. Plots showing frequency ranges from 50 to 260 Hz for male talkers and 130 to 300 Hz for female talkers were used for analysis. During the measurement of f_0, each recorded stimulus was displayed as an acoustic waveform and a wide-band spectrogram. The onset of voicing was

identified as the first vertical striation (glottal pulse) extending through the first, second and third formants in the spectrogram. This definition of voicing onset is somewhat less reliable, in terms of time, than the onset of periodicity measured from the waveform alone (Francis, Ciocca, and Yu, 2003), but it is a highly conservative marker chosen to maximize the accuracy of automatic pitch-tracking. It should be noted, however, that our reliance on automatic pitch tracking (in most cases), may have resulted in some divergence of our estimate of the duration of f_0 perturbations from that reported by researchers who compute f_0 from direct measurement of single periods (e.g.,Löfqvist *et al.*, 1989; Xu and Xu, 2003). In the case of the present method, a window of 35 ms centered at the point of measurement would result in a margin of error of about 10–15 ms in terms of estimate of the duration of f_0 perturbations. In terms of accuracy of f_0 measurements, our results may be slightly less accurate for female talkers than for males (because we are averaging over more cycles), but interestingly the f_0 patterns look very much the same (see Sec. IC1, below), especially for unaspirated stops. So it is likely that any effect of averaging on precision of f_0 estimate was relatively small.

Following Hombert (1978) the most prominent f_0 changes related to aspiration were expected to be found during the first 100 ms after voicing onset and, because Cantonese is a tonal language, most probably within the first 30–50 ms. Therefore, f_0 was measured at the onset of voicing (time 0) and subsequently at 10, 20, 40, 70, and 100 ms into the vowel. These specific values were selected arbitrarily, but with the goal of maximizing the probability of pinpointing the duration of voicing-related effects on f_0 without requiring an inordinate number of measures.

To permit more accurate comparison across male and female talker groups, prior to statistical analysis frequency values in Hz were converted to cents using the equation $C = 1200 \log_2(f/127.09)$ (Traunmüller, 2005). All analyses of variance involving repeated measures with more than two levels were computed using a standard univariate model with Greenhouse-Geisser and Huynh-Feldt adjustments to degrees of freedom to compensate for the effects of violations of compound symmetry and sphericity (Greenhouse and Geisser, 1959; Huynh and Feldt, 1970). When the degrees of freedom as adjusted by the two methods differed, the more conservative values are reported.

B. Results

Before analyzing f_0, the average overall durations of vowels with each of the three tones in this experiment (HL, HR, and LF) were measured to determine whether vowel duration might interact with tone. Average vowel durations were: HL, 274 ms; HR, 286 ms; and LF, 268 ms, suggesting that f_0 is likely to be a much more important property than duration for identifying these tones. Separate analyses were carried out for the two sets of stimuli: (i) initial stops differing in aspiration and place of articulation, and (ii) initial stops differing in aspiration and in syllables with different tone.
FIG. 1. Mean f_0 for aspirated and unaspirated syllables with high level tone. Error bars indicate standard error of the mean.

1. Aspiration and place of articulation

The first analysis was carried out on stimuli with the same tone (HL) but different places of articulation (bilabial, alveolar, and velar) to determine if place of articulation affects onset f_0. A mixed factorial ANOVA with two levels of aspiration, two levels of gender, three levels of place of articulation (POA), and six levels of time interval showed a significant effect of gender, $F(1,14)=119.59$, $p<0.001$, and of time, $F(1.75,24.46)=50.67$, $p<0.001$, but not of aspiration, $F(1,14)=1.22$, $p=0.29$, or of POA, $F(1.82,25.46)$, $p=0.69$. The only significant interactions were between time and gender, $F(1.75,24.46)=3.60$, $p=0.05$, and aspiration and time, $F(1.47,20.56)$, $p=0.001$. Figure 1 shows the overall average f_0 of tokens with HL tones collapsed over place of articulation during the first 100 ms after voicing onset for the two aspiration categories (aspirated stops $[p^h]$, $[t^h]$,$[k^h]$ versus unaspirated stops $[p]$, $[t]$, $[k]$) for both genders.

Additional posthoc (Tukey HSD) comparisons were performed using means pooled over place of articulation to compare temporally adjacent frequency values (e.g., 0 ms vs. 10 ms) both within and between consonant classes (aspirated vs unaspirated). All results reported as significant are at the $p<0.05$ level. For female talkers, f_0 immediately following unaspirated stops (time=0 ms) was significantly higher (256 Hz) than all other points in both the aspirated and unaspirated series (ranging from 237 Hz to 244 Hz) and this was the only significant pairwise comparison either within or between series. For the male talkers the situation was somewhat more complex. In the unaspirated series, frequency at the first point (time=0 ms) was significantly greater (152 Hz) than all other points in this series, and none of these other unaspirated series' points were significantly different from one another (ranging from 138 Hz to 142 Hz). In the aspirated series no adjacent points were significantly different from one another, but there was a gradual decrease in f_0 such that, for example, the first point (0 ms,148 Hz) was significantly different from the last three (142, 139, and 138 Hz, respectively), and the second (10 ms, 142 Hz) and third (20 ms, 140 Hz) were significantly different from the last two. Comparing the aspirated and unaspirated f_0 curves showed no significant difference between the two series at any measurement point, although a trend similar to that of

the female talkers can be observed: Only at 0 ms was the frequency of the unaspirated series greater than in the aspirated one (151 vs 148 Hz).

Based on the overall similarity of the male and female f_0 contours, the ANOVA was recalculated excluding the between-subjects factor of gender. Results for the combined group were similar to, but less equivocal than, those found in the analysis including gender. There was a significant effect of time, $F(1.58, 23.65) = 43.17$, $p < 0.001$, and a significant interaction between aspiration and time, $F(1.46, 21.83) = 12.34$, $p = 0.001$. No other main effects or interactions were significant. Post hoc (Tukey HSD) analysis showed that the aspirated and unaspirated series differed only at the 0 ms point, with the unaspirated series showing a significantly higher f_0 than the aspirated one. Both curves showed a slight decline in frequency, although this effect is more gradual but also more pronounced in the aspirated series. In the unaspirated series, the first point (0 ms) was significantly higher than all other points, and the second point (10 ms) was significantly higher in frequency than the final two points (70 ms and 100 ms). There were no significant differences found for any pairwise comparison between the final four points (20 ms, 40 ms, 70 ms, and 100 ms) of the unaspirated series, suggesting that the duration of the consonantal effect was no greater than 20 ms. In the aspirated series the first point (0 ms) was significantly higher in frequency than the last three points (40 ms, 70 ms, and 100 ms), while the second (10 ms) and third (20 ms) points were significantly higher in frequency than the final two points (70 ms and 100 ms). The fourth point (40 ms) was significantly higher in frequency than the final point (100 ms), but no other pairwise comparisons among points in the aspirated series showed a significant difference, suggesting that the duration of the consonantal effect was around 40 ms.

In summary, for both male and female talkers, f_0 declined suddenly from 0 to 10 ms in the unaspirated series, but remained more or less level in the aspirated one (declining gradually for the male but not female talkers). For both male and female talkers, frequency patterns across the two series were similar, and generally corresponded to the combined (across gender) analysis in which little or no difference was found between the two series at 10 ms post voicing onset or beyond, but frequency at 0 ms was significantly higher in the unaspirated series than in the aspirated one. Overall, this suggests a pattern of decrease in f_0 following both unaspirated and aspirated stops in Cantonese, but the decline is more abrupt following unaspirated as compared with aspirated consonants.

2. Aspiration and tone

The second analysis was carried out on the measurements of the stimuli with the same place of articulation (bilabial) but different tones (55, 25, and 21). This analysis was designed to investigate whether the differential effects of aspirated and unaspirated consonants on the f_0 of following vowels is realized differently on syllables with different lexical tones. Results are shown in Fig. 2.

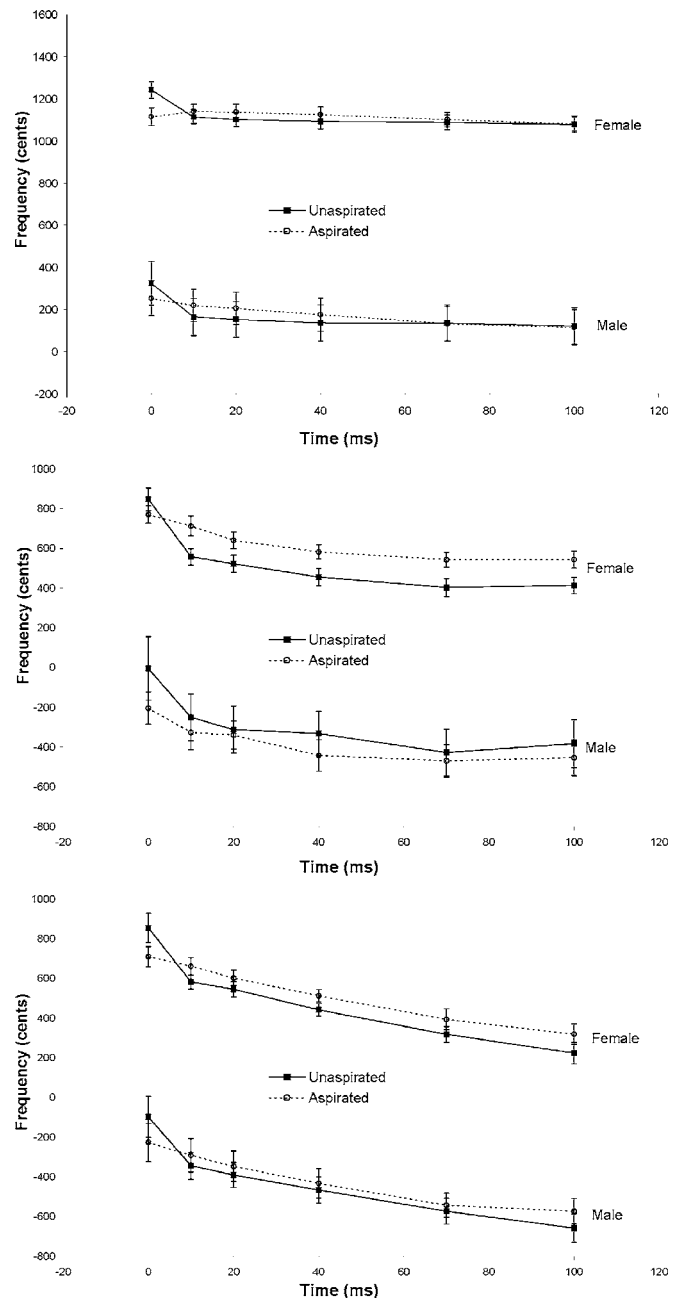
A four-way mixed factorial repeated measures ANOVA with factors gender, aspiration, tone (3 levels) and time was


FIG. 2. Mean f_0 for syllables beginning with aspirated and unaspirated bilabial stops and having either high level (2a), high rising (2b), or low level tones (2c). Error bars indicate standard error of the mean. Note that each subgraph shows a Y axis of 1800 cents, though the starting and ending frequencies differ for different tones.

conducted. Results showed a significant effect of gender, $F(1, 14) = 142.39$, $p < 0.001$, tone, $F(1.29, 17.00) = 181.62$, $p < 0.001$, and time, $F(2.07, 28.94) = 152.75$, $p < 0.001$, and significant interactions between tone and time, $F(2.63, 36.78) = 28.52$, $p < 0.001$, and between aspiration and time $F(2.47, 34.54) = 20.77$, $p < 0.001$. No other main effects or interactions were significant.

The observation that gender did not interact with any other variable suggests that both male and female talkers showed the same effects of tone, time and aspiration on onset f_0. Therefore, post hoc (Tukey HSD) analysis were carried out on means pooled over gender. Results showed that, at contemporaneous points across all three tones, the only sig-

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Francis *et al.*: F0 and consonant aspiration   2889

nificant differences due to aspiration were found at 0 ms, where the unaspirated tokens were higher in frequency than the aspirated ones. The only other case in which the aspirated and unaspirated series differed in frequency at the same time was in the 21 (low falling) tone at 100 ms post voicing onset, where there was a significant difference in f_0 between unaspirated (male 87 Hz, female 145 Hz) and aspirated (male 92 Hz, female 153 Hz) consonants.

Results of the post hoc (Tukey HSD) analysis of differences between f_0 measurement points for the high level (55), high rising (25), and low falling (21) tones showed that [results for the high level (55) tone here are for the bilabial tokens only] for the high level (55) tone following unaspirated stops, f_0 was significantly greater at the first (0 ms) measurement point than at all other points, but no other pairwise comparisons showed a significant difference, suggesting that the consonantal effect extends no more than 10 ms into the vowel. For the aspirated series, the first (0 ms) and second (10 ms) points were significantly higher in frequency than the last (100 ms) point, but no other comparisons reached significance suggesting that the effect of the consonant extends no more than 20 ms into the vowel. For the 25 tone, in both series (aspirated and unaspirated) steps 5 (70 ms) and 6 (100 ms) were significantly lower in frequency than the first three steps (0 ms, 10 ms, and 20 ms), but not different from one another or the 40 ms step, suggesting that the consonantal effect ends within 40 ms after voicing onset. For the 21 tone most comparisons reached significance, and in the unaspirated condition even then last step (100 ms) was significantly lower in frequency than the preceding one (70 ms). This result suggests that the consonantal effect may extend up to or beyond 100 ms into the vowel of syllables with a low falling (21) tone (though see discussion, below, regarding the interaction of tones and consonant effects).

C. Discussion

The results of this first experiment are consistent with the hypothesis that consonantal effects on onset f_0 in Cantonese result from a combination of intrinsic physiological/ aerodynamic constraints and of the intentional manipulation of f_0 for the enhancement of voicing cues.

1. Direction of change

All of the syllables investigated in this study showed a generally level or falling f_0 contour over the first 100 ms, consistent with the phonetically voiceless status of both aspirated and unaspirated stops in Cantonese. That is, Cantonese appears to follow the pattern observed in Korean (Kagaya, 1974), Hindi (Kagaya and Hirose, 1975), Thai (Gandour, 1974), and other dialects of Chinese (Wu, Gan: Shi, 1998; Mandarin: Xu and Xu, 2003) rather than that exhibited by English (House and Fairbanks, 1953; Lehiste and Peterson, 1961; Löfqvist et al. 1989): Both long- and short-lag consonants induce a falling f_0 contour at the onset of voicing, though this drop is stronger after unaspirated consonants than after aspirated ones.

These results support two distinct (but probably complementary) physical explanations of the effect of consonant voicing on onset f_0, a muscular/physiological one and an aerodynamic one. According to Halle and Stevens' (1971) "muscular hypothesis," the vocal folds are slack during voiced consonant closures but stiff during voiceless stop closures and subsequent aspiration through the onset of voicing, leading to a higher onset f_0 following voiceless consonants than following voiced stops (see also Löfqvist et al., 1989). Since Cantonese unaspirated stops are associated with a higher onset f_0 than are aspirated ones, Cantonese unaspirated stops are likely to be produced with tenser vocal folds than aspirated consonants, though both may be produced with an overall greater degree of tenseness than, for example, English (phonologically) voiced stops. This conclusion is supported by a number of physiological studies discussed by Shi (1998), suggesting that vocal cord tension at the onset of voicing is higher for voiceless unaspirated stops than for voiceless aspirated stops in Hindi (Kagaya and Hirose, 1975), Thai (Ewan, 1976, cited in Hombert, 1978), and Korean (Kagaya, 1974).

The present findings are also consistent with an aerodynamic account such as that presented by Ladefoged (1971). He argued that the main difference between the production of voiceless aspirated and unaspirated stops is that, at the oral release phase, the glottis is widely opened for aspirated stops, but more or less closed for unaspirated stops. Thus, prior to the onset of voicing more air is released from the lungs through the glottis following aspirated stops than is released following unaspirated stops. Unaspirated stops, which also have a short voice onset time, should exhibit a smaller decrease in subglottal pressure, and therefore a higher initial rate of vocal fold vibration, than aspirated stops prior to the onset of voicing (cf. discussion by Shi, 1998) concerning similar aerodynamic effects in the production of Mandarin initial stop consonants. In the present study, unaspirated stops exhibited a consistently higher onset f_0 than aspirated ones, suggesting that their production does indeed lead to a higher trans-glottal pressure differential at the onset of voicing compared to that of aspirated stops.

Interestingly, while the present results are consistent with a broad range of physiological and aerodynamic accounts of consonantal effects on onset f_0, they appear to conflict with Zee's (1980) findings that Cantonese aspirated stops showed a higher onset f_0 than unaspirated stops. One possible reason for this disagreement is that Zee averaged f_0 over the first 30 ms of each syllable. This averaging process would have made it difficult to identify f_0 patterns similar to those presented here in which the most significant effects were found in the first 10 ms after voicing onset. Indeed, when considering only syllables with a high level tone and beginning with bilabial stops as produced by male talkers in the present study (the conditions most comparable to those of Zee, 1980), averaging the measurements taken at 0, 10, 20, and 40 ms shows an average onset f_0 of 143 Hz for the unaspirated series, and 145 Hz for the aspirated series. While the difference between these values is much smaller than those given by Zee (1980) (average differences of 10, 6, and 12 Hz for three male talkers, based on measurements from

ten productions each of /pei55/ ["sorrow"] and /pʰei55/ ["to spread"]), the trend is similar; moreover, three individuals in the present study exhibited comparable f_0 differences (14 Hz, 5 Hz, and 4 Hz) between aspirated and unaspirated bilabials. Still, the present results strongly suggest that there is little or no physiological contribution of consonant voicing to onset f_0 patterns in Cantonese beyond the first few tens of milliseconds of the vowel.

The findings presented here for Cantonese, and those obtained by Xu and Xu (2003) for Mandarin, also have implications for broader theories of stop consonant production and for the mechanisms of producing a phonological voicing contrast. Keating (1984) proposed a model to resolve the terminological problem that derives from considering, for example, both English and Spanish stop consonants as contrasting according to voicing, despite clear differences in their phonetic realizations. According to Keating's proposal, different languages may instantiate the phonological features [+voice] and [−voice] in different ways such that, for example, a phonologically [+voice] segment in Cantonese or English is realized as a {voiceless unaspirated} stop, while in Spanish a phonologically [+voice] segment would be realized as a {voiced} stop. The results of the present experiment suggest that languages may differ even at the phonetic level, such that the English and Cantonese {voiceless unaspirated} stops have different effects on onset f_0 (lowering in English but raising, if only at the very onset of voicing, in Cantonese). Two possible explanations for this phenomenon have been proposed: Either onset f_0 effects are based on the *phonological* feature involved (such that all [+voice] segments depress onset f_0, while all [−voice] segments raise it), or the Cantonese and English stops may be realized with different patterns of laryngeal muscle movements, each accomplishing laryngeal closure/release in the same time relative to oral closure/release gestures but resulting in different effects on onset f_0.

Previous studies showing an effect of consonant *aspiration* (as opposed to voicing) on onset f_0 have been conducted in languages contrasting more than two phonological voicing classes (e.g., Thai: Gandour, 1974; Hindi: Kagaya and Hirose, 1975; and Korean: Kagaya, 1974); these studies specifically compared phonetically voiceless unaspirated to voiceless aspirated consonants. Interestingly, for at least two of these languages (Hindi and Korean), it has been argued that additional contrastive dimensions beyond that of laryngeal timing must be involved in generating the complete set of contrasts in the language (Abramson, 1977). Kingston and Diehl (1994) distinguish between two voicing-related features, [voice] and [spread glottis], and imply that, e.g. in Thai, the feature [±voice] distinguishes the phonetically voiced ([+voice]) from the phonetically voiceless unaspirated ([−voice]) stops, while the feature [±spread glottis] distinguishes the phonetically voiceless unaspirated ([−spread glottis]) from the phonetically voiceless aspirated ([+spread glottis]) stops. A similar pattern may obtain for Cantonese (and Mandarin), except that Cantonese and Mandarin simply lack the [+voice] category (that is, both the [+spread glottis] and the [−spread glottis] stops are [−voice]). This argument seems to be consistent with the findings of Löfqvist *et al.*

(1989), who showed that the production of both Dutch and English *phonologically voiceless* stops is associated with increased cricothyroid muscle activity. Such an increase in muscle activity presumably increased the longitudinal tension in the vocal folds and resulted in a generally higher onset f_0, although these stops have a short-lag VOT in Dutch (10–15 ms) but a long-lag (60–80 ms) in English. In order to successfully instantiate the long vs short-lag VOT contrast, other laryngeal maneuvers (presumably associated with the feature [±spread glottis]) must be invoked. According to this hypothesis, increased cricothyroid activity is associated with suppression of voicing regardless of the duration of that suppression, and is present in both the voiceless aspirated and voiceless unaspirated consonants in Cantonese, but only in the voiceless aspirated stops in English. The results of the present study suggest that the presence of such cricothyroid activity is automatic, but that the gestures controlling its duration (beyond the first few tens of ms) are not.

2. Duration of effect

In the present study the maximum duration of the effect of consonants on onset f_0 appears to be about 40 ms for the high level (55) and high rising (25) tones, with the effect being somewhat shorter in the high level than in the high rising conditions, while in the low falling condition f_0 continued to decline beyond 70 ms. This pattern is quite commensurate with the results shown by Xu and Xu (2003), and is clearly related to the overall f_0 pattern of each tone. In Cantonese, as in Mandarin, the f_0 contours of level tones typically remain mostly level, sometimes with a slight rise at the onset (Bauer and Benedict, 1997; Xu and Xu, 2003). Thus, these syllables show us the effect of the consonant without any interaction with a tonal contour. In contrast, rising tones typically show a short fall over the course of the first 1/4 to 1/3 of the syllable (Bauer and Benedict, 1997; Francis *et al.*, 2003; Moore and Jongman, 1997; Xu and Xu, 2003), and falling tones typically fall over the course of the entire syllable (Bauer and Benedict, 1997; Xu and Xu, 2003). Thus, in the high level tone, we see the "purest" effect of the consonant, with the f_0 contour more or less leveling off within about 20 ms of the onset of voicing. In the high rising (25) syllables we see the consonantal effect occurring in conjunction with the expected, initially slightly falling tonal contour, leading to the appearance of a consonantal effect out to about 40 ms post voicing onset. Finally, in the low falling (21) tone the longer consonantal effect (70 ms or more in duration) is most likely due to the normal falling f_0 contour for this tone. A close examination of the graphs shown by Xu and Xu (2003) suggests a similar pattern for Mandarin: Consonantal effects do not appear much beyond the first few tens of ms following voicing onset, even in the case of the Mandarin Falling (51) tone.

This finding is consistent with the proposal of Hombert (1978) that tone language speakers have less freedom to vary f_0 patterns as a consequence of voicing (or aspiration). The generally level or falling f_0 pattern in both the aspirated and unaspirated series is consistent with Halle and Stevens' (1971) model of voicing (both series are voiceless). However, the brevity of the effect in Cantonese as compared to

English supports Hombert's (1977) viewpoint that speakers of tone languages actively minimize the intrinsic effect of preceding consonants on f_0 of the following vowels so as to keep each tone maximally perceptually distinct. Alternatively, the aspiration effects on onset f_0 observed in tonal languages might reflect the natural extent of consonant-related influence (extending somewhere between 10 and 50 ms following voicing onset), while the patterns observed for English might result from language-specific exaggeration of these tendencies. On the basis of the present evidence it is not possible to draw any firm conclusions regarding these two conflicting hypotheses, but some speculation is possible.

Onset f_0 differences have been shown to be a sufficient cue to the voicing contrast in English initial stops when the voicing-related f_0 perturbations lasted for about 55 to 60 ms (Haggard *et al.*, 1970). Robinson and Patterson (1995) demonstrated that a minimum of six to eight cycles of a periodic sound are necessary before pitch can be accurately identified. With respect to the present case, this would translate to at least 42–56 ms for a male with an f_0 of 142 Hz, and 25–33 ms for a female with a f_0 of 230 Hz. These durations are consistent with the results presented by Haggard *et al.* (1970), but they are considerably longer than those observed in the present study. If the present results reflect the natural (intrinsic) extent of aspiration effects on onset f_0, then the English pattern (extending out to 100 ms or more) would result from an extension of that natural tendency to nearly twice what would be necessary for listeners to hear the f_0 effects. On the other hand, if the English pattern reflects the natural (unsuppressed) extent of aspiration effects on onset f_0, then the pattern observed here would indicate a much greater degree of suppression than would be necessary to eliminate perceptual evidence of the consonant effects on f_0. A reasonable conclusion then would seem to be that the English pattern reflects some degree of enhancement, while the pattern observed here reflects at least some degree of suppression. In the next experiment, we explore Cantonese listeners' perception of onset f_0 as a cue to the aspiration contrast in syllable-initial stop consonants.

III. EXPERIMENT 2: PERCEPTION

Following Kingston and Diehl (1995), VOT and onset f_0 may "cohere" perceptually (that is, they may both function as cues to the same phonetic feature contrast) either because they arise from the same physiological phenomena in production (cf. Abramson, 1977) or because they affect the auditory system in similar ways (cf. Kingston and Macmillan, 1995). In both cases, the coherence of the two cues may be considered automatic in that it derives from basic physiological properties and does not have to be learned through of linguistic experience. By contrast, it is possible that two cues may cohere due to learned co-variation. That is, over the course of development, listeners may become so accustomed to hearing the two together that the presence of either cue is alone sufficient for perceiving a given contrast, even though there may be no necessary physiological or perceptual relationship between them (cf. Ohala, 1981 and related discussion by Kingston and Macmillan, 1995). In the case of Can-

tonese listeners, who have experienced relatively little perceptible relationship between onset f_0 and VOT in their native language, the ability to use onset f_0 as a cue to the voicing contrast would suggest a basic perceptual (not learned) basis for the relationship between onset f_0 and other stronger cues to aspiration. To investigate this possibility, in the second experiment we investigated Cantonese listeners' ability to use onset f_0 (alone) as a cue to the perception of the Cantonese stop consonant voicing contrast.

A. Methods

1. Subjects

Eighteen native Cantonese speakers, six men and twelve women, reporting normal speech and hearing abilities volunteered for this study. Their age ranged from 22 to 31 (mean age=23.3). All had some experience listening to English in the course of their education (comparable to the experience of the participants in experiment 1), though none used English significantly outside of the university.

2. Stimuli and apparatus

All stimuli were derived from a single CV syllable created by digitally splicing naturally-produced, but resynthesized, burst and aspiration noise onto a synthetic vowel. The natural token (the word /pʰa55/ "on all fours") was selected from a set of many CV syllables produced by a college-aged male native speaker of Cantonese. An aspirated token was selected as the base rather than an unaspirated one to simplify resynthesis. For example, in our experience, it is generally easier (results in a more natural sounding resynthesis) to reduce the amplitude of aspiration noise that is already present than it is to add in aspiration noise that is not there to begin with. A syllable with a high level tone was selected because experiment 1 showed that syllables with this tone do not exhibit an effect of consonant aspiration on onset f_0 beyond the first 10 ms of the vowel at any place of articulation. Thus, Cantonese speakers likely have no prior experience with the covariation of onset f_0 (beyond the first 10 ms) and aspiration in syllables with this tone. The specific token was selected based on the cleanliness of the recording, and the relative smoothness of the acoustic signal (lack of any unexplained acoustic events that might interfere with resynthesis).

The burst and aspiration noise from this token were subsequently manipulated in a manner designed to give rise to approximately equal numbers of /pa55/ and /pʰa55/ percepts (the base syllable). Resynthesis was accomplished using the pitch synchronous overlap and add (PSOLA) algorithm (cf. Huang, Acero, and Hon, 2001, pp. 820–823; Moulines and Charpentier, 1990) as implemented in Praat 4.0.5. To make the burst and aspiration-related cues of the base syllable ambiguous, VOT was compressed to 20 ms and the peak amplitude of the burst and aspiration noise was reduced by 50%, corresponding to values that were shown in an unpublished study in our lab to result in approximately equal numbers of aspirated and unaspirated responses. Informal testing of the final syllable (including the synthetic vowel described below) suggested that the resulting syllable was heard approximately equally as a /p/ or a /pʰ/. The base syllable was
FIG. 3. Spectrogram and acoustic waveform of the syllable [pʰa] with 157 Hz onset f_0 and 80 ms duration of f_0 change, as used in experiment 2.

FIG. 4. Mean proportion of "aspirated" responses to stimuli with f_0 beginning at one of four onset frequencies and one of four durations of onset transition. Error bars indicate standard error of the mean.

420 ms in duration (equivalent to that of the natural syllable), and it was generated using SenSyn (Sensimetrics, Inc.). Synthesis parameters were derived from measurements made at 5 ms intervals of the f_0, amplitude envelope and the first four formant frequencies of the same syllable [pʰa55] "on all fours" from which the burst release was extracted. A spectrogram and acoustic waveform are shown in Fig. 3.

Sixteen different syllables were generated from this base syllable by fully crossing four levels of starting f_0 (127 Hz, 137 Hz, 147 Hz, and 157 Hz) and four levels of f_0 transition duration (10 ms, 20 ms, 40 ms, and 80 ms). For example, in the first stimulus, f_0 began at 127 Hz and fell to the original vowel f_0 (125 Hz) over the course of the first 10 ms following the onset of voicing (ending at a point corresponding to the 30 ms synthesis entry in the synthesizer parameters). The f_0 of the next token also began at 127 Hz, but took 20 ms to reach 122 Hz f_0 (corresponding to an endpoint at the 40 ms point in the synthesized sound). The choice of 157 Hz as the maximum onset f_0 value was based on the mean score of male subjects producing [p] in experiment 1, and subsequent values were selected in arbitrary 10 ms steps below that, encompassing the average range of productions of [p] and [pʰ] by male speakers in experiment 1. The average f_0 of the talker selected for stimulus production in experiment 2 was comparable to the average range of male talkers in experiment 1. All properties of the burst release, aspiration noise, and all properties of the vowel other than f_0 remained the same across all tokens.

3. Procedure

The experiment was carried out in an IAC single-walled sound booth. Stimuli were presented binaurally in randomized order via Sennheiser HD-590 headphones. Stimulus presentation and response collection was controlled by a Hypercard stack running on Macintosh 7100 computer. On each trial listeners heard a single syllable and were instructed to identify it as either /pʰa55/ "on all fours" or /pa55/ "father" by clicking on one of two on-screen button inscribed with the appropriate Chinese characters. Characters were always
presented side-by-side, in the same order for each participant. Participants completed a total of 16 blocks of 16 trials each (4 levels of onset f_0 times 4 levels of transition duration), with stimulus order randomized within blocks. The first block was treated as a practice block and not scored, although participants were not aware of this at the time of testing. Thus there were a total of 15 scored responses to each stimulus by each participant.

B. Results

Responses were collected and scored in terms of the proportion of "unaspirated" /pa55/ "father" responses for each stimulus, and were submitted to a two-way analysis of variance with repeated measures. Results (shown in Fig. 4) showed a significant effect of onset f_0, $F(3,51)=44.23$, $p<0.001$ and of duration, $F(3,51)=30.42$, $p<0.001$, and a significant interaction between the two, $F(9,153)=11.89$, $p<0.001$. Posthoc (Tukey HSD, $\alpha=0.05$) analysis showed that there was no significant difference in response proportion between any of the tokens with different onset frequencies when the duration of f_0 transition was only 10 ms in duration. For all stimuli with longer f_0 transition durations, the contour with a 157 Hz starting frequency was identified as /pʰa/ "on all fours" (aspirated) significantly more often than any other contour regardless of the duration of the f_0 transition. Listeners identified the 147 Hz contour as /pʰa/ significantly more often than the 127 Hz or 137 Hz contour when the transition was at least 40 ms (though the difference between the 137 Hz and 147 Hz contours disappeared at 80 ms of transition duration). Only at 80 ms transition did listeners perceive the 137 Hz contour as significantly more aspirated (less unaspirated) than the 127 Hz contour.

C. Discussion

Cantonese listeners were able to use onset f_0 as a cue to consonant aspiration in the absence of other, more typical cues. However, there are two important qualifications to this conclusion. First, listeners in experiment 2 were unable to use onset f_0 as a cue to aspiration when onset f_0 varied only

over the 10-ms window shown in experiment 1 to differ between aspirated and unaspirated productions. Thus, Cantonese listeners do not appear to be able to perceive aspiration-related onset f_0 differences that occur in the production of their native language. Second, the manner in which onset f_0 functioned as a cue to consonant aspiration was precisely opposite to what one might have expected if Cantonese listeners' decisions were based on their prior experience with Cantonese. As shown in experiment 1, the onset f_0 of Cantonese unaspirated consonants starts *higher* than that of aspirated consonants, but in experiment 2 stimuli with higher onset f_0 values (e.g., 157 Hz) were generally identified *less* often as unaspirated stops than were those with lower onset f_0 values. Thus, Cantonese listeners' use of onset f_0 in making aspiration decisions must result from something other than their native language experience.

This pattern of results supports a model of voicing/aspiration perception in which onset f_0 can serve as a cue, not because it habitually occurs in conjunction with the cues to the primary contrast (as it does in English), but because it contributes indirectly to some more general, language-independent perceptual phenomenon (cf. Kingston and Diehl's, 1994 "low frequency property"). That is, onset f_0 differences may contribute indirectly to some more general property of the signal that Cantonese listeners are still able to interpret as cuing an aspiration contrast. One factor that may have helped in this transfer or extension of a more general cue is the listeners' experience with English. All of the participants in the present experiment were familiar with English, and used it on a daily basis in the course of their studies at the University of Hong Kong, where they were tested. An attempt was made to minimize the influence of English in the testing context, as all experiments were run in Cantonese and responses were made by clicking on Cantonese characters. Moreover, the English that listeners are exposed to in Hong Kong is typically a non-native variety; most secondary school teachers are native speakers of Cantonese, not English, and the same is increasingly true at the University level. Thus, it is not clear whether the English to which these listeners were exposed even presented a truly English-like pattern of covariation between VOT and onset f_0 cues. However, it is still possible that these listeners obtained some degree of experience with using the low frequency property to distinguish between English voiced and voiceless stops, and that this experience may have contributed to their ability to apply the same cue to the native aspiration contrast in the context of the present experiment.

IV. GENERAL DISCUSSION

The present results provide further support for the hypothesis that the effect of consonant voicing on onset f_0 in English results in part from what Kingston and Diehl (1994) call a controlled process—one that is intentionally manipulated by talkers to produce a desired perceptual effect, and in part from a intrinsic effect of the laryngeal gestures involved in voicing. The intrinsic effect may involve activity of the cricothyroid muscle, perhaps as part of a system for suppressing voicing (Löfqvist *et al.*, 1989), that results in an

increased onset f_0 following voiceless consonants. The active control, in turn, appears primarily to limit the duration of this effect. In the case of voicing in nontonal languages, the role of this active control may be to prolong this effect in order to enhance of consonantal distinctiveness: Presumably, stops tend to sound more voiced when f_0 can be heard to clearly rise into the vowel, and more voiceless when they are clearly followed by a falling f_0. In Cantonese, Mandarin, Thai and other tonal languages, talkers are apparently able to restrict the production of consonant-related perturbations of onset f_0 to the first few tens of milliseconds following the onset of voicing, presumably in order to maintain the integrity of the f_0 contour as a cue to lexical tone identity. The fact that Cantonese listeners are still able to use onset f_0 as a cue for consonantal aspiration differences, despite the lack of such distinctions in their native language, is consistent with Kingston and Diehl's (1994) suggestion that (i) distinguishing voicing/aspiration contrasts may involve attention to a "low frequency property," and that (ii) this property is perceptually enhanced by a variety of independent acoustic cues, including onset f_0. The present results demonstrate that this property (or something similar) is accessible to Cantonese listeners despite their lack of consistent native language experience with onset f_0 differences beyond the first few tens of milliseconds into the vowel.

Since onset f_0 variation beyond the first few tens of ms can be controlled by speakers, longer-term changes in f_0 (e.g., in English) cannot be entirely the involuntary consequences of voicing gestures (i.e., they are not purely intrinsic, physiologically determined, by-products of such gestures). The observation that Cantonese listeners were able to use onset f_0 as a cue to a their native aspiration contrast is consistent with the hypothesis that the use of onset f_0 as a cue to voicing in English and other nontonal languages may derive from some kind of auditory enhancement, perhaps similar to the low frequency property discussed by Kingston and Diehl (1994). However, the present results can also be explained in terms of transfer from listeners' experience with the English pattern of consonantal influence on onset f_0. Future research will be necessary to investigate the use of this cue by native speakers of Cantonese (or other tonal language) who are not familiar with English (or any other language with an English-like pattern of consonantal influence on onset f_0).

On first rahmonic amplitude in the analysis of synthesized aperiodic voice signals

Peter J. Murphy

Department of Electronic and Computer Engineering, University of Limerick, Limerick, Ireland

Rahmonics comprise the prominent peaks in the cepstrum of voiced speech; their locations correspond to the fundamental period and its multiples. The amplitude of the first rahmonic, R1, has previously been used to indicate voice quality. Although a correspondence between R1 and the richness of the harmonic spectrum for voiced speech is well recognized, a formal description has remained absent. A theoretical description of rahmonic analysis of voiced speech containing aspiration noise is provided, leading to a characterization of R1. The theory suggests that R1 is directly proportional to the geometric mean harmonics-to-noise ratio (gmHNR), where the gmHNR is defined as the mean of the individual spectral (i.e. at specific frequency locations) harmonics-to-noise ratios in dB. This hypothesis is validated using synthetically generated voice signals. R1 is shown to be directly proportional to gmHNR (measured directly from the dB spectrum). It is shown that R1 (estimated from speech) is directly proportional to R1 taken from the glottal signal. R1 and gmHNR (measured spectrally) underestimate the actual gmHNR when (averaged) noise levels exceed harmonic levels. Limiting the number of harmonics in the analysis window overcomes this problem and also alleviates the (temporal) window length/f0 dependence of R1 when estimated period synchronously. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2355483]

I. INTRODUCTION

A. Acoustic measures of voice signal regularity

The measurement of regularity of the acoustic voice signal in sustained phonations can provide useful markers for differentiating between normal and pathological voice types (e.g., Kasuya *et al.*, 1986) or for describing general aspects of voice quality (e.g., Hanson, 1997). Temporal regularity of a voice signal resulting from a sustained phonation can be broadly classified in terms of the dimensions of periodicity and wave shape.

Aperiodicity of the voice signal can result from jitter, shimmer, aspiration noise, nonlinear phenomena, interperiod glottal wave shape differences, nonstationarity of the vocal tract, or some combination of these attributes. Measures of these attributes are commonly used to assess pathological voice types. A popular measurement for extracting the degree of aperiodicity of the voice signal is the harmonics-to-noise ratio (HNR); it quantifies the ratio between the periodic and aperiodic components in the signal (Murphy, 1999).

Although a detailed description of voice quality in connected speech entails tracking many time varying acoustic parameters, general acoustic descriptors in the context of sustained phonation have proven useful (cf. Ladefoged and Antonanzas-Barroso, 1985; Klatt and Klatt, 1990; Childers and Lee, 1991; Alku and Vilkman, 1996, Hanson, 1997). These descriptions include temporal and spectral measures that characterize the broad temporal wave shape features of the signal. Measures include H1-H2 [the amplitude difference between the first two harmonics (expressed in dB)], various spectral tilt measures and temporal details of the

glottal flow. These measures, together with aperiodicity measures provide for a broad classification of voice quality.

A number of studies have shown that the amplitude of the first rahmonic peak in the cepstrum (R1) provides a good global descriptor of voice quality. The purpose of the present work is to provide a formal description of R1 and to validate this with the use of synthesis data. The development shows that R1 is directly proportional to the average of the harmonic to between harmonic ratios in the logarithmic spectrum. Before reviewing the use of R1 for voice quality analysis, a brief introduction to the real cepstrum is provided.

B. Voice quality analysis using first rahmonic amplitude

Voiced speech consists of the convolution between a periodic glottal pulse and the combined impulse response of the vocal tract and lip radiation load. Taking the logarithm of the squared amplitude of the Fourier transform of this signal results in a harmonic power spectrum in dB. The cepstral procedure involves taking the inverse Fourier transform of the logarithmic power spectrum. Because the logarithmic power spectrum consists of equally spaced harmonics, a peak in the inverse Fourier transform of this signal (the cepstrum) occurs at a point corresponding to the fundamental period (cf. Rabiner and Schafer, 1978), Fig. 1. The prominent peak at the fundamental period is termed the first rahmonic. Further peaks are termed 2nd, 3rd, etc. rahmonics.

Investigations into the assessment of (pathological) voice qualities and/or aberrant vocal fold vibration using the amplitude of the first rahmonic, R1 include the work of Koike (1986), Koike and Kohda (1991), Hillenbrand *et al.*
FIG. 1. Spectrum and cepstrum of voiced speech (synthesized vowel /a/ at $f0 = 110$ Hz) illustrating rahmonics at the fundamental period and its multiples.

(1994), Dejonckere and Wieneke (1994), Heman-Ackah *et al.* (2002) and Awan and Roy (2006).[1] Koike and Kohda (1991) observe the effect of surgery to the vocal folds on the prominent cepstral peak in the speech cepstrum. The location of the first rahmonic is used to determine the fundamental period and the height of this peak is used as an indicator of periodicity of the waveform. They state the following:

> "The correspondence between the elongation of the dominant cepstral peak and an improvement of the perceived voice quality also seems noteworthy. Although the regularity of the speech signal can be revealed by the height of the dominant cepstral peak, the scale on the ordinate of the cepstral display is not linear. This makes quantitative analysis of the length of the peaks rather complicated. Quantitative analysis of the height of the cepstral peak has not been attempted in the present study for this reason," p. 264

They note the convenience with which the fundamental period can be measured using cepstral analysis and that the analysis can be performed objectively without human judgment. Dejonckere and Wieneke (1994) note that the amplitude of the harmonic peaks above the noise level in the power spectrum reduce with increasing noise levels and as a consequence the corresponding cepstral peaks reduce in amplitude. They also report that jitter in the waveform leads to reduced harmonic levels and increased between harmonic levels leading to a reduction in the amplitude of the cepstral peaks. They observe that there is no general agreement on the scaling of cepstral results but since the logarithmic power spectrum is expressed in dB that its inverse Fourier transform (the cepstrum) can also be expressed in dB. They report that the main cepstral peak integrates both high frequency noise and perturbation characteristics of pathological voice and hence the measure shows promise for quantifying improvements in voice quality following phonosurgery.

Hillenbrand *et al.* (1994) calculate the height of the first cepstral peak using a normalization procedure and find the resulting index (termed CPP — cepstral peak prominence) to correlate well (correlation coefficient$=0.84$) with the perceptual impression of breathiness. They note that "a highly periodic signal should show a well defined harmonic structure and, consequently, a more prominent cepstral peak than a less periodic signal," p. 772. Herman-Ackah *et al.* (2002) report that the CPP index provides an indication of the harmonic structure for voiced speech and that it correlates strongly with perceptual measurements of dysphonia. In comparison with alternative acoustic indices (e.g., jitter, shimmer, and various spectral tilt and noise measures) Herman-Ackah *et al.* (2002), Hillenbrand *et al.* (1994), Dejonckere and Wieneke (1994) and Awan and Roy (2006) independently report that the cepstral peak provides a superior correlate of overall voice quality.

In the studies cited above that use R1 it is observed that increased levels of noise and perturbation in the voice signal are reflected by a reduction in the measure. However, it is also noted that a formal description of the cepstral peak remains absent. The present study provides a theoretical description of cepstral analysis of voiced speech containing aspiration noise, which leads to a characterization of R1 as a measure directly proportional to a geometric mean harmonics-to-noise ratio (gmHNR). The technique is then tested on a set of synthetically generated voice signals containing various aperiodicities. In a preliminary validation, R1 is correlated against gmHNR measured directly from the dB spectrum. A number of spectral analysis procedures are implemented, including period asynchronous, period synchronous, and a harmonic-limited procedure. A discussion is given in terms of the present results on synthesis data and on the consequence of the characterization on the results of previous studies involving human voice signals.

II. METHOD

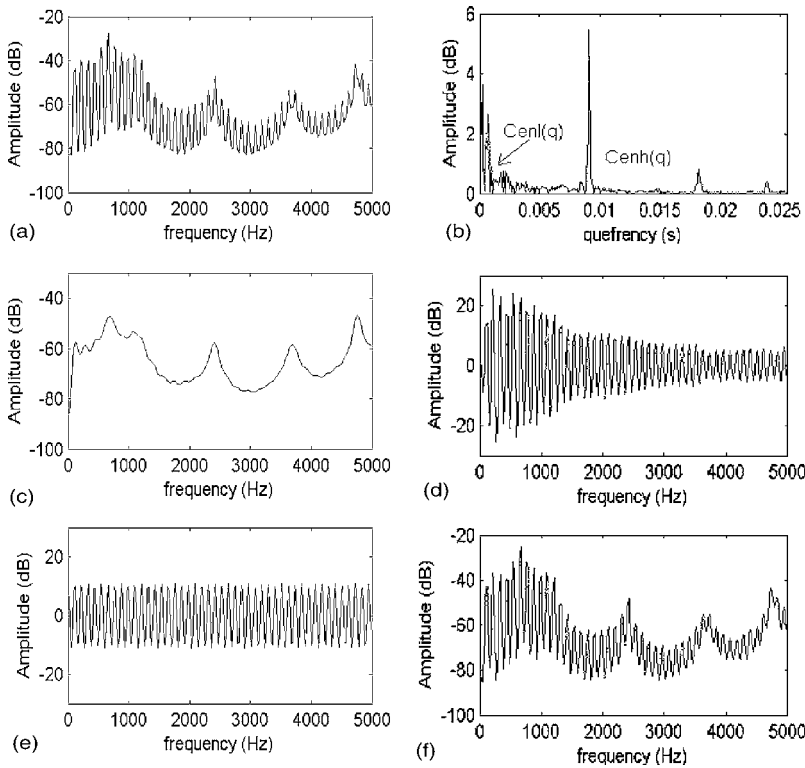
Noll (1967) pointed the way forward to a practical interpretation of the cepstrum stating that "the spectrum itself can be regarded as a signal and can be processed by standard signal-analysis techniques" (p. 309). The present description


FIG. 2. (a) Averaged spectrum for synthesized vowel /a/ ($f0 = 110$ Hz) containing 1% glottal noise (512 sample points sampled at 10 kHz, 50% overlap, 1.5 s). (b) Cepstrum of the signal in (a). (c) Fourier transform of low-passed liftered cepstrum [$C_{enl}(q)$]. (d) Fourier transform of cepstrum liftered in the region of the first rahmonic. (e) Fourier transform of first rahmonic peak. (f) Sum of Fourier transforms of liftered cepstra in (c) and (d).

considers taking the inverse Fourier transform of the logarithmic power spectrum of voiced speech containing aspiration noise. This development leads to a characterization of R1, which suggests that it is directly proportional to a geometric mean harmonics-to-noise ratio.

A simple representation for voiced speech containing aspiration noise [$s_{en}(t)$] can be written as

$$s_{en}(t) = \{[e(t) * g(t)] + n(t)\} * v(t) * r(t), \tag{1}$$

where $e(t)$ is a periodic impulse train, $g(t)$ is a single glottal pulse, $v(t)$ and $r(t)$ represent the vocal tract impulse response and the radiation load, respectively, $*$ indicates convolution, $s_{en}(t)$ is a periodic voiced speech waveform plus aspiration noise, and $n(t)$ represents aspiration noise.

Applying a window, (w), gives

$$s_{en}^w(t) = \{[e(t) * g(t)] + n(t)\} * v(t) * r(t) \times w(t). \tag{2}$$

The window function, $w(t)$, can be moved inside the convolution, provided the window length is sufficiently long (Oppenheim et al., 1968), to give

$$s_{en}^w(t) = \{[ew(t) * g(t)] + n_w(t)\} * v(t) * r(t). \tag{3}$$

Taking the Fourier transform gives

$$S_{en}^w(f) = [E_w(f) \times G(f) + N_w(f)] \times V(f) \times R(f). \tag{4}$$

where capital letters indicate the Fourier transforms of the corresponding temporal descriptors. Taking the logarithm of the magnitude squared values and approximating the signal energy at harmonic locations, $\log|S_{en}^w|_h^2$ and at between-harmonic locations, $\log|S_{en}^w(f)|_{bh}^2$, gives

$$\log|S_{en}^w(f)|_h^2 = \log|E_w(f) \times G(f) \times V(f) \times R(f)|^2, \tag{5}$$

$$\log|S_{en}^w(f)|_{bh}^2 = \log|N_w(f) \times V(f) \times R(f)|^2. \tag{6}$$

Although noise is present at all frequencies in the spectrum, when spectral averaging is applied, the harmonics approach the true harmonic values and the between-harmonics approach the true noise variance [Fig. 2(a)]. In the spectral averaging process the voiced speech signal is broken up into frames and successive frames are overlapped. A spectrum is produced for each frame and an average of these spectra is taken.

Taking the cepstrum of $s_{en}^w(t)$ gives

$$C_{en}(q) = \text{IDFT}[\log|S_{en}^w(f)|^2], \tag{7}$$

where IDFT is the Inverse Discrete Fourier Transform and "q" indicates quefrency.

The cepstrum translates to low and high quefrency components:

$$C_{en}(q) = \begin{cases} C_{enl}(q), & 0 < q < q_c, \\ C_{enh}(q), & q_c < q < q_{max}, \end{cases} \tag{8}$$

where "q" indicates quefrency, q_c indicates the cutoff point between high and low quefrency regions, and the subscripts "l" and "h" indicate low and high quefrency, respectively (Fig. 2). The low quefrency region is specified from 0 ms up to a quefrency corresponding to the first rahmonic minus the width of its main lobe and significant side lobes.

The low quefrency cepstral coefficients [$C_{enl}(q)$] reflect a combination due to the glottal flow excited vocal tract plus radiation [the last three terms in Eq. (5)] and the noise excited vocal tract plus radiation [Eq. (6)]. The high quefrency [$C_{enh}(q)$] is characterized by the rahmonic peaks spaced at the fundamental period and its multiples [Fig. 2(b)]. This separation of speech components in the cepstrum allows for

various filtering (liftering in the quefrency domain) operations. Figure 2(c) shows the Fourier transform of the cepstrum low-pass liftered below the first rahmonic (samples after 6.2 ms are set to zero) while Fig. 2(d) shows the Fourier transform of the cepstrum that has been set to zero everywhere except in the region (±3 ms) of the first rahmonic. The latter figure provides an approximation to the harmonics-to-noise structure in the original spectrum, with the spectral envelope removed. These Fourier transformed liftered signals [Fig. 2(c) and 2(d)] are added in Fig. 2(f), providing a close approximation to the original spectrum in Fig. 2(a).

The amplitudes of the rahmonics reflect the richness of the harmonic structure (in logarithmic scale). Specifically, the amplitude of the first rahmonic, R1, is dependent (as are all the rahmonics) on the depth of the valleys between adjacent harmonic locations [consider taking the inverse Fourier transform of the spectrum in Fig. 2(a)]. The amplitudes of the harmonic locations are determined by $|E_w(f) \times G(f) \times V(f) \times R(f)|^2$ while the amplitudes of the "between harmonic" locations are determined by $|N_w(f) \times V(f) \times R(f)|^2$. Therefore, the noise contributions can be seen to limit the height of the first rahmonic amplitude. Consequently, estimating the amplitude of the first rahmonic provides some indication of the harmonics-to-noise ratio content of the signal. R1 is determined by the average of the difference between harmonic and "between harmonic" energies in the dB spectrum, and hence it is not directly related to the HNR of the radiated speech waveform because it is, to a first order approximation, independent of the envelope in the original spectrum. Furthermore, because the spectrum is in dB, the resulting index is proportional to an average of dB values. Figure 2(e) shows the Fourier transform of the cepstrum, where every point except the first rahmonic peak has been set to zero. The amplitude of the resulting signal can be seen to be an average of the signal in Fig. 2(d). Finding an average of dB values is equivalent to determining the geometric mean HNR of the power spectrum (gmHNR — expressed in dB). The term geometric mean comes from the fact that the averaging involves logarithms and is therefore equivalent to taking the product of linear values and taking the Mth root (and then taking the logarithm), where M refers to the number of harmonic to between-harmonic estimates.

The geometric mean harmonics-to-noise ratio (gmHNR) is defined as

$$\text{gmHNR} = \frac{20}{M}\sum_{f=0}^{M} \log 10\left(\frac{|E(f) \times G(f) \times V(f) \times R(f)|}{|N(f) \times V(f) \times R(f)|}\right).$$

(9)

This can be approximately written as[2]

$$\text{gmHNR}' = \frac{20}{M}\sum_{f=0}^{M} \log 10\left(\frac{|E(f) \times G(f)|}{|N(f)|}\right),$$

(10)

and, hence, the measure is, to a first approximation, independent of the vocal tract resonance and radiation load, which is desirable for quantifying a glottal source signal-to-noise ratio. The geometric mean harmonics-to-noise ratio, gmHNR,

is equivalent to a conventional HNR estimate of the glottal source (GHNR) only when the HNR is constant for all frequencies. This is satisfied when shimmer (only) is present in the glottal source signal (Murphy, 2000). In general, the measure represents a geometric mean of the linear HNRs determined for each harmonic/between-harmonic of the glottal source (with the overall result being expressed in dB). Equivalently, it represents an arithmetic mean of the dB HNRs for each harmonic/between-harmonic location.

The rahmonic analysis development suggests that R1 is directly proportional to gmHNR, i.e.,

$$\text{R1} \propto \text{gmHNR}. \tag{11}$$

A direct proportionality rather than equality is assigned in Eq. (11) because the spectral wave shape (harmonic - between harmonic pattern) is not a pure sinusoidal signal but rather has a characteristic wave shape depending on the fundamental frequency and the temporal analysis window length.

III. ANALYSIS

A. Synthetic speech signals

A sequence of glottal pulses (type C, Rosenberg, 1971) is used as input into a delay line digital filter, with filter coefficients set to represent the vowel /a/ (Rabiner and Schafer, 1978). Radiation at the lips is modeled by the first order difference equation $R(z) = 1 - z^{-1}$. The sampling frequency is 10 kHz and 1.5 s are synthesized.

Aperiodicity is introduced by altering the glottal source in a 110 Hz waveform. Random shimmer is introduced by adding a random variable gain factor (of a given std. dev. ranging from 1% to 32%) to the amplitude of the fundamental period impulse train prior to convolution with the glottal pulse. Random jitter is synthesized at levels from std. dev. 1% to 6 % through time scaling of glottal waveforms. Random noise is introduced via a random noise generator arranged to give mean zero white Gaussian noise of a user specified variance (std. dev. 1% to 32%). Further signals are also created for three levels of random noise (4%, 8%, and 16%) for signals beginning at 80 Hz and increasing in six, approximately equispaced steps of 60 Hz up to 350 Hz.

B. Spectral and cepstral processing

The synthesis signals are analyzed using period-asynchronous and period-synchronous windowing. For the asynchronous analysis Hamming window lengths of 256, 512, 1024, 2048, and 4096 are used. These frames are hopped by half this window length (e.g., by 256 points for a 512 point window) for the 1.5 s available. For the period-synchronous analysis 4, 6, 8, 10, and 12 fundamental periods are used and hopped by half this number. The default value of fundamental period is used, making the method essentially period asynchronous when the jitter signals are analyzed. The linear spectra resulting from the hopped windowed segments are averaged and a single dB spectrum is calculated. The resulting dB spectra are inverse Fourier transformed to provide the cepstral coefficients and R1 is located using a peak-picking algorithm. The peak-picking algorithm simply

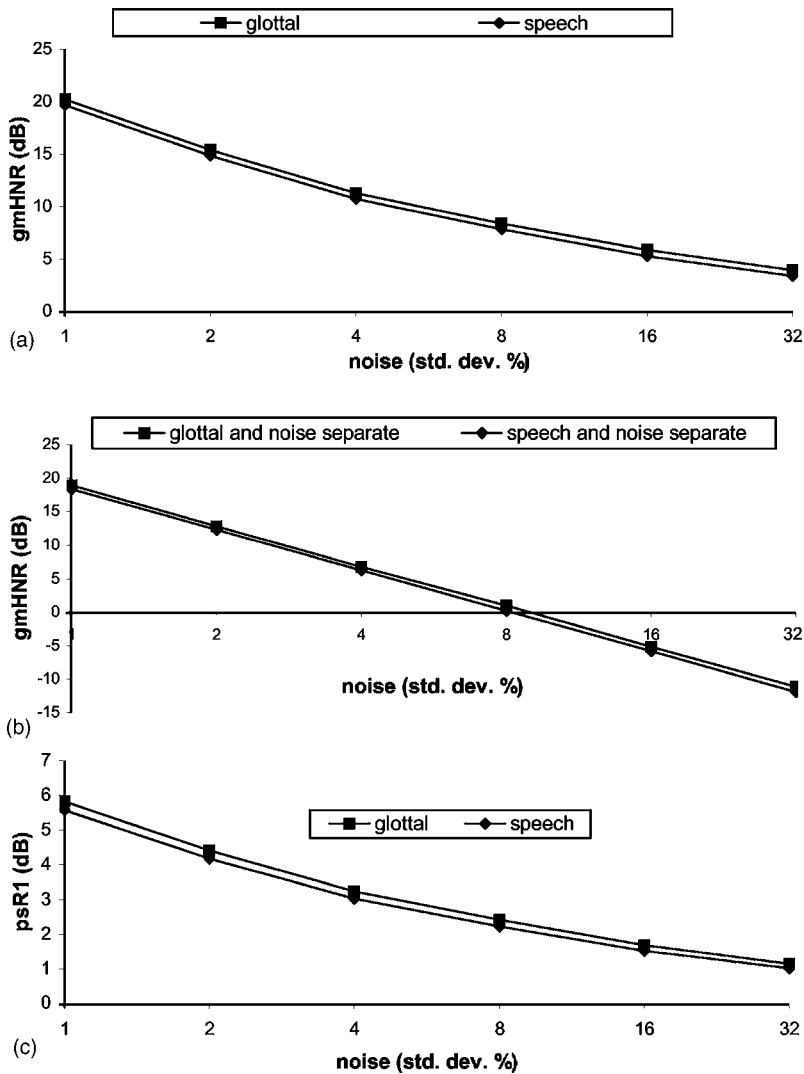

FIG. 3. Period synchronous analysis (six periods) for synthesized glottal pulse and vowel /a/ at 110 Hz for six levels of glottal noise (a) gmHNR (harmonics and noise estimated from noisy signals) (b) gmHNR (harmonics and noise estimated from separate signals: noise-free glottal and speech signals and noise-only signals) (c) psR1 (estimated from noisy signals).

searches for the maximum amplitude in the region of the expected fundamental period, T0, which is known for the synthesis data. The amplitude is taken directly from the cepstrum without further processing. For the dB spectra produced (for a window length of six fundamental periods) a spectral measure of gmHNR is calculated through estimating the harmonic and between-harmonic levels directly.[3]

IV. RESULTS

In order to test the algorithms in a systematic manner, synthetically generated glottal and speech signals are analyzed. The unit for R1 is the dB as it represents a mean of dB values. In order to validate that gmHNR (calculated from the dB speech spectrum) and gmHNR (calculated from the dB glottal spectrum) are approximately equal [Eq. (9) and Eq. (10)] and to validate that R1 is directly proportional to gmHNR, gmHNR is estimated directly from the dB spectrum (i.e., signal energy is estimated at harmonic locations and noise is estimated halfway between harmonic locations). For this analysis "x" % noise is added to the glottal source and the averaged spectrum (expressed in dB) is produced for the corresponding glottal and speech signals (a period synchronous window length of six periods, hopped by three periods, is used; $f0=110$ Hz). gmHNR is extracted from the resulting

spectra as shown in Fig. 3(a). In Fig. 3(b) gmHNR is measured by estimating the harmonic peaks from noise-free spectra [i.e., from the averaged spectra (expressed in dB)] of the glottal and speech signals with no noise added to the glottal source. Similarly, the between-harmonic (i.e., noise) estimates are taken directly from noise only dB spectra (no glottal or speech signals present). A Spearman's correlation of gmHNR (speech) and gmHNR (glottal) gives $\rho=1.00$ significant at the 0.01 level for the data in Fig. 3(b). In Fig. 3(c), psR1 (period synchronous R1) is estimated from the cepstrum using the same spectra as used for gmHNR in Fig. 3(a). A Spearman correlation provides a $\rho=1$, significant at the 0.01 level for all paired correlations between gmHNR (glottal, speech) and psR1 (glottal, speech).

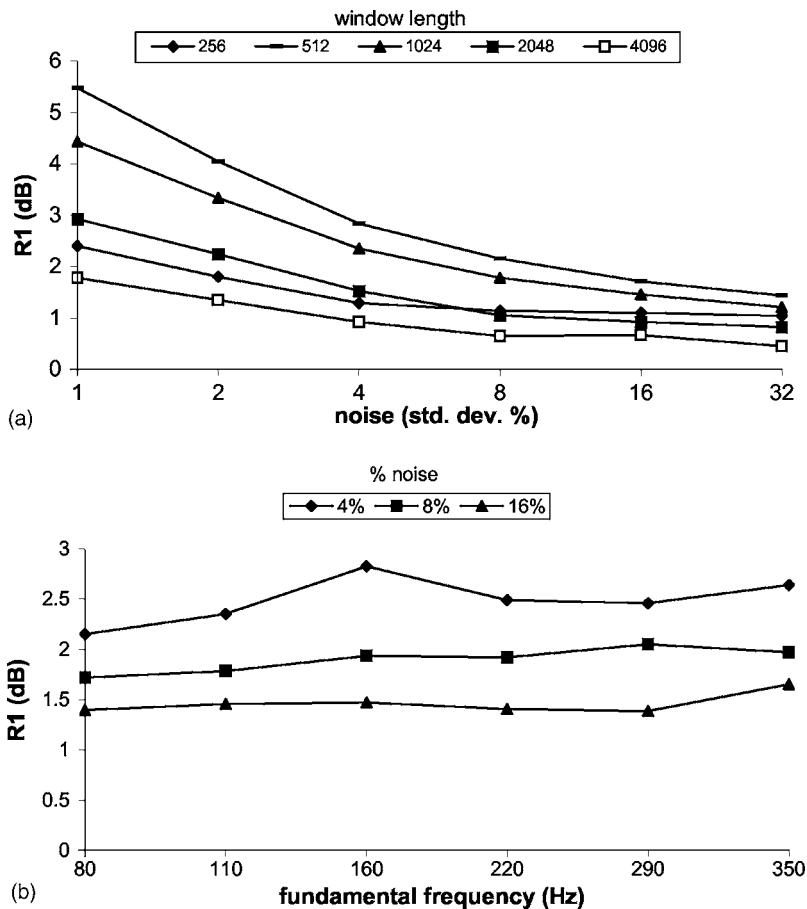
The R1 values resulting from a period-asynchronous cepstral analysis (window lengths 256, 512, 1024, 2048, and 4096) of voiced speech ($f0=110$ Hz) with six levels of random noise (1% in doubling of levels to 32%) are shown in Fig. 4(a). At a given noise level (e.g., 2%), R1 decreases as the window length increases (except for the lowest window size, 256). R1 (period-asynchronous, window length 1024) is shown to be approximately equispaced and somewhat invariant across $f0$ when tested against three noise levels for six different fundamental frequencies [Fig. 4(b)].


FIG. 4. (a) Period asynchronous R1 for a 110 Hz synthesized vowel /a/ with six levels of glottal noise and five window lengths. The linear spectra resulting from the hopped windowed segments are averaged and a single dB spectrum is calculated from which R1 is estimated. (b) Period asynchronous R1 plotted against $f0$ for the synthesized vowel /a/ with three levels of glottal noise (window length=1024).

Period-synchronous R1 (psR1) is tested for the 110 Hz signal [Fig. 5(a)] for window lengths of 4, 6, 8, 10, and 12 fundamental periods and for the range of $f0$ values using a window length of six fundamental periods [Fig. 5(b)]. In all subsequent period synchronous analyses, a window length of six fundamental periods is used. In Fig. 6 the spectrum is limited to the first 13 harmonics and psR1 is shown to be equispaced and largely invariant across $f0$ for three noise levels for the range of $f0$ values (the full 1.5 s data record is used for each $f0$).

Figure 7 shows a linear response of (a) gmHNR and (b) psR1 for glottal and speech waveforms (spectrum limited to the first 13 harmonics) with respect to the doubling of noise levels. Figure 8 shows that gmHNR and psR1 (for glottal and speech data using complete and harmonic limited spectra) respond linearly with the doubling of shimmer levels. Figure 9 shows that gmHNR and psR1 (for glottal and speech data using complete and harmonic limited spectra) decrease nonlinearly with respect to linear increases in jitter levels. A Spearman correlation gives $\rho=1.00$, significant at the 0.01 level for all paired correlations between gmHNR (speech), psR1 (speech), gmHNR (glottal), and psR1 (glottal) versus noise, shimmer and jitter, respectively, when estimated from complete and harmonic limited spectra.

V. DISCUSSION

A. Results for synthesis data

The key to understanding the results of the cepstral analysis lies in examining the underlying spectral character-

istics. Figure 3(a) validates that gmHNR (measured directly from the dB spectrum) is directly proportional for the speech and glottal signals (they have almost the same values). This is noteworthy because it indicates that an acoustic measurement taken from the voiced speech waveform can potentially be used to infer information directly related to the glottal source, which is desirable from a noninvasive, clinical diagnostic viewpoint. Figure 3(c) similarly shows that psR1 is directly proportional for the speech and glottal signals and a Spearman correlation between gmHNR and psR1 provides a $\rho=1$, significant at the 0.01 level, confirming that the hypothesis put forward under METHOD is correct. However, it is noted that gmHNR and psR1 (in contrast to a conventional HNR estimate) do not vary linearly with the doubling of noise levels. Equation (9) and Eq. (10) suggest that a doubling of noise levels would lead to a linear decrease in the gmHNR value. The nonlinear decrease in psR1 and gmHNR is due to the fact that as noise levels exceed harmonic levels (at higher frequencies) in the averaged spectrum the level of harmonics are overestimated, leading to overestimates of gmHNR.[4] Figure 3(b) illustrates gmHNR extracted from the spectrum where harmonics are estimated from noise free, glottal, and speech signals. The noise is estimated from glottal and speech free signals (i.e., noise only is present). The resulting response of gmHNR with respect to the doubling of noise levels is linear (in this case the ratio decreases in steps of approximately 6 dB/doubling of noise levels, as per a conventional HNR estimator).

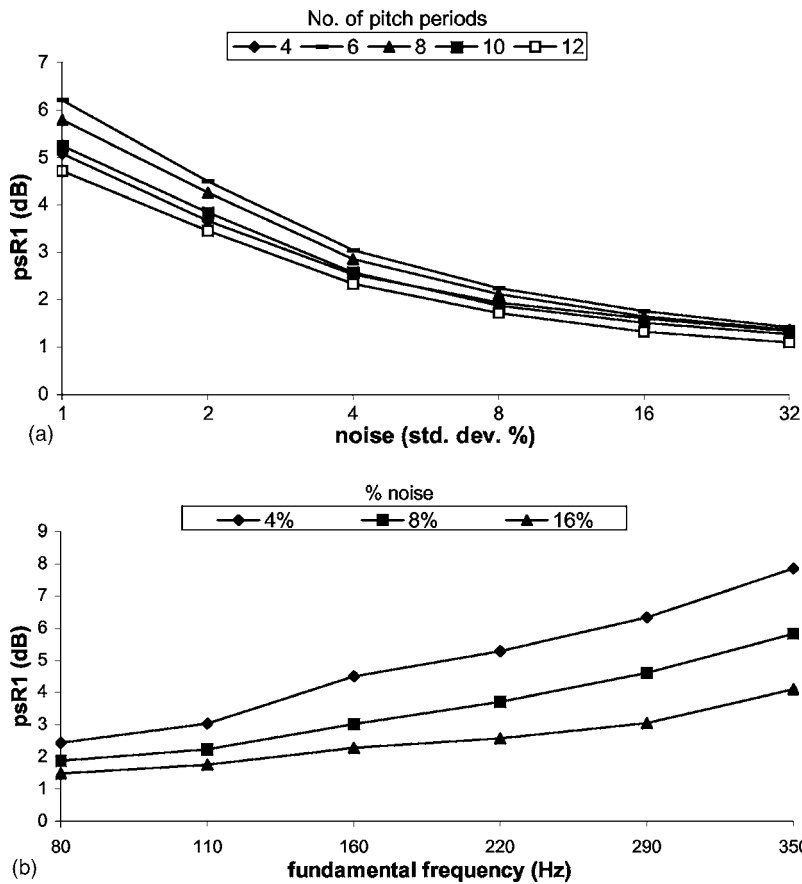
In the asynchronous analyses illustrated in Fig. 4, the


FIG. 5. (a) Period synchronous R1 (psR1) versus glottal noise levels for varying window lengths. (b) Period synchronous R1 (psR1—six periods) versus fundamental frequency for three glottal noise levels.

nonlinear decrease of R1 with respect to the doubling of noise levels is again observed. As the window length increases (ignoring 256 initially), the value of R1, at a given noise level, decreases. This can be interpreted as the increased harmonic resolution leading to a decreased sinusoidal nature of the spectrum [Figs. 10(b) and 10(c)]. Conversely, the window length=256 provides a lower R1 due to a reduction in spectral resolution, i.e., even though the spectrum is somewhat sinusoidal in nature (compared to window length=1024, for example) the troughs are not as steep as for the case of window length=512 due to the decreased spectral resolution (Fig. 10). For the longer window lengths (2048 and 4096) as the noise level increases beyond 8% there is only a slight variation in R1. This happens at 4% for the 256 sample window length.
FIG. 6. Period synchronous R1 (psR1) with the spectrum limited to the first 13 harmonics versus fundamental frequency for three levels of noise.

The variation of R1 with respect to $f0$ is examined in Fig. 5 (window length=1024 points). It has been stated previously that gmHNR is, to a first approximation, independent of the vocal tract, hence it might be anticipated that R1 is independent of $f0$. The plot of R1 vs $f0$ for three levels of random noise indicates that the variation is not that of a conventional HNR. The trend of increasing HNR with increasing fundamental frequency for synthetic speech signals has been observed previously and is due to the difference in excitation of the vocal tract formants as the fundamental frequency increases (Murphy, 1999). Although the measurements of R1 are reasonably consistent across $f0$, some variation persists, as indicated in the figure. In fact, the seemingly flat response of R1 vs $f0$ can be seen to result from a counterbalancing of two aspects related to the spacing of the harmonics in the spectrum. As $f0$ increases, R1 potentially increases due to an overall increase in the average harmonics-to-noise ratios in dB over the frequency range of interest (in this case 0 to 5 kHz), whereas it decreases due to the increased frequency resolution that results from the harmonics being spaced farther apart [Figs. 11(a) and 11(b)].

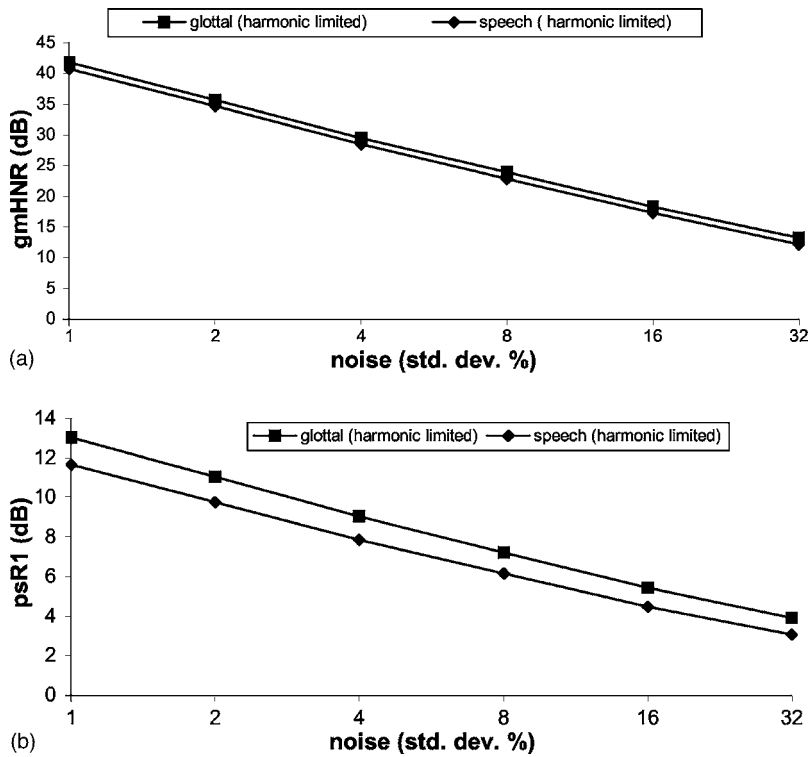
Period synchronous R1 (psR1) is shown for the 110 Hz signal in Fig. 5(a). It shows a similar trend to the asynchronous analysis with psR1 reducing nonlinearly as noise levels double. Except for the case of four fundamental periods (91 samples at 10 kHz sampling×4), as the window length increases R1 decreases. As for the period-asynchronous case, this trend is due to harmonic resolution. Six fundamental periods are chosen for further analysis. The variation of psR1 vs $f0$ is shown in Fig. 5(b). This trend is similar to the


FIG. 7. (a) gmHNR (spectrum limited to the first 13 harmonics) and (b) psR1 (spectrum limited to the first 13 harmonics) versus noise for the 110 Hz synthesized glottal and speech signals.

variation of HNR vs $f0$ (Murphy, 1999), however, the origin of the trend is different. In a conventional HNR measurement, the index is dependent on the vocal tract resonances, whereas the gmHNR is, to a first approximation, not. The $f0$ dependence of the index in this case arises from the spacing of the harmonics over the frequency range of interest [Figs. 11(c) and 11(d)]. From the figure it can be seen that the 110 Hz signal has many smaller dB HNRs than the 220 Hz signal, due to the greater number of harmonics, leading to a lower value of R1. Because the measure is period synchronous in this case the harmonic resolution is equal across $f0$ and hence does not offer the counterbalancing of the asynchronous analysis.

As stated previously, ideally the acoustic analysis should
FIG. 8. (a) gmHNR (complete spectrum and spectrum limited to the first 13 harmonics) and (b) psR1 (complete spectrum and spectrum limited to the first 13 harmonics) versus shimmer for the 110 Hz synthesized glottal and speech signals.

reflect levels of source aperiodicity, independent of $f0$. In an attempt to make psR1 an $f0$ independent measure, a set number of harmonics ($k=13$) is taken in the spectrum prior to taking the inverse Fourier transform (Fig. 6). An approximately flat response with respect to $f0$ is observed. A second important advantage of limiting the analysis to a set number of harmonics is illustrated in Fig. 7. The graph shows that (a) gmHNR (speech and glottal—spectrum limited to the first 13 harmonics) and (b) psR1 (speech and glottal—spectrum limited to the first 13 harmonics) decrease linearly with the doubling of noise levels. By limiting the spectrum to, in this case, the first 13 harmonics, the harmonic levels are not ex-

ceeded as the noise level increases. The (harmonic limited) gmHNR values are almost the same at a given noise level for the glottal and speech data. However, psR1 estimated from the harmonic limited spectrum for the glottal signal is approximately 1 dB greater than when estimated from the harmonic limited speech spectrum. This is because of the zero Hertz or dc term for the glottal signal. In the estimation of gmHNR, the dc term is ignored. The dc term can be included in gmHNR or, conversely, the harmonic spectrum could be band limited to begin at the first harmonic prior to taking the

FIG. 11. Averaged, period asynchronous spectrum (1024 samples) of (a) 110 Hz and (b) 220 Hz synthesized /a/ vowel with 4% glottal noise. Averaged period-synchronous spectrum (six fundamental periods) of the same vowel [(c) 110 Hz and (d) 220 Hz].

psR1 estimate. Alternatively, the average signal amplitude over the window can be subtracted from the glottal signal as a preprocessing step.

In Fig. 8, gmHNR and psR1 are plotted against shimmer. gmHNR (estimated from the complete spectrum and the spectrum limited to the first 13 harmonics) decreases approximately linearly with doubling of shimmer levels for the glottal and speech data. The four estimates of gmHNR for a given noise level are approximately equal. Spectrally, shimmer results in a HNR that is equal at all frequencies (Murphy, 2000); it can be seen that harmonic/between-harmonic difference remains constant throughout the spectrum [Fig. 12(a)] and hence gmHNR taken from the complete spectrum and the harmonic limited spectrum are expected to be similar. As the HNR is equal at each harmonic/between harmonic, it is expected that gmHNR would equal the actual HNR (at least for the glottal signals, i.e., 40, 34, 28, 22, 16, and 10 dB for 1, 2%, 4%, 8%, 16%, 32% std. dev. shimmer levels, respectively). Although approximately 6 dB decreases are observed for the doubling of shimmer levels, gmHNR values are overestimated by approximately 8 dB. The four estimates of psR1 are also approximately equal at a given noise level. However, psR1 estimated from the harmonic limited spectrum for the glottal signal is again approximately 1 dB greater than for the harmonic limited speech spectrum. For a conventional HNR estimator, noise and shimmer levels of the same level produce the same HNR values. This contrasts HNR with gmHNR and psR1; the latter indices are different for shimmer and random noise of the same level (Fig. 3, Fig. 7, Fig. 8).

The averaged spectrum for random jitter [Fig. 12(b)] shows an early harmonic structure that deteriorates with increasing frequency. psR1 reflects these alterations in harmonic structure (Fig. 9). However, the result of averaging jittered signal spectra is quite different from the result of averaging spectra due to periodic signals plus noise. In the latter case, the harmonics approach the true signal harmonics and the noise approaches the true noise variance. In averaging the jittered signal spectra, no greater insight into quantifying the level of aperiodicity is apparent. The averaging appears to smooth out the jittered harmonics at higher frequencies and a subharmonic regime is not as evident. gmHNR and psR1 decrease nonlinearly with increased jitter for the complete spectrum and the spectrum limited to the first 13 harmonics for the glottal and speech data. The harmonic limited spectra have higher values of gmHNR and psR1 due to the relative richness of harmonic structure over this interval. Again there is an approximate 1 dB difference in psR1 (glottal—harmonic limited) compared to psR1 (speech—harmonic limited), which is attributed to the dc term of the glottal signal. Despite the strong correlations between gmHNR and psR1 for jittered signals, caution should be taken when interpreting R1 and gmHNR relationships in this case. For nonaveraged spectra of jittered signals, a subharmonic regime is usually in evidence (cf. Murphy, 2000), which may contribute differently to gmHNR and psR1 and may also increase the amplitude of the second rahmonic. Broadening of the bandwidths of the low frequency harmonics may also shift the first rahmonic location slightly. A formal study of these issues is required.

B. First rahmonic amplitude and human voice signals

A number of studies cited in the introduction (Heman-Ackah *et al.*, 2002; Hillenbrand *et al.*, 1994; Dejonckere and Wieneke, 1994; Awan and Roy, 2006) state that the first cepstral peak (R1) provides a superior acoustic index (when compared with indices such as jitter, shimmer, and various spectral tilt and noise measures) for differentiating between normal and, pathological or breathy, voice quality. It has been shown in the present development that R1 provides an indication of the geometric mean harmonics-to-noise ratio, i.e., it provides an overall index of the richness of the harmonic spectrum in dB. The synthesis shows that noise and shimmer increase between-harmonic amplitudes in the averaged spectra and hence lead to reduced values of R1. Shim-
FIG. 12. Averaged, period asynchronous spectrum (512 samples) of synthesized /a/ vowel with (a) 2% shimmer and (b) 1% jitter.

mer is shown to influence R1 in a different manner from noise, as expected for a gmHNR, as detailed in the previous section. Jitter deteriorates the existing harmonic structure and increases the between-harmonics, leading to a reduced value of R1. Hence aperiodicity in the temporal waveform is reflected in the spectrum leading to a reduction in R1. Although this is also the case for a HNR estimator, the exact nature of the changes in the indices is different due to the geometric mean inherent in the R1 measure.

Because R1 provides average information regarding harmonics-to-noise ratio components in the dB spectrum, it perhaps provides information more closely associated with spectrographic (logarithmic display of amplitude) evaluation of voiced speech containing glottal noise than a conventional HNR estimator. The spectrogram displays the speech signal in terms of a gray scale representing logarithm intensity, hence when an observer makes an estimate regarding the HNR of the signal, he or she is forming a judgment based on logarithmic data. The fact that the index provides an average of logarithmic values effectively gives greater weight to the higher frequency noise components in the spectrum, which may also make the measure more perceptually relevant than a conventional HNR estimator.

A further aspect of the spectrum, not investigated through the present synthesis, concerns spectral slope. A primary correlate of breathy voice quality is spectral slope, typically given as -18 dB/octave compared to -12 dB/octave for normal voice (Childers and Lee, 1991). This slope will not affect the calculation of a conventional HNR (as long as the harmonic level exceeds the noise level in the averaged spectrum). However, based on the characterization of R1 being directly proportional to an average of dB HNRs at harmonic/between-harmonic locations spectral slope due too the glottal source will influence R1, even if the underlying signals have equal HNR values. This may be observed by directly substituting appropriate values into Eq. (9) or equivalently it is noted that a breathy voice is characterized by a more sinusoidal flow waveform with corresponding increased relative first harmonic and reduced higher harmonics. Due to the reduced periodicity in the dB spectrum, a reduced R1 value results independent of noise and perturbation considerations. This inference suggests another possible reason as to why R1 provides a better indicator of voice quality, when compared against other acoustic indices, in the studies cited.

An additional characteristic of R1 that may account for the strong performance of the measure as an indicator of voice quality (Hillenbrand *et al.*, 1994; Dejonckere and Wieneke, 1994; Heman-Ackah *et al.*, 2002 and Awan and Roy, 2006) is the relative $f0$ independence of the measure when compared to a conventional HNR estimate in a period-asynchronous analysis. Hillenbrand *et al.* (1994) and Heman-Ackah *et al.* (2002) use 25.6 ms sampled at 10 kHz, Dejonckere and Wieneke (1994) use 100 ms sampled at 20 kHz and Awan and Roy (2006) use 41 ms sampled at 25 kHz, i.e., the analyses are period asynchronous and, hence, in the case of R1 in the present synthesis, less sensitive to variation with $f0$.

VI. CONCLUSION

A theoretical analysis of the cepstrum of voiced speech containing aspiration noise predicts that the first rahmonic amplitude, R1 is directly proportional to the geometric mean harmonics-to-noise ratio (gmHNR, where gmHNR is defined as the mean of the individual harmonic to between harmonic ratios in dB). Tests on the synthesis of glottal and speech signals containing glottal noise validate the hypothesis. In addition, gmHNR (estimated directly from the speech spectrum) is shown to be approximately equal to gmHNR (estimated directly from the glottal spectrum). This approximation is also shown for R1 (speech and glottal). gmHNR and R1 are shown to decrease in a nonlinear manner with the doubling of noise levels. This is shown to be due to the fact that noise levels exceed harmonic levels (at higher frequencies) as the noise increases. Limiting the harmonics in the spectrum causes the response to the doubling of noise levels to become linear (i.e., higher harmonics are no longer exceeded in amplitude by the noise level). Limiting the spectrum to a set number of harmonics all alleviates the $f0$ dependence of the measure in a pitch synchronous analysis. The responses of psR1 and gmHNR to shimmer and jitter, respectively, are also shown to be highly correlated.

A number of reasons are inferred as to why this single acoustic index provides a strong gross correlate of voice quality: (a) the relative $f0$ independence characteristic when extracted via a period-asynchronous analysis, (b) the relative vocal tract independence of the measure, (c) greater weight is given to higher frequencies (when compared with a conventional HNR), and (d) the glottal source spectral slope sensitivity property. This is not to suggest, however, that a true multidimensional acoustic characterization of voice quality is not required. In contrast to a single global indicator, finding accurate measures that reflect specific aspects of voice quality remains an important research goal. The harmonic limited period synchronous R1 measure extracted from the dB spectrum of voiced speech shows promise for quantifying glottal signal-to-noise attributes.

[1] For completeness it is mentioned that an alternative signal-to-noise estimation technique using a region centered on the first rahmonic peak is given in Yegnanarayana *et al.* (1998). However, the cepstral processing is only used as a preprocessing step to isolate the harmonics for their recursive algorithm used in HNR estimation.

[2] In reality, signal energy is estimated at harmonic locations and noise energy is estimated at "between harmonic" locations and hence Eq. (10) is only approximately equal to Eq. (9).

[3] In de Krom (1993) and Qi and Hillman (1997) it appears that the obtained signal to noise index is also extracted directly from the power spectrum in dBs, i.e., an average of dB values (of each harmonics-to-noise ratio estimate at a given frequency) is estimated and hence is equivalent to gmHNR [Eq. (9)]. Therefore comments in Secs. V and VI regarding gmHNR are also attributable to the indices derived from these techniques. These methods can also be used to extract a conventional HNR estimate, which sums

the signal and noise energies in linear scale before taking the logarithm of their quotient.

[4]This is also the case for a conventional HNR measure but the overestimates of the higher harmonics have relatively little effect because the ratio is dominated by the low frequency energy.

Speech recognition in normal hearing and sensorineural hearing loss as a function of the number of spectral channels

Deniz Başkent[a]

House Ear Institute, Department of Auditory Implants, 2100 West Third Street,
Los Angeles, California 90057

Speech recognition by normal-hearing listeners improves as a function of the number of spectral channels when tested with a noiseband vocoder simulating cochlear implant signal processing. Speech recognition by the best cochlear implant users, however, saturates around eight channels and does not improve when more electrodes are activated, presumably due to reduced frequency selectivity caused by channel interactions. Listeners with sensorineural hearing loss may also have reduced frequency selectivity due to cochlear damage and the resulting reduction in the nonlinear cochlear mechanisms. The present study investigates whether such a limitation in spectral information transmission would be observed with hearing-impaired listeners, similar to implant users. To test the hypothesis, hearing-impaired subjects were selected from a population of patients with moderate hearing loss of cochlear origin, where the frequency selectivity would be expected to be poorer compared to normal hearing. Hearing-impaired subjects were tested for vowel and consonant recognition in steady-state background noise of varying levels using a noiseband vocoder and as a function of the number of spectral channels. For comparison, normal-hearing subjects were tested with the same stimuli at different presentation levels. In quiet and low background noise, performance by normal-hearing and hearing-impaired subjects was similar. In higher background noise, performance by hearing-impaired subjects saturated around eight channels, while performance by normal-hearing subjects continued to increase up to 12–16 channels with vowels, and 10–12 channels with consonants. A similar trend was observed for most of the presentation levels at which the normal-hearing subjects were tested. Therefore, it is unlikely that the effects observed with hearing-impaired subjects were due to insufficient audibility or high presentation levels. Consequently, the results with hearing-impaired subjects were similar to previous results obtained with implant users, but only for background noise conditions. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354017]

I. INTRODUCTION

Two factors that affect speech recognition by listeners with sensorineural hearing loss (SNHL) considerably are reduced audibility, due to elevated hearing thresholds, and suprathreshold deficits. In his model for recognition of speech in noise by hearing-impaired (HI) listeners, Plomp (1978) termed these factors as "attenuation" and "distortion," respectively. The attenuation problem can mainly be solved by amplification of sound to levels above the auditory thresholds. The solutions to the distortion problem are, however, not as straightforward. One form of distortion is related to reduced frequency selectivity, commonly seen in moderate to profound hearing loss of cochlear origin. The main cause for reduced frequency selectivity is thought to be damage in outer hair cells (OHCs). OHCs are believed to be an essential part of the active mechanism in cochlea that gives rise to cochlear nonlinearities such as the basilar membrane compression (Oxenham and Plack, 1997). The cochlear nonlinearities contribute to sharp tuning of the auditory filters

(AFs) in normal hearing (NH). When there is damage in the cochlea, particularly in the OHCs, the nonlinearities might be reduced and the AFs might be broadened (Glasberg and Moore, 1986; Baker and Rosen, 2002).

Festen and Plomp (1983) observed that speech recognition by HI listeners in quiet was mainly affected by audiometric thresholds, while speech recognition in noise was affected by frequency resolution. The correlation between reduced frequency resolution and poor speech intelligibility in noise was later confirmed by other studies (Stelmachowicz *et al.*, 1985; Noordhoek *et al.*, 2000). In a study by Leek and Summers (1996), listeners with broad AFs were observed to need higher spectral contrast for discrimination of vowel-like stimuli presented in noise. It was hypothesized that a reduced SNR in the internal auditory representation of speech might be an explanation for the detrimental effects of reduced frequency resolution. Some studies also showed a correlation in quiet listening conditions; Turner and Henn (1989) observed that input filter patterns, a measure of frequency resolution, were correlated with recognition of vowels, and Henry *et al.* (2005) observed that the capability of resolving spectral peaks of rippled noise was correlated with recognition of vowels and consonants.

Reduced frequency selectivity of hearing impairment was simulated with NH listeners as well. When speech was degraded by spectral smearing to simulate broadened AFs, speech recognition by NH listeners dropped, and the presence of the background noise amplified the detrimental effects (ter Keurs *et al.*, 1992, 1993; Baer and Moore, 1993; Boothroyd *et al.*, 1996).

Another method widely used to systematically explore the effects of temporal and spectral degradations on perception of speech is the noiseband vocoder (Shannon *et al.*, 1995; Xu *et al.*, 2005). In vocoder processing, speech signal is filtered into a number of spectral bands and narrow bands of noise are modulated with the envelopes extracted from individual bands. The final product is a synthesis of modulated noise bands. The processed speech has only crude spectral and temporal elements of the input speech. Cochlear implants (CIs) similarly deliver mainly speech envelope information, by modulating the current that stimulates the auditory nerve, and the gross spectral information, by stimulating distinct tonotopic places along the cochlea. Due to the similarity in the processing, despite the unknown percept of electrical stimulation, the noiseband vocoder has also been used to simulate CI processing with NH listeners.

Using a noiseband vocoder, spectral resolution of speech stimulus can be manipulated by changing the number of spectral channels. When vocoder speech was presented to NH subjects, performance increased as a function of the number of spectral channels. When CI users were tested under similar conditions, however, their performance usually saturated by 4–8 electrodes, and did not improve as more electrodes were activated (Fishman *et al.*, 1997; Friesen *et al.*, 2001; Garnham *et al.*, 2002). This finding suggests that, similar to HI listeners, implant users also have reduced frequency selectivity; they were unable to make use of the fine spectral resolution provided by the larger number of electrodes. However, unlike HI listeners, the main limiting factor for frequency resolution by implant users is believed to be channel interactions, caused by the summation of electric current fields or stimulation of the same nerve population by electrical pulses sent from different electrodes (Shannon, 1983).

Turner *et al.* (1995, 1999) used vocoder processing to explore the effects of reduced temporal or spectral resolution due to hearing impairment on perception of consonants in quiet. In the earlier study (Turner *et al.*, 1995), when a single-channel noiseband vocoder was used to eliminate all spectral cues, HI and NH listeners performed similarly. It was concluded that HI listeners were able to receive temporal information similar to NH listeners. In the second study, Turner *et al.* (1999) varied the number of channels from one to eight. The hypothesis was if the reduced frequency resolution of HI listeners was a limiting factor, the HI performance would reach an asymptote at a smaller number of channels compared to NH listeners, as it was the case with CI users. Performance by both subject groups continued to increase as a function of the number of spectral channels. However, except for the one-channel condition, performance by HI listeners was lower than NH listeners. Turner *et al.* concluded that even though HI listeners were able to make use of the temporal cues with one-channel processing, they were unable to combine the information from multiple channels as efficiently as NH listeners.

In the present study, it is hypothesized that the limitation can be observed if the experimental conditions of Turner *et al.* (1999) were expanded. There are several factors that might have prevented Turner *et al.* (1999) from fully observing the limiting effects of reduced spectral resolution on the speech recognition performance of HI listeners. The present study was designed by improving several factors: (1) In the Turner *et al.* (1999) study, the number of channels was increased only up to eight channels. Friesen *et al.* (2001) observed most difference in the performance by NH and CI subjects for number of channels higher than seven. For smaller number of channels, performance by implant users was lower than the performance by NH listeners, except for the single-channel condition, similar to findings by Turner *et al.* (1999). In the present study, the number of channels was varied from 2 to 40. (2) Previous studies showed strongest effects of reduced frequency selectivity due to hearing impairment on the perception of speech in noise (Festen and Plomp, 1983; Horst, 1987; Leek and Summers, 1996). Therefore, background noise of varying levels was added to the experimental conditions. (3) Perception of vowels has generally been observed to be more sensitive to spectral manipulations than consonants (Boothroyd *et al.*, 1996; ter Keurs *et al.* 1992; Turner and Henn, 1989). Therefore, the effects of changing the number of spectral channels could be stronger with vowel perception. In the present study, vowels were used as stimuli as well as consonants. (4) As mentioned above, audibility is one of the main factors affecting speech perception performance by HI listeners (i.e., Plomp, 1978). If it is not carefully controlled for, it might be difficult to separate the effects of suprathreshold deficits from the effects of audibility. Turner *et al.* (1999) maximized the audibility for HI listeners and used high presentation levels with NH listeners. In the present study, the audibility was similarly maximized for HI listeners. The presentation levels for NH listeners, however, were set at different levels to identify possible audibility effects. (5) It is also important to select the appropriate level of hearing loss. In the study by Turner *et al.* (1999), the baseline consonant recognition scores with unprocessed stimuli were considerably low with two out of six HI subjects. One of the two subjects with low scores had a severe hearing loss at high frequencies. Therefore, this subject probably did not have access to spectral information higher than 2 kHz, a region important for perception of consonants. In the present study, the inclusion criteria comprised having relatively flat hearing loss, from 50 to 60 dB HL, for frequencies up to 6 kHz. OHC damage was further confirmed by otoacoustic emission (OAE) measurements. To reduce possible audibility effects at higher frequencies, vocoder processing was limited to frequencies lower than 6 kHz.

The second purpose of the present study was to compare the results with HI listeners to the results with CI users (Friesen *et al.*, 2001).

HI listeners have inherently reduced frequency selectivity in the auditory system while the frequency selectivity of

TABLE I. Information about the HI subjects.

Subject	Age	Cause of the hearing loss	Age at diagnosis of the hearing loss (years)	Hearing aid user	Hearing thresholds (dB HL) of the test ear at the audiometric frequencies (Hz)					
					250	500	1000	2000	4000	6000
S1	34	German Measles	Shortly after birth	N	55	60	55	60	60	70
S2	62	Presbycusis	54	Y	40	50	60	50	50	65

S4	63	Presbycusis	58	Y	45	55	55	50	55	65

CI users is thought to be mainly limited by channel interactions of the device processing. Therefore, many researchers proposed ways to minimize channel interactions in order to increase the effective number of spectral channels. For example, the "Continuous Interleaved Sampling" strategy, which delivers current pulses interleaved in time, was developed after strong channel interactions were observed with simultaneous activation of multiple electrodes (Wilson et al., 1991). Electrode designs were improved to minimize current spread (e.g., Gstoettner et al., 2001). Also different modes of stimulation, such as bipolar (BP) or tripolar (TP), have been suggested as an alternative to monopolar (MP) mode (i.e., Bierer and Middlebrooks, 2002). Many improvements in signal processing, hardware design, or stimulation methods have been shown to result in more localized stimulation patterns in physiological or psychophysical experiments. However, a beneficial effect of reduced channel interactions on the perception of speech has not been clearly demonstrated.

Studies on channel interactions may produce different results depending on the experimental design. In animal experiments, for example, the current level is usually set at a fixed dB level above threshold for all conditions. Stimuli are not loudness-balanced as this would require extensive training, and the dynamic range cannot be measured as the animals are incapable of reporting the maximum acceptable loudness levels. In BP and TP modes, the return electrodes are closer to the active electrode. Therefore, at the same current level, MP configuration would produce a wider stimulation pattern than the BP and TP configurations (Bierer and Middlebrooks, 2002). A higher degree of channel interaction was also observed with the MP configuration (Bierer and Middlebrooks, 2004). With human subjects, on the other hand, the stimuli can be loudness-balanced and the dynamic range can be measured. Usually, a small current is sufficient to produce the same loudness in MP mode as the BP or TP modes, as a larger population of nerves is stimulated in the MP mode due to the far positioning of the return electrode. When Kwon and van den Honert (2006) normalized the data using loudness-balancing and dynamic range measurements, the channel interaction patterns were similar for MP and BP modes. This observation might provide an explanation for why different stimulation modes do not always produce different speech recognition performance (i.e., Pfingst et al., 1997; 2001).

The results with other measures of channel interactions have been mixed as well. Cazals et al. (1990) have not found a correlation between forward-masking patterns and speech

recognition performance by CI users. Chatterjee and Shannon (1998) observed that one subject with the lowest sentence recognition scores had masking patterns with greatest dependence on masker level and on probe delay. Throckmorton and Collins (1999) measured channel interactions using electrode discrimination and forward masking and measured speech intelligibility with a number of stimuli of varying complexity. The results from both methods were correlated with some, but not all, measures of speech recognition. Stickney et al. (2006) showed that high levels of electric field interactions were correlated with low speech intelligibility performance for a simultaneous speech processing strategy (Simultaneous Analog Stimulation), but not for a sequential speech processing strategy (Continuous Interleaved Sampling).

The absence of a robust correlation between channel interactions (as measured in psychophysical or physiological studies) and speech recognition may imply that there might be other factors limiting the frequency selectivity, presumably originating in the auditory system, in addition to channel interactions caused by implant processing. In the present study, subjects with moderate SNHL also served as a model for an auditory system with inherently reduced frequency selectivity. It was explored if reduced frequency resolution in the auditory system could affect the performance in a manner similar to reduced frequency resolution observed with CI users.

II. METHODS

A. Subjects

Four HI subjects, aged 34–63 years (with an average of 52.75 years), participated in the study. All HI subjects were reported to have hearing loss of cochlear origin by their clinicians. All subjects other than S1 had symmetrical hearing loss. In the nontest ear, S1 had a mild hearing loss for low- to mid-frequencies, and a moderate hearing loss for higher frequencies; audiometric thresholds were rising from 35 to 25 dB HL for frequencies less than 1 kHz, sloping down from 25 to 55 dB HL for frequencies up to 4 kHz, and flat at 55 dB HL at higher frequencies. Detailed information about the HI subjects can be found in Table I.

Each subject was tested on one ear only. Test ears met the following criteria: (1) Relatively flat audiogram: A prescription method would have allowed customized amplification; however, it would also alter the spectral shape of speech. To prevent such additional factors that might affect

the results, HI subjects with relatively flat audiogram were selected and the speech was made audible at all frequencies by changing the overall presentation level only.

(2) Pure tone thresholds around 50–60 dB HL for the audiometric frequencies of 250 Hz to 6 kHz: Moore (1996) suggested that for hearing loss up to 45 dB HL audibility is the most important factor for perception of speech; for higher degrees of hearing loss, effects of suprathreshold deficits can also be observed (Carney and Nelson, 1983). van Tasell (1993) suggested that a hearing loss less than 60 dB HL is generally associated with OHC loss. For these reasons, HI subjects were selected from a population of patients with hearing loss varying between 50–60 dB HL. These levels were optimal for the present study; the potential audibility effects could be minimized by proper amplification, and the suprathreshold deficits, presumably due to OHC loss, could still be observed.

(3) Nonfunctioning outer hair cells: One of the main assumptions in the present study is that the cochlear damage is primarily in the OHCs. OAEs are generally associated with the active mechanism in the cochlea and thought to represent the OHC function (Norton, 1992). Therefore, damage in OHCs was confirmed with (the absence of) OAEs.

(4) No dead regions: If there is additional damage in the inner hair cell or auditory nerve, the speech intelligibility performance would further be affected, and in possibly different ways depending on the pathology. To rule out dead regions, the Threshold Equalizing Noise (TEN) test (Moore *et al.*, 2000) was used. There was no elevation in the masked pure-tone thresholds with the TEN test for three subjects. The test was not applicable for subject S1 as the subject found the masking noise levels of the test uncomfortably high.

As a control group, five NH subjects, aged 27–35 years (with an average of 29.00 years), were tested with the same experimental conditions. NH subjects had thresholds better than 20 dB HL at audiometric frequencies from 250 Hz to 8 kHz. The right ear was chosen as the test ear for all NH subjects.

All subjects were native speakers of American English. The average pure tone thresholds of the test ears for both subject groups are shown in Fig. 1.

B. Stimuli

The speech recognition task was identification of medial vowels and consonants. Vowel stimuli (Hillenbrand *et al.*, 1995) consisted of twelve medial vowels presented in an /h/-vowel-/d/ context (heed, hid, head, had, hod, hawed, hood, who'd, hud, heard, hayed, hoed). The phonemes were spoken by 3 female and 3 male talkers and a total of 72 tokens were presented for each condition. Chance level on this test was 8.33% correct. Consonant stimuli (Shannon *et al.*, 1999) consisted of 20 medial consonants (/b tʃ d ð f g ʒ k l m n p r s ʃ t v w j z/), presented in an /a/-consonant-/a/ context. The phonemes were spoken by 2 female and 2 male talkers and a total of 80 tokens were presented for each condition. Chance level for this test was 5% correct.

For all stimuli, percent correct scores (PCS) were corrected for chance using the equation
FIG. 1. Average pure tone hearing thresholds of the subjects, shown in dB HL. The open symbols show the thresholds of NH listeners for the audiometric frequencies from 250 Hz to 8 kHz, and the filled symbols show the thresholds of the HI listeners for the audiometric frequencies from 250 Hz to 6 kHz. Error bars show one standard deviation.

$$PCS_{corrected\ for\ chance} = (PCS_{raw}\text{-Chance level})/$$
$$(100\text{-Chance level}) \times 100.$$

In the corrected scores, a performance at 0% represents a performance at chance level.

In all experiments, a broadband noise with speech-shaped spectrum (SSN) was used. SSN was generated by filtering white noise using a Butterworth lowpass filter with a rollover of −12 dB\octave and a cutoff frequency of 800 Hz. The same SSN was also presented to the contralateral ear at a level 25 dB lower than the stimulus presentation level, to mask possible acoustic leakage to the nontest ear. The main motivation was to prevent one subject (S1) with asymmetrical hearing loss from listening with the better ear.

A Bruel and Kjaer artificial ear was used for calibration of the experimental setup. A reference tone signal at 1 kHz was generated with a total rms value of 65 dBA at the headphone output. The reference tone was used in setting the presentation level of stimuli to correct dBA values. The setting of the Crown Amplifier was fixed for the maximum presentation level of 95 dBA and a Tucker-Davis attenuator was used to produce the desired presentation levels. For the conditions with background noise, the speech and noise levels were proportionally adjusted to have the appropriate SNR, by using total rms values. The level of the combined signal was set to the presentation level. As a result, speech level decreased slightly as the SNR decreased.

C. Experimental procedure

The stimuli were processed with the noiseband vocoder (Shannon *et al.*, 1995) in real-time and presented using the CAST software created by Qian-Jie Fu at the House Ear Institute.

The overall frequency range of speech was limited to 200–6000 Hz. First, the stimulus was processed into a number of spectral channels using a set of Butterworth bandpass

filters with a rollover of −24 dB\octave. The cutoff frequencies were determined by logarithmically dividing the input spectral range of 200–6000 Hz. The envelopes were extracted using half-wave rectification followed by a Butterworth lowpass filter with a cutoff frequency of 160 Hz and a rollover of −24 dB\octave. These bands were the analysis bands of the vocoder. The carrier noise bands were obtained by filtering wideband noise with the same set of bandpass filters. The envelopes from the analysis bands were used to modulate the carrier noise bands. In the last stage, modulated noise bands were combined to produce the processed stimulus, which at this point had only the coarse spectral and temporal information of the original stimulus and most fine structure was absent.

Phoneme recognition by NH and HI listeners was measured with unprocessed original stimuli and as a function of the number of spectral bands (2, 4, 6, 8, 10, 12, 16, 24, and 40 channels) of the vocoder, at varying background noise levels (quiet, SNR=10 dB, SNR=0 dB for vowels and consonants, and SNR=−5 dB for vowels only). The presentation level for the HI group was chosen to provide maximum audibility and comfort. NH listeners were tested at three presentation levels (experiments 1–3). The selection of the presentation levels is explained in detail in next section.

In experiment 4, an attempt was made to simulate the broad AFs with NH subjects. Dreschler and Plomp (1980) suggested two possible types of deterioration in the AF shape in SNHL: (1) critical bandwidth is broader; (2) slopes of the tuning curves are shallower. In experiment 2, the second type of deterioration was simulated by changing the filter slopes of the vocoder bandpass filters from −24 dB\octave to −6 dB\octave, while the cutoff frequencies remained the same. Shallower filter skirts resulted in considerable overlap between adjacent bands and produced spectrally smeared stimuli.

The speech stimuli were presented monaurally over Sennheiser HDA 200 headphones in a double-wall soundproof booth. A menu with the list of all possible phonemes was shown on the screen during testing. The subject identified the phoneme that was presented by selecting the appropriate entry in the menu using the mouse. The presentation order of individual tokens in each condition and the testing order of different conditions were randomized to minimize learning effects. As an additional caution, HI subjects were given one practice session of 2 h with similar testing procedure, where feedback was also provided, prior to actual data collection. NH subjects were familiar with noiseband vocoder technique from previous studies and therefore were not given a practice session. All subjects were allowed a preview of the stimuli at the beginning of each test.

NH subjects were tested once with each condition. Most HI subjects were tested more than once depending on subject's availability. Subjects S1 and S4 were tested twice for each condition. Subject S2 was tested three times with consonants for the noise conditions of 10 dB and 0 dB SNR, and three times with vowels for the noise conditions of 0 dB and −5 dB SNR.
FIG. 2. Performance intensity (PI) functions. The average percent correct scores are plotted as a function of the stimulus presentation level. Open and filled symbols show the PI functions for NH and HI subjects, respectively. The stimuli were vowels and consonants, as shown in the left and right panels, respectively. The error bars show one standard deviation.

III. AUDIBILITY AND PRESENTATION LEVELS

The comfortable level for conversational speech is around 60–70 dB SPL. However, if speech was presented at an overall presentation level of 65 dB SPL in the present study, HI listeners would have insufficient audibility due to their elevated hearing thresholds. The presentation level for HI users, therefore, had to be set at higher levels to maximize audibility. On the other hand, the highest level could not exceed 100 dB SPL or so, as the stimuli would become uncomfortably loud due to loudness recruitment. For a fair comparison, the comfortable level of 65 dB SPL was not used with NH listeners either. Instead, the presentation levels were selected to be similar, either in sensation or in absolute levels, to the levels used with HI subjects.

The present study controls for the level effects using performance intensity (PI) functions, which were obtained by measuring percent correct scores with the test stimuli as a function of the overall presentation level. This method was preferred over using an amplification based on pure-tone thresholds or Speech Intelligibility Index (SII, ANSI S3.5-1997), as the PI functions provided a functional measure of how well the subjects performed with the specific stimuli used in the present study. The PI functions measured with unprocessed vowels and consonants are shown in the left and right panels, respectively, in Fig. 2. The open and filled symbols show the percent scores, corrected for chance, for NH and HI listeners, respectively.

The figure shows that NH listeners had a wide dynamic range for optimal presentation levels. From 35–40 dBA to 90 dBA, speech intelligibility was best and the loudness was reported to be comfortable. 50% of the peak PI levels (PI-50) was observed around 10–20 dBA. In contrast, speech intelligibility by HI listeners was best for high presentation levels, ranging from 80 to 95 dBA. For higher levels the stimulus was uncomfortably loud. PI-50 was observed for presentation levels around 60–65 dBA. As a result, the optimal listening levels were limited to the range from 80 to 95 dBA for HI subjects, significantly smaller than the range of optimal levels for NH listeners.

Note that even at the loudest presentation levels, the vowel recognition by HI listeners was slightly lower than the

Deniz Başkent: Frequency selectivity in sensorineural hearing loss
FIG. 3. Average vowel recognition scores, corrected for chance, shown as a function of the number of spectral channels. From left to right panel the background noise changes from quiet to SNR=−5 dB. The open and filled symbols show the performance by NH and HI listeners, respectively. The stars under the scores show the significant difference in the performance ($p < 0.05$) by NH and HI listeners based on a posthoc Tukey multiple comparisons test, following a two-way mixed ANOVA. The performance by NH and HI groups for the unprocessed stimuli was compared using a t-test ($p < 0.05$). The arrows above and below the data indicate the number of channels where the performance by NH and HI listeners, respectively, asymptoted.

NH listeners. When the vowel confusion matrices were analyzed, it was observed that all HI subjects and two out of five NH subjects had difficulty distinguishing the phoneme pair of "hod/hawed." Turner and Henn (1989) showed that recognition of vowels by HI listeners could be low if the formants of the vowels are similar. As the vowels used in their study were synthetically produced, the duration, which can be a robust cue for differentiating vowels with similar formants, was the same for all phonemes. For the pair of "hod/hawed," the formants are similar, and the duration cue is also not useful as both phonemes are of long duration. Differentiating these phonemes might have been a more difficult task for HI listeners than the NH listeners. The confusion caused by this one vowel pair could be an explanation for the slight difference observed in the performance by NH and HI listeners.

In the experiments, the presentation level for HI subjects was limited to the range from 85 to 95 dBA where all subjects had the best speech recognition. Subjects were given the flexibility to select the most comfortable level within this range. In general, higher levels were preferred for consonants than vowels. Subject S1, who had the poorest pure tone thresholds among all subjects, preferred louder levels.

NH subjects were tested at three presentation levels selected by comparing the PI functions of the two subject groups:

(A) Experiments 1 and 4: Comparable to HI subjects in sensation level (SL) with respect to PI-50; 35 dBA for vowels and 50 dBA for consonants.

The presentation levels of 85–95 dBA, at which the HI subjects were tested, were 25–30 dB higher than the presentation level at PI-50. For NH subjects, PI-50 was observed around 10 dBA for vowels, and around 20 dBA for consonants. The PI-50 presentation levels were defined as the reference value of 0 dB SL for each subject group. The presentation levels used for NH subjects were, then, made comparable to levels used with HI subjects in SL, by adding 25 dB to 10 dBA for vowels, and by adding 30 dB to 20 dBA for consonants.

(B) Experiment 2: Low level with reduced audibility; 20 dBA for vowels and 30 dBA for consonants.

To see the effects of decreased audibility the presentation levels were set to only 10 dB higher than the levels at PI-50. As a result, the levels were lower by 15–20 dB com-

pared to experiment 1. It can be seen on the PI functions that the performance by NH subjects at these levels is poorer than the best performance (Fig. 2).

(C) Experiment 3: Comparable in absolute level, 85 dBA.

The shapes of AFs are level-dependent. As the level increases the filter shape becomes broader and more asymmetrical with an elevation on the low-frequency side (Glasberg and Moore, 2000). Therefore, even in NH subjects, frequency selectivity might be different at higher stimulus levels. A clear connection between the changes in AF shapes and overall speech perception has not been shown, yet several studies suggested that speech recognition by NH listeners might differ at high presentation levels. Studebaker *et al.* (1999), for example, observed a decrease in the intelligibility of speech in noise as the level increased from 64 to 99 dB SPL. Hornsby *et al.* (2005) observed a decrease in the transmission of consonant features at high levels. To account for potential effects of high presentation levels, NH listeners were tested at an absolute presentation level similar to the levels used with HI subjects.

IV. RESULTS

A. Experiment 1: Effect of the number of spectral channels

In experiment 1, presentation levels were 85–95 dBA for HI listeners. For NH listeners, the levels were set to 35 and 50 dBA, comparable to the levels selected for HI listeners in SL (as defined with respect to PI-50 levels), for vowel and consonant recognition tasks, respectively.

Percent correct scores for vowel recognition, averaged across subjects and corrected for chance, are plotted in Fig. 3, as a function of the number of spectral channels and for varying background noise levels. Performance by NH and HI groups is shown with open and filled symbols, respectively.

Performance by NH and HI listeners was compared using a two-may mixed Analysis of Variance (ANOVA), with the main factors of subject group and number of channels, and the interaction between the two factors. Performance by both groups increased as the number of the channels increased for all background noise conditions ($p < 0.001$). The effect of the number of channels was similarly significant for all experiments reported in the present study, and therefore

TABLE II. F values of the two-way mixed ANOVA, used for comparing the performance by NH and HI subjects in experiments 1–3. The main effect of number of channels, which was significant for all experiments ($p < 0.001$), was not included. The main effect of subject group and the interaction between group and number of channels are shown for recognition of vowels and consonants, presented in varying background noise levels.

	Vowel recognition			Consonant recognition		
	Noise	Group factor $F(1,7)$	Group-channel interaction $F(8,56)$	Noise	Group factor $F(1,7)$	Group-channel interaction $F(8,56)$
Expt 1: Comfortable level	Quiet	3.10	0.37	Quiet	24.88[b]	0.83
	SNR=10 dB	3.94	1.03	SNR=10 dB	18.30[b]	7.73[b]
	SNR=0 dB	16.11[b]	3.15[b]	SNR=0 dB	17.40[b]	8.02[b]
	SNR=−5 dB	22.33[b]	4.13[b]

	SNR=−5 dB	6.73[a]	2.66[a]	SNR=0 dB	55.30[b]	3.13[b]

[a]$p < 0.05$.
[b]$p < 0.01$.

will not be mentioned in reporting the results of the following experiments for simplicity. The F values are shown in Table II for the main factor of subject group and the interaction between group and number of channels. The F values with 'a' and 'b' denote significance at the levels of $p < 0.05$ and $p < 0.01$, respectively.

Following the ANOVA, a posthoc Tukey multiple comparisons test was used to compare all scores in pairs. The Tukey comparisons for the main factor of subject group within the same number of channels were used to identify the specific conditions where the performance by NH and HI listeners differed significantly. The scores with the unprocessed stimuli were not included in the ANOVA, therefore they were compared using a t-test. In Fig. 3, the conditions where the difference in the scores was statistically significant ($p < 0.05$) are shown by the dots under the scores. The Tukey comparisons for the main factor of number of channels within NH or HI subjects were used to identify the number of channels where the performance by that subject group reached the asymptote. For each subject group, the highest percent correct scores were used in the comparisons. The lowest number of channels where the performance did not differ significantly compared to the highest percent correct scores was accepted as the saturation point. In Fig. 3, the number of channels where the performance reached the asymptote is shown by arrows above the data, for NH listeners, and below the data, for HI listeners. Table III summarizes the number of channels at the saturation point for all experiments of the present study.

There was no significant main effect of group on vowel recognition in quiet and at the low noise level of SNR =10 dB. For both NH and HI subjects, performance reached the asymptote around 8 channels (Fig. 3, left panels; Table III). However, performance by NH and HI subjects differed significantly when the background noise level was higher;

there was a significant effect of subject group ($p < 0.01$) and a significant interaction ($p < 0.01$) between group and number of channels, as shown in Table II for SNR=0 dB and SNR=−5 dB. As the noise level increased, NH listeners were able to employ a higher number of spectral channels. NH performance increased up to 12 and 16 channels for SNR=0 dB and SNR=−5 dB, respectively, while performance by HI listeners saturated at 8 channels for all noise conditions (Fig. 3, right panels; Table III).

Figure 4 shows the average percent correct scores for consonant recognition, corrected for chance, as a function of the number of spectral channels and for varying background noise levels.

There was a significant main effect of subject group on

TABLE III. The summary for the number of channels where vowel and consonant recognition by NH and HI subjects saturated.

	Vowels				Consonants		
	Quiet	SNR= 10 dB	SNR= 0 dB	SNR= −5 dB	Quiet	SNR= 10 dB	SNR= 0 dB

Deniz Başkent: Frequency selectivity in sensorineural hearing loss
FIG. 4. Similar to Fig. 3, except for the stimuli were consonants and the background noise increases from quiet to SNR=0 dB, from left to right panels. The open and filled symbols show the scores by NH and HI subjects, respectively. The dots under the scores denote the specific conditions where the performance was significantly different ($p < 0.05$) between NH and HI listeners. The arrows show the number of channels where the performance by a specific subject group reached the asymptote.

consonant recognition in all background noise conditions ($p < 0.01$, as shown in Table II). In quiet, however, the patterns were similar as the interaction between group and channels was not significant, and performance by both groups reached the asymptote around 8 channels (Fig. 4, left panel; Table III). At higher noise levels, on the other hand, the patterns were significantly different; there was a significant interaction of group and channels at SNR=10 dB and SNR =0 dB ($p < 0.01$, as shown in Table II). As the background noise increased from SNR=10 dB to SNR=0 dB, performance by NH subjects increased up to 10 and 12 channels, respectively, while performance by HI listeners saturated by 8 channels for both noise conditions (Fig. 4, right panels; Table III).

Note that, for both vowels and consonants, there was a difference in the performance by NH and HI listeners even in the quiet and unprocessed conditions. The difference in the performance with unprocessed stimuli generally increased as the noise level increased; the drop in the performance by HI listeners was sharper than the drop in the performance by NH listeners as a function of the background noise level. When the noiseband vocoder processing was added, there was generally a further drop from the performance with the unprocessed condition, even at the highest number of channels used in the present experiment. The difference in the performance

between the 40-channel and unprocessed conditions are shown in percent correct scores in Table IV, for both subject groups and for both vowels and consonants. A paired t-test was used to determine statistical significance. The drop in the performance from the unprocessed condition to the 40-channel processing condition also increased with increasing noise, and this effect was generally more pronounced with HI listeners (Table IV).

B. Experiment 2: Effects of audibility

In experiment 2, the effect of reduced audibility on recognition of vocoder speech was explored. The presentation level for NH listeners was reduced by 15–20 dB compared to experiment 1; the vowels were presented at 20 dBA and the consonants were presented at 30 dBA. Only the noise conditions from experiment 1 where the patterns of the performance by two subject groups were significantly different were repeated. The average percent correct scores at the low presentation levels are presented in Fig. 5, superimposed with the scores from experiment 1. Figure 5(A) shows the results for vowel recognition with background noise of SNR=0 dB and SNR=−5 dB in the left and right panels, respectively. Figure 5(B) shows the scores for consonant recognition with SNR=10 dB and SNR=0 dB in the left and right panels, respectively. In each panel, open and filled circles replicate the scores by NH and HI subjects, respectively, from experiment 1. Open triangles show the scores by NH subjects when the stimuli were presented at lower levels.

The performance by NH listeners at the low presentation level and the performance by HI listeners from experiment 1 were compared using a two-way mixed ANOVA, with the main factors of subject group and number of channels, and the interaction between the two factors. The F values are shown in Table II for the main factor of group and the interaction between group and number of channels. A Tukey test was used to compare the scores with the vocoder processed conditions, and a t-test was used to compare the scores with the unprocessed conditions. The dots under the data show the conditions where the performance by NH listeners at the low presentation level and the performance by HI subjects differed significantly ($p < 0.05$). The Tukey test was also used to determine the number of channels where the performance reached the asymptote, as it was shown by arrows above the data, for NH listeners, and below the data, for HI listeners (Fig. 5).

The effect of presentation level on performance by NH listeners was explored by comparing the scores measured at

TABLE IV. The difference in performance between unprocessed and 40-channel processing conditions shown in percent correct score for vowels and consonants and for each subject group.

	Vowels				Consonants		
	Quiet	SNR= 10 dB	SNR= 0 dB	SNR= −5 dB	Quiet	SNR= 10 dB	SNR= 0 dB
NH subjects	4.40%	6.36%[a]	3.94%	14.54%[a]	6.05%[a]	5.79%[a]	11.58%
HI subjects	1.08%	2.65%[b]	15.26%[b]	15.82%	11.99%[b]	16.34%[b]	24.89%[b]

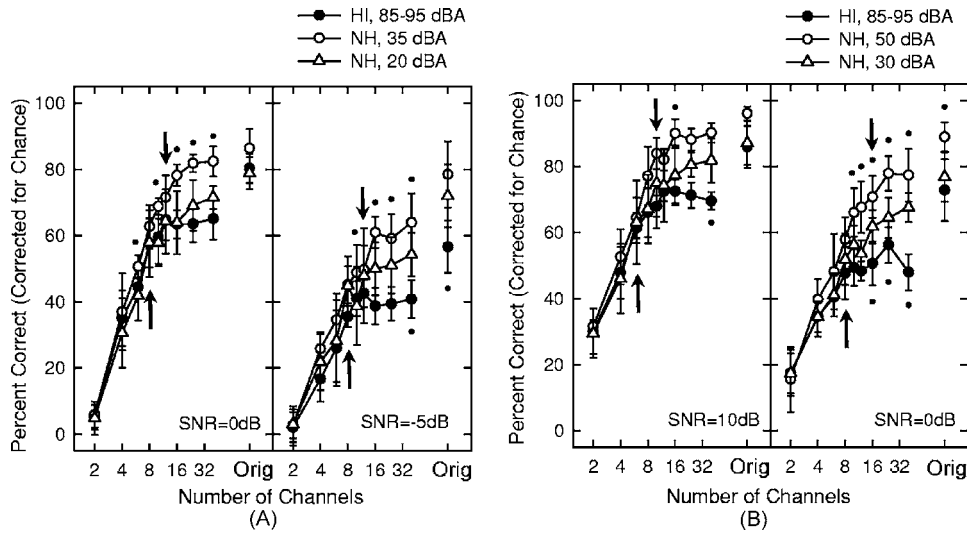
[b]Paired t-test: $p < 0.01$.


FIG. 5. Average phoneme recognition scores by NH listeners from experiment 2, where the presentation level was low, presented with the results from experiment 1, where the presentation level was comfortable. (A) shows the vowel recognition scores by HI listeners (filled circles, replicated from Fig. 3) and by NH listeners with stimuli presented at 35 dBA (open circles, replicated from Fig. 3) and at the low level of 20 dBA (open triangles). Left and right panels show the results with background noise at SNR=0 dB and SNR=−5 dB, respectively. (B) shows the consonant recognition scores by HI listeners (filled circles, replicated from Fig. 4) and by NH listeners when the stimuli were presented at 50 dBA (open circles, replicated from Fig. 4) and at the low level of 30 dBA (open triangles). Left and right panels show the results with background noise at SNR=10 dB and SNR=0 dB, respectively, The small dots above the open circles indicate the conditions where the performance by NH subjects dropped significantly as a result of reduced presentation level, shown with a Tukey test ($p < 0.05$). The small dots under the data indicate the conditions where the performance by NH subjects at the reduced presentation level was significantly different than the performance by HI subjects, shown with a Tukey test ($p < 0.05$). The conditions with unprocessed original stimuli were compared with a t-test ($p < 0.05$). The arrows above and below the data indicate the number of channels where the performance by NH and HI listeners, respectively, asymptoted.

the low presentation level of experiment 2 and the scores measured at the comfortable level of experiment 1. A two-way repeated-measures (RM) ANOVA with the main factors of presentation level and number of channels was used. The corresponding F values are presented for the main factor of presentation level and the interaction between level and number of channels in Table V. The dots above the data show the conditions where the performance by NH listeners at two presentation levels differed significantly, as shown by the Tukey or t-test ($p < 0.05$).

The results, presented in Fig. 5, show that reduced audibility generally produced lower scores than the scores at comfortable level. In unprocessed conditions, performance

by NH listeners at low presentation level was more similar to performance by HI listeners. Even with the highest number of channels, performance with processed stimuli was lower than the unprocessed conditions for both subjects groups; however, the drop in performance with vocoder processing was generally larger for HI listeners.

In the conditions with processed vowels, there was a significant main effect of presentation level on NH performance at SNR=0 dB noise level ($p < 0.05$, Table V). No significant effect of level at SNR=−5 dB, and no significant interaction at both background noise levels were observed. The lower scores by NH listeners, obtained in experiment 2 as a result of the low presentation level of 20 dBA, were not

TABLE V. F values of the two-way RM ANOVA. Performance by NH listeners at low and high presentation levels (experiments 2 and 3, respectively) was compared to performance by NH listeners at comfortable levels (experiment 1). The main effect of the presentation level and the interaction between level and number of channels are shown for recognition of vowels and consonants, presented in varying background noise levels.

	Vowel recognition			Consonant recognition		
	Noise	Level factor $F(1,4)$	Level-channel interaction $F(8,32)$	Noise	Level factor $F(1,4)$	Level-channel interaction $F(8,32)$
Expt 2: Low level for NH listeners	SNR=0 dB	15.53[a]	1.33	SNR=10 dB	2.97	1.50
	SNR=−5 dB	7.30	1.63	SNR=0 dB	10.83[a]	2.59[a]
Exp 3: High level for NH listeners	SNR=0 dB	4.12	1.23	SNR=10 dB	0.66	2.39[a]
	SNR=−5 dB	1.67	1.65	SNR=0 dB	2.77	2.41[a]

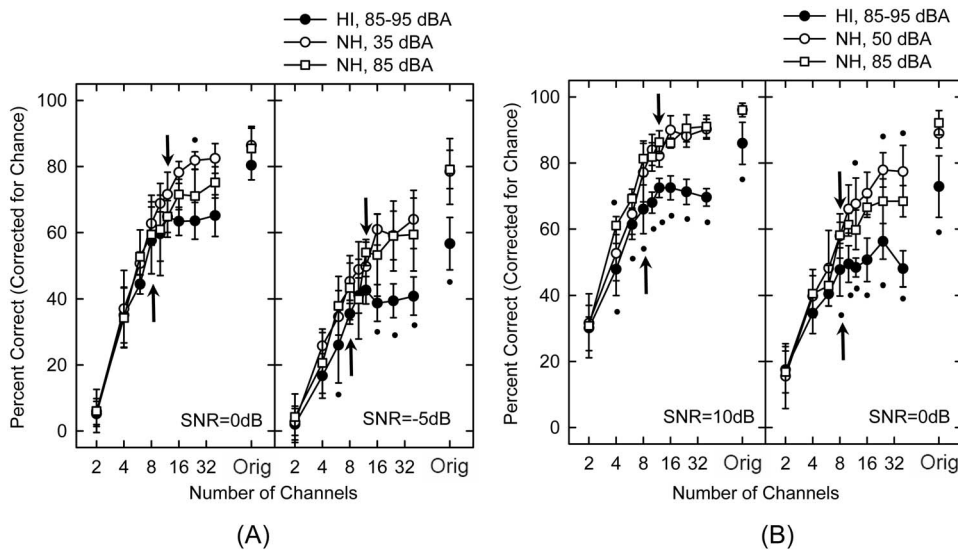
[a]$p < 0.05$.


FIG. 6. Similar to Fig. 5, the filled and open circles show the scores by HI and NH listeners, respectively, replicated from experiment 1. The open squares show the percent correct scores by NH listeners with stimuli presented at the high level of 85 dBA.

significantly different than the scores by HI listeners (Table II). However, performance by NH subjects at this low level increased up to 12 channels; a larger number than 8 channels where performance by HI listeners reached the asymptote [Fig. 5(A); Table III].

In the conditions with processed consonants, the low presentation level did not change the performance by NH listeners at SNR=10 dB significantly; however, it resulted in a significant drop in scores at SNR=0 dB compared to the comfortable level, as shown by the significant main effect of level and the interaction ($p < 0.05$, Table V). Performance by NH listeners at the low level of 30 dBA was similar to performance by HI listeners for the SNR=10 dB noise level; but at SNR=0 dB there was a significant main effect of subject group ($p < 0.05$, Table II). The interaction between group and channels was significantly different at both noise levels ($p < 0.05$ at SNR=10 dB and $p < 0.01$ at SNR=0 dB, Table II), indicating a difference in the trends of the scores by NH and HI listeners. The Tukey test further showed that performance by NH subjects at the low presentation level increased up to 10 and 16 channels for the background noise conditions of SNR=10 dB and SNR=0 dB, respectively, while performance of HI subjects reached the asymptote at 8 channels [Fig. 5(B); Table III].

C. Experiment 3: Effects of high presentation level

In experiment 3, NH subjects were tested at a high presentation level of 85 dBA, comparable to the high presentation levels of 85–95 dBA used with HI listeners. The average percent correct scores at high levels, corrected for chance, are shown in Fig. 6 presented with scores from experiment 1. The open squares show the scores by NH listeners at the high presentation level of 85 dBA. The open circles show the scores by NH listeners from experiment 1, where vowels and consonants were presented at the comfortable levels of 35 and 50 dBA, respectively. The filled circles show the scores by HI listeners from experiment 1. The vowel recognition scores at SNR=0 dB and SNR=−5 dB are presented in the left and right panels, respectively, of Fig. 6(A). The consonant recognition scores at SNR=10 dB and SNR=0 dB are

presented in the left and right panels, respectively, of Fig. 6(B). The dots under the data show the conditions where the performance differed between NH and HI listeners, when both subject groups were tested at high presentation levels. The dots above the data show the conditions where the performance by NH listeners at comfortable and high presentation levels was different. The arrows below and above the data show the number of channels where the performance by HI and NH listeners at high levels, respectively, saturated.

In the unprocessed conditions, the scores by NH listeners did not change when the presentation level was increased from the comfortable levels of 35 and 50 dBA to the loud level of 85 dBA.

In the conditions with processed vowels, increasing the presentation level did not change the scores by NH listeners significantly; at both background noise conditions there was no significant main effect of level and no significant interaction (Table V). When performance at high presentation level was compared to performance by HI listeners, there was also no significant main effect of group and no interaction of group and channels at SNR=0 dB; however, performance by NH listeners saturated around 12 channels while performance by HI listeners saturated around 8 [Fig. 6(A), left panel; Table III]. There was a significant main effect of group and significant interaction at SNR=−5 dB ($p < 0.05$, Table II). The number of channels at saturation point was 12 for NH listeners, and 8 for HI listeners [Fig. 6(A), right panel; Table III].

In the conditions with processed consonants, increasing the presentation level did not change the consonant recognition scores by NH listeners significantly; however, there was significant interaction between level and number of channels in both background noise levels ($p < 0.05$, Table V). The scores by NH and HI listeners tested at similar absolute levels were significantly different in both background noise levels; there was a significant main effect of group and significant interaction ($p < 0.01$, Table II). At SNR=10 dB, performance by NH listeners asymptoted at 12 channels while performance by HI listeners asymptoted at 8 channels

Arrows below the data show the number of channels at the asymptote for HI listeners.

[Fig. 6(B), left panel; Table III]. At SNR=0 dB, performance by both subject groups asymptoted at 8 channels [Fig. 6(B), right panel; Table III].

D. Analysis of consonant features

The ratio of spectral to temporal information required for the perception of the consonant features increases from voicing to manner to place of articulation (van Tasell *et al.*, 1992; Turner *et al.*, 1995). ter Keurs *et al.* (1992) and Boo-

throyd *et al.* (1996), for example, showed that spectral smearing affected the perception of the place feature most. To observe the effect of vocoder processing on perception of these features, consonant confusion matrices of experiments 1–3 were analyzed for the production based categories of voicing, manner, and place of articulation (Miller and Nicely, 1955).

The information transmission percent correct scores are presented for the noise conditions of SNR=10 dB and SNR=0 dB in the top and bottom panels of Fig. 7, respectively. The panels from left to right show the scores for voicing, manner, and place of articulation. Filled circles show the scores by HI subjects. Open symbols show the scores by NH subjects for three presentation levels; open circles for 50 dBA, open triangles for 30 dBA, and open squares for 85 dBA. The standard deviations were omitted for clarity.

The F values of the two-way mixed ANOVA that was used to compare the perception of features by NH and HI listeners are presented in Table VI. The F values of the two-way RM ANOVA that was used to compare the perception of features by NH listeners at different presentation levels are presented in Table VII. The number of channels where the performance reached the asymptote was determined by the Tukey test. These values are summarized in Table VIII, and are also shown in Fig. 7 by the arrows above and below the data for NH and HI listeners, respectively.

The left panels of Fig. 7 show that the voicing transmission patterns by NH listeners were similar at all presentation levels (Table VII) and performance by NH listeners was generally better than HI listeners (Table VI). The two-way mixed ANOVA showed that the interaction between group and channels was significantly different only in experiment 1 where the presentation level was set to the comfortable level of 50 dBA for NH listeners. The Tukey test confirmed this finding; performance by NH listeners reached the asymptote at 10 channels while performance by HI listeners reached the asymptote at 4 channels (Table VIII), in both background noise levels. In experiments 2 and 3, where the presentation levels for NH listeners were low (30 dBA) and high (85 dBA), respectively, both subject groups had the

asymptotic performance at 4 channels at SNR=10 dB noise level. At the higher noise level of SNR=0 dB, performance by NH subjects continued to increase up to 8–10 channels (Table VIII).

The middle panels of Fig. 7 show that the transmission of manner feature by NH listeners was similar at the levels of 50 and 85 dBA (Table VII), and at both levels NH listeners performed significantly better than HI listeners (Table VI). However, when the presentation level was reduced to 30 dBA, the performance dropped; the perception of manner by NH subjects at the low level of 30 dBA was similar to perception of manner by HI listeners (Table VI). The two-way mixed ANOVA showed a significant interaction of hearing loss and channels in experiment 1 for SNR=0 dB and experiment 3 for SNR=10 dB. However, the overall results of the Tukey test showed that the number of channels at performance saturation was similar (8 or 10) for both subject groups and in all experiments (Table VIII).

The right panels of Fig. 7 show that the transmission of place by NH listeners was similar at all presentation levels for SNR=10 dB. At SNR=0 dB, performance at the comfortable level of 50 dBA was significantly better than performance at the lower and higher presentation levels of 30 and 85 dBA (Table VII). There was also significant interaction between level and channels when the performance by NH listeners was compared at 50 and 85 dBA (Table VII). Performance by NH subjects was generally better than the HI

subjects, and there was a significant interaction between group and channels in most settings (Table VI). At SNR =10 dB, the number of channels where the performance saturated was slightly higher for NH listeners (10–12) compared to HI listeners (8; as shown in Table VIII). At SNR =0 dB, perception of place cue by HI listeners increased up to 6 channels. Place perception by NH listeners, on the other hand, increased up to 16 channels at the presentation levels of 30 and 50 dBA, and up to 8 channels at the presentation level of 85 dBA (Table VIII).

E. Experiment 4: Simulation of broad auditory filters

In experiment 4, the broad AFs were simulated with NH subjects by changing the filter slopes of the vocoder filters from a rollover of −24 dB\octave to a rollover of −6 dB\octave. In the first part, only the carrier filters were changed while the same analysis bands were used; this setup can be interpreted as a simulation of an input signal with good spectral resolution while the receiving component of the transmission system has reduced spectral resolution. In the second part, both carrier and analysis filters were made wider. This setup can be interpreted as a simulation of a transmission system with overall reduced spectral resolution.

The average vowel and consonant recognition scores, corrected for chance, are shown in Figs. 8(A) and 8(B), respectively, as a function of the number of spectral channels.

The filled and open circles show the scores by HI and NH listeners, respectively, replicated from experiment 1. (A) and (B) show the vowel recognition scores with a background noise of SNR=0 dB and the consonant recognition scores with a background noise of SNR=10 dB, respectively. The open diamonds and the open triangles show the scores by NH listeners when the carrier filter slope was made shallower and when both the carrier and analysis filter slopes were made shallower, respectively. The arrows above the data show the number of channels where the performance by NH listeners reached the asymptote. The arrows below the data show the same for HI listeners.

The open and filled circles replicate the scores of HI and NH subjects, respectively, from experiment 1. The open diamonds show the average scores by NH subjects where only the carrier filter slopes were made shallower. The open triangles show the performance where both carrier and analysis filter slopes were made shallower. Vowels were presented in the background noise of SNR=0 dB, and consonants were presented in the background noise of SNR=10 dB. The presentation levels of the phonemes were the same comfortable level as in experiment 1; 35 dBA for vowels, and 50 dBA for consonants.

A two-way mixed ANOVA was used to compare the results by NH listeners tested with wide vocoder filters and the results by HI listeners. A two-way RM ANOVA was used

to compare the results by NH listeners with narrow and wide filters. The corresponding F values are presented in Table IX. The number of channels at the saturation point is shown in Table III, and is denoted by arrows above and below the data for NH and HI listeners, respectively, in Fig. 8.

When only the carrier filters were made wider, the performance by NH listeners did not change significantly (as shown by the open diamonds in Fig. 8 and also in the lower portion of Table IX). The number of channels where the performance saturated, however, increased from 10–12 to 16 (Table III). A stronger effect was observed when carrier and analysis filters were manipulated together (as shown by open triangles in Fig. 8). The scores by NH listeners dropped significantly and there was a significant interaction between fil-

ter bandwidth and channels (as shown in the lower portion of Table IX). The number of channels where the performance saturated increased from 10–12 to 24 (Table III).

Despite the substantial changes observed in the performance by NH listeners, either method failed to reproduce the trends seen in data by HI listeners. There was an overall reduction in the scores and the difference between the scores by NH and HI listeners was smaller as a result of these manipulations. However, the interaction between group and channels was generally significant (Table IX), indicating that the trends in the data by the two subject groups were different. The number of channels at the saturation point was higher with NH listeners than with HI listeners; 16 or 24 compared to 8 channels (Table III).

V. DISCUSSION

Turner *et al.* (1999) measured consonant recognition in quiet by NH and HI listeners as a function of the number of vocoder channels. The number of the channels varied from one to eight and the performance by HI listeners was poorer than NH listeners for all conditions, except for the single-channel processing. Yet, the performance by both subject groups increased as a function of the number of channels, contrary to the expectation that the performance by HI listeners would saturate at a smaller number of channels due to the limiting effect of reduced spectral resolution.

Friesen *et al.* (2001), however, observed a limiting effect of reduced spectral resolution on the perception of speech by CI users. When recognition of phonemes and sentences, processed with a noiseband vocoder, was measured with NH listeners as a function of the number of spectral channels, the performance increased up to 20 channels. Under similar listening conditions, the performance by CI users saturated around seven electrodes.

In the present study, it was hypothesized that a similar limiting effect of reduced spectral resolution might also be observed with HI listeners if the conditions from Turner *et al.* (1999) study were extended to a greater number of channels. Vowels were included in the stimuli as they were hypothesized to be more sensitive to spectral manipulations. The number of channels varied from 2 to 40, an upper limit selected on purpose higher than eight channels where the saturation in performance was observed with best CI users. Similar to the Friesen *et al.* (2001) study, background noise was added, as many studies showed that speech recognition by HI listeners in noise might be correlated with spectral resolution. Additionally, strict inclusion criteria were followed in the recruitment of the HI subjects and audibility was controlled by testing NH listeners at varying presentation levels.

In experiment 1, phoneme recognition was measured at similar sensation levels, determined from performance intensity functions by taking PI-50 levels as the reference for each subject group. Vowel recognition by NH and HI listeners, measured as a function of the number of vocoder channels, were similar in quiet and at the low background noise level of SNR=10 dB; the performance by both subject groups increased up to 8 channels before reaching plateau. Results

with consonant recognition in quiet were consistent with results by Turner *et al.* (1999); HI listeners generally had lower scores compared to NH listeners, but the trend in the performance was similar.

The limiting effects of reduced spectral resolution, similar to that reported by Friesen *et al.* (2001) with CI subjects, were observed with HI subjects only when the background noise level was increased. In all noise conditions, the performance by HI listeners saturated by 8 channels. Performance by NH listeners, on the other hand, increased up to 12 and 16 channels with vowel recognition at the noise levels of SNR =0 dB and SNR=−5 dB, respectively, and up to 10 and 12 channels with consonant recognition at SNR=10 dB and SNR=0 dB, respectively. This finding implies that while NH listeners could utilize a higher number of channels in challenging listening situations, such as when background noise was added, HI listeners did not show such ability.

The confusion matrices, obtained with consonants in background noise, were further analyzed for the transmission of the production based categories of voicing, manner, and place of articulation. Perception of the place feature is generally most sensitive to spectral degradations; therefore the effects were expected to be seen mainly with place. Consistent with this expectation, perception of place differed for NH and HI listeners; performance by HI listeners saturated by 6–8 channels while performance by NH listeners saturated by 10–16 channels. On the other hand, because perception of voicing and manner rely heavily on the temporal cues, the difference in the performance by NH and HI listeners was expected to be smaller with these features. Perception of manner was similar by the two subject groups. However, contrary to expectations, perception of voicing differed for NH and HI listeners; the number of channels at the saturation point was higher with NH listeners than with HI listeners when measured at similar SL (10 vs 4 channels).

A. Presentation levels

Audibility has a significant effect on speech recognition by HI listeners. It might become an even more important factor for challenging listening conditions such as perception of speech degraded by vocoder processing and presented in background noise. In experiment 2, audibility was reduced by testing NH subjects at quiet levels. When the levels were lowered by 15–20 dB compared to experiment 1, the percent correct scores by NH subjects dropped and the reduced performance was more comparable to the performance by HI subjects, for both processed and unprocessed conditions. Hence, audibility had a significant effect on speech recognition by NH subjects as well. However, even at these reduced performance levels, the trends in the performance by the two subject groups still differed. Performance by NH subjects increased up to 12 channels with vowels and up to 10–16 channels with consonants while performance by HI subjects saturated at 8 channels. This observation shows that the inability of the HI subjects to utilize more than eight spectral channels was probably not due to insufficient audibility.

Testing NH subjects at a relatively low presentation level, as it was done in experiment 1, is a reasonable attempt

to equalize the listening conditions for both subject groups in loudness, audibility, and comfort. However, by doing so, some potentially detrimental factors due to high presentation levels, such as broadening of AFs (Glasberg and Moore, 2000) or reduced speech recognition in noise (Studebaker *et al.*, 1999), might be overlooked.

To explore the effects of high presentation levels, NH subjects were tested at an absolute presentation level comparable to the presentation level used with the HI group (experiment 3). NH performance did not change significantly compared to experiment 1, for both processed and unprocessed conditions. The performance by NH subjects at the high presentation level was still significantly different when compared to HI listeners; the performance increased up to 12 channels with vowels and 8–12 channels with consonants. Therefore, it is unlikely that the effects observed in the study were due to distortions caused by high presentation levels. However, it is an interesting finding that no effect of AF widening, presumably due to high presentation levels, was observed on performance by NH listeners.

Note that in the present study the audiometric thresholds and the performance intensity functions were measured in quiet, and the presentation levels were adjusted based on these measurements. It is possible that the detection thresholds by HI listeners are considerably higher in noise, yet the present study did not control for this factor.

B. Spectral resolution

The noiseband vocoder was used to systematically degrade the speech stimulus. When background noise was added to the processing, it was observed that HI listeners were not able to use as many vocoder channels as NH listeners for the perception of phonemes. It was hypothesized that this effect was mostly due to reduced frequency resolution of hearing impairment. The inclusion criteria for HI subjects had been determined such that the probability of reduced spectral resolution was maximized; the subjects were selected from a group of patients with flat SNHL ranging from 50 to 60 dB HL, with no OAE and no apparent dead regions.

In most conditions with background noise, the number of channels where the performance by NH listeners saturated was 1.5–2 times larger than the number of channels where the performance by HI listeners saturated. With the assumption that the difference was mostly due to reduced spectral resolution of hearing impairment, this finding implies that the effective average spectral resolution by HI subjects was 1.5–2 times poorer compared to NH subjects in the noisy listening conditions. Even though it is not possible to deduce a conclusion about individual AF shapes for the HI subjects from this observation, it should be noted that this finding is within the ranges of AF broadening observed in SNHL in previous studies. Glasberg and Moore (1986) reported that AFs of impaired ears were broader compared to AFs in normal ears. When expressed in equivalent rectangular bandwidth (ERB), despite the large variation in the data, there were many subjects who showed a broadening in AF bandwidth by a factor of 2. Similarly, Stelmachowicz *et al.* (1985)

observed a reduction in Q10 values or the slopes of the low-frequency (LF) end of the psychophysical tuning curves (PTC), another measure for frequency resolution, by a factor of two for many HI subjects compared to NH subjects. These HI subjects had around 50 dB HL or more at the audiometric frequency of 2000 Hz, which is comparable to the hearing loss of the HI subjects in the present study.

Background noise was a major factor for observing the differences in the performance by NH and HI listeners. (1) The difference in the number of channels at the saturation point was observed only in noise. (2) There was a sharper drop in the performance by HI listeners in the unprocessed conditions as the noise level increased. (3) The additional drop in the performance from unprocessed to 40-channel processing condition was generally larger with HI listeners when there was background noise. These findings are consistent with earlier observations that speech perception by HI listeners in quiet is mainly determined by audibility (Festen and Plomp, 1983) while speech perception in noise is more sensitive to suprathreshold deficits (Noordhoek *et al.*, 2000), such as the reduced spectral resolution (Horst, 1987; van Schijndel *et al.*, 2001). In the present study, the difference between NH and HI listeners might have been small in quiet conditions because the audibility was maximized for HI listeners, and the effects of reduced spectral resolution might have showed in noise. One possible explanation for the reduced performance by HI listeners in noise was made by Leek and Summers (1996) who observed that HI listeners with broader AFs needed higher spectral contrast for recognition of speech in noise compared to NH listeners; they suggested that the wide AFs resulted in an internal representation with poorer SNR. The findings of the present study are consistent with this hypothesis; vowel recognition scores by HI listeners at SNR=10 dB, for example, were similar to scores by NH listeners at a higher noise level of SNR =0 dB.

In Experiment 4, the slopes of the vocoder bandpass filters were made shallower in an attempt to simulate broad AFs with NH listeners. Two simulation methods were used: (1) only the carrier filters were made wider, or (2) both the carrier and analysis filters were made wider. The first simulation method did not change the performance significantly. With the second method, the overall performance by NH subjects dropped and the scores were more comparable to the scores by HI listeners. However, the trends by the two subject groups were still different; the scores by NH listeners continued to increase to higher number of channels than HI listeners. Hence, the second simulation method also failed to reproduce the trend of the HI performance.

Fu and Nogaki (2005) used a similar spectral smearing method to simulate the reduced frequency selectivity of CI users with NH subjects. They were able to reproduce the performance by CI users in gated background noise, measured in Speech Reception Threshold (SRT), with NH listeners. However, they measured the SRT only with 4, 8, and 16 channel vocoders, as the main parameter of interest was the frequency of the gated noise. In the present study, the main interest was the change in overall performance as a function of the number of spectral channels, which varied over a

wider range of values (2–40) in steady background noise. Similar to Fu and Nogaki (2005), the performance by NH subjects dropped significantly with spectral smearing at 4, 8, and 16 channel conditions. However, when the performance by NH and HI listeners was compared over the entire range of the number of channels used, the trends were significantly different.

The failure to replicate the early saturating characteristic of the HI performance might indicate that the spectral sharpening mechanism of the healthy cochlea is highly effective, to the degree that NH listeners can make use of even minimal spectral contrast of heavily smeared speech stimulus. Baer and Moore (1993), for example, had to simulate AFs six times wider (in ERB) than normal to observe a degradation in speech recognition by NH listeners. A second possibility is that the method used in the present study to simulate broad AFs, where the same cutoff frequencies were used for the filters and only the filter slopes were made shallower, was not entirely adequate. As alternative methods, filter bandwidth could be increased to simulate broad critical bandwidth, as it was suggested by Dreschler and Plomp (1980), or asymmetrical filter shapes could be implemented, to simulate the irregular AF shapes observed with some HI listeners (Sommers and Humes, 1993).

C. Age effects

Some results of the present study were not entirely consistent with the assumption that the effects observed with the vocoder processing and in background noise were due to reduced spectral resolution of hearing impairment. For example, making the vocoder filter skirts shallower failed to replicate the performance by HI listeners with NH listeners, as it was discussed in the previous section. Also, when NH listeners were tested at a high level of 85 dBA, where AFs would presumably be wider (Glasberg and Moore, 2000), the saturation point of the NH performance did not move to a lower number of channels. Moore and Glasberg (2000) observed that the AF shape became asymmetrical with an elevation on the low-frequency side only. It is possible that the AF widening in NH listeners at high levels is to a smaller degree than the AF widening due to cochlear damage (Carney and Nelson, 1983). However, it is also possible that there were additional factors that affected the performance by HI listeners.

Previous research has shown that frequency resolution is generally related to the degree of hearing loss and is independent of age (Peters and Moore, 1992). A correlation with age is usually seen with temporal resolution; older listeners, for example, perform poorly in gap detection task (Snell, 1997; Strouse et al., 1998). This deficit due to aging is thought to be a possible factor for the difficulties that elderly people have in understanding speech in noise (Dubno et al., 1984; Snell and Frisina, 2000). In the present study, HI listeners were older than the NH listeners on average. This might have resulted in potentially different temporal processing abilities between the two subject groups and might have additionally affected the results.

Souza and Boike (2006) repeated the study by Turner et al. (1999) with HI subjects of varying age. The performance by older subjects was generally lower compared to younger subjects for all vocoder processing conditions. However, the trend in data was similar; recognition of consonants increased up to 8 channels by all subjects. When the consonant features were analyzed for voicing, manner and place, the only feature that was correlated with age was voicing; older subjects had similar perception of manner and place as younger subjects, but the perception of voicing was poorer by the older subjects.

In the present study, the place cue was expected to be affected most by the spectral degradations. However, in addition to place cue, the transmission of voicing was also affected. The similarity of this finding to observations by Souza and Boike (2006) implies that the HI subjects of the present study might have had deficits in both temporal and spectral processing mechanisms, and the effects of these deficits might have been observed in the perception of different features.

An interesting extension to the present study would be to acquire individual measures from subjects for spectral and temporal resolution, and to correlate these measures with performance by a specific subject. Such a study would provide a more definitive answer to the question if the effects observed in the present study were mainly due to reduced spectral resolution as it was hypothesized.

D. Comparison with implant users

Friesen et al. (2001) observed that performance by CI users saturated at a smaller number of channels compared to NH listeners. To explore how the results with implant users compare to results with HI listeners, vowel recognition scores were reproduced from Friesen et al. (2001) and superimposed with scores from the present study, for corresponding noise conditions. In Fig. 9, the open and filled circles show the vowel recognition scores from experiment 1 for NH and HI listeners, respectively. The hatched area shows the range of scores, with upper and lower borders defined by best and worst performance by CI users, respectively. The solid line shows the average performance by Nucleus-22 implant users. The scores were measured using the same vowel stimuli in both studies, and the scores with implant users were also corrected for chance level for consistency.

The combined results in Fig. 9 show that at SNR =0 dB, the performance by CI and HI listeners similarly saturated at smaller number of channels (i.e., 7 and 8, respectively) compared to NH listeners (12 channels). The average CI performance was considerably lower than average NH and HI performance, but the best CI performance was similar to the average HI performance. These observations are consistent with results reported by Henry et al. (2005) that showed that the frequency resolution with HI listeners was poorer than NH listeners and better than CI listeners, and only the best implant users performed at levels similar to HI listeners.

The poor peformance by implant users, compared to NH and HI listeners, show that there are probably many factors that affect speech recognition by CI users. After all, electric
FIG. 9. Average vowel recognition scores by NH and HI listeners presented with average scores by CI users replicated from the study by Friesen *et al.* (2001). From left to right panels the background noise increases. The open and filled symbols show the performance by NH and HI listeners, respectively. The solid line shows the average scores by Nucleus-22 implant users. The hatched area shows the range of the scores by CI subjects.

hearing works on an entirely different mechanism than the acoustic hearing. On the other hand, there was at least one setting (SNR=0 dB) of the present study that produced similar trend in performance by HI and CI listeners. This similarity can be interpreted that an auditory system with inherently reduced frequency resolution, either due to a loss in the peripheral nonlinear mechanism or maybe even due to deficits in the central auditory system, might have a limiting effect on performance similar to CI users whose performance is believed to be limited mainly due to channel interactions. On a more speculative note, one can hypothesize that there might be such factors in addition to channel interactions that are further degrading the CI performance. However, the results of the current study did not completely support this hypothesis as the effects with HI listeners were seen only in noise and there were indications that the performance by HI listeners might have been additionally affected by factors such as reduced temporal resolution, which is usually not observed with implant users.

Auditory measures of selective and divided attention in young and older adults using single-talker competition

Larry E. Humes, Jae Hee Lee, and Maureen P. Coughlin
Department of Speech and Hearing Sciences, Indiana University, Bloomington, Indiana 47405-7002

In this study, two experiments were conducted on auditory selective and divided attention in which the listening task involved the identification of words in sentences spoken by one talker while a second talker produced a very similar competing sentence. Ten young normal-hearing (YNH) and 13 elderly hearing-impaired (EHI) listeners participated in each experiment. The type of attention cue used was the main difference between experiments. Across both experiments, several consistent trends were observed. First, in eight of the nine divided-attention tasks across both experiments, the EHI subjects performed significantly worse than the YNH subjects. By comparison, significant differences in performance between age groups were only observed on three of the nine selective-attention tasks. Finally, there were consistent individual differences in performance across both experiments. Correlational analyses performed on the data from the 13 older adults suggested that the individual differences in performance were associated with individual differences in memory (digit span). Among the elderly, differences in age or differences in hearing loss did not contribute to the individual differences observed in either experiment. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354070]

I. INTRODUCTION

A common complaint of older adults is that they can hear speech, but cannot understand it. This is especially true when listening to speech in a background of noise or while other people are talking. A working group of the Committee on Hearing and Bioacoustics and Biomechanics (CHABA) of the National Research Council, reviewing the work on the speech communication problems of older adults available through the early 1980s, offered several hypotheses regarding the causes of such communication problems (CHABA, 1988). Briefly, these hypotheses were (1) the peripheral auditory hypothesis, which suggested that the difficulties were primarily attributable to the sensorineural hearing loss and cochlear pathology that is common among older adults; (2) the central-auditory hypothesis, which posited age-related, modality-specific, changes in the auditory portions of the central nervous system from the lower brainstem through auditory centers of the cortex; and (3) the cognitive hypothesis, which suggested age-related decline in general cognitive functions, such as memory, attention, and speed of processing. The working group also recognized that it was possible to have various combinations of these factors at work in a given individual.

In the years since this CHABA working group report, our laboratory, among others, has demonstrated repeatedly that hearing loss, or audible bandwidth, represents the primary (but not sole) factor underlying the problems experienced by older adults when listening to speech in quiet or in noise (van Rooij, Plomp and Orlebeke, 1989; Jerger, Jerger, and Pirozzolo, 1989; van Rooij and Plomp, 1990, 1992; Helfer and Wilber, 1990; Humes and Roberts, 1990; Humes and Christopherson, 1991; Lee and Humes, 1993; Humes *et al.*, 1994; Souza and Turner, 1994; Humes, 1996; Divenyi

and Haupt, 1997a, 1997b; Humes, 2002). Most recently, we found this to be true even for time-compressed speech presented at high sound levels designed to reduce, but not eliminate, the negative impact of high-frequency sensorineural hearing loss (Humes, 2005).

For most older adults with speech-communication problems, the best way to address these problems is through amplification, such as that provided by personal hearing aids. Hearing aids fit to older individuals following typical clinical procedures, however, do not always guarantee the full audibility of speech to the wearer (Humes, 1991; Humes and Halling, 1993). In that regard, it is not surprising that other studies, including another study from our laboratory, examining *aided* speech communication in quiet and noise in older adults and using hearing aids fit under typical clinical procedures, still found that audibility of the speech stimuli played a primary role in determining individual differences in performance (Humes, 2002; Walden and Walden, 2004).

In more recent work in our laboratory with older adults, we have used laboratory-based approaches to amplification to assure suitable audibility of the speech stimuli through at least 4000 Hz. The first such study in this series (Coughlin, 2004) examined the speech-identification differences between young normal-hearing adults and older hearing-impaired listeners when the Coordinate Response Measure (CRM; Bolia *et al.*, 2000) was used as both the target and competing speech, with separate talkers used for each. The CRM is a sentence-length test that requires the listener to identify the last two words of the sentence from a closed set of alternatives (one of four colors followed by one of eight numbers; e.g., "red 4", "blue 2"). When audibility through 4000 Hz was assured, hearing loss no longer explained individual differences in speech-identification performance among the 19 older adults in that experiment. Yet, when the

performance of young adults was compared to older adults, the latter still needed about a 6-dB better target-to-competition ratio than the young adults to achieve the same levels of performance under otherwise equivalent conditions. Thus, it would appear that, when audibility has been eliminated as a factor, other factors may emerge that impact differences in performance between younger and older adults or among older adults.

In keeping with the conceptual framework laid out by the CHABA working group (CHABA, 1988), other possibilities could include age-related modality-specific changes in central-auditory processing or amodal cognitive processing. In the CRM speech-identification task used by Coughlin (2004), two similar sentences were presented simultaneously to the same ear and the target message was identified by a name (or "call sign") at the beginning of the target sentence. Thus, the listeners needed to attend to the target sentence associated with a particular call-sign ("Baron") and ignore a very similar competing message spoken by a different talker and using a different call sign (e.g., "Charlie," "Laker," etc.). As a result, the task required the listener to selectively attend to the target sentence identified by the target call sign. Consequently, it is possible that age-related differences in selective attention could have contributed to the older adults' need for a better target-to-competition ratio than required by the young adults. Age-related differences in selective attention have been observed previously [see reviews by McDowd and Shaw (2000) and Rogers (2000)], although, for at least some measures of selective attention, these age effects have been attributed to memory deficits or age-related mental slowing (Verhaeghen and De Meersman, 1998a, 1998b) rather than attention deficits *per se*.

In the present study we sought to examine age-related differences in auditory measures of attention using the same CRM single-talker-competition paradigm used by Coughlin (2004). Auditory measures of both selective and divided attention were included in this study to provide a broader picture of possible age-related changes in attention. Age-related deficits in divided attention have also been reported previously (see the review by McDowd and Shaw, 2000), although general age-related mental slowing may again play a role in such deficits (Verhaeghen *et al.*, 2003).

Another issue examined in this study had to do with the relative strength of various auditory cues in selective and divided attention. In particular, does it matter whether the cue for the auditory measures of attention is one based on localization/lateralization (ear), lexical information (call sign), or acoustical/indexical information in the speech stimulus (talker gender)? In Experiment 1, monaural and dichotic presentation conditions were used to measure auditory selective and divided attention with the cues being either ear or call sign. The match between the gender of the target and competing talkers was also manipulated as a repeated-measures independent variable in this experiment. In general, for young normal-hearing listeners, the CRM speech-identification task is easier when the gender of the target and competing talker differ, presumably due to better segregation of the two auditory objects (Brungart, 2001; Coughlin, 2004). It was hypothesized that those cues associated with

physical aspects of the perceived auditory object, such as its location (ear) or fundamental frequency (gender), will prove stronger than the arbitrary lexical labels (call signs) attached to those objects.

In experiment 2, the effect of talker uncertainty on measures of attention was also examined, with the range of conditions varying from the same male and female talkers for a given block of trials to the specific talker randomly selected from a set of four for each gender from trial to trial. Brungart and Simpson (2004) have previously reported little effect of talker uncertainty on the CRM task for young adults, whether the testing was conducted monauralally or dichotically. In other contexts, however, older adults have been found to show larger decrements in performance with increasing talker uncertainty (Sommers, 1997). In addition, Coughlin (2004) demonstrated the effects of talker uncertainty with the CRM test in both young normal-hearing and elderly hearing-impaired adults. As a result, the effects of talker uncertainty were examined further in experiment 2.

Finally, as noted, one of the important procedural aspects of the earlier study by Coughlin (2004) was the use of spectrally shaped speech materials for the older adults with hearing loss. In particular, in that study spectral shaping was applied to ensure audibility of the CRM speech materials through 4000 Hz. By doing so, there was no significant correlation between performance on the CRM and high-frequency hearing thresholds. Steps were taken in this study as well to ensure sufficient audibility of the CRM speech stimulus through at least 4000 Hz for all listeners. Details are provided in the next section.

II. METHODS

A. Participants

Two groups of listeners differing in age and hearing loss were tested: (1) elderly hearing impaired (EHI) and (2) young normal hearing (YNH). There were 10 YNH participants, 5 males and 5 females, for experiment 1 and 2 with 7 of the 10 who participated in experiment 1 also participating in experiment 2. The mean age for the YNH participants in experiment 1 was 25.4 years and ranged from 21 to 34 years whereas the mean age was 25.9 years and ranged from 22 to 34 years for those in experiment 2. All YNH subjects passed a pure-tone air-conduction screening at 20 dB HL (ANSI, 1996) from 250 through 8000 Hz in octave intervals, passed the Mini-Mental Status Exam (a MMSE score of at least 27 of 30; Folstein, Folstein, and McHugh, 1975), and had forward digit spans of at least 5 (i.e., could recall sequences of at least 5 digits) and backward digit spans of at least 4.

There were 13 EHI participants, 9 male and 4 female, and the same 13 completed both experiments in this study. These individuals ranged in age from 61 to 81 years with a mean age of 76.2 years. The EHI listeners had varying degrees of sensorineural hearing loss, as illustrated in Fig. 1. Three EHI listeners had interaural asymmetries in pure-tone thresholds exceeding 15 dB for at least one frequency, but all such asymmetries were at frequencies of 4000 Hz or higher.
FIG. 1. Air-conduction hearing thresholds for the left (top) and right (bottom) ears of each of the 13 elderly hearing-impaired (EHI) listeners in this study. The same line types are used to represent the audiograms of each subject in each panel. The filled circles depict the mean hearing thresholds for each ear.

All 13 participants passed the MMSE (a score of at least 27) and had forward digit spans of at least 5 and backward digit spans of at least 4.

All EHI subjects were community dwelling at the time of testing. They were paid $10/hour for their participation. The YNH participants were recruited from the general Indiana University (IU) campus community via flyers and the undergraduate and graduate divisions of the IU Department of Speech and Hearing Sciences via e-mail. They were paid $7/h for their participation.

B. Stimuli and apparatus

The Coordinate Response Measure corpus (CRM; Bolia *et al.*, 2000) was chosen as a sentence-level speech test for this project. The structure of each sentence is identical, with

each sentence using the form "Ready (call sign), go to (color) (number) now." By instructing the listener to attend only to the designated call sign while ignoring competing sentences, it is possible to investigate the effectiveness of masking or interference from competing speech signals. The corpus consists of every combination of the eight call signs (arrow, baron, charlie, eagle, hopper, laker, ringo, tiger), four colors (blue, green, red, white) and eight numbers (1–8), resulting in 256 phrases for each talker. Four male and four female talkers yield a total of 2,048 phrases or sentences. Brungart (2001) reported that two talkers, one of each gender, yield scores when used as a target or competing talker that differ somewhat from the remaining talkers. Therefore, in experiment 1, only six talkers (three males and three females) were used. In experiment 2, in which talker uncertainty was manipulated, it was decided that all eight talkers should be used to expand the amount of talker uncertainty available.

Using CoolEdit Pro 2000 (Syntrillium, version 1.2a), the CRM sentences were converted from binary files (*.bin) to wave files (*.wav) and from stereo to mono recordings for use in a custom MATLAB (Mathworks, version 6.5) program. The MATLAB program was designed to present two stimuli simultaneously through Tucker Davis Technologies (TDT) System-III equipment. The sampling rate was 48 828 Hz. The stimuli were either added digitally and routed through one channel of a 16-bit digital-to-analog converter (DA1) for monaural presentation or presented separately through channel 1 (target) and 2 (competition) of the DA1 for dichotic presentation. The stimuli were then sent to a headphone buffer (TDT HB7) and finally output via matched insert earphones (E-A-R, ER-3A).

1. Calibration

The CRM corpus was designed so that each sentence was equated for the total rms power. For a calibration of the unshaped CRM used with the YNH listeners, a 30 s calibration noise and calibration tone (1000 Hz) were created and equated using Cool Edit Pro 2000. The calibration tone was matched to the peak levels for the speech materials and was used to determine the maximum possible presentation level without peak clipping. Once this maximum output setting was established, the calibration noise was used to measure the maximum levels in one-third octave bands from 125 through 8000 Hz.

The calibration noise was matched in spectrum and average rms amplitude to the long-term spectrum and average rms amplitude of the CRM materials. To determine the long-term average speech spectrum values of the CRM stimuli, the target CRM sentences used in this study were digitized using Cool Edit Pro 2000 and concatenated to create one large file of all eight talkers. The average amplitude spectrum of the concatenated wave file was then measured and the calibration noise was shaped digitally using a 1/3-octave-band graphic equalizer within Cool Edit Pro 2000 until the shaped noise was within 3 dB of the long-term-average speech spectrum for the CRM materials from 100 through 7500 Hz. This calibration stimulus was then presented through the TDT hardware and insert earphones
FIG. 2. The relative long-term average rms amplitude spectrum (50 ms window) for all CRM sentences using one of the eight call signs ("Hopper") before spectral shaping (dotted line) and after spectral shaping (solid line). This figure illustrates the amount of spectral shaping applied to all CRM materials for the 13 EHI listeners.

coupled to an HA-2 2 cm³ coupler (ANSI, 1996). Overall (linear) and one-third-octave band sound pressure levels were measured using a Larson Davis model 800B sound level meter (with a Larson Davis model 2575 1 in. microphone) and recorded. An overall sound pressure level of 87 dB SPL for the unshaped CRM stimuli was used with all YNH listeners.

Next, given the presence of varying degrees of sloping, high-frequency sensorineural hearing loss in all the older listeners (see Fig. 1), the CRM materials underwent spectral shaping to increase the amplitude at 125, 250, 500, 1000, 2000, 4000, and 6000 Hz by 2, 2, 2, 5.5, 10.5, 11.5, and 20 dB, respectively. This effectively flattened the one-third-octave-band spectrum acoustically at 100 dB SPL (±2 dB) from 200 through 4000 Hz in the HA-2 2 cm³ coupler. A comparison of the amplitude spectra for the shaped and unshaped stimuli is provided in Fig. 2 for a sample of CRM sentences (those making use of the call sign, "Hopper"). The digital wave files for the spectrally shaped CRM sentences were examined to find the peak amplitude following shaping, which turned out to be the color "red" spoken by one of the talkers. This segment of the waveform was excised, copied, and concatenated to produce a long calibration file that was used to set the peak amplitude of the playback system to avoid peak clipping. The same spectral shaping was then applied to the calibration noise and the overall sound pressure level and 1/3-octave-band levels in the HA-2 2 cm³ coupler were measured for this calibration noise using a Larson Davis model 800B sound level meter (with a Larson Davis model 2575 1 in. microphone) and recorded. The maximum sound pressure level, with no attenuation in the system and without peak clipping, was 114 dB SPL. With full attenuation at the headphone buffer, the presentation level was 87 dB SPL. The 1/3-octave-band level at a center frequency of 4000 Hz (73 dB SPL) was then noted for this default presentation level. As long as the listener's pure-tone hearing threshold at 4000 Hz in the right ear, expressed in dB SPL *re*: 2 cm³ coupler, was at least 15 dB lower (⩽58 dB SPL) than 1/3-octave-band level of the CRM calibration

noise at a center frequency of 4000 Hz, then the default overall presentation level of 87 dB SPL was used. This ensured that the rms spectrum of the speech stimulus would be at least 15 dB above the hearing threshold through 4000 Hz. The assumption here is that hearing threshold for pure tones and 1/3-octave-band noises are equivalent in hearing-impaired listeners (Cox and McDaniel, 1986). If the listener's hearing threshold at 4000 Hz was such that the 1/3-octave-band level of the CRM stimuli at that same frequency was not at least 15 dB above threshold, then the attenuation of the headphone buffer was decreased in 3-dB steps until this goal was achieved. Given the headphone-buffer step size of 3 dB, this means that the speech energy at 4000 Hz was 15–17 dB above threshold at that frequency. Given the speech spectra (Fig. 2) and the patterns of hearing loss (Fig. 1), this also ensured that the long-term-average rms speech spectrum was at least 15 dB above threshold at lower frequencies as well. All of the YNH subjects and 5 of the 13 EHI subjects were tested at the default level of 87 dB SPL, although, as noted, the YNH listeners did not listen to the spectrally shaped CRM materials. For the remaining 8 EHI listeners, 2 were tested at 90 dB SPL, 5 at 99 dB SPL, and 1 at 105 dB SPL. For all conditions in this study, the target and competing sentences were presented at the same sound pressure level for a 0 dB target-to-competition ratio (TCR).

C. General procedures

After administering the initial MMSE and digit-span measures, similar procedures were followed in experiments 1 and 2. The procedural details in common to both experiments are reviewed here.

The subject was seated in a single-walled sound booth in front of a computer monitor and was given written instructions for the CRM test. CRM test presentation was designed so that participants would hear 32 presentations of competing sentence pairs per test block. Thirty-two presentations per test block allowed for representation of each color and number combination as the target without repetition. The participants first received one 32-sentence block as practice in each cue condition. The participants listened to a total of 4 blocks of 32 sentence pairs, or 128 sentence pairs per condition. The listener indicated the color and number coordinates of the target sentence by selecting one of four rectangular buttons arranged in a column on the left side of the computer screen, labeled by both the color name and the color itself (i.e., a red rectangle with a text label of "red"), and then selecting a number from a column of numbers listing 1 through 8 on the right side of the computer screen. Most subjects in both groups used a computer mouse to make their color-number selections, but if any subjects, particularly among the EHI group, had difficulty with the use of the computer mouse, a touch-screen monitor was used instead. Trial-to-trial feedback was not provided.

In both experiments, a large-font (40-point, Times New Roman) orthographic cue (call sign, right/left, or male/female), which signaled the target sentence for that particular block of trials, was presented three times in the upper left portion of the computer screen. To minimize confusion with

other colors displayed simultaneously on the screen, the cue was displayed in a purple font, centered within a white rectangular box measuring 1.5 cm vertically and 4.5 cm horizontally. The duration of the orthographic cue was 0.8 second, with an interval of 0.2 second between each presentation. Thus, the orthographic cueing of the target sentence required a total duration of 3 s. For measures of selective attention, on each trial in a block, the 3 s cue interval ended immediately before the presentation of a sentence pair. For selective attention, the listener could respond by selecting the target color-number coordinates immediately after the presentation of the sentence pair had been completed. For divided attention, the 3 s cue interval was initiated immediately following the presentation of the sentence pair and responses were not possible until the end of the cue interval. Because of the different memory constraints imposed on the measures of selective and divided attention in this study, these two measures are considered to be separate dependent variables in subsequent analyses (rather than two values of a single independent variable, attention type).

When the cue was ear (experiment 1), the words "Right" or "Left" were used as the orthographic cue. When the cue was call sign (experiment 1), the cue was one of the eight possible call signs for the CRM (e.g., "Charlie"). When the cue was talker gender (experiment 2), the words "Male" or "Female" were used as the orthographic cue. In each block of 32 trials for a given cue condition, each possible cue value occurred an equal number of times and the order was randomized. For example, when the call sign was the cue, in a given block of 32 trials, each of the 8 possible call signs appeared as a target four times, in random order, and competing call sign values were also equally distributed in random order (with the exception that the same call sign could not be used for both target and competing sentences on a given trial).

The EHI listeners also received a control condition in which two blocks of 32 trials of the CRM were presented to each ear without a competing stimulus. This was used to verify that these listeners could, in fact, identify the color-number coordinates with a high degree of accuracy given the spectral shaping provided.

The CRM testing was self-paced with the inter-trial interval controlled by the subject. The elderly subjects showed some variability in the time required to complete the testing. In general, with each session requiring 90–120 min to complete, older listeners required more sessions (6–8) than the younger listeners (5) to complete all testing. Additional experiment-specific procedural details are provided below.

III. EXPERIMENT 1

A. Experiment-specific procedures

There were a total of six conditions examined in this experiment for selective attention and six for divided attention. For both selective and divided attention, two of six conditions made use of dichotic stimulus presentation and the ear cue, two used dichotic presentation and the call-sign cue, and two used monaural presentation and the call-sign cue. An additional independent variable examined in experiment 1 was the agreement between talker genders for the target and competing speech stimuli. Target and competing talkers were either the same or different gender for a given block of trials. When the talkers were the same gender, each was chosen randomly without replacement from among a pool of 3 talkers on each trial. When the talkers were of opposite gender, each was chosen randomly from a pool of 3 talkers for each gender on each trial. For target and competing talkers of either the same or different gender, random selection was constrained so that male and female talkers were each used as the target talker half the time. For all dichotic stimulus presentation conditions, half the trials in a block presented the target stimulus to the right ear and half to the left ear in random order. For monaural presentation, the right ear was always the stimulus ear. As noted previously, three of the elderly subjects had an interaural asymmetry of pure-tone thresholds exceeding 15 dB, but these were all confined to frequencies of 4000 Hz or higher, and the right ear (test ear) always had the better hearing thresholds.

The six conditions for each type of attention measure in this experiment represent an unbalanced research design because it is not possible to use the ear cue in monaural listening. As a result, there are two overlapping sets of 2×2 factorial repeated-measures combinations represented in the six conditions. When the dichotic ear-cue conditions are compared to the dichotic call-sign-cue conditions, the 2×2 factorial design represents all combinations of type of cue (ear or call sign) and gender match between the target and competing talkers (same or different) for both selective and divided attention. When the results for the dichotic and monaural call-sign cue conditions are analyzed, then the two repeated-measures independent variables are gender match and presentation mode (monaural or dichotic) for measures of both selective and divided attention. The subject group was the only between-subject independent variable and there were two values for this variable (young normal hearing, elderly hearing impaired).

B. Results and discussion

For the control conditions, in which two blocks of 32 trials of a single talker, *without a competing talker*, were presented to each ear, all scores for each ear and each of the 13 older adults exceeded 96% and 21 of the 26 scores were 100%. Thus, with the spectral shaping used in this study, none of the EHI listeners had any difficulty identifying the correct color-number coordinates when the spectrally shaped target stimulus was presented without a competing sentence.

The individual percent-correct scores for all subjects were transformed into rationalized arcsine units (RAU; Studebaker, 1985) to stabilize the error variance. Means and standard errors for both groups of listeners and all six test conditions are shown in Fig. 3 for the measures of selective attention (top panel) and divided attention (bottom panel). As noted previously, given the unbalanced design across the six conditions in this experiment, the six conditions were divided into two overlapping sets of four conditions each, for statistical analysis. For both selective attention and divided attention, one set of four conditions included those for which

effects of cue type $[F(1,21)=67.7]$ and gender match $[F(1,21)=26.5)$ were observed such that scores were generally higher in dichotic listening for the ear cue than for the call-sign cue and for different talker genders rather than same talker genders. In addition, the main effect of the subject group was not significant $[F(1,21)=2.8]$. There was, however, a significant interaction between gender match and group $[F(1,21)=9.1]$. An inspection of the data in the left and center portions of the top panel reveals that the older subjects show a greater increase in performance than the younger subjects when gender match changes from the same to different.

In the corresponding GLM analysis involving divided attention and dichotic listening conditions (left and center portions of lower panel in Fig. 3), significant main effects of cue type $[F(1,21)=110.5]$ and subject group $[F(1,21)=20.8]$ were observed, but the effect of gender match was not significant $[F(1,21)=0.9]$. Two interactions, however, were found to be significant as well, both involving the subject group. Specifically, subject group interacted significantly with cue type $[F(1,21)=11.0]$ and gender match $[F(1,21)=5.6]$. Regarding the interaction of group and cue type, the ear cue yielded higher scores than the call-sign cue, but the difference was larger for the young, normal-hearing listeners. With regard to the interaction of group with gender match, there appears to be a slight effect of gender match for the older subjects only, such that performance was higher when the gender of the target and competing talkers differed.

In summary, for both young and older adults and selective and divided attention, the ear cue yielded higher performance in dichotic listening than the call-sign cue. In addition, for both selective and divided attention, the gender match between target and competing talkers was a significant factor in dichotic listening for the older adults such that scores were higher in these subjects when the two talkers differed in gender. It is interesting that gender match of the two talkers had a significant effect for the EHI listeners, even when the two talkers were delivered to opposite ears. This clearly cannot be an issue related to increased "energetic" masking in the EHI group, as there is no physical or peripheral interaction among the target and competing stimuli when delivered to opposite ears.

To examine group differences for each of the four dichotic conditions, a series of independent-group t tests were performed. Here, given four comparisons, the criterion p value of 0.05 was divided by 4 and $p < 0.0125$ was established as the criterion for significance (i.e., p was adjusted for multiple comparisons). Using this significance criterion, none of the group comparisons were significant for selective attention, but three of the four group comparisons were significant for divided attention. These significant group differences have been marked in the left and center panels of Fig. 3 with asterisks.

2. Effects of mode of presentation, gender match, and group

A parallel set of analyses were performed for the four conditions in the center and right portions of Fig. 3 for both selective attention (top panel) and divided attention (bottom

FIG. 3. Means and standard errors (error bars) of the transformed percent-correct scores for the CRM for each of the 12 listening conditions in experiment 1 and both groups of subjects (grey bars: YNH; black bars: EHI). Asterisks mark significant ($p<0.01$) differences between the two groups.

dichotic stimulus presentation was employed (left and center portions of each panel in Fig. 3), whereas the other set of four conditions included those for which the call sign was the cue (center and right portions of each panel in Fig. 3). A total of four mixed-model General Linear Model (GLM) analyses were conducted using a 2×2 factorial design for the repeated-measures variables and a between-subject factor of group (YNH or EHI). In the first two analyses, the repeated-measures variables were cue type (ear versus call sign) and gender match (same versus different), with separate analyses performed on the measures of selective and divided attention. In the next two analyses, the repeated-measures variables were presentation mode (monaural versus dichotic) and gender match (same versus different), with separate analyses again performed for measures of selective and divided attention.

1. Effects of cue type, gender match, and group

For the first GLM analysis involving selective attention in dichotic listening conditions, significant ($p<0.01$) main

panel). In this case, significant main effects were observed for each of the three independent variables [presentation mode: $F(1,21)=422.5$; gender match of talkers: $F(1,21)=190.4$; and group: $F(1,21)=7.6$], but one two-way and one three-way interaction involving various combinations of these variables were also significant. Specifically, the interaction between the presentation mode and gender match [$F(1,21)=75.7$] and the three-way interaction of presentation mode, gender match, and group [$F(1,21)=11.1$] were significant. Overall, from an inspection of Fig. 3, these results indicate that there was a significant effect of gender match in both presentation modes, but it was larger for monaural presentations and the younger listeners. Clearly, this complex pattern of significant findings is driven by the extremely low performance of both subject groups for the monaural presentation mode when the target and competing talkers were the same gender. Finally, the asterisk in the right portion of the top panel of Fig. 3 indicates that the older adults performed more poorly than the young adults in this condition (independent-sample t test with p values adjusted for multiple comparisons, as previously).

For divided attention (the center and right portions of the bottom panel of Fig. 3), parallel GLM analyses revealed identical statistical findings as those reported for selective attention. Specifically, significant main effects were observed for each of the three independent variables [presentation mode: $F(1,21)=106.0$; gender match of talkers: $F(1,21)=43.3$; and group: $F(1,21)=16.0$], but one two-way and one three-way interaction involving various combinations of these variables were also significant. The interaction between presentation mode and gender match [$F(1,21)=50.9$] and the three-way interaction of the presentation mode, gender match, and group [$F(1,21)=12.8$] were significant. As before, from an inspection of the bottom panel of Fig. 3, these results indicate that there was a significant effect of gender match in both presentation modes, but it was larger for monaural presentations and the younger listeners. Once again, this complex pattern of significant findings appears to be driven by the low performance of both subject groups for the monaural presentation mode when the target and competing talkers are the same gender. This clearly was the most challenging listening situation for both groups of listeners and for both the selective- and divided-attention tasks. Finally, the asterisks in the center and right portions of the bottom panel of Fig. 3 indicate that the older adults performed more poorly than the young adults for three of the four divided-attention conditions (independent-sample t tests with p values adjusted for multiple comparisons).

In Fig. 3, note that the data for the monaural, call-sign cue, same-gender listening condition revealed the lowest performance for both groups and both types of attention. In this listening condition, it is most difficult to segregate the target and competing stimuli and both groups perform poorly when it is difficult to perform this segregation. When segregation of the target and competing stimuli has been facilitated through differences in talker gender (monaural presentation, call-sign cue, different gender) or laterality/location (dichotic presentation, call-sign cue, same gender), the relative improvements in performance are more sizable for the young

adults than for the older adults. Thus, the younger adults appear to benefit more than the older adults, on average, from the segregation of the target and competing messages.

3. Correlations and individual differences

Correlational analyses of the individual data for all 23 subjects were performed for the six selective-attention measures and the six divided attention measures. Correlations were computed for each group separately as well, but the patterns of correlations were very similar for each group and for both groups combined so only the latter are summarized here. For the 6 measures of selective attention there are 15 possible pairwise correlations, and 10 of these were positive, strong ($r>0.75$ in 9 of the 10 cases), and statistically significant ($p<0.01$). All five nonsignificant correlations were between performance measured for the monaural condition using the call-sign cue and the same gender for target and competing talkers and performance measured for the other five conditions. That is, performance in this very difficult condition was not correlated with performance in any of the other conditions. Performance in the other five conditions, however, was strongly correlated such that those who did well in one of those five conditions tended to do well in the others.

For the divided-attention conditions, the pattern of correlations was somewhat similar to that observed for selective attention. The five correlations with performance for the monaural listening, call-sign cue, same-gender condition were once again lower than the rest, but here the correlations were stronger ($0.46<r<0.71$) than observed for selective attention with four of the five being statistically significant. Further, for the remaining ten correlations involving performance measured in the other five conditions, all were significant and the correlations ranged from 0.78 to 0.94. All told, 14 of the 15 correlations for divided attention were significant and 13 of them were at least 0.70.

Six correlations were also calculated between the measures of selective and divided attention; one correlation for each of the six test conditions. These correlations ranged from 0.51 to 0.83 with five of the six being significant ($p<0.01$). Thus, those who did better on the measures of selective attention tended to do better on the measures of divided attention, at least for conditions that were otherwise identical (presentation mode or cue type and gender match).

Correlations were also computed between each of the six measures of selective and divided attention and age, average high-frequency hearing loss (1000, 2000, and 4000 Hz) in both ears, hearing loss asymmetry (the average high-frequency hearing loss in the right ear minus that in the left ear), and average digit-span score (average of forward and backward digit span measures) for the 13 older adults. It should be noted that there were no significant correlations among these four potential "explanatory" variables themselves. For the six measures of selective attention, there was only one significant ($p<0.05$) correlation observed. This was a negative correlation ($r=-0.62$) between hearing loss asymmetry and performance in the ear-cue, same-gender condition. However, the correlation with hearing loss asymmetry approached significance ($r=-0.52$, $p=0.07$) for the
FIG. 4. Scatter plot of transformed percent-correct CRM scores for dichotic listening conditions as a function of monaural listening for the same conditions. The call sign was always the cue and only conditions making use of different talker gender are included in this figure. Data from the 10 YNH subjects are shown by filled symbols and for the 13 EHI subject by the unfilled symbols. Circles represent values for selective-attention conditions and squares for divided-attention conditions. For the data from the YNH listeners, the Pearson-r correlation coefficient between monaural and dichotic performance was 0.94, whereas it was 0.87 for the EHI listeners.

corresponding condition with the call-sign cue. In addition, two other moderate correlations ($r=0.53$ and 0.54) for measures of selective attention approached significance ($p=0.06$) and these were with the digit-span measure. For divided attention, the only significant correlations were with digit span. Four of the six measures of divided attention were significantly correlated ($0.61 < r < 0.77$) with digit span and the other two ($r=0.54$ and 0.52) approached significance ($p=0.06$ and 0.07, respectively).

The foregoing analysis of individual data suggests that there may be common mechanisms underlying the identification of speech from one talker with another talker speaking in the background, regardless of whether the competing talkers are presented to the same ear (monaural) or to different ears (dichotic). Further, these two attentional mechanisms (selective and divided) are strongly correlated.

The scatter plot in Fig. 4 further emphasizes that the differences in performance on dichotic selective- and divided-attention tasks are closely related to similar differences observed for monaural presentations of these same stimuli. In this figure, only the data for the different-gender conditions and call-sign cue are presented. The same-gender conditions were very difficult for monaural presentations, not correlated with other measures, especially for selective attention, and likely reflected an inability of the subject to segregate the two messages. As such, it is probably not appropriate to examine attention for two competing stimuli if the stimuli cannot be perceived as two separate stimuli. In addition, the scatter plot was generated only for conditions using the call-sign cue because that is the only cue in common across the monaural and dichotic presentation conditions. In

Fig. 4, note that, for both age groups, as performance in either the selective- or divided-attention task increases for monaural presentation (x axis), performance also increases for the corresponding task with dichotic presentation (y axis). In fact, the correlation coefficient between scores for monaural and dichotic conditions is 0.94 for young adults and 0.87 for older adults. This suggests, at least for these stimuli and conditions, that the performance in dichotic conditions may reflect individual differences in the same cognitive mechanisms underlying performance in monaural conditions and not necessarily central-auditory factors, such as binaural processing, that are modality specific and unique to dichotic processing.

IV. EXPERIMENT 2

A. Experiment-specific procedures

There were a total of six conditions in this experiment; three each for selective and divided attention. All presentations were monaural (right ear) and the cue was always talker gender (male or female). The sole repeated-measures independent variable was talker uncertainty for both dependent variables (measures of selective and divided attention). There were three levels of talker uncertainty examined: minimum, medium, and maximum uncertainty. For "minimum uncertainty," the same male talker and the same female talker were used for all 32 trials in a block and for all four blocks. For "medium uncertainty," the same talker of one gender was used as one talker across trials while the other talker was randomly selected on each trial from among four possible talkers of the opposite gender. There were two variations of this "medium uncertainty" case: one in which the fixed talker was male and the variable talkers were female and one in which the fixed talker was female and the variable talkers were male. Four blocks of 32 trials were completed for each of these variations of the "medium uncertainty" conditions and the results for all eight blocks were averaged. Finally, for "maximum uncertainty" one male and one female were chosen randomly for each trial from the four possible talkers for each gender. The randomization was constrained such that each of the eight talkers appeared four times as the target talker and four times as the competing talker in a block of 32 trials. Thus, there was one repeated-measures independent variable (talker uncertainty) with three values. The subject group was again the only between-subject independent variable and there were two values for this variable (young normal hearing, elderly hearing impaired).

B. Results and discussion

1. Effects of stimulus uncertainty and group

In this experiment, the use of talker gender as a cue for selective and divided attention was examined in the same 13 elderly adults and 10 young adults, 7 of whom had participated in experiment 1. Given the use of talker gender as the cue, the genders of the target and competing talkers were always different and gender match was no longer a viable independent variable. Instead, the variation in talker voices from trial to trial, referred to here as talker uncertainty, was manipulated systematically.

Talker-Gender Cue, Monaural
FIG. 5. Means and standard errors (error bars) of the transformed percent-correct scores for the CRM for each of the six listening conditions in experiment 2 and both groups of subjects (grey bars: YNH; black bars: EHI). Asterisks mark significant ($p < 0.01$) differences between the two groups.

Figure 5 presents the means and standard errors, in RAUs, for the three levels of stimulus uncertainty included in experiment 2, with the selective-attention measures in the left half of the figure and the divided-attention measures in the right half. Casual visual inspection of these data suggests that, in general, performance was lower in the divided-attention tasks than in the comparable selective-attention tasks and that older adults generally performed worse than young adults. Two 2×3 mixed-model GLM analyses were performed, one for the measures of selective attention and one for the measures of divided attention.

The GLM analysis on the measures of selective attention (the left half of Fig. 5) revealed a significant main effect of subject group [$F(1,21)=8.1$], but not uncertainty [$F(2,42)=2.1$]. In addition, there was no interaction between uncertainty and group [$F(2,42)=1.0$]. Multiple independent-sample t tests were computed to examine the differences in performance between groups for each uncertainty condition. The criterion p value was again adjusted for multiple comparisons ($p=0.05/3=0.0167$) and the asterisks in the left half of Fig. 5 mark those conditions for which a significant difference between groups was observed. The older adults performed significantly worse than the younger adults on two of the three selective-attention tasks, the two having greater amounts of stimulus uncertainty.

The GLM analysis on the measures of divided attention (the right half of Fig. 5) revealed a significant main effect of subject group [$F(1,21)=27.3$] and uncertainty [$F(2,42)=4.8$]. The group x uncertainty interaction was not significant [$F(2,42)=0.9$]. With regard to stimulus uncertainty, post hoc paired-sample t tests (adjusted for multiple comparisons) indicated that the mean performance for the maximum uncertainty condition was significantly lower than that for the minimum uncertainty condition. No other paired comparisons involving stimulus uncertainty were significant. To examine the effect of subject group in more detail, mul-

tiple independent-sample t tests were computed for each uncertainty condition, with the criterion p value adjusted for multiple comparisons. The asterisks in the right half of Fig. 5 mark those conditions for which a significant difference between groups was observed. The older adults performed significantly worse than the younger adults on all three divided-attention tasks.

To summarize the group data, the EHI adults performed significantly worse than YNH adults in five of the six conditions included in this experiment. These findings are consistent with the findings of experiment 1, but using talker gender as the cue rather than the call sign or ear. The results from this experiment with regard to uncertainty were less clear. There was no effect of uncertainty on measures of selective attention, but there was on measures of divided attention. Although a statistically significant effect of stimulus uncertainty was observed between the minimum and maximum uncertainty conditions for the measures of divided attention, the mean differences in performance over this range of uncertainty were not large (4-5 RAU) for either group. This small effect could be due to the restricted range of talker uncertainty available for the CRM materials used in this experiment. Moreover, a significant interaction between the effects of uncertainty and group was not observed for either measure of attention suggesting that the effects of uncertainty, or lack thereof, were equivalent for both young normal-hearing subjects and elderly hearing-impaired listeners. As noted previously, others have found older adults to be more vulnerable to such talker uncertainty or variability in other contexts (Sommers, 1997), although a much wider range of uncertainty was encompassed in that study than in this experiment. In addition, Brungart and Simpson (2004) found no significant effects of talker uncertainty on the CRM task in young adults, whereas Coughlin (2004) observed significant effects of talker uncertainty in both young and older adults on the CRM task (for selective attention).

2. Correlations and individual differences

With regard to the individual data from experiment 2, correlations across the three stimulus uncertainty conditions for each measure of attention were all strong, positive, and statistically significant ($p < 0.05$). Specifically, the three pairwise correlations for selective attention were 0.91, 0.89, and 0.92 and those for divided attention were 0.95, 0.91, and 0.93 for the entire set of 23 subjects. Similar correlations were also observed within each group separately. Finally, when the three measures of selective attention were correlated with the three measures of divided attention for all 23 subjects, the nine correlations ranged from 0.68 to 0.87 and were all statistically significant. Thus, an individual who performed well on any of the tasks in this experiment tended to perform well on all of the tasks, regardless of the type of attention being measured or the amount of stimulus uncertainty.

Correlations were also computed between each of the six measures of selective and divided attention and age, average high-frequency hearing loss (1000, 2000, and 4000 Hz) in both ears, and average digit-span score (average of forward and backward digit span measures) for the 13

Humes, Lee, and Coughlin: Auditory selective and divided attention

older adults. It should be noted that there were no significant correlations among these three potential "explanatory" variables. For divided attention measures, the only significant correlation that was observed was a negative correlation ($r = -0.62$) between age and performance on the maximum uncertainty condition. Thus, among the 13 older adults, the older the subject, the lower the score for divided attention under maximum uncertainty conditions. For selective attention, all three measures of selective attention were correlated significantly with digit span ($0.57 < r < 0.64$) and there were no significant correlations with age or hearing loss among the 13 older adults. Thus, for the measures of selective attention used here, those with better short-term memory performed better than those with poorer short-term memory.

V. GENERAL DISCUSSION

Across both experiments 1 and 2, several consistent trends were observed when using the CRM and two competing talkers to measure attention in young and older adults. First, in general, for both young and older adults, divided-attention tasks yielded lower scores than comparable selective-attention tasks. This was not unexpected since divided attention is known to place greater demands on memory (Pashler, 1998). This was true for both monaural and dichotic presentation modes and all three types of attention cue used (ear, call sign, talker gender). The lone exception probably being when monaural, same-gender conditions were used in experiment 1. This was also the condition yielding overall performance for both age groups that was well below that of any other test condition in either experiment. It is likely that, in this condition, the two competing talkers were difficult to segregate given similar fundamental frequencies (Assmann and Summerfield, 1990; Culling and Darwin, 1993; Arehart, King, and McLean-Mudgett, 1997; Summers and Leek, 1998) and energetic forms of masking predominated, making it extremely difficult to hear out or segregate the two auditory stimuli and respond accordingly.

A second general trend across experiments was related to the difference between the performance of young and old adults. In particular, in eight of the nine divided-attention measures across both experiments, the EHI subjects performed significantly worse than the YNH subjects. This was true regardless of the presentation mode, the type of cue used, the gender match between target and competing talkers, or the amount of talker uncertainty. By comparison, significant differences in performance between age groups were only observed on three of the nine selective-attention tasks.

Another common finding across both experiments pertained to the strong correlation among CRM scores for a given experiment, suggesting considerable redundancy and a common underlying factor or factors. There were consistent individual differences in performance in both experiments such that high performers tended to score high on all conditions and lower performers tended to score low on all conditions. Subsequent correlations between performance and age, digit span, and hearing loss for the 13 older adults suggested that, at least for this age group, the individual differences in performance were associated frequently with indi-

vidual differences in memory (digit span). As noted in the Introduction, the observations of age differences in performance on selective- and divided-attention tasks, as well as the association of individual differences in performance with memory among the older adults, have been noted before (Verhaeghen and De Meersman, 1998a, 1998b; Verhaeghen *et al.*, 2003). In our particular implementation of attention measurements in experiments 1 and 2, the subjects were required to hold the orthographic cue (ear, call sign, or gender) in memory for about 1.5–2.0 s before responding with the color-number coordinates for measures of selective attention. For divided-attention measures, the subjects had to hold the stimuli in memory for about 3 s before the orthographic cueing was completed and response collection enabled. Thus, in this study, as in previous studies, age-related differences in attention could be mediated by corresponding differences in memory.

The absence of other correlations, with age, hearing loss, or hearing loss asymmetry (with one exception in experiment 1), is perhaps as important as these significant correlations. Among the elderly, differences in age or differences in hearing loss did not contribute to individual differences in performance from either experiment. Use of spectral shaping to minimize audibility limitations appeared to be effective, as was also the case in Coughlin (2004), although a slightly different approach was taken to ensure audibility through 4000 Hz in the previous study.

The percentage of errors in each experiment, for each type of attention and each group of subjects, that resulted from intrusions of the color or number coordinates, or both, from the competing stimulus was examined. An "intrusion" of the competing color-number coordinates simply means that the listener's response included the color, number, or color-and-number coordinates from the competing talker. GLM analyses of the percentage of intrusions for each experiment, revealed only significant ($p < 0.01$) main effects of type of attention in each experiment, but no significant ($p > 0.05$) differences between groups or interactions between group and type of attention. Selective attention revealed a greater percentage of intrusions than divided attention. Since the competing response coordinates could not have the same color or number as the target, on any given trial, that left three possible colors and seven possible numbers for use as coordinates in the competing message. Thus, there is a 1/3 chance the color alone from the competing stimulus would be reported by guessing, a 1/7 chance for the number alone, and a 1/21 chance that both the color and number of the competing stimulus would be reported randomly. Summing all these possible intrusion probabilities results in a total intrusion percentage of errors of 11/21 (i.e., (1/3+1/7 +1/21) or 52.4%.

For color-only intrusions, the percentage of errors that were of this type were not unlike those expected by chance, except for the divided attention conditions for the EHI subjects. In this case, the percentage of color-only intrusions was quite a bit less than would be expected by random guessing. For number-only intrusions, the percentages of errors that were of this type were fairly consistent across all subject and attention combinations and were also not unlike
FIG. 6. The mean percentage of errors due to color+number intrusions. The percentage of intrusions expected by chance is represented by a horizontal dashed line.

those expected by chance. The situation was considerably different, however, for the color+number intrusions and these intrusions are illustrated in Fig. 6. As shown, the percentages of errors that were of this type were about three to five times greater than those expected by chance. The analysis of the percentage of errors that are intrusions from the competing stimulus, especially for the color+number intrusions, provides further support for the notion that the underlying processing reflects attentional capabilities. The listeners were less able to tune out, inhibit, or suppress the competing coordinates and these coordinates surface as responses in the errors much more frequently than would be expected by chance alone. It has frequently been shown that older adults are less able to inhibit irrelevant or competing sensory information (e.g., Hasher and Zacks, 1988; Hasher *et al.*, 2006), including the situation of attending to a target talker and ignoring a competing talker (Sommers and Danielson, 1999; Tun, O'Kane, and Wingfield, 2002), although age differences in the interference of a competing talker with the target talker have not always been observed (e.g., Li *et al.*, 2004). In the present study, however, although the older adults made more errors than the young adults in most conditions, the relative percentage of color + number intrusion errors was lower for older adults (Fig. 6). Thus, it was more often the case that *neither* the target or competing coordinates were identified correctly by the older adults whereas younger adults were superior at recalling both (incorrectly in the case of color + number intrusions).

It should be kept in mind that the target-to-competition ratio in this study was 0 dB and, for the EHI listeners, both stimuli underwent the same amount of spectral shaping. Overall, therefore, the target and competing stimuli are equivalent in energetic terms and it is impossible to state which stimulus is the energetic "masker" and which is the "signal." That is, it is not the case that the competing coordinates emerged more frequently among the errors because the competing stimulus masked, in an energetic sense, the target coordinates. Rather, given acoustically, and presum-

ably perceptually, equivalent target and competing stimuli, attention and memory processes determined both the percentage of target coordinates recalled correctly *and* the large percentage of the errors attributable to the competing coordinates.

The use of the same stimuli and same call-sign cue for four dichotic and four monaural conditions in experiment 1 enabled a comparison of the individual differences in performance for both presentation modes (Fig. 4). Strong correlations of about 0.9 between monaural and dichotic performance for selective and divided attention and in young and elderly adults strongly suggests that there are common underlying mechanisms for these two presentation modes. It is suggested here that the common underlying mechanism is attention or attention+memory; in either case, a cognitive process. Thus, individual differences in performance on other dichotic speech-identification or speech-recognition tasks may also be attributable to underlying individual differences in attention. As such, these measures of dichotic speech processing should not be considered to be pure measures of "central auditory" processing, especially when used with older adults (e.g., Jerger *et al.*, 1989; Hallgren *et al.*, 2001; Humes, 2005).

Finally, the mean CRM scores for selective and divided attention conditions across experiments 1 and 2 for both age groups (Figs. 3 and 5) were compared. Mean values were computed for each group and for the four cue/presentation mode conditions used in the two experiments. For experiment 1, only the conditions using talkers of different genders were averaged since different genders were always used in experiment 2. In addition, since the trial-to-trial uncertainty in experiment 1 was most like the medium-uncertainty conditions from experiment 2, the medium-uncertainty condition from that experiment was used in this across-experiment comparison. From these across-experiment comparisons, the spatial/laterality (ear) cue in dichotic listening yielded the highest mean performance for both age groups and for both selective and divided attention. Likewise, the call-sign cue in the monaural listening condition yielded the lowest performance within each attention type and for both groups. The ordering of the two middle cues/conditions, however, was not as clear. For selective attention, for example, the call-sign cue in dichotic listening tended to produce somewhat higher scores than the gender cue in monaural listening conditions, whereas there was no such trend, or even an opposite trend, for these two cue/condition combinations in the divided-attention task. Caution should be exercised when comparing performance across cues and conditions, however, because, despite attempts to equate various factors across experiments and conditions, this has not been fully accomplished. For example, for the call sign as a cue, there were eight alternatives, whereas for the other two cues, gender and ear, there were only two alternatives. In that sense, there was more uncertainty with regard to the potential cues from trial to trial when call sign was used. To examine the role of cue uncertainty, additional experiments with call sign restricted to only two choices, just as gender and ear, would be required. Nonetheless, it appears that those cues associated with physical aspects of the perceived auditory object,

Humes, Lee, and Coughlin: Auditory selective and divided attention

such as its location (ear) or fundamental frequency (gender), are stronger than the arbitrary lexical labels (call signs) attached to those objects.

The harmonic structure can be easily recognized in time-frequency representation of speech signals in adverse environment. The harmonicity is a measure of the completeness of a harmonic structure. This paper presents a new harmonic structure measure that extends the conventional harmonicity to a set of harmonicities. They are expressed in terms of the grid harmonicity, the temporal harmonicity, the segment-spectral harmonicity, and the segmental harmonicity. The grid harmonicity measures the completeness of individual harmonics in each frame. The grid harmonicities in a frame are summed up to form a temporal harmonicity for representing the strength of harmonicity. The segment-spectral harmonicity, computed by summing specific grid harmonicity over a segment, evaluates the integrity of individual harmonics across a segment. The segmental harmonicity evaluates the total strength of harmonic structure within a segment. This set of harmonicities is available for a systematic analysis of the harmonic structure and effective to several speech processing tasks. The applications to speech distortion analysis, robust fundamental frequency estimation, robust voicing detection, and speech enhancement are demonstrated. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2356838]

I. INTRODUCTION

The harmonic structure can be easily recognized in time-frequency representation of speech signals even in environments of very low signal-to-noise ratio (SNR). The harmonicity denotes the degree to which a signal is harmonic or periodic. For speech signals, harmonicity is synonymous with the degree of voicing. Many methods have been derived to evaluate the harmonic structure of speech signals. The normalized autocorrelation is a simple yet effective method to estimate the periodicity of a signal. The harmonics-to-noise ratio (HNR) measured in the autocorrelation domain is a useful method for estimating the harmonicity (Boersma, 1993). Some cepstrum-based techniques are used to provide more efficient algorithm for determining the HNR (Krom, 1993; Qi and Hillman, 1997; Murphy, 2000). The HNR can also be implemented in the instantaneous frequency amplitude spectrum (IFAS) (Arifianto and Kobayashi, 2003).

Though these methods are good enough for HNR determination and fundamental frequency (F0) estimation, they do not provide sufficient information for further analysis of the harmonic structure, for example, investigating the distortion of individual harmonics within a frame or a segment. This paper presents a work that extends conventional harmonicity measures to a set of harmonicities. They are expressed in terms of the grid harmonicity, the temporal harmonicity,

the segment-spectral harmonicity, and the segmental harmonicity. The grid harmonicity is the lower-level harmonicity that measures the completeness of individual harmonics in each frame. Other harmonicities are derived from the grid harmonicity at selected time, frequency, and segmental indices. This set of harmonicities permits a systematic analysis of the harmonic structure. They can be applied to numerous speech processing tasks, such as the speech distortion analysis, the robust fundamental frequency (F0) estimation, the robust voicing detection, and the speech enhancement.

When the speech is corrupted by an additive noise, its harmonic structure is partially distorted. The type and level of corrupting noise determine the degree and distribution of the distortion. The proposed harmonicities represent the completeness of the harmonic structure of a speech signal in different domains. Notably, the lower harmonicity corresponds to larger distortion or worse speech quality. These harmonicities provide the accurate and detailed information in the speech distortion analysis.

The fundamental frequency (F0) estimation is necessary for many applications, such as in speech coding, speech recognition, speech enhancement, and prosody extraction. Numerous F0 estimation algorithms have been developed (de Cheveigné and Kawahara, 2001; Kasi and Zahorian, 2002). However, many of those algorithms suffer from noise corruptions. Nevertheless, the validation of F0 candidates using harmonic measure can easily eliminate those incorrect F0 candidates and thereby increase the robustness of F0 estimation. This comes from the fact that the harmonic structure

[a)]Electronic mail: yuat@ms25.hinet.net
[b)]Electronic mail: hcwang@ee.nthu.edu.tw

associated with the correct F0 maximizes the harmonicity. The robust property of harmonic structure can be used for voicing detection. It provides a tool for extracting the voiced segments in noisy speech processing.

The knowledge of the harmonic structure of voiced speech should be integrated into an enhancement system to further improve the speech quality. The comb filtering and the sinusoidal modeling are well-known approaches for high-quality speech reproduction (Nehorai and Porat, 1986; McAulay and Quatieri, 1986). Rather than designing a new enhancement algorithm, a two-stage scheme, including a front enhancement process and a postenhancement process, is proposed for the speech enhancement. Any existing enhancement algorithm can be a front enhancement process. The detailed speech information obtained from harmonic analysis is then used in the postenhancement process to further improve the speech quality. The postenhancement process is designed to further reduce the noise and smooth the discontinuity of speech harmonics. The comb filter with its gain and bandwidth adapting to factors derived from temporal and segment-spectral harmonicities provides an example of this application.

The remainder of this paper is organized as follows. In Sec. II, new harmonic structure measures are introduced. The applications of proposed harmonicities to the speech distortion analysis, the robust F0 estimation, the voicing detection, and the speech enhancement are respectively described in Secs. III–VI. Some experimental results are demonstrated. Section VII gives the discussion and conclusion.

II. NEW HARMONIC STRUCTURE MEASURES

To provide a systematic harmonic structure analysis, a set of harmonicities is proposed. They include grid harmonicity, temporal harmonicity, segment-spectral harmonicity, and segmental harmonicity. The grid harmonicity measures the completeness of individual harmonics at every frame. Grid harmonicities in a frame are summed up to form a temporal harmonicity for representing the strength of harmonicity. The segment-spectral harmonicity evaluates the integrity of individual harmonics across a segment. The segmental harmonicity measures the whole strength of harmonic structure within a segment. The formulations of these harmonicities are described as follows.

A. Grid harmonicity

The grid harmonicity measures the magnitude ratio of the harmonics to its surrounding noise. It represents the completeness of an individual harmonics in a frame. The formulation of the grid harmonicity involves three components: (1) the local spectral dominance, (2) the temporal variation factor, and (3) the neighbor dominance. These three components confirm the existence of a spectral maximum in spectral domain for a voiced speech frame.

1. Local spectral dominance

Let $e(n,m)$ be the sum of weighted magnitude spectral densities around the mth harmonics at the frequency bin index mk_0. The summation range is $[(m-\eta)k_0, (m+\eta)k_0]$. Then $e(n,m)$ is expressed as follows,

$$e(n,m) = \sum_{k=\lfloor(m-\eta)k_0\rfloor}^{\lceil(m+\eta)k_0\rceil} S(n,k)\phi(k-mk_0). \tag{1}$$

where $S(n,k)$ denotes the magnitude spectral density of an analyzed signal in the nth frame, and k is the frequency bin index. k_0 is the frequency bin index of fundamental frequency. η is a fractional factor to specify the summation range. In this study, we set η to 0.5. $\phi(k)$ is a harmonics selecting function defined by the following equation,

$$\phi(k) = e^{-k^2/2\sigma^2}, \tag{2}$$

where σ^2 denotes a factor controlling the width of the harmonics selecting function. σ is chosen to be proportional to the number of frequency bins in the summation range. In this study σ^2 is set to 100. Then the local spectral dominance of mth harmonics evaluated in the nth frame is defined by

$$h_D(n,m) = \frac{e(n,m)}{\sum_{k=\lfloor(m-\eta)k_0\rfloor}^{\lceil(m+\eta)k_0\rceil} S(n,k)(1-\phi(k-mk_0))}. \tag{3}$$

Equation (3) shows that $h_D(n,m)$ is large if the harmonic does exist at mk_0. Contrarily, if the signal is nonharmonic, $h_D(n,m)$ will be a small value. Therefore, we consider $h_D(n,m)$ as a factor to evaluate the existence of a harmonic. If the speech signal is sampled at 16 kHz and transformed to the frequency domain by using fast Fourier transform (FTT) with 1024 points, the resolution in frequency domain is 15.626 Hz per frequency bin. The fundamental frequency of the speech signal is in the range of 80 to 400 Hz so that the range of k_0 is about from 5 to 25. The summation range, $[(m-\eta)k_0, (m+\eta)k_0]$, should contain at least 5 points when η is set to 0.5. In this summation range, $1-\phi(k-mk_0)$ is nonzero except at the point of $k=mk_0$. The denominator of Eq. (3) is a sum of at least four nonzero terms. Since these nonzero terms are nonnegative, the situation of singularity cannot happen.

2. Temporal variation factor

Since the harmonic structure is stable during a short time period, we can expect a small change of spectral magnitude between consecutive frames. This property can be measured by the temporal variation defined as follows,

$$D_T(n,m) = \frac{|S(n,mk_0) - S(n-1,mk_0)|}{S(n,mk_0) + S(n-1,mk_0)}$$
$$+ \frac{|S(n+1,mk_0) - S(n,mk_0)|}{S(n+1,mk_0) + S(n,mk_0)}. \tag{4}$$

This temporal variation can be converged to a value ranging between 0 and 1 by using a sigmoid function. Then a temporal variation factor is formulated as

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

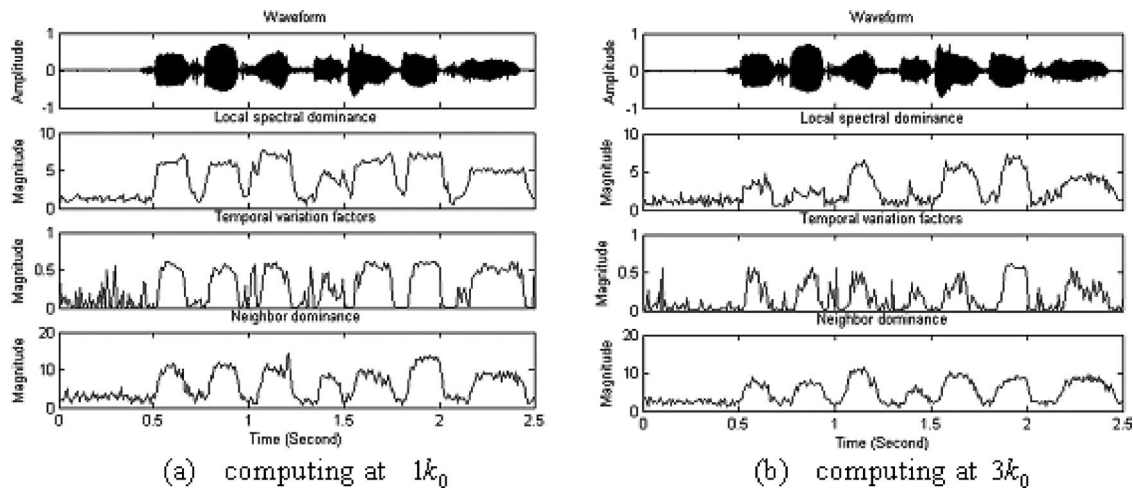
A. Yu and H. Wang: New speech harmonic structure measure   2939


FIG. 1. Correlations of three components in computing Grid harmonicity: The sentence is spoken in Mandarin Chinese, "qi2 shi2 ta1 xi3 huan1 he1 cha2 (In fact she likes tea)."

$$h_T(n,m) = \frac{1}{1 + e^{a(D_T(n,m)-b)}}, \qquad (5)$$

where a and b define the property of transformation. In this study a and b are empirically set to 5 and 0.3, respectively. Accordingly, we can see that the temporal variation factor is large when the variation of spectral magnitude between consecutive frames is small. This implies a large temporal variation factor corresponds to a high possibility of the presence of harmonics.

3. Neighbor dominance

A number of harmonics should appear in the spectrum for a harmonic signal, and the nearby harmonics should be predictable. For this reason, we define another factor by the following equation to detect the existence of a harmonic:

$$h_N(n,m) = h_D(n,m-1) + h_D(n,m+1). \qquad (6)$$

The spectral dominance at mth harmonics should be proportional to the spectral dominances of neighboring harmonics. If the harmonic exists, $h_N(n,m)$ should be a large value. Otherwise, $h_N(n,m)$ is small.

The correlation among these three components, i.e., local spectral dominance, temporal variation factor, and neighbor dominance, is demonstrated in Fig. 1. The given utterance is a sentence spoken in Mandarin Chinese which is marked by Pinyin, "qi2 shi2 ta1 xi3 huan1 he1 cha2." This sentence means "In fact, she likes tea." There are seven syllables in this sentence. We can observe clearly the seven voiced segments.

From Fig. 1, it is obvious that these three components are large in voiced regions and small in noise or unvoiced frames. The harmonics of a signal can be confirmed when three components are large. Based on the above observation, we empirically define the grid harmonicity as the product of the local spectral dominance, the temporal variation factor, and the neighbor dominance:

$$H_G(n,m) = h_D(n,m)h_T(n,m)h_N(n,m). \qquad (7)$$

This function provides an effective discrimination between harmonic and nonharmonic signals. For the speech signal, this measure can be used to discriminate the voiced and unvoiced speech. Figure 2 illustrates the spectrogram and the grid harmonicity of the given utterance in Fig. 1. It is worthwhile to note that the computation of $H_G(n,m)$ needs an available fundamental frequency k_0. A conventional F0 algorithm can be applied to estimate the initial k_0. Then a search around the initial estimate is performed to find the accurate k_0. The criterion is to maximize the sum of all $H_G(n,m)$ in the frame.

B. Temporal harmonicity

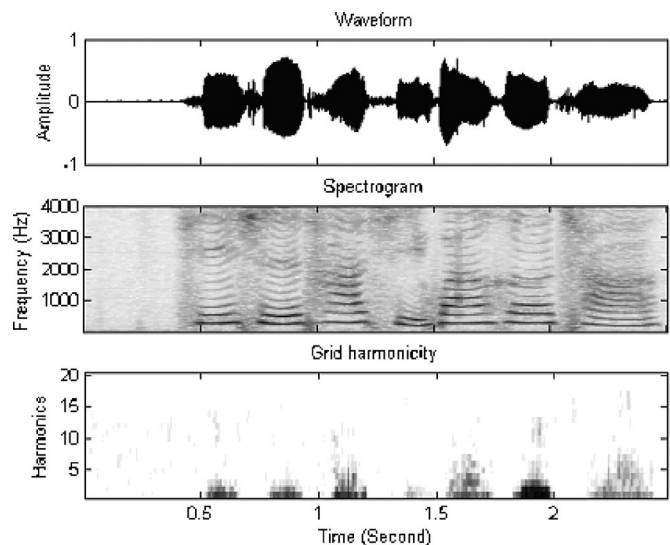
Temporal harmonicity represents the strength of harmonicity in a frame. This measure is defined by the weighted sum of grid harmonicities in a frame:


FIG. 2. Grid harmonicity of an utterance: The sentence is the same as that in Fig. 1.
FIG. 3. Temporal harmonicity of an utterance: The sentence is the same as that in Fig. 1.

FIG. 4. Segment-spectral harmonicities of the first four segments in an utterance: segment 1—"qi2", segment 2—"shi2", segment 3—"ta1", and segment 4—"xi3".

$$H_T(n) = \sum_{m=1}^{M(n)} \alpha(n,m)H_G(n,m), \quad \alpha(n,m) = \frac{e(n,m)}{\sum_{p=1}^{M(n)} e(n,p)},$$

(8)

where $M(n)$ represents the number of harmonics in the nth frame. This integer, $M(n)$, varies with frames according to their harmonics property. In a voiced speech frame, $M(n)$ tends to be larger when the F0 is lower. $\alpha(n,m)$ plays the role of a weighting factor to $H_G(n,m)$. $H_T(n)$ is a large value if the harmonics do exist in the nth frame. It is synonymous with the degree of voicing. Figure 3 illustrates the temporal harmonicity of the same utterance as shown in Fig. 1. It shows that the temporal harmonicity is large when the frame is a voiced signal. This term provides a good measure for discriminating those voiced speech frames.

C. Segment-spectral harmonicity

The segment-spectral harmonicity measures the integrity of a specific harmonic in a speech segment. For mth harmonics existing in a segment of consecutive frames, we define a measure named segment-spectral harmonicity as the weighted sum of grid harmonicities over the segment,

$$H_S(l,m) = \sum_{n=\text{SegBegin}(l)}^{\text{SegEnd}(l)} \beta(n,m,l)H_G(n,m),$$

(9)

$$\beta(n,m,l) = \frac{e(n,m)}{\sum_{q=\text{SegBegin}(l)}^{\text{SegEnd}(l)} e(q,m)},$$

where $\text{SegBegin}(l)$ and $\text{SegEnd}(l)$ represent the first and last frame indexes belonging to the lth segment, respectively. $H_G(n,m)$ is weighted by $\beta(n,m,l)$ in computing $H_S(l,m)$. The location of a voiced segment is detected by using the temporal harmonicity. Then $\text{SegBegin}(l)$ and $\text{SegEnd}(l)$ are

determined. Figure 4 shows the segment-spectral harmonicities for first four segments of the utterance in Fig. 1. In this utterance, a segment corresponds to a syllable. We can see that the segment-spectral harmonicity is large at lower harmonics and becomes small at higher harmonics. It reveals that the lower harmonics get more complete than the higher harmonics.

The definition of segment-spectral harmonicity shown in Eq. (9) indicates that the grid harmonicity of a specific harmonic is weighted and summed over the segment. The magnitude of segment-spectral harmonicity represents the average distribution of frequency components of a segment.

D. Segmental harmonicity

Segmental harmonicity is a measure of the whole harmonic structure within a segment. This is evaluated by summing all the weighted grid harmonicities over a segment:

$$H(l) = \sum_{n=\text{SegBegin}(l)}^{\text{SegEnd}(l)} \sum_{m=1}^{M(n)} \gamma(n,m,l)H_G(n,m),$$

(10)

$$\gamma(n,m,l) = \frac{e(n,m)}{\sum_{q=\text{SegBegin}(l)}^{\text{SegEnd}(l)} \sum_{p=1}^{M(q)} e(q,p)},$$

$H(l)$ would be high when the segment is a harmonic signal. In other words, the degree of voicing for a speech segment can be indicated by the high segmental harmonicity. Figure 5 illustrates the segmental harmonicities of the given utterance. The magnitude of the segmental harmonicity indicates the completeness of the harmonics structure of a segment.

III. SPEECH DISTORTION ANALYSIS

When a speech signal is corrupted by an additive noise, the harmonic structure will be partially distorted. The type and level of corrupting noise determine the degree and distribution of the harmonic structure distortion. Accordingly,
FIG. 5. Segmental harmonicities of an utterance: The sentence is the same as that in Fig. 1.

the spectrum of the speech signal is distorted. The proposed harmonicities can be used to evaluate the speech distortion in different scopes. The grid harmonicity measures the completeness of an individual harmonic in each frame. The segment-spectral harmonicity examines the completeness of an individual harmonic in a speech segment. The temporal harmonicity evaluates the weighted strength of all harmonics in a frame. Finally, the segmental harmonicity is used to give a measure to the entire harmonic structure within a segment. Based on these harmonicity measures, we can acquire the detailed distortion information due to the noise corruption.

Figure 6 shows the case of speech corrupted with car noise at SNR=0 dB. The harmonic structure is partially distorted, but is still easily to be recognized. However, some distortion at lower harmonics is obvious. Many higher harmonics are even invisible in the spectrogram. Besides, the magnitudes of segmental harmonicities are reduced as being compared with the clean speech in Fig. 5. The reduction of segmental harmonicity corresponds to the degree of distortion to a segment.

The examples of segment-spectral harmonicities under noise corruption are illustrated in Fig. 7. It shows that the

additive noise causes different degrees of distortion to harmonic structures. Comparing with the case of clean speech in Fig. 4, the magnitudes of segment-spectral harmonicity for most segments are reduced. More distortion appears at higher harmonics.

IV. ROBUST FUNDAMENTAL FREQUENCY ESTIMATION

The fundamental frequency (F0) estimation is required in many applications, such as speech coding, speech recognition, speech enhancement, and prosody extraction. With such a wide range of interests, many F0 estimation algorithms have been developed to fit their specific applications. A comprehensive study of F0 tracking was presented by Hess (1983). Most F0 estimation algorithms involve four phases: the preparation, the preprocessing, the F0 candidate picking, and the postprocessing. In the preparation phase, the speech signal is windowed and represented in a sequence of frames. The preprocessing stage minimizes those factors that are not helpful or are even harmful to F0 tracking, such as the formant structure. Typically this stage includes some band-pass filtering and nonlinear techniques (Rabiner, 1977). In the stage of F0 candidate picking, F0 candidates are generated via an auxiliary function that assigns higher probability to more likely F0 candidates at each frame. The auxiliary function can be formulated in several domains, such as in time (Qian and Kimaresan, 1996), autocorrelation (Wise *et al.*, 1976), normalized cross correlation (Kasi and Zahorian, 2002) AMDF, cepstrum (Noll, 1967), and subharmonic spectrum (Hess, 1983) domains. The postprocessing stage involves the process of searching for the most possible F0 candidates and forming an F0 track. The most common approach applies the technique of dynamic programming to determine an optimal F0 track.

Though the F0 estimation has been developed for many years, it still remains nontrivial to robustly identify the correct F0 from its double and half values. The uncertainty in picking an F0 candidate makes the F0 estimation algorithms complicated and not robust. However, the validation of F0 candidates based on harmonic structure analysis alleviates this problem. Since a harmonic structure with correct F0 maximizes the temporal harmonicity in a frame, we can
FIG. 6. Temporal harmonicity and segmental harmonicity of a speech corrupted by the car noise: The sentence is the same as that in Fig. 1.

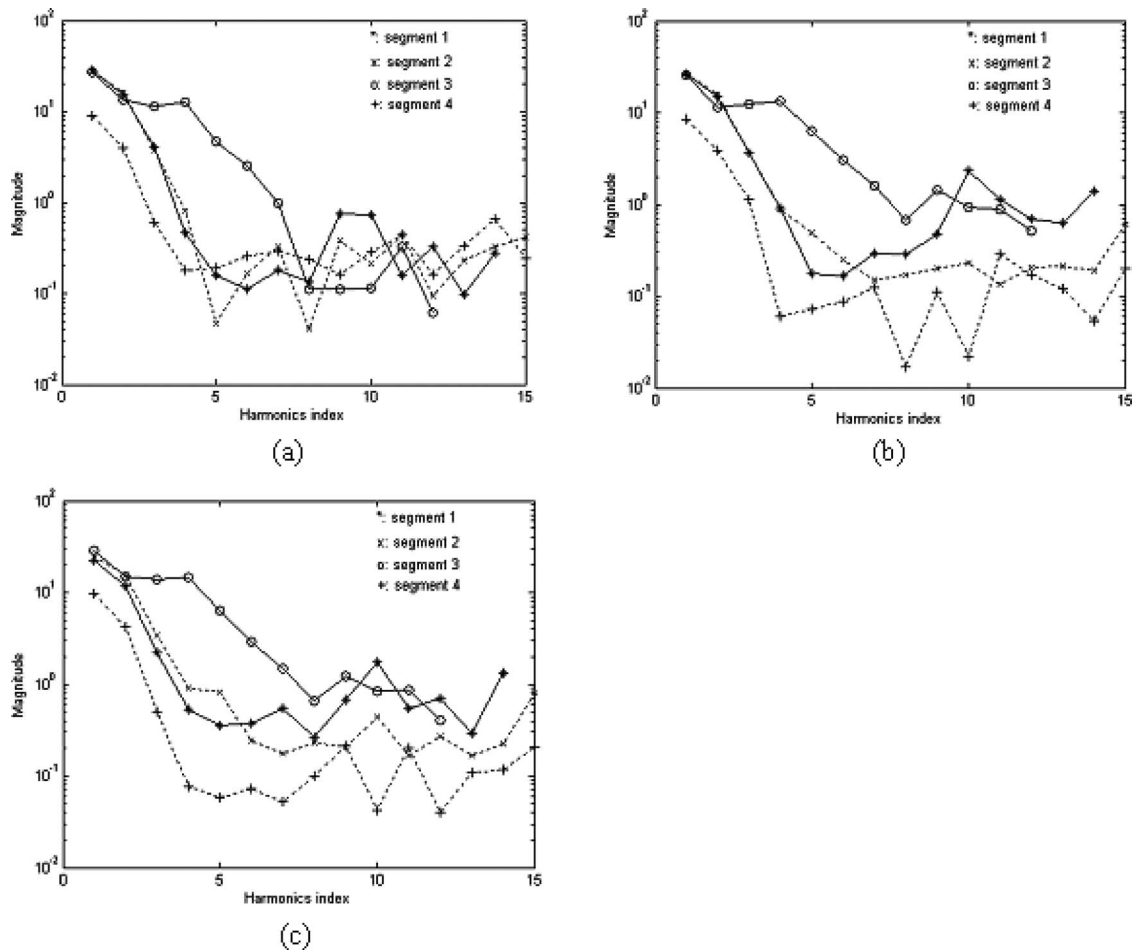
A. Yu and H. Wang: New speech harmonic structure measure


FIG. 7. Segment-spectral harmonicities of first four segments: (a) speech corrupted by white noise, (b) speech corrupted by car noise, and (c) speech corrupted by subway noise. All the noise levels are at SNR = 0 dB..
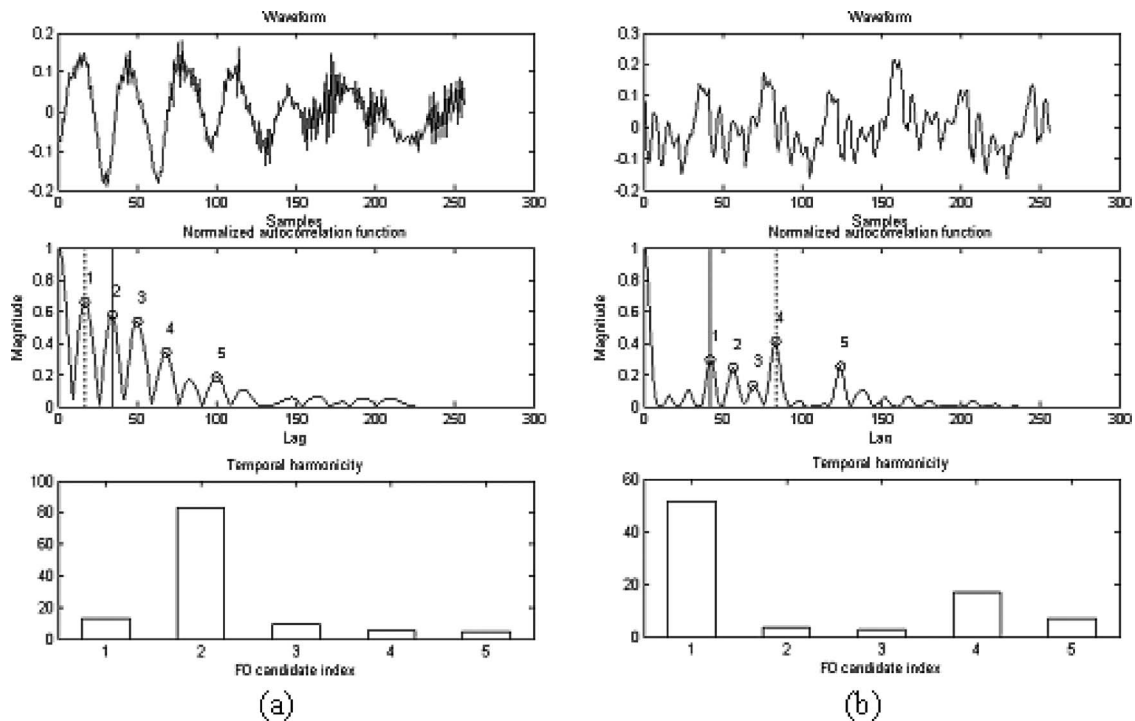

FIG. 8. Harmonicity checking for autocorrelation-based F0 estimation: (a) correction from half estimate error and (b) correction from double estimate error. (Five F0 candidates are marked by small circles. The arrow points to the location of maximal peak where there is the estimated F0 based on autocorrelation. The vertical solid line indicates the corrected F0 after harmonicity checking.)

check the temporal harmonicity to determine the correct F0. Figure 8 displays two examples involving wrong candidates picking frequently encountered in the F0 estimation. The F0 can be identified by observing the waveform of the speech signal and its autocorrelation function. However, the maximal peak of the autocorrelation function may not be the correct F0. Instead, the maximal peak may appear at half or a multiple of the correct F0 so as to lead to an incorrect F0 estimation. Figure 8 shows two examples. First five peaks are indicated by small circles in the plots. If we pick the highest peaks, the example (a) gives a half F0 estimate, and the example (b) gives the double F0 estimate. The temporal harmonicities of five F0 candidates for these two examples are illustrated at the bottom of Fig. 8. According to the temporal harmonicities, we can find that the correct F0 should be at the second peak in example (a) because it gives the highest temporal harmonicity. Similarly, the correct F0 should be at the first peak in example (b). These examples show that the temporal harmonicity can be used for correcting the F0 estimation.

An experiment was conducted to evaluate this validation process. Ten utterances were used as the testing data. Each utterance was corrupted with white noise at levels of SNR ranging from −5 to 30 dB with a 5-dB step. The top five peaks from the autocorrelation function were chosen as F0 candidates. The temporal harmonicity was calculated for each F0 candidate for the validation of estimated F0. No smoothing between frames was performed. A manually labeled F0 track was used as the reference. The F0 estimate was considered to be correct if the estimated F0 was within 20% of the reference F0. The error rate is in the range of 5% at SNR=30 dB to 14% at SNR=−5 dB.

Another experiment was conducted to show the effectiveness of the validation process. The experiment was arranged as follows: (1) The F0 candidates were obtained from five domains, i.e., autocorrelation, AMDF, harmonic peaks, subharmonic sum, and cepstrum. (2) A 3-point median filter was used to filter out the outliers and thus obtained the final F0 track. (3) No harmonicity checking was performed for the baseline testing. (4) The performance was evaluated using

TABLE I. The average temporal harmonicities of noise.

Noise type	Average temporal harmonicity
Airport	2.97
Babble	3.01
Car	1.40
Exhibition	2.15
Restaurant	2.43
Street	2.45
Subway	1.50
Train	2.33
White	1.22
Human speech	25.7

two measures, the gross error and the normalized mean square error. These measures are defined as follows:

(a) Gross errors: The error rate is the percentage of frames with F0 estimate deviating from that of the reference by more than 20%. This measure is based only on voiced frames.

(b) Normalized mean square error: The normalized mean square error is defined as follows;

$$\varepsilon = \frac{\sum [x(i) - y(i)]^2}{\sum [x(i)]^2}, \tag{11}$$

where $x(i)$ denotes the reference track, $y(i)$ represents the computed track, and i is the index of the voiced frame.

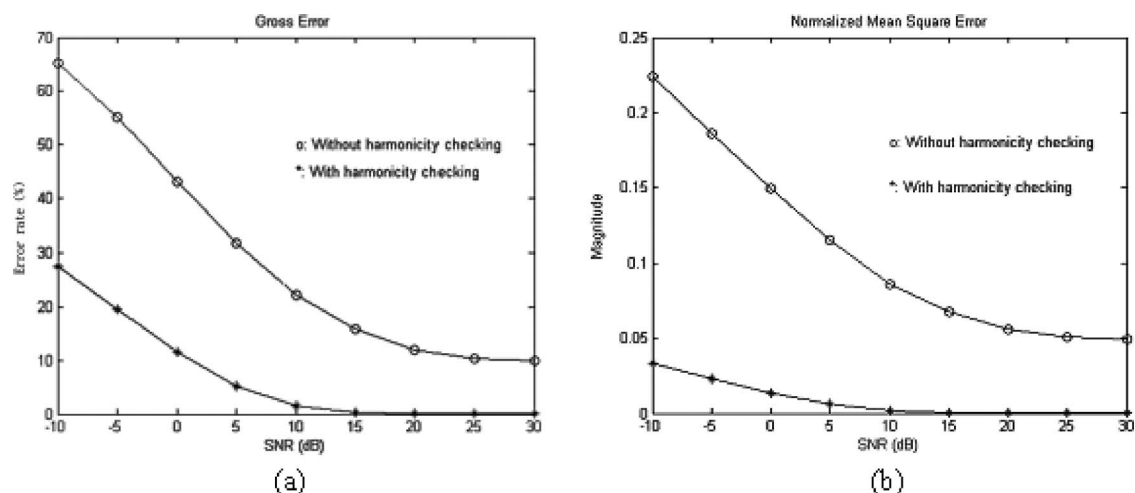
The experiment used ten utterances of Mandarin speech. Nine noises listed in Table I were used as additive noises. The speech signals sampled at 8 kHz were degraded by the noises with specific SNR ranging from −10 to 30 dB, with a 5-dB step. Figures 9(a) and 9(b) display the average performances of F0 estimation from five domains. These figures clearly reveal that the F0 estimation performance can be significantly improved by applying the harmonicity checking in the validation process.


FIG. 9. The performances of F0 estimation: (a) average gross error rates of F0 estimation and (b) average normalized mean square errors of F0 estimation. (The F0 candidates were obtained from five domains, i.e., autocorrelation, AMDF, harmonic peaks, subharmonic sum, and Cepstrum.)

V. ROBUST VOICING DETECTION

The voicing detection is an important issue in speech processing, such as speech recognition, speech coding, speech enhancement, and telephony applications (Gerven and Xie, 1997; McKinley and Whipple, 1997; Berthommier and Glotin, 1999; Kobatake *et al.*, 1989). The earlier algorithms may be based on Itakura LPC distance measure (Rabiner and Sambur, 1997), energy levels, zero crossing rates (Junqua *et al.*, 1991), cepstral features (Haigh and Mason, 1993), adaptive noise modeling of voice signals (Yoma *et al.*, 1996), and periodicity measurement (Tucker, 1992). Unfortunately, these algorithms are not robust to noise, particularly nonstationary noise. The proposed harmonicity provides another method of voicing detection.

The existence of harmonic structure provides a simple and robust indicator for identifying human speech. Table I
FIG. 11. Comparison of voicing detection methods based on HNR measure and based on harmonic measure.
FIG. 12. Structure of the proposed two-stage speech enhancement system.

lists the average temporal harmonicities of nine noises, and the average temporal harmonicity of clean speech. The remarkable difference in temporal harmonicity between noise and speech implies that the temporal harmonicity is an appropriate parameter for voicing discrimination. Based on the information of Table I, it is easy to set a threshold for voicing detection.

In an experiment, the speech was corrupted by various noises. The temporal harmonicities of noisy speech in various noise conditions were computed. Figure 10 shows the average temporal harmonicities of these noisy speech signals. It demonstrated that the temporal harmonicity of noisy speech is still higher than that of noise. This provides a method for robust voicing detection.

The experimental condition for using the temporal harmonicity to determine the voicing status of speech frames is identical to that in the F0 estimation experiment. Figure 11 illustrates the experimental result. The error rates of the conventional method for voicing determination based on harmonics-to-noise ratio (HNR) are plotted for comparison. The error rate is defined as the percentage of frames where the tracker disagrees with the reference in voicing decision. The result reveals that the method based on the average temporal harmonicity outperforms the HNR method.

VI. POSTSPEECH ENHANCEMENT

Many speech enhancement algorithms have been proposed (Lim *et al.*, 1974; Ephraim and Malah, 1984, 1985; Tsoukalas *et al.*, 1997; Wolfe and Godsill, 2000). However, few of these algorithms closely incorporated with speech characteristics. The knowledge of harmonic structures of voiced speech should be incorporated into the enhancement system to further improve the speech quality. Rather than designing a new enhancement algorithm, this study proposes a two-stage scheme: a front enhancement process followed by a postenhancement process. Figure 12 shows the function blocks of this two-stage scheme. An existing enhancement algorithm can be applied as the front enhancement process. The postenhancement process utilizes the detailed speech information obtained from the harmonicity analysis to further improve the speech quality.

For a voiced frame, a comb filter is applied to block out the noise components around the harmonics. The frame-based enhancement often causes discontinuous harmonics. The discontinuity may result in artificial noises. Temporally smoothing the harmonics magnitude in a segment can reduce these unpleasant sounds. The comb filter with gain and bandwidth adapted by the factors derived from temporal and segment-spectral harmonicities is proposed for reducing the artificial noises.
FIG. 13. Spectrum of the comb filter with gain and bandwidth adapted by harmonicities.

The proposed comb filter is implemented in the frequency domain,

$$\Phi(n,k,l) = \sum_{m=1}^{M(n)} g(n,m,l)\,\vartheta(k-mk_0,m,l), \qquad (12)$$

where $M(n)$ denotes the number of harmonics at the nth frame, k_0 is the frequency bin index of the fundamental frequency, $g(n,m,l)$ is a gain function for smoothing the harmonics magnitude in the lth segment, and $\vartheta(k,m,l)$ is the kernel function of the comb filter defined as

$$\vartheta(k,m,l) = e^{-k^2/2\sigma^2(m,l)}, \qquad (13)$$

where $\sigma^2(m,l)$ represents a factor for controlling the bandwidth of the kernel function. Narrower bandwidth of the kernel function makes the shape of the comb filter sharper and hence removes more noise around the harmonics. The sharp comb filter does not produce unnatural sounding for strong harmonics, but incurs artificial sounding for weak ones. To avoid this artificial sounding, $\sigma^2(m,l)$ is formulated as a function inverse proportional to the segment-spectral harmonicity,

$$\sigma^2(m,l) = \frac{\sigma_0^2}{1+\mu H_S(l,m)}. \qquad (14)$$

In Eq. (14), $H_S(l,m)$ is the segment-spectral harmonicity of the mth harmonics in the lth segment. $\sigma_0^2=120$ and $\mu=0.02$ are empirically set for the enhancement experiment.

The gain function $g(n,m,l)$ is formulated as

$$g(n,m,l) = (1-\zeta(m,l)) + \zeta(m,l)\hat{g}(n,m,l), \qquad (15)$$

where $\hat{g}(n,m,l)$ is an adjusted gain function in order to make the harmonics smooth in a segment, and $\zeta(m,l)$ is an interpolation factor defined by

$$\zeta(m,l) = \min\left(\frac{1}{1+e^{c(m)(H_S(l,m)-d(m))}},\lambda(m)\right), \qquad (16)$$

where $c(m)$ and $d(m)$ are factors for controlling the harmonics smoothing for mth harmonics. $d(m)$ is set to 2 and $c(m)$ is set to 0.3 empirically for all m. $\lambda(m)$ is the upper bound for the interpolation factor $\zeta(m,l)$. In this study $\lambda(m)$ is set to 0.2 for all m. The situation of $\zeta(m,l)=0$ corresponds to the case of no harmonics smoothing. $\zeta(m,l)$ is limited to $\lambda(m)$ in order to prevent from oversmoothing. The adjusted gain function $\hat{g}(n,m,l)$ is defined as follows,

$$\hat{g}(n,m,l) = \frac{\hat{e}(n,m,l)}{e(n,m)}, \qquad (17)$$

where $\hat{e}(n,m,l)$ is a target value for obtaining the smooth harmonics,

$$\hat{e}(n,m,l) = \frac{H_T(n)}{\sum_{n=\text{SegBegin}(l)}^{\text{SegEnd}(l)} H_T(n)}\left(\sum_{n=\text{SegBegin}(l)}^{\text{SegEnd}(l)} e(n,m)\right). \qquad (18)$$

Equation (18) indicates that $e(n,m)$ of the mth harmonics is recalculated in the lth segment according to a factor specified by $H_T(n)/\sum_{n=\text{SegBegin}(l)}^{\text{SegEnd}(l)} H_T(n)$. This modification smoothes the discontinuous harmonics caused by the front enhancement process. Figure 13 illustrates a comb filter with adjustable gain and bandwidth.

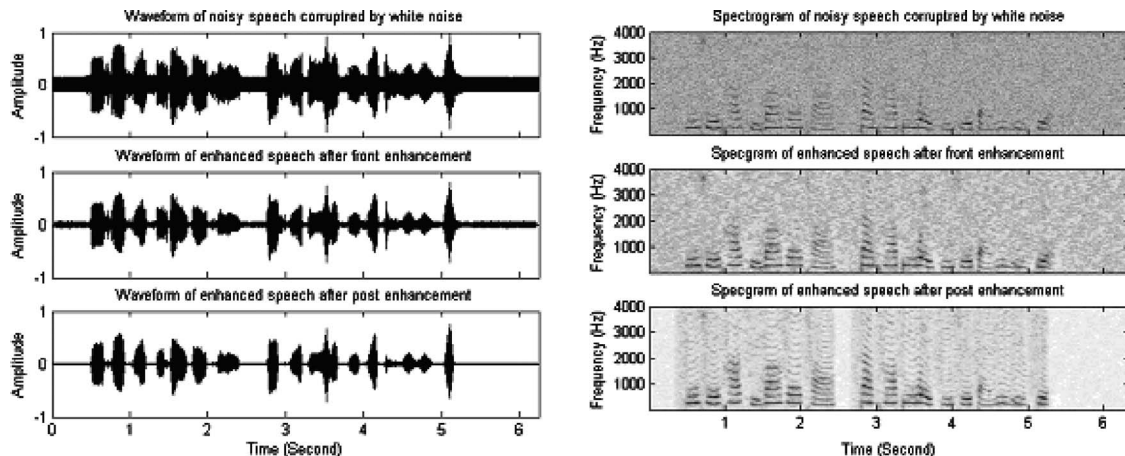
Subjective and objective evaluations were conducted to evaluate the proposed method. The testing data were ten utterances of Mandarin Chinese. The white noise and F16 noise served as additive noises (Varga *et al.*, 1992). The speech signals sampled at 8 kHz were degraded by the above-mentioned noises, with SNRs ranging from −5 to 10 dB, with a 5-dB step. Three enhancement algorithms, including spectral subtraction, Wiener filtering, and log-


FIG. 14. Result of speech enhancement: The utterance is a sentence spoken in Mandarin Chinese, "qi2 shi2 ta1 xi3 huan1 he1 cha2, dan4 ta1 bing4 wei4 ji2 shi2 fan3 yin4 yi4 jian4. (In fact she likes tea, but she does not response immediately)."

spectral-amplitude (LSA) estimation (Ephraim and Malah, 1985), were separately applied in the front enhancement process.

A minimum statistics method estimated the noise spectrum from the testing utterance for all enhancement algorithms (Martin, 1994). In the postenhancement process, the speech frame contained 256 samples with an overlap of 192 samples. A 2048-point FFT with zero padding transformed the speech waveform into the frequency domain. After the enhancement process in the frequency domain, the spectrum was transformed back to the time domain and truncated to 256 samples. The "overlap-add method" smoothed the speech data between consecutive frames (Oppenheim and Schafer, 1989).

Figure 14 shows the speech enhancement for the case of corrupting by white noise with SNR=5 dB. The given utterance is a sentence spoken in Mandarin Chinese, "qi2 shi2 ta1 xi3 huan1 he1 cha2, dan4 ta1 bing4 wei4 ji2 shi2 fan3 yin4 yi4 jian4 (In fact she likes tea, but she does not response immediately)." Waveforms and spectrograms of the noisy speech and two versions of enhanced speech, with and without the postenhancement process, are displayed.

It is obvious that the noisy speech suffers from a severe distortion in harmonics structures. The existing speech en-

hancement algorithms can reduce the noise. The postenhancement process based on harmonic analysis can further remove the artificial noises. By using the comb filter, a reconstruction of harmonics structures can be achieved. Tables II and III show the segmental SNR improvements with and without the postenhancement process (PE). It indicates that the SNR of enhanced speech in every case is increased and the SNR improvement can be up to 2.8 dB.

The result of MOS evaluation with scores ranging from 1 to 5 is shown in Table IV. Fifteen listeners, including ten males and five females, participated in the listening test. Ten utterances of Mandarin Chinese corrupted with two kinds of noises were played. Table IV shows that the postenhancement process has significantly improved the subjective quality. The improvements mainly come from the fact that the proposed method effectively smoothes the temporal evolvement of harmonics and thereby decreases the occurrence of artificial noises.

VII. CONCLUSION

This paper presents a set of harmonicities, i.e., grid, temporal, segment-spectral, and segmental harmonicities. These new harmonicities can be used for the systematic analysis of

TABLE II. Segmental SNR improvements for speech corrupted by white noise.

harmonic structure in an utterance so as to be applied to many tasks in speech and harmonic signal processing. In this study, applications to the speech distortion analysis, the robust F0 estimation, the robust voicing detection, and the speech enhancement are demonstrated. A series of experiments was conducted to show the effectiveness of the proposed harmonics analysis. It allows a detailed understanding of the spectral distortion in noise corruption conditions. The temporal harmonicity can be used for the validation of F0 estimation and the robust voicing detection. When the temporal and segment-spectral harmonicities are used to control an adjustable comb filter in the postenhancement process of a two-stage speech enhancement system, the artificial noise can be further reduced.

APPENDIX: LIST OF PARAMETERS

Parameter	Related equation	Description
$e(n,m)$	(1)	Sum of weighted magnitude spectral densities around the mth harmonics at the frequency bin index mk_0 in nth frame
$[(m-\eta)k_0,(m+\eta)k_0]$	(1)	Summation range for computing $e(n,m)$
$S(n,k)$	(1)	Magnitude spectral density of an analyzed signal in nth frame and kth frequency bin index
$\phi(k)$	(1), (2)	Harmonics selecting function
$h_D(n,m)$	(3)	Local spectral dominance of mth harmonics evaluated in nth frame
$D_T(n,m)$	(4)	Spectral magnitude variation between adjacent frames of mth harmonics evaluated in nth frame
$h_T(n,m)$	(5)	Temporal variation factor of mth harmonics evaluated in nth frame, with value between 0 and 1
$h_N(n,m)$	(6)	Neighbor dominance of mth harmonics evaluated in nth frame
$H_G(n,m)$	(7)	Grid harmonicity of mth harmonics evaluated in nth frame
$H_T(n)$	(8)	Temporal harmonicity evaluated in nth frame
$\alpha(n,m)$	(8)	Weighting factor for computing $H_T(n)$
$H_S(l,m)$	(9)	Segment-spectral harmonicity of mth harmonics evaluated over lth segment
$\beta(n,m,l)$	(9)	Weighting factor for computing $H_S(l,m)$
$H(l)$	(10)	Whole harmonic measure within lth segment
$\gamma(n,m,l)$	(10)	Weighting factor for computing $H(l)$
$\Phi(n,k,l)$	(12)	Comb filter for kth harmonics in nth frame and lth segment
$g(n,m,l)$	(12)	Gain function for smoothing the harmonics magnitude at mth harmonics
$\vartheta(k,m,l)$	(12), (13)	Kernel function of the comb filter
$g(n,m,l)$	(15)	Gain function

An automatic call recognition (ACR) process is described that uses image processing techniques on spectrogram images to detect and classify constant-frequency cricket and frog calls recorded amidst a background of evening sounds found in a lowland Costa Rican rainforest. This process involves using image blur filters along with thresholding filters to isolate likely calling events. Features of these events, notably the event's central frequency, duration and bandwidth, along with the type of blur filter applied, are used with a Bayesian classifier to make identifications of the different calls. Of the 22 distinct sonotypes (calls presumed to be species-specific) recorded in the study site, 17 of them were recorded in high enough numbers to both train and test the classifier. The classifier approaches 100% true-positive accuracy for these 17 sonotypes, but also has a high false-negative rate (over 50% for 4 sonotypes). The very high true-positive accuracy of this process enables its use for monitoring singing crickets (and some frog species) in tropical forests. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2355479]

I. INTRODUCTION

Biodiversity documentation is the first step in its effective conservation. Yet practical implementation of species-level surveys in tropical ecosystems invariably runs into the problem of taxonomic impediment, or the lack of expertise to provide the necessary identification of collected organisms. In addition, the need to physically collect specimens to produce species diversity estimates often proves costly, time consuming, and logistically difficult. For some groups of organisms using their acoustic signals provides a viable alternative to specimen collecting, and allows for monitoring of species richness, presence or absence of indicator species, or even estimates of abundance.[1]

Acoustic signaling is a widespread behavior among many terrestrial and aquatic animals.[2] Cicadas, orthopteroid insects (crickets, katydids, and relatives), frogs, birds, and bats are only some of the groups that can be monitored acoustically. Crickets (Orthoptera: Grylloidea) are particularly well suited for the purpose of acoustic monitoring because the range of frequencies employed by most species as a whole (1–12 kHz) is audible to humans, their signals are simple (few species employ frequency modulation), and their calls are species-specific.[3]

In most species of crickets the males produce audible calls using a modified area on their first pair of wings known as the stridulatory apparatus. Its basic design consists of a row of teeth on the underside of the right wing (the stridulatory file) that produce sounds when rubbed against a hardened edge (the scraper) of the left wing. The signal is amplified by the vibration of a membranous area of the wing (the mirror). In some species additional sound amplification and redirection is achieved by using leaves as acoustic baffles, or by singing from horn-shaped burrows. The resulting signal serves primarily as an attractant to conspecific females, and in most cases is unique and easily recognizable. This allows us to record and recognize individual acoustic signatures of each species (sonotypes) present in an area. The specificity of cricket calls even allows for using them to describe species in the absence of distinctive morphological characters typically used by insect taxonomists,[4,5] and to use the calls to identify species in the field.[6]

In many tropical ecosystems crickets dominate the acoustic space both in terms of the number of species signaling at any given moment, and the frequency spectrum of their calls. Most of the cricket calls' energy is within the audible part of the sound spectrum, and only some members of the subfamily Phalangopsinae produce ultrasonic calls in the range above 22 kHz.[7] This concentration of crickets' calls within the audible part of the spectrum, and their abundance in most ecosystems, makes them ideal candidates for long-term monitoring. At the same time crickets are very sensitive indicators of environmental change, as exemplified recently by the extinction of a number of Hawaiian species

due to invasion of exotic ant species.[8] Acoustic monitoring has already been successfully implemented in detection of rare or endangered insect species in temperate zones,[9] and the same technique can be used to monitor species richness and the presence of species indicative of particular changing habitat parameters in tropical ecosystems.[10]

Multiple encouraging papers on automated recognition of bioacoustics signals have been recently published for a range of animals, including bats,[11–13] birds,[14,15] anurans,[16] and Orthoptera.[17–19] Since cricket songs have a simple structure, the more involved techniques used in human speech recognition that have shown promise in bird song identification,[15] such as dynamic time warping and hidden Markov models, add unnecessary complication. Current research on Orthoptera call recognition[17–19] rely heavily on time-domain signal processing and require a high signal to noise ratio in order to properly analyze call waveforms. This same problem holds true with frequency-domain features commonly used in sound recognition such as spectrum flux and spectral power,[20,21] and mixed species choruses that vary in composition make these tools less useful. This reliance on low background noise severely limits the ability of these approaches to accurately identify crickets in tropical rainforests since numerous cricket species often call simultaneously and some of the quieter sounds present might be from crickets we are trying to detect. In the work presented here, an image processing approach is suggested as a method for detecting and classifying cricket (and some frog) calls recorded amidst the constellation of background noises typically found shortly after sunset in tropical forests.

II. MATERIALS AND METHODS

A. Sound recordings

In the work presented here we used field recordings of crickets from a lowland rainforest in La Selva Biological Station located in NE Costa Rica. Some of the recordings were made with in-house autonomous recording units that were placed midcanopy, and deployed to acoustically monitor crickets nightly for weeks at a time. However, to quicker

assemble a library of cricket calls at the site, hand-held recorders were also used. The autonomous recorders were placed midcanopy to effectively record sounds originating from both the canopy and the ground.[22] These devices used a PDA to make a 10 min recording nightly, starting 1 h after local sunset. PDAs where chosen since software can be written for them to make high-quality digital recordings at scheduled intervals. We used Hewlett Packard iPAC 5555 PDAs with a custombuilt power supply (rechargeable NiMH battery pack) and weatherproof case, and in-house scheduled-recording software.[23] The devices record sound at 44.1 kHz with 16-bit resolution and use a 16-element microphone and amplifier designed by the Bioacoustics Research Program at Cornell University. The microphone has a toroid beam-pattern and is very effective at collecting sounds within the canopy.

A spectrogram of a typical canopy recording is shown in Fig. 1; most of the sounds are from crickets and frogs. There are at least 8 distinct sonotypes (6 crickets and 2 frogs) present amidst a background of more distant individuals. While the frog calls are known for La Selva, no known libraries of cricket calls exist for the area. Work is still ongoing in assigning species labels to each acoustic signature and in the work presented here we designate our classifications as sonotype number.

B. Automatic call recognition (ACR)

The ACR process we use involves operating on a spectrogram image of a sound. Spectrograms created with a FFT size of 512 points, a Hanning window, and a 50% window overlap provide sufficient resolution in both time (5.8 ms) and frequency (86.1 Hz) to allow detection and classification of dozens of sonotypes at our site. As shown in Fig. 2, once
FIG. 2. Steps in automatic call recognition using the image processing presented here.
FIG. 3. 1 min average of spectrogram and zones to look for cricket and frog calls. Zone 1=0–0.75 kHz; Zone 2=0.75–3.6 kHz; Zone 3=3.6–7.1 kHz; Zone 4 =7.1–8.6 kHz; Zone 5=8.6–22 kHz.

the spectrogram is generated, the image is then filtered, events are detected, and finally the events are classified. Details for each of these steps follow.

C. Image filtering

The images are filtered in 3 steps. Initially the images are broken into 4–5 frequency bands within which to look for calls. The image is then sent through a blur filter. Finally, the image is sent through a thresholding filter, where a threshold level is applied independently for each frequency band.

The images are broken into 4–5 frequency bands based on relative background noise level. This allows the cutoff threshold of the thresholding filter to be adjusted for each frequency band, allowing calls in other frequency bands that are fainter than the background in the loudest frequency band to stand out. These frequency bands are chosen by calculating the average value of the intensity within the first minute of the spectrogram across all frequencies (Fig. 3). The different frequency bands are chosen by setting their boundaries as the positions which bound the various frequency intensity peaks. Bands are set to group intensity peaks such that intensity minimums are not higher than relative peaks within the band. In Fig. 3, band 3 (3.6 kHz–7.1 kHz) has the most intensity. If it were merged with frequency band 2 or 4, calls in those frequency ranges would not have a high enough dB level to be above the cutoff level of the thresholding filter and would not be detected. In the work presented here, these bands were chosen manually, however this step could be safely automated by using the frequency bin values generated in the first minute of each recording since they stay consistent throughout each of our 10 min canopy recordings.

1. Blur filters

For many loud constant-frequency calls, this filter can be bypassed. However, when the signal to noise ratio drops, bypassing this filter and going straight to the thresholding filter will extract only fragments of full calls. This is shown

in the long call centered around 5.25 kHz in Fig. 4, where only the first 80% of the call is shown as continuous when the thresholding filter is applied. With a higher signal to noise ratio, the entire call would be revealed as continuous. The event detection algorithm discussed shortly looks for continuous call chunks, and smaller call fragments would not necessarily be grouped together. A remedy for this is to use a filter to blur the image in order to get call fragments to connect. This works very well with a boxcar averaging blur filter applied prior to the thresholding filter, set to slightly blur only in time, not in frequency. With a boxcar averaging filter, the grey-scale value of each pixel in the new image $\widetilde{P}_{r,c}$ in row r and column c is the average of all the initial image pixel values $P_{r,c}$ within a rectangular swath (mask) centered over it, with width w and height h. With indices i and j, the boxcar averaging filter can be written as

$$\widetilde{P}_{r,c} = \frac{\sum_{i=-h}^{h} \sum_{j=-w}^{w} P_{r+i,c+j}}{(2h+1)(2w+1)}.$$

In the work presented here, we set $w=1$ and $h=0$, creating a slight blur in time, and none in frequency. This is effective for connecting most cricket call fragments. With our sampling rate and spectrogram parameters, this limits our time resolution to be on the order of 10 ms, which is sufficiently long for the crickets we recorded. The results of both the boxcar averaging blur filter with the thresholding filter and the thresholding filter on its own are shown in Fig. 5. The top image is of the spectrogram without any filtering, the middle with a thresholding filter, and the bottom image with both a boxcar averaging blur and thresholding filter. The thresholding filter is applied on the second frequency band. Two calls of the same sonotype are shown. The leftmost call is from a nearby individual, and the rightmost is from a more distant individual. This demonstrates how the signal detection degrades as the signal to noise ratio diminishes. Notice how the rightmost call in
FIG. 4. Thresholding filter example. Calls are separated from the background. Note that the lower frequency call (5.5 kHz) in the filtered image (bottom) becomes fragmented toward the end. The louder calls present remain intact in the filtered image. Blurring the image before applying the thresholding filter minimizes call fragmentation.

FIG. 5. Boxcar averaging blur filter with thresholding filter example. The thresholding filter is used in the bottom 2 images, between 750 Hz–3.6 kHz. The boxcar averaging blur filter is applied in the lower image. Note how the call fragments of the rightmost call in the middle image are connected to form a continuous call when both filters are applied in the bottom image, allowing easier identification. The call on the left is from an individual of the same species that is closer to the microphone.

the thresholding only filter is fragmented, whereas the call is continuous with the boxcar averaging blur filter.

Some cricket calls consist of a series of discrete chirps and this pulse train is repeated periodically. In these cases, applying a Gaussian blur filter

$$\widetilde{P}_{r,c} = \frac{\sum_{i=-2h}^{2h} \sum_{j=-2w}^{2w} P_{r+i,c+j} e^{-(i^2/2h^2)} e^{-(j^2/2w^2)}}{(4h+1)(4w+1)}$$

can smooth the pulse train into a continuous dash and facilitate detection. Here, the pixel values of the new image are generated on a weighted average (based on a normalized Gaussian distribution) of the pixel values of the initial image within a particular swath centered over each pixel. This can be seen in Fig. 6 with the sonotype consisting of a pulse train near 3 kHz. Images on the left are without the blur filter and the ones on the right are made with a Gaussian blur filter with $w=3$ and $h=0.5$. The lower 2 images show how the detection results change once the thresholding filter is applied. In the bottom left image where the blur filter is not used, each individual pulse is detected, whereas in the bottom right image where the blur filter is used, the entire

pulse train is detected as a single unit. In this image it is also interesting to see how the 5.5 kHz sonotype stands out more prominently from the background as the image is blurred. In the work presented here, we chose to use both of these blur filters empirically, based on their performance, and in the detection process, they are each run independently on all the sounds and are used to detect different sonotypes. In this way, the type of blur filter used serves as one of the features or parameters with which to classify a sonotype.

2. Thresholding filter

The purpose of the thresholding filter is to set a threshold of an intensity level required to consider a call present, and to condition the image for the event detection process. This process is done for each frequency band independently, each with a slightly different threshold level. The threshold level for each frequency band is set as an intensity level relative to the sound present in that frequency band (based on a running 10 s average). For the sound shown in Fig. 3, the sound level is a little higher in bands 3 and 4 than in bands 2 and 5, and a threshold level of 8 dB relative to the within-frequency band sound level is used, whereas a 9 dB threshold is used in bands 2 and 5. No known sonotypes from the site are low enough in frequency to be in band 1, so a threshold level on that band was not set. Adjusting the threshold levels slightly depending on the signal to noise ratio allows the calls to stand out better; however, keeping the threshold level at 8 dB would have produced good results. For the work presented here, these threshold levels were chosen manually, and better results might be obtainable
FIG. 6. Gaussian-blur with thresholding filter example. The blur filter is applied to the images on the right. In the lower images, a thresholding filter is applied. Note that when both filters are applied, the entire pulse train is selected as the event, not just the individual pulses as in the bottom left image. This facilitates the call recognition process. Also notice how the sonotype at 5.5 kHz is more prominent in the blurred image. This shows how blurring can make a pattern more pronounced.

in an automated process by running the same sections at a range of threshold levels and using the results that yield the most events.

D. Event detection

After the filtering, a block detection algorithm is run to find events within the spectrogram that might be cricket calls. This algorithm goes through the filtered image keeping track of blocks of nonblank pixels that meet specific structural requirements based on 4 parameters: maximum bandwidth (8 pixels, 689 Hz), maximum time allowed to exceed bandwidth (4 pixels, 23 ms), minimum duration (3 pixels, 17 ms), and maximum duration (241 pixels, 1.4 s). The values for these parameters are set near the extreme values of the collection of sonotypes to minimize computation time on events that will not be classified as known sonotypes. During the exploratory phase, when sonotype ranges are being determined, this added efficiency can lead to missed calls. Since we are looking for constant-frequency calls, there is an additional constraint that as the image is swept along the time axis, at least one pixel in the current time band must fit within the frequency bandwidth swept out to that point by the event. This allows the event bandwidth to increase throughout a call, but does not allow it to capture steep sweeping calls; though, it could be modified to do so. The "maximum time allowed to exceed bandwidth" parameter allows short-time broadband noise such as a rain drop to not interfere with detecting a call.

E. Event classification

Once the events in the spectrogram are detected, features are automatically measured from these pixel clusters and the calls are classified as particular sonotypes, or as unknown events. The features measured from each event are the central frequency, bandwidth, duration, and type of blur filter used. These features separate the sonotypes recorded at our site with little overlap, and we designed a Bayesian classifier to label events as belonging to particular sonotypes. Distributions of the features of the training set of sonotypes are used to generate 95% confidence intervals for these features

for each sonotype, and these intervals serve as the decision bounds for the classifier. For the sonotypes we recorded enough times to both train and test, these 4 features completely separate each sonotype. However, for 2 of the sonotypes that we recorded in too low of number to both train and test the classifier, the additional features of the time gap between similar calls as well as the number of similar calls in a pulse train are required to fully separate these sonotypes from others. Since we have very few recordings of these sonotypes, these 2 additional features were not automatically generated in our testing sets, and these additional sonotypes went undetected in our testing trials (none were even detected manually).

III. FIELD RESULTS

Twenty-two distinct constant-frequency sonotypes were identified from the site. Two sonotypes, ST101 and ST102, are from frogs, whereas the remaining sonotypes are from crickets. Most of the sonotypes are separable with the central frequency, duration, and blur filter used. Figure 7 shows the distribution of training samples for the 22 sonotypes recorded, plotted as central frequency vs duration. A Gaussian blur filter is used to find sonotype 2; each of the other 21 sonotypes are found by applying a boxcar averaging blur filter. A 95% confidence interval of the distribution of each sonotype is shown as an ellipse over the distribution points. A few of the ellipses have some overlap (ST 15, ST 22, ST 23) and require additional features for separation. These 95% confidence intervals serve as the decision boundaries for the Bayesian classifier. Only 1 call for sonotype 8 and 9 was found, so the arbitrarily set confidence interval around them only serves to show the approximate bounds with which to try to detect those calls (no additional calls were found for either sonotype).

A confusion matrix for the 17 sonotypes recorded enough times to both train and test, separated with only 4 features (central frequency, duration, bandwidth, and blur filter), is shown in Table I. Sonotypes 6, 8, 9, 14, and 15, present in Fig. 7, were not found enough times to do both training and testing, and are absent from Table I. "Unknown"
FIG. 7. (Color online) Two of the features used to separate sonotypes, central frequency and call duration, are shown for 22 sonotypes. The estimated 95% confidence interval around the distributions are represented by ellipses. Gaps between the sonotypes indicate possible openings for additional species we did not record.

TABLE II. Accuracy measures for 17 sonotypes based on the confusion matrix in Table I.

	True positive	False negative	Train/test detections (N)
ST 1	97.78%	78.85%	3/44
ST 2	100%	17.86%	25/46
ST 7	100%	71.55%	290/865
ST 10	100%	25.00%	20/114
ST 11	100%	26.32%	8/28
ST 12	100%	17.85%	50/336
ST 13	98.15%	24.64%	75/159
ST 16	100%	67.82%	24/65
ST 17	100%	11.58%	298/741
ST 18	100%	42.78%	56/226
ST 19	100%	38.89%	15/55
ST 20	100%	08.62%	40/371
ST 21	100%	41.30%	12/27
ST 22	100%	08.33%	50/363
ST 23	100%	37.50%	10/35
ST 101	100%	68.42%	7/6
ST 102	100%	42.16%	279/834

calls are defined as events that have feature values outside of the estimated ranges of the sonotypes defined by the training set. Since many crickets call in pulse trains, instead of choosing training and testing sets randomly, entire pulse trains were used for either training or testing. This was done by designating the first samples of sonotypes found within sound files manually as the training set, and sonotypes found manually in subsequent files as the testing set. Accuracy percentages from the confusion matrix are shown in Table II, along with the number of training and testing samples. Sample number of test detections are counted as the number of correct detections of a sonotype during the testing phase.

IV. DISCUSSION

One of the interesting aspects of the sonotypes in Fig. 7 is their distribution. The degree to which the sonotype fea-

ture values overlap provides insight into how accurate the classifier is. With no overlap in these distributions, the classifier will be 100% accurate in its classifications. The shape of the collective distribution of sonotype features and the degree to which this area is filled with sonotypes is also noteworthy. The sonotype feature distributions collectively in Fig. 7 appear bound by a curve, limiting cricket calls between approximately 3 kHz and 12 kHz, and allowing a wider range of call durations at the lower frequencies, gradually shortening maximum call duration up to the 12 kHz calls. It is likely that the bounds of this curve are determined by the stridulatory apparatus of the crickets at our site. If the area of usable feature space is bound by cricket physiology, then the degree to which this area is saturated with cricket sonotypes might be insightful in determining the degree to which the ensemble of cricket species at a site have remained

TABLE I. Confusion matrix for 17 sonotypes. Actual classifications are in the leftmost column, and the assigned classifications in the topmost row. Correct identifications are indicated on the diagonal. Events labeled as "unknown" by the classifier are shown in the column labeled "UNKN."

intact. Gaps in feature space could also be due to lack of time spent collecting recordings for an area, and sonotype overlaps could occur without causing interference problems if those species seldom call at the same time of day or year. Interesting gaps that exist in Fig. 7 include the frequency range between 8.6 kHz and 11.7 kHz, and calls over 0.3 s long between 3.6 kHz and 5 kHz. Implications for these gaps require further study.

For most sonotypes shown in Fig. 7, the duration varies more than central frequency. Some of this is an accurate representation for the variation in call length, such as for sonotype 16. For other sonotypes, such as sonotype 2, the lower end of the distribution is a little misleadingly stretched. When the sonotypes are recorded with a high signal to noise ratio, their features are measured accurately. However, when the sonotype is fainter, only fragments of the call are detected. The blur filter goes a long way towards connecting these fragments, but with sonotype 2 in particular, the intensity of the call increases throughout the duration of the call (Fig. 6) and the measured duration of the call will vary depending on how loud the quieter beginning of the call is (how far away the insect is from the microphone). By accepting a larger range in the call duration, the Bayesian classifier is able to detect more distant individuals than it would otherwise. By increasing the acceptable range of a feature like this, the possibility of misclassification increases if the range of features of different sonotypes begin to overlap. To avoid misclassification in this situation, additional features are needed. Sonotype 2 is the only sonotype listed that is measured after a Gaussian blur is applied, so the use of the filter itself would safely allow accurate classification if sonotype 2 had feature distributions that overlapped different sonotypes.

The central frequency of the sonotypes have some spread to them, some more than others. The variation captured in Fig. 7 mostly reflects the variation within a pulse train and the variation between individuals. Air temperature can play a large role in central frequency shift of a sonotype but did not for the work presented here since the air temperature during the recordings varied little within the extremes of 22.5 °C and 24.4 °C. In cases where air temperature can change more dramatically, training set sonotypes need to be recorded at multiple temperatures. Central frequency does not noticeably shift as a function of air temperature for all cricket species, but for the species that air temperature does affect this way, the shift in central frequency is linear.[24,25] For these sonotypes, once the linear relationship between central frequency and air temperature is found, air temperature during a recording should be used as a parameter to estimate the acceptable distribution of central frequencies for these sonotypes when trying to detect them.

A. Improving performance

The approach to ACR described in this work very accurately identifies our sonotypes, but the emphasis is clearly on keeping a high true-positive accuracy at the expense of false-negative accuracy. Our application is in monitoring sonotypes from canopy recordings, and since most crickets call in

pulse trains, presence and absence can be readily determined even by detecting only some of the pulses in those pulse trains. In general, there is no need to detect each call within the entire sequence of calls. Two separate sources of error arose to lower the true-positive accuracy in 2 sonotypes down from 100%, although still above 97.5% (Table II). In one instance, a consecutive string of sonotype 102 calls completely overlapped to create an event that matched sonotype 1. In the other instance, a few faint calls of sonotype 16 had degraded to the point that they resembled the shorter and smaller bandwidth calls of sonotype 13. Each of these instances point out how the duration and bandwidth features detected from events can lead to some misclassifications with sonotypes that have overlapping central frequency distributions. To decrease these misclassifications, additional features such as the time gap between similar events and the number of similar events within a specified amount of time (duration of a pulse train) can be used to make accurate identifications. These features look to have little variance for many of the sonotypes, particularly the short duration ones which are more likely to lead to misclassifications. To detect these features, most of the calls within a sequence of calls will need to be detected. Call sequences recorded with a high signal to noise ratio have enough of their calls detected to measure these features. Requiring these features for classification would increase the false-negative percentage for these sonotypes, but would also improve the true-positive percentage to nearly 100%.

Most crickets call in a rather continuous pulse train, and when trying to establish the presence or absence of sonotypes, it is not necessary to detect each call within a pulse train, only some of them. Table II shows that the false-negative classification percentage of 4 sonotypes is above 50%. While not generally a problem when detecting presence or absence of a sonotype, it is desirable for these percentages to be lower. The reason for these high values is mostly due to not having a wide enough distribution of feature values for those sonotypes. For sonotypes 1 and 101, this is likely due to having small training sets ($N=3$ and 7, respectfully). The other 2 sonotypes, ST7 and ST16, have many more training samples, but they are likely not varied enough. Each training set was chosen as the first sonotype instances encountered, not randomized from a group of known instances. Randomizing this training process would likely allow the feature distributions for these sonotypes to be expanded while keeping the number of training samples the same.

B. Finding novel calls

When looking at class distributions similar to the ones shown in Fig. 7, the possibility of using clustering techniques to determine class boundaries in an automated way looks intriguing. In this paper, the class assignment of the training sonotypes is done manually by grouping calls that look nearly identical and are often part of a continuous series of call sequences, and they are presumed to come from the same species. If the training was done with isolated calls recorded with a high signal to noise ratio, using automated

clustering techniques might well be possible. The training sets, though, are created from field recordings with various background sounds. This results in miscellaneous noises being classified as events along with sonotypes. Since the sonotypes are not necessarily more numerous than miscellaneous noises, the events are manually classified.

After the training phase, clustering of unknown calls might provide an automated way to find novel calls, at least those that have a duration longer than 0.2 s. Most of the unknown events are short in duration, and applying a minimum duration filter goes far towards weeding out events that are not novel sonotypes. Once enough of these filtered events are found, a clustering method such as from Diday[26] might be useful in finding clusters that correspond to novel sonotypes. A dynamic clustering method such as this would likely be a good choice since it allows the clusters to be elongated, as many of the manually classified sonotype clusters are.

V. CONCLUSIONS

The ACR process described in this paper detects constant-frequency cricket and frog calls with a high true-positive accuracy. The accuracy of this approach largely depends on how comprehensively sonotypes are known for an area, and to what extent the sonotype feature values overlap. The success of this process shows that image processing techniques applied to spectrogram images can provide a useful approach in ACR applications. This process works with recordings made in tropical forests, where multiple species can call simultaneously and numerous background noises are present, and can be used to monitor presence or absence of cricket species that have constant-frequency calls, or relative abundance measures if there are multiple recording locations. Potential for misclassification of cricket sonotypes is largely dependent on how complete the libraries of cricket calls for an area are, and how well variation in those calls is known. The more complete an understanding there is for the type of calls that can be encountered, the more accurately the feature-space can be partitioned for each sonotype, and the more accurately the automated process will run.

Detection of acoustic cavitation in the heart with microbubble contrast agents *in vivo*: A mechanism for ultrasound-induced arrhythmias

Claudio Rota, Carol H. Raeman, Sally Z. Child, and Diane Dalecki[a]
Biomedical Engineering and the Rochester Center for Biomedical Ultrasound, University of Rochester,
309 Hopeman Building, P.O. Box 270168, Rochester, New York 14627

Ultrasound fields can produce premature cardiac contractions under appropriate exposure conditions. The pressure threshold for ultrasound-induced premature contractions is significantly lowered when microbubble contrast agents are present in the vasculature. The objective of this study was to measure directly ultrasound-induced cavitation in the murine heart *in vivo* and correlate the occurrence of cavitation with the production of premature cardiac contractions. A passive cavitation detection technique was used to quantify cavitation activity in the heart. Experiments were performed with anesthetized, adult mice given intravenous injections of either a contrast agent (Optison®) or saline. Murine hearts were exposed to ultrasound pulses (200 kHz, 1 ms, 0.1–0.25 MPa). Premature beats were produced in mice injected with Optison® and the likelihood of producing a premature beat increased with increasing pressure amplitude. Similarly, cavitation was detected in mice injected with Optison® and the amplitude of the passive cavitation detector signal increased with increasing exposure amplitude. Furthermore, there was a direct correlation between the extent of cavitation and the likelihood of ultrasound producing a premature beat. Neither premature beats nor cavitation activity were observed in animals injected with saline and exposed to ultrasound. These results are consistent with acoustic cavitation as a mechanism for this bioeffect. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2346132]

I. INTRODUCTION

Alterations in cardiac rhythm can occur in response to ultrasound at appropriate exposure conditions. Early work by Smailys *et al.* (1981) demonstrated that continuous-wave (CW) ultrasound could stop ventricular fibrillation in the dog heart *in vivo*. Lithotripter fields can produce premature cardiac contractions in mammalian and amphibian hearts *in vivo* (Dalecki *et al.*, 1991; Delius *et al.*, 1994). The threshold for producing a premature contraction with a lithotripter is 2–5 MPa when the pulse is delivered to the heart during the most sensitive phase of the cardiac cycle (i.e., TP segment, diastole) (Dalecki *et al.*, 1991; Delius *et al.*, 1994). A single pulse of ultrasound at high amplitude can also produce premature contractions in laboratory animals (Dalecki *et al.*, 1993a, b; MacRobbie *et al.*, 1997). The threshold for producing a premature contraction in the murine heart with a single 5-ms pulse of ultrasound at 1.2 MHz is ~2 MPa (MacRobbie *et al.*, 1997). The threshold increases with increasing frequency and decreasing pulse duration (Dalecki *et al.*, 1993a, b). A series of repetitive, high-amplitude ultrasound pulses can capture and pace the heart *in vivo* (Dalecki *et al.*, 1993a). Studies have shown that neither thermal nor radiation force mechanisms are responsible for ultrasound-induced premature contractions (Dalecki *et al.*, 1993b, 1997a).

Ultrasound contrast agents are stabilized microbubbles that are injected intravascularly to enhance diagnostic ultrasound imaging. Some ultrasound imaging techniques that use contrast agents depend upon the acoustic excitation of the microbubbles *in vivo*. Acoustic cavitation describes the interaction of a sound field with an existing gas cavity. Under appropriate exposure conditions, cavitation can produce various physical phenomena, including localized shear stresses, high collapse temperatures and pressures, microstreaming, and shock formation (e.g., Young, 1989). Evidence from numerous studies indicates that the presence of microbubble contrast agents in the blood can decrease the threshold for various ultrasound-induced biological effects *in vitro* and *in vivo*, such as hemolysis, capillary rupture, and sonoporation (for review see AIUM, 2000; NCRP, 2002; Dalecki, 2005a).

The stimulation of a premature cardiac contraction without contrast agents requires a high-amplitude ultrasound pulse of long duration, as discussed above. Thus, there is no evidence for the production of premature cardiac contractions with diagnostic ultrasound in the absence of contrast agents. However, recent studies indicate that when microbubble contrast agents are present in the blood, the threshold for ultrasound-induced premature contractions is reduced significantly compared to the threshold in the absence of contrast agents (van der Wouw *et al.*, 2000; Li *et al.*, 2003, 2004; Dalecki *et al.*, 2005b; Rota, 2005). For instance, the acoustic pressure threshold for producing a premature beat in the mouse with a 1.2-MHz, 5-ms pulse of ultrasound is approximately an order of magnitude lower with contrast

[a]Author to whom all correspondence should be addressed. Electronic mail: dalecki@bme.rochester.edu

agents (Dalecki *et al.*, 2005b) compared to the threshold without contrast agents (MacRobbie *et al.*, 1997). Furthermore, premature contractions can be produced with diagnostically relevant ultrasound exposures when contrast agents are in the blood (van der Wouw *et al.*, 2000; Li *et al.*, 2003, 2004; Dalecki *et al.*, 2005b; Rota, 2005). Li *et al.* (2003, 2004) found a threshold of ~1 MPa for the production of premature contractions in rats injected with a microbubble contrast agent and exposed to a commercial diagnostic imaging device operating at 1.7 MHz. The threshold for premature contractions in mice injected with contrast agent and exposed to a single, 10-μs pulse of ultrasound at 1.2 MHz is also ~1 MPa (Dalecki *et al.*, 2005b). Premature beats have also been reported in humans injected with an experimental contrast agent and exposed to diagnostic ultrasound at 1.66 MHz with end-systolic triggering and a mechanical index (MI) of 1.5 (van der Wouw *et al.*, 2000). The increased sensitivity of the heart to ultrasound exposure when contrast agents are present is consistent with acoustic cavitation as a mechanism for ultrasound-induced premature cardiac contractions.

In this study, we tested directly the role of acoustic cavitation as a mechanism for ultrasound-induced premature contractions in the presence of microbubble contrast agents. Experiments were designed to measure ultrasound-induced cavitation in the murine heart *in vivo* and to determine whether the occurrence of cavitation is correlated with the production of premature cardiac contractions. A passive cavitation detection (PCD) technique was used to quantify cavitation activity in the heart. A low ultrasound frequency (200 kHz) and long pulse duration (1 ms) were used to lower the threshold for acoustic cavitation. We hypothesized a direct correlation between the occurrence of cavitation and the production of premature cardiac contractions *in vivo*.

II. EXPERIMENTAL METHODS

A. Exposure apparatus

The acoustic source for this investigation was a 200-kHz, 4-cm diameter, unfocused transducer (Model P19, Airmar Technology Corp., Milford, NH). A wave-form generator was used to produce a sinusoidal signal (Hewlett Packard, Model HP33120) at 200 kHz with pulse duration of 1 ms. An attenuator (Kay Elemetrics Corp., PMAX) and rf amplifier (Model 1040L, ENI, Rochester, NY) controlled the amplitude of the signal delivered to the transducer. Acoustic fields were calibrated daily with a probe hydrophone (TC-4038, Reson Inc., Goleta, CA) in a tank of degassed and deionized water. The hydrophone was attached to and moved by a three-way positioning system. The transaxial −6-dB beam width of the transducer was 3.0 cm at a distance of 9 cm from the source.

The apparatus used in this study is shown in Fig. 1. This top view of the water tank illustrates the relative orientation of the 200-kHz source and the 5-MHz passive cavitation detection (PCD) transducer with respect to the exposure site (vial or mouse). The 5-MHz PCD transducer was positioned at a 45-deg angle with respect to the 200-kHz source. For *in vitro* studies, the exposure site consisted of a 4.6-mL dispos-

TOP-VIEW
FIG. 1. Exposure setup for passive cavitation detection (PCD) *in vitro* (with vials) and *in vivo* (with mice). The ultrasound source was a 200-kHz unfocused transducer. The PCD transducer was a 5-MHz focused source.

able polyethylene pipet (Fisher Scientific) positioned at a distance of 9 cm, on-axis, from the 200-kHz source. For *in vivo* studies, mouse hearts were also positioned at a distance of 9 cm, on-axis, from the 200-kHz transducer.

A 5-MHz focused transducer (V309, Panametrics, MA) was used as the PCD transducer. For this transducer, the −3-dB axial beam width was 3.5 cm and the −3-dB transaxial beam width was 1 mm. Alignment of the focus of the 5-MHz PCD transducer with the exposure site of the 200-kHz source was accomplished by using the PCD transducer as a pulser receiver (Model 5052PR, Panametrics, MA). A hydrophone was first used to determine coordinates from a fixed pointer in the water tank to the exposure site in the 200-kHz field. Using these coordinates, a 0.1-in. diameter steel ball was then positioned at the exposure site. The 5-MHz PCD transducer was focused on the exposure site by maximizing the received echo signal from the steel ball.

The output of the 5-MHz PCD transducer was connected to a 2-MHz high-pass filter (Model 3940, Krohn-Hite Corp., MA). The cut-off frequency of 2 MHz ensured removal of the 200-kHz incident and scattered field from the spectrum of the PCD output. The filtered PCD output signal was displayed on a digital oscilloscope (Model LT342 WaveRunner, LeCroy Corp., NY). The extent of cavitation activity was quantified as the root-mean-square (rms) of the signal received by the PCD transducer (e.g., Everbach *et al.*, 1997).

B. *In vitro* protocol

Experiments were performed initially with an *in vitro* model in order to validate the cavitation detection technique and provide insight for interpreting later measurements of cavitation *in vivo*. Experiments *in vitro* were performed using cylindrical disposable vials (i.e., polyethylene transfer pipets, Fisher Scientific) approximately 1.4 cm in diameter and 4 cm in height. Each vial was filled with either (1) air, (2) degassed water, or (3) degassed water with Optison®. In samples with microbubble contrast agent, the Optison® was administered as a single injection (0.02 mL) into the pipet immediately prior to the experiment. Each vial was positioned on axis, at a distance of 9 cm from the 200-kHz source, using coordinates obtained by hydrophone measurements from a fixed pointer in the tank to the exposure site.

The PCD apparatus was used to quantify the extent of cavitation activity produced in the vial by exposure to pulses of ultrasound from the 200-kHz source. For each vial (air, water, and water+Optison®), ten, 200-kHz ultrasound pulses

J. Acoust. Soc. Am., Vol. 120, No. 5, November 2006

Rota *et al.*: Detection of cavitation in the heart   2959

were delivered with a pulse repetition period of ~2 s. The duration of each pulse was 1 ms. Peak pressure amplitudes investigated were 0.05, 0.1, 0.2, and 0.25 MPa. Each vial was exposed to only one pressure amplitude (total of ten pulses per vial). During each exposure, the PCD output was recorded and downloaded to a computer. Measurements were also performed without any vial in the field (free field).

C. *In vivo* protocol

All animal protocols were approved by the University of Rochester Committee on Animal Resources. Adult, male (CD1) mice (~30 g) were anesthetized by intramuscular injections of ketamine hydrochloride (60 mg/kg) and xylazine hydrochloride (10 mg/kg) using a 26-gauge needle. Following anesthesia, the ventral chest area was shaved and depilated (Nair®, Church & Dwight Co., Inc., Princeton, NJ) to minimize entrapment of air bubbles on the skin during exposure. Each mouse was secured on a custom-made holder and supported by limb restraints. Dissection of several mice determined the location of the mouse heart to be ~1-cm cephalad to the caudal tip of the sternum and 2–3 mm to the animal's left side. This point was marked with a dot on the skin surface to aid in positioning the heart in the acoustic field. The animal holder was then attached to the three-way positioning system and placed in the water tank. Using coordinates between a fixed pointer and the exposure site determined using the hydrophone, the marked dot on the skin was positioned at the exposure site. The focus of the PCD detector was aligned with the exposure site of the 200-kHz source as described previously. The PCD transducer was then used as a pulse/echo device to ensure that the focus was on the heart and not the highly reflective lungs.

A three-lead electrocardiogram (ECG) was obtained by subcutaneous placement of 25-gauge needles in the limbs. The ECG signal was acquired via a data acquisition system (PowerLab/8SP, ML785, ADInstruments, Grand Junction, CO) that allowed direct monitoring of the ECG on a personal computer and storage of the ECG for further analysis. A front-end preamplifier acquired the ECG signal from the animal (BioAmplifier ML136, ADInstruments, Grand Junction, CO). The ECG signal was sampled at a rate of 1 kHz. A custom-designed triggering device was used to trigger the 200-kHz source at the desired time during the cardiac cycle (diastole). Both the ECG and triggering signal were recorded by the data acquisition system.

Experiments were performed with mice injected with either Optison® or saline. Injections were performed with a 25-gauge needle from a modified ButterflyOptison® infusion set (Dalecki *et al.*, 1997b) inserted into the tail vein of the mouse, and secured with surgical tape (Micropore™, 3M, St. Paul, MN). Each animal received two bolus injections of either Optison® or saline at separate times during the experiment. For Optison® injections, 0.01 mL of the contrast agent was diluted in 0.3 mL of saline to obtain a dose of 3 μL/bolus. Each animal was administered with the same total injection volume (100 μL/bolus). The first bolus was delivered prior to the first ultrasound pulse, and the second bolus was given halfway through the experiment. Mice in-
FIG. 2. Acoustic cavitation detected inside a water-filled vial prior to (a) and after (b) an injection of Optison® The start and end of the 200-kHz ultrasound pulse are shown by the arrows. The ultrasound pulse duration was 1 ms and the peak pressure amplitude was 0.2 MPa. Time/division: 0.2 ms.

jected with Optison® ($n=10$) and mice injected with saline ($n=5$) underwent the same experimental protocol.

Experiments were performed to correlate ultrasound-induced premature contractions with the extent of cavitation activity in the heart as measured with the PCD transducer. Each ultrasound exposure consisted of a 1-ms pulse of 200-kHz ultrasound delivered to the heart during diastole. Acoustic pulses were delivered during diastole because previous studies have shown that the lowest threshold for ultrasound-induced premature beats occurs when the ultrasound pulse is delivered during diastole (Dalecki *et al.*, 1993a; MacRobbie *et al.*, 1997). Peak pressure amplitudes investigated were 0.1, 0.15, 0.2, and 0.25 MPa. Each mouse received ten pulses at each pressure amplitude (i.e., a total of 40 pulses) in a randomized order. The time between each exposure pulse was ~5 s. The PCD apparatus was used to quantify the extent of cavitation activity produced in the heart by each pulse of ultrasound from the 200-kHz source. Simultaneously, an investigator blind to exposure condition observed the ECG and recorded whether or not each ultrasound pulse produced a premature contraction. At the end of each experiment, animals were euthanized under anesthesia and the heart was examined for gross hemorrhage.

III. RESULTS

A. *In vitro* results

In vitro studies primarily provided validation of the PCD technique that was later implemented with mice *in vivo*. Figure 2 shows an example of the signal received by the PCD transducer from a water vial exposed to an ultrasound pulse both prior to and after an injection of Optison®. The ultrasound pulse was at 200 kHz with pulse duration of 1 ms and pressure amplitude of 0.2 MPa. The beginning and end of the ultrasound pulse are marked by the arrows (ON and OFF, respectively). Without microbubbles present in the water vial

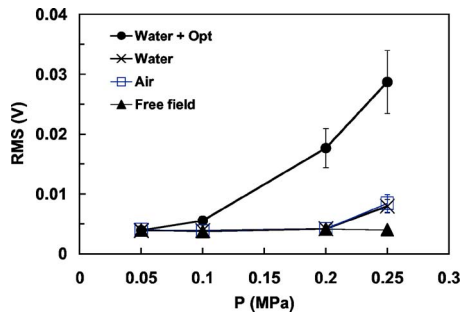
Rota *et al.*: Detection of cavitation in the heart


FIG. 3. Cavitation detection *in vitro*. Plotted are the mean rms (RMS) values of the output of the PCD transducer as a function of pressure amplitude of the 200-kHz ultrasound pulse. Each data point is an average of ten measurements (i.e., ten acoustic pulses) from five separate vials (total of 50 measurements). Measurements were performed with vials filled with degassed water+Optison® (solid circles), degassed water (crosses), air (open squares), or with no vial, free field measurements, (solid triangles). Error bars are standard error of the mean.

[Fig. 2(a)], no cavitation activity was detected. With microbubbles [Fig. 2(b)], significant cavitation levels were measured for the entire duration of the ultrasound pulse. Spectral analysis of the PCD output verified that the 200-kHz incident and scattered field were removed from the signal by the 2-MHz high-pass filter. The PCD output from vials with microbubbles had a broadband noise spectrum as expected from the violent collapse of bubbles in inertial cavitation.

Results of cavitation detection experiments using different vial contents are summarized in Fig. 3. This figure presents the mean of the rms (RMS) signals from the PCD transducer as a function of pressure amplitude of the incident 200-kHz ultrasound pulse. Each data point is an average of ten measurements (ten pulses/pressure amplitude) from n =5 separate vials. Thus, each data point is the mean of 50 measurements. At 0.05 MPa, RMS values were indistinguishable from the noise floor and from free field measurements (solid triangles) regardless of the vial content. This finding confirmed that the 2-MHz filter successfully removed any incident or reflected sound from the PCD output. For instance, without the 2-MHz filter, an air-filled vial (simulating the highly reflecting lung) produced a strong signal due to reflection of the 200-kHz sound (i.e., a pressure release interface). Instead, with the filter, RMS values from both air (open squares) and water (crosses) vials were negligible up to ~0.25 MPa. The small yet measurable increase in RMS found with both air and water vials at 0.25 MPa likely indicates that cavitation activity may have occurred in the water medium surrounding the vials only at this highest pressure amplitude.

In vials containing Optison® and water (solid circles), the mean of the rms (RMS) signals from the PCD was significantly increased compared to free field measurements with pressure amplitudes as low as 0.1 MPa (Fig. 3). Furthermore, RMS ms values in the presence of Optison® were substantially greater than air or water vials alone. The magnitude of the RMS of the PCD signal in the presence of Optison® increased with increasing pressure amplitude of the 200-kHz incident field.
FIG. 4. ECG demonstrating ultrasound-induced premature contractions in a mouse injected with Optison® and exposed to 200 kHz ultrasound pulses. Each ultrasound pulse was of duration of 1 ms. Ultrasound pressure amplitudes were 0.15 and 0.2 MPa (first and second arrows, respectively).

B. *In vivo* results

An ECG illustrating a premature cardiac beat produced by a single ultrasound pulse is shown in Fig. 4. In the figure, two premature ventricular contractions are shown for a mouse injected with Optison® microbubbles and exposed to ultrasound. Both premature contractions developed immediately following the delivery of a 200-kHz ultrasound pulse of 1-ms duration (arrows indicate delivery of the ultrasound pulse). Pressure amplitudes were 0.15 and 0.2 MPa (first and second arrows, respectively). Typical features of a premature beat included a premature and abnormal ventricular depolarization signal (QRS), commonly followed by a compensatory pause. No evidence of gross hemorrhage to the myocardium was found in any mice.

Figure 5 depicts the mean percentage of pulses producing a premature beat as a function of pressure amplitude. For each pressure amplitude, the percentage of delivered pulses resulting in a premature cardiac contraction was determined for each mouse, and then results from all mice were used to determine the mean percentage for each exposure condition. Each data point is the mean of either 100 measurements (Optison®, $n=10$) or 50 measurements (saline, $n=5$). No premature beats were observed in any of the mice injected with saline and exposed to ultrasound (open diamonds). In comparison, in mice injected with Optison® (solid circles), the mean percentage of pulses producing a premature beat increased with increasing pressure amplitude. The increase was approximately linear up to 0.2 MPa, at which point pulse
FIG. 5. Mean percentage of ultrasound pulses producing a premature beat as a function of pressure amplitude of the 200-kHz incident pulse. Pulse duration was 1 ms. Solid circles are data for mice injected with Optison® ($n=10$) and open triangles are data for mice injected with saline ($n=5$).

FIG. 6. Acoustic cavitation detected in the mouse heart *in vivo*. Shown is the output of the PCD transducer following delivery of an ultrasound pulse to a mouse heart with contrast agent. Ultrasound pulse was at 200 kHz with pulse duration of 1 ms and pressure amplitude of 0.2 MPa. PCD signal was filtered with a 2-MHz high-pass filter. An expanded view of the PCD signal is shown at bottom. Time/div.=0.2 ms (top).

effectiveness leveled off since the heart was nearly 100% responsive to ultrasound stimulation. Standard errors of the mean (SEM) decreased with increasing pressure amplitude indicating less variance in cardiac response at the highest acoustic pressures.

During the ultrasound exposures, the PCD transducer was used to quantify the extent of cavitation activity in the heart. An example of cavitation detected in vivo is shown in Fig. 6. In this example, the mouse was injected with Optison[®] microbubbles and exposed to a pulse of ultrasound (200 kHz, 1 ms) at a pressure amplitude of 0.2 MPa. Figure 7 depicts the results of cavitation measurements *in vivo* for
FIG. 7. Cavitation detection *in vivo*. Plotted are the mean rms (RMS) values of the output of the PCD transducer as a function of pressure amplitude of the 200-kHz ultrasound pulse. Pulse duration was 1 ms. Results are shown for both mice injected with Optison[®] (solid circles) and mice injected with saline (open diamonds). Each data point is the mean of either 100 measurements (Optison[®], $n=10$) or 50 measurements (Saline, $n=5$). Error bars are standard error of the mean.
FIG. 8. Correlation between the amplitude of the rms of PCD output and premature beats in mice injected with Optison[®] ($n=10$). Ultrasound frequency and pulse duration were 200 kHz and 1 ms, respectively. Pressure amplitudes were 0.1, 0.15, 0.2, and 0.25 MPa.

mice injected with either saline (open diamonds) or Optison[®] (solid circles). In the figure, the mean (RMS) of the PCD transducer output is plotted as a function of pressure amplitude of the incident 200-kHz ultrasound pulse. Each data point is the mean of either 100 measurements (Optison[®], number of mice=$n=10$) or 50 measurements (saline, $n=5$). In mice injected with Optison[®], the RMS of the PCD signal increased linearly with increasing pressure amplitude of the 200-kHz incident ultrasound pulse ($R^2=0.999$). In animals injected with saline, RMS measurements were indistinguishable from the noise floor. As in experiments *in vitro*, there was a slight increase in the RMS at 0.25 MPa that presumably is indicative of cavitation in the water only at this highest pressure amplitude.

The correlation between amplitude of the rms PCD signal and ultrasound-induced premature beats in mice injected with Optison[®] is shown in Fig. 8. In the figure, the mean percentage of pulses producing a premature beat is plotted as a function of the rms of the PCD output for five ranges of rms values. The data were pooled from all animals injected with Optison[®] ($n=10$). When small rms values were detected (<0.01 V), few pulses resulted in a premature beat (15.1%). However, an increase in the amplitude of the PCD output correlated with a monotonic increase in the percentage of pulses producing a premature beat. Thus, the figure indicates that as the extent of cavitation activity increased (as quantified by the rms of the PCD signal), the likelihood of producing a premature cardiac contraction increased.

IV. DISCUSSION

Microbubbles undergoing acoustic cavitation act as secondary sources of sound. Detection and analysis of these acoustic emissions is often used as a way to monitor the occurrence of acoustic cavitation and distinguish between noninertial and inertial cavitation (Neppiras, 1980; Apfel, 1981). At low exposure pressures, the spectrum of the acoustic emissions from nonlinear oscillations of microbubbles includes harmonics, ultraharmonics, and subharmonics of the exposure frequency (Apfel, 1981; Leighton, 1994). Spectra

of acoustic emissions for inertial cavitation activity are characterized by a broadband distribution of frequencies, white noise, attributable to the violent collapse of bubbles (Akulichev, 1971; Neppiras, 1980; Apfel, 1981; Ilychev *et al.*, 1989; Leighton, 1994; Everbach *et al.*, 1997).

Passive cavitation detection has been employed in numerous studies to detect and monitor acoustic cavitation *in vitro* (e.g., Atchley *et al.*, 1988; Roy *et al.*, 1990; Holland and Apfel, 1990; Crum *et al.*, 1992; Everbach *et al.*, 1997). A limited number of studies have used the PCD technique to detect cavitation *in vivo*. Investigations have used the technique to demonstrate the production of acoustic cavitation in tissues exposed to lithotripter fields (e.g., Bailey *et al.*, 2005; Zhong *et al.*, 1997) or high intensity focused ultrasound (e.g., Thomas *et al.*, 2005). Porter *et al.*, (2001) used a PCD technique to detect intramyocardial cavitation in open-chest dogs exposed to pulsed ultrasound at 1.7 MHz after intravenous injections of a contrast agent.

In this investigation, we used a PCD technique to test directly the role of cavitation in ultrasound-induced premature cardiac contractions in mice injected with microbubble contrast agents. The design of this study provided an ideal opportunity to demonstrate a direct correlation of an ultrasound bioeffect with cavitation *in vivo*. A premature contraction is an "all-or-nothing" bioeffect that can be observed noninvasively immediately after delivery of an ultrasound pulse. Thus, for each acoustic pulse delivered to the heart, we were able to immediately correlate the extent of cavitation activity measured by the PCD transducer with the effectiveness of the pulse in producing a premature cardiac contraction.

Initial measurements of acoustic cavitation detection were performed *in vitro* to validate the measurement technique and provide insight necessary for interpreting the measurements of cavitation activity in mice *in vivo*. *In vitro* tests provided evidence that neither the incident nor the reflected sound fields were detected in the high-pass filtered (2 MHz cutoff) output signal of the PCD transducer. The filtered PCD signal amplitudes measured without any vial in the field and with either air or water vials were negligible up to ~0.2 MPa (Fig. 3). In comparison, in vials containing Optison®, the magnitude of the mean rms of the PCD signal increased with increasing pressure amplitude of the 200-kHz incident field (Fig. 3).

No premature contractions were observed in any mice injected with saline and exposed to ultrasound (Fig. 5). Also, in mice injected with saline, there was no significant increase in the RMS of the PCD signal with increasing exposure amplitude (Fig. 7). Thus, in mice injected with saline and exposed to ultrasound, no cavitation activity was detected and no premature contractions were produced. In comparison, ultrasound was an effective stimulus of premature beats in mice injected with Optison® (Fig. 5). For mice injected with contrast agent, both the mean percentage of ultrasound pulses producing a premature beat (Fig. 5) and the RMS of the PCD signal (Fig. 7) increased with increasing pressure amplitude. Furthermore, there was a direct correlation between the extent of cavitation, quantified by the PCD transducer signal, and the likelihood of producing a premature contraction with ultrasound (Fig. 8).

In this investigation, a low-acoustic frequency, long pulse duration (200 kHz, 1 ms), and low-contrast agent dose (3 μL/bolus) were chosen to minimize gross vascular damage to the heart while still maintaining the effectiveness of the ultrasound in producing premature contractions (Rota, 2005). Indeed, there was no evidence of gross hemorrhage on the surface of the heart in any of the mice injected with either saline or contrast agents and exposed to ultrasound pulses (200 kHz, 1 ms) with pressure amplitudes ranging from 0.1 to 0.25 MPa. This is in contrast to recent reports of myocardial microvessel rupture in mice and rats injected with contrast agents and exposed to ultrasound at diagnostic frequencies (Li *et al.*, 2003; 2004; Dalecki *et al.*, 2005b; Miller *et al.*, 2005). Li *et al.* (2003, 2004) determined a pressure threshold of 0.5 MPa for production of microvascular damage in rats injected with microbubble contrast agent and exposed to a clinical diagnostic device operating at 1.7 MHz. In rats injected with contrast agent, Miller *et al.* (2005) did not find a direct correlation between ultrasound-induced myocyte injury and the production of premature beats. The ability of ultrasound at 200 kHz in the presence of microbubble contrast agents to stimulate premature beats without any gross evidence of vascular damage to the myocardium suggests that ultrasound-induced premature contractions are a highly sensitive indicator of cavitation *in vivo*.

V. CONCLUSION

This study implemented a passive cavitation detection technique to measure acoustic cavitation in the murine heart *in vivo* when microbubble contrast agents were present in the blood. There was a direct correlation between the amplitude of the passive cavitation detector output and the likelihood of producing a premature beat with a pulse of ultrasound. These results provide direct evidence in support of inertial cavitation as a mechanism for ultrasound-induced premature cardiac contractions in the presence of microbubble contrast agents.

Advantages of the Hilbert Huang transform for marine mammals signals analysis

Olivier Adam[a]

Laboratoire Images, Signaux et Systèmes Intelligents groupe Ingénierie des Signaux Neuro-Sensoriels
Université Paris 12 – 61 av de Gaulle, 94000 Creteil, France

While marine mammals emit variant signals (in time and frequency), the Fourier spectrogram appears to be the most widely used spectral estimator. In certain cases, this approach is suboptimal, particularly for odontocete click analysis and when the signal-to-noise ratio varies during the continuous recordings. We introduce the Hilbert Huang transform (HHT) as an efficient means for analysis of bioacoustical signals. To evaluate this method, we compare results obtained from three time-frequency representations: the Fourier spectrogram, the wavelet transform, and the Hilbert Huang transform. The results show that HHT is a viable alternative to the wavelet transform. The chosen examples illustrate certain advantages. (1) This method requires the calculation of the Hilbert transform; the time-frequency resolution is not restricted by the uncertainty principle; the frequency resolution is finer than with the Fourier spectrogram. (2) The original signal decomposition into successive modes is complete. If we were to multiply some of these modes, this would contribute to attenuate the presence of noise in the original signal and to being able to select pertinent information. (3) Frequency evolution for each mode can be analyzed as one-dimensional (1D) signal. We not need a complex 2D post-treatment as is usually required for feature extraction. © *2006 Acoustical Society of America.* [DOI: 10.1121/1.2354003]

I. INTRODUCTION

This paper describes an endeavor to use the Hilbert Huang transform (HHT) to analyze bioacoustic signals, particularly vocalizations and clicks emitted by marine mammals.

Our aim is not to generalize the results of this approach when applied to the emitted signals of all marine mammals but, rather, to show its efficiency in analyzing certain vocalizations and clicks. The objective is to contribute to extract some features from these signals, as present techniques used for both detecting signals emitted by marine mammals and for defining an acoustic signature call for improvements (Erbe, 2000; Tiemann and Porter, 2003).

Using passive acoustics, the final applications could involve the tracking of certain "deep water" species (such as sperm whales "physeter macrocephalus"), supplementing visual observations, reducing significantly the percentage of missed trackline groups (Barlow and Shannon, 2004), and estimating the number of animals in a specific marine zone.

Bioacoustic signals emitted by whales present a variability of characteristics between species and between different individuals within the same species (Nakamura and Akamatsu, 2004). Moreover, these signals could be complex when numerous individuals emit sounds simultaneously. Also, these signals deteriorate with the presence of noise (natural or anthropogenic); this signal-to-noise ratio is liable to vary during the entire recording. The easiest approach for detecting and extracting signals from continuous recordings is to use an energy function. This detector is not optimal

when certain features of these signals are known *a priori*. To improve its performance, different signal processing algorithms could be proposed. Some of them provide a time-frequency or time-scale representation. These algorithms are broken down into three steps: step (1) signal preprocessing; step (2) selection of a decomposition method; and step (3) feature extraction. (1) Step 1 focuses on pertinent information present in the recordings. Usually, it consists of selecting the frequency bandwidth corresponding to signals emitted by the considered species. Each marine mammal species emits signals with specific frequency range; this bandwidth is considered for analysis. Signals must also be filtered for noise, reverberation, and multipath effects. (2) Different methods can be used during step 2: the Fourier spectrogram, the AR model, the wavelet transform, etc. (3) The interpretation of the time-frequency or time-scale representation obtained from step 2 could be achieved manually or inserted in an automatic decision algorithm: statistical approach, artificial neural networks, hidden Markov models, etc.

This paper focuses on the second step. This step could be particularly important in this process because it has consequences on the third step. We will evaluate the advantages of the HHT by considering the consequences on step 3.

Time-frequency or time-scale representation is an integral step in the segmentation and the characterization of the signals. Different methods are evaluated but often the Fourier spectrogram is the final choice for analyzing marine mammal recordings. Recently, Mellinger (2005) used this method to detect different species. Jarvis *et al.* (2003) also proposed the Fourier spectrogram for detecting different species of toothed whales. Because this approach is limited by the Heisenberg uncertainty principle, the authors have to

a)Electronic mail: adam@univ-paris12.fr

make choices based on their applications. They set a noise variable threshold (NVT) that adapts to the background noise. For example, in (Jarvis *et al.*, 2003), the resolutions in time and frequency are chosen, respectively, at about 10 ms and 50 Hz. Next, Fourier spectrograms are compared to a threshold and a binary time-frequency representation is provided—this representation will be used in step 3.

Because this threshold is often set manually in the beginning of the process and kept constant for the complete analysis of all the recordings, it seems difficult to characterize a complete marine mammal vocalization or click. Indeed, in this case, continuous recordings present nonstationary characteristics: the signals emitted by marine mammals are intermittent and when these signals are present, their features vary in time. Moreover, the signal-to-noise ratio varies during the recordings. In the end, this threshold could always be suboptimal.

However, some local information could be extracted from Fourier time-frequency representations (Altes, 1980; Kadambe and Orr, 1995; Kuperman *et al.*, 2001; Hory *et al.*, 2002). For vocalizations, Matthews *et al.* (1999) extracted pertinent characteristics such as the start, end (duration), minimum, maximum, and central frequencies, and number of inflections. Gillespie (2004) provides species classification from Fourier spectrogram results. Oswald *et al.* (2003) proposed using multivariate discriminating function analysis for classifying vocalizations of different whales. This classification is also based on the results of the Fourier spectrogram. Backpropagation neural networks could be used for detecting features from the whales' spectrograms, even when obstructed by noise (Erbe, 2000; Potter *et al.*, 1994).

For signals emitted by marine mammals, it appears that the Fourier spectrogram is the most known and applied approach for step 2, i.e., after the filtering of the signals and before feature extraction.

Note that the Fourier approach is adapted for harmonic signals. Sinusoids are sufficient for analyzing vocalizations from gray whales (Dalheim, 1984) but not for odontocete clicks.

Cohen (1995) has shown that the Fourier estimator is limited to linear time-frequency analysis. In many cases, vocalizations are analyzed despite these restrictions, such as in human speech—vowels could be considered quasistationary ($\sim$20 ms) for voice phonemes. These hypotheses are too strong for marine mammal signals due to the presence of brief vocalizations or transient clicks (Ioana and Quinquis, 2004). Thus, resulting spectrograms have to be interpreted using precaution. In the end, the Fourier estimator is maybe not the optimal estimator for the analysis of continuous recordings when the goal is to extract certain features from the time-frequency representation of odontocete clicks; and moreover, when noise is susceptible to variant properties.

Different signal processing approaches are proposed here and considered more appropriate than Fourier estimators for nonstationary signals analysis (Boashash, 2003). These methods consist of decomposing the original signals into a specific vector basis, similar to the use of Fourier estimators (decomposition into complex exponentials). The wavelet transform is one example (Meyer, 1993). Thus, the

first step for providing these time-frequency or time-scale representations is to determine what kind of vector basis is necessary and optimal for decomposition. For different studies, the vector basis is chosen according to the selected application: The same basis cannot be used in analyzing signals from different marine mammals or different individuals of the same species. Various authors have illustrated the advantages of the wavelet family used for their own specific applications—Fargues and Bennett (1995) justified the use of the Morlet mother wavelet; in 1998, Huele and De Haes preferred the analysis using the packet wavelet; and Lopatka *et al.* (2005) presented better results obtained with the Daubechies mother wavelet.

Introducing the HHT proposed by Huang *et al.* (1998) appears to be an alternative for characterizing these bioacoustic signals. This method does not need any vectors for decomposition. Signals are decomposed into themselves; this means that no specific vectors are required and, consequently, no bias is introduced during the decomposition process. Theoretical details are briefly presented in the next section. Afterward, the results are presented on simulated signals and real marine mammal recordings. The conclusion highlights the significance of our results.

II. METHOD

The Hilbert Huang transform was introduced by Huang *et al.* (1998). This method can be presented in two phases. First, signals are decomposed into a finite set of intrinsic mode functions (IMF). This first step is called empirical mode decomposition (EMD). Then, the Hilbert transform (HT) is applied and a time-frequency representation is performed.

A. Empirical mode decomposition

Decomposition consists of extracting monocomponent contributions, called IMF, from the signals based on the localization of their extrema. Upper and lower envelopes are calculated; then the average of these two envelopes is calculated. A residual signal is obtained from the difference between the original signal and its mean. This process, called the *sifting process*, is repeated until the final mean satisfies two conditions: (1) the number of extrema and the number of zero crossings must either equal zero or differ at most by one, and (2) at any point, the mean value of the two envelopes is equal to zero (Huang, 1998). The signal s is decomposed by

$$s[n] = \sum_{i=1}^{M} c_i[n] + T_M[n], \tag{1}$$

with c_i the ith mode of the signal. c is also called the intrinsic mode function (IMF). T_M is the residue.

Note that this decomposition is complete. It means that the sum of all modes c_i equals the original signal. The selection of some of the modes corresponds to filtering the signal (Flandrin *et al.*, 2003).

Olivier Adam: Hilbert Huang transform bioacoustic signal analysis

The number of modes depends on the shift time-window length. But contrary to the Fourier transform, the frequency resolution does not depend on the time-window width.

B. Hilbert transform

A time-frequency representation can be obtained from the modes. Huang *et al.* (1998) proposed the use of the Hilbert transform

$$s_H[n] = \text{HT}(s[n]) = s[n] \otimes \frac{1}{\pi n}. \qquad (2)$$

Let us define the analytic signal

$$s_A[n] = s[n] + js_H[n] \qquad (3)$$

with $j^2 = -1$.

s_A could be written

$$s_A[n] = a[n]e^{j\theta[n]} \qquad (4)$$

with magnitude $a[n] = \sqrt{s^2[n] + s_H^2[n]}$ and phase $\theta[n] = \arctan s_H[n]/s[n]$.

From the Hilbert transform, the frequency is defined by Eq. (5)

$$f[n] = \frac{1}{2\pi} \frac{d\theta[n]}{dn}. \qquad (5)$$

This definition of the frequency, called instantaneous frequency, prevents limitations of the uncertainty principle. The representation of the triplet $\{n, f_i[n], a_i[n]\}$ in the time-frequency plane is provided for each IMF $(i = 1, \ldots, M)$. The Hilbert spectrum $H[n, f]$ is expressed as the sum of the Hilbert spectrums of each IMF.

The margin spectrum is defined at time $n = l/F_s$

$$h\left(\frac{l}{F_s}\right) = \sum_{f=f_0}^{f_1} H\left[\frac{l}{F_s}, f\right] \qquad (6)$$

with f_0 and f_1 the considered frequency range. F_s is the sampling frequency.

III. RESULTS

Before showing results on real recordings, we illustrate the performance of this method on simulated signals.

A. About the time-frequency resolution

Let us define the following chirp with a linear frequency varying from $0.01F_s$ to $0.3F_s$, where F_s is the sampling frequency. Figure 1 shows the comparison of three time-frequency representations.

First, the Fourier spectrogram has been calculated. Note that the rectangular or Bartlett window could be applied on the original signal before performing the Fourier transform because we need only focus on the maximum of the main frequency. The Hanning and Hamming windows are not justified in our case because their use would minimize the secondary lobes effects and not focus on the maximum position. Figure 1(a) shows results obtained with a Bartlett time window with the length $256/F_s$; the overlapping is 97%. The frequency resolution is around $4 \cdot 10^{-3} F_s$.
FIG. 1. Time—Frequency representation of a chirp. (a) Fourier spectrogram (time-window = 0,256 sec; overlapping = 97%). Illustration of the Heisenberg uncertainty principle. (b) Morlet wavelet transform. (c) Hilbert transform.

Second, Fig. 1(b) represents results obtained with the wavelet transform. Different wavelet families were tested—Mexican hat, Morlet, Haar, Daubechies—and finally our choice, the Morlet mother wavelet because it is well adapted for the analysis of this chirp (signal with a large frequency variation).

Note that the Morlet wavelet, defined in (Goupillaud *et al.*, 1984) is

$$\psi(t) = e^{-j2\pi f_0 t} e^{-(t/\sigma)2} \qquad (6')$$

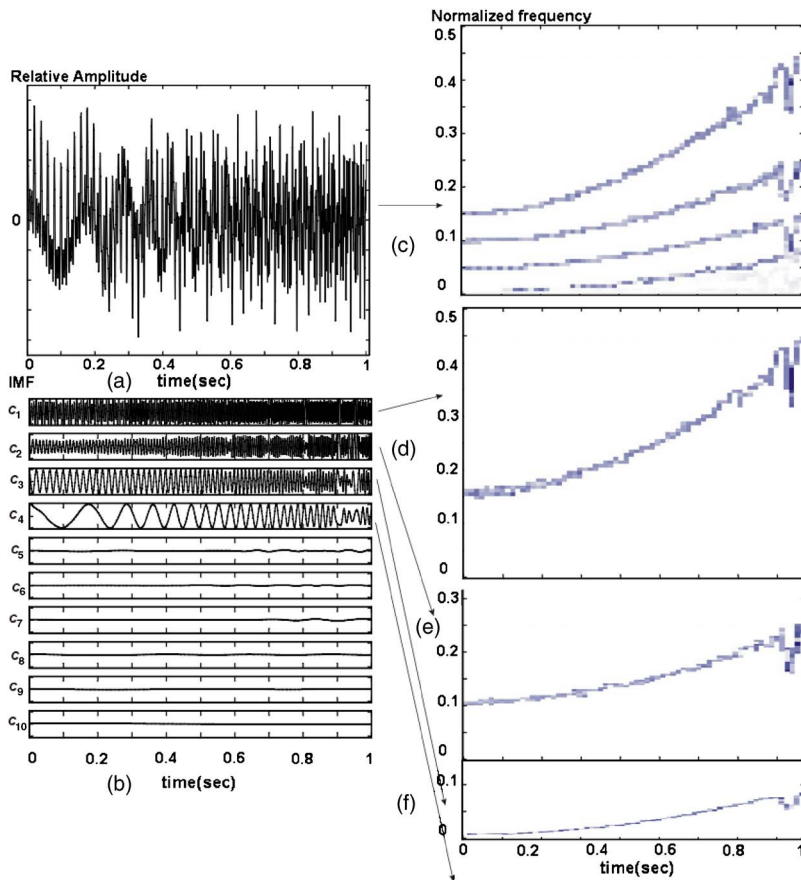
with a the modulation term and σ the scale parameter which is used for fixing the window length.


FIG. 2. (Color online) Illustration of the empirical mode decomposition of four chirps and the time-frequency representation obtained from the Hilbert transform. (a) Original signal. (b) EMD generates ten modes. (c) Time-frequency representation of the original signal. (d–f) Time-frequency representation of the first, second, third…chirp.

As defined for the HHT, we can calculate the energy of the spectrum at a given time $n = l/F_s$

$$E\left(\frac{l}{F_s}\right) = \sum_{f=f_0}^{f_1} c_w^2\left[\frac{l}{F_s}, f\right] \quad (7)$$

with c_w the wavelet coefficients. The energy E is calculated from the coefficients corresponding to the frequency band-width $[f_0, f_1]$.

Third, the last representation shows the instantaneous frequency calculated from the Hilbert transform. The HHT gives a finer time-frequency resolution than the two other methods, as we can see in Fig. 1(c).

This is clearly one of the advantages of the HHT.

B. Application on a combination of different chirps

Different kinds of chirps are used in many underwater acoustics applications: geophysics, localization, etc. These signals have finite length (usually short time) and present a linear variation of their frequencies. Some applications need chirps whose slope of frequency curves are convex or concave. These specific signals could be used for the definition of the model of natural sounds (Lewicki, 2002).

In this section, the goal is not to compare the results obtained with the HHT with other time-frequency representations, as shown previously. Rather, we wish to illustrate the first HHT step: the empirical mode decomposition.

Thus, we create a simulated signal which is the sum of four different chirps (the frequency of these signals increases in time). This signal is shown in Fig. 2(a). Ten IMF are

calculated from the original signal. The first four IMF contain the pertinent information from the four chirps. The following IMF are present due to side effects and in part because of the presence of noise. We note that the IMF are ordered from the high-frequency chirp to the lowest frequency chirp as shown in Fig. 2(b).

Then, the time-frequency representations are performed. Figure 2(c) shows results from the original signal. We clearly distinguish the presence of the four chirps. Figures 2(d)–2(f) are, respectively, the Hilbert transform of the first IMF, second IMF, third IMF (we did not add the fourth IMF to simplify the illustration). Because the IMF are mono-component signals, each time-frequency representation corresponds to the frequency variation of one chirp.

This result is another advantage of the HHT.

C. Application on signals emitted by whales

After testing the HHT on simulated signals, we have evaluated the performance on real signals. We would like to apply this method to whale signals analysis. Like in speech processing, we can distinguish two classes of signals: vocalization and clicks. The first class contains all harmonic signals. This is the case of vocalizations of killer whales, humpback whales, gray whales, etc. The second class contains only transient pulses, such as clicks. These clicks are repetitive, like those emitted by killer whales, dolphins, belugas, sperm whales, etc.

1. Illustration of killer whale vocalizations

Some vocalizations emitted by whales are similar to simulated chirps (Lewicki, 2002). These chirps have variant shapes; meaning that the vocalizations could be approximated with a linear or concave varying frequency. The duration fluctuates from 10 ms (killer whales) to more than 5 s (humpback whales).

In this part of our work, we have considered recordings of signals emitted by a group of killer whales. We isolated one specific vocalization to illustrate the performance of the HHT. Figure 3 shows the comparison between the three time-frequency representations.

Even if the resolution both in time and frequency is finer with the Hilbert spectrum, the presence of noise in the recordings perturbs the calculation of the instantaneous frequency, as we can see in Fig. 3(c). The presence of noise degrades the Fourier spectrogram as well [Fig. 3(a)]. The wavelet transform appears more robust [Fig. 3(b)].

To improve the time-frequency representation provided by the HHT, we have to focus on the IMF decomposition. In this particular example, the original vocalization containing noise is decomposed into 14 IMF [Fig. 4(a)]. In the last IMF, the noise is diffused. Thus, taking into account only the first IMF is equivalent to filtering the original vocalization.

Figure 4(c) shows the time frequency of the part of the vocalization calculated from the first mode. This signal is without noise. Feature extraction from this time-frequency representation will be easier; this step is illustrated by characterizing the vocalization fluctuations. We have chosen to fit the successive values of the instantaneous frequency by a polynomial regression [Fig. 4(d)].

This result is yet another advantage of the HHT.

2. Illustration of sperm whales creaks

As mentioned in the Introduction, the Fourier estimators are particularly suited to harmonic signals. Results could be difficult to interpret when applied to transient signals, as is the case with clicks emitted by sperm whales or beaked whales. Detection of clicks in continuous recordings is still a challenge for detection algorithms. The non-trivial tasks are threefold: (1) to distinguish the presence of clicks, providing the best time-frequency resolution possible is generally the goal of methods based on time-frequency representations, especially for time-delay measurements (Kuperman *et al.* 2001; Jarvis *et al.* 2003); (2) to identify the successive pulses in the click and separate the complete click from its echoes, and (3) to extract pertinent patterns.

Different detectors have been proposed as alternatives to those based on the Fourier estimators. The wavelet transform seems more suitable for the decomposition of these kinds of signals.

In this section, we illustrate the advantages of the HHT when compared to the Fourier spectrogram and the wavelet transform for analysis of these signals and particularly of sperm whale clicks.

Sperm whales emit different kinds of clicks: regular clicks, creaks, codas (Wahlberg, 2002). Because regular clicks have high directionality, source levels up to ≥ 200 dB
FIG. 3. (Color online) Time-frequency representation of a killer whale vocalization. (a) Time signal. (b) Performed with the Fourier transform. (c) Performed with the Morlet wavelet transform. (d) Performed with the HHT.

re: 1 μPa and are repetitive (around one per second), the performance of each technique is evaluated when applied to regular clicks. It is more difficult to find results on creaks detection in existing specialized literature, in spite of the importance of these signals. Creaks contain successive

clicks, with various amplitudes and variant rhythm. This intrinsic variability in time domain is shown in Figs. 5(a), 5(b1), and 5(b2). Figure 5(a) shows one hundred clicks in a sperm whale creak.

The Fourier spectrogram, the wavelet transform and the HHT were applied. These time-frequency representations were used for detecting the click presence in the creak—by using a simple threshold or by pinpointing the spectrum energy maximum.

Table I gives results obtained from the spectral energy. From the Fourier spectrogram, this energy maximum was calculated

$$\max_l \sum_{k=k_0}^{K} S_w^2 \left[\frac{l}{F_s}, k \right] \tag{8}$$

with $S_w = |fft(\cdot)|$, l is the number of the sample ($l = 0, \dots, N - 1$ with N the length of the click), k_0 corresponds to $0.05 F_s$ and K to $0.3 F_s$. [Energy maximums from the HHT and from the wavelet transform were, respectively, calculated with Eqs. (6) and (7)].

We calculate the maximum of energy when the click is present, called $En(click)$ and when the click is absent (only noise), called $En(noise)$. We focus on the ratio between $En(click)$ and $En(noise)$. Results are grouped according to signal-to-noise ratio (SNR). Note that high SNR are obtained with clicks present in sequences of regular clicks and low SNR with clicks present in creaks.

In Table I, in regular clicks, $En(noise)$ is inferior to 1, showing that noise is weak in this specific recording. The three methods result in large ratios between $En(click)$ and $En(noise)$. With a ratio over 20:1, a detector based on a threshold could be envisioned. Also, when $\text{SNR} \approx 20$ dB, the Fourier spectrogram could be sufficient for detecting clicks.

For analyzing creaks, it could be more complex. As mentioned above, sperm whales modulate the amplitude of their clicks during creaks. The clicks detector could be efficient if the ratio between $En(click)$ and $En(noise)$ is still over 20:1. From $\text{SNR} \approx 10$ dB, we obtained a ratio of 6.5:1 for the

Fourier spectrogram (it was three times less than with regular clicks) while when applying the wavelet transform and the HHT, this ratio is still high ($>25:1$).

When the SNR decreases further, distinguishing the signal parts when clicks are present from signal parts when only noise is present becomes more difficult when using a threshold based on the Fourier spectrogram alone. The ratio is lower than 3:1 when SNR is equal to 5 dB. This is not the case with the wavelet transform and the HHT which are more resistant when SNR decreases. We note that underwater noise is nonuniformly distributed on all IMF and by choosing only the first IMF, we can easily reduce its impact (0.07) and keep a sufficient ratio (36.3:1) between $En(click)$ and $En(noise)$.

The higher the ratio, the more justified the use of a threshold for detecting clicks.

IV. DISCUSSION

While the Fourier spectrogram is the classical estimator for providing a time-frequency representation and analyzing signals emitted by whales, the HHT has some significant advantages: The decomposition does not need any vector basis, the decomposition is finite, and it is possible to provide a time-frequency representation.

Like with other methods of decomposition (Fourier, wavelet), EMD allows the filtering of the original signal and the focusing on the range of whale frequencies. Note that in certain cases, when noise perturbs the calculation of the instantaneous frequency ($\text{SNR} < 0$ dB and noise frequency band overlap with signal frequency band), another time-frequency representation applied on the IMF could be favored to the Hilbert transform (Janosi and Muller, 2005).

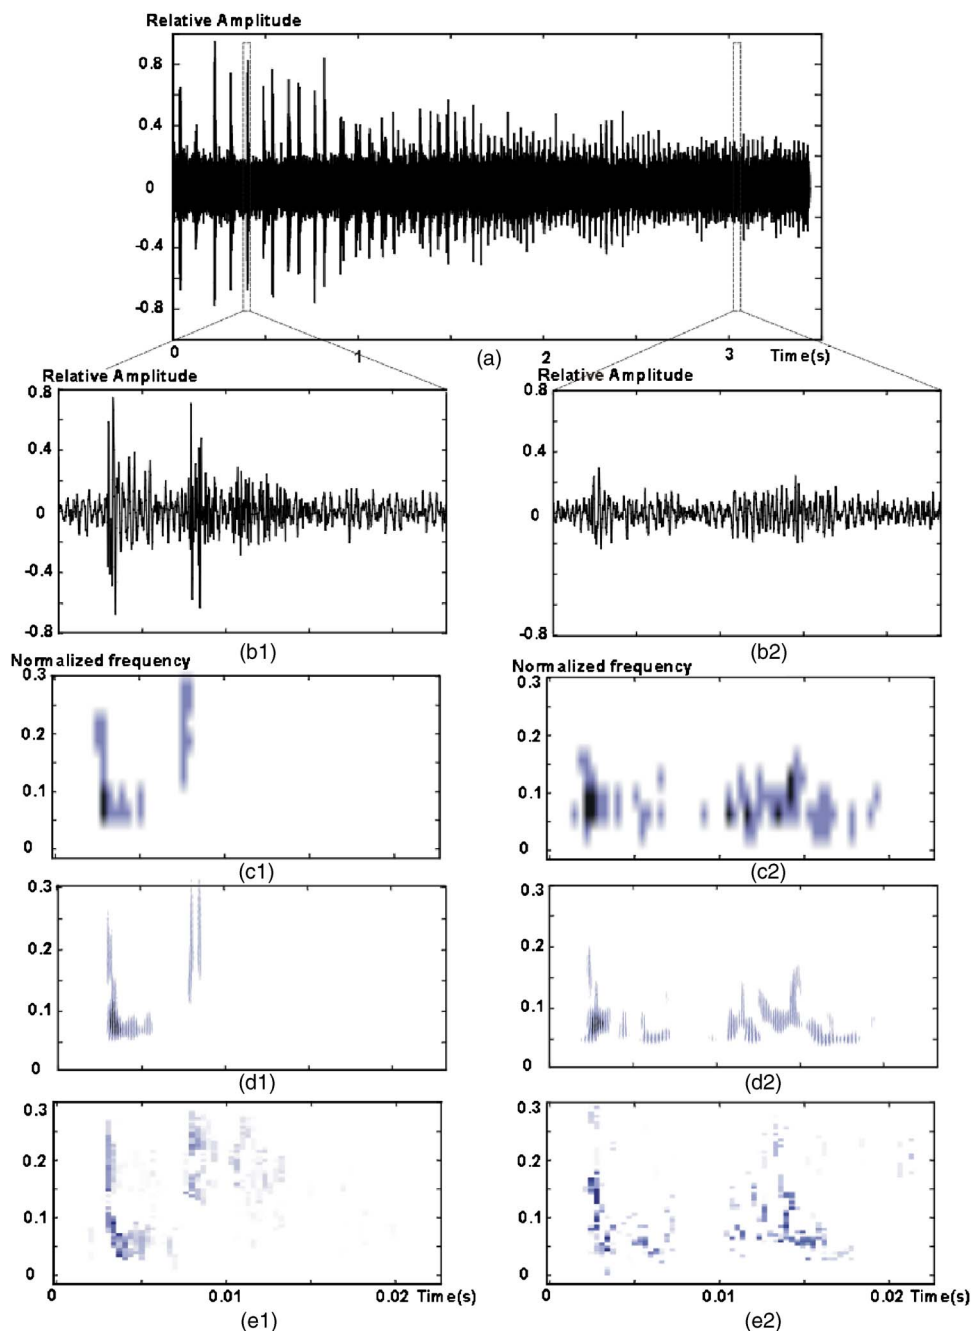
For signal analysis, the Fourier spectrogram requires the use of a time window. The features of this time window influence time-frequency representation; a compromise has to be set between focusing on the time resolution and on the frequency resolution. When frequency changes during recordings, this compromise must vary as well; consequently


FIG. 5. (Color online) Comparison of sperm whale creak detection. (a) Sperm whale creak. (b1–2) Time-signal of sperm whale clicks. (c1–2) Fourier spectrogram. (d1–2) Morlet wavelet transform. (e1–2) The HHT.

the fixed length for this time window is not the optimal choice. Contrary to the Fourier spectrogram, the time window used for the HHT does not impact the frequency resolution.

The HHT has one more advantage: the time-frequency representation is the plot of the instantaneous frequency. This

means that we do not have to choose a specific threshold for obtaining this binary time-frequency representation.

Moreover, the time-frequency representation can be analyzed by considering instantaneous frequencies calculated from each IMF, such as the one-dimensional (1D) signals. Step 3 becomes easier: To extract any kind of information

TABLE I. Energy maximum of the three time-frequency representations. *En*(*click*) and *En*(*noise*) are the measurements of the energy maximum, respectively, in the presence of click or only of noise. Mean calculated on 20 clicks extracted from regular clicks, 20 clicks from creaks with SNR ≈ 10 dB, and 20 clicks from creaks with SNR ≈ 5 dB.

Clicks from	SNR	Fourier spectrogram			Wavelet transform			HHT		
		En(*click*)	*En*(*noise*)	Ratio	*En*(*click*)	*En*(*noise*)	Ratio	*En*(*click*)	*En*(*noise*)	Ratio
Regular Clicks	20 dB	15.55	0.78	19.9:1	56.30	0.81	69.5:1	17.52	0.18	97.3:1
Creaks	10 dB	11.99	1.85	6.5:1	47.74	1.78	26.8:1	8.22	0.22	37.4:1
Creaks	5 dB	4.15	1.56	2.7:1	25.02	1.43	17.5:1	2.54	0.07	36.3:1

from the time-frequency representation, it is not necessary to define a complex 2D post-treatment as is often done. In (Hory *et al.*, 2002; Mellinger, 2005), post-treatments require contour models for contour extractions of vocalization patterns. These kinds of 2D algorithms could be an obstacle for real time application. With the HHT time-frequency representation, we directly access the change of frequencies, as illustrated in Fig. 4. We can focus this treatment on a specific IMF which contains the pertinent information—for example, only the first five modes are considered when regular sperm whale clicks have to be analyzed (Adam, 2006). With each monocomponent vocalization, only a single IMF can be used for extracting different characteristics. The evolution of frequency obtained from the Hilbert transform of this IMF can be parametrized by a polynomial fit—choosing a three-order polynomial regression is sufficient for the example shown in Fig. 4(d)—facilitating the compression and the extraction of the classical information, such as the vocalization duration and the start and end of the vocalization frequency, etc. Thus this information can be used for classification, as input of a decision system, such as an artificial neural network, for example.

This is perhaps the most important advantage of the HHT.

Regarding the transient signals emitted by whales, such as sperm whale clicks, the wavelet transform and the HHT show better robustness than the Fourier spectrogram when the SNR decreases. This property could be used with success for detectors based on a threshold.

Because the clicks are transient and of the impulse type, the wavelet transform and the HHT are attractive alternatives to the Fourier estimator. The coefficients of the wavelet transform could be used for defining an acoustic signature (Lopatka, 2005). By isolating the maximum of the instantaneous frequency of only the four first modes, the HHT analysis contributes to this objective.

V. CONCLUSION

This paper presents an application of the Hilbert Huang transform applied to bioacoustics signals, and particularly vocalizations and clicks emitted by whales, present in continuous recordings. This technique contributes to characterizing these kinds of signals, and could be used successfully in the definition of detectors and/or classifiers.

In this paper, we have compared three different time-frequency representations (Fourier spectrogram, Morlet wavelet transform, and the HHT). With the calculation of the instantaneous frequency, the Hilbert transform allows for the concentration of frequency energy and the avoidance of the uncertainty principle.

As with the other methods, it is possible to define filters based on the HHT, i.e., the analysis could be done with certain specific modes resulting from the decomposition. Retaining one or few IMF is done to denoise the original signal. This approach also corresponds to retaining only the modes containing the pertinent information. This technique could contribute to distinguishing two whales which emit signals simultaneously.

Finally, it is possible to analyze the frequency variation of each IMF with 1D technique and not 2D approaches, as is commonly done for extracting information from the time-frequency representations.

Semi-automatic classification of bird vocalizations using spectral peak tracks

Zhixin Chen[a)] and Robert C. Maher[b)]

*Department of Electrical and Computer Engineering, Montana State University,
Bozeman, Montana 59717-3780*

Automatic off-line classification and recognition of bird vocalizations has been a subject of interest to ornithologists and pattern detection researchers for many years. Several new applications, including bird vocalization classification for aircraft bird strike avoidance, will require real time classification in the presence of noise and other disturbances. The vocalizations of many common bird species can be represented using a sum-of-sinusoids model. An experiment using computer software to perform peak tracking of spectral analysis data demonstrates the usefulness of the sum-of-sinusoids model for rapid automatic recognition of isolated bird syllables. The technique derives a set of spectral features by time-variant analysis of the recorded bird vocalizations, then performs a calculation of the degree to which the derived parameters match a set of stored templates that were determined from a set of reference bird vocalizations. The results of this relatively simple technique are favorable for both clean and noisy recordings. © *2006 Acoustical Society of America.*
[DOI: 10.1121/1.2345831]

I. INTRODUCTION

Several engineering applications require real time identification of birds while in flight, foraging, or roosting. These include systems to help avoid collisions between birds and aircraft (Pascarelle *et al.*, 2004), systems to track migratory birds in the vicinity of wind turbine generators (NWCC, 2004), and ornithological measurements systems to help understand avian behavior and migratory patterns, particularly at night and in unfavorable meteorological conditions. Among the possible means to identify the bird species are their vocalizations. Thus, there exists a need for research in on-line acoustical bird classification systems capable of running unattended and in real time.

In recent years many off-line techniques for classifying bird species based on recorded vocalizations have been proposed and developed. The most successful techniques are based on manual inspection and labeling of bird sound spectrographs by experts, but this process is tedious and dependent upon the subjective judgment of the observer (Kogan and Margoliash, 1998). The reliability of classification can be improved if a panel of experts is used, but this is expensive, time consuming, and unsuitable for real time classification. Nevertheless, the fact that the manual inspection of sound spectrographs tends to yield correct judgments has encouraged research into automatic classification using objective standards derived from expert opinions.

Several of the existing automatic off-line bird vocalization classification techniques are based on traditional speech recognition methods (Rabiner and Juang, 1993). Anderson, Dave, and Margoliash (1996) used dynamic time warping (DTW) for automatic recognition of birdsong syllables from continuous recordings. Their method directly compared the spectrograms of input bird sounds with those of a set of predefined templates representative of categories chosen by the investigator. They applied this method to vocalizations from two bird species recorded in a low noise environment and achieved 97% accuracy in the syllables of stereotyped songs and 84% accuracy in the syllables of plastic (variable or indistinct syllable) songs. The method did not use amplitude normalization, so the results may be sensitive to amplitude differences. Kogan and Margoliash (1998) used DTW and hidden Markov models (HMM) to classify bird sounds based on the syllables extracted from continuous recordings. Their method began by extracting linear predictive coding (LPC) coefficients or mel-frequency cepstral coefficients (MFCC) from a set of bird syllables and then used DTW or HMM for recognition. This method was found to perform well for two specific birds in a low noise environment. The method worked less well in noisy environments or with short duration bird vocalizations. Ito, Mori, and Iwasaki (1996) extracted two time-varying spectral features from syllables and used dynamic programming (DP) matching to classify budgerigar contact calls, and found that the method performed well. However, only the frequencies of the spectral features were used, not the spectral powers, so the method may not be appropriate for other bird sounds with different spectral structure.

Other researchers have developed classification methods specifically tailored to bird vocalizations. McIlraith and Card (1997) conducted research on the recognition of songs of six bird species. In their method the bird songs were represented with spectral and temporal parameters of the songs. They reduced the complexity of the search space by selecting features exhibiting the greatest discrimination, then used a neural network for classifying the bird songs. Their method achieved good performance but the neural classifier required

---

[a)]Electronic mail: chen@montana.edu
[b)]Corresponding author. Electronic mail: rob.maher@montana.edu

considerable computation. Härmä (2003) proposed an alternative method for bird sound classification. He observed that for many songbird vocalizations, a large class of syllables can be approximated as brief sinusoidal pulses with time varying amplitude and frequency. Although this model is too simple for certain bird sounds, the system provided good recognition results for species with tonal vocalizations. In a subsequent study, Härmä and Somervuo (2004) classified bird sounds into four classes based on their harmonic structure, where each harmonic component was modeled with one time-varying sinusoid. No classification statistics were reported, but they found that the signal models appropriately represented the spectral structure of 93% of the syllables in their database.

In summary, the existing methods are well suited to their specific application, but they also have some limitations. The DTW and HMM techniques did not perform well in noisy environments or for bird sounds with short duration and variable amplitude. The neural classifier required a very high computational complexity. The use of one or two spectral peak tracks is appealing for its simplicity and robustness to noise. Thus, in this paper we describe a spectral pattern detection method with relatively low computational complexity (i.e., suitable for a final implementation in real time) that can be used to classify in real time tonal bird vocalizations (harmonic or inharmonic) in the presence of realistic background noise levels.

The remaining sections of this paper are organized as follows. First, we review briefly the basic structure and terminology of bird vocalizations. We then describe the rationale and features of the proposed semi-automatic classification method, including our simulation results and interpretation, and compare the results to classification based on conventional DTW and HMM methods. Finally, we conclude with a summary and several suggestions for future research in this area.

II. BIRD SOUNDS

Birds are able to produce a wide variety of sounds. Air from the lungs is forced through the bronchi to the syrinx, which is the major source of vibratory modulation. Sound from the syrinx passes through the resonant structures of the trachea, larynx, mouth, and beak.

Bird vocalizations can be divided into the general categories of elements, syllables, phrases, calls, and songs (Krebs and Kroodsma, 1980; Catchpole and Slater, 1995). *Elements* can be regarded as the elementary sonic units in bird vocalizations. A *syllable* includes one or more elements and is usually a few to a few hundred milliseconds in duration. *Phrases* are short groupings of syllables. *Calls* are generally compact sequences of phrases, while *songs* are long and complex vocalizations. An example of the hierarchy is shown in Fig. 1. The reader is cautioned to be aware that the details of each category often show individual and geographic variations and temporal plasticity, even within a single species (Kroodsma and Miller, 1996; Krebs and Kroodsma, 1980). Thus, a classification strategy consisting of a simple tone sequence detector tuned to match a specific
FIG. 1. Descriptive hierarchy of bird vocalization. The bird vocalization can be divided into four hierarchical levels: element, syllable, phrase, and song (or call). The classification experiment reported in this paper operates at the syllable level in the hierarchy.

example bird song is unlikely to be useful in engineering applications due to natural variation in the song details.

Syllables can range from being nearly tonal whistles, to harmonic sounds with a distinct fundamental frequency, to inharmonic bursts, or even to being noise like (Nowicki, 1997; Kahrs and Avanzini, 2001; Fagerlund, 2004). In the case of voiced harmonic sounds, the fundamental frequency range typically lies between 500 and 5000 Hz. The spectral content of a harmonic sound can also vary with time as the bird changes the shape and length of the vocal tract and beak. Figure 2 shows examples from songs and calls from different species, illustrating only a small variety of the complex sounds birds can produce.

III. CLASSIFICATION METHOD AND EXPERIMENTAL RATIONALE

The bird sound classification problem is similar to many existing pattern detection and classification problems. The classification procedure described in this paper follows the standard design cycle of Duda *et al.* (2001), as depicted in Fig. 3.

The *data collection* process included the acquisition of audio recordings using recording apparatus similar to what is anticipated in a real time classification system. The data were obtained in the field with a variety of ambient noise sources such as wind, motor traffic, and aircraft.

The *feature choice* process was based on our examination of the spectrotemporal characteristics of the bird sounds of interest. This examination was supplemented by a review of prior research into bird sound recognition and our prior experience with a variety of signal processing methods useful for data extraction in speech, environmental sounds, and music. For the purposes of classification in the presence of background noise, we have found that subsyllable elements are difficult to use in practice simply due to the difficulty in extracting reliable signal parameters for such short segments. Meanwhile, ornithologists report that higher level phrases, calls, and songs often contain regional and individual variations that will add additional degrees of freedom to the classification problem (Krebs and Kroodsma, 1980). This led us
FIG. 2. Example time-variant spectra of bird sounds from several bird species. (a) Mourning dove (*Zenaida macroura*), (b) Red-tailed hawk (*Buteo jamaicensis*), (c) Red-winged blackbird (*Agelaius phoeniceus*), (d) Herring gull (*Larus argentatus*), (e) Brown-headed cowbird (*Molothrus ater*), (f) Mallard (*Anas platyrhynchos*).

to focus on syllable-level classification as the starting point for our proposed method. Restricting the process to single syllables allows the problem to be tractable, but a fully practical automatic classification system will need to accommodate the many different syllables associated with a particular bird species. Nevertheless, the characteristic strengths and weaknesses of our proposed classification method can be assessed using a single syllable study.

We observed the patterns and trends in our bird sound database and developed a set of discrimination parameters including spectral frequencies, frequency differences, track shape, spectral power, and track duration. The resulting framework uses measurements of the principal peak tracks in each sound syllable based on our observations and measurements of the recorded sound set.

The classifier *model choice* and *training* processes (de-

scribed in the following section) consisted of selecting a representative syllable from each desired bird species in the database, deriving the features, or discrimination parameters, according to the basic peak track model, and then determining an allowable discrepancy between the derived features and the data for which a match would still be allowed.

The *evaluation* process, described in Sec. V, consisted of an iterative procedure comparing the error rate of the proposed classifier under a range of parameter range adjustments and additive noise conditions.

IV. DESCRIPTION OF THE SPECTRAL PEAK TRACKS METHOD

As mentioned above, spectral features have been found to be useful for bird syllable classification. Specifically, the use of spectral peak tracks provides a compact, distinctive, and computationally tractable basis for classification (Härmä, 2003). A spectral peak track is formed by segmenting the input signal into a set of overlapping short-time frames, calculating the Fourier transform magnitude for each short-time frame, and then matching peaks from one spectral magnitude frame to the next. If the input signal contains underlying sinusoidal partials, the resulting spectral peaks will persist for several successive frames. The corresponding peaks (e.g., peaks nearest in frequency on successive frames) are identified and linked from one frame to the next to form a connected sequence, known as a *peak track*, indicating the amplitude and frequency trajectory of the underlying partial. The vocal sounds of many birds are found to be well modeled by the peak track model (Härmä and Somervuo, 2004).

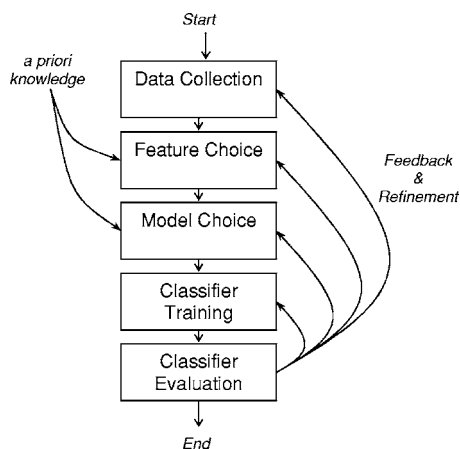
We extend the basic peak track method by including a variable number of peak tracks, which allows tonal, harmonic, or inharmonic combinations. We also enhance the


FIG. 3. Pattern classification design cycle (Duda *et al.*, 2001). Although numerous pattern matching procedures have been proposed and demonstrated, no universal system yet exists. Nonetheless, the design cycle depicted here is a useful common starting point for classification system design.

robustness of the peak track method by encoding the power and shape of the spectral peak tracks to capture the additional characteristic behavior of each vocalization.

In the proposed method we extract a variable number of spectral peak tracks from one syllable of the desired bird sound. The number of peak tracks selected is determined by the relative power of the tracks from the entire syllable. A set of descriptive parameters is then derived from the selected spectral peak tracks. These parameters include the frequencies, frequency differences, track shape, relative powers, and the track duration. We have found these parameters to work well in the presence of moderate noise and competing background sounds. The method also has low computational complexity and ease of implementation.

In the following sections we describe the three major steps of the spectral peak tracks method: spectral peak tracks search, feature extraction, and target and recognition.

A. Spectral peak tracks search

Step A1: The first processing step is to determine the spectral peak tracks of the syllable. A digital recording of the syllable with 16-bit samples and a 16 kHz sample rate is first high pass filtered with a 100 Hz cutoff in order to remove the low frequency background noise attributable to wind or mechanical sounds. The filtered signal is then segmented into Hamming windowed 256-sample frames with 128-sample overlap (8 ms frame hop). This is a reasonable frame rate based on the expected spacing of the spectral peaks. The *raw spectral representation* (i.e., the short-time discrete Fourier transform) is obtained with a Fast Fourier Transform (FFT) algorithm.

15 frames (120 ms) of the sample recording from the time interval prior to the start of the vocalization are used to estimate the background noise level. The average noise level for the 15 frames is calculated and used to set the amplitude threshold for the subsequent peak track detection. The estimated background noise level is also used to clarify the onset and release boundary of the syllable, and to distinguish the temporal boundaries of syllables with two or more parts. A simple energy-based detection algorithm is used to identify syllables with more than one part. If more than one part is found, only the part with the largest energy is retained, but the multipart detection is noted for use during the matching and recognition process.

Step A2: Next, the spectral peak tracks are derived using the McAulay and Quatieri (MQ) procedure (McAulay and Quatieri, 1986; Smith and Serra, 1987; Ellis, 2003). We refer to this step as the *coarse search*. In each frame the magnitude of the FFT data is examined to locate peaks in the spectrum. A peak is identified by three adjacent spectral magnitude coefficients within a frame where the middle coefficient is larger than both its higher and lower frequency neighboring coefficients, and the magnitude also exceeds the noise threshold determined in Step A1. This is done to remove peaks with very weak magnitude that are likely to be caused by background noise or by sidelobes of the Hamming window spectrum. We use a quadratic fit for the three spectral coefficients defining the peak in order to refine the frequency and magnitude estimate for the peak (Smith and Serra, 1987).

The refined peaks in one frame are compared to the peaks in the subsequent frame, and those spectral peaks that match well from one frame to the next are connected to form candidate peak tracks. A good peak-to-peak match is determined by locating a peak in the subsequent frame that is closest in frequency to each peak in the current frame. Acceptable matches are also restricted by a maximum rate of change in frequency corresponding to the most rapid frequency sweep found in actual bird syllables. We have found that a 200 Hz range works well for spectral peaks with frequencies above 2 kHz, while a 100 Hz range is used as the allowable frequency difference for peaks below 2 kHz. In some cases there will not be a suitable matching peak in the subsequent frame, while in other cases there may be several possible matches. Any conflicts are resolved by finding the match that minimizes the frequency and magnitude difference between the tentatively matched peaks. If no good match is found, we assume that the current peak is not continuous with any of the existing peak tracks, and the peak track associated with that peak is marked as "dead." Similarly, if a peak in the subsequent frame is not found to be a match for any of the peaks in the current frame, the new peak is considered as the "birth" of a new peak track. Thus, the coarse search process continues for each frame of spectral data, creating sets of candidate peak tracks.

Step A3: The spectral peak tracks produced by the coarse search in Step A2 may be discontinuous, too short, or otherwise inconsistent and poorly constructed. Therefore, a *fine search* is conducted to seek a higher level of structure in the syllable peak track data. We first identify any brief gaps (three or fewer frames) in the candidate peak tracks and reconnect across the gap under the assumption that the gap is due to noise or thresholding. Next, we prune away tracks that are inconsistent with the expected fundamental frequency range of the bird vocalization, such as tracks below 500 Hz. We then eliminate any closely spaced tracks, keeping the track with the larger magnitude, again under the assumption that the weaker track is due to spurious noise. Finally, we calculate the mean or median frequency, track length, and track power for every peak track and store the results of the fine search in the track analysis database.

Step A4: If the track list derived for the syllable has only one spectral peak track, the peak track search is terminated. If the track list includes two or more tracks, a second fine search is conducted. First, any relatively weak peak tracks are eliminated from the track list, thereby retaining only the tracks with the greatest signal to noise ratio. These strong peak tracks are sorted according to power and duration. If any of the strong peak tracks are found to be much shorter or longer in duration than the strongest peak track, or if the onset or offset of one of the weaker tracks is considerably different from the strongest peak track, those marginal tracks are eliminated from the track list. The resulting list of primary peak tracks (usually eight or fewer tracks) is retained for use in the matching procedure.

An example of the primary peak tracks for a harmonic syllable is shown in Fig. 4. The syllable has five spectral

FIG. 5. Frequency range and shape example. (a) Peak track representation of a syllable from bird species I, (b) Peak track representation of a syllable from bird species II. The classification algorithm compares both the range (frequency extent) and the shape of the spectral peak tracks to improve the reliability of the syllable classification.

FIG. 4. Result of the spectral peak tracks search. (a) Frequency versus time representation (spectrogram) of one syllable of a red-tailed hawk (*Buteo jamaicensis*), (b) Spectrogram showing the search results from the spectral peak track method, (c) A three-dimensional representation of the spectrogram (amplitude versus frequency versus time).

peak tracks. Among these tracks, Track D is the most significant, Track B is the next most significant, followed by Track C, Track A, and finally Track E. Since Tracks A and E are sufficiently weak to be immersed in the background noise, they are not retained in the search phase. Consequently, only Tracks D, B, and C are selected in the spectral peak tracks search phase.

B. Feature extraction

Once the primary spectral peak tracks are determined, we analyze the track contours to obtain a set of descriptive parameters. The parameters include the frequencies, the frequency differences, the relative power, the shape, and the duration of the spectral peak tracks. These parameters were selected based on several key insights. First, the peak track frequencies are observed to be distinctive for many of the bird species in our recorded database, and are therefore considered useful for pattern classification (see the example in Fig. 5). Second, we recognize that there are different bird species with syllables in overlapping spectral ranges, meaning that calculating only the mean frequency will be insuffi-

cient to distinguish between the species. In some cases the presence of several peak tracks with specific frequency relationships can be a key discriminator between species, while in other cases the shape and trend of the peak tracks may be the most important distinguishing feature. Finally, it may be that two different syllables are otherwise similar in frequency range, track frequency spacing, and track shape. In these cases we have found that comparisons between the relative power and the total duration of the tracks are necessary to obtain a reliable discrimination between the species.

For each primary track we first calculate the frequency at the start, end, midpoint, first quartile and third quartile point, which are F_1, F_2, F_3, F_4, and F_5 respectively. Next, we calculate the difference between the mean frequencies of the three primary tracks, which we denote as FD_1 and FD_2. Note that if there is only one primary track in the syllable, both FD_1 and FD_2 will be set to the mean frequency of the track, while if there are only two tracks in the syllable, both FD_1 and FD_2 will be set to the difference between the mean frequencies of these two tracks.

Next, a simple calculation is performed to describe the *shape* of each track. The shape is described by three parameters, S_1, S_2, and S_3. The first parameter, S_1, is expressed as

$$S_1 = \frac{F_3 - F_1}{\text{Frame\_Num\_1}}, \tag{1}$$

where F_1 is the starting frequency, F_3 is the midpoint frequency, and Frame_Num_1 is the number of frames be-

TABLE I. Output parameters for bird syllables. The first column represents the number of syllable parts and peak tracks. The second column represents the twelve parameters for each peak track.

Overall description	For each track
Number of parts in the syllable	Starting frequency (F_1)
Number of peak tracks	Ending frequency (F_2)
	Middle frequency (F_3)
	1st quartile frequency (F_4)
	3rd quartile frequency (F_5)
	Frequency difference (FD_1)
	Frequency difference (FD_2)
	Shape (S_1)
	Shape (S_2)
	Standard deviation (S_3)
	Relative power
	Duration

tween the start point and the middle point of the peak track. Similarly, the second parameter, S_2, is expressed as

$$S_2 = \frac{F_3 - F_2}{\text{Frame\_Num\_2}}, \quad (2)$$

where F_2 is the ending frequency and Frame_Num_2 is the number of frames between the endpoint and the middle point of the peak track. The third parameter, S_3, is the standard deviation of the frequency of the track calculated over the entire duration.

Finally, we also calculate the relative power of each track by determining the fraction of the total power in each frame due to the current track's peak, then averaging these power fractions over the length of the track.

The 12 parameters derived for each peak track have different units and magnitudes. Therefore, the parameters are normalized so that the parameter vector can be used in a distance calculation for classification. Of course, any number of mathematical functions could be invented for the distance calculation. We have developed a set of empirical coefficients that balance the variation of each dimension: scaling the frequency and frequency difference parameters by 62.5, scaling the shape parameters by 1.6, scaling the power by 2, and scaling the duration by 125 frames provides this balance.

The final step for feature extraction is to collect the derived parameters into a data structure ready for the subsequent matching process. Table I shows the output parameter summary.

C. Target and recognition

The target phase is conducted with representative vocalizations for each bird species to be tested. The representative vocalizations are intended to represent the desired syllable in the best possible manner, so the selection is conducted manually. The spectral peak tracks and features are extracted for each representative vocalization, creating a template for each bird syllable in the test set. These syllable templates then become the target database for the matching process, as described next.

The recognition phase begins with a recorded segment of an unknown bird sound. In our study the sound is assumed to be edited manually to contain a suitable segment for the matching process.

Step C1: Determine the number of syllable parts and peak tracks and store them in the output parameter list for the unknown sound.

Step C2: Calculate the *frequency distance* and the *number of syllable parts* match between the unknown sound and each template in the target database. The first five parameters (frequencies F_1 through F_5) are used in this step because in our experience the frequency information has been found to be the most important parameter of the matching process. The strongest peak track from the template is compared to each peak track in the test sound since the strongest peak track may differ from one example to the next even within the same species. If the number of syllable parts in the test sound differs from the number of parts in a template, the frequency distance is increased as a "penalty" to account for the lower likelihood of a match.

Step C3: (a) If the minimum distance between the unknown sound and at least one of the target templates is less than an empirically determined threshold (e.g., 8 Hz, or approximately 1% of the typical fundamental frequency component), we assert that a match has been found and the template with the minimum distance from the unknown sound is deemed to be the recognition result. Note that this small difference is unlikely, considering the noise and level differences inherent in real signals. Otherwise, the potential target matches are sorted and the two templates with the smallest distances from the unknown sound are identified for further comparison.

(b) Conversely, if the frequency distance between the unknown sound and one of the target templates is large, e.g., the mean frequency difference is greater than 800 Hz, the target template is classified as a very poor match to the unknown sound, and the recognition process proceeds with the next potential match.

(c) If the number of peak tracks in the unknown sound differs substantially (e.g., a difference greater than four) from the target template, the target is considered a poor match and the recognition process moves onto the next target template. For example, if the unknown sound is nearly a pure tone with a single peak track while a target template contains seven peak tracks, we assume the unknown sound cannot be the same bird species as the template.

Step C4: If the process has identified several candidate target templates based on the frequency distance calculations, now all 12 parameters are used to calculate the total weighted distance between the unknown sound and the candidate templates. We have found that better matching results are obtained if a penalty is included for mismatched tracks: 10% multiplied by the absolute track count difference between the unknown sound and the target template is added to the distance calculation.

The target template with the minimum distance is deemed the best match to the unknown sound.

V. SIMULATION AND DISCUSSION

The original raw simulation database of bird vocalizations contained sounds with varying formats and signal integrity. Some of the sounds came from recordings in the vicinity of an airport and therefore contain substantial background noise, while other sounds came from archival records with extremely low noise. The original sample rates ranged from 8 to 24 kHz, and both mono and stereo recordings were part of the raw database.

To facilitate the simulation all recordings were converted to monophonic, 16 kHz sample rate, and 16 bits per sample. For the purposes of verifying the performance of the peak track algorithm, recordings containing multiple syllables were manually edited to isolate a single syllable with a gap at the head and tail of the syllable. The rationale for this editing step was that if the algorithm failed under these optimal conditions it would not make sense to treat the continuous syllable case, nor the real time parameter extraction process.

A. Test database

Twelve bird species were part of the test database. Each bird species had 20 sound files, including similar syllables from separate raw recordings. The species included Mallard (*Anas platyrhynchos*), American Crow (*Corvus brachyrhynchos*), Canada Goose (*Branta canadensis*), Baltimore Oriole (*Icterus galbula*), Common Nighthawk (*Chordeiles minor*), Killdeer (*Charadrius vociferous*), Osprey (*Pandion haliaetus*), Northern Cardinal (*Cardinalis cardinalis*), Blue Jay (*Cyanocitta cristata*), Great Horned Owl (*Bubo virginianus*), Trumpeter Swan (*Cygnus buccinator*), and Herring Gull (*Larus argentatus*). These bird species are common in North America and relevant to the aviation and wind turbine bird strike avoidance problem. With the exception of the Mallard syllables, all the sounds contained strong tonal components that are well matched to the spectral peak track model. Despite the lack of predominantly tonal components in the Mallard examples, the method still achieved satisfactory results on the database, as described below.

As an additional assessment measure, we augmented the database with 16 synthesized syllables: 5 single tones (or chirps), 5 harmonic sounds, 5 inharmonic sounds, and 1 two-part syllable. The augmented database elements, or *distracters*, are deterministically generated and therefore provide a means to determine the sensitivity of the matching procedure. Thus, the total database contained 28 different syllable sets, designated Category 0 through Category 27, with 20 syllable recordings in each set. The bird species category designations are shown in Table II.

In this study, we first evaluated the database with two conventional classification methods used in speech recognition (Rabiner and Juang, 1993), then with the peak track method described in this paper.

B. Classification by DTW and HMM

The first conventional classification system was based on linear prediction cepstral coefficients (LPCC) and dynamic time warping (DTW) methods (Rabiner *et al.*, 1978).

TABLE II. Bird species category designations. Category 0 through 11 are natural bird species. Category 12 through 27 are synthetic test signals with deterministic parameters.

Category	Description
0	Mallard (*Anas platyrhynchos*)
1	American Crow (*Corvus brachyrhynchos*)
2	Canada Goose (*Branta canadensis*)
3	Baltimore Oriole (*Icterus galbula*)
4	Common Nighthawk (*Chordeiles minor*)
5	Killdeer (*Charadrius vociferous*)
6	Osprey (*Pandion haliaetus*)
7	Northern Cardinal (*Cardinalis cardinalis*)
8	Blue Jay (*Cyanocitta cristata*)
9	Great Horned Owl (*Bubo virginianus*)
10	Trumpeter Swan (*Cygnus buccinator*)
11	Herring Gull (*Larus argentatus*)
12	Single chirp. Frequency linearly increases.
13	Single chirp. Frequency linearly decreases.
14	Single chirp. Frequency linearly increases and then decreases.
15	Single chirp. Frequency linearly decreases and then increases
16	Single tone.
17	Harmonic chirp. Frequency linearly increases.
18	Harmonic chirp. Frequency linearly decreases.
19	Harmonic chirp. Frequency linearly increases and then decreases.
20	Harmonic chirp. Frequency linearly decreases and then increases
21	Harmonic tone.
22	Inharmonic chirp. Frequency linearly increases.
23	Inharmonic chirp. Frequency linearly decreases.
24	Inharmonic chirp. Frequency linearly increases and then decreases.
25	Inharmonic chirp. Frequency linearly decreases and then increases
26	Inharmonic tone.
27	One syllable has two parts: inharmonic tone plus inharmonic chirp.

The second conventional system was based on mel-frequency cepstral coefficients (MFCC) and hidden Markov models (HMM) (Rabiner, 1989).

The conventional classifiers have been successful for speech recognition because both the linear prediction model and the cepstral model are well suited to the human speech production mechanism. Specifically, the speech spectrum is characterized by a harmonic sequence attributable to the glottis excitation (vocal fold vibrations) and a set of relatively broad resonances (formants) due to the vocal tract. As mentioned in Sec. II, bird vocalizations are similarly produced by an excitation source that is spectrally shaped by resonances of the trachea, larynx, mouth, and beak. However, the differences in the excitation signal and the generally smaller dimensions of the bird vocal structure compared to the human speech production system result in more widely spaced spectral partials and more narrowly spaced resonances in typical bird sounds compared to human speech patterns. Thus, a conventional speech recognition technique will not necessarily work well with bird sounds, and this concern is borne out in the following test results.

1. Description of the classification system based on LPCC and DTW

Bird vocalization is a time-dependent process. Two similar bird syllables may have a different duration because these syllables may be pronounced at different rates. Consequently, a straightforward method that compares the value of the first syllable at time t to that of the second bird syllable at the same relative time may not correctly classify a given syllable. Instead, an algorithm must be used to search the space of mappings from the time sequence of the first bird syllable to that of the second bird syllable. Dynamic time warping is a standard technique used to perform time alignment of two syllables with different duration (Vintsyuk, 1971).

In order for the DTW technique to be tested for bird syllable classification, a reference template must first be chosen and stored for every bird species. The classification process entails matching the incoming bird syllable with the stored templates. The templates and the incoming bird syllable are represented as a sequence of parameter vectors and the best matching template is the one that exhibits the minimum path aligning the input bird syllable to the template. The search space for the DTW method is constrained in such a way that the mapping function between the time axis of the input signal and the time axis of the template must be monotonically increasing with time so that the ordering of events in both the input and the template are preserved. The global distance score for a mapping path is simply the sum of local distances that make up the path.

The first preprocessing step in using DTW is the creation of bird syllable templates to be identified from the input bird syllable. In the current study, templates were selected manually to achieve the best recognition results. The second preprocessing step is to extract feature vectors for the templates and the input bird syllable. In this step, a digital recording of the syllable with 16-bit samples and a 16 kHz sample rate is first high pass filtered with a 100 Hz cutoff in order to remove the low frequency background noise attributable to wind or mechanical sounds. The filtered signal is then segmented into Hamming windowed 320-sample (20 ms) frames with 160-sample overlap (10 ms frame hop). The energy-based detection method mentioned in Sec. IV is used to detect the onset and offset of the sound signal. The frames between the onset and offset are transformed into the feature vectors on a frame-by-frame basis. Thirteen LPC coefficients $[a_1 \, a_2 \ldots a_P]$ $(P=13)$ are calculated using Durbin's recursive algorithm for every frame. To improve the recognition accuracy, the LPC coefficients are transformed into 18 LPCC coefficients $[c_1 \, c_2 \ldots c_P \ldots c_L]$ $(L=18)$ using the following equations:

$$c_1 = a_1, \tag{3}$$

$$c_n = a_n + \sum_{k=1}^{n-1} \left[\frac{n-k}{n} \cdot a_k \cdot c_{(n-k)} \right], \quad 2 \le n \le P, \tag{4}$$

$$c_n = \sum_{k=1}^{P} \left[\frac{n-k}{n} \cdot a_k \cdot c_{(n-k)} \right], \quad P+1 \le n \le L. \tag{5}$$

Note that the first order LPCC coefficient represents the spectral energy, which is generally not normalized between input signals, so c_1 is not used for the distance computation described next.

After generating the feature vectors for the templates and input bird syllables, the comparison is made by nonuniformly adjusting the time axis of the input syllable to achieve the best match to the template. In the matching process for an input bird syllable with M frames and a template with N frames, the time frames of the input bird syllable and the time frames of the templates are organized in a lattice (i,j), where i and j are the indexes of the time frames of the input syllable and the template, respectively. The quality of the match is measured recursively by the formula

$$D(i,j) = \min[D(i-1,j-1), D(i-1,j), D(i,j-1)]$$
$$+ d(i,j), \tag{6}$$

where $d(i,j)$ is the Euclidean distance between the two multidimensional vectors of the input signal at time frame i and the template at time frame j, and therefore $D(i,j)$ is the global distance up to (i,j). Given the initial condition $D(1,1) = d(1,1)$, we have the basis for an efficient recursive algorithm for computing $D(i,j)$. The final global distance $D(M,N)$ gives us the overall matching score of the template with the input. The input syllable is then classified as the species corresponding to the template with the lowest matching score.

2. Description of the classification system based on MFCC and HMM

The Hidden Markov Model is a doubly stochastic process with an underlying "hidden" stochastic process that is not observable, but can only be observed through another set of stochastic processes that produce the sequence of observed symbols (Rabiner, 1989). The HMM comprises a finite set of states, each of which is associated with a specific probability distribution. Transitions among the states are governed by a set of transition probabilities. In a particular state an observation can be generated according to the associated probability distribution.

The HMM can be used to model the bird sound generation statistically. It has been used for bird sound recognition due to its ability to characterize bird sounds in a mathematically tractable manner (Kogan and Margoliash, 1998). In contrast to the deterministic template matching of DTW, HMM uses a statistical representation. Therefore, this model can accumulate more information and possibly generalize better than techniques based on fixed templates.

The HMM procedure implemented for this study includes the same preprocessing as for the DTW procedure: 16-bit samples, 16 kHz sample rate, and 100 Hz high pass filtering, and the energy-based onset/offset detection described in Sec. IV. The reference templates are selected manually and include three sound files from each Category as the training cadre. Each preprocessed signal is segmented

into Hamming windowed 256-sample (16 ms) frames with 128-sample overlap (8 ms frame hop). The frames between the onset and offset are transformed into 13-dimensional mel-frequency cepstral coefficient feature vectors using 26 mel filterbanks, on a frame-by-frame basis. The MFCC coefficients are a compact representation, which is the result of a cosine transform of the real logarithm of the short-term energy spectrum expressed on a mel-frequency scale (Zheng *et al.*, 2001). As with the first order LPCC coefficient in the DTW method, the first order MFCC coefficient is not considered in the distance computation.

A continuous HMM representation was used in the traditional HMM-based classification system employed for this study. The HMM was a left-to-right model with six states. The densities of the observation probabilities in the emitting states were modeled as mixtures of two multidimensional Gaussian distributions with diagonal covariance matrices. The Baum-Welch algorithm was used in the training step employing the three manually selected bird syllables. One set of HMM parameters were generated for every bird species. The trained HMM parameters were then used for recognition using the Viterbi algorithm (Viterbi, 1967).

3. Simulation tests using the conventional classifiers

The sensitivity of the classification algorithms to noise was evaluated with an additional group of simulations. For each simulation the 560 example files (including the Template files) were deliberately contaminated with separate segments of uniformly distributed (white) noise to achieve a specified signal-to-noise ratio (SNR). The simulations included SNRs from 30 to 3 dB in steps of 3 or 6 dB.

A more likely practical situation would occur when using a set of "clean" Templates but testing with noisy Category recordings, i.e., field recordings that would ordinarily be obtained under less than ideal conditions. Thus, a separate simulation was used to examine this condition.

The DTW performance on the bird sound database is shown in Table III. The results indicate a likelihood of error for DTW with the original recorded signals of approximately 1/10 (i.e., 90% correct matches), with performance degrading to 71% correct classification under low signal-to-noise conditions.

The performance on the sound database for the conventional HMM system is shown in Table IV. The results show a likelihood of error for HMM of approximately 1/20 (95% correct matches) under high signal-to-noise conditions, degrading to 76% correct with noisy data.

Although the conventional procedures are moderately successful on the sound database used in this study and correspond well to prior results reported in the literature, the performance degradation with decreasing SNR is a serious shortcoming for a practical, robust system.

C. Classification by the spectral peak track method

The spectral peak track method requires a reference template for each bird species in the database. One representative syllable from each of the 28 Categories was selected manually, designated Template 0 through Template 27, and used as the training cadre.

The first test of the peak track procedures described in Sec. IV was to distinguish between single part and two-part syllables. The simple energy based detection algorithm performs well with the bird sounds in the database: all 560 example sounds were correctly classified. However, only 40 examples (Category 11 and Category 27) contained two-part syllables, so additional verification will be needed before assuming the simple algorithm is sufficient.

In the classification experiment, each of the 560 syllable recordings was processed using the peak track method described above. Here 238 out of 240 natural bird sounds were correctly classified (error rate 2/240), while the error rate was 5/560 (99% correct matches) for the entire natural and synthetic database at a high SNR. These results indicate that the peak track method was well suited to this particular database.

The five misclassified examples were examined. The first misclassification was a Category 3 example mistaken for Category 0. The particular example contained a frequency change from 3000 to 2500 Hz, while the Template 3 reference had a 3000 to 2000 Hz change. The resulting distance was closer to Template 0, causing the mismatch.

The second error was due to an example from Category 0 being mistaken for Category 1. In this case there are two peak tracks in Template 0, while the processed input example was found to have three significant peak tracks. The differing

TABLE V. Performance of the spectral peak tracks method (2/240 means that the error count was 2 out of 240).

SNR (dB)	12 natural sounds		28 total sounds	
	Noisy training set	Clean training set	Noisy training set	Clean training set
Original	2/240	2/240	5/560	5/560
30	3/240	3/240	6/560	6/560
24	5/240	5/240	8/560	8/560
18	4/240	4/240	7/560	7/560
12	3/240	3/240	6/560	6/560
9	6/240	6/240	9/560	9/560
6	8/240	14/240	9/560	14/560
3	11/240	18/240	11/560	18/560

number of peak tracks caused this example to have a greater distance from Template 0 than from Template 1 that has three peak tracks, therefore causing the misclassification.

The other errors were because of examples from Category 11 being mistaken for Category 27. The Category 11 examples are a natural bird sounds, while Category 27 contains synthesized examples with relatively strong peak track powers that were included specifically as distracters (successful in triggering a misclassification in this case). The Template 11 data contains two peak tracks, while the processed input examples were found to have four significant peak tracks. The differing number of peak tracks caused these examples to have a greater distance from Template 11 than from Template 27, thereby causing the misclassifications.

The classification performance degraded as the SNR decreased from 30 to 24 dB. When the SNR decreased from 24 to 12 dB, the classification accuracy unexpectedly improved, despite the degraded signal quality. An examination of the Category 11 signal revealed that the additive noise slightly altered the relative power of the peak tracks, causing the distance between the Category 11 signal and Template 11 to be less than the distance between Category 11 and Template 27. A similar subtle change occurred between a Category 3 signal and Template 0, causing a correct classification. Decreasing the SNR to 9, 6, and 3 dB degraded the classification accuracy, although the overall performance was still good (95% correct at 3 dB SNR), as shown in Table V.

When using "clean" Templates but testing with noisy Category recordings, the classification accuracy was unaffected until the SNR decreased to 6 and 3 dB. The performance differed between the noisy and clean Template cases, but not in a significant manner. Thus, based on this simulated noise test the peak track method does not appear to be particularly sensitive to the SNR difference between the Template and the test samples.

D. Discussion

As indicated by the results in Tables III, IV, and V, the spectral peak track method provided better overall results than the conventional DTW and HMM methods, particularly in the low signal-to-noise ratio tests. There are two expected reasons for this result. First, the conventional methods based on a linear prediction model have difficulty with the sparse spectrum of the bird syllables in the test database: insufficient information is present in each syllable recording to create a unique and easily distinguishable LPC model. The frequency spacing of the spectral components is relatively wide compared to the underlying resonances of the bird vocal tract, indicating that the linear prediction methods are mismatched to the signals in the database. Second, the conventional model parameters are quite sensitive to existing background noise, reverberation, and competing sounds in the recordings. The results in Tables III and IV for the 12 natural sounds and for the 28 total sounds show that the conventional systems operated better on the artificial distracter signals than on the natural sounds with inherent background noise. For these reasons it is useful to consider alternative pattern classification techniques, such as the spectral peak track method presented in this paper.

VI. CONCLUSION

The spectral peak track method described in this paper appears to work as designed for isolated bird syllables, and the simulation results are better in comparison to conventional DTW and HMM methods used to classify the same database. The proposed method extends the prior peak track methods by using a variable number of tracks to represent each syllable by determining the relative power of each detected spectral track. This method accommodates tonal, harmonic, or inharmonic syllables, and bases the pattern classification on the strongest tracks present in each syllable. The set of parameters derived for each significant peak track was quite robust in the presence of simulated additive noise, which is an encouraging result for future applications of this technique in classifying bird vocalizations.

However, the proposed method is inappropriate for use with bird vocalizations containing aperiodic or noise-like components because the assumption of connected peak tracks is violated in these cases. The proposed method is also inappropriate if the underlying spectral components change too rapidly in frequency or fluctuate in amplitude such that the peak tracks cannot be determined reliably. Research is continuing on methods to classify such rapidly varying signals, and also to identify broadband and noisy sounds.

In the current system we manually extract one syllable from the recorded bird sounds and save the data in a separate sound file. However, in an on-line real time production application it will be necessary to demonstrate an automatic syllable extraction method. Thus, there remain a variety of engineering challenges to deploying this system for real-time classification.

Equation (8) should read

$$\beta_1/\beta_0 = \{1/2[(1 + \nu^2)^{1/2} + 1]/(1 + \nu^2)\}^{1/2}. \tag{8}$$

Equation (16) should read

$$\alpha_{cl} = \alpha_1(\beta_2/\beta_0) = (2\pi f/c_0)\left[\frac{1/2[(1 + \nu^2)^{1/2} - 1][1 + (x')^2]}{[1 + \nu^2][1 + (\sigma x')^2]}\right]^{1/2}. \tag{16}$$

The first sentence in the paragraph on page 1014 that begins "The second term in Eq. (14) is the attenuation coefficient. . ." should read "The second term in Eq. (15) is the attenuation coefficient. . .".

Equation (18) should read

$$\alpha_{rot} = \alpha_2(\beta_1/\beta_0) = (2\pi f/c_0)X_{ON}\left[\frac{(\sigma^2 - 1)x}{2\sigma}\right]\left[\frac{1/2[(1 + \nu^2)^{1/2} + 1]}{[1 + \nu^2][1 + (\sigma x')^2][1 + (x')^2]}\right]^{1/2}. \tag{18}$$

In Section IV-A, on page 1017, the line just above Eq. (27) should end with a reference: ". . .and the atmospheric temperature T, as[7]. . .".

In the paragraph below Eq. (27) on page 1017, for consistency, the symbol for the normalized relaxing specific heat on line 4 should be given as C_i'/R and similarly on lines 3 and 4 in the next paragraph and in the caption for Figure 3.

In Section IV-B4 on page 1019, after Eq. (31), units should be added to L so that the line should read ". . .where $L = \exp(-7.72T_r)$, Hz."

In Table II, the entry under column A_0 for Pressure, Leg V should be 7.63380E-01.

These corrections are all typographical in nature and do not affect any of the figures, which were plotted using the correct equations shown above.

1aID1. How can auditory presence be generated and controlled? Masayuki Morimoto (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Nada, Kobe 657-8501 Japan)

This paper reviews key results of many listening tests on auditory presence, especially auditory localization (AL) and auditory spatial impression (ASI) by the author. The author gave the first demonstration that AL in any direction can be simulated through two loudspeakers using head-related transfer functions (HRTFs). However, individual differences in HRTFs affect the accuracy of AL. It is basically possible to localize sound images in any direction using median-plane HRTFs combined with interaural differences. Furthermore, HRTFs can be simplified by the combination of only some spectral peaks and notches. Meanwhile, the author demonstrated that ASI comprises at least two perceptual components. One is auditory source width (ASW), defined as the width of a sound image fused temporally and spatially with the direct sound image. The other is listener envelopment (LEV), which is the degree of fullness of sound images around the listener, excluding the sound image composing ASW. A listener can perceive these two components separately. The perception of ASW and LEV has a close connection with the law of the first wavefront. Acoustic components under the upper limit of the law contribute to ASW, and acoustic components beyond the upper limit of the law contribute to LEV.

1aID2. Therapeutic ultrasound. Lawrence Crum (Ctr. for Industrial and Med. Ultrasound, Appl. Phys. Lab., 1013 NE 40th St., Seattle, WA 98105, lac@apl.washington.edu)

The use of ultrasound in medicine is now quite commonplace, especially with the recent introduction of small, portable, and relatively inexpensive, hand-held diagnostic imaging devices. Moreover, ultrasound has expanded beyond the imaging realm, with methods and applications extending to novel therapeutic and surgical uses. Among these applications are tissue ablation, acoustocautery, lipoplasty, site-specific and ultrasound mediated drug activity, extracorporeal lithotripsy, and the enhancement of natural physiological functions such as wound healing and tissue regeneration. A particularly attractive aspect of this technology is that diagnostic and therapeutic systems can be combined to produce totally noninvasive, image-guided, bloodless surgery. This general lecture will review a number of these exciting new applications of ultrasound and address some of the basic scientific questions and future challenges in developing these methods and technologies for general use in our society. We shall particularly emphasize the use of high-intensity focused ultrasound (HIFU) in the treatment of benign and malignant tumors as well as the induction of acoustic hemostasis, especially in organs that are difficult to treat using conventional medical and surgical techniques. 1aAA1. A transparency model and its applications for simulation of reflector arrays and sound transmission. Claus Lynge Christensen and Jens Holger Rindel (Odeon A/S, Oersted-DTU, Bldg. 352, 2800 Lyngby, Denmark)

The paper describes a new method for simulating the frequency-dependent reflection and transmission of reflector arrays, and the frequency-dependent airborne sound insulation between rooms by means of a room acoustic computer model. The method makes use of a transparency method in the ray-tracing process. In the first step of the calculation the rays hitting the relevant surfaces may either be reflected or transmitted, using a probability of 50%. In the next step the impulse responses in the receiver positions are calculated using a frequency-dependent correction to account for the reflected or transmitted energy. The method applied for the reflector array is based on a theoretical model that takes into account the dimensions of the reflecting surface, path lengths, and angle of incidence. The transmission calculation is based on the users' data for the frequency-dependent transmission loss of the partition, and this is useful for the auralization of sound transmission through different building constructions. The acoustic properties like volume, reverberation time, and the area of the transmitting surfaces are included in the simulation.

11:20

1aAA2. Numerical determination of scattering coefficients of wall surfaces for geometrical room acoustic simulation. Tetsuya Sakuma, Yoshiyuki Kosaka, and Yuki Tachioka (Grad. School of Frontier Sci., Univ. of Tokyo, 5-1-5 Kashiwanoha, Kashiwa-shi, Chiba 277-8563, Japan, sakuma@k.u-tokyo.ac.jp)

There exist a dozen geometrical room acoustic simulation programs which include scattering coefficients of wall surfaces to generate more realistic sound energy reflection. In the light of this utilization, a measurement method of the random-incidence scattering coefficient has been recently standardized by ISO 17497-1, while a numerical technique with BEM is developed to determine the scattering coefficient. First, one case study is done to investigate the behavior of scattering performance of periodical surfaces with sinusoid, triangles and rectangles, with changing the height of surface roughness. As a result, it is seen that the height-to-period ratio of about 30% maximizes the scattering coefficient in the range of middle and high frequency. Second, another case study of geometrical room acoustic simulation is done for a rectangular room composed of uneven reflective walls and absorptive ceiling and floor. Geometrical simulation is performed on a variety of conditions with changing the scattering coefficient, and the reverberation times simulated are compared with those given by wave-based simulation at every octave bands. From the correspondence in reverberation time, the scattering coefficients of the walls are estimated, and its frequency characteristics are compared with those given by the former numerical determination.

11:40

1aAA3. Edge diffraction in computer modeling of room acoustics. U. Peter Svensson (Acoust. Group, Dept. of Electron. and Telecommunications, Norwegian Univ. of Sci. and Technol., NO-7491 Trondheim, Norway, svensson@iet.ntnu.no) and Paul T. Calamia (Rensselaer Polytechnic Inst., Troy, NY)

Computer modeling in room acoustics is typically based on geometrical acoustics techniques. Limitations with such methods include, among other things, a lack of diffraction modeling, which primarily leads to inaccuracies at low frequencies. The inclusion of diffraction modeling is quite straightforward for first-order diffraction, which can be combined with specular reflections of any order. One impractical aspect, however, is that the number of diffraction components can be extremely high, and grows faster (with the reflection order) than the number of specular reflections does. At the same time, the importance, or magnitude, of the diffraction components will differ over an immense range. This variation can be exploited by estimating the importance of each diffraction contribution by the magnitude of its onset, and skipping the remainder of the calculations for those that are deemed too weak. This will be demonstrated for some typical geometrical cases including a set of overhead reflectors, an orchestra pit, and a convex hall shape for which diffraction is less critical. Results indicate that "diffraction culling" can provide a significant reduction in computation time with only small effects on the overall responses for the tested geometries. [This research has been supported by the Research Council of Norway].

1aAB1. Assessing marine mammal abundance, density and habitat use with acoustics. Robert Gisiner (Office of Naval Res., 875 North Randolph St., Ste. 1425, Arlington, VA 22203)

Counting marine mammals is challenging: when seen they usually cannot be heard, and when heard they usually cannot be seen. Both methods miss some fraction of the population, but how does one reconcile two sampling methods that are uncalibrated themselves and will be difficult to calibrate against each other? Three approaches to calibration are reviewed. The one-way calibration approach treats one method as correct and derives a correction function for estimating population data from the other method. The parallel independent approach derives sources of error for each method independently and then compares population estimates: close agreement would strengthen confidence in both methods. The concurrent approach attempts to reconcile each visual detection to an acoustic detection and vice versa, with estimated total numbers derived from the intersection of the two sets. Examples of each method will be provided to illustrate the challenges and potential of each approach.

10:45

1aAB2. Reducing source localization errors: A visualization method to help guide the design, calibration, and use of widely separated acoustic sensor arrays. Catherine L. Berchok, Gerald L. D'Spain, and John A. Hildebrand (Marine Physical Lab., Scripps Inst. of Oceanogr., La Jolla, CA 93940-0701, cberchok@ucsd.edu)

The use of acoustic arrays to obtain source positions of vocalizing animals has become quite common in field studies of wild animal populations, but the results presented rarely include error bounds, leading to a false sense of confidence in the animal locations. As research from the acoustics community has shown, these source localization errors vary with respect to bearing and distance from the array and are generated by measurement uncertainties associated with the propagation environment, field equipment, and data processing/analysis methods. However, these errors can be reduced by making informed decisions about the design, calibration, and deployment of the arrays and by including measurements of amplitude ratios and vector sensor bearings in addition to time-of-arrival differences. A numerical method is presented here that allows for visualization and quantification of the impact of measurement uncertainties on source localization error bounds for widely spaced acoustic sensor array. This method will be used to show how quick comparisons of source localization error bound maps can help determine appropriate array designs for a particular field application. Among the parameters compared are array geometry, beamforming techniques, and measurement of various combinations of properties of the received acoustic field. [Work supported by a Hunt Postdoctoral Fellowship.]

11:00

1aAB3. Detection distances of the sounds of large whales recorded on hydrophones in the offshore Gulf of Alaska. Kathleen Stafford, Sue Moore (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98115, stafford@apl.washington.edu), and David Mellinger (Oregon State Univ., Newport, OR 97365)

The current status of most species of endangered baleen whales, including blue, fin, and humpback whales, in the Gulf of Alaska is unknown due to a lack of basic information on distribution and seasonal abundance. Remote passive acoustic monitoring can provide this information for vocal whales. However, to begin to estimate an index of abundance of calling animals, the distance at which they can be detected needs to be determined. In order to estimate transmission loss, a parabolic equation acoustic propagation model was used to provide mean loss estimates along four transects at $0.1a$ intervals to $5a$ to the N, E, S, and W from each of four receivers moored in the sound channel for species-specific frequencies and at depths at which the animals are thought to produce sound. For all species and locations, the detection range was largely determined by the choice of ambient noise levels. This suggests that masking due to anthropogenic noise could limit the range over which these animals can be detected by the moored instrument and, more importantly, the range over which they might communicate.

11:15

1aAB4. An archive of odontocete sounds for automatic call recognition. David K. Mellinger, Sharon L. Nieukirk, and Sara L. Heimlich (Cooperative Inst. for Marine Resources Studies, Oregon State Univ., 2030 SE Marine Sci. Dr., Newport, OR 97365, david.mellinger@oregonstate.edu)

Acoustic remote monitoring using automatic detection of cetacean sounds is becoming widely used to study species' seasonal distributions and to monitor and mitigate human impacts on cetaceans. To date, most work on automatic detection has focused on baleen whales and a handful of odontocetes, principally sperm whales and harbor porpoises. To further the development of detection methods for other odontocetes (particularly beaked whales, which have become the focus of much interest), it would be helpful to have standardized training and testing datasets. In preparing such datasets, several questions must be addressed: What recordings are available? How certain are the species IDs for these, and how should differing levels of certainty be handled? What is the recording quality? How should recordings be presented and annotated to make them most useful for automatic detection research? Are there any recordings known to be made on-axis with respect to the animal? How are multiple overlapping animals handled? How are mixed-species groups handled? Are data needs different for clicks and whistles? What metadata will be most useful for detection? For localization? How should recordings and metadata be stored and made them available on the net? Partial or full solutions to these questions will be presented.

1aAB5. Automatic vocal individual recognition of acorn woodpecker (*Melanerpes formicivorus*) based on hidden Markov models. Yuan Yao (Dept. of Ecology and Evolutionary Biol., Univ. of California, Los Angeles, Los Angeles, CA 90095, yaoyuan@ucla.edu), Ying Lin (Univ. of Arizona, Tucson, AZ 85721), Andreas Ali, and Charles Taylor (Univ. of California, Los Angeles, Los Angeles, CA 90095)

The acorn woodpecker (*Melanerpes formicivorus*) is a highly social cooperatively breeding species. A variety of conspecific interactions inside and between family groups is mediated by vocalizations. In the current study, acoustic sensor networks are used to monitor vocal behaviors of acorn woodpecker. In order to identify the callers in our behavioral study, we present a method for the automatic vocal individual recognition using hidden Markov models (HMMs). Field recordings from eight woodpeckers in two family groups were made in northern California. Individual identification accuracy is 92.65% for isolated waka calls, 84.31% for isolated syllable wa, 73.04% for isolated syllable ka, using 7-state HMMs with MFCC_E_D parametrization. For the continuous recordings, the recognition rate is 66.67%–100.00%. We studied the influence of two major factors in the performance of the HMMs: (i) different structures of HMMs and parametrizations of data, (ii) different qualities of signals, including degraded calls after propagation and calls from two simultaneous sources split by using beamforming of sensor networks. These results suggest that HMMs, combined with sensor networks, are a promising tool for data collection in vocal behavioral studies of animals.

1aAB6. Cetacean vocalization tracking using an adaptive Poisson rate estimator. Owen P. Kenny and Craig R. McPherson (Dept. of Elec. and Comput. Eng., James Cook Univ., Douglas 4811, Queensland, Australia)

This paper presents algorithms for tracking the formant structure of cetacean vocalizations using auditory modeling and adaptive filtering to estimate the Poisson intensity of nerve firing rates. These rates are in turn related to the instantaneous frequency of the formant vocalisation. The auditory model considered in this paper produces a process described as a spike train representing the auditory nerve firing, the Poisson intensity of which is determined by an underlying modulation process. Previous work [Kenny *et al.*, *Adaptive Filter for Speech Enhancement Using Poisson Rates from an Auditory Model*, paper presented at the WESPAC VIII, Melbourne, Australia (2003); C. McPherson, *Development of a Toolkit for Analysing and Localising Underwater Acoustic Signals* (James Cook University, Townsville, 2005)] has shown that this modulation process can be evaluated from the conditional expectation of the Poisson rate given inter-spike arrival time observations. The paper also addresses the application of adaptive filters to update the estimator parameters for different acoustic environments, which is unknown. These algorithms have been applied to real field recordings of interacting false killer whales (*Pseudorca crassidens*) and results from experiment of shown individualisation and extraction of individual narrow-band vocalizations.

1aAOa1. A broadband acoustic system for resonance classification of swimbladder-bearing fish. Timothy K. Stanton, Dezhang Chu (Appl. Ocean Phys. & Eng. Dept., Woods Hole Oceanogr. Inst., M.S. #11, Woods Hole, MA 02543, tstanton@whoi.edu), J. Michael Jech (Northeast Fisheries Sci. Ctr., Woods Hole, MA 02543), and James D. Irish (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

A commercial system originally designed for surveying the seafloor has been adapted for measuring the swimbladder resonance of swimbladder-bearing fish. The new towed system has three broadband active acoustic echosounders with nearly continuous coverage of the frequency band 2–110 kHz (with some gaps). The lower frequency bands are used for measuring the resonance, while the highest band can detect zooplankton. A pulse-compression approach (cross correlating the transmit waveform with the echoes) is used to exploit the bandwidth through significantly improving the range resolution to 20, 10, and 2 cm (low-, med-, and high-frequency bands, respectively). The system has been successfully deployed as deeply as 200 m and observed resonances at approximately 3 kHz for herring. Because of the 10–20-cm range resolution at the low frequencies, fish near the towbody could be resolved from one another and fish swimming within 1 m of the seafloor could be distinguished from the seafloor. This system is compared with previous approaches of measuring swimbladder resonance. The potential of the resonance classification method for significantly reducing ambiguities associated with interpreting acoustic echo data compared with traditional high-frequency narrow-band systems (10's to 100's of kHz) is discussed.

11:25

1aAOa2. Effects of scattering layer composition, animal size, and numerical density on the frequency dependence of volume backscatter. Kelly Benoit-Bird (College of Oceanic and Atmospheric Sci., Oregon State Univ., Corvallis, OR 97331)

The mesopelagic boundary community around the Hawaiian Islands is a land-associated, sound scattering layer that undergoes diel migrations with both a vertical and horizontal component. A video camera system was developed to quantitatively examine the numerical density, size, and taxonomic composition of micronekton. The camera system was combined with a four-frequency vessel-mounted echosounder system (38, 70, 120, and 200 kHz) to document the full migration range of micronekton and describe the changes in composition and density throughout their diel migration. Migrating animals split into multiple, distinct layers at night with differences in micronekton density, composition, and size. These differences were correlated with differences in the frequency response of volume backscatter. The relationship between these variables and backscatter intensity relationship between frequencies is complex. The results suggest strong partitioning of habitat by these animals in space and time, which, along with the high densities of animals, indicate that competition is important in driving the behavior and structuring the community.

11:45

1aAOa3. Probing the deep: Acoustic characterization of the Mid-Atlantic Ridge ecosystem. John K. Horne, Cairistiona I. H. Anderson (School of Aquatic and Fishery Sci., Univ. of Washington, Box 355020, Seattle, Wa 98195), Olav Rune Godoe, and Ruben Patel (Inst. of Marine Res., Nordnes 5817, Bergen, Norway)

Implementation of the ecosystem approach to resource management potentially increases the use of acoustics during assessment surveys. A Census of Marine Life survey on the mid-Atlantic ridge during summer 2004 was an opportunity to develop a practical approach. The Norwegian vessel, *G. O. Sars*, is an acoustically-quieted platform equipped with a five-frequency (18, 38, 70, 120, and 200 kHz) echosounder, acoustic Doppler current profilers (ADCPs), multibeam sonars, and a deep-towbody. Paucity of information on species composition limited the ability to conduct a traditional acoustic survey. Acoustic structure independent of biological sampling was quantified and then integrated acoustic density and target strength observations with biological community composition and length frequency data. Species were not assigned backscatter thresholds or water column regions at the onset of analysis. Near-real-time products monitored biomass distributions: daily echograms, target strengths, and frequency-differenced echograms. Persistent biological layers at different depths occurred in the water column. Layers or components migrated toward the surface during dark hours. Modes of target strength frequency distributions and trawl catch compositions differed among layers. The use of acoustic and net technologies can be integrated with near-real-time analytic results to quantitatively characterize pelagic ecosystems. [Work supported by ONR, IMR, and NOAA Fisheries.]

1aAOb1. Current structure measurements by the coastal acoustic tomography. Arata Kaneko, Keisuke Yamaguchi, Ju Lin, Noriaki Gohda (Grad. School of Eng., Hiroshima Univ., 1-4-1 Kagamiyama, Higashi-Hiroshima, Hiroshima 739-8527, Japan), Hong Zheng (SEA Corp., Ichikawa, Chiba 272-0127, Japan), and Yoshio Takasugi (Chugoku Ctr. of Natl. Inst. of Adv. Industrial Sci. and Technol., Kure, Hiroshima 737-0197, Japan)

The coastal acoustic tomography (CAT), coastal-sea application of deep-sea acoustic tomography (Munk and Wunsch, 1978), is proposed as an advanced technology to map current structures in the coastal sea. A sequence of successful experiments was recently carried out in the coastal seas with various oceanographic conditions around Japan (Yamaguchi *et al.*, 2005; Kaneko *et al.*, 2005; Lin *et al.*, 2005). In the Tokyo Bay experiment of November 2002, the 2-D tidal currents inducing a clockwise residual circulation were mapped by eight CAT systems, located at both the eastern and western coasts of the bay. The vortex-embedded tidal currents with a maximum velocity of 5 ms^{-1} were targets in the Kanmon Strait experiment of March 2003. In the Hiroshima Bay experiment of

September 2003, the stratified sea was shifted to the homogenized sea after the passage of a typhoon. The transition of tidal current structures before and after the typhoon was well measured by seven CAT systems, located at the northern coast and on the southern oyster rafts. The procedure of 2-D current mapping for the coastal seas with depths shallower than about 30 m is well established through a sequence of CAT experiments mentioned above.

11:25

1aAOb2. Shallow-water tomography: Is it a good idea? James F. Lynch and Timothy F. Duda (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543, Jlynch@whoi.edu)

There seems to be a feeling among ocean acousticians that anything that can be measured acoustically should be measured acoustically. However, there are two drawbacks to that point of view, comforting as it might be to us acousticians. First, many things that one would think are measurable with acoustics are actually not measurable, or are only barely so. And second, acoustics may turn out to be a poor or cost-ineffective measurement compared to other techniques. In this paper, we will look at whether acoustic tomography is viable, can produce high-quality measurements, and is cost effective in shallow water. We will use feature resolution, cost, reliability, intrusiveness, averaging properties, and other measures to obtain a weighted description of how effective tomography is for typical shallow-water (coastal) applications and then compare this to the same measure for other (conventional) oceanographic measurement systems. [Work supported by ONR.]

11:45

1aAOb3. Ocean acoustic tomography using high-frequency systems. Michael B. Porter, Katherine H. Kim, Martin Siderius (Heat, Light, and Sound Res. Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130, mikeporter@hlsresearch.com), Mohsen Badiey (Univ. of Delaware, Newark, DE 19716), Thomas Folegot (NATO Undersea Res. Ctr., 19138 La Spezia, Italy), and the KauaiEx Group (NUWC)

New system concepts have emerged in which large numbers of acoustic and environmental sensors are networked together in littoral areas. The spatial scales for these networks are much finer—features such as linear and nonlinear internal waves/tides can affect both network and sensor performance. A vision readily comes together in which ocean acoustic tomography is used to monitor the finescale, using the network to relay travel-time information in real time and also to probe the environment. Further, travel-time information may be assimilated into an ocean circulation model together with direct current and temperature measurements from fixed and mobile platforms to provide nowcasts and forecasts of the local ocean weather. The acoustic tomography in this vision uses a much higher frequency band (e.g., 8–16 kHz) than has traditionally been used and there has been some skepticism about the feasibility of doing tomography in this band. Using data from two large experiments in Hawaii (KauaiEx and MakaiEx), we show that (1) HF signals can be used to clearly measure the channel impulse response, (2) changes in the impulse response are directly linked to changes in the oceanography, and, therefore, (3) HF signals can be used to invert for the ocean structure.

Invited Papers

10:30

1aBB1. Ultrasound-enhanced thrombolysis. Christy K. Holland, Saurabh Datta, Sampada S. Vaidya (Dept. of Biomed. Eng., MSB 6167, 231 Albert Sabin Way, Cincinnati, OH 45208), Jason M. Meunier, George J. Shaw (Dept. of Emergency Medicine), and Constantin-C. Coussios (Univ. of Oxford, Oxford OX1 3PJ, UK)

Substantial enhancement of recombinant tissue plasminogen activator (rt-PA) thrombolysis can be achieved with ultrasound, suggesting its use as an adjunctive treatment in thrombolytic therapy for stroke. This enhancement may be due to acoustic cavitation, thermal effects, forced convection of rt-PA, or biochemical enhancement. The effect of US duty cycle on the lytic efficacy of pulsed 120-kHz ultrasound in a human *in vitro* clot model was investigated, using a time-lapse microscopic imaging technique. The initial lytic rate increased linearly with duty cycle. In addition, a passive cavitation detection scheme was used to explore stable and inertial cavitation as potential mechanisms for ultrasound-enhanced thrombolysis. Porcine clots were exposed to pulsed ultrasound and rt-PA *in vitro* for 30 min using four separate ultrasound treatment regimes: (i) no cavitation (0.15 MPa); (ii) stable cavitation alone (0.24

MPa), (iii) stable and inertial cavitation combined (0.36 MPa); or (iv) no ultrasound. Percent clot mass loss after each treatment was used to determine thrombolysis efficacy. Clots exposed to stable cavitation and rt-PA exhibited the highest mass loss. Significant enhancement of thrombolysis correlates with presence of cavitation and stable cavitation appears to play a more important role in the enhancement of thrombolysis.

10:50

1aBB2. *In situ* microbubble generation from liquid precursor for diagnostic and therapeutic application. Ken-ichi Kawabata, Akiko Yoshizawa, Takashi Azuma, Hideki Yoshikawa, Hiroko Watanabe, Kazuaki Sasaki, Koji Hirata, and Shin-ichiro Umemura (Central Res. Lab., Hitachi, Ltd., Japan)

Stabilized microbubbles show high echogenicity and characteristic nonlinear acoustic responses and also work as "sensitizers" for HIFU therapy. Accordingly, if microbbles were selectively placed in targets inside the body, targeted diagnosis and therapy would be possible. However, unfortunately, microbubbles are too large to apply tissues other than in vessels. For tumor detection and therapy, we propose the use of a nano-sized liquid precursor of microbubbles, which is small enough to accumulate in tumor tissues and generate microbubbles with ultrasound pulses. We have developed emulsion-based precursors containing perfluoropentane and found that microbubbles can be produced with a 10 μ pulse of 2-MHz ultrasound at intensities of more than about 150 W/cm^2 in water. The intensity threshold was controllable by the added nonvolatile fluorocarbons. The microbubble generation was also observed in mice tumors at the same ultrasound intensity range. It was also found that when microbubbles were generated in tumor tissues, CW ultrasound exposure resulted in tumor damage. Our results indicate the potential usefulness of our precursor for targeted ultrasound diagnosis and therapy. [Part of this work was supported by the Japanese Ministry of Education, Culture, Sports, Science and Technology through a grant-in-aid for the creation of innovations through business-academic public sector cooperation.]

11:10

1aBB3. Developing novel therapeutic strategies through biological effects of ultrasound. Sumit Paliwal and Samir Mitragotri (Dept. of Chemical Eng., Univ. of California, Santa Barbara, CA 93106)

Ultrasound-mediated cavitation has been shown to facilitate delivery of drugs across biological barriers in cells and tissues. However, these nonthermal mechanisms can also trigger various biochemical pathways in the biological milieu, opening up doors to interesting ultrasonic therapeutic applications. For example, a brief application of ultrasound followed by treatment with quercetin (a poorly potent chemotherapeutic drug) becomes selectively cytotoxic towards prostate and skin cancer cells. As opposed to the increased delivery of drugs to cancer cells, this treatment methodology is hypothesized to be mediated through inhibition of heat shock protein-hsp72, a vital stress-protein essential for the survival of cancer cells. Additional examples demonstrating the use of ultrasound's biological effects for therapeutic applications will be discussed. For example, ultrasound is demonstrated to work as a vaccination adjuvant by activating the Langerhans cells (immune cells present in skin) and leading to a robust immune response against tetanus toxoid. Overall, this presentation will demonstrate the increasing importance of ultrasound's role as a biological sensitizer enabling novel therapeutic strategies, a role which is beyond its conventional use as a drug delivery tool.

Contributed Papers

11:30

1aBB4. Ultrasound-mediated nanoparticle drug delivery in an *in vivo* tumor model. Balasundar I. Raju, Christopher S. Hall (345 Scarborough Rd., Briarcliff Manor, NY 10510; balasundar.raju@philips.com), Miachael S. Hughes, Samuel A. Wickline, and Gregory M. Lanza (Washington Univ. School of Medicine, MO 63130)

One of the exciting possible future clinical uses of ultrasound is site-targeted drug delivery using focused acoustic energy. In an earlier study, it was shown that ultrasound exposure promoted lipid delivery from nanoparticles into melanoma cells in culture [Crowder *et al.*, UMB 2005]. In order to extend the study to *in vivo* situations, a novel, combined ultrasound therapeutic and imaging system was developed. The system consisted of a therapeutic transducer (-6-dB BW 1.1 to 2.3 MHz; natural focus 8 cm; f-number 1) with a centrally located and coregistered imaging transducer connected to a commercial ultrasound imaging system. The system provided capability for arbitrary acoustic excitation, electronic axial steering, and mechanical translation of the therapy transducer as well as real-time acquisition of images. The device was tested on bilateral murine tumor models (MDA435). Tumor images provided real-time feedback for treatment planning. The animals were injected with perfluorooctyl bromide nanoparticles targeted to $\alpha_v\beta_3$ integrin and with a radioactive complex. Initial results showed that application of therapeutic ultrasound affected the delivery of the radioactive complex as measured by radioactivity 24 h postinjection. Experimental results and experiences will be

presented detailing the importance of imaging for *in vivo* treatment guidance and planning.

11:45

1aBB5. Ultrasound-assisted penetration of rt-PA into clots to enhance thrombolysis. Saurabh Datta, Sampada Vaidya (Dept. of Biomed. Eng., Univ. of Cincinnati, 231 Albert Sabin Way, Cincinnati, OH 45267-0586), Shauna Beiler (VAMC 410, Cincinnati, OH 45220), Gabrielle De Courten-Myer, and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH)

Enhanced rt-PA thrombolysis has been shown in the presence of pulsed ultrasound. Porcine clots were exposed to ultrasound (120 kHz, 80% duty cycle, 1667-Hz PRF, 30 min) and rt-PA at exposure levels exhibiting no cavitation (0.15 MPa), stable cavitation (SC) alone (0.24 MPa), and inertial and stable (IC+SC) combined (0.37 MPa). A separate group of clots was also exposed to rt-PA alone (sham). Percent clot mass loss after each treatment was used to determine thrombolysis efficacy. Cavitation activity was monitored throughout the exposure. After the treatment protocol, penetration of rt-PA and plasminogen was evaluated by immunofluorescene imaging. The highest percent mass loss was observed for SC exposure (26.8%) followed by the IC+SC exposure (19.8%) and the lowest for no cavitation exposure (14.7%). The penetration of rt-PA was distinctly higher for clots exposed to SC compared to unexposed clots. Enhancement of thrombolysis is related to presence of cavitation and SC exposure appears to enhance thrombolysis by facilitating more rt-PA penetration into the clot.

1aBB6. Enhancement of recombinant tissue-plasminogen activator (rt-PA) activity with 2-MHz transcranial Doppler ultrasound. Tyrone M. Porter, Christy K. Holland (Dept. of Biomed. Eng., Univ. of Cincinnati, 231 Albert Sabin Way, Cincinnati, OH 45267-0586), Jason M. Meunier, and George J. Shaw (Univ. of Cincinnati, Cincinnati, OH 45267-0769)

A video microscopy technique was developed to monitor the lytic activity of recombinant tissue plasminogen activator (rt-PA) in combination with 2-MHz transcranial Doppler ultrasound (TCD). Human whole blood clots formed on silk sutures were treated with TCD pulses alone [pulse length = 10 cycles, pulse repetition frequency (PRF) = 10.5 kHz, $P_{neg} = 0.18 - 0.47$ MPa], rt-PA alone (3 μg/ml), and rt-PA with TCD pulses in human fresh frozen plasma for 30 min. An inverted optical microscope was used to acquire images of the clot during treatment. The extent of clot lysis was determined by assessing clot width as a function of time. The average percent change in clot width at 30 min was comparable ($\sim$25%) for clots treated with rt-PA and TCD pulses for all output pressures. However, the initial lytic rate (within the first 5 min) was directly related to the TCD pressure output. The initial lytic activity of rt-PA and 2-MHz TCD pulses ($P_{neg} = 0.18$ MPa, PRF = 10.5 kHz, duty cycle = 13%) was similar to the initial lytic activity of rt-PA and 120-kHz ultrasound pulses ($P_{neg} = 0.18$ MPa, PRF = 1667 Hz, duty cycle = 20%).

1aBB7. Ultrasound and biodegradable nanoparticles for anticancer drug and gene delivery. Rinat Esenaliev, Olga Chumakova, Inga Cicenaite (Ctr. for Biomed. Eng., UTMB, Galveston, TX), Shilla Chakrabarty, Mark Evers (UTMB, Galveston, TX), and Valery Andreev (Moscow State Univ., Moscow, Russia)

Poor penetration of macromolecular drugs and genes in tumor cells substantially limits efficacy and safety of cancer chemo- and biotherapy. Cavitation induced by interaction of ultrasound with nanoparticles accumulated in tumors due to the enhanced permeability and retention effect may provide efficient drug and gene delivery in tumor cells. Biodegradable polymer (PLGA) air-filled nanoparticles manufactured in our laboratory were used for enhancement of drug and gene delivery *in vitro* and *in vivo* in human breast, prostate, or ovarian tumors of nude mice (two tumors in each animal). Our specially designed confocal ultrasound system allowed for irradiation and cavitation detection *in vitro* and *in vivo*. It was found that the nanoparticles substantially decrease cavitation threshold and increase cavitation activity *in vitro* and *in vivo*. Moreover, we obtained three-fold increase of tumor cell transfection *in vivo* compared to non-irradiated control tumors of same mice. Substantial tumor necrosis was achieved when macromolecular anticancer drug anti-IGFBP-2 was used in combination with the nanoparticles and ultrasound. Our results indicate that biodegradable polymer nanoparticles and ultrasound can be used for enhancement of drug and gene delivery in tumors. [These studies were supported by the DoD Prostate Cancer Research Program (Grant No. W81XWH-04-1-0247) and Breast Cancer Research Program (Grant No. DAMD17-01-1-0416).]

Musical Acoustics: Music Performance

Lydia Ayers, Cochair
Hong Kong Univ. of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

Akira Nishimura, Cochair
Tokyo Univ. of Information Sciences, Dept. of Media and Cultural Studies, Faculty of Informatics, 1200-1 Yatoh-cho, Wakaba-ku, Chiba 265-8501, Japan

Contributed Papers

1aMU1. Anticipatory motion in piano performance. Werner Goebl and Caroline Palmer (Dept. of Psych., McGill Univ., 1205 Dr. Penfield Ave., Montreal, QC H3A 1B1, Canada, werner.goebl@mail.mcgill.ca)

Recent motor control studies of piano performance address the anticipatory movements of pianists fingers. The reported study investigated anticipatory motion under manipulations of performance rate or tempo. It was tested whether faster tempi require larger anticipatory preparation, as suggested in piano pedagogy literature. Sixteen skilled pianists repeatedly performed short isochronous melodies from memory at four different tempi (from 500 to 143 ms inter-onset intervals). A passive 3-D motion capture system tracked the movements of 40 markers on the hand, fingers, and the piano keys. The melodies manipulated both the repositioning of certain fingers (thumb and pinkie finger) on the keyboard and the distance between repeating finger movements (three or six tones). Functional data analysis techniques were applied to the analysis of motion trajectories. Data analyses are presented that indicate that the repositioning movement of a finger toward its next goal (keypress) begins sooner at faster tempi than at slower tempi in the x plane (sideways motion on the keyboard).

Applications to piano practice will be discussed. [Work supported by the Austrian Science Fund, NSERC, and the Canada Research Chairs program.]

1aMU2. Effects of altered auditory feedback on piano performance. Noriyuki Takahashi (Kyoto City Univ. of Arts, 13-6 Kutsukake-cho, Oe, Nishikyo-ku, Kyoto, 610-1197, Japan, m03904@kcua.ac.jp) and Minoru Tsuzaki (Kyoto City Univ. of Arts, Kyoto 610-1197, Japan)

Some studies in the field of developmental psychology have suggested that a complex task executed by an expert includes the automated and sequential execution of some subordinate skills. In this study, we regard the development of musical performance as the length of motor control of a musical instrument carried out with a feedforward process. We then verify this assumption through a performance experiment using skilled and unskilled pianists. Both pianists play one musical figure repeatedly in the experiment. In the middle of the performance, a mapping function between the key velocity and its sound output is altered. It is expected that

pianists would try to correct their performance when receiving this altered auditory feedback. By checking the point at which they start to correct, we can infer the length of the unit used with the feedforward process. It is expected that the correction would occur at a specific point in the musical figure if skilled pianists have a certain length unit of automated motor control. On the other hand, the point of correction would have less consistency in the case of unskilled pianists. [Work supported by the Grant-in-Aid for Scientific Research A, No. 16200016, JSPS.]

11:00

1aMU3. An analysis of note deviation manner in piano music. Yukiko Toda, Yosuke Nakayama, Takuya Okura, Naoto Yasuda, and Shigeki Okawa (Chiba Inst. of Technol., 2-17-1 Tsudanuma, Narashino, Chiba 275-0016, Japan)

Human music performance usually contains "out-of-score" features such as players' physical characteristics and emotional expressions besides the on-score information (notes, rests, and various marks). Although those features are not written on scores, they have a very important role to add an artistic sense to the music. As one of the "out-of-score" features, the deviation manner of each note between the score and the human performance is focused on. In this study, among various genres and forms of music, F. Chopin's mazurkas (a form of Polish folk dance), which have triple time and the accent on the second or third beat, are used. By limiting the music genres, it becomes simplified to compare the tendency of players. For the experimental dataset (three pianists, 51 mazurkas), after extracting the fluctuations (time differences) from the regular position of each note, the Fourier transform is applied to the sequence. As a result, a significant difference among the players and the playing modes is obtained, which show the temporal and the rhythm patterns. As a future work, by using the patterns, it is possible to create a virtual performer who has/imitates a certain player or a certain playing mode.

11:15

1aMU4. A technical look at swing rhythm in music. Kenneth A. Lindsay and Peter R. Nordquist (Southern Oregon Univ., 1250 Siskiyou Blvd., Ashland, OR 97520, nordquip@sou.edu)

We investigate swing rhythm in music using computer analysis techniques. Swing is not a genre of music, rather a style of performance. The same musical piece (data) can be played in swing or straight time. Musical notes and structure are identical in both performances, but the notes temporal patterns have slight, significant differences between straight and swing performances. We demonstrate a technical approach analyzing these differences, and show examples of several styles of swing: American Swing, Brasilian Samba, Jamaican Reggae. Prior research into swing rhythm discovered swing ratio representing the temporal variation of the music as performed compared to the music as written. Our work shows that in some cases swing ratio is inadequate to properly model the real patterns of temporal variation. We have extracted details showing swing exists hierarchically, i.e., the patterns of temporal variation played at one time scale may differ from the types of patterns of temporal variation played at a slower or faster time scale. We also show examples of different instruments playing swing differently from each other, locking together at certain canonical time locations that represent standard counting and subdivision of the musical meter. This latter phenomenon has been previously investigated as ensemble swing.

11:30

1aMU5. A jazz arrangement system yielding a guitar chord-form sequence. Koji Sawayama, Norio Emura, Masuzo Yanagida (Doshisha Univ., 1-3, Tatara-Miyakodani, Kyo-tanabe, Kyoto, 610-0321, Japan, dtf0751@mail4.doshisha.ac.jp), and Masanobu Miura (Ryukoku Univ., Otsu, 520-2194, Japan)

Many guitar scores of rock or pop music arranged in jazz style are available all over the world. The amount of software for arranging given sequence of chord names and books of arrangement in jazz style has been growing for these past decades. Using this software, even amateur guitarists can play their favorite tunes in jazz style without knowledge of jazz theory. Most of these software systems, however, do not take musical appropriateness into account. So, sounds of chord-form sequence output by these software systems often mismatch the input melody. Proposed here is a system that generates a chord-form sequence in jazz style for a given set of melody and chord-name sequence. The system analyzes an input set of given melody and chord-name sequence based on jazz theory, and yields the chord-form sequence considering the melody line. It is confirmed that the chord-form sequence yielded by this system meets user requirements and is more preferable than that by software systems on the market. [Work supported by Academic Frontier Project, Doshisha Univ., Knowledge Cluster Project, MEXT, Grant-in Aid for Scientific Research (No.16700154), MEXT, HRC, Ryukoku Univ.]

11:45

1aMU6. A modular system yielding jazz-style arrangement for a given melody and sequence of chord names. Norio Emura, Masuzo Yanagida (1-3, Tatara-Miyakodani, Kyo-Tanabe, Kyoto, 610-0321 Japan, etf1702@mail4.doshisha.ac.jp), and Masanobu Miura (Otsu 520-2194, Japan)

There are many music systems available on the market, such as ones for automatic arrangement of music pieces given as note sequences for solo piano into a piano score in a specific style. Those systems, however, are usually designed to generate music by concatenating existing arrangement patterns, so we cannot expect those systems to meet user requirements. This paper proposes a system that arranges a given set of melody expressed as a note sequence and a chord name sequence into a piano score in modern jazz style based on so-called "jazz theory." The system is implemented in the classical theory of harmony and arrangement techniques described in jazz theory in a modular system. Proposed is a system that gives arrangement by integrating several modules according to structure of input music and user requirements. Performance of the proposed system is evaluated by comparing results given by the proposed system with those given by popular arrangement systems available on the market. Experimental results show that arrangement by the proposed system is significantly superior to arrangement by other systems available on the market. [Work supported by Academic Frontier Project, Doshisha Univ., Knowledge Cluster Project, MEXT, Grant-in Aid for Scientific Research (No. 16700154), MEXT, HRC, Ryukoku Univ.]

Speech Communication: Communicative Speech Synthesis and Spoken Dialog

Alan Black, Cochair

Carnegie Mellon Univ., Language Technologies Inst., 5000 Forbes Ave., Pittsburgh, PA 15213

Yoshinori Sagisaka, Cochair

Waseda Univ., GITI, 297 Building, 1-3-10 Nishi Waseda, Shinjuku-ku, Tokyo, 169-0051, Japan

Chair's Introduction—10:30

Invited Papers

10:35

1aSC1. Hidden Markov model-based speech synthesis as a tool for constructing comunicative spoken dialog systems. Keiichi Tokuda (Dept. Computer Sci. and Eng., Nagoya Inst. of Technol., Gokiso-cho, Showa-ku, Nagoya 466-8555, Japan)

For constructing spoken dialog systems which can realize natural human-computer interaction, speech synthesis systems are required to have an ability to generate speech with arbitrary speaker's voice and various speaking styles and/or emotional expressions. Although state-of-the-art speech synthesis systems based on unit selection and concatenation can generate natural-sounding speech, it is still difficult to synthesize various voices flexibly because they need a large-scale speech corpus for each voice. In recent years, a kind of corpus-based speech synthesis system based on hidden Markov models (HMMs) has been developed, which has the following features: (1) original speaker's characteristics can easily be reproduced because all speech features, not only spectral parameters but also fundamental frequencies and durations, are modeled in a unified framework of HMM, and then generated from the trained HMMs themselves; (2) using a very small amount of adaptation speech data, voice characteristics can easily be modified by transforming HMM parameters by a speaker adaptation technique used in speech recognition systems. From these features, the HMM-based speech synthesis approach is expected to be used as a tool for constructing communicative spoken dialog systems: keeping such a viewpoint in mind, basic algorithms and techniques for HMM-based speech synthesis are reviewed.

10:55

1aSC2. Modeling prosody in speech processing. Yang Liu (Computer Sci. Dept., Univ. of Texas at Dallas, MS EC-31, Box 83068, Richardson, TX 75083-0688)

Prosody is an important aspect of speech. In spoken language processing, effective prosody modeling helps to identify additional information beyond words (i.e., "how it is said" instead of "what is said") and thus better understand speech. In this talk, we will discuss how prosodic information is utilized in various speech processing tasks. Prosodic features are extracted to represent duration, pitch, and energy, with different normalization, and modeled using machine learning techniques. Research has shown that prosody provides valuable information for tasks such as automatic identification of important events in spoken language (e.g., sentence boundaries or punctuation, disfluencies, discourse markers, topics, and emotions in dialog). These phenomena are important for enriching speech recognition output and helping downstream language processing modules. Modeling prosodic variation across speakers is also useful for these tasks, as well as for developing speaker recognition systems. Additionally, some issues in machine learning techniques in prosody modeling will be discussed. Understanding how prosody is used to signal interesting events in speech will help to build better synthesis models for generating more natural and expressive speech.

11:15

1aSC3. Expressive speech synthesis using multilevel unit selection. Esther Klabbers and Jan van Santen (Ctr. for Spoken Lang. Understanding, OGI School of Sci. & Eng., OHSU, 20000 NW Walker Rd., Beaverton, OR 97006, klabbers@cslu.ogi.edu)

Generating natural sounding and meaningful prosody is a central challenge in text-to-speech synthesis, especially when generating expressive speech. Recently, we proposed a multilevel unit sequence synthesis approach, based on the general superpositional model of intonation, which describes a pitch contour as the sum of component curves that are each associated with different phonological levels, specifically the phoneme, foot, and phrase. During synthesis, segmental perturbation curves, accent curves, and phrase curves are extracted from the acoustic signal and are combined into target pitch curves; these target curves are then imposed on the acoustic unit sequences using standard pitch modification methods. This approach represents an attempt to combine the strengths of the two dominant approaches to speech synthesis: unit selection synthesis, which preserves all details of natural speech but struggles with coverage of the very large combinatorial space of phoneme sequences and prosodic contexts, and diphone synthesis, which addresses coverage by generating rule-based synthetic target prosody and imposing it on acoustic units using signal modification methods. This approach minimizes prosodic modification artifacts, optimizes the naturalness of the target pitch contour by using quasi-natural contours, yet avoids the combinatorial explosion of standard unit selection synthesis.

1aSC4. Realization of rhythmic dialogue on spoken dialogue system using paralinguistic information. Shinya Fujie and Tetsunori Kobayashi (Dept. Comput. Sci., Waseda Univ., 3-4-1 Okubo, Rm. 55N-509, Shinjuku-ku, Tokyo 169-8555, Japan)

Paralinguistic information recognition and its application to spoken dialogue system are discussed. Paralinguistic information brings various useful cues that cannot be obtained from linguistic information. The system may know, for example, who should speak next, how the user really feels, and so on. In this paper, we implement several paralingusitic information recognition systems, such as prosody-based attitude recognition system, back-channel feedback generation/recognition system, head gesture recognition system, and so on. Finally, we combine them into the spoken dialogue system on the humanoid robot, and realize a rhythmic dialogue.

10:30

1aUW1. The focused acoustic fields time reversal experiment series. Mark Stevenson, Piero Guerrini (NATO Undersea Res. Ctr., La Spezia, Italy), Tuncay Akal, Heechun Song, Karim Sabra, Philippe Roux, William S. Hodgkiss, and William A. Kuperman (Scripps Inst. of Oceanogr., La Jolla, CA)

We review a progression of at-sea experiments that brought the concept of underwater, acoustic time-reversal (TR) focusing in the sea from an unverified hypothesis to reality. When the experiments began, it was completely unknown whether the time-varying nature of the oceanic environment would support sufficient temporal stability for the method to succeed, even at long ($\lambda > 3$ m) acoustic wavelengths. A 10-year progression of experiments showed that not only was this possible, but that various applications could be implemented using higher frequency sound (up to 18 kHz), including phase coherent digital communications. Our most recent experiment, FAF-06, investigated multiuser applications for passive TR communications using small transmit and receive arrays. We demonstrated throughput of 10 kbps at several km range in a shallow-water propagation channel where the transfer function had an ISI span of several hundred symbols. [Work supported by NATO and ONR.]

10:45

1aUW2. Beam sweeping in sediment layer using phase-conjugated pseudo sound sources. Yoshiaki Tsurugaya, Toshiaki Kikuchi[a], Ryoichi Iwase[b], and Koich Mizutani[c] (NEC Corp., 1-10 Nishinchou Fuchu-city, Tokyo, 183-8501, y-tsurugaya@bp.jp.nec.com)

When an object that is buried in a sediment layer is detected from the diagonal, detection is hampered by reflection from the bottom surface. Stated in different terms, the sound-wave energy that reaches the object is small because of the reflection and refraction that occurs at the bottom surface when a sound wave is applied to the object in the sediment for diagonal detection. To alleviate that problem, a pseudo sound source can be set up in sediment layer. The sound wave radiated from the pseudo sound source is then received by a time-reversal array. The sound wave can be injected into the sediment layer by reversing the received signal with time and radiating it again from the time-reversal array. The beam can hit the target through movement of this pseudo sound source along the bottom surface. The sound wave that hits the target is reflected and returns in water. The sound wave is subsequently reflected many times at the

surface and bottom and is diffused over time. The passive-phase conjugate processing is then given to the received diffusing signal to reduce this diffusion. The pulse is compressed by this processing, thereby obtaining the target position. [a]Currently at NDA; [b]Currently at JAMSTEC; [c]Currently at Univ. of Tsukuba.

11:00

1aUW3. Synchronized time-reversal focusing with application to virtual array formation, beam forming, and remote imaging. Shane C. Walker, Philippe Roux, and W. A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., Univ. of California, San Diego, La Jolla, CA 92093)

By sampling and time reversing the field from a distant probe source, a time-reversal mirror (TRM) can produce an intense acoustic focus at the probe source location. Extending this idea to a collection of sources, this work demonstrates that a TRM can generate a virtual array at a downrange location, which can act as a remote platform for time delay beam forming and other coherent wavefront techniques useful for imaging in the vicinity of the virtual array. The technique requires no *a priori* information about the environment, only the knowledge of the source fields and a means for synchronizing them. In one promising application the TRM is used to coherently image an extended region around a distant passive array. The geometry of the source array is arbitrary. Recent advances in self-adaptive acoustic Green's function determination may provide opportunities to apply this method without need for a source array. Simulation and experimental results are discussed.

11:15

1aUW4. Robust wideband time-reversal using time-domain principal component analysis. W. J. Higley, Philippe Roux, W. S. Hodgkiss, W. A. Kuperman, Heechun Song, Tungay Akal (Marine Physical Lab., SIO, UCSD, 9500 Gilman Dr., La Jolla, CA 92093-0238), and J. Mark Stevenson (NATO Undersea Res. Ctr., La Spezia, Italy)

Time reversal (TR), a two-step process, involves time reversing the measured transfer functions from a source and then retransmitting this signal to produce a focus back at the source position. When attempting TR in a fluctuating ocean environment, it is desirable to alter the transmitted signal such that it produces a more robust focus. This has typically been done with work based on frequency domain analysis. In contrast, this

work, using oceanic data measured during FAF05, is broadband and the development is totally in the time domain. Different definitions of robustness give different optimal answers to the question of how to design the most robust transformation of the time-reversed data of the first step in the TR process. Two definitions of robustness are studied, one related to outage probability and another related to average power. For each definition, a different approach to a practical approximation is taken. In the case of outage probability, we iteratively solve a minimax optimization problem. In the case of average power, principal component analysis is performed on time-domain data.

11:30

1aUW5. Identification and classification of resonant targets with iterative, single-channel time reversal in a noisy environment. Zachary J. Waters, R. Glynn Holt, Ronald A. Roy (Dept. of Aerosp. and Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215), and Benjamin R. Dzikowicz (NSWC-Panama City, Panama City, FL 32407)

The identification and classification of mines resting on and buried beneath the sea floor is an important and challenging problem. Previous numerical results indicate that iterative time reversal using a single-element transducer increases the signal-to-noise ratio of the backscattered return while simultaneously converging to a narrow-band signal characteristic of the scattering target [D. M. Pierson, "Buried object detection using time-reversed acoustics," Ph.D. dissertation, North Carolina State University 2003]. This technique offers an inexpensive and simple means for maximizing signal level in a noisy or cluttered environment. We investigate this phenomena through experiments performed in a water tank using a 6.35-mm-diam hollow steel sphere and broadband $Q \sim 1.5$) piston transducers operating in the 100-kHz to 2-MHz frequency range. Time-reversal convergence of the interrogation pulse was readily achieved using a variety of broadband (0.1–2 MHz) pulses to initiate the process. Results

indicate that the spectrum of the echo rapidly converges to the dominant resonant mode of the target, with a significant enhancement in signal level even in the presence of broadband noise and coherent clutter returns. [Work supported by Office of Naval Research Award No. N000140610044.]

11:45

1aUW6. Experiment of time-reversal communication in deep ocean. Takuya Shimura, Yoshitaka Watanabe, and Hiroshi Ochi (JAMSTEC/MARITEC, 2-15, Natsushima-cho, Yokosuka-City, 237-0061, Japan, shimurat@jamstec.go.jp)

The basic study on the long horizontal acoustic communication using time-reversal waves have been carried out by the authors, and the method of combining time reversal and adaptive filter was proposed to enhance the communication accuracy and to achieve the communication with a moving source-receiver. This time-reversal technique will be applied to the communication in the deep ocean with an autonomous underwater vehicle, "Urashima," which is being developed in JAMSTEC. The experiment was executed to demonstrate the effectiveness of the proposed method in the area at the depth of 1000 m in Suruga-bay. In the experiment, the 500-Hz projectors were used, and the range between the focus and the time-reversal array (TRA) was 10 km. The measurement system of the TRA side was moored with the underwater winch to compose the virtual array by changing its depth. Unfortunately, the projector of the TRA side had a breakdown, so it was abandoned to execute active time-reversal communication. However, experiments of passive time-reversal communication could be achieved. It was verified that the proposed method makes it possible to assure the communication channel with the TRA that consists of 20 elements. [This work was supported by MEXT KAKENHI 16686050.]

Chair's Introduction—1:00

Invited Papers

1:05

1pAA1. Numerical analysis of sound propagation in rooms using the finite difference time domain method. Shinichi Sakamoto, Ayumi Ushiyama, and Hiroshi Nagatomo (Inst. of Industrial Sci., The Univ. of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8505, Japan, sakamo@iis.u-tokyo.ac.jp)

Impulse response is an important quantity for room acoustics. To predict the impulse response, several types of calculation methods based on wave theory, such as the boundary element method (BEM), finite element method (FEM) and finite difference method (FDM), are being investigated. Among them, the authors are exploring application of the finite difference time domain (FDTD) method to calculate room sound fields. Using the method, by which the acoustical quantities at discrete grid points of a closed field are successively solved step-by-step according to vector operations, the impulse responses can be obtained directly in a time domain using little computer memory storage. Furthermore, changes of spatial distributions of room sound fields in time can be obtained easily by storing the sound pressure at grid points and displaying them by animation. In this presentation, several examples of the FDTD analyses of room impulse responses are reported and computer animation of their room sound fields is introduced. In addition, examination of the applicability of prediction of the impulse responses by comparison with *in situ* measurement of a small hall is discussed.

1:25

1pAA2. Applications of large-scale finite-element sound-field analysis utilizing Architectural Institute of Japan-benchmark platform. Toru Otsuru, Noriko Okamoto, and Takeshi Okuzono (Faculty of Eng., Oita Univ., 700 Dannoharu, Oita 870-1192, Japan, otsuru@cc.oita-u.ac.jp)

A computational system, namely large-scale finite-element sound-field analysis(LsFE-SFA), has been developed by the authors. It is based on the finite-element method (FEM) with an iterative solver of linear equation that can reduce memory requirement of the system drastically. To show the effectiveness of LsFE-SFA, sound fields in a reverberation room and in a music hall were analyzed. The problem settings are provided by the web site of ''AIJ-Benchmark Platform for Computational Acoustics,'' which is run by a subcommittee of Architectural Institute of Japan (AIJ). First, sound-pressure level distribution maps at about 300 points in the reverberation room computed by LsFE-SFA were compared with those by measurement to show the accuracy of LsFE-SFA to be within 1-dB difference. The frequencies investigated were in 1/3-octave bands with the center frequency raging from 63 to 250 Hz. In the computations, boundary absorption is modeled by use of normal impedance that was measured *in situ* by use of the authors' newly proposed method, or EA-Noise method. Next, the diffuser shapes on the walls in the music hall were examined by LsFE-SFA to give better diffuseness. The investigations showed the effectiveness of LsFE-SFA.

1:45

1pAA3. The application of boundary integral equation methods to the numerical calculation of transient waves in rooms. Yasuhito Kawai (Dept. of Architecture, Kansai Univ., 3-35, Yamatecho 3, Suita, Osaka, 564-8680 Japan)

The boundary integral equations derived from Kirchhoff's formula and its normal derivative form are available for the numerical calculation of transient waves in rooms. The two equations are compared in view of the stability and accuracy in the numerical calculation of responses in a rigid cubic room in which rigorous responses can be obtained by the image method. Some source waves and some problems appear in the numerical implementation such as the singular integrals, and the treatment of absorbent surfaces is also investigated. Finally, it is shown that the boundary integral equation method is a powerful tool to obtain transient waves in rooms.

2:05

1pAA4. Fogg Art Museum lecture room: A calibrated recreation of the birthplace of room acoustics. Brian F. G. Katz (Percept. Située, LIMSI-CNRS, BP 133, F91403 Orsay, France, brian.katz@limsi.fr) and Ewart A. Wetherill (28 Cove Rd., Alameda, CA 94502))

At the end of the 19th century, Wallace Clement Sabine undertook the task of correcting the acoustics of the Fogg Art Museum lecture hall. His work on this acoustically difficult (semi-circular, domed, arched) auditorium was the basis for his monumental work on reverberation time and absorption, beginning the science of room acoustics as it is now known. The room underwent various renovations over 70 years, concluding with its demolition in 1973. Just prior to this event, one author was fortunate to have measured several room impulse responses. Through the use of architectural plans and the few existing photos, a computational room acoustical model was created. This model was calibrated using the historically important measurements as a reference. The geometrical model incorporates the room's various architectural phases. Using computer auralizations, the room is now accessible in acoustical terms, with the ability to ''perience'' an educated rendering of the acoustics of the room as Sabine found it in 1895. The results of this study, particularly the geometrical model, are intended for public use and are made generally available for room acoustics students and researchers who chose to follow in Sabine's footsteps (www.catt.se/FoggArtMusum.htm). Portions of this presentation were presented at Forum Acousticum 2005.

2:25

1pAA5. Auralization of an orchestra using multichannel and multisource technique. Michelle C. Vigeant, Lily M. Wang (Architectural Eng. Prog., Univ. of Nebraska—Lincoln, Peter Kiewit Inst., 1110 S. 67th St., Omaha, NE 68182-0681, mvigeant@mail.unomaha.edu), and Jens Holger Rindel (Tech. Univ. of Denmark, DK-2800 Kgs. Lyngby, Denmark)

Previous work has shown the importance of including source directivity in computer modeling for auralizations. A newer method to capture source directivity in auralizations is the multichannel technique, which uses multichannel anechoic recordings. In this study, five-channel anechoic recordings were obtained for every orchestral part of two symphonies at the Technical University of Denmark. Five-channel auralizations were then created for each instrument, located at its typical position on-stage in a concert hall, by convolving five impulse responses from sources that each represent approximately one-fifth of a sphere with the corresponding anechoic recording channel and mixing these together. The multichannel auralizations from each instrument were subsequently combined to produce a full multichannel auralization of the entire orchestra. The results from listening tests will be presented, illustrating the perceived changes in realism, source width and depth, and source separation between the output of this full orchestral mix of multichannel auralizations and other auralization methods, including the following: (*i*) a mix of single-channel auralizations from each instrument, and auralizations made with a single channel orchestral anechoic recording using (*ii*) a surface source and (*iii*) a single omni-directional source. [Work supported by the National Science Foundation.]

2:45

1pAA6. Prediction of scattering coefficients for use in room-acoustic simulation. Wolfgang Ahnert, Stefan Feistel, and Steffen Bock (Ahnert Feistel Media Group, Berlin, Germany)

While absorption coefficients have become easily available and published worldwide, computer modeling of room acoustics suffers until today under the lack of data for scattering surfaces. As a result, in most cases rules of thumb have to be used. In this work a new approach of predicting scattering coefficients is introduced. Based on the geometrical parameters of the surface, the complex reflection properties are calculated utilizing an elementary-wave method. In this respect, computed data are compared afterwards with measurement data and its applicability for use in acoustic simulation is investigated.

3:00

1pAA7. A comparison of computer modeling auralization and binaural room recordings for a multipurpose high school auditorium utilizing an orchestral shell, overhead panels, and clouds.. Ron Freiheit (Wenger Corp., 555 Park Dr., Owatonna, MN 55060)

The development of auralization techniques has provided a new method to demonstrate potential acoustical benefits of changes in design or the application of acoustic treatments in specific spaces. It's useful to compare the results from the auralization process with actual binaural recordings in the physical space to discover similarities and differences. A typical high school proscenium-style, multipurpose auditorium was modeled, including an orchestral shell, overhead panels, and clouds. Auralizations were made of the auditorium at various locations in the audience area and on stage, with and without the shell and overhead panels, in place. These were compared with binaural recordings made at the same locations within the auditorium. Auralization metrics will be compared with the binaural recordings, highlighting the changes made with the shell and overhead panels in place, along with the similarities and differences between the two methods.

3:15–3:30   Break

3:30

1pAA8. Optimal dispersion/dissipation-error finite-difference method for room impulse response simulation. Yusuke Naka (Dept. of Aerosp. and Mech. Eng., Boston Univ., 677 Beacon St., Boston, MA 02215, ynaka@bu.edu), Assad A. Oberai (Rensselaer Polytechnic Inst., Troy, NY 12180), and Barbara G. Shinn-Cunningham (Boston Univ., Boston, MA 02215)

The finite difference method is suitable for the calculation of acoustic impulse responses because of its computational simplicity and efficiency. However, for room acoustics applications, where reverberation makes it necessary to calculate the room impulse response and acoustic energy over a long duration, most standard finite-difference formulations are not practical because of the accumulation of dispersion and dissipation errors. In order to calculate very long impulse responses, a new, efficient, high-order finite-difference method is developed in this study. The new method is optimized to minimize the total dispersion and dissipation errors and hence the error accumulated in each time step resulting from discretization in both space and time. The error of the new method is significantly reduced so that the impulse response can be calculated over the whole reverberation time (about 1 to 3 s), using a relatively coarse spatial (6 grid points per wavelength) and a moderate temporal (CFL = 1.0) resolutions. [Work supported by AFOSR.]

3:45

1pAA9. Temporal decay of broadband sound fields in enclosures using a boundary element method. Donald Bliss, Ben Manning (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708, donald.bliss@duke.edu), and Jerry Rouse (Sandia Natl. Labs, Albuquerque, NM 87185-0847)

A method to predict time-dependent behavior of sound fields in enclosures with diffuse reflection boundaries is described. A boundary element formulation utilizes broadband energy-intensity boundary sources, including propagation time delays. Temporal behavior is expressed in terms of a higher-dimensional eigenvalue/eigenmode problem, with source strength distributions expressed as eigenmodes. A temporal interpolation scheme is used to reexpress the actual delays as a set of integer-multiple delays. The interpolation scheme produces a discrete set of primary eigenvalues and eigenvectors, the total number of which is an integer multiple M of the number of panels N. The value of M is set by the number of interpolation subdivisions of the enclosure wave transit time. For decay from steady-state conditions, the initial value problem involves specifying the initial panel strengths, and $M-1$ time derivatives of each panel strength set to zero. In temporal decay from steady state, solutions exhibit rapid short-time spatial redistribution of energy, followed by long-time decay of a predominant spatial eigenmode. Long-time decay depends on the behavior of the most slowly decaying eigenmode and the relative source-panel strengths do not depend on initial conditions. Short-time adjustment and decay depends on initial source characteristics and the distribution of wall absorption.

4:00

1pAA10. Boundary element prediction of steady-state broadband interior sound fields using absorption-based scaling. Donald Bliss (Mech. Eng. and Mater. Sci., Duke Univ., Durham, NC 27708, donald.bliss@duke.edu) and Jerry Rouse (Sandia Natl. Labs, Albuquerque, NM 87185-0847)

Energy-intensity boundary elements are used in combination with the method of absorption-based scaling to predict steady-state broadband sound fields in enclosures with diffuse reflection boundaries. The wall absorption is expressed in terms of an overall absorption parameter—the spatially averaged value—and spatial variations around this mean. Boundary element strengths are expressed in a power series of the overall absorption, treated as a small parameter, thereby giving a separate problem at each order. The first problem has a uniform mean-square pressure proportional to the reciprocal of the absorption parameter. The second problem gives mean-square pressure and intensity distributions that are independent of the absorption parameter and are primarily responsible for the spatial variation of the reverberant field. This problem depends on the location of sources and the spatial distribution of absorption, but not overall absorption. Higher order problems proceed in powers of the absorption parameter, as corrections to the primary spatial variation. Boundary element solutions are obtained for each order, and the simplest model for spatial variation gives fairly accurate predictions. The method gives physical understanding of the causes of the spatial variation of enclosure sound fields and provides specific insights into the behavior and design of acoustic spaces.

4:15

1pAA11. Comparison of sound fields in rooms computed by finite-element method and by cone beam method. Noriko Okamoto, Toru Otsuru, Reiji Tomiku (Oita Univ., 700 Dannoharu, Oita-city, Oita 870-1192, Japan, nokamoto@cc.oita-u.ac.jp), Takeshi Okuzono, Kouta Isobe (Oita Univ., Oita, Japan), and Hiroshi Furuya (Kyushu Kyoritsu Univ., Fukuoka 807-8585, Japan)

Sound fields in realistic rooms were simulated by different kinds of computational methods, and comparisons were conducted. One is based on the wave acoustics and the other is based on the geometrical acoustics, i.e., the finite-element method (FEM) and the conical beam method

(CBM). As for the software applied here, the authors have developed their own FEM code, namely LsFE-SFA, to conduct FEM computations, and they employed commercial software, i.e. RAYNOISE, to conduct CBM computations. First, theoretical basis of LsFE-SFA was given briefly. Next, sound-pressure distributions in a reverberation room with the volume of 165 cubic meters were computed by both methods to compare the agreement with measured sound-pressure levels. The boundary conditions due to the sound absorption were changed to examine the relation between the absorbent condition and the agreements. The agreement between FEM and measurement were found to be better throughout the examination. Next, both FEM and CBM were applied onto the analysis of large-scale sound fields in a multipurpose hall with the volume of 37 000 cubic meters to discuss the agreement and difference in detail.

4:30

1pAA12. Absorption and aperture size effects on subjective response to complex computer modeled coupled volume systems. David T. Bradley (BRC Acoust. & Technol. Consulting, 1741 1st Ave. S, Ste. 401, Seattle, WA 98134, dbradley@brcacoustics.com) and Lily M. Wang (Univ. of Nebraska-Lincoln, Omaha, NE 68182-0681)

A typical coupled volume concert hall consists of a large, absorbent main volume linked to a smaller, reverberant auxiliary space through a series of acoustically transparent openings. This type of space can exhibit a nonexponential sound decay, a phenomenon that is referred to as the double slope effect (DSE). An imagined, realistic coupled volume concert hall has been computer modeled, and room impulse responses of the space have been obtained. Several configurations of the hall were conceived in which the absorption and aperture size were modified. Paired-comparison tests were conducted to determine listener preference for the sound fields developed from auralizations of the configurations. The results from this subjective testing were statistically analyzed using multidimensional scaling methods. The analysis showed that listener preference increased with decreasing DSE, with highest preference levels for low and medium DSE. These results will be presented and contrasted with objective parameters calculated from the room impulse responses of the computer-modeled configurations.

4:45

1pAA13. Numerical analysis for attenuation due to sound absorption in small and large closed spaces using finite-element method. Takao Yamaguchi (Dept. of Mech. Systems Eng., Gunma Univ., 1-5-1 Tenjin-cho, Kiryu, Gunma 376-8515, Japan), Junichi Kanazawa (Musashino Damping Technol., Tachikawa 190-0002, Japan), and Katsuji Akamatsu (Machinery Acoust., Nada-ku, Kobe 657-0015, Japan)

A finite element for media having sound absorption is derived and a code is developed. For this element, an unknown parameter is pressure, and both effective density and bulk modulus of the media have complex quantity to represent damped sound fields. This model for the media having sound absorption was adopted by H. Utsuno's research group for their boundary element formulation [Utsuno et al., AIAA J. **28**(11), 1870–1875 (1990)]. Firstly, a three-dimensional sound field in a small closed space ($306 \times 255 \times 204$ mm^3), containing a sound-absorbing material, is calculated using the finite element method. Validity of the calculated response is verified by comparison with the corresponding experimental result carried by H. Utsuno. Secondly, a two-dimensional sound field in relatively large closed space (about 7×3 m^2) is calculated varying damping of its medium. The shape of the large space is rectangle, and the rectangular space has a roof. Distribution of sound pressure is calculated when the velocity of the roof is given as white noise. Under the low damping condition for the medium, distribution of sound pressure is almost uniform like the diffused sound field. Under the high damping condition for the medium, sound pressure become larger when the observation point is closer to the roof.

5:00

1pAA14. Real-time audio rendering system for virtual reality. Tobias Lentz, Dirk Schroeder, Gottfried K. Behler, and Michael Vorlaender (Inst. fuer Technische Akustik, RWTH Aachen Univ., D-52056 Aachen, Germany)

Systems of virtual acoustics are more and more coming into the focus of research and application. Creating a virtual sound scene with spatially distributed sources requires a technique for adding spatial cues to audio signals and an appropriate reproduction. A real-time audio rendering system is introduced that combines room acoustics, dynamic crosstalk cancellation, and multitrack binaural synthesis for virtual acoustical imaging. The room acoustics component takes into account the full up-to-date algorithmic approach of specular reflections and scattering, but with real-time processing. The real-time performance of the software was reached by introduction of a flexible framework for the interactive auralisation of virtual environments. The concept of scene graphs for the efficient and flexible linkage of autonomous-operating subscenes by means of so-called portals has been incorporated into the existing framework, combined with an underlying BSP-tree structure for processing geometry issues very fast. Using this framework enables a significant reduction of computation time for both applied algorithms (deterministic image sources and a stochastic ray tracer). This enables the simulation of indoor or outdoor spatial distributed sources and, in addition to that, near-to-head sources for a freely moving listener in room-mounted virtual environments without the use of headphones.

5:15

1pAA15. Effects of peg's positions of low-registered strings on acoustic gain by a stage riser: Theoretical model analysis. Shinsuke Nakanishi (Dept. of Integrated Architecture, Hiroshima Intl. Univ., Hirokoshingai, Kure, Hiroshima 737-0112 Japan, s-nakani@it.hirokoku-u.ac.jp)

This paper theoretically analyzes acoustic gain by a stage riser, which has been observed when playing the low strings, e.g., a violoncello and a double bass, on the riser in concert auditoria [Beranek et al., J. Acoust. Soc. Am. **36**, 1247–1262 (1964)]. The previous paper reported that "the tone quality increased in richness with the risers, particularly when the pegs of the instruments were placed about 4 in. from the edge" as musician's comments. The author discusses effects of the peg's positions of the low strings on the acoustic gain, through numerical examples of theoretical model analysis. The solution of a sound field is obtained when playing the low string on the riser placed on the rigid floor, which receives a spherical incident wave and mechanical excitation force from the low string. Numerical examples show that peg's positions of the low string affect peaks and dips of the acoustic gain, which are caused by eigenvibrations of a top plate of the riser. And, the acoustic gain becomes a positive value at more frequencies as the standing position of the low string shifts towards the riser's edge.

5:30

1pAA16. The program battle at Ganz Hall. Candice Tillery and Jay Pleckham (Columbia College Chicago, 33 E. Congress, Chicago, IL 60605, listen_42@sbcglobal.net)

Current modeling programs offer a wide range of analysis and prediction tools, as well as detailed modeling capabilities and user friendly formats. However, these tools are only useful if they can do their job correctly. The accuracy of the program, its cost, and its relevance to the environment in question are all vitally important when selecting software for a project. This paper addresses these issues through a comparison of two of today's most popular modeling programs: CARA and EASE. An acoustical analysis was performed on Roosevelt University's Ganz Hall, which seats 195 people and is used primarily for student recitals. Data were acquired concerning the hall's reverberation and frequency response. Numerous calculations were performed to determine the room's musical clarity, speech clarity, and early decay time. The hall was then modeled in the two programs in question, and the results were compared to determine each program's accuracy.

5:45

1pAA17. Parallel computing on the sound fields by bread slicing method. Yasuhiro Tokita (Waseda Environ. Res. Inst., Waseda Univ., 1011 Okuboyama, Nishitomida, Honjou, Saitama, 367-0035, Japan), Yasuhiro Oikawa, and Yoshio Yamasaki (Waseda Univ., Honjou, Saitama 367-0035, Japan)

Numerical analyses by the explicit scheme of the finite difference method greatly reduce the number of known variables that are needed to solve an unknown variable in comparison with the implicit methods. This fact means that the amount of communications decreases among each node of the computer cluster on parallel computing. Generally, on the parallel computing of the distributed memory system, the communicating time occupies most of the total calculating time. Therefore, the reduction to the amount of the communication directly causes the reduction of the calculating time. The parallel computing by the explicit scheme of the finite difference method can enable the building up of high-performance algorithms. In order to reduce the amount of communication among each node, one has proposed a method to divide the field of numerical analyses. It is called the ''bread slicing method.'' With this method, the fields must be divided into pieces parallel to the section that has the least area. The results showed that the method in this study enabled the total amount of communication in the computer cluster to be reduced and the geometries of communication to be made simpler.

6:00

1pAA18. Theoretical analysis of statistical properties of the sound-pressure field and sound energy density field in rectangular enclosures. Buye Xu and Scott D. Sommerfeldt (Dept. of Phys. and Astron., Brigham Young Univ., Provo, UT 84602)

The sound-pressure field and sound energy density (ED) field for rectangular enclosures are obtained theoretically by solving the Helmholtz equation and Euler's equation with low-energy absorption boundaries. Based on those results, both analytic and numerical methods are applied to compute some statistical properties. The results of the statistical analysis show that the spatial variation of the ED field is generally much less than that of the pressure field in reverberant enclosures. In addition, a modified ED quantity is developed and will be discussed.

1:30

1pAB1. Humpback whale social sounds: Sources levels and response to playback. Michael J. Noad, Rebecca Dunlop (School of Veterinary Sci., Univ., of Queensland, St. Lucia, Qld, 4072, Australia, mnoad@uq.edu.au), Douglas H. Cato (Defence Sci. and Tech Org., Pyrmont, NSW 2009, Australia), Dale Stokes (Scripps Inst. of Oceanogr., La Jolla, CA 92037), Patrick Miller, and Nicoletta Biassoni (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

Humpback whale ''social sounds'' appear to be used in communication when whales interact but they have received little study in comparison to the song. During experiments as part of the Humpback whale Acoustics Research Collaboration (HARC), whales migrating past the study site on the east coast of Australia produced a wide range of social sounds. Whales were tracked visually using a theodolite and singers were tracked acoustically using an array of five widely spaced hydrophones. Source levels of social sounds were calculated from the received level of the sounds, corrected for measured propagation loss. Playbacks of social sounds were made using a J11 transducer and the consequent reactions were recorded in terms of the change in direction of the migrating whales in relation to the playback position. In one playback, a DTAG was place on a female with calf. Playback of social sounds resulted in significant changes in the course of the migrating whales, in some cases towards the transducer while in others it was away from the transducer. From the estimates of source levels it is possible to assess the effectiveness of the playback and the range of influence of social sounds. [Work supported by ONR and DSTO.]

1pAB2. Megaclicks: Tagged humpback whales produce click trains and buzzes during foraging. Alison K. Stimpert, Whitlow W. L. Au (MMRP/Hawaii Inst. of Marine Biol., P.O. Box 1106, Kailua, HI 96734, stimpert@hawaii.edu), Mark P. Johnson (Woods Hole Oceanog. Inst., Woods Hole, MA 02543), David N. Wiley (Stellwagen Bank Natl. Marine Sanctuary, Scituate, MA 02066, USA), and Roland Arsenault (Univ. of New Hampshire, Durham, NH 03824)

Mysticetes and odontocetes differ in many morphological and behavioral aspects related to feeding. Odontocetes echolocate using clicks to localize prey, while the mechanism through which mysticetes orient and find food is unknown. In this study, DTAGs were deployed on four humpback whales (*Megaptera novaeangliae*) observed feeding off the northeastern United States. From two of the four tagged whales, bouts of clicks produced with a temporal pattern resembling odontocete echolocation were recorded and 102 bouts of megaclicks were identified. Spectrally, megaclicks were unlike previously reported humpback sounds or odontocete clicks, and also had much lower amplitudes (peak frequency $\sim$1700 Hz, RL 148 ± 6 dB Re: 1 uPa peak). Interclick intervals (ICI) were bimodally distributed (peaks at 25 and 80 ms), with shorter ICIs occurring at the end of megaclick bouts, in a pattern similar to an odontocete terminal buzz used in foraging. Behavioral sensor data supported a possible foraging function for megaclicks. All megaclick bouts occurred during nighttime hours, and the terminal buzz was associated with a sharp body roll of greater than 70 deg. Low source levels, among other characteristics, contraindicate an echolocation function; however, further analysis and research is required to distinguish among this and other hypotheses for sound function.

1pAB3. Temporal, geographic, and density variations in the acoustic activity of snapping shrimp. Marc O. Lammers, Sara Stieb, Whitlow W.L. Au, T. Aran Mooney (Hawaii Inst. of Marine Biol., P.O. Box 1106, Kailua, HI 96734), Russell E. Brainard, and Kevin Wong (Pacific Islands Fisheries Sci. Ctr., Honolulu, HI 96814)

The sounds produced by snapping shrimp (genus *Synalpheus* and *Alpheus*) are the main contributors to the ambient sound field of shallow-water tropical and subtropical marine habitats worldwide. Despite this, relatively little is known about the temporal and spatial variability of snapping shrimp activity. To investigate this issue further, ecological acoustic recorders (EARs) were utilized to obtain time-series records of the ambient sound field from multiple locations in Hawaii and American Samoa. Strong diel trends marked by sharp increases in acoustic activity during crepuscular periods were observed at all sites. However, sites varied greatly both in absolute sound levels and relative fluxes between day and night. In addition, fluctuations in snapping shrimp sound levels were found to track lunar cycles, with higher levels occurring during the new moon. To further investigate the reason for the higher levels observed during crepuscular periods, individual shrimp were localized using a three-hydrophone line array on both a coral reef and a mud and algae habitat in Kaneohe Bay, Hawaii. The density of acoustically active shrimp was found to be higher during the sunset period than during the day or at night.

2:15

1pAB4. An automated approach to detecting pulsive gray whale (*Eschrichtius robustus*) vocalizations within acoustic data to estimate call rate changes over time in Laguna San Ignacio. Melania Guerra, Aaron M. Thode (Marine Physical Lab, SIO UCSD, 9500 Gilman Dr., La Jolla, CA 92037-0238), Marilyn E. Dahlheim (Natl. Marine Mammal Lab, Seattle, WA 98115), Jorge Urban (UABCS, La Paz, Mexico), and Amanda M. Koltz (Cornell Univ., Ithaca, NY 14853)

Acoustic recordings of type 1b gray whale calls were made in San Ignacio Lagoon, during the wintering months of 2005 and 2006 when these animals were present to breed and raise calves. A collection of horizontal, bottom-mounted arrays containing two or three elements monitored the mouth of the lagoon over consecutive days, targeting vocalizations below 1 kHz. Because these pulsive calls are highly variable in the timing and number of pulses, standardized detection methods involving matched-filtering or spectrogram correlation have been unsuccessful. A sequence of automated procedures programed in MATLAB and ISHMAEL was implemented to assist with the detection of calls within the dataset. Simple manual recognition based on human judgment was also performed on the shorter time series to serve as an independent check. Results for hourly call rates were computed for both seasons individually. A similar such acoustic dataset had been previously collected by Dahlheim (1987) in the years 1982–84 and analyzed manually. This dataset would be digitized and examined with the new automated analyses in order to compare changes in average call rates over the two-decade interval. A rough relationship with animals present can be drawn, as census numbers are available for both periods.

2:30

1pAB5. Characteristics of the deep scattering layer in the Gulf of Mexico as they relate to sperm whale diving and foraging behavior. Alyson J. Azzara (Dept. of Oceanogr., Texas A&M Univ., College Station, TX 77843-3146, alygirl@tamu.edu), Aaron Thode (Scripps Inst. of Oceanogr., 9500 Gilman Dr., San Diego, CA 92109), Tom Norris (Sci. Applications Intl. Corp., San Diego, CA), Kelly Benoit-Bird, and Douglas C. Biggs (Oregon State Univ., Corvallis, OR 97331)

In June 2005 we used a 38-kHz ADCP and two Simrad fishery echo-sounders to collect backscatter data and passive acoustic array recordings of sperm whale sounds, as part of the Sperm Whale Seismic Study (SWSS). Dive profiles and presumed foraging depths of the whales were derived using a 3-D tracking technique [see abstract by Thode and Norris (this conference)]. Relationships are examined between dive profiles and acoustic backscatter intensity measurements from the main deep scattering layer (DSL) at a daytime depth of 400–600 m. Passive detections of creaks, believed to be associated with prey acquisition, are merged with dive profiles to provide insight between mid-water backscatter returns and foraging effort. Results to date indicate whales diving in three depth ranges: deeper than 800 m, between 500 and 800 m, and less than 500 m. Dive patterns indicate some whales dive through the main DSL into deeper secondary layers seen by the 38-kHz ADCP. There seems to be no difference in dive patterns between night and day. Calibration analysis of ADCP backscatter versus 70-kHz Simrad backscatter shows a positive functional relationship, with 4 units of relative acoustic backscatter intensity equal to 1 dB of Sv.

2:45

1pAB6. Bottom-mounted hydrophones used to investigate sperm whale click and swim characteristics. Eva-Marie Nosal and L. Neil Frazer (Dept. of Geology and Geophys., Univ. of Hawaii, 1680 East-West Rd., Honolulu, HI 96822)

A method that relies solely on the time difference between direct and reflected arrivals (DRTD) on individual hydrophones was previously used to localize a single sperm whale [E.-M. Nosal and L. N. Frazer, Appl. Acoust., Special Ed.: Detection and Localization of Marine Mammals using Passive Acoustics (in press)]. Regular clicks in recordings from five bottom-mounted hydrophones in the AUTEC range were used in the localization. In this study, the DRTD method is extended by incorporating time differences (between hydrophones) of direct arrivals to refine the track of the whale and to determine the time of generation of individual clicks. Clicks, which have a multi-pulse structure, are analyzed in detail to determine changes in interpulse intervals (IPI) with time. The resulting time, location, and IPI information are used to investigate swim patterns and directionality characteristics of regular sperm whale clicks. [Work supported by ONR. Data provided by NUWC for the 2nd International Workshop on Detection and Localization of Marine Mammals using Passive Acoustics.]

3:00

1pAB7. 3-D tracking of sperm whale dive profiles from a towed hydrophone array in ray-refractive environments. Aaron Thode (Marine Physical Lab., Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0238, thode@mpl.ucsd.ed), Tom Norris (Sci. Applications Intl. Corp., San Diego, CA), Alyson Azzara, Ann Jochens, and Doug Biggs (Texas A&M Univ., College Station, TX 77843)

During the past 3 years the U.S.-based Sperm Whale Seismic Study (SWSS) has supported the development of a mobile three-dimensional passive acoustic tracking system. Acoustic data were recorded on a single four-element wide-aperture hydrophone array, towed at 80–100-m depth. The array was subdivided into forward and rear two-element subarrays, separated by 200-m aperture. To fix a location of an impulsive sound, three quantities are measured: the time difference between direct-path arrivals on the forward and rear subarrays, the time difference between the direct and surface-reflected paths on the rear subarray, and the acoustic bearing measured on the rear subarray. These quantities, combined with independent measurements of hydrophone depths and cable inclination, are postprocessed using a MATLAB GUI into range-depth position fixes by implementing an efficient numerical procedure that uses precomputed look-up tables to account for ray-refraction effects caused by depth-dependent sound-speed profiles. The predicted time difference between the direct and surface-reflected paths on the forward subarray is compared with the measured data to adjust for array tilt and depth measurement error. A by-product of this processing is a semiautomated detector to detect distinctive creak sounds. [Work supported by the U.S. Minerals Management Service and the Industry Research Funders Coalition.]

3:15

1pAB8. Direct underwater visual and acoustic observations of echolocation behavior of sperm whales around a longline. Aaron Thode (Marine Physical Lab., Scripps Inst. of Oceanogr., UCSD, La Jolla CA 92093-0238), Jan Straley, Kendall Folkert, Victoria O'Connell (Univ. of Alaska Southeast, Sitka, AK 99835), Linda Behnken (Alaska Longline Fishermens Assoc., Sitka, AK 99835), and Amanda Koltz (Cornell Univ., Ithaca, NY 14853)

Sperm whales (*Physeter macrocephalus*) have learned to approach and deprecate fishing vessels longlining for black cod in the Gulf of Alaska. In May 2006, off Sitka, Alaska, a video camera was placed inside an underwater housing with an external hydrophone mount, attached to a longline that had been partially hauled to the surface, and lowered between depths of 90 and 120 m, with black cod (*Anoploploma fimbria*) attached 2 to 4 m above the camera as bait. The camera was mounted facing towards the surface to exploit the ambient light and to eliminate the need for artificial lighting. An additional hydrophone was deployed at 17-m depth during the 40–60-m deployments, and a third autonomous acoustic recorder was usually mounted 1.3 m below the camera. During one encounter a whale investigated the line, producing characteristic creak sounds that were recorded on the three hydrophones, and which were subsequently time-aligned using vessel noise as a reference, in order to permit acoustic tracking. During the second encounter a whale interacted with two fish within 4 m of the camera, but only the camera hydrophone was available. Preliminary analysis of the echolocation behavior displayed by both animals is presented. [Work sponsored by the National Geographic Society and the North Pacific Research Board.]

3:45

1pAB9. Three-dimensional passive acoustic tracking of sperm whale behavior with widely separated vertical arrays in the Gulf of Alaska. Christopher O. Tiemann (Appl. Res. Labs., Univ. of Texas, Austin, TX 78713), Aaron M. Thode (UCSD, La Jolla CA 92093-0238), Jan Straley, Kendall Folkert (Univ. of Alaska Southeast, Sitka, AK 99835), and Victoria O'Connell (Alaska State Fish and Game, Sitka, AK 99835)

The Southeast Alaska Sperm Whale Avoidance Project (SEASWAP) was started in 2002 to study the increasing depredation encounters between sperm whales and longline fishermen near Sitka, Alaska. In 2005, the acoustic component of the study included passive acoustic data from four autonomous recorders attached to the anchor lines of two longlines spaced 3 miles apart, essentially turning them into temporary vertical arrays and allowing the monitoring of sperm whale vocal activity during fishing operations. Although the use of multipath arrival information from recorded sperm whale clicks has been a standard procedure for range-depth tracking, with the added knowledge of azimuthally dependent bathymetry relative to an array, a three-dimensional track of whale motion can be obtained from the same multipath information. The evolution of multipath arrival patterns is matched to range-, depth-, and azimuth-dependent modeled arrival patterns to generate an estimate of whale motion. The use of an acoustic propagation model can also account for all waveguide physics such as interaction with range-dependent bathymetry and ray refraction. Acoustic tracking results concurrent with whale encounters will be presented and compared to visual sightings.

4:00

1pAB10. Variation in sound production in relation to behavior of bottlenose dolphins (*Tursiops aduncus*). Michelle Lemon (Marine Mammal Res. Group, GSE, Macquarie Univ., Sydney, Australia, Defence Sci. and Tech Org., Pyrmont, Australia, and michelle.lemon@dsto.defence.gov.au), Douglas H. Cato (Defence Sci. and Tech Org., Pyrmont, New South Wales, Australia), Tim P. Lynch (Jervis Bay Marine Park, Huskisson, New South Wales, Australia), and Robert G. Harcourt (Macquarie Univ., Sydney, Australia)

Dolphins are social animals that inhabit an opaque environment where visual cues are often limited, thus acoustic signals play an important role in inter- and intragroup communication. Phonations may be used to signal conspecifics, in navigation, or in the detection of prey, and may vary with behavior, environmental conditions, or geographic location. Variation in the acoustic and surface behavior of two geographically separated and genetically differentiated populations of bottlenose dolphins in Southeastern Australia were investigated over a 3-year period. Two hypotheses were tested: (1) vocal repertoire varies with behavior; and (2) variation in vocal repertoire may have arisen due to geographic isolation. Overall rate of sound production by the dolphins was similar in each field site but varied significantly with behavioral activity. Call rates were highest with behavior that involved increased arousal, such as socializing and foraging. Whistle rates and the duration of echolocation click bouts were similar for each location, however, burst-pulsed sounds varied significantly with behavioral state and between the field areas. This difference may relate to differences in social behavior between populations and be driven by variability in social structure and environmental conditions. [Research supported by Australian Geographic, PADI Foundation and Macquarie University.]

1pAB11. Observation studies based on echolocation click signals of Irrawaddy dolphins in Chilika lagoon. Rajendar Bahl (Ctr. for Appl. Res. in Electron., IIT Delhi, Hauz Khas, New Delhi, India, rbahl@care.iitd.ernet.in), Tamaki Ura, Tomoki Inoue, Harumi Sugimatsu, Takeshi Sakamaki (Univ of Tokyo, Meguro, Tokyo 153-8505, Japan), Junichi Kojima (KDDI R&D Labs. Inc., Saitama 356-8502, Japan), Tomonari Akamatsu (Natl. Res. Inst. of Fisheries Eng., Ibaraki 314-0408, Japan), Hideyuki Takahashi (System Giken Co. Ltd., Kanagawa 253-0085, Japan), Ajit Pattnaik, Muntaz Khan (Chilika Dev. Authority, Orissa, India), Sandeep Behera (Freshwater and Wetlands Prog., New Delhi 110003, India), and Sudhakar Kar (Off. of Princip. CCF (Wildlife) Chief Wildlife Warden, Bhubaneswar 751012, India)

A resident population of Irrawaddy dolphins, *Orcaella brevirostris*, in Chilika lagoon in eastern India has been recently monitored based on their echolocation clicks. The free-ranging animals were monitored over several days in their natural habitat. A horizontal three-hydrophone line array was used for click data collection and off-line analysis of click trains to obtain underwater movements in shallow water of typical depth less than 3 m. The lagoon waters being placid provided a good surface echo that has been used to obtain depth information of the individual click sounds. This paper augments previous data on the broadband click characteristics [S. M. Van Parijs, G. J. Parra, and P. J. Corkeron, J. Acoust. Soc. Am. **108**, 1938–1940 (2000)] and also provides a glimpse into the individual behavior of the dolphins. An estimate of the click lag time of the animal's biosonar has also been obtained for the first time for a free-ranging animal.

4:30

1pAB12. On the use of the Teager energy operator for the detection of clicks in free-ranging dolphins. Marie A. Roch (Dept. of Comput. Sci., 5500 Campanile Dr., San Diego State Univ., San Diego, CA 92182-7720), Melissa S. Soldevilla, Jessica C. Burtenshaw, E. Elizabeth Henderson, Sean M. Wiggins, and John A. Hildebrand (Univ. of California at San Diego, La Jolla, CA 92093-0205)

The detection of individual clicks produced by odontocetes is useful for many bioacoustic tasks such as the analysis of interclick interval, classification of odontocete species, etc. Automation of this task is required for

the large data sets gathered by remote instruments that can collect terabytes of information over short time periods. A method is presented that locates individual clicks using the Teager energy operator, which is a time-domain metric designed to measure fast variations in signal energy. The Teager energy of a high-pass filtered signal is analyzed by a rule-based classifier that determines the location of individual clicks. The click start can be determined with very high accuracy. Click ends are reasonably well characterized, but the ends of clicks are difficult to determine, even by human experts, due to the influence of external factors such as acoustic reflections. The proposed method is compared with existing techniques and is demonstrated on the calls of several species of free-ranging odontocetes resident in the Southern California Bight and the Gulf of Mexico: bottlenose dolphins (*Tursiops truncatus*), short and long beaked common dolphins (*Delphinus delphis*, *Delphinus capensis*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), and Risso's dolphins (*Grampus griseus*).

4:45

1pAB13. The acoustic recording of bottlenose dolphin (*Tursiops truncatus*) phonations: Problems and contributions. Carmen Bazúa-Durán and Axel Herrera-Hernández (Lab. Acústica, Facultad de Ciencias, UNAM, Ciudad Universitaria, 04510 México, D.F., México, bazua@servidor.unam.mx)

Bottlenose dolphin sounds have been studied for decades; however, more needs to be investigated. This work demonstrates that results obtained in wild dolphin studies greatly depend on the recording system used. Dolphin phonations were simultaneously recorded with two systems, a narrow-band (<24 kHz) and a broadband (<180 kHz), and were analyzed using spectral characteristics (narrow-band: 512 points, Hamming window, 50% overlap; broadband: 2048 points, Hamming window, 50% overlap) to determine the acoustic repertoire as echolocation click trains (EC), whistles (W), and burst pulses (BP). As expected, the number of BP and EC recorded was considerably larger with the broadband system than with the narrowband; whereas the number of W recorded was greater with the narrowband system than with the broadband (it was expected to obtain the same number of W with both systems). As W are less intense than BP or EC, when gain is adjusted for recording BP or EC, the recording system is not able to record the less intense W. Therefore, it is not possible to capture the same number of dolphin phonations with the same recording system. One should use at least two different recording systems to adequately describe dolphin phonations. [Work supported by CONACyT-Campeche and PAPIIT-UNAM.]

1pAB14. Acoustic monitoring of resident, offshore, and transient killer whales off the Washington coast. Erin M. Oleson, Sean M. Wiggins, and John A. Hildebrand (Scripps Inst. of Oceanogr., Univ. of California San Diego, 9500 Gilman Dr., #0205, La Jolla, CA 92093, eoleson@ucsd.edu)

Three acoustically distinct populations of killer whales representing each of the known ecotypes (resident, offshore, transient) were recorded in the Summer–Fall of 2004 off the southern Olympic Coast of Washington. Two high-frequency acoustic recording packages (HARPs) continuously recording at 80-kHz sample rate were deployed to assess the seasonal occurrence of vocal odontocetes in this region. From mid-July to early-October the population-specific discrete calls of killer whales were heard on 8 days and were classified to population by Volker Deecke (UBC) and John Ford (DFO-Canada) using an acoustic ID catalogue. West Coast Transient killer whales producing calls of the California dialect were heard on three occasions from August through October. Offshore killer whales were heard twice in August–September, and Northern Resident killer whales were heard once in August. Although Northern Resident killer whales have been extensively studied within Puget Sound and coastal British Columbia, they have been visually sighted only once off the northern Olympic Peninsula, making their detection at this offshore southerly location unique. Endangered Southern Resident killer whales were not heard at this site from July–October. Analysis of year-round data from a site further offshore is underway. [Funded by Chief of Naval Operations-N45.]

5:15

1pAB15. High-frequency Acoustic Recording Package (HARP) for long-term monitoring of marine mammals. Sean M. Wiggins, Chris Garsha, Greg Campbell, and John A. Hildebrand (Univ. California-San Diego, 9500 Gilman Dr., 0205, La Jolla, CA 92093-0205, swiggins@ucsd.edu)

Advancements in low-power and high-data-capacity computer technology during the past decade have been adapted to autonomously record sounds from marine mammals over long time periods. Acoustic monitoring has advantages over traditional visual surveys including greater detection ranges, continuous long-term monitoring in remote locations under various weather conditions, and lower cost. However, until recently, the technology required to autonomously record whale sounds over long durations has been limited to low-frequency (' 1000 Hz) baleen whales. The need for a broader-band, higher-data capacity system capable of autonomously recording toothed whales and other marine mammals for long periods has prompted the development of a High-frequency Acoustic Recording Package (HARP) capable of sample rates up to 200 kHz. The HARP design is described and data analysis strategies are discussed using examples of broadband recorded data. [Work supported by the U.S. Navy CNO-N45.]

1pAOa1. Broadband backscatter measurements of individual Hawaiian mesopelagic boundary community animals. Whitlow W. L. Au (Hawaii Instititute of Marine Biol., Univ. of Hawaii, P.O. Box 1106, Kailua, HI 86734) and Kelly J. Benoit-Bird (Oregon State Univ., Corvallis, OR 97331-5503)

Broadband simulated dolphin echolocation signals were used to measure the *ex situ* backscatter properties of mesopelagic boundary community animals. The signal had a peak frequency of 100 kHz, 3-dB bandwidth of 35 kHz, and duration of 80μs. Subjects were captured by trawling with a 2-m-opening Isaacs-Kidd midwater trawl. Backscatter measurements were conducted on the deck of the ship in a 2000-L seawater plastic tank with the transducer placed on the bottom, pointed upwards. Anesthetized animals were suspended in the transducer's beam by nylon monofilament lines connected to a support device constructed out of dowels. Backscatter measurements were obtained in both the dorsal and lateral aspects for seven myctophids and only in the dorsal aspect for the other 13 myctophids, 6 shrimps, and 3 squids. The echoes from the myctophids and shrimps usually had two highlights, one from the surface of the animal nearest the transducer and a second probably from the signal propagating through the body of the subject and reflecting off the opposite surface of the animal. The squid echoes consisted mainly of a single highlight but sometimes with a low-amplitude secondary highlight. The target strength had a rippled pattern in the frequency domain showing a distinct null.

1:20

1pAOa2. Acoustic measurements of volume backscattering strength from red tide phytoplankton, *Cochlodinium polykrikoides*. Tae-Hoon Bok, Dong-Guk Paeng (Faculty of Marine Industry Eng., College of Ocean, Cheju Nat'l Univ., Ara-dong, jeju-si, jeju-do, Korea, 690-756), Eunhye Kim, and Jungyul Na (Hanyang Univ., Sa-dong, Ansan-si, Kyeonggi-do, Korea, 425-791)

This research is to measure the volume backscattering strength, Sv, of the *Cochlodinium polykrikoides* (the main species of red tide in Korea) in order to investigate the possibilities of early detection of red tide using high-frequency transducers (5, 10 MHz). First, the Sv from the cultured *C. polykrikoides* was measured with the population density in the laboratory. Next, ultrasonic transducers were attached to the side of a research vessel, and the Sv was measured over 9-km ship track near Yeosu in the Korean southern sea. Seawater at three stations was sampled, and the number of *C. polykrikoides* was counted to compare the theoretical Sv with the measured one. The results show that the measured Sv was in agreement with the theoretical one. The Sv when the light was on was measured to be higher than that when the light was off in the laboratory, probably due to the increase of size and density of *C. polykrikoides* during photosynthesis. In the field experiment, the Sv was measured in real time with the position information from the Global Positioning System data. This research proposes the use of underwater ultrasonic technology for early detection of red tide in real time.

1pAOa3. Measurements of target strength spectra of metal spheres and fish by using broadband sonar signals of dolphin. Tomohito Imaizumi, Masahiko Furusawa (Tokyo Univ. of Marine Sci. and Technol., 4-5-7 Kounan, Minato Tokyo, 108-8477, Japan, imaizumitomohito@yahoo.co.jp), Tomonari Akamatsu (Fisheries Res. Agency of Japan, Kamisu, Ibaraki 314-0408, Japan), Yasushi Nishimori, and Shinji Ogawa (Furuno Electric Co., Ltd., Nishinomiya-city, 662-8580, Japan)

Dolphins identify prey by using their broadband sonar signals. Considering that the spectrum of fish target strength (TS) leads to identification of objects, we measured the spectrum using dolphin's sonar signals with a broadband system. The TS spectrum is obtained by dividing the echo spectrum by the incident spectrum while setting the projector and hydrophone face to face. First, we measured the broadband form function of a tungsten carbide and copper sphere in a water tank and confirmed good agreements with theoretical value. Second, we measured the spectra of TS of three species of anaesthetized fish in a water tank. Although the spectra showed nearly similar tendencies of past measurements, they changed according to the species, the individual, and the tilt angle. Third, we measured TS spectra of fish suspended by nylon monofilament line in the open sea in semi-*in-situ*. We tried to remove the directivity of transducers by a tungsten carbide sphere suspended near the fish. The change of the TS spectra should be important information for the fish identification.

1pAOa4. Variations of echosounder transducer performance versus water temperature. David A. Demer and Josiah Renfree (NOAA/ NMFS/Southwest Fisheries Sci. Ctr., 8604 La Jolla Shores Dr., La Jolla, CA, 92037)

Electroacoustic transducers are central components of multi-frequency echosounders used in remote target identification and acoustical surveys for fish and zooplankton. While these transducers, constructed from multiple materials such as piezoelectric ceramics, polyurethanes, and metals, are designed to be insensitive to performance changes versus time, pressure, and temperature, it has been shown that appreciable changes in echosounder system gains result from shifts in transducer resonant frequency, quality factor, and electrical impedance versus water temperature. Because it is standard practice to calibrate echosounder systems in one environment and apply the resulting gains to interpret data collected over a range of sea temperatures, the survey results may be significantly biased. The bias may be different for estimates derived from each echosounder frequency. The magnitudes of these frequency-dependent biases depend upon the temperature-dependent performances of the survey transducers, and the

range of temperatures encountered during the survey. Here, the performance has been measured for ten commonly used survey transducers versus water temperature ranging from 1 to 18 °C, using four different techniques. Temperature-dependent system gain corrections are proposed that can be used to minimize bias in multifrequency target identifications and biomass estimations. [Funding was provided by the NMFS Advanced Sampling Technology Working Group.]

1pAOa5. Calibrating split beam transducers at depth. Egil Ona and Geir Pedersen (Inst. of Marine Res., P.O. Box 1870, 5817, Bergen, Norway)

A new echo sounder probe for target strength measurements in deep water have been used to calibrate the depth performance of several pressure-stabilized split beam transducers. The probe carries three Simrad EK60 echo sounders and can be operated on 6500 m optical cable to about 1500-m depth. The transducers are mounted on a motorized, revolving platform. Digital angle sensors monitor transducer orientation, and an electronic compass also monitors transducer rotation. Calibration includes standard sensitivity parameters for split beam transducers, but also the equivalent beam angle and angle sensitivity at different depths. Examples of target strength data on marine animals will also be shown.

2:20

1pAOa6. Standard-target calibration of active sonars used to quantify aquatic organisms. Kenneth G. Foote (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

The span of sonars being calibrated by the standard-target method continues to grow. In this retrospective of the past 25 years, the essence of the method is reviewed for both narrow-band and broadband systems. Applications to scientific echo sounders with operating frequencies from 18 kHz to 3.2 MHz are summarized. Applications to multibeam sonars that provide the water-column signal, with frequencies of 90, 200, 240, and 400 kHz, are also summarized. A planned application to a parametric sonar, with primary frequencies in the range 15–21 kHz and difference-frequency band 0.5–6 kHz, is described. The method is applicable to ordinary midfrequency sonars. In each example, particular standard targets are specified. Diameters vary from 10 mm for a sphere of tungsten carbide with 6% cobalt binder for use at low megahertz frequencies, to 60 mm for a sphere of electrolytic-grade copper for use at 38 kHz, to 280 mm for a sphere of aluminum alloy for use at low-kilohertz frequencies.

2:35

1pAOa7. New scientific multibeam systems (ME70 and MS70) for fishery research applications. Lars Nonboe Andersen, Sverre Berg, Ole Bernt Gammelster, and Even Borten Lunde (Simrad AS, P.O. Box 111, 3191 Horten, Norway, fish_research@simrad.com)

Fishery scientists have for many years been requesting calibrated multibeam systems specially designed for fishery research applications. Simrad AS, Norway, has, in cooperation with IFREMER, France, developed a new multibeam echo sounder (ME70) and with IMR, Norway, a new multibeam sonar (MS70) for fishery research applications. Both systems have 800 transmitting and receiving channels and are based on similar hardware and software platforms. The systems are characterized by calibrated narrow beams, low sidelobe levels, high instantaneous dynamic range, and operate in the frequency range 70–120 kHz. The echo sounder is designed for high operating flexibility, with a configurable fan of 1–45 roll/pitch stabilized split beams with opening angles ~2 to ~7. In addition, two configurable reference beams are available for comparison with standard echo sounder systems. The sonar is mounted on a drop keel, looking horizontally, covering a horizontal sector of 60 and a vertical sector of 45. This coverage matrix is generated using 500 roll stabilized beams, 25 beams horizontally with a resolution of ~3, and 20 beams vertically with a resolution of ~4. Both systems are designed for fish-stock assessment and fish-behavior studies. Results from system measurements will be presented.

Invited Papers

3:10

1pAOa8. First results with the new scientific multibeam echo-sounder ME70. Verena Trenkel (Ifremer Ctr. de Nantes, BP 21105 44311, Nantes Cedex 03, France), Valerie Mazauric, and Laurent Berger (Ifremer Ctr. de Brest, Plouzane, France)

Multibeam echo-sounders and sonars are increasingly used in fisheries acoustics for studying school structure and behavior and for abundance estimation. However, data quality and a poor signal-to-noise ratio obtained with the existing multibeam echo-sounders preclude quantitative biomass estimation as carried out with the traditional single beam echo-sounders. In order to overcome these shortcomings, Ifremer and Simrad AS started in 2003 the development of the new and highly flexible calibrated multibeam echo-sounder ME70 designed for studying a wide range of scientific questions. This paper will present the full functionalities of the ME70 and preliminary results obtained with the system installed onboard the research vessel *Thalassa*. It will also provide first indications of its performance. Data have been collected on small pelagic fish species in the bay of Biscay, using simultaneously the traditional single beam echo-sounders and the ME70 with different beam configurations. Preliminary comparisons of fish school descriptors and biomass estimates based on single- and multibeam data allow us to quantify the effect of the gain in sampling coverage and the high angular resolution of the new system.

3:30

1pAOa9. First data from sea trials with the new MS70 multibeam sonar. Egil Ona, John Dalen, Hans Petter Knudsen, Ruben Patel (Inst. of Marine Res., P.O. Box 1870, 5817 Bergen, Norway), Lars Nonboe Andersen, and Sverre Berg (Simrad A/S, 3191, Horten, Norway)

The new multi-beam sonar, MS70, is a horizontally observing sonar yielding very high spatial resolution when operating all 500 beams, covering the frequency band 75–112 kHz. The sonar has undergone sea trials from *R/V G. O. Sars* from December 2005. The presentation includes preliminary results obtained during this period. Topics covered will be sonar performance objectives, calibration methods, and preliminary results from calibration and school data acquisition. Examples of raw and processed 3-D and 4-D data from a stationary and surveying vessel on small sprat schools and large herring schools will be shown.

1pAOa10. Development of a quantitative scanning sonar system and sea trial for a fish school of herring. Yasushi Nishimori (Furuno Elec. Co., Ltd., 9-52 Ashihara-cho, Nishinomiya, 662-8580, Japan), Kohji Iida, Tohru Mukai (Hokkaido Univ., Hakodate, 041-8611, Japan), Yong Tang (Dalian Fisheries Univ., Dalian, 116023, China), Masaki Ogata, Kohzoh Tokuyama, and Emi Okazaki (Furuno Elec. Co., Ltd., Nishinomiya, 662-8580 Japan)

A quantitative sonar system enabling data recording, calibration, and numerical analysis of fish schools was developed based on the commercial scanning sonar. This system is equipped with a newly developed algorithm for estimation of the abundance of a fish school using three-dimensional echo integration. Estimation was made on the condition that the target strength of all fish is identical and known and the weight of a single fish is known. The field recording was performed to evaluate the algorithm. The school of spring spawning herring were scanned three-dimensionally and recorded using two different scanning methods. Two methods were applied in different distances between the school and vessel. The volume and three-dimensional echo integration for these two recorded dates were calculated and compared to each other. It was found that the variance of three-dimensional echo integration is smaller compared with the variance of volume. A compensation of abundance estimation using average target strength was tried and its effectivity was examined.

1pAOa11. Measurement of scattering directivity and behavior of fish schools using multibeam sonar. George Cutter, Jr. and David Demer (NOAA Southwest Fisheries Sci. Ctr., 8604 La Jolla Shores Dr., La Jolla, CA 92038)

Fish dispersion and abundance are commonly estimated from volume backscattering coefficients (sv) of animals located directly beneath the survey vessel, inside a narrow transducer beamwidth. Fish density (#/m^2) is estimated from a ratio of integrated sv and a representative backscattering cross-sectional area. Fish biomass is estimated from the product of fish density and the area sampled. Uncertainty in biomass estimates can arise from small sampling volumes, and the scattering directivities of the fish coupled with their orientations relative to the acoustic beam. Multibeam sonars can be used to increase the observational volumes, but add the complexity of a wider range of incident angles. If fish size and packing density are constant throughout a school, then the variation in sv versus aspect angle can be attributed to fish orientation. With modeling and multibeam sonar measurements, the following null hypotheses are explored: (1) The variability of sv versus roll angle is nearly uniform; (2) For measurements made with beams at or near vertical, sv variability is primarily due to the pitch angle; (3) For measurements with nonvertical beams, such as the outer beams of multibeam echosounders, sv variability is primarily due to the yaw angle.

4:25

1pAOa12. Advances in the evaluation of acoustic beamformed backscatter data for fisheries applications. Chris Malzone (The RESON Group, 100 Lopez Rd. Goleta, CA 93117, cmalzone@reson.com), Matthew Wilson (SonarData Pty Ltd, Hobart TAS 7001 Australia), and Pat Iampietro (CSU Monterey Bay, Seaside, CA 93955)

Single-beam echosounders are well-established tools for fisheries research. However, single-beam echosounder geometry is limited to a very small ensonification volume located within a 3 to 15-deg cone directly beneath the vessel. Recent advances in multibeam echosounder technology provide the option to collect backscatter and water-column data during an IHO order 1 hydrographic survey. Such comprehensive data sets are valuable for scientific and management purposes since they expand the volume in which water-column data are collected, and they provide as well a potential method to link the biology to the habitat. However, water-column information collected with multibeam echosounders poses several challenges, including increased data storage requirements, a need for data decimation, and survey methodology considerations. In this paper, concurrently acquired backscatter data from a split-beam scientific echosounder and multibeam echosounder are analyzed for relative abundance, spatial distribution, and avoidance behavior of pelagic organisms, primarily the market squid *Loligo opalescens* and various finfish. Aspects of the data sets are then explored, compared, and contrasted. Proposed solutions to some of the challenges posed by multibeam sonar water-column analysis are then reviewed and placed within a overall framework for fisheries applications.

4:40

1pAOa13. Mapping fish schools with a high-resolution multibeam sonar. Mark Trevorrow (Defence R&D Canada Atlantic, 9 Grove St., Dartmouth, NS, B2Y 3Z7 Canada, mark.trevorrow@drdc-rddc.gc.ca)

In late 2002 an evaluation of a high-resolution multibeam sonar (RESON SeaBat 8125) for mapping mid-water fish schools was performed in Knight Inlet, BC. The ship-mounted multibeam sonar operated at 455 kHz and provided 240 one-half-degree beams in the across-track plane with one-degree along-track beam width. Simultaneous measurements were made with a conventional 200-kHz echo-sounder. Acoustic calibrations of this multibeam sonar will be discussed, showing some range- and angle-dependent variations in sensitivity. The multibeam sonar was able to provide well-resolved mid-water images of fish schools (likely juvenile herring), sampling many fish schools missed by the echo-sounder and revealing cross-track fish school shape. Comparison of near-vertical volumetric scattering strengths between the multi-beam sonar and echo-sounder show reasonable agreement. Discussions on the combined use of conventional and multibeam sonars for fish surveys will be given.

4:55

1pAOa14. Multibeam assessments of Australian seabed habitats. Iain Parnum, Alexander Gavrilov, Paulus Siwabessy, and John Penrose (Ctr. for Marine Sci. and Technol., Curtin Univ. of Technol., G.P.O. Box UU1987, Perth, Western Australia 6845)

In the period 2003–2006 a major program of shallow seabed habitat assessment has been undertaken in Australian coastal seas. As part of the Coastal Water Habitat Mapping (CWHM) project of the national Cooperative Research Centre for Coastal Zone, Estuary and Waterway Management, research into optimal use of acoustic techniques for habitat assessment has been undertaken. Echo sounder, side scan, and multibeam acoustic systems have been used and evaluated in this program. Multibeam systems have been primarily employed with particular attention being given to combining topography data with associated measures of backscatter intensity. The emphasis on shallow waters, generally 50-m depth or less, and high-frequency multibeam systems with up to 240 beams has provided data sets with relatively high levels of spatial resolution. Measures of backscatter variation with incident angle have been incorporated into the interpretation process and a new angular dependence correction algorithm developed for production of backscatter imagery. The processing techniques developed in the CWHM project have been evaluated using towed video data for a variety of tropical and temperate coastal environments around Australia.

1pAOa15. Acoustic identification and density estimate of *Diaphus theta* (myctophidae) off Hokkaido, Japan. Hiroki Yasuma, Kazushi Miyashita (Field Sci. Ctr. for the Northern Biosphere, Hokkaido Univ., 3-1-1, Minato, Hakodate, Hokkaido, 041-8611, Japan), and Orio Yamamura (Hokkaido Natl. Fisheries Res. Inst., Kushiro, 085-0802, Japan)

Diaphus theta is the most abundant micronektonic fish in the northwestern Pacific. Field acoustic data and biological samples were obtained both day and night off of eastern Hokkaido, Japan in September 2006 to estimate the fish density and diel changes of its vertical distribution. Differences of acoustical target strength (TS) values between at 38 and 120 kHz were applied to identify *D. theta* echos using field echo data. Theoretical estimation using swimbladder acoustic scattering models showed that the TS difference (TS 120-38 kHz) of larger fishes (over 60 mm) was between −4 and 1 dB; that for smaller fishes (less 60 mm) was less than .4 dB. These values differed from those of other major component species of the deep-scattering layer, such as krill and pollock, suggesting that the echo from *D. theta* is acoustically identifiable. Diel vertical distributions of *D. theta* were estimated after identification. Relatively dense schools were observed at around 400-m depth during daytime, although the schools were scattered widely above 100-m depth during nighttime. These results matched those obtained by biological sampling. In the surface layer (above 100 m), the estimated fish densities were about tenfold higher at nighttime than in daytime.

1pAOa16. Measurement of fish school abundances in shallow sea using omnidirectional multibeam sonar. Yong Tang (Dalian Fisheries Univ., 52 Heishijiao-jie Shahekou, Dalian, 116023, China;tang@dlfu.edu.cn), Kohji Iida, Tohru Mukai (Hokkaido Univ., Hakodate, 041-8611, Japan), and Yasushi Nishimori (Furuno Elec. Co., Ltd., Nishinomiya, 662-8580 Japan)

Previous studies had been constructed in the use of commercial scanning sonar to estimate the abundance of pelagic fish school. However, a relatively narrow dynamic range and lack of linear signal processing limited the application of sonar. In this research, quantitative omnidirectional multi-beam sonar (FSV30 research version, 24 kHz, Furuno) was used to investigate a fish school in a shallow area. The raw volume backscattering strength signal (RSV, output signal with $20 \log r$ TVG and coefficient of multiple echo) of the fish school echoes were recorded and then its biomass was confirmed using purse seine capture. In postprocessing, the fish school echoes were extracted from the sonar echogram using the image processing method (polygon and a low-pass filter). The relationships between a school's biomass, its echo area, the maximum, and the average RSV of each ping were considered for various species. Results showed a positive correlation between the sonar-measured school area and school biomass, but no correlation between the RSV and school biomass. Also, the echo integration method for sonar survey using RSV in broad area and methods for averaging the target strength (TS) in three dimensions with respect to echo integration method were also discussed.

1pAOb1. Precise measurement of travel time difference for reciprocal transmission of Central Equatorial Pacific tomography. Hiroyuki Hachiya (Dept. of Information & Image Sci., Chiba Univ., 1-33 Yayoi-cho, Inage-ku, Chiba 263-8522, Japan), Toshiaki Nakamura (Natl. Defense Acad., Kanagawa 239-8686, Japan), Hidetoshi Fujimori, and Iwao Nakano (Japan Agency for Marine-Earth Sci. and Technol., Yokosuka 237-0061, Japan)

We present the estimation results of the travel time difference in reciprocal transmission data collected during the tomography experiment performed by Japan Agency for Marine-Earth Science and Technology (JAMSTEC) in the Central Equatorial Pacific. A precise estimation of travel time is essential for measuring ocean current using ocean acoustic tomography. We estimate the variation of the correlation of reciprocal propagated sound transmissions. Generally, reciprocal propagation sound waveforms that are transmitted at the same time are similar mutually, and it is considered that their correlation is high. However, it is found that reciprocal sound waveforms sometimes become different in the experiment. The vertical arriving angle of ray is measured using the phase differences between the receivers of a 30-m-long receiving array. The theoretical analysis of phase deviation using the Rice distribution is presented. From the ray identification results, the travel time difference between corresponding rays of reciprocal transmissions can be estimated. Since the phase of a ray signal is very stable, the precision of the travel time difference using phase difference is 6 times higher than the conventional estimation. The combination of the amplitude and phase information is effective for observing the ocean structure change.

1pAOb2. Ocean acoustic thermometry and the seasonal cycle of temperature in the North Pacific Ocean. Brian D. Dushaw, R. Andrew, B. Howe, J. Mercer (Appl. Phys. Lab., Univ. of Washington, 1013 N.E. 40th St., Seattle, WA 98105-6698, dushaw@apl.washington.edu), B. Cornuelle, M. Dzieciuch, W. Munk, P. Worcester (Scripps Inst. of Oceanogr., La Jolla, CA), T. Birdsall, K. Metzger (Univ. of Michigan, Ann Arbor, MI), D. Menemenlis, and R. Spindel (California Insitute of Technol., Pasadena, CA)

With several years of long-range (several Mm) acoustic propagation data obtained during the Acoustic Thermometry of Ocean Climate (ATOC) and North Pacific Acoustic Laboratory (NPAL) projects, the seasonal cycle of ocean temperature in the North Pacific can be examined. Acoustic transmissions have been made from a source located off the northern Californian coast and from a source located north of Kauai, HI to several receivers of opportunity located in the North Pacific Basin. The acoustic data are a high signal-to-noise measure of large-scale temperature with excellent temporal resolution. Although only a few realizations of the seasonal cycle are available, it is clear that inter- and intraannual variabilities are large contributions to the time series, with signal amplitudes comparable to the seasonal cycle. Such variabilities are likely advective in origin. The time scales for some of the changes in temperature are short, sometimes of order weeks. Not all available acoustic paths are suitable for assessing the seasonal cycle, however. Near Hawaii, the acoustic sampling does not extend to the near-surface waters, so seasonal variations there are not measured. The acoustic results will be compared to measures of the seasonal cycle by satellite altimetry, profiling floats, and the ECCO numerical ocean model.

1pAOb3. The Long-range Ocean Acoustic Propagation EXperiment (LOAPEX): An overview. James A. Mercer, Bruce M. Howe, Rex K. Andrew, Michael A. Wolfson (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, mercer@apl.washington.edu), Peter F. Worcester, Matthew A. Dzieciuch (Univ. of California, La Jolla, CA 92093), and John A. Colosi (Naval Postgrad. School, Monterey, CA 93943)

The Long-range Ocean Acoustic Propagation EXperiment (LOAPEX), conducted in the NE Pacific Ocean, provided acoustic transmissions from a ship-suspended source at eight widely separated stations, and from a cabled acoustic source near the Island of Kauai, HI. The transmissions were received on several bottom-mounted horizontal hydrophone arrays distributed about the NE Pacific Ocean Basin and two, nearly colocated, vertical hydrophone line arrays spanning roughly 3500 m of the water column. Ranges varied from 50 km to several Mm. The goals of the experiment are (i) to study the evolution, with distance (range), of the acoustic arrival pattern and in particular the dependence of the spatial and temporal coherence; (ii) to investigate the nature of the deep caustics and the associated arrivals well below their turning depths; (iii) to analyze the effects of the ocean bottom near the bottom-mounted acoustic source cabled to Kauai; and (iv) to produce a thermal snapshot of the NE Pacific Ocean. The experiment goals, design, and methods are described as well as preliminary data results. [Work supported by ONR.]

1pAOb4. The SPICEX (Spice Experiment) component of the 2004 North Pacific Acoustic Laboratory (NPAL) experiment: An overview. Peter F. Worcester, Matthew A. Dzieciuch, Lora J. Van Uffelen, Daniel L. Rudnick, Bruce D. Cornuelle, and Walter H. Munk (Scripps Inst. of Oceanogr., Univ. of California at San Diego, La Jolla, CA 92093)

The objectives of the SPICEX component of the 2004 North Pacific Acoustic Laboratory (NPAL) experiment were (i) to elucidate the relative roles of internal waves, ocean spice, and internal tides in causing acoustic fluctuations; (ii) to understand the acoustic scattering far into the geometric shadow zone beneath caustics previously seen on bottom-mounted SOSUS receivers (shadow-zone arrivals); and (iii) to explore the range dependence of the fluctuation statistics. Two vertical line array receivers deployed in close proximity in the central North Pacific Ocean, together spanning much of the water column, recorded transmissions from broadband 250-Hz sources moored at the sound channel axis (750 m) and at surface conjugate depth (3000 m) at ranges of 500 and 1000 km from June through November 2004. Extensive environmental measurements were made along the acoustic path. The acoustic data from SPICEX reveal the vertical structure of the deep shadow zone arrivals. Internal waves are able to account for much of the observed vertical scattering in the reception finale, but other mechanisms seem necessary to account for the early shadow zone arrivals. Receptions from the abyssal sources show scattering occurring predominantly along the acoustic time fronts, as previously suggested by simulations, rather than across them.

1pAOb5. An overview of BASSEX (Basin Acoustic Seamount Scattering Experiment). Arthur B. Baggeroer (MIT, Cambridge, MA 02139), Kevin D. Heaney (OASIS, Inc., Lexington, MA), Peter F. Worcester, Matthew Dzieiuch (UCSD, La Jolla, CA 92037), James Mercer, Rex Andrew, and Bruce Howe (Univ. of Washington, Seattle, WA 98105)

BASSEX exploited the signals transmitted from the SPICEX, LOAPEX, and NPAL Kauai sources to examine the forward scattering from the Kermit-Roosevelt Seamounts near the Mendocino Fault in the northeast Pacific. The receiver was the FORA (four octave research array) from Pennsylvania State University. This array was towed at 300 m and had approximate resolutions of 2 and 6 deg for the 250- and 75-Hz signal transmissions. These were beamformed and pulse compressed for analyzing the multipath receptions from the sources. Source-receiver ranges covered from 250 to 1600 km provide a very rich data set. Data for forward- and backscattering from the slope near the NPAL source north of Kauai were also obtained. The analysis so far has demonstrated forward-scattering shadow convergence zones as well as diffraction from the seamounts. The upslope/downslope path structure near the Kauai source has also been analyzed. Both ray path and full wave acoustic modeling have been used for path identification as well as a theoretical model for modal scattering from a cone within an acoustic wave guide. [Work supported by ONR Code 321, Ocean Acoustics.]

1pAOb6. Ray and finite frequency kernel stability in the presence of realistic eddies. Bruce D. Cornuelle and Matthew A. Dzieciuch (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr, La Jolla CA 92093, bcornuelle@ucsd.edu)

Many recent studies have focused on the instability of ray paths (and therefore ray sampling kernels) in an ocean sound-speed field perturbed by internal waves. In many parts of the world's oceans there is synoptic scale eddy and planetary wave activity that produces sound-speed anomalies of larger scale than the internal waves, and of equal or larger magnitude. These are the features to be imaged by ocean tomography experiments, but the linearized forward problem that relates the travel time anomaly of the observed rays to the sound-speed anomalies may be invalid for realistic levels of eddy variability. This problem has been studied in the past for ray kernels by a number of authors, some of whom have concluded that nonlinearity requires iteration of the inversion process. We will compare and contrast the linearity of ray travel time kernel, finite frequency travel time kernels, and finite frequency kernels for other observables, such as pulse shape, in the presence of realistic variability for the N. Philippine sea, as estimated by ocean models and historical data. The travel time signals and nonlinearity due to the synoptic variability will be compared to that for internal waves. [Work supported by ONR.]

3:05–3:20 Break

Contributed Papers

1pAOb7. Seafloor hydrophone and vertical geophone observations during the North Pacific Acoustic Laboratory/Long-range Ocean Acoustic Propagation Experiment (NPAL/LOAPEX). Ralph A. Stephen (Woods Hole Oceanog. Inst., Woods Hole, MA 02543-1542, rstephen@whoi.edu), James A. Mercer, Rex K. Andrew (Univ. of Washington, Seattle, WA 98105-6698), and John A. Colosi (Naval Postgrad. School, Monterey, CA 93943)

Four OBSs (ocean bottom seismometers), consisting of one hydrophone and one vertical component geophone channel each, were deployed below the deep vertical line array (DVLA) on the North Pacific Acoustic Laboratory/Long-range Ocean Acoustic Propagation Experiment (NPAL/LOAPEX). The OBSs were deployed at 2 km offset north, south, east, and west from the nominal DVLA location. Data, sampled at 500 sps, were recorded continuously from the deployment in September 2004 for over 100 days. The OBSs were on the seafloor in about 5000 m of water and would be in the shadow zone for long-range, ducted propagation in the sound channel. The goals of the deployment were (1) to quantify the amount of energy that leaks out of the sound channel into the shadow zone; (2) to measure the relative sensitivity (signal-to-noise) of seafloor hydrophones and vertical component geophones to long-range signals; and (3) to study the physics of earthquake generated T-phases. Leakage was observed out to 3200 km on the vertical component geophone and out to 1000 km on the hydrophone. The ratio of the pressure to vertical velocity varies between arrivals on the same trace. [The OBS deployments were funded by contributions from ONR, NSF, and WHOI. Data analysis funded by ONR.]

1pAOb8. Mean acoustic field in long-range ocean acoustic propagation experiment (LOAPEX). Rex K. Andrew, Frank S. Henyey, James A. Mercer, Bruce M. Howe (Appl. Phys. Lab., Univ of Washington, 1013 NE 40th St., Seattle, WA 92105), Peter F. Worcester, and Matthew A. Dzieciuch (Univ. of California at San Diego, La Jolla, CA 92093)

We extract the low-frequency (70-Hz) mean acoustic pressure field, and the mean acoustic field up to time shifts, from the LOAPEX receptions on the vertical line arrays, for transmissions at various ranges. Means are taken over time intervals of order a day. Source and receiver motion is removed from the data, and possibly tides and other slow phenomena. The experimental results are compared to predictions from theoretical calculations assuming scattering by internal waves. The theoretical calculations make the Markov approximation that the sound-speed fluctuation correlations can be replaced by an operator at a single range. The calculations use modes rather than rays, because of the very low frequency, thus differing from the version of the Markov approximation that assumes delta-correlated sound-speed fluctuations.

1pAOb9. Mixed layer effects on acoustic arrival structure. Lora J. Van Uffelen, Peter F. Worcester, Matthew A. Dzieciuch, and Daniel L. Rudnick (Scripps Inst. of Oceanogr., UCSD, La Jolla, CA 92093-0238, lvanuffe@ucsd.edu)

Oceanic mixed layers develop as the summer sun warms the upper layer of the water column and turbulence from early autumn storms stirs this heat downward, forming a well-mixed layer with constant temperature and salinity. The mixed layer is therefore thinnest in summer, when the surface is warm and the winds are relatively weak, and deepest in late winter. Receptions from moored 250-Hz acoustic sources at ranges of 500 and 1000 km in the North Pacific were recorded on vertical line array receivers from June through November 2004, spanning the early development of the winter mixed layer. The time-evolving character of the acoustic arrival structure throughout this transmission period will be investigated to explore the effect of a changing mixed layer environment on long-range acoustic propagation. Particular consideration will be given to variability in the early branches of the acoustic timefronts, which correspond to steep rays interacting with the upper ocean.

1pAOb10. Analysis of low-mode arrivals at 500 and 1000-km ranges in the North Pacific. Kathleen E. Wage (George Mason Univ., 4400 Univ. Dr., MSN 1G5, Fairfax, VA 22030, kwage@gmu.edu), Peter F. Worcester, and Matthew A. Dzieciuch (UCSD, La Jolla, CA 92093)

Experimental measurements of low-mode signals in the deep ocean are needed to verify statistical models and to design improved processing algorithms for these signals. Several long-range propagation experiments provided estimates of low mode statistics at ranges between 3 and 5 megameters [Wage *et al.*, J. Acoust. Soc. Am. **117**, 1565–1581 (2005)]. The 2004–2005 SPICE experiment included measurements at shorter ranges and a higher frequency than previous experiments. A 40-element vertical line array (VLA) received signals from two broadband sources at ranges of 500 and 1000 km. Both sources were moored at depths near the sound-channel axis; thus, they directly excited the lowest modes. The VLA was designed to spatially resolve 20 modes at the center frequency of 250 Hz. In addition to hydrophones the SPICE array included temperature and salinity sensors, which can be used to infer sound speed, and hence mode shapes, at the VLA. This talk describes an analysis of the low-mode arrivals in the SPICE data set. The presentation will include a discussion of mode filter design, focusing on how often the filter coefficients need to be updated to avoid problems with environmental mismatch. [Work supported by ONR.]

4:20

1pAOb11. Seamount geo-acoustic inversion from an acoustic scattering experiment (NPAL-04). Kevin D. Heaney (OASIS Inc., 11006 Clara Barton Dr., Fairfax Station, VA 22039), Arthur B. Baggeroer (MIT, Cambridge, MA 02139), Peter F. Worcester, and Matthew A. Dzieciuch (Univ. of California, La Jolla, CA 92093)

It is thought that the deep ocean has thick, soft sediment due to millennia of build up from detritus. An open question is the sediment thickness on vast seamounts that rise many km from the ocean floor. Acoustic scattering from the Kermit-Roosevelt seamount (39.2O N 146.3 O W) in the central Pacific during the Basin Acoustic Seamount Scattering Experiment (BASSEX-04) in August of 2004 is used to address this question. The Kermit-Roosevelt seamount rises from a floor of 5400 m to a maximum height of 977 m below the surface. Broadband transmissions (100 Hz bandwidth, 250 Hz center frequency, 12.276 s period length) from two sources suspended (800 m depth, ranges of 521 and 625 km) were received on towed array (300 m depth, 200 m aperture) in the vicinity of the seamount. Combining array gain and time-bandwidth gain from the matched filter it is possible to clearly identify energy that has scattered from the seamount in 15 transmissions. These receptions are used to infer the sediment thickness and type as a function of the water depth. An efficient PE computational approach is applied as well as a reflection-coefficient ray-based approach.

4:35

1pAOb12. Mode processing of transient signals using a deficient vertical receiving array, with application to LOAPEX measurements. Ilya A. Udovydchenkov, Michael G. Brown (RSMAS, AMP, Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149), Peter F. Worcester, Matthew A. Dzieciuch, Lora J. Van Uffelen (Univ. of California at San Diego, La Jolla, CA, 92093), James A. Mercer, Bruce M. Howe, and Rex K. Andrew (Univ. of Washington, Seattle, WA 98195)

Mode processing of transient signals in a deep ocean environment using a deficient vertical receiving array is considered. Here, ''deficient'' implies that the vertical array is too sparse to resolve modes and/or has gaps. It is well known that mode processing of cw signals using a deficient array leads to significant modal cross-talk, i.e., nonzero projections of mode n energy onto mode m, $m \neq n$. It is shown, using simulated wave fields, that when phase-coherent processing is employed, transient signals are less sensitive to modal cross-talk than their cw counterparts. An explanation of this behavior is provided. Mode processing of a subset of the measurements made during the LOAPEX experiment at approximately 1 Mm range with $f_0 = 75$ Hz, $\Delta f = 35$ Hz is shown to give robust estimates of modal group time spreads for mode numbers $0 \leq m \leq 70$. [Work supported by ONR.]

4:50

1pAOb13. Horizontal coherence of tracked arrivals in the North Pacific Acoustic Laboratory98 (NPAL98). Matthew A. Dzieciuch (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., La Jolla, CA 92093, mad@ucsd.edu), Michael D. Vera (The Univ. of Southern Mississippi, Hattiesburg, MS), and The NPAL Group (J. A. Colosi, B. D. Cornuelle, B. D. Dushaw, B. M. Howe, J. A. Mercer, W. H. Munk, R. C. Spindel, and P. F. Worcester)

The NPAL98 experiment offered a unique opportunity to study horizontal coherence because of the deployment of a billboard array. The billboard consisted of five vertical line arrays with a 3600-m horizontal aperture listening to a 75-Hz acoustic signal 3500 km away. Original estimates of horizontal coherence were complicated by the bottom-interacting sound field, which made it difficult to track individual arrivals. Thus, previous studies of the horizontal coherence in this experiment were limited to the arrival pattern in aggregate. By using a turning-point filter and a rake correlator, it is now possible to track individual arrivals during the NPAL98 experiment. We can thus measure the coherence of individual early non-bottom-interacting arrivals. Results are compared to recent calculated predictions using both Monte Carlo and path-integral methods for the same environment. [Work supported by ONR.]

1pAOb14. The range evolution of the mean wavefront intensity for the long-range ocean acoustic propagation experiment (LOAPEX) off-axis source transmissions. Jinshan Xu (MIT/WHOI Joint Program in Oceanogr. and Oceanog. Eng., Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), John A. Colosi (Naval Postgrad. School, Monterey, CA 93943), James A. Mercer, Bruce M. Howe, Rex K. Andrew (Univ. of Washington, Seattle, WA 98105), Peter F. Worcester, and Matthew Dzieciuch (UCSD, La Jolla, CA 92093)

One of the main objectives of the NPAL 2004 experiment, LOAPEX (Long-range Ocean Acoustic Propagation EXperiment), which was conducted between 10 September and 10 October 2004, was to better understand the roles of scattering and diffraction in general. The LOAPEX measurement provided acoustic transmission data for ranges of 50, 250, 500, 1000, 1600, 2300, and 3200 km. By placing the source off-axis in order to avoid exciting low-order modes, we are able to study phenomena of the significant in-filling of acoustic energy into the finale region. Our focus will be on the transmissions for the off-axis source location (nominally 350-m depth), and the acoustic receptions as recorded on the 1400-m-long axial receiving array. The observation of the mean intensity of the wavefront arrival pattern at each range will be compared to deterministic ray and parabolic equation calculations. The following questions will be addressed here: (1) How does high angle acoustic energy from an off-axis source transfer energy to low angles in the axial region of the waveguide? (2) What are the relative contributions from diffraction and scattering? (3) How does this energy transfer scale with range? [Work supported by ONR.]

1pBB1. Acoustic computed tomography: Waves of approaches. James F. Greenleaf (Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55901)

Computed tomography (CT) using acoustic waves was invented at about the same time as MRI. The method of computing attenuation from projections was a direct analog of the x-ray CT approach. However, the method of computing speed from the time of flight of the acoustic ray was a larger logical jump. The field started with straight ray, earliest arrival time methods and has matured to what can be termed the full wave equation inversion method. The extension from two dimensions to three, although essential in the body, did not find a practical solution until very recently. The inverse problem represented by this field has found the attention of many investigators over the years. Practical medical implementations continue being investigated by several investigators more than 30 years after the first invention of the method. Acoustic tomography has been applied in nonmedical areas including oceanography, seismic, and solar sciences. Time awaits its success in medicine.

2:00

1pBB2. From laboratory to clinical trials: An odyssey of ultrasound inverse scattering imaging for breast cancer diagnosis. Steven A. Johnson, David T. Borup, James W. Wiskin, Michael Berggren, Barry Hanover, Frank Setinsek, Scott Olsen, and Karleen Callahan (Techniscan, Inc., 1011 East Murray Holladay Rd., Salt Lake City, UT 84117)

Techniscan has completed a local phase of clinical trials of a unique inverse scattering breast cancer scanner. The scanner is based on transmission of plane waves from 0.3 to 2 MHz through the breast to a receiver on the opposite side of the breast. The receiver consists of a 2-D array of six rows by 160 columns. These elements are multiplexed by a factor of 12 into 80 analog to digital converters. The dual transducer-head design allows the inversion of the transmission data to create two independent quantitative images, one of speed of sound and a second of attenuation. The two heads are mechanically attached to a hollow rotating shaft, to provide 360 deg of mechanical motion. Typically, 180 to 360 steps per 360-deg rotation and 2-mm vertical steps are used to create a data set that is inverted into a 3-D image of 240 by 240 by 70 voxels. A unique set of custom circuit boards was constructed to implement scanner electronics. The next scanner version with anticipated inverse scattering resolution of 1 mm or less and reflection tomography resolution of 0.5 mm or less should improve performance. Clinical images to date and performance will be discussed.

2:20

1pBB3. Image reconstruction using eigenfunctions of a scattering operator. Robert Waag (Dept. of Elec. and Comput. Eng. and Dept. of Imaging Sci., Univ. of Rochester, Rochester, NY 14627)

A multiple-frequency iterative inverse scattering method is reviewed. In the method, scattered acoustic fields are described using a scattering operator with eigenfunctions that correspond to far-field patterns of an effective source distribution. Incident-wave patterns determined using the eigenfunctions focus on the distribution. The focusing properties of the eigenfunctions are employed to reconstruct an object by using products of numerically calculated fields defined by weighted products of the eigenfunctions. The full range of frequencies present in an incident pulse waveform is employed. Iteration using a linearized version of the method and calculated scattering from an estimate of the object permits reconstruction of large-scale high-contrast objects. The method is illustrated using calculated and measured data. In the calculations, an exact solution for scattering from nonconcentric lossy cylinders with parallel axes was employed to obtain the scattered field. In the measurements, a novel ring-transducer system was used to obtain the incident and total fields. The results of simulations and experiments show that the method converges and is accurate for high-contrast large-scale tissue-mimicking objects. Reconstructions using measured scattering from random media have considerably less speckle than conventional b-scan images, implying that the inverse scattering method can clearly demonstrate small high-contrast inclusions.

1pBB4. Optical coherence-based imaging and sensing in biomedicine and biotechnology. Joseph A. Izatt (Duke Univ., Campus Box 90281, Durham NC 27708)

Optical coherence-based imaging techniques including optical coherence tomography (OCT), optical coherence microscopy (OCM), and spectral domain phase microscopy (SDPM) use low-coherence spectral interferometry to obtain nanometer to micron-scale measurements of structure, motion, and molecular composition in living cells, tissues, and organisms. OCT has become a standard diagnostic tool in clinical ophthalmology and is under investigation for other human diagnostic applications including cancer detection and evaluation of cardiovascular disease. Within the past few years, dramatic technology advances have increased the performance of OCT and OCM systems manyfold, and they are now capable of micron-scale two- and three-dimensional functional and molecular imaging noninvasively in living systems. Applications of these new technologies for high-throughput noninvasive phenotyping and rapid 3D imaging in small animals and developmental biology models is particularly compelling. Related technology advances have enabled the design of highly phase-stable interference microscopes capable of resolving nanometer-scale structures and motions in living cells with ms temporal resolution. These new capabilities are being used to probe cellular internal and external surfaces and their responses to chemical and mechanical stimuli. I will review our ongoing work at Duke in these areas. [Work supported by NIH Grants RR019769, EY013516, EB006338, and EY017393.]

1pBB5. Whole breast imaging with ultrasound tomography: First clinical results at the Karmanos cancer institute. Neb Duric, Peter Littrup, Earle Holsapple, and Olsi Rama (Karmanos Cancer Inst., 4100 John R, Detroit, MI 48201)

Although mammography is the gold standard for breast imaging, it leads to a high rate of biopsies of benign lesions and a significant false negative rate for women with dense breasts. A clinical breast-imaging device, based on the principles of ultrasound tomography, is being developed in response to this imaging performance gap. The computed ultrasound risk evaluation (CURE) system has been designed with the clinical goal of providing fast, whole-breast, operator-independent imaging, capable of differentiating breast masses. In an initial assessment of its *in vivo* performance, 50 patients were examined with CURE. The following results were demonstrated: (*i*) tomographic imaging of breast architecture, (*ii*) in-plane spatial resolution of 0.5 mm in reflection and 4 mm in transmission, (*iii*) imaging of breast masses in reflection and transmission mode (sound speed and attenuation, and (*iv*) differentiation of breast masses was shown to be feasible. These initial results indicate that operator-independent, whole-breast imaging and the detection and characterization of breast masses are feasible. Future studies will focus on improved detection and differentiation of masses with the long-term goal of improving the specificity of breast exams. [The authors acknowledge financial support from the Karmanos Cancer Institute and the NIH (grant R43 CA108072-01).]

1pBB6. Advanced tomographic algorithms and their potential applications to ultrasound imaging. Xiaochuan Pan, Samuel LeRoque, Emil Sidky (Dept. of Rad., MC2026, The Univ. of Chicago, 5841 S. Maryland Ave., Chicago, IL 60637, xpan@uchicago.edu), and Mark Anastasio (Illinois Inst. of Technol.)

The success of computed tomography has led to the development of a wide variety of tomographic imaging techniques. There has always been a great interest in ultrasound-based tomographic imaging because it can provide detailed, quantitative information about the imaged subject, which can be used for diagnosis, evaluation, and monitoring of cancer and other diseases. Tomographic imaging relies not only upon the imaging system for data acquisition but also upon the algorithms for image recovery from the data. In the last decade or so, there has been a tremendous development of innovative algorithms for tomographic imaging. One important breakthrough is that an artifact-free ROI image within the subject can be obtained from, e.g., truncated data. This breakthrough has led to the development of the so-called targeted-ROI imaging strategy in which one can substantially reduce imaging effort and artifacts. There have also been significant advances in reconstructing images from highly incomplete data acquired, e.g., at a small number of views and/or over a limited angular range. In this paper, we will discuss these new developments and their potential applications to ultrasound-based imaging. We will use examples to illustrate how they can be exploited for reconstructing images in different types of ultrasound-based tomographic imaging.

Contributed Papers

1pBB7. On the use of inverse scattering tomographic methods for quantitative ultrasound techniques. Roberto J. Lavarello and Michael L. Oelze (Dept. of Elec. and Comput. Eng., Univ. of Illinois at Urbana-Champaign, 405 N. Mathews Ave., Urbana, IL 61801)

The application of the distorted Born iterative method (DBIM) is proposed to construct tomographic images of small scale structures. Specifically, DBIM is proposed as a tool to construct better ultrasonic models of cells in order to improve the accuracy of quantitative ultrasound (QUS) analysis. An alternative implementation of DBIM valid for measurement configurations where the receiver positions are fixed is discussed. In addition, a method for the selection of the regularization parameter is deter-

mined, based on the Rayleigh quotient iteration. QUS imaging has been used to differentiate malignant from benign tissue. Recently, cells have been hypothesized as an important source of scattering in tissue. Generating tomographic images of sound speed and density of cells would allow better models to be constructed. Because the contrast mechanism in cells is unknown, the effect of variable density is explored. Stage II–III Xenopus oocytes are proposed as an initial cell model for scattering, with typical sizes ranging between 300 and 600 μm. Based on measurements of the propagation delay through oocytes, it was determined that their diameters correspond to at most 24 resolution cells when using single-frequency DBIM. Hence, frequency hopping may be required to discriminate smaller features inside the oocytes.

1pBB8. Linear sampling method for acoustic inverse scattering in breast microcalcification detection.
Matthew A. Lewis, Peiying Liu, Edmond Richer, Peter P. Antich (Dept. of Radiol., UT Southwestern Medical Ctr. at Dallas, 5323 Harry Hines Blvd., Dallas, TX 75390-9058, matthew.lewis@utsouthwestern.edu), and Stuart G. Johnson (UT Austin, Austin, TX)

In women under age 40, the breast may be too dense for mammographic screening and microcalcification detection. A nonionizing method would be preferred for frequent screening in patients with significant risk factors for developing breast cancer. Ultrasonic detection of microcalcifications has been problematic since frequencies above 10 MHz suffer from appreciable attenuation in soft tissues. Transmission diffraction tomography is by construction a low-pass filter and insensitive to scattering caused by small, hard inhomogeneities. A more general form of acoustic inverse scattering is therefore needed for microcalcification detection and localization by ultrasound. An advanced scalar inverse scattering theory developed by Colton, Kirsch, and others [D. Colton, J. Coyle, and P. Monk. SIAM Review **42**(3), 369–414 (2000)] in the electromagnetic inverse scattering community for determining the location and shape of scatterers with size on the order of the wavelength (the so-called resonance region) has been simulated in the context of breast microcalcification detection. This method was shown to be related to both multiple signal classification and time-reversal algorithms [M. Cheney. Inverse Problems **17**, 581–585 (2001)] [S.K. Lehman and A.J. Devaney J. Acoust. Soc. Am. **113**(5), 2742–2753 (2003)]. Translation of this method to a heterogeneous soft-tissue background is a significant challenge.

4:25

1pBB9. Full wave nonlinear inverse scattering for transmission breast imaging.
James Wiskin (Techni Scan Medical Systems, 1011 Murray Holladay Rd., Salt Lake City, UT, 84117, jwiskin@techniscanmedical.com), David Borup, and Steven Johnson

Ultrasound has been proposed as an adjunct diagnostic modality for 25+ years. However, initial studies were hampered by relatively low resolution. Over the past 20 years there has been a tremendous amount of research carried out in inverse scattering, the mathematical foundation behind quantitative determination of the coefficients of a partial differential equation. In particular, the research at TechniScan, Inc., and the Dept. of Bioengineering, Univ. of Utah, has culminated in algorithms that give approximately millimeter resolution, and quantitative accuracy, in 2-D and 3-D problems. We invert the full nonlinear acoustic inverse scattering problem (no Born/Rytov approximation) in 2-D and 3-D. We reconstruct a phantom with known inclusions. The image space is $241 \times 241 \times 135 = \sim 7.8$ Megapixels or larger. Each pixel is $0.8 \times 0.8 \times 1.0 mm^3$ in size. The data is collected on a 6 by 160 element array, positioned 180 views surrounding the breast. The transmitted wave is a plane wave chirp. Reconstruction time is ~ 2 h on a six-node cluster of Pentium Ms. This paper will discuss theoretical algorithm development, practical issues that result in images, and a device presently being used in a clinical setting. We show several reconstructed images from ~ 400 volunteers.

4:40

1pBB10. Radial reflection diffraction tomography.
Sean K. Lehman (Lawrence Livermore Natl. Lab., L-154, 7000 East Ave., Livermore, CA 94550) and Stephen J. Norton (Geophex, Ltd., Raleigh, NC 27603)

A wave-based tomographic imaging algorithm based upon a single, rotating, radially outward oriented transducer has been developed. At successive angular locations at a fixed radius, the transducer launches a primary field and collects the backscattered field in a "pitch/catch" operation. The hardware configuration, operating mode, and data collection method are identical to that of most medical intravascular ultrasound (IVUS) systems. The goal is to develop a wave-based imaging algorithm using diffraction tomography techniques. Given the hardware configuration and the imaging method, this system is referred to as "radial reflection diffraction tomography." Two hardware configurations are considered: a multimonostatic mode using a single transducer as described

above, and a multistatic mode consisting of a single transmitter and an aperture formed by multiple receivers. The probe is mounted at the end of a catheter or snaking tube inserted into a part or medium with the goal of forming images of the plane perpendicular to the axis of rotation. An analytic expression for the multimonostatic inverse is derived but ultimately a Hilbert space inverse wave algorithm is used to construct images using both operating modes. Applications include improved IVUS imaging, bore hole tomography, and nondestructive evaluation (NDE) of parts with existing access holes.

1pBB11. Ultrasonic reflection imaging with a heterogeneous background for breast cancer detection and diagnosis.
Lianjie Huang (Los Alamos Natl. Lab., M.S. D443, Los Alamos, NM 87545), Youli Quan (Stanford Univ., Stanford, CA 94305), Nebojsa Duric, and Cuiping Li (Karmanos Cancer Inst., Detroit, MI 48201)

Sound speeds and densities of breast tissue vary in space, and those of tumors are different from the surrounding tissues. These differences in mechanical properties cause scattering of ultrasonic waves, particularly in dense breasts. An ultrasonic reflection imaging method using a heterogeneous background is presented to properly account for scattering off heterogeneities within the breast. The method is based on downward continuation of ultrasonic wave fields in the frequency-space and frequency-wave-number domains. Synthetic ultrasonic data for scatterers within a heterogeneous breast model were used to investigate the imaging resolution of the method. Imaging examples using ultrasonic data acquired using a clinical prototype, consisting of an ultrasound scanner with a ring transducer array, are presented. The heterogeneous background sound-speed models were obtained using transmission tomography. The imaging results are compared with those obtained using a homogeneous background. The study demonstrates that imaging with heterogeneous backgrounds significantly improves image quality and resolution. [This work was supported through the DOE Laboratory-Directed Research and Development program at Los Alamos National Laboratory.]

1pBB12. Photoacoustic imaging with a planar measurement array: Improving the resolution using image sources.
Benjamin T. Cox (Dept. of Med. Phys. and Bioengineering, Univ. College London, Gower St., London, WC1E 6BT, UK, bencox@mpb.ucl.ac.uk), Simon. R. Arridge, and Paul C. Beard (Univ. College London, Gower St., London, WC1E 6BT, UK)

Biomedical photoacoustic (PA) imaging is a soft-tissue imaging modality that combines the high spatial resolution of ultrasound (US) with the contrast and spectroscopic opportunities afforded by imaging optical absorption. Exact reconstruction algorithms for PA imaging have been described for spherical, cylindrical, and planar sensor arrays. Many applications to date have used a cylindrical measurement geometry because a single US transducer may be scanned straightforwardly in a circle around a sample. However, planar US arrays composed of piezo or optical elements with small element sizes and fast acquisition times are readily available, making them an attractive option for imaging applications. To capture sufficient data for an exact PA reconstruction with a planar geometry requires an infinitely wide array. In practice, of course, it will be finite, resulting in a loss of resolution and introducing artefacts into the image. To overcome this limitation, it is proposed that acoustic image sources are used to generate a periodically repeating sound field that can be reconstructed exactly from measurements made over a finite aperture. [This work was funded by the EPSRC, UK]

5:25

1pBB13. An acoustic technique to assess particle distribution following transcutaneous needle-free injection. Jamie Condliffe, Jamie R. T. Collin, George Costigan, and Constantin-C. Coussios (Inst. of Biomed.. Eng., Dept. of Eng. Sci., Univ. of Oxford, 17 Parks Rd., Oxford OX3 0DH, UK, constantin.coussios@eng.ox.ac.uk)

Needle-free injection is a novel technique enabling pain-free transdermal drug and vaccine delivery. The present work aims at developing a noninvasive, ultrasonic technique to assess distribution of drug particles delivered in this manner beneath an optically opaque layer, such as the skin. Drug particles are modeled as a monodisperse distribution of 50-μm polystyrene spheres that are injected into an agar-based tissue-mimicking material, which they penetrate to a mean depth of 500 μm. A 15-MHz broadband focused immersion transducer, driven in pulse-echo mode, was used to scan the surface of the agar phantom. By assuming that the mean-squared voltage of the received waveform is proportional to the number of particles encountered by the incident pulse, a 3-D map of particle distribution was generated. The resulting acoustic microscopy data were validated by examining phantom slices of thickness similar to the acoustic pulse length under a conventional optical microscope. The acoustic technique was found to provide a good prediction of the mean particle penetration depth and an accurate map of transverse particle distribution in planes normal to the direction of injection. It thus shows great promise as a noninvasive means of assessing the efficacy of needle-free injection, both *in vitro* and *in vivo*.

5:40

1pBB14. Speckle reduction of echographic image by transmitting ultrasonic waves of double peak spectrum. Iwaki Akiyama (Shonan Inst. of Technol., 1-1-25 Tsujido-nishikaigan, Fujisawa 251-8511 Japan), Shigemi Saito (Tokai Univ., Shimizu-ku, Shizuoka, 424-8610 Japan), and Akihisa Ohya (Univ. of Tsukuba, Tsukuba, Ibaraki, 305-8573 Japan)

Speckle noise of ultrasonic echography is a major issue. To reduce the speckle noise a method of summation after logarithmic compression of higher order harmonic images is proposed. The feasibility is confirmed by the phantom experiments using a mechanical scanner system equipped with a bi-layered structure transducer of PZT and PVDF. The dynamic range of harmonic components higher than the third, however, is not enough for effective speckle reduction. In this study a method of using difference and sum frequency components as well as harmonic components by transmitting pulsed waves of double peak spectrum is proposed. To compare the dynamic range of those components the numerical simulation of transmitting the ultrasonic waves of 2 and 6 MHz and those of 2 and 8 MHz in absorbing media is carried out. An attenuation coefficient of 1.0 dB/cm/MHz is assumed. As a result, complex beam patterns are formed due to degeneration between second harmonic and difference frequency components of 4 MHz in the former case. In the latter case three focal beam patterns of 4-, 6-, and 8-MHz components within 40 dB in dynamic range are formed. Consequently this method has the potential to apply for the biological tissues. [Work supported by a Grant-in-Aid for Scientific Research.]

1pEA1. Subbottom profiling using synthetic aperture processing. Steven Schock (Dept. of Ocean Eng., Florida Atlantic Univ., 777 Glades Rd., Boca Raton, FL 33431, schock@oe.fau.edu)

Using synthetic aperture processing, a chirp sonar generates reflection profiles of the seabed. Synthetic aperture processing is implemented by calculating the vertical change in the positions of acoustic transducers between transmission and using the offsets to time shift the acoustic data so that horizontal reflectors are summed coherently. The calculated changes in the positions of the acoustic transducers between transmission events are based on Doppler velocity log and inertial measurement unit measurements of vehicle motion. Imagery generated from reflection profiles of seabeds with various sediment types are used to quantity the improvement in the spatial resolution and the SNR of reflection profiles as a function of the length of the synthetic aperture. [Work supported by Office of Naval Research.]

1:25

1pEA2. Chirp seismic surveying of shallowly buried fluvial systems on the outer New Jersey continental shelf: Mapping channel morphology and internal stratigraphy in 3D. John Goff, Sylvia Nordfjord, James Austin, Jr. (Inst. for Geophys., Jackson School of Geosciences, Univ. of Texas, Austin, TX 78759), and Steven Schock (Florida Atlantic Univ.)

The outer New Jersey continental shelf has been the focus of Office of Naval Research-sponsored acoustic studies for more than a decade. As part of this effort, ONR has funded a number of field programs to characterize the geologic history and sedimentary properties of the shallow seabed. We report here on a chirp seismic campaign conducted in 2001, with particular focus on characterizing the morphology and internal stratigraphy of shallowly buried fluvial channel systems that are widespread in this region. These channels were formed during the last glacial lowstand, and then filled and buried by sediments during sea level rise. Mapping the channel morphology in 3D presented a significant challenge. Although coverage (200-m line spacing) was dense, application of

standard interpolation techniques resulted in poor representation of channel continuity along sinuous pathways. We developed a technique for transforming the seismic horizon data into a channel-oriented reference frame, wherein the channel is effectively straight and simple interpolation techniques can be used to maintain channel continuity. Seismic units within the channel fill could be discerned based on bounding reflectors and acoustic character and mapped throughout the 3D channel systems. These units provide a record of sea level change and drowned-river estuary development.

1:45

1pEA3. Removing multiples and depth imaging and inverting primaries without knowing or determining the velocity model: A response to pressing seismic challenges. Arthur B. Weglein (Phys. Dept., Univ. of Houston, 4800 Calhoun, Houston, TX 77004, aweglein@uh.edu)

The isolated task specific subseries of the inverse scattering series represents a direct response to many pressing seismic exploration challenges. Those challenges often involve removing multiply reflected events and locating and identifying targets when the subsurface properties and boundaries are rapidly varying and beyond all current methods to adequately predict and estimate. The goal of these fundamentally new concepts and algorithms is to make currently inaccessible targets accessible and accessible targets better defined. We will exemplify these new algorithms with synthetic and field data. Open issues and plans will be discussed.

2:05

1pEA4. Seismic imaging of subduction zone deformational structures using 3D seismic profiling. Nathan L. Bangs (Inst. for Geophys., Univ. of Texas, 4412 Spicewood Springs Rd., Austin, TX 78759, nathan@ig.utexas.edu)

In the past 15–20 years, considerable efforts have been made to image complex deformational structures beneath the seafloor at subduction zones using seismic imaging techniques. The goals have been to: 1) accurately image structures to determine the geometry of thrust faults controlling the deformation and tectonics of plate collision at subduction zones, and 2) to determine the rock physical properties from seismic reflections to infer fault zone mechanical properties and examine conditions leading to fault rupture and earthquake generation. Subduction zones generate the world's largest and most destructive earthquakes and tsunamis and accurate seismic images of faults to depths of 6–7 km below seafloor offer an opportunity to examine conditions at these inaccessible depths. Three-dimensional seismic techniques have proven to be critical for sampling the reflected wavefield at the sea surface sufficiently to be able to migrate reflections to their proper subsurface positions and construct accurate images. I will present examples of these 3-D seismic reflection images, analyses of these data, and future directions. [Work supported by NSF.]

2:25

1pEA5. Application of CHIRP data to neotectonic, sediment dispersal and sea level studies. Elizabeth Johnstone and Neal Driscoll (Scripps Inst. of Oceanogr., Univ. of California San Diego, La Jolla, CA 92093-0244)

CHIRP seismic data will be presented in order to demonstrate the importance of subbottom imaging in addressing fundamental problems in Earth sciences. Examples from actively deforming regions in California place important constraints on the rupture history along major fault systems as well as tectonic control on sediment preservation and exposure of hardgrounds on the seafloor. Tectonic deformation creates a rich tapestry of geologic substrate exposed on the seafloor, ranging from mobile sands to lithified hardgrounds. It is this heterogeneity of the seafloor that creates different biological ecosytems and consequent increased biodiversity. CHIRP data have also provided new insights into sediment dispersal and clinoform development in the Gulf of Papua. In the northern gulf, oblique clinoforms suggest the rate of sediment supply has outstripped the formation of accommodation, whereas in the south the sigmoidal package indicates that accommodation increased faster than sediment supply. The morphology and internal geometry of the clinoform itself are inherently three-dimensional. The underlying physiography also appears to play an important role in governing sediment dispersal and distribution.

1pEA6. A multibeam subbottom profiler. Jerald W. Caruthers (Univ. of Southern Mississippi, 1020 Balch Blvd., Stennis Space Center, MS 39529) and Sean Griffin (Omni Technologies, Inc., Stennis Space Center, MS 39529)

A multibeam subbottom profiling system (MSBPS) is being built with funding from the Defense University Research Instrumentation Program (DURIP) in coordination with the Office of Naval Research. The MSBPS is being constructed from three T70 Neptune Sonar transducer modules in a line. Each T70 has five 11.5-kHz elements in each of two parallel lines. The resulting system is composed of 15 elements in each line with a total length of 1.3 m separated by about 8.5 cm. Each line has full beamwidths to the 3-dB points of about 5×70 deg. The system will be used in an interferometric mode between the two lines. [This work is supported by ONR 321OA.]

3:15

1pEA7. Using ambient noise and vector sensor arrays to form a subbottom profiler. Paul Hursky and Martin Siderius (Heat, Light, and Sound Res. Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130)

Surface-generated ambient noise is distributed in time, but its correlation produces a strong impulse that is excellent for imaging the ocean floor. This technique has been experimentally demonstrated using vertical line arrays of pressure phones. The up-looking endfire beam (for ambient noise traveling down) is cross-correlated with the down-looking endfire beam (for the ambient noise reflected from the bottom, traveling up). Each layer in the bottom produces a distinct reflection. Previous work has required somewhat large vertical arrays. A towed horizontal array would be much better and allow us to make measurements with a mobile platform. The problem is that a horizontal line array cannot distinguish up from down—a broadside beam is symmetric with respect to the axis of the array. Vector sensors, sensing both pressure and particle velocity, have additional degrees of freedom for overcoming such ambiguities. We will show how vector sensors make it possible to implement such an ambient

noise subbottom profiler, either in a greatly reduced vertical array or in a horizontal (towed) array configuration. We will also show results of processing data collected on a four-element vector sensor array and a much larger pressures-only array during the Makai experiment.

baffles and waveguides was also investigated. A theoretical discussion is also included. This work represents the practical employment of MHD transducers to undersea digital communication. [Work supported by General Atomics.]

3:30

1pEA8. Development of practical broadband magnetohydrodynamic transducers for undersea digital communication. Eric Berkenpas and Corey Jaskolski (Hydro Technologies, 700 Automation Dr., CO 80550)

Demand for broadband underwater digital communication is being driven by development of tetherless autonomous underwater vehicles (AUVs). Current communications methods employ typically piezoelectric transducers. While efficient, and broadband as receivers, these transducers exhibit significant frequency dependence when transmitting, thus limiting their utility in digital communications. Magnetohydrodynamic (MHD) transducers generate acoustic waves in seawater by applying time-varying Lorentz force to moving ionic charges in the presence of a magnetic field. MHD transducers are ultracompliant, exhibit wide-frequency bandwidth, and are therefore attractive for high-speed undersea digital communications. This paper reports on exploratory development MHD transducers with the goal of improved transduction efficiency and bandwidth. Novel MHD transducer structures were fabricated with permanent magnet, parallel electrode structures, and planar interdigitated electrode structures. To evaluate transducer performance, an automated transducer test setup was assembled incorporating a 7500-L saltwater test environment, a time-gated high-current signal source, and a wideband hydrophone. Use of acoustic

1pEA9. Influence of nonlinear propagation on calibration of hydrophone sensitivity using a two-transducer reciprocity method. Masahiro Yoshioka and Sojun Sato (Natl. Metrology Inst. of Japan, Natl. Inst. of Adv. Industrial Sci. and Technol., Tsukuba Central 3, 1-1-1 Umezono, Tsukuba, Ibaraki, 305-8563 Japan)

This paper describes the phenomenon by which the measured value depends on the ultrasound pressure in the measurement field when the hydrophone sensitivity has been calibrated using the two-transducer reciprocity method. This dependence is attributable to nonlinear ultrasonic propagation. However, the international standard, IEC 60866:1987, "Characteristics and calibration of hydrophones for operation in the frequency range 0.5 MHz to 15 MHz," provides a correction factor for diffraction and attenuation derived assuming linear propagation of sound. We attempted to derive the correction factor from the ultrasound pressure distribution calculated using the Khokhlov-Zabolotskaya-Kuznetsov (KZK) equation, which is well known as a nonlinear ultrasonic model. Results demonstrated that the dependence of the calibrated sensitivity value on measured sound pressure is quantitatively explainable. The hydrophone sensitivity can be calibrated properly by compensating for the influence of ultrasonic nonlinear propagation using the KZK equation.

Contributed Papers

1:30

1pMU1. Voice quality of artistic expression in Noh: An analysis-synthesis study on source-related parameters. Hideki Kawahara (Faculty of Systems Eng., Wakayama Univ., 930 Sakaedani, Wakayama, 640-8510 Japan), Osamu Fujimura (Intl. Inst. for Adv. Studies, Sorakugun, Kyoto 619-0225 Japan), and Yasuyuki Konpaku (Konparu School of Noh, Nara, Japan)

High-quality recordings of Noh vocalizations, produced by one of the authors, were made in an anechoic chamber, comparing vocal styles and emotional expression, using the same sample text from classical Noh. The recorded signals were subject to analysis, synthesis, and morphing by using STRAIGHT. The morphing procedure generated mean parameter settings for comparing two subtly differentiated voicing styles, traditionally called "wagin" soft vocalization, and "gougin," strong vocalization, to investigate the relation between signal parameters and communicative functions. STRAIGHT extracts three parameters from recorded speech signals: fundamental frequency, smoothed spectrogram, and a time-frequency aperiodicity map. The fundamental frequency and the time-frequency aperiodicity, in other words, source-related parameters, were systematically manipulated to investigate their role in artistic expression.

1:45

1pMU2. Spectro-temporal analysis of Palauan chants. Birgit Abels (Ruhr Univ., Imam Husnu Sok. 1/1, IStanbul Bochum, Germany) and Jonas Braasch (Rensselaer Polytechnic Inst., NY)

A field study was carried out to determine how songs from the repertory of chants in Palau have changed over the last century. To this end, several chanters were recorded during recent fieldwork; these sound documents were then compared to items from several historic collections of sound recordings from the Phonogram Archives Berlin, Germany, and the Pacific Collection, Library of the University of Hawai'i at Manoa. The available recordings cover the time span from 1909–2006. Analytical results were derived in the form of spectrograms both for recent recordings from the years 2005/2006 and historic ones from 1963. They confirmed the auditory impression that chanting in Palau today has moved away from a recitative style, relying predominantly on the speaking voice, towards a performance practice the sound ideal of which is the singing voice. Also, the range of pitch employed in these chants has expanded. Spectral analysis also revealed how, in particular genres, the musical form of group chants is structured by the changing contours of a frequency band that is

resolved at phrasal ends, when the singers narrow the range of this tonal cluster. This unique technique is one of the core musical elements of the Palauan singing tradition.

2:00

1pMU3. Spectral modification technique in conversion of musical notes or tempos for singing voice synthesis system. Hideki Banno, Kumi Ohta, Masato Kawazoe, and Fumitada Itakura (Faculty of Sci. and Technol., Meijo Univ., 1-501, Shiogamaguchi, Tenpaku-ku, Nagoya-shi 468-8502, Japan, banno@ccmfs.meijo-u.ac.jp)

The STRAIGHT time-frequency representations (spectrograms) of singing voice signals in various musical notes and various tempos are observed to develop a high-quality synthesis system of singing voice. The spectrogram of STRAIGHT, which is a very high-quality analysis-synthesis system, can represent the vocal tract information accurately. A conversion system of a musical note or a tempo of an input singing voice signal has been implemented based on the observation. As a result of the observation, the frequency warping of the STRAIGHT spectrogram based on a DP matching algorithm has been introduced into the system. It was found that the method using a differential of a smoothed spectrum as a spectral distance measure in the frequency warping produces subjectively better quality than that using a smoothed spectrum directly. It was also found that the method without spectral modification, i.e., only with pitch/tempo modification in the conversion, produces better quality than that using a differential of a smoothed spectrum. This can be caused by the destruction of naturalness in the method using a differential of a smoothed spectrum.

2:15

1pMU4. Physical modeling vocal synthesis. David Howard, M. Jack Mullen, and Damian Murphy (Audio Lab., Intelligent Systems Res. Group, Dept. of Electron., Univ. of York, Heslington, York YO10 5DD, UK. dh@ohm.york.ac.uk)

Physical modeling music synthesis produces results that are often described as being "organic" or "warm." A two-dimensional waveguide mesh has been developed for vocal synthesis that models the adult male oral tract. The input is either the LF glottal source model or a user-provided waveform file. The mesh shape, which is based on MRI data of a human vocal tract, can be changed dynamically using an impedance well approach to allow sounds such as diphthongs to be synthesized without clicking. The impedance well approach enables the mesh shape to be varied without removing or adding elements, actions that cause audible clicking in the acoustic output. The system has been implemented as a real-time MIDI-controlled synthesizer, taking its inspiration from the von Kempelin speaking machine, and this will be demonstrated live as part of the presentation. The system is set up to allow a continuous glottal source to be applied that includes vibrato, and thus the real-time output it currently produces is close to being vocalized. It should be noted, though, that appropriate variation of the lip opening does produce a voiced bilabial plosive, demonstrating the potential for moving towards a full speech synthesis system in the future.

2:30

1pMU5. Analysis of acoustic features affecting singing-voice perception and its application to singing-voice synthesis from speaking-voice using STRAIGHT. Takeshi Saitou (ATR Cognit. Information Sci. Lab, 2-2-2 Hikaridai Seika-cho Souraku-gun, Kyoto 619-0288, Japan), Masashi Unoki, and Masato Akagi (School of Information Sci. Japan Adv. Inst. of Sci. and Technol., Nomi Ishikawa 923-1292 Japan)

A singing-voice synthesis method that can be transformed from a speaking voice into a singing voice using STRAIGHT is proposed. This method comprises three sections: the F0 control model, spectral sequence control model, and duration control model. These models were constructed by analyzing characteristics of each acoustical feature that affects singing-voice perception through psychoacoustic experiments. The F0 control

model generates a singing-voice F0 contour through consideration of four F0 fluctuations: overshoot, vibrato, preparation, and fine (unsteady) fluctuation that affect the naturalness of a singing voice. The spectral sequence control model modifies the speaking-voice spectral shape into a singing-voice spectral shape by controlling a singer's formant, which is a remarkable peak of a spectral envelope at around 3 kHz, and amplitude modulation of formants synchronized with vibrato. The duration control model stretches the speaking-voice phoneme duration into a singing-voice phoneme duration based on note duration. Results show that the proposed method can synthesize a natural singing voice, whose sound quality resembles that of an actual singing voice.

3:00

1pMU6. Automatic detection of head voice in sung musical signals via machine learning classification of time-varying partial intensities. Ryan J. Cassidy and Gautham J. Mysore (Dept. of Music, Ctr. for Comput. Res. in Music and Acoust., 541 Lasuen Mall, Stanford, CA 94305)

The automatic detection of portions of a musical signal produced according to time-varying performance parameters is an important problem in musical signal processing. The present work attempts such a task: the algorithms presented seek to determine from a sung input signal which portions of the signal are sung using the head voice, also known as falsetto in the case of a male singer. In the authors' prior work [Mysore *et al.*, Asilomar Conf. Signal. Sys. Comp. (2006) (submitted)], a machine learning technique known as a support vector classifier [Boyd and Vandenberghe, 2004] was used to identify falsetto portions of a sung signal using the mel-frequency cepstral coefficients (MFCCs) of that signal (computed at a frame rate of 50 Hz). In the present work, the time-varying amplitudes of the first four harmonics, relative to the intensity of the fundamental, and as estimated by the quadratically interpolated fast Fourier transform (QIFFT) [Abe and Smith, ICASSP 2005], are used as a basis for classification. Preliminary experiments show a successful classification rate of over 95% for the QIFFT-based technique, compared to approximately 90% success with the prior MFCC-based approach. [Ryan J. Cassidy supported by the Natural Sciences and Engineering Research Council of Canada.]

3:15

1pMU7. A proposal of discrimination method between voice and music using Gaussian mixture models and similarity in a music selection. Takuma Yoshida, Masaaki Ishigame, Yoshiaki Ito, and Kazunori Kojima (Iwate Prefectural Univ., Sugo 152-52, Takizawa, Iwate, 020-0193, Japan, g231e038@edu.soft.iwate-pu.ac.jp)

We have proposed a method for automatic music boundary detection using similarity in a music selection. The method is able to capture a whole position of a consecutive music selection, although the boundary position of a music selection is likely to be roughly estimated. In this paper, we propose a new method that combines a GMM (Gaussian mixture model) discrimination method between music and voice with the previously proposed method. The GMM enables us to determine strict boundary positions. On the other hand, the GMM often misdetects boundaries that are not actual boundaries, such as changing points of music instruments, the point of modulation in a music selection, and so on. We, therefore, exclude the GMM misdiscrimination in a music selection by the previously proposed method, and also realize the precise detection of music boundaries by the GMM. We conducted various experiments using open music selections that are provided by RWC, and the results showed the proposed method could improve the performance of music boundary detection, compared with the previous method and the method using only the GMM.

3:30

1pMU8. Acoustical analysis of nonlinguistic sounds. Yell Inverso, Corine Bickley, and Charles Limb (Gadlaudet Univ., 800 Florida Ave. NE, Washington, DC 20011, danielle.inverso@gallaudet.edu)

The perception of speech is an undisputed important goal for cochlear implantation; however, the reception of nonlinguistic sounds (NLS) is also important. Nonlinguistic sounds are important for one's safety and they are considered to have importance to a person's sense of connection to and welfare in one's environment. NLS are different from speech, and the perception and acoustic characteristics of NLS have not been studied adequately to allow clinicians to fit CIs for optimal recognition of both speech and NLS. The specific categories of nonlinguistic sounds to be evaluated in this study are (1) human vocal/nonverbal, such as a baby crying or a person coughing; (2) mechanical/alerting, such as a telephone or an alarm clock buzzing; (3) nature/inanimate, such as weather sounds; (4) animal/insect, such as a dog barking; and (5) musical instruments such as the strum of a guitar. In this ongoing study, 50 listeners (half adults with normal hearing and half adult post-ling deafened CI users) are being evaluated with respect to their ability to identify the sources of a variety of common, everyday NLS. In this poster, an acoustic analysis of a representative set of the stimuli will be presented.

3:45

1pMU9. A psycho-acoustical analysis of vocal effort by opera singers. Konrad Skirlis, Densil Cabrera, and Anna Connolly (P.O. Box A2106, Sydney South 1235 NSW, Australia, audiodarnok@yahoo.com)

A singer's vocal output will be affected by a number of factors such as the size of the auditorium used for the performance. In this paper, the "large hall" and "small hall" voices of singers were explored in terms of the specific loudness pattern, which represents the distribution of loudness

in the auditory system. Recordings of seven professional opera singers were made in an anechoic room and in a small recital hall. Singers were asked to imagine they were in a small hall for one set of recordings and in a large hall for another set. Each singer sang the same song under these two "conditions." The recordings were then analyzed to determine spectral and temporal changes. Spectral analysis was used to calculate the strength of the singers formant under these conditions, and this was compared with the specific loudness patterns. Results help us to understand why the singer's formant is so important for vocal projection.

4:00

1pMU10. The effect of seating arrangement on choral sound in a nonselected mixed collegiate choral ensemble. Wei-Chun Wang (St. Johns Univ., 499, Sec. 4, Tam King Rd., Tamsui, Taipei, 25135 Taiwan, R. O. C.)

With both macroarrangement concerns and microarrangement concerns, choral directors use singer's placement as an essential technique to find compatible voices by listening to individual voices in various combinations. This study investigated the effect of seating arrangements, musical textures, and language familiarity on the choral balance and choral blend in an inexperienced collegiate choral ensemble. After ten rehearsals directed by the investigator, 48 nonselected choristers of a curricular SATB choral ensemble sang four musical excerpts, with the combination of two musical textures (homophonic and polyphonic compositions) and two types of languages (native and foreign language), a cappella in three formations (a sectional block, a mixed quartet, and a hybrid formation) in a chapel. Five experienced judges evaluated the screened live performance by rating the choral balance and choral blend on seven-point scales. The process was repeated. For blend only, sectional and hybrid formations were favored for polyphonic excerpts. The excerpts sung in native language were rated higher than the foreign excerpts, in particular for blend.

Physical Acoustics and Engineering Acoustics: Infrasound

Milton A. Garces, Chair

Univ. of Hawaii, Infrasound Lab., 73-4460 Queen Kaahumanu Hwy., Kailua-Kona, HI 96740-2638

Chair's Introduction—1:00

Invited Papers

1:05

1pPAa1. Contribution of continuous infrasound monitoring to scientific research. Alexis Le Pichon, Karl Antier (CEA/DASE BP12, Bruyeres-le-Chatel, France), Lars Ceranna (Federal Inst. of Geosciences and Natural Resources, 30655 Hannover, Germany), Doug Drob (NRL, Washington, DC 20375), and Michel Lardy (IRD Ctr., 98848 Noumea Cedex, New-Caledonia)

Continuous automatic processing of the data is being performed at the French NDC from a number of IMS-type infrasound stations in order to detect and characterize coherent infrasonic waves recorded on the arrays. A large number of detections are associated with natural phenomena. Infrasonic waves generated by strong earthquakes occurring within region of high mountains are of great interest. Such events allow the evaluation of the relative contributions of the different source mechanisms involved in large earthquakes, and offer an opportunity to improve our understanding of the amplification of ground displacement caused by the topography. Microbaroms as well as mountain waves are quasipermanent sources of infrasonic waves detected on a global scale. Their monitoring reveals clear periodic trends in the detected bearings and signal amplitude, providing further confirmation that long-range propagation strongly depends on the atmospheric conditions. Signals from volcanic activities also offer a unique opportunity for atmospheric studies. At large propagation ranges from the volcanoes, infrasound measurements can be used as input of inversion procedures to evaluate more precisely the vertical structure of the wind in a range of altitude unaccessible to ground-based or satellite measurements.

1pPAa2. Infrasound associated with stratospheric ash injection, window-shattering explosions, and incandescent avalanches at Tungurahua Volcano, Ecuador. Milton Garces, David Fee, Sara McNamara (Infrasound Lab., Univ. of Hawaii, Manoa, 73-4460 Queen Kaahumanu Hwy., #119, Kailua-Kona, HI 96740-2638, Milton@isla.hawaii.edu), David McCormack (Geological Survey of Canada, Ottawa, ON K1A 0Y3, Canada), and Henry E. Bass (NCPA, University, MS 39688)

On July 14, 2006, Tungurahua volcano in Ecuador initiated a dramatic eruptive sequence that caused the evacuation of villagers, the destruction of crops, and the reports of ash clouds above 15 km. Acoustic signals have been recorded by the prototype infrasound acoustic-surveillance system (ASHE) currently operating in Ecuador. The infrasonic signals recorded by the ASHE included explosions, pyroclastic flows, and a sustained low frequency vibration of the ground. We present the features of the different types of eruption signals, and discuss the physics of eruptive processes and volcanic ash injection into the atmosphere. We also compare the July 2006 ash-rich eruption sequence with the May 2006 eruptive episode, which injected very little ash into the atmosphere. Results are of significance for the future operational use of acoustic monitoring of volcanic activity for aviation safety.

1:45

1pPAa3. Infrasound from tornadoes and other severe storms. John M. Noble (U.S. Army Res. Lab., 2800 Powder Mill Rd., Attn: AMSRD-ARL-CI-ES, Adelphi, MD 20783, jnoble@arl.army.mil) and Alfred J. Bedard, Jr. (NOAA/Earth System Res. Lab./PSD/CIRES, Boulder, CO 80305)

Infrasound arrays have been used for a long time to detect and monitor man-made and natural acoustic sources below 20 Hz. Much of the earlier work on infrasound from severe weather was below 0.1 Hz and was related to severe weather penetrating the tropopause. It was noticed when violent thunderstorms passed near an array that a coherent signal would be detected coming from the same direction as the storm. By correlating the measurements with visual, satellite, and Doppler radar observations, the characteristics of the storm could be studied to determine what type of storm would cause the production of infrasound. Most of the storms that would produce an infrasonic signal were the strong supercell-type storms that produced intense gust fronts and tornadoes. More recent measurements at frequencies above 0.1 Hz have been associated with tornadoes and tornadic storms. Following on these observations, NOAA established an infrasonic network to evaluate the use of infrasound for tornado detection and warning. This network has operated since 2003 and is still being optimized and evaluated. This talk will cover the studies that have been conducted and numerical models developed to try and explain this phenomenon.

2:05

1pPAa4. High-altitude infrasound propagation experiment. Bill Andre (U.S. Army Space and Missile Defense Command, P.O. Box 1500, Huntsville, AL 35807, andreb@smdc.army.mil) and Henry E. Bass (Natl. Ctr. for Physical Acoust., University, MS 38677)

Experimental verification of propagation predictions and sensor performance for infrasound frequencies that propagate long distance (greater than 100 km) are difficult to perform due to the rarity of controlled sources. If the source is elevated, the lower atmospheric pressure allows an explosion of a given charge weight to expand further during the supersonic phase, resulting in a lower fundamental frequency. A 50-lb charge exploded at 40 km yields a fundamental frequency similar to a 500-ton explosion at ground level. During the fall of 2005 and the winter and summer of 2006, experiments were conducted at White Sands Missile Range, NM, where an Orion rocket lifted a 50-lb explosive charge to altitudes between 30 and 40 km. Launches occurred near 0200 and 0600 MST. Portable infrasound arrays to record events were deployed in New Mexico, Texas, Arizona, and California to complement permanent arrays. Infrasound recordings were supplemented with extensive meteorological measurements. Data analysis is in a preliminary stage. The High Altitude Infrasound Propagation Experiment resulted from collaboration between several U.S. Army and Navy commands, University of Mississippi, Southern Methodist University, University of Hawaii, University of California at San Diego, University of Alaska at Fairbanks, BBN Technologies, SAIC, and Los Alamos National Laboratory.

2:25

1pPAa5. Modeling the propagation of volcanic infrasound with a 3-D parabolic equation. Joseph F. Lingevitch, Geoffrey F. Edelmann, Douglas P. Drob, and Michael D. Collins (Naval Res. Lab., 4555 Overlook Ave. SW, Washington, DC 20375)

Active volcanoes are significant sources of infrasound in the 1–4-Hz frequency band and are detectable at ranges of hundreds of kilometers. The propagation is affected by the atmospheric temperature, wind, and attenuation profiles, which are range and time dependent. In this paper, a 3-D atmospheric parabolic equation method that accurately incorporates the effects of wind is applied to modeling volcanic infrasound propagation. A parabolic equation is derived using a narrow angle operator approximation in azimuth and a wide angle approximation in depth to account for wind-induced refraction that can trap or disperse sound energy, leading to large variations of propagation with wind conditions. The atmospheric specification for this model is derived from the attenuation coefficients of Sutherland and Bass [J. Acoust. Soc. Am. **115**, 1012–1032 (2004)] and the temperature/wind profiles from the Naval Research Laboratory Ground to Space model [J. Geophys. Res. **108**, 4680–4691 (2003)], which provides global atmospheric profiles from the ground to 200 km

altitude updated four times daily. Signal amplitude and direction of arrival estimates from the model are compared with measurements of volcanic infrasound at listening stations several hundred kilometers from the source. [Work supported by ONR.]

2:40

1pPAa6. Infrasonic scattering studies using time-domain parabolic equation (TDPE) and gravity wave models. David E. Norris (BBN Technologies, 1300 N. 17th St, Ste. 400, Arlington, VA 22209)

The time-domain parabolic equation (TDPE) model is useful in predicting infrasonic waveforms, as it can account for diffraction and scattering mechanisms. In this study, a split-step Fourier (SSF) implementation of the TDPE is used to study infrasonic propagation. Scattering is modeled using a spectral gravity wave model, and multiple gravity wave realizations are used to quantify the uncertainty in waveform properties introduced by scattering from the gravity wave inhomogeneities. TDPE predictions are compared to specific infrasonic events and conclusions regarding the dominant propagation mechanisms are presented.

2:55

1pPAa7. The deep sound of one wave plunging. Milton Garces, David Fee, Sara McNamara (Infrasound Lab., Univ. of Hawaii, Manoa, 73-4460 Queen Kaahumanu Hwy., #119, Kailua-Kona, HI 96740-2638), Jerome Aucan, and Mark Merrifield (Univ. of Hawaii, Manoa, Honolulu, HI 96822)

The ability to provide infrasound estimates of breaking ocean wave height and period in shallow reefs, steep rocky coastlines, and sand beaches has been demonstrated in previous work. Yet defining the source process and isolating the source pressure function remained elusive because of ambiguity introduced by complex coastlines and multiple breaker zones. Due to the steep bathymetry and the its proximity to land, the Temae reef in the northeast coast of Moorea island, French Polynesia, provided a well constrained experimental environment where individual breaking waves could be identified and recorded. Synchronous wave height, infrasonic, seismic, and visual recordings of individual waves breaking against the shallow reef ledge were made and correlated. We characterize a possible source mechanism for surf infrasound and demonstrate the capability to acoustically track alongshore traveling (peeling) plunging waves. We also introduce preliminary results on remote infrasonic monitoring of the surf zone in the North Shore of Hawaii during the 2006-07 Winter high surf season.

3:10–3:25 Break

3:25

1pPAa8. Low-frequency acoustic propagation in a shallow water internal wave field. Geoffrey F. Edelmann, Joseph F. Lingevitch, and David C. Calvo (U.S. Naval Res. Lab., 4555 Overlook Ave. SW, Code 7145, Washington, DC 20375)

A fully 3-D parabolic equation is used to simulate low-frequency acoustic propagation through a nonlinear internal wave field. Previous simulations have shown that acoustic propagation is dependent on the relative orientation between the direction of the internal wave train and the acoustic signal. When the acoustic and internal waves are parallel, a simple 2-D vertical refraction is the dominant interaction. As the two waves become perpendicular, horizontal refraction of the acoustic signal due to azimuthal coupling has been suggested [Frank *et al.*, J. Acoust. Soc. Am. **118**, 723–734 (2005)]. Comparisons of 3-D acoustic propagation through an internal wave field with and without azimuthal coupling will be made. The parabolic equation used makes a narrow angle operator approximation in azimuth and a wide angle approximation in depth. We will extend the previous work such that coupling in both the horizontal and vertical direction will be calculated simultaneously. [This work is supported by the Office of Naval Research.]

3:40

1pPAa9. Infrasonic wave observations at Fairbanks, AK, of Augustine volcano eruptions during January 2006. Charles Wilson, Steve McNutt, John Olson, and Guy Tytgat (Geophysical Inst., Univ. of Alaska, Fairbanks, AK)

The recent Augustine eruptions, from the 11th to the 28th of January 2006, have produced a series of ten infrasonic signals observed at the I53US array. The eruption times for the signals were provided by the Alaska Volcanic Observatory at UAF using a Chaparral microphone present on Augustine Island a few kilometers from the crater. The bearing and distance of Augustine from I53US are respectively 207.8 deg and 675 km. The analysis of the signals is done with a least-squares detector/estimator that calculates, among other things, the horizontal trace-velocity and the azimuth of arrival of the signal. The average values of the trace-velocity and azimuth for all ten Augustine signals are 0.336 ± 0.0136 km/s and 208.7 ± 1.5 deg. respectively. The celerity for each signal was calculated using the range 675 km and the individual travel times to I53US. The average celerity for all ten eruption signals was 0.287 ± 0.018 km/s. Ray tracing studies, using wind speed and temperature profiles supplied by Dr. Doug Drob at NRL, have shown that both stratospheric and thermospheric ray paths are present in the data set.

3:55

1pPAa10. Infrasound signals detected by the observation system in Isumi, Japan. Takahiko Murayama, Motohiro Honma, Mami Nogami, Takayuki Otsu, Takafumi Amano, Yasuharu Saitoh, Nobuo Arai, and Toyomi Sakamoto (Res. Dept., Japan Weather Assoc., 3-1-1 Higashi-Ikebukuro, Toshima-ku, Tokyo 170-6055 Japan)

An infrasound observation system is installed in Isumi, Japan (35.3N, 140.3E) as the component of the International Monitoring System for CTBT. The observation system was deployed on November 2004. It comprises a six-element array. Five elements of the array are deployed as a pentagon with sides approximately 1.2 km long. The sixth element is located within the pentagon-shaped array. Until now, some interesting infrasound signals were observed. One of them was the infrasound wave produced by the large earthquake that occurred off the Pacific coast of North-East Japan on 16 August 2005. The infrasound wave-train, which had a spindle-shaped envelope, was detected following the arrival of the seismic wave. The arrival direction of the infrasound wave, which had maximum amplitude, indicated the direction of the land area, which had maximum intensity. The time difference between the on-set time of that infrasound wave and the origin-time of the earthquake coincided with the travel time for propagation in the atmosphere between the area that had maximum intensity and the observation site. Therefore, it was estimated that the observed infrasound waves were produced by shaking ground. In this paper, some remarkable infrasound signals including the above are discussed.

4:10

1pPAa11. Infrasound wind noise contributions. Richard Raspet, Jiao Yu, and Jeremy Webster (Univ. of Mississippi, University, MS 38677)

In a recent study [J. Acoust. Soc. Am. **119**(2), 834–843 (2006)] predictions of various noise contributions were compared to measured wind noise from various devices and windscreens. The fluctuating stagnation pressure, the turbulence-turbulence interaction pressure, and the self-noise contributions in the inertial range were calculated from the measured wind velocity spectrum and compared to measurements. In that study the bare microphone agreed well with the predicted stagnation pressure spectrum, and a heavily windscreened microphone agreed well with the predicted turbulence-turbulence interaction spectrum. In this paper we extend the analysis and the measurements into the source region of the spectra—well into the infrasound range. In addition we predict the spectral contribution due to the turbulence-mean shear interaction. The prediction displays a steep slope in the inertial range and may dominate at low frequencies. [Research supported by the U.S. Army TACOM-ARDEC at Picatinny Arsenal, NJ.]

4:25

1pPAa12. Comparitive study of wind noise reduction devices. Jeremy Webster, Richard Raspet, and Jiao Yu (Univ. of Missississppi, University, MS 38677)

Spherical porous foam windscreens are commonly used to reduce wind noise in acoustic measurements. We have argued [J. Acoust. Soc. Am. **119**(2), 834–843 (2006)] that the wind noise measured outdoors will lie between the predicted fluctuating stagnation pressure generated by the microphone interaction with the incoming air flow for bare microphones and the turbulence-turbulence interaction pressure for a very large wind screen. The pressure level measured in a moderate size screen will lie between these two extremes. Different transducer geometries and arrangements have been used in aerodynamic and meteorological studies to measure the "fluctuating static pressure" without interference from transducer generated wind noise. In this paper we compare measurements of wind noise using bare microphones, microphones in foam windscreens, streamlined probes, the Quad Disk, and microphones mounted in flat plates. The purpose of this study is to clarify the principles involved in wind noise generation by transducer-turbulence interaction. [Research supported by the U.S. Army TACOM-ARDEC at Picatinny Arsenal, NJ.]

1pPAb1. Determination of elastic properties and interatomic force constants using inelastic neutron scattering. Robert McQueeney (Dept. of Phys. and Astron., Ames Lab., Iowa State Univ., Ames, IA 50011)

Neutron scattering is the most powerful technique for measuring vibrational excitation spectra. With single-crystal samples, the complete phonon dispersion relation can be measured. At small phonon wavelengths, the slope of the dispersion curve is related directly to the elastic constants of the material. Information from shorter wavelength phonons can be used to determine parameters for interatomic force models or compared to first-principles calculations. Model parameters can then be used to calculate phonon densities-of-states and consequently connect to the thermodynamics. Polycrystalline samples yield less information, but the data is directly related to the phonon density-of-states for Bravais lattices. Measurements on polycrystalline samples have the advantage of being fast and are more useful for parametric studies of the lattice dynamics (with temperature, for example). These ideas will be used to discuss several interesting systems, most notably Pu metal and Fe-Ga magnetostrictive alloys. [This work is supported by the U.S. Department of Energy.]

1pPAb2. Elastic constants, Blackman diagrams, and new lanthanide-actinide insights. Hassel Ledbetter and Albert Migliori (Los Alamos Natl. Lab., Los Alamos, NM 87545, hledbet@lanl.gov)

Using monocrystal elastic constants and Blackman diagrams, one can infer material interconnections, physical-property trends, and knowledge about interatomic bonding. After reviewing briefly the fcc-metal case, focus shifts to Ce, Pu, Th, with known monocrystal fcc elastic constants, the C_{ij}. For fcc U and a few other cases, one can deduce the C_{ij}. From these results about the actinides, there follow several conclusions: (1) elastic anisotropy ranges widely; (2) Poisson ratios are low; (3) interatomic bonding varies widely; (4) all show unusual *negative* Cauchy pressures; (5) a strong covalent-bonding component occurs, perhaps related to localized f-electrons; (6) δ-Pu behaves most oddly; (7) δ-Pu shares some bonding features with fcc alkali metals. 1pPAb3. Elastic response of exotic ferromagnets? Veerle Keppens, Yanbing Luan, Sriparna Bhattacharya, Ivan Sergienko (The Univ. of Tennessee, Knoxville TN 37934), David Mandrus, and Brian Sales (Oak Ridge Natl. Lab., Oak Ridge, TN 37831)

Resonant ultrasound spectroscopy (RUS) measurements have been carried out as a function of temperature (2–300 K) and magnetic field (0–2 T) for a series of exotic ferromagnetic materials, including $Eu_8Ga_{16}Ge_{30}$ ($T_c \simeq 32$ K), $EuFe_4Sb_{12}$ ($T_c \simeq 82$ K), Au_4V ($T_c \simeq 46$ K), and $Yb_{14}MnSb_{11}$ ($T_c \simeq 53$ K). The different materials show remarkable differences in their elastic response near the Curie temperature, revealing a sudden softening at T_c in $EuFe_4Sb_{12}$, and a stiffening of the elastic moduli at T_c in $Yb_{14}MnSb_{11}$. Ongoing attempts to theoretically model the data using Landau theory will be discussed. [Work was supported by the National Science Foundation under Grant No. DMR0506292. Oak Ridge National Laboratory is managed by UT-Batelle, LLC, for the U.S. Department of Energy under Contract No. DE-AC05-00OR22725.]

1pPAb4. Measuring elastic constants of novel materials and thin films using small sample resonant ultrasound spectroscopy. J. D. Maynard (The Penn State Univ., University Park, PA 16802)

One of the most important undertakings for materials is the measurement of the elastic constants. As derivatives of the free energy with respect to atomic displacements, the elastic constants are closely connected to the thermodynamic properties of the material, including the specific heat, the Debye temperature, the Gruneisen parameter, etc. The elastic constants are a sensitive probe of the lattice environment in which all solid state phenomena occur, particularly in the vicinity of a phase transition. Novel materials to which RUS might be applied are often available only in small samples, and for these cases we have developed a small sample RUS

3033   J. Acoust. Soc. Am., Vol. 120, No. 5, Pt. 2, November 2006

Fourth Joint Meeting: ASA and ASJ   **3033**

apparatus that can measure bulk samples only a few hundred microns in size and thin films a few hundred nanometers in thickness. Thin films are particularly interesting because substrate induced strains in the lattice may produce dramatic changes in the elastic and thermodynamic properties. In this talk, small sample RUS measurements on the new superconductor magnesium diboride and colossal magnetoresistance materials, in bulk and thin film forms, will be discussed.

1pPAb5. Ultrasonic studies of hydrogen absorbing materials: Quasicrystals, nanocrystals, and intermetallic compounds. Robert G. Leisure (Dept. of Phys., Colorado State Univ., Fort Collins, CO 80523-1875)

Resonant ultrasound spectroscopy was used to study several materials—nanocrystalline palladium, quasicrystalline Ti-Zr-Ni, and a number of intermetallic compounds—that have the ability to absorb considerable amount of hydrogen, and thus are of potential use for hydrogen storage. Elastic energies are relevant to the thermodynamics of such systems, which are often described by a lattice gas model. Elastic interactions between dissolved H atoms lead to a critical temperature and precipitation of a hydride phase below the critical temperature. The energetics of hydride precipitation depend on the elastic constants. Thus, it is important that the elastic properties of such systems be measured. In addition, these materials are of interest for several other reasons. The elastic constants and internal friction for the hydrogen-free materials were measured over a temperature range of 3 to 300 K, and in a few cases to higher temperatures. These results will be discussed and interpreted. [This work was supported by the U.S. National Science Foundation under Grant DMR-0070808.]

1pPAb6. Osmium's full elastic tensor between 5 K and 300 K. Cristian Pantea (Los Alamos Natl. Lab., Los Alamos, NM 87545)

Reported values of the zero-pressure bulk modulus of Os are both above and below that of diamond, creating a controversy as to which is the least compressible material. This work is another such study, but using two measurement techniques on two types of Os specimens. The full elastic tensor for osmium was measured using resonant ultrasound spectroscopy between 5 K and 300 K on polycrystalline and monocrystalline specimens and confirmed at ambient temperature using a pulse-echo-overlap measurement. It was found that osmium is more compressible than diamond (bulk modulus: 405 GPa for Os, versus 442 GPa for diamond). The independent elastic moduli of osmium are in relatively good agreement with the theory of Fast [Phys. Rev. B **51**, 17431 (1995)]. However, the Debye temperature determined from low-temperature monocrystal elastic-moduli measurements extrapolated to 0 K disagrees with most previous reports and is in good agreement with one specific-heat measurement.

1pPAb7. Excitation of elastic and capillary waves by electric field tweezers and its application to material characterization. Maiko Hosoda, Hideo Ogawa, and Hiroyasu Nomura (Tokyo Denki Univ., Ishizaka, Hatoyama, Saitama 350-0394, Japan)

We recently developed the electric tweezers system to excite the surface vibration for the measurement of local mechanical properties of soft condensed materials. A periodical electric field applied onto the material surface by a conductive thin needle induces the Maxwell stress and picks up the sample surface. We can determine the shear elasticity of the sample from the absolute displacement of the deformation, and the viscosity from its dynamic response, respectively. The numerical simulation predicts that the electric voltage of 100 V applied to the gap of 100 Em between the needle edge and surface induces the deformation of several nm, which was experimentally confirmed by the optical lever technique. The remarkable feature of the system is that the characteristic scale of the surface deformation, such as the depth and width of the medium motion, is dominated by the gap and, therefore, we can uniquely determine the complex mechanical impedance and the surface energy by observing the dynamic surface response in a wide range of the gap and oscillation frequency. The system was applied to the gelatin gel at various concentrations and we found the results obtained are well explained by the previously known complex elasticity of the material.

1pPAb8. Direct observation of phonon relaxation by optical beating light scattering spectroscopy. Keiji Sakai (Inst. of Industrial Sci., Univ. of Tokyo, 4-6-1 Komaba, Meguro-Ku, Tokyo 153-8505, Japan)

A novel dynamic light scattering system to observe elastic relaxation phenomena with hyper frequency resolution was developed. The principle of the measurement is based on the theory, which describes the dynamic structure factor of fluid under the condition of the frequency-dependent compressibility. The dynamic structure factor, which is usually composed of the Brillouin and Rayleigh triplet, is modulated and shows an additional central component that directly reflects the whole aspect of the relaxation. In the experiment, the output from a frequency-doubled cw-YAG laser was incident into the liquid sample and the power spectrum of the light scattered into the backward direction was analyzed by the optical beating spectroscopy technique. The sample is liquid acetic acid that is known to show a strong ultrasonic relaxation around 1 MHz due to the molecular association process. We could find, in the observed spectrum, the central component introduced by the phenomenon, whose relaxation frequency and strength can be obtained from the width and the intensity of the observed central peak, respectively. The results show very good agreement with those previously obtained by the conventional ultrasonic spectroscopy technique. The recent experiment of the thermal phonon resonance will also be shown.

1pPAb9. High resolution Brillouin scattering in solid and gases. Takeshi Yogi and Keiji Sakai (Dept. of Appl. Phys., Univ. of Tokyo, 4-6-1 Komaba Meguro-ku, Tokyo, 153-8505, Japan, yogitake@iis.u-tokyo.ac.jp)

The experimental system of our optical beating Brillouin spectroscopy was improved, which can observe the phonon propagation with the resolution of 1 kHz. The increased sensitivity and frequency resolution were demonstrated in the observation of phonon spectrum in solids of fused silica and also in gases, nitrogen, and freon $CHClF_2$: for their weak light-scattering ability, these substances are very tough specimens for Brillouin scattering studies, and the classical spectrometer of Fabry-Pérot etalon has been so far used for the frequency analysis. The phonon peaks were observed with the present light beating system in nitrogen and freon near 300 K over the wave-number range from $2\pi = 6.20 \times 10^3$ to 3.09×10^5 m^{-1}, the pressure range from 14.8 to 177 kPa. The observed spectra were well fitted with the Lorentzian curve representing the phonon lifetime, and the phase velocity. The phase velocity of phonon in fused silica agrees well

with that obtained by ultrasonic measurement, while the phonon dispersions obtained for gases show the relaxational behavior due to the coupling to the rotational and vibrational motion of molecules.

1pPAb10. Hypersonic phononic crystals. Taras Gorishnyy, Chaitanya K. Ullal, Martin Maldovan, Edwin L. Thomas (Dept. of Mater. Sci. and Eng., MIT, Cambridge, MA 02139), and Ji-Hyun Jang (MIT, Cambridge, MA 02139)

Phononic crystals are structures with spatially periodic variations in density and sound velocities. The most fascinating feature of phononic crystals is the existence of stop bands or band gaps in their dispersion relation, where no phonons are allowed to propagate. As a result, phononic crystals have great promise for achieving precise control over propagation of sound and other mechanical waves. In this talk our recent investigation of 2-D and 3-D hypersonic phononic crystals with band gaps in GHz frequency range will be presented and their potential applications as acoustic mirrors, lenses, waveguides, etc. will be discussed. High-quality single-crystalline structures were fabricated using interference lithography. Their phonon dispersion relation was directly measured with Brillouin light scattering. Finite-element analysis was employed to compute theoretical dispersion relation and provide interpretation for the experimentally observed propagation modes [T. Gorishnyy *et al.*, Phys. Rev. Let. **94**, 115501 (2005); T. Gorishnyy *et al.*, Physics World **18** (12), 24–29 (2005)]. [Work supported by NSF Grants DMR-0308133 and DMR-0414974.]

1pPAb11. Acoustical properties of two-dimensional sonic crystals. Francisco Cervera, Elisabeth Schwarz, Daniel Torrent, Suitberto Cabrera, and José Sánchez-Dehesa (Wave Phenomena Group, Nanophotonics Technol. Ctr., Polytechnic Univ. of Valencia, C/ Camino de vera s/n, E-46022 Valencia, Spain)

The transmittance and reflectance spectra of two-dimensional sonic crystals made of hexagonal arrays of cylindrical bars in water is reported. The balance of sound fluxes is analyzed by studying angle-resolved spectra of transmitted and reflected sound for all directions in space. A characterization of the acoustic band structure along the two high symmetry directions in the lattice (i.e., ΓX and ΓJ directions) in a large region of frequencies will be presented. It is shown that, for example, the shape of the stop band features in different types of acoustical spectra is interlinked and must be studied jointly to understand acoustical phenomena in these materials. Moreover, the dependence of acoustical properties as a function of the number of layers is also studied. The experiments are compared with theoretical simulations based on multiple scattering theory. [Work supported by MEC of Spain.]

1pPAb12. Design of resonant ultrasound systems for use with very small samples. Ben Migliori (UCSD, 9500 Gilman Dr., San Diego, CA 92122), Albert Migliori, and Jon Betts (NHMFL-LANL, Los Alamos, NM 87545)

The design of resonant ultrasound (RUS) systems for small samples, whether used in small-bore cryostats at low temperature and high field or at room temperature, presents several unique challenges. These include alignment and containment of the sample, thermal contraction of construction materials, ease of use, and robustness in the presence of large ($¿10$ T) magnetic fields. Such problems may be resolved through the use of novel (and often easily obtained) materials as well as unique designs. At the National High magnetic Field Laboratory (NHMFL) we have addressed these problems and built a sub-4 K cryostat RUS measurement system capable of reliably measuring samples '1 mm in diameter. Examples of such a cryostat systems, designed for conditions ranging from room temperature and zero field to '4 K and ¿10 T, as well as explanations of the necessary design parameters and recommended materials are presented. Examples of RUS measurements with this system are presented.

1pPAb13. Nondiffractive propagation in sonic crystals. Victor J. Sanchez-Morcillo, Isabel Perez-Arjona, Javier Redondo, Victor Espinosa (Dept. de Fisica Aplicada, Universidad Politecnica de Valencia, Ctra. Natzaret-Oliva s/n 46730 Grao de Gandia, Spain), and Kestutis Staliunas (Universitat Politecnica de Catalunya, E-08222 Terrassa, Spain)

Sonic crystals are media with a periodic modulation of the acoustic parameters, such as the density and the bulk modulus. They have recently attracted a great interest, because of their potential applications in the control of sound propagation, used as reflectors, focusers, or waveguides. All these properties are related with the dispersion introduced by the crystal anisotropy. We report on the nondiffractive propagation of sound in two-dimensional sonic crystals. It is shown that, for given frequencies and directions of incidence, a narrow sonic beam can propagate without diffractive broadening. Such nondiffractive sonic beams exist in crystals with perfect symmetry and do not require the presence of defects, differently from other waveguiding phenomena reported previously. The cancellation of diffraction has been predicted using the plane-wave expansion method to evaluate the dispersion surfaces of the crystal and the spatial dispersion (isofrequency) curves. It occurs for frequencies and wave vectors for which dispersion curves have zero curvature, denoting a transition between focusing and defocusing regimes. By means of perturbative techniques, a simple analytical expression for the nondiffractive conditions has been obtained. The phenomenon is also demonstrated by numerical integration of the acoustic equations using FDTD techniques. [Support from Spanish MEC, Project FIS2005-07931-C03-01/03, is acknowledged.]

1pPAb14. Strobo-photoelastic visualization of Lamb-type waves with negative group velocity in a solid/fluid/solid trilayer. Ken Yamamoto (Kobayasi Inst. of Physical Res., 3-20-41 Higashi-Motomachi, Kokubunji, Tokyo, 185-0022, ken-yamamoto@kobayasi-riken.or.jp)

An elastic wave with negative group velocity transports energy in the direction opposite to the phase velocity. This phenomenon exists in certain modes of Lamb waves propagating in a solid plate, but only over a very narrow range of frequency-thickness products and Poisson's ratios of a plate material. A minimum value of the negative group velocity of a mode is dominated by the Poisson's ratio of a material. A similar phenomenon also appears in Lamb-type waves that are guided in a symmetric solid/fluid/solid trilayer. Derivation of the dispersion equation of Lamb-type waves emphasizes the existence of the negative group velocity in certain modes. The existence of negative group velocity depends not only on the modes, frequency-thickness product, and Poisson's ratio, but also on the fluid layer thickness. The magnitude of negative group velocity is controlled by changing the fluid layer thickness. Direct evidence is presented of the negative group velocity that is obtained by means of stroboscopic photoelastic visualization of pulsed Lamb-type waves propagating in a glass/water/glass trilayer. A time-sequence photoelastic image shows the wave-phase behavior and the pulse envelope propagating in the opposite direction.

1pSC1. Improving quality of small body transmitted ordinary speech with statistical voice conversion. Hidehiko Sekimoto, Tomoki Toda, Hiroshi Saruwatari, and Kiyohiro Shikano (Nara Inst. of Sci. and Technol., 8916-5, Takayama-cho, Ikoma-shi, Nara, 630-0192 Japan)

The explosive spread of cellular phones enables us to communicate with each other at any time or place. Although cellular phones are convenient, there are still some problems. For example, it is difficult to send intelligible speech under noisy conditions, which is a fatal problem especially when talking privately using small speech in crowds. To improve the quality of small speech under such situations, a new speech communication style is proposed using a nonaudible murmur (NAM) microphone [Nakajima *et al.*, Eurospeech (2003), pp. IV-2601–2604]. The NAM microphone is robust to eternal noise, although body transmission causes quality degradation. In this paper, to improve the sound quality of small body transmitted ordinary speech (SBTOS), which is small speech recorded with a NAM microphone, two conversion methods that reflect a statistical voice conversion method based on Gaussian mixture models (GMMs) [Toda *et al.* Interspeech (2005), pp. 1957–1960] are conducted. One conversion method is from SBTOS to ordinary speech (SBTPS-to-SP), and the other is from SBTOS to small speech (SBTOS-to-SSP). SBTOS-to-SSP has more consistent correspondence of voiced/unvoiced segments between input and output speech than SBTOS-to-SP. The results of objective and subjective evaluations show that SBTOS-to-SSP outperforms SBTOS-to-SP.

1pSC2. Evaluation of eigenvoice conversion based on Gaussian mixture model. Yamato Ohtani, Tomoki Toda, Hiroshi Saruwatari, and Kiyohiro Shikano (Grad. School of Information Sci., Nara Inst. of Sci. 8916-5, Takayama-cho, Ikoma-city, Nara, Japan 630-0192)

Eigenvoice conversion (EVC) has been proposed as a new framework of voice conversion (VC) based on the Gaussian mixture model (GMM) [Toda *et al.*, "Eigenvoice Conversion Based on Gaussian Mixture Model," ICSLP, Pittsburgh, Sept. 2006]. This paper evaluates the performance of EVC in conversion from one source speaker's voice to an arbitrary target speakers' voices. This framework trains canonical GMM (EV-GMM) in advance using multiple parallel data sets consisting of utterance pairs of the source and many prestored target speakers. This model is adapted to a specific target speaker by estimating a small number of free parameters using a few utterances of the target speaker. This paper compares spectral distortion between converted and target voices in EVC with conventional VC based on GMM when varying the amount of training data and the number of mixtures. Results show EVC outperforms conventional VC when using small amounts of training data. EVC can effectively train a

complex conversion model using the information of many prestored speakers. By contrast, conventional VC needs a large-sized parallel data set for training. It also shows the results of subjective evaluations of speech quality and conversion accuracy for speaker individuality.

1pSC3. Evaluating naturalness of speeches morphed by independently using the interpolation ratios of the time-frequency axes and amplitude. Toru Takahashi, Masanori Morise, and Toshio Irino (Faculty of Systems Eng., Wakayama Univ., 930, Sakaedani, Wakayama, Japan, 640-8510, tall@sys.wakayama-u.ac.jp)

In speech morphing procedure [Kawahara *et al.*, Proc. IEEE-ICASSP 2003, Vol. I, pp. 256–259], two parameters exist for controlling the degree of morphing between the source and target: the interpolation ratios of the time-frequency axes and amplitude. Conventional morphing methods use only a single path in which both ratios are identical. It has, however, been reported that perception of naturalness degrades around a morphing ratio of 0.5. It was assumed that there would be better combination of the ratios with maintaining the quality. It was surveyed that the naturalness contour is within a two-dimensional morphing space. The morphed speech sounds are synthesized in combinations of 11 axis ratios (between 0 and 1 by 0.1 step) and 11 amplitude ratios. Synthetic sounds (121 in all) were presented to subjects to judge the naturalness rate. The optimum path will be described at a presentation to be given at this conference. [This research was partly supported by the "e-Society Leading Project" of the Ministry Education, Culture, Sports, Science, and Technology.]

1pSC4. Building an English speech synthetic voice using a voice transformation model from a Japanese male voice. Akemi Iida (School of Media Sci., Tokyo Univ. of Technol., 1404-1, Katakura-cho, Hachiouji, Tokyo, 192-0982, Japan, ake@media.teu.ac.jp), Shimpei Kajima, Kiichi Yasu, Takayuki Arai (Sophia Univ., Tokyo, 102-8554, Japan), and Tsutomu Sugawara (Sophia Univ., Tokyo, 102-8554, Japan)

This work reports development of an English speech synthetic voice using a voice transformation model for a Japanese amyotrophic lateral sclerosis patient as part of a project of developing a bilingual communication aid for this patient. The patient, who had a tracheotomy 3 years ago and had difficulty in speaking, wishes to speak in his own voice in his native language and in English. A Japanese speech synthesis system was developed using ATR CHATR 6 years ago and the authors have worked in developing a diphone-based synthesis using FESTIVAL speech synthesis system and FESTVOX by having the patient read the diphone list. However,

3036   J. Acoust. Soc. Am., Vol. 120, No. 5, Pt. 2, November 2006

Fourth Joint Meeting: ASA and ASJ   **3036**

it was not an easy task for the patient to phonate and, moreover, to pronounce words in a foreign language. We therefore used a voice transformation model in FESTIVAL to develop the patient's English speech synthetic voice which enables text-to-speech synthesis. We trained using 30 sentences read by the patient and those synthesized with an existing FESTIVAL diphone voice created from a recording of a native English speaker. An evaluation including a listening experiment was conducted and the result of this voice conversion showed that the synthesized voice successfully reflected the voice quality of the patient.

1pSC5. An MRI-based time-domain speech synthesis system. Tatsuya Kitamura, Hironori Takemoto, Parham Mokhtari (NICT/ATR Cognit. Information Sci. Labs., 2-2-2 Hikaridai, Seikacho, Sorakugun, Kyoto, 619-0288, Japan), and Toshio Hirai (Arcadia, Inc., Minoushi, Osaka, 562-0003, Japan)

A speech synthesis system was developed based on Maedas method [S. Maeda, Speech Commun. **1**, 199–229 (1982)], which simulates acoustic wave propagation in the vocal tract in the time domain. This system has a GUI interface that allows fine control of synthesis parameters and timing. In addition, the piriform fossae were included to the vocal tract model, resulting in antiresonances in speech spectra at the frequency region from 4 to 5 kHz. The system can produce all the Japanese phonemes using vocal tract area-functions (VTAFs) extracted from 3-D cine-MRI obtained during production of VCV or CVCV sequences for a male speaker. The system can be used to synthesize Japanese sentences with high naturalness and intelligibility by concatenating segmental units and controlling the glottal source using the GUI interface. Since a time-varying VTAF is obtained by interpolating between VTAFs, the dataset size of the system is significantly smaller than that of corpus-based speech synthesizers. The speaker-specific VTAFs and inclusion of the piriform fossae permit us to reproduce speaker-specific spectral shapes, not only the lower formants but also higher frequency regions that contribute to the perception of speaker individualities. [Work supported by NICT, SCOPE-R, and Grant-in-And for Scientific Research of Japan.]

1pSC6. Database size and naturalness in concatenative speech synthesis. H. Timothy Bunnell, James T. Mantell, and James B. Polikoff (Speech Res. Lab., A. I. duPont Hospital for Children, 1600 Rockland Rd., Wilmington, DE 19803)

Unit concatenation TTS systems seek to maximize perceived naturalness by minimizing the amount of signal processing applied to the recorded speech on which they are based. To generate distinct suprasegmentals for a given segmental sequence (e.g., to convey variation in focus or emotion), it is necessary to record and store multiple instances of the same segments that vary in fundamental frequency and voice quality. At the expense of naturalness, concatenative systems can store a minimal segmental inventory and synthesize suprasegmental factors by manipulating $f0$ and voice quality via signal processing. Classic diphone synthesis (where only a single instance of each diphone sequence is stored) represents the limiting case of this strategy. The present study explores aspects of the trade-off between perceived naturalness and segmental inventory size using the ModelTalker TTS system. Twenty-five speakers each recorded about 1650 utterances. From these, databases were constructed that limited the maximum number of alternate diphones usable for synthesis in five conditions to 1, 5, 10, 20, and 40. Sentences were synthesized from these databases using either full or no $f0$ control. Results of listening tests wherein subjects rate the naturalness of each sentence will be presented. [Work supported by NIDCD.]

1pSC7. Optimization of target cost weights in concatenative speech synthesis with very short segments of 5-ms duration. Toshio Hirai (Arcadia, Inc., 3-1-15 Nishishoji, Mino, Osaka 5620003, Japan, thirai@arcadia.co.jp)

If a concatenative speech synthesis system uses more short speech segments, it increases the potential to generate natural speech because the concatenation variation becomes greater. Recently, a synthesis approach was proposed in which very short (5 ms) segments are used [T. Hirai and S. Tenpaku, 5th ISCA Speech Synthesis Workshop, pp. 37–42 (2004), http://www.ssw5.org/]. In that approach, the target cost (how close a database segment is to desired segment) was defined as the simple average of the root mean squares (rms's) of the difference between the features of the database segment and the desired segment for simplicity. Therefore, it has been expected to optimize the weight of each rms. A Japanese speech database was used to optimize the weights and to evaluate its effects. For corpus construction, 150 utterances were selected from the database. Ten other utterances were selected randomly for generation of feature time series as natural targets for synthesis. Half of them were used for optimization using many weight combinations in synthesis to determine the optimal weight set that shows the minimum concatenation distortion. Distortion for the other half of the utterance synthesis with optimized weights was reduced 34.4% compared to the former approach.

1pSC8. Improving Japanese syllable unit selection using search space with small acoustical features variance. Takaaki Moriyama and Seiichi Tenpaku (Arcadia, Inc., 3-1-15, Nishishoji, Mino, Osaka, 5620003 Japan, taka@arcadia.co.jp)

Usually in concatenative text-to-speech systems, suitable units are selected according to acoustical features. However, a method to reduce calculation costs has been proposed, which is using syllable notations and positions along with the mora length [Murakami *et al.*, Trans. IEICE **J85-D-II**(7), 1157–1165 (2002)]. An enlargement of the corpus to synthesize longer phrases lowers the quality of synthesized speech because of increased feature variance within syllable units with identical notation. Methods to produce detailed groups in which the feature's variance is smaller than syllable units, and to synthesize speech using these groups, are proposed. To produce the groups, a mel-cepstrum distance is used as a measure for evaluation. In this method, the quality of synthesized speech that is given an ideal group sequence might improve, as the distance between units is close within the same group. As a first step to evaluate the proposed method, five groups were generated from a Japanese corpus; then, speech that was synthesized to replace one unit in natural speech to others in the same groups was examined. Results of this listening experiment indicated that an average of the naturalness for these speech types was greater than 80%.

1pSC9. Toward hidden Markov model-based spontaneous speech synthesis. Tatsuya Akagawa, Koji Iwano, and Sadaoki Furui (Dept. of Comput. Sci., Tokyo Inst. of Technolology, 2-12-1-W8-77 Ookayama, Meguro-ku, Tokyo, 152-8552 Japan, akagawa@furui.cs.titech.ac.jp)

This paper investigates several issues of spontaneous speech synthesis. Although state-of-the-art synthesis systems can achieve highly intelligible speech, their naturalness is still low. Therefore, much work must still be done to achieve the goal of synthesizing natural, spontaneous speech. To model spontaneous speech using a limited amount of data, we used an HMM-based speech synthesizer based on three features: cepstral features modeled by HMMs, and duration and fundamental frequency features modeled using Quantification Theory Type I. The models were trained with approximately 17 min of spontaneous lecture speech, from a single speaker, which was extracted from the Corpus of Spontaneous Japanese (CSJ). For comparison, utterances by the same speaker, reading a transcription of the same lecture, were used to train analogous models for read speech. Spontaneity of the synthesized speech was evaluated by subjective pair comparison tests. Results obtained from 18 subjects showed that the preference score for the synthesized spontaneous speech was significantly

1p TUE. PM

higher than that for the synthesized read speech. This implies that HMM-based speech synthesis using actual spontaneous utterances for model training is effective at producing natural speech. Additional subjective evaluation tests were also conducted to analyze the effects of individual features on the impression of spontaneity.

1pSC10. Clustering strategies for hidden Markov model-based polyglot synthesis. Javier Latorre, Koji Iwano, and Sadaoki Furui (Tokyo Inst. of Technol., Ookayama 2-12-1, Meguro-ku, Tokyo, 152-8552, Japan, latorre@furui.cs.titech.ac.jp)

A speaker-adaptable polyglot synthesizer is a system that can synthesize multiple languages with different voices. In our approach, we mix data from multiple speakers in different languages to create an HMM-based multilingual average voice. This average voice is then adapted to a target speaker with a small amount of speech data from that speaker. Using this adapted voice our system is able to synthesize any of the languages for which it was trained, with a voice that mimics that of the target speaker. The main technical difficulty of this approach is how to cluster the acoustic models to create a voice that sounds equal for all the languages. In this paper we analyze different possible strategies for clustering the HMMs and compared them on a perceptual test. The results showed that questions that refer only to the phonetic features and ignore the original language of the sounds produced voices with more foreign accent but that sound clearly more consistent across languages. Surprisingly, this foreign accent affected neither the intelligibility nor the naturalness of the synthetic speech. Therefore for polyglot speech synthesis the overall better performance was obtained by clustering strategies based only on the phonetic features of the sounds.

1pSC11. Concept-to-speech conversion for reply speech generation in a spoken dialogue system for road guidance and its prosodic control. Yuji Yagi, Seiya Takada, Keikichi Hirose, and Nobuaki Minematsu (School of Eng., Univ. of Tokyo, Bldg. No. 2, 7-3-1, Hongo, Bunkyo-ku, Tokyo, Japan, yagi@gavo.t.u-tokyo.ac.jp)

Because of advancements of speech and language processing, a number of spoken dialogue systems have been constructed. However, because most of them adopt existing text-to-speech synthesizers to generate output speech, it is rather difficult to reflect all the linguistic information that is obtained during the reply sentence generation. To resolve this situation, a framework must correctly reflect higher-level linguistic information, such as syntactic structure and discourse information, on the prosody of output speech: concept-to-speech conversion, where reply sentences are generated from information (to be transmitted) and converted into speech in a unified process. A spoken dialogue system for road guidance was constructed, and concept-to-speech conversion was realized in the system. The linguistic information of the generated sentence is handled in tag LISP form to retain the syntactic structures throughout the process. Moreover, a new method of sentence generation from concept was realized with this system: it handles a concept in phrase units and aggregates them to form a sentence. It is tested whether the linguistic information could be reflected properly on the prosody of output speech. Results of listening experiments verified the effectiveness of our proposed method.

1pSC12. Vector-based language generation for associatively evoking environmental images. Kiyoaki Aikawa and Akemi Iida (School of Media Sci., Tokyo Univ. of Technol., 1404-1 Katakuracho, Hachioji, Tokyo 192-0982, Japan)

A novel language generation method was proposed for spoken dialogue systems. The method selected verbal expressions for sensory inputs using a vector-based method. A weather-reporter system was implemented with seven input categories of weather parameters including temperature, humidity, wind velocity, and cloud cover. The system selected the most appropriate short phrase for representing the measured weather parameters

to let the listener associatively imagine the reporter's weather condition descriptions. The system included 149 short phrases for weather expressions, each represented by a 62-element vector called the template vector. Given the 62-element input vector for a set of weather parameters, one or two phrases were selected based on the similarity measured between the input and template vectors. The system was able to produce an expression by combining a couple of phrases. A dissimilarity measuring algorithm was proposed to assign the conjunction "and" or adversative "but" automatically to conjoin two phrases. A bilingual capability was also added for enabling the system to output English and Japanese phrases. For English outputs, sentence-initial phrases were added to the selected phrases depending on the similarity value, while sentence-finals were added for Japanese outputs. Evaluation experiments showed that automatic conjunction assignment can function with high reliability.

1pSC13. Development project for screen reader interface dynamically hastens speech while giving emphasized information to the tactile sense. Tohru Ifukube (Res. Ctr. for Adv. Sci. and Technol., The Univ. of Tokyo, Tokyo, 153-8904, Japan) and Shinta Kimura (Animo Ltd., Naka-ku, Yokohama-shi, 231-0015, Japan)

In present screen readers for blind people, users are still required to continue listening to synthesized voices and also they might easily miss important points of a document. A development project of a new screen reader interface has been promoted in cooperation with Japan's Ministry (METI). The interface named TAJODA can dynamically control the speech rate while giving rich texts to the tactile sense. The speech rate can be changed according to word units by clicking a button of the interface using a thumb. From evaluation tests using sightless people, the maximum speech rate was determined at around 2000 morae/minute. Seven vibro-tactile patterns were selected for presenting rich texts onto an index finger using a tactile matrix display (2×8). Both speech and tactile information are synchronized automatically through a USB interface. It was also ascertained that users can read some documents two to three times faster using the TAJODA interface [Asakwa *et al.*, IEICE Trans. **E87**-D(6) (2004)].

1pSC14. Decision-tree-based $F0$ quantization for hidden Markov model-based speech coding at 100 bit/s. Yoshihiro Itogawa, Heiga Zen, Yoshihiko Nankaku, Akinobu Li, and Keiichi Tokuda (Dept. of Comput. Sci., Nagoya Inst. of Technol., Gokiso-cho, Showa-ku, Nagoya, 466-8555 Japan)

A decision-tree-based quantization scheme for a very low bit rate speech coder based on HMMs is described. The encoder carries out HMM-based phoneme recognition and then recognized phonemes, state durations, and $F0$ sequence are quantized, Huffman coded, and transmitted. In the decoder, sequences of mel-cepstral coefficient vectors and $F0$'s are generated from the concatenated HMM-using the HMM-based speech synthesis technique. Finally, a speech waveform is synthesized by the MLSA filter using the generated mel-cepstral coefficient and $F0$ sequences. In the previous system, we train an MSD-VQ codebook for each phoneme for $F0$ quantization. Although this scheme can quantize $F0$ sequences efficiently, to achieve a better speech quality, larger codebook sizes are required. It leads to an increase in the bit rate of the system. To avoid this problem, we cluster $F0$ sequences using phonetic decision trees and then train a codebook for each leaf node. In the encoding and decoding, codebooks to be used can be determined by tracing the decision tree. It allows us to use smaller codebook sizes since the number of codebooks can be augmented without increase in bit rate. A subjective listening test result shows that the proposed scheme improves the quality of coded speech.

1pSC15. Speech enhancement during analysis-synthesis by harmonic plus noise model. Parveen K. Lehana and Prem C. Pandey (EE Dept., Indian Inst. of Technol. Bombay, Powai Mumbai 400076, India, pcpandey@ee.iitb.ac.in)

Speech analysis-synthesis in codecs and voice transformation often introduces distortion in the resynthesized output, particularly if the input is corrupted by noise. The harmonic plus noise model (HNM), particularly suited for voice transformation, divides speech signal into harmonic and noise parts. The harmonic part is synthesized by taking the summation of pitch harmonics up to a frequency called maximum voiced frequency, and the spectrum above this frequency is attributed to the noise part. Removal of nonharmonic components in harmonic part may result in noise rejection, while the errors in the estimation of harmonics may lead to distortion. Investigations were conducted to assess the speech enhancement obtainable through HNM on broadband noise corrupted speech signal. Listening tests showed that both the input and the resynthesized signals were perceived as distortion-free for SNR greater than 10 dB. In the 0–10-dB range, both the signals had no loss of intelligibility, but listeners rated the resynthesized signal as having higher quality. No enhancement was obtained for SNR values lower than 0 dB. Hence, for higher noise levels, spectral subtraction or other enhancement techniques should be employed along with analysis-synthesis.

1pSC16. Enhancement of electrolaryngeal speech by spectral subtraction with minimum statistics-based noise estimation. Priyanko Mitra and Prem C. Pandey (EE Dept., Indian Inst. of Technol. Bombay, Powai Mumbai 400076, India, pcpandey@ee.iitb.ac.in)

Transcervical electrolarynx is a vibrator held against the neck tissue by a laryngectomy patient to provide excitation to the vocal tract, as a substitute to that provided by glottal vibrations. The electrolaryngeal speech suffers from lack of voicing and pitch control, low-frequency deficiency, and presence of background noise, caused by leakage of acoustic energy from the vibrator and vibrator-tissue interface. Pitch-synchronous application of spectral subtraction has been used for reducing the self-leakage noise, with averaging-based noise estimation on an initial segment with closed lips. But, the leakage noise spectrum varies with speech production and vibrator orientation and pressure. A dynamic estimation of noise is carried out by using minimum statistics, with two-pitch period analysis frames and one period overlap. Minimum value of each spectral sample in a set of past frames is used for dynamically estimating the magnitude spectrum of noise. This is subtracted from the magnitude spectrum of noisy speech and the signal is reconstructed using the original phase spectrum. Smoothing of the estimated noise spectrum resulted in better noise cancellation. Quality of electrolaryngeal speech is further enhanced by spectral deficit compensation of the magnitude spectrum.

1pSC17. Evaluating the perceptual quality of speech signals enhanced using the Modified Phase Opponency model. Om D. Deshmukh and Carol Y. Espy-Wilson (Dept. of Elec. & Comput. Eng., A. V. Williams Bldg., Univ. of Maryland, College Park, MD 20742)

Previously, we presented a speech enhancement algorithm based on the auditorily motivated MPO model. It was shown that the MPO-based speech enhancement scheme is robust to fluctuating noise. Compared to the output of several other speech enhancement techniques, the MPO-enhanced speech signals exhibit the lowest increase in Itakura-Saito, log-area-ratio, and log-likelihood-ratio-based distortion measures as the SNR reduces. In the present work, the performance of the MPO speech enhancement is compared with that of the other techniques using subjective evaluations. Three normal-hearing subjects were recruited to perform two-alternative, forced-choice preference tasks. Each sentence was presented twice: one of them was enhanced using the MPO scheme and the other was either left unprocessed or enhanced using one of three other speech enhancement techniques. Sentences are 5-digits long and corrupted by additive subway noise at −5, 0, 5, or 15-dB SNR. Most of the time, the MPO-enhanced speech signal was preferred weakly. Moreover, the MPO-

processed clean speech signal was preferred over clean unprocessed speech signal just as many times as the clean unprocessed speech signal was preferred, indicating that the MPO processing does not introduce any perceptual artifacts in clean speech. [Work supported by NSF BCS0236707 DOD H9823005C0425.]

1pSC18. Noise reduction of speech using multiband noise subtraction and adaptive filtering methods in two stages. Md. Ekramul Hamid, Keita Ogawa, and Takeshi Fukabayashi (Grad. School of Elec. Sci. and Tech., Shizuoka Univ., 3-5-1 Jouhoku, Hamamatsu 432-856, Japan)

Real-world noise is mostly colored having nonuniform power distribution over the whole spectrum. A single-channel two-stage method with multiband processing technique is presented in this paper. Initially a noise dominant signal is estimated from the observed speech and obtained the first noise-reduced speech by subtracting the signal. The noise-dominant signal is estimated from the valleys of the spectrum whose amplitudes are tuned by the estimated noise degree. The bandwise estimated noise degree is obtained from *a priori* function as a function of a parameter obtained from the autocorrelation of the noisy speech. The outcome of the first stage is allowed to process by the second stage in bandwise to obtain more enhanced speech. Blind source separation technique is employed that consists of two adaptive filters. The least-mean-square algorithm based on steepest-descent method is implemented to update the filter coefficients in an iterative manner. The method addresses the situations in which the input signal-to-noise ratio varies substantially and a fixed number of iteration of the least-mean-square algorithm for each signal-to-noise ratio is time consuming. Therefore, a function has been proposed that estimates the minimum iteration number required for a given value of the noise degree of noisy speech.

1pSC19. Speech interface for operating information technological home appliances. Masanori Enoki, Tadashige Noguchi, Tsubasa Arai, Ayako Miyake (Doshisha Univ., 1-3, Tatara-Miyakodani, Kyotanabe, Kyoto, 610-0321, Japan), Kohei Yasui, Kenko Ota, Masuzo Yanagida (Doshisha Univ., Kyoto, 610-0321, Japan), and Masaki Ida (OMRON Corp., Kyoto, 619-0283, Japan)

Information technological (IT) home appliances are becoming highly advanced by being connected to the Internet. Conventional push-button systems on remote controllers cannot suffice for IT home appliances because of their complicated requirements for versatile and complex functions. Speech input is expected to be a good substitute or supplement for push-button systems. Effects of introducing speech input to a TV system are evaluated, implementing facilities of on-line program retrieval besides ordinary functions of controlling the TV sets. One of the problems with introducing speech input is degradation of speech recognition rate due to being affected by surrounding noises and waves reflected on the surface of walls, ceiling, and so on. So, the test system introduced reduction of known noise, dereverberation scheme, delay-and-sum beamformer and blind source separation by independent component analysis as preprocessing for speech recognition. Effects of introducing these types of preprocessing are investigated comparing speech recognition rates in case of employing these types of preprocessing with those in the case of not employing these types of preprocessing. [Work supported by Knowledge Cluster Project, MEXT, and by Academic Frontier Project, Doshisha Univ.]

1pSC20. Speech detection using Real Adaboost in car environments. Tetsuya Takiguchi, Hiroyoshi Matsuda, and Yasuo Ariki (Dept. of Comput. and System Eng., Kobe Univ., 1-1 Rokkodai, Nada, Kobe, 657-8501, Japan, takigu@kobe-u.ac.jp)

In real noisy environments, a speech detection algorithm plays an especially important role for noise reduction, speech recognition, and so on. In this paper, a speech/nonspeech detection algorithm using Real Adaboost

is described, which can achieve extremely high detection rates. Boosting is a technique of combining a set weak classifiers to form one high-performance prediction rule, and Real Adaboost [R. E. Schapire and Y. Singer, Mach Learn. **37**, 3, 297–336, (1999)] is an adaptive boosting algorithm in which the rule for combining the weak classifiers adapts to the problem and is able to yield extremely efficient classifiers. The Real Adaboost algorithm is investigated for speech/nonspeech detection problem. The proposed method shows an increasing speech detection rate in car environments, comparable with that of the detector based on GMM (Gaussian mixture model), where the detection accuracy rate was 98% for the proposed method and 92% for GMM in a car at highway speed. The results of the experiments clarified the effectiveness of the proposed method.

1pSC21. Nonrestrictive and long-term monitoring system of utterance and a laughing voice: Laughometer. Masafumi Matsumura, Yutaka Kawabata, Ryoji Suzuki, and Masaki Yoshida (Faculty of Biomed. Eng., Osaka Electro-Commun. Univ., 1130-70 Kiyotaki, Shijonawate, Osaka 575-0063, Japan)

It is said that laughter is the best medicine. Laughter is known to be effective for relieving stress and promoting health. Therefore, this study is intended to clarify the relationship between laughter and physiological factors related to health promotion. We developed a hands-free wireless system (Laughometer) that monitors laughter (a laughing voice) in every-day conversations. This Laughometer detects vocal cord vibrations using a bone-conductive microphone attached to the skin on the neck. Based on data from repeated vocalizations of laughter, this apparatus can distinguish features of laughter in everyday conversations. Based on the mean fluctuation (standard deviation) in syllable intervals, 90% of laughs are differentiable from normal conversation. While attending a live rakugo comedy show, the number and duration of laughs were monitored by analyzing laryngeal voice (approximately 1-h duration). The mean differentiation rate for laughing voice was 94%, thereby confirming the efficacy of laughter recognition based on fluctuation in syllable intervals.

1pSC22. Development of nonvoice dialogue interface for robot systems. Ryuichi Nisimura and Aki Hashizume (Faculty of Systems Eng., Wakayama Univ., 930 Sakaedani, Wakayama 640-8510, Japan, nisimura@sys.wakayama-u.ac.jp)

In this presentation, a nonvoice dialogue interface scheme for robot systems to improve the flexibility of human-robot interaction is proposed. A prototype system with a microphone in a plastic doll has been developed to examine its potential for distinguishing interaction noises and human utterances. It realizes a simple, one-input one-response interaction with perception of a user's action. For example, the system can reply "Ouch!" when its body or head is beaten by a user. It is also able to make a response to a calling by the voice. This scheme would provide a new interaction style, unlike conventional spoken dialogue systems in which a user's rough actions were treated as meaningless obstacles. It identifies the source of noises based on GMM (Gaussian mixture model) noise recognition [A. Lee *et al.*, Proc. INTERSPEECH, 1, 173–176 (2004)]. Thirteen-class GMMs were constructed from voices and noises like slapping or stroking the head, and knocking the body, which were recorded via trial testing the prototype system. It is possible to discriminate noises and utterances by comparing acoustic likelihoods from GMMs. The experiment investigates performances of acoustic feature vectors consisting of MFCC (mel frequency cepstral coefficients) to identify interaction noises.

1pSC23. An evaluation of hands-free voice activity detection algorithm based on weighted cross-power spectrum phase analysis and zero crossing detector. Takamasa Tanaka, Yuki Denda, Masato Nakayama (Grad. School of Sci. and Eng., Ritsumeikan Univ., 1-1-1 Noji Higashi, Kusatsu, Shiga 525-8577, Japan, rs012019@se.ritsumei.ac.jp), and Takanobu Nishiura (Ritsumeikan Univ., Kusatsu, Shiga 525-8577, Japan)

VAD (voice activity detection) is necessary for recognizing hands-free speech. However, conventional VADs could not achieve enough detection performance in real noisy environments because they utilize only time-sequence information or only spatial-sequence information of captured signals. To cope with this problem, we have already proposed noise-robust hands-free VAD by composing the time-sequence and spatial-sequence information. The conventional ZCD (zero crossing detector) was employed to acquire the time-sequence information, and weighted CSP (cross-power spectrum phase) analysis that was a specialized DOA (direction of arrival) estimation algorithm for speech signal was also employed to acquire the spatial-sequence information. However, this algorithm can insufficiently improve the VAD performance in higher noisy environments. To overcome this problem, in this paper, we try to utilize talker direction information and attempt the environmental adaptation of our former algorithm. As a result of evaluation experiments in real acoustic environment, the proposed hands-free VAD could achieve a more effective performance than the conventional VAD and our former VAD. [Work supported by MEXT of Japan.]

1pSC24. A study of robust omnidirectional audio-visual talker localization algorithm with microphone array and omnidirectional image. Yuki Denda (Grad. School of Sci. and Eng., 1-1-1 Nojihigashi, Kusatsu, Japan, gr021052@se.ritsumei.ac.jp), Tanaknobu Nishiura, and Yoichi Yamashita (College of Information Sci. and Eng., 1-1-1 Nojihigashi, Kusatsu, Japan)

In video conferencing environments, it is very important to localize the talker. However, conventional audio signal-based algorithms often suffer from audio interference, and conventional visual signal-based algorithms fail in the presence of visual interference. To deal with these problems, this paper proposes a robust omnidirectional audio-visual talker localization algorithm that not only exploits audio feature parameters, but also subordinately uses visual feature parameters. To achieve omnidirectional audio-visual talker localization, paired-omnidirectional microphones are employed as an audio sensor, and an omnidirectional camera is employed as a visual sensor. For robust talker localization, audio feature parameters are extracted using weighted cross-power spectrum phase (CSP) analysis and CSP coefficient subtraction, and visual feature parameters are extracted using background subtraction and skin-color detection. The talker is finally located by the fusing of weighted audio/visual feature parameters, and the weight of this feature parameter fusion is automatically controlled based on the reliable criterion of audio feature parameters. The results of localization experiments in an actual room revealed that the proposed audio-visual talker localization algorithm is superior to that of conventional localizers using only audio or visual feature parameters, but not both. [Work supported by MEXT of Japan.]

1pSC25. Application of harmonic plus noise model for enhancing speaker recognition. Gidda Reddy Gangula, Prem C. Pandey, and Parveen K. Lehana (EE Dept., Indian Inst. of Technol. Bombay, Powai Mumbai 400076, India, pcpandey@ee.iitb.ac.in)

Speaker recognition systems mostly employ mel frequency cepstral coefficients (MFCC). Performance of these systems is generally affected by background noise, transmission medium, etc. Further, they do not perform well in text-independent environment with limited training data. For enhanced performance, the set of parameters used should separate the speaker-dependent information from the linguistic information. Towards this end, application of parameters of the harmonic plus noise model (HNM)-based analysis is investigated. HNM divides the speech spectrum

into harmonic and noise bands separated by a dynamically varying maximum voiced frequency. This frequency is a speaker-dependent parameter and its estimation is not affected by moderate SNR degradation. A speaker recognition system was devised using three HNM parameters, namely, maximum voiced frequency, relative noise band energy, and pitch. It gave-performed comparably to that of MFCC-based recognition, for a group of ten speakers. An enhanced performance was observed by using MFCC and the three HNM parameters together, indicating the suitability of HNM for speaker recognition.

1pSC26. Noisy speech recognition using modification of spectral envelopes and smoothing and emphasis method by image filters. Yoichi Midorikawa and Masanori Akita (Faculty of Eng., Oita Univ., 700 Dannoharu, Oita, 870-1192, Japan)

The purpose of this study is to propose an improvement of the speech recognition under the noisy environment. Automatic speech recognition (ASR) systems are most effective in noiseless environments. We propose a method for ASR with signals contaminated with colored noise using modification of the spectral envelope shape. Our previous study has proposed a method of speech recognition for the signals polluted with color noise by modifying spectral envelope shape by rules. The proposed method is based on cepstral analysis. We have proposed the modified rules for adding valleys are defined. These methods are applied to the enhancement system of noisy signals and the performance of the system is improved. However, these rules only make use of frequency domain. Therefore, the cepstral coefficients of neighboring frames become independent of time domain. In this study, we apply the smoothing and emphasis method by image filters to the modification of spectral envelope shape. As a result, performance of speech recognition is improved.

1pSC27. Noisy speech recognition based on codebook normalization of discrete-mixture hidden Markov models. Tetsuo Kosaka, hidden Markov Models, Masaharu Katoh, and Masaki Kohda (Faculty of Eng., Yamagata Univ., Yonezawa-city, Yamagata, 992-8510 Japan, tkosaka@yz.yamagata-u.ac.jp)

This paper presents a new method of robust speech recognition under noisy conditions based on discrete-mixture HMMs (DMHMMs). The DM-HMMs were proposed originally to reduce calculation costs. Recently, we applied DMHMMs to noisy speech recognition and found that they were effective for modeling noisy speech [Kosaka *et al.*, Proc. of ICA04 (2004), Vol. II, pp. 1691–1694]. For further improvement of noisy speech recognition, we propose a novel normalization method for DMHMM codebooks. The codebook normalization method is based on histogram equalization (HEQ). The HEQ is commonly applied for feature space normalization. The DMHMM codebooks were normalized in this study. Therefore, this method is considered as normalization not in feature space, but in model space. Some merits are inherent in choosing model space normalization. In model space normalization, a transformation function can be prepared for each acoustic model. In addition, it is not necessary to normalize input parameters frame-by-frame. The proposed method was compared with both conventional continuous-mixture HMMs (CHMMs) and DMH-MMs. That comparison showed that the proposed method obtained the best performance: an average relative improvement of 29.2% over the CHMM baseline.

1pSC28. Robust speech recognition for home environments using factorial hidden Markov models. Agnieszka Betkowska, Koichi Shinoda, and Sadaoki Furui (Dept. of Comput. Sci., Tokyo Inst. of Technol., 2-12-1, Ookayama, Meguro-ku, Tokyo, 152-8552 Japan, agabet@furui.cs.titech.ac.jp)

In this paper we present a speech recognition system for the home environment that is robust to nonstationary sudden noise such as doors slamming, knocking, and falling objects. This noise appears rapidly and

lasts for a short period of time. Additionally the SNR is difficult to estimate. As a compensation model for this task, we investigated the use of the factorial hidden Markov model (FHMM) architecture proposed by Deoras (2004). In our method, a hidden Markov Model (HMM) for each word in a dictionary and an HMM for sudden noise are employed to build a factorial HMM to recognize noisy speech. Since the factorial HMM defined by Deoras applies only to static features of the observation vector during the recognition process, we extended it to work with dynamic features. The proposed method was evaluated with a database recorded by a personal robot, PaPeRo, in the houses of 12 Japanese families. The experiments were conducted for both synthesized speech (at different SNRs) and real noisy speech, which was recorded by the robot. In both cases, our method showed significant improvement over HMMs trained with clean speech data.

1pSC29. A phoneme duration model considering speaking-rate and linguistic features for speech recognition. Yuichi Ohkawa (Grad. School of Educational Informatics, Tohoku Univ., 27-1, Kawauchi, Aoba-ku, Sendai 980-8576, Japan), Akinori Ito, Motoyuki Suzuki, and Shozo Makino (Tohoku Univ., Aramaki, Aoba-ku, Sendai 980-8579, Japan)

In this paper, we proposed a method of phoneme duration modeling for speech recognition. A phoneme with extremely short or long duration often causes a decline of performance of speech recognition. In order to improve performance of recognition, an estimation of phoneme duration determined by various parameters is required. However, there was no usual method of duration modeling for speech recognition considering the influence of both speaking-rate and linguistic feature (phoneme location in sentence, part-of-speech, *et al.*), which influence phoneme duration strongly. Therefore, we modeled influence of speaking-rate by two-dimensional normal distribution of phoneme duration and local average of vowel duration. Each normal distribution is determined by tree-based clustering with various questions, which include linguistic feature. With an experiment of estimation of phoneme duration by this model, we acquired 20.8% reduction of standard deviation of estimation error. We also used the proposed duration model for rescoring of *N*-best hypothesis of speech recognition. With an experiment of rescoring of recognition results for spontaneous speech, we acquired significant reduction of 4.7% in phoneme error rate.

1pSC30. Investigation of model-based error rate estimation techniques for speaker-independent large-vocabulary recognition tasks. Atsuhiko Kai and Shoji Nakamori (Faculty of Eng., Shizuoka Univ., 3-5-1, Johoku, Hamamatsu, Shizuoka, 432-8561, Japan)

This paper proposes model-based error rate estimation techniques for HMM-based speech recognition systems and shows their effectiveness in several speaker-independent task conditions. The proposed techniques are based on an HMM-based error rate estimation method [C.-S. Huang *et al.*, IEEE Trans. SAP, **11**, No. 6, 581–589 (2003)], which only depends on subword-based pronunciation lexicon knowledge. This study assumes the need of the dynamic change of open vocabulary. The vocabulary size is varied between 5000 and 25 000 words. Two types of formalizations are investigated. They utilize the Bhattacharyya distance as a local distance measure between two competing word classes which are modeled by syllable-unit HMMs. A misclassification measure, which is similar to the one used by minimum classification error (MCE) training methods, is used for estimating error rate. The correlation between the error rates for testing utterances by 20 speakers and the estimated error rates for varied vocabulary sizes are evaluated. Except for one speaker, the correlation coefficient above 0.8 was obtained for both proposed formulations. Moreover, when the uttered words are clustered to five coarse classes of different estimated error rates, the correct rate of relative consistency between those adjacent classes was above 90% on average.

1pSC31. Large-scale continuous speech recognition system design using discriminative training. Erik McDermott and Atsushi Nakamura (NTT Commun. Sci. Labs, NTT Corp., Hikari-dai 2-4, Seikacho, Soraku-gun, Kyoto-fu 619-0237, Japan, mcd@cslab.kecl.ntt.co.jp)

Discriminative training is difficult to implement but essential to attaining state-of-the-art performance in automatic speech recognition systems today. Most of the discriminative training results for large scale recognition tasks (with vocabularies well over 10 000 words) so far use the maximum mutual information (MMI) framework, but recent results for the minimum classification error (MCE) framework suggest that MCE too yields significant improvements in recognition accuracy and system compactness on large-scale tasks. MCE embodies rather well the general intuition that recognition system design should attempt to improve performance (i.e., recognition accuracy) directly, by optimizing a criterion function that is closely related to performance, rather than indirectly, by optimizing a criterion such as overall log likelihood that does not reflect performance. This presentation provides an overview of the MCE framework, and describes recent MCE speech recognition results obtained with both the MIT Galaxy system and the NTT Communication Science Labs SOLON system. The tasks examined include a 33 000-word vocabulary telephone-based spontaneous speech weather information task, a 22 000-word telephone-based name recognition task, and a 100 000-word Japanese lecture speech transcription task.

1pSC32. Hyperparameter estimation for speech recognition based on variational Bayesian approach. Kei Hashimoto, Heiga Zen, Yoshihiko Nankaku, Lee Akinobu (Nagoya Inst. of Technol., Dept. of Comput. Sci. and Eng., Gokiso-cho, Showa-ku, Nagoya, 466-8555 Japan, bonanza@ics.nitech.ac.jp), and Keiichi Tokuda (Nagoya Inst. of Technol., Nagoya, 466-8555 Japan)

A hyperparameter estimation technique for HMM-based speech recognition using variational Bayesian (VB) approach is proposed. In recent speech recognition systems, the ML and MDL criteria have been adopted for training HMMs and the context clustering, respectively. However, since the ML estimator produces a point estimate of parameters, the estimation accuracy is reduced with insufficient data. The MDL criterion is also affected by the amount of training data due to an asymptotic approximation. To avoid this problem, the VB method has been applied to HMM-based speech recognition. By using the VB approach, it is expected that the higher generalization ability is achieved and an appropriate model structure can be selected in the context clustering. In the Bayesian framework, the predictive distribution is obtained by integrating the likelihood function with respect to the prior density. Therefore, the performance of the Bayesian method depends on the setting of hyperparameters representing the prior distribution. However, the detailed investigation for hyperparameter estimation has not been conducted in the speech recognition field. This study proposes an estimation technique of hyperparameters based on the maximization of the marginal likelihood for HMM-based speech recognition. Experimental results show that the proposed technique can estimate appropriate hyperparameters from training data.

1pSC33. An investigation of early reflection signal based on impulse response on automatic speech recognition. Yoshiki Hirano, Yuki Denda, Masato Nakayama (Grad. School of Sci. and Eng., Ritsumeikan Univ., 1-1-1 Noji Higashi, Kusatsu, Shiga 525-8577, Japan, rs037021@se.ritsumei.ac.jp), and Takanobu Nishiura (Ritsumeikan Univ., Kusatsu, Shiga 525-8577, Japan)

Early reflection signals (especially, within 50 ms from direct sound arrival) are useful to speech listening for human being. On the other hand, the higher the reflection energy becomes, the more present automatic speech recognition performance decreases, subject to using clean acoustic phoneme model. However, it was not clear that early reflections are useful or useless to recognize the speech on distant-talking speech recognition, because reverberation time was employed as reverberation criterion. It is a unique time and does not depend on source position in a room. In addition,

it can only express the time in which sound attenuation becomes -60 dB and cannot express the early reflection that strongly influences speech recognition performance. Therefore, it should be nonsuitable reverberation criterion for distant-talking speech recognition. To overcome this problem, we investigate the relation between early reflections and distant-talking speech recognition performance based on impulse response between talker and microphone towards newly suitable reverberation criterion on distant-talking speech recognition. As a result of evaluation experiments in real acoustic environments, we could confirm the relation between speech recognition performance and early reflection signals. In future work, we will try to propose the newly suitable reverberation criterion. [Work supported by MEXT of Japan.]

1pSC34. Acoustic modeling with contextual additive structure for hidden Markov model-based speech recognition. Kazuhiro Nakamura, Heiga Zen, Yoshihiro Nankaku, and Keiichi Tokuda (Gokiso-cho, Showa-ku, Nagoya 466-8555, Japan)

This study proposes an acoustic modeling technique based on an additive structure of context dependencies for HMM-based speech recognition. Context dependent models, e.g., triphone HMMs, are widely employed in speech recognition systems. Generally the dependency between phonetic contexts and acoustic feature distributions is direct, i.e., if a context is given, the Gaussian distribution is specified immediately. However, more complex dependencies can be considered. This study assumes an additive structure of acoustic feature components that have different context dependencies. For example, if the left and right phones are assumed as contexts of additive components, the generative process of the triphone feature is as follows: the additive components of left and right contexts are generated independently from each distribution and then added to the monophone feature. Since the output probability distribution is composed of the sum of the mean vectors and covariance matrices of additive components, a number of different distributions can be efficiently represented by a combination of fewer distributions. However, it is unknown which kinds of contexts have additive dependencies to acoustic features. Therefore, this study proposes a context clustering algorithm for the additive structure model. The proposed algorithm automatically extracts additive components by constructing multiple decision trees simultaneously.

1pSC35. Towards an efficient archive of spontaneous speech: Design of computer-assisted speech transcription system. Hiroaki Nanjo (Faculty of Sci. and Technol., Ryukoku Univ., Seta, Otsu 520-2194, Japan) and Tatsuya Kawahara (Kyoto Univ., Sakyo-ku, Kyoto 606-8501, Japan)

Computer-assisted speech transcription (CAST) system for making archives such as meeting minutes and lecture notes is addressed. For such a system, automatic speech recognition (ASR) of spontaneous speech is promising, but ASR results of spontaneous speech contain a lot of errors. Moreover, the ASR errors are essentially inevitable. Therefore, it is significant to design a good interface with which users can correct errors easily in order to take advantages of ASR for making speech archives. It is From these points of view that our CAST system is designed. Specifically, the system has three correction interfaces: (1) pointing device for selection from competitive candidates, (2) microphone for respeaking, and (3) keyboard. One of the most significant correction methods is selection from competitive candidates, thus more accurate competitive candidates are required. Therefore, generation methods of competitive candidates are discussed. Then, a speech recognition strategy (decoding method) based on the minimum Bayes-risk (MBR) framework is discussed. Since MBR decoding can distinguish and deal with content words and functional words, which are conventionally treated in a same manner, the approach is expected to generate more content words in competitive candidates.

1pSC36. Acoustic modeling of spontaneous speech of Japanese preschool children. Izumi Shindo, Tobias Cincarek, Tomoki Toda, Hiroshi Saruwatari, and Kiyohiro Shikano (Nara Inst. of Sci. and Technol., 8916-5 Takayama-cho, Ikoma-shi, Nara 630-0192, Japan)

In recent years, there is an increasing demand for speech recognition of children. However, the recognition of children's speech, especially preschool children (2 to 5 years of age), is very difficult. For example, recognition accuracy using a children's acoustic model provided by the Japanese Dictation Toolkit is only 21.4%. Many different variations of child speech with palatal sounds and pronunciation error decrease recognition performance. This paper proposes a recognition method that investigates the characteristics of preschool children's speech using experimental data and considers phonetic changes. Mapping between standard and altered pronunciations of words is determined. In experiments, a large amount of spontaneous child speech (2 to 15 years of age) was collected with the speech-oriented public guidance system, "Takemaru-kun," which is currently available. Recognition performance increases to 49.2% by acoustic model adaptation of preschool children's speech. When allowing multiple pronunciation variations per word during recognition, further improvement to 52.0% is achieved.

1pSC37. Robust speech recognition for the control of wheelchairs by inarticulate speech of the severely disabled. Hiroaki Kojima, Akira Sasou, Soo-Young Suk, Shi-Wook Lee, and Ken Sadohara (Natl. Inst. of Adv. Industrial Sci. and Technol. (AIST), Central 2, Umezono, Tsukuba, Ibaraki 305-8568, Japan, h.kojima@aist.go.jp)

The goal of this research is to develop voice-controlled wheelchairs that can be operated by inarticulate speech affected by severe cerebral palsy or quadriplegia, for instance. In this case, principal factors obstructing recognition performance are significant pronunciation variation caused by difficulty in stable articulation and bad influences of variety of noise in the real environment. To cope with the pronunciation variations, pronunciation lexicons that consist of multitemplates of reference patterns are utilized. The reference patterns are represented with subphonetic codes, which can describe variations of inarticulate speech more precisely than ordinary phonetic transcriptions. Pronunciation lexicons are generated by generalizing coded samples into compact representation of templates based on DP and data mining. For noise robustness, a voice activity detection method is investigated in order to circumvent friction of microphone, cough, etc. A sound source localization using a microphone array is also integrated in order to reject sounds from outside of the wheelchair. These methods are integrated into a system that can be mounted on a wheelchair. A usability test operated by a severe cerebral palsy patient in the real environment results in 95.8% accuracy within 1404 samples for the recognition of the five-command set. [Work supported by MEXT.]

1pSC38. Selection of recognition candidates based on parallel recognition of sentences and partial words in spoken dialogue. Makiho Kawakami (Faculty of Eng., Chiba Univ.; 1-33 Yayoi-cho, Inage-ku, Chiba 263-8522, Japan), Hiromasa Terashi, Masafumi Nishida, Yasuo Horiuchi, and Akira Ichikawa (Chiba Univ., Inage-ku, Chiba 263-8522, Japan)

We have proposed a method that predicts a user's utterances in spoken dialogue systems by recognizing prediction sentences of each dialogue state, thereby decreasing recognition errors. However, the conventional method might repeat recognition errors because it confirms the whole sentence even if it recognizes only a part of a long word, such as a compound word, correctly. For this study, we introduce a method using decoders based on prediction sentences and partial words obtained by dividing long words. The proposed method can confirm a user's utterances by selecting a candidate to a partial matched word using recognition results of the prediction sentence and a divided partial word. We conducted experiments for 560 utterances of seven persons using a navigation system. Results showed that the word recognition accuracy was 81.1%. The rate at which recognition results by the prediction sentence and a divided

partial word were an exact or partial match was 70.5%. The rate of recognition errors when the recognition results were an exact or partial match was 0.9%. Therefore, we demonstrated that it is possible to confirm a user's utterances using the proposed method by selecting recognition candidates.

1pSC39. Multiple utterance prediction based on a tree structure of dialogue states. Hiromasa Terashi, Masafumi Nishida, Yasuo Horiuchi, and Akira Ichikawa (Grad. School of Sci. and Technol., Chiba Univ., 1-33 Yayoi-cho, Inage-ku, Chiba 263-8522, Japan)

A problem of spoken dialogue systems is that recognition errors increase when the recognition-word vocabulary is large. To solve the problem, we propose a method to predict a user's utterances by recognizing prediction sentences of each dialogue state. The method can judge whether the user's utterance is within the range of prediction using decoders based on a prediction sentence and a large word vocabulary. However, the conventional method performs processing to lead in a prediction frequently when a topic changes because even an utterance within a domain is treated as an utterance of the prediction outside. In this study, we propose a new method using multiple predictions by performing recognition based on all prediction sentences in a domain. The proposed method produces a tree structure for dialogue states in a domain and regards child nodes of an arbitrary node as within the range of prediction. We conducted experiments for 451 utterances of 15 dialogues by ten persons using the university guide system. As a result, recognition accuracy of prediction sentences was 97.7% and the judgment accuracy of utterance predictions was 88.2%; high performance was obtained using the proposed method. Results demonstrate that it is possible to perform flexible dialogue control.

1pSC40. Document-level optimization in speech recognition. Rie Nakazato, Kugatsu Sadamitsu, and Mikio Yamamoto (Univ. of Tsukuba, 1-1-1 Tennodai, Tsukuba-shi, Ibaraki-ken, 305-8573, Japan)

Most ASR systems optimize scores at the sentence level because language models are designed to assign a meaningful probability to a sentence, but not to a document. However, in the last half-decade, NIPS people have specifically examined aspect-based global language models and developed generative text models such as the latent Dirichlet allocation (LDA), which can assign a meaningful probability to an entire document. We investigated a system to recognize all sentences in a read document, maximizing a global score including the document probability, in addition to assigning acoustic and local language probabilities. Document level optimization using global scores engenders a combinatorial problem in its implementation. Therefore, we used the rescoring framework with N-best recognition results for each sentence in a read document and the hill-climbing method to search for approximately optimal recognition results. In this study, we compare mixture of unigrams (MU), Dirichlet mixtures (DM), and LDAs as generative text models in experiments using read document speech data in Japanese Newspaper Article Sentences (JNAS) and academic presentation speech data in The Corpus of Spontaneous Japanese (CSJ).

1pSC41. Generating search query in unsupervised language model adaptaion using WWW. Yasutomo Kajiura, Motoyuki Suzuki, Akinori Ito, and Shozo Makino (Grad. School of Eng., Tohoku Univ., Aramaki, Aoba-ku, Sendai-shi, Miyagi, 980-9579 Japan, makino@ecei.tohoku.ac.jp)

To improve the accuracy of an LVCSR (large vocabulary continuous speech recognition) system, it is effective to gather text data related to the topic of the input speech and adapt the language model using the text data. Several systems have been developed that gather text data from World Wide Web using keywords specified by a user. Those systems require the user to be involved in the transcription process. However, it is desirable to automate the entire process. To automate the text collection, we propose a method to create an adapted language model by collecting topic-related

text from World Wide Web. The proposed method composes the search query from the first recognition result, and it gathers text data from the WWW and adapts the language model. Then the input speech is decoded again using the adapted language model. As the first recognition result contains recognition errors, we developed a method to exclude the misrecognized words using word-based confidence score and similarities between keywords. To evaluate the proposed method, we carried out adaptation experiments.

1pSC42. Collection of multimodal data in real-world driving. Takashi Kusakawa, Chiyomi Miyajima (Grad. School of Information Sci., Nagoya Univ., Furo-cho, Chikusa-ku, Nagoya 464-8603, Japan, kusakawa@sp.m.is.nagoya-u.ac.jp), Takanori Nishino (Nagoya Univ., 464-8603, Japan), Katsunobu Itou (Hosei Univ.), and Kazuya Takeda (Nagoya Univ., 464-8603, Japan)

Our research group has recently developed a new data collection vehicle equipped with various sensors for the synchronous recording of multimodal data including speech, video, driving behavior, and physiological signals. Driver speech is recorded with 12 microphones distributed throughout the vehicle. Face images and a view of the road ahead are captured with three CCD cameras. Driving behavior signals including gas and brake pedal pressures, steering angles, vehicle velocities, and following distances are recorded. Physiological sensors are mounted to measure the drivers' heart rate, skin conductance, and emotion-based sweating on the palm of the hand and sole of the foot. The multimodal data are collected while driving on city roads and expressways during four different tasks: reading random four-character alphanumeric strings, reading words on billboards and signs seen while driving, interacting with a spoken dialogue system to retrieve and play music, and talking on a cell phone with a human navigator using a hands-free device. Data collection is currently underway. The multimodal database will be published in the future for various research purposes such as noise-robust speech recognition in car environments, detection of driver stress while driving, and the prediction of driving behaviors for improving intelligent transportation systems.

1pSC43. Comparison of visual features for audio-visual speech recognition using the AURORA-2J-AV database. Takahiro Togo, Yukitaka Nimura, Takayuki Kitasaka, Kensaku Mori, Yasuhito Suenaga, Chiyomi Miyajima, and Kazuya Takeda (Dept. of Media Sci., Grad. School of Information Sci., Nagoya Univ., Furo-cho, Chikusa-ku, Nagoya 464-8603, Japan, ttogo@suenagam.is.nagoya-u.ac.jp)

Various techniques for noise-robust speech recognition have been developed for many years. However, speech recognition in nonstationary noisy environments, such as in car conditions, is still a very challenging research problem. Audio-visual speech recognition is a promising technique for improving noise robustness in such adverse acoustic conditions. Our research group has recently developed an audio-visual speech database "AURORA-2J-AV" following the AURORA2 database protocol, which has been widely used for evaluating the performance of audio-only speech recognition techniques. The AURORA-2J-AV database consists of audio speech signals and two types of image sequences: color and infrared human face images recorded when multi-digit numbers are spoken by about 100 native Japanese speakers. Visual noise as well as acoustic noise is added to the database after recording for simulating various conditions. Audio-visual speech recognition experiments are conducted using the audio speech and infrared images of the AURORA-2J-AV database. Two visual features, correlation coefficients (CCs) between two successive image frames and principal component scores (PCSs) of lip images, are compared in various signal-to-noise ratio (SNR) conditions. Experimental results show that CCs outperform PCSs at high SNRs, while PCSs function better at lower SNRs.

1pSC44. A method for estimating the degree of a speaker's anger using acoustic features and linguistic representation. Yoshiko Arimoto (Grad. School of Bionics, Comput. & Media Sci., Tokyo Univ. of Technol., 1401-1 Katakura, Hachioji, Tokyo, 192-0982, Japan), Sumio Ohno, and Hitoshi Iida (Tokyo Univ. of Tech., Hachioji, Tokyo, 192-0982, Japan)

Automatic speech recognition (ASR) systems are greatly demanded for customer service systems. With advanced interactive voice response systems, humans have more opportunities to have dialogues with computers. Existing dialogue systems process linguistic information, but do not process paralinguistic information. Therefore, computers are able to obtain less information during a human-computer dialogue than a human can during a human-human dialogue. This report describes a study of the estimation method of degree of speakers' anger emotion using acoustic features and linguistic representation expressed in utterances during a natural dialogue. To record utterances expressing the users' internal anger emotion, we set pseudo-dialogues to induce irritation arising from discontentment with the ASR system performance and to induce exasperation against the operator while the user makes a complaint. A five-scale subjective evaluation was conducted to mark each utterance with a score as the actual measurement of anger emotion. As a result of this, an emotional speech corpus was produced. We examine the acoustic features and features of linguistic representation of each utterance with reference to these anger score. Then we conduct experiments to estimate automatically the degree of anger emotion using parameters selected from those features.

1pSC45. Marking up Japanese Map Task Dialogue Corpus. Tomoko Ohsuga, Shuichi Itahashi (Natl. Inst. of Informatics, 2-1-2 Hitotsubashi, Chiyoda-ku, Tokyo 101-8430, Japan, osuga@nii.ac.jp), and Syun Tutiya (Chiba Univ.)

This presentation reports an outline of marking up the Japanese Map Task Dialogue Corpus. The project was conducted by an independent group of researchers from the faculties of Chiba University and other institutions. This corpus contains 128 dialogues by 64 Japanese native speakers. The basic design of the dialogues and recordings conform to the original HCRC Map Task Corpus of the University of Edinburgh. Two speakers participated in the map task dialogues; an instruction giver who has a map with a route and an instruction follower who has a map without a route. The giver verbally instructs the follower to draw the route on his/her map. The corpus is marked up according to XML-based TEI (Text Encoding Initiative) P5 format, which is developed in an effort to provide interchangeable and shareable text data. The transcriptions of TEI format are viewed as "tags" that describe the start and end times of utterances, the duration of pauses, nonverbal events, and synchronization of overlapping utterances. This corpus will be available through NII-SRC (Speech Resources Consortium).

1pSC46. Towards the detection of potentially hazardous situations in vehicle traffic using driver speech and brake pedal operation. Lucas Malta (Grad. School of Information Sci., Nagoya Univ., Nagoya-shi, Chikusa-ku Higashiyama-doori 5-10 Nakanishi biru 306 - Japan, malta@sp.m.is.nagoya-u.ac.jp), Chiyomi Miyajima (Nagoya Univ., Japan), Katsunobu Itou (Hosei Univ., Japan), and Kazuya Takeda (Nagoya Univ., Japan)

A method for automatic detection of potentially dangerous situations in motor vehicle traffic is introduced. Unlike precedent works, which typically relied on camera arrays or road-traffic monitoring sensors to detect collision incidents, the proposed approach specifically incorporates changes in a drivers' behavior, detected through driver speech and brake pedal operation. Experiments were performed using a large real-world multimedia driving database of 493 drivers, obtained from the Centre for Integrated Acoustic Information Research (CIAIR, Nagoya University). The drivers, who interacted verbally with a human operator, uttered expletive words to express negative feelings in 11 of the 25 situations that we selected as potentially hazardous. In 17 of them, sudden and intense com-

pression of the brake pedal was observed. The proposed lexicographical speech-feature-based method also detected 33 false alarms to detect 80% of these 11 scenes. As for the other 17 scenes, our method based on two-dimensional histograms of brake pressure and its dynamics achieved an 80% detection rate for 473 false alarms. Analyses of data recorded while drivers interacted with a machine and a Wizard of Oz system as well as a rank of the most commonly uttered words in dangerous situations are also presented.

1pSC47. Computational complexity of a distance-based active search algorithm. Masahide Sugiyama (The Univ. of AIZU, Tsuruga, Ikki-machi, Aizu-Wakamatsu-shi, Fukushima, 965-8580 Japan)

An efficient pattern (segment) search in a large-scale database is a very important technology in current widespreaded Internet society. To achieve efficient searches, many efficient pattern search algorithms have been proposed. Active search (AS) is one of them; it is based on skipping of search calculation. Initially, AS was formulated between two histograms using a similarity measure. In fact, AS can be formulated using L_p distance, where p is greater than 1. The search efficiency can be evaluated using a number of distance calculations. The first result in this paper shows that the L_1 distance in AS gives the minimum number of distance calculations among L_p distances. This property can be derived from a newly derived inequality between the L_p and L_1 norm on output probability space. A new distance can be derived from positive weighting of any distance. The second result of this paper is that the average skip width for any weighed L_p distance cannot be greater than the most efficient distance. Therefore, no positive combination of L_p can be more efficient than L_1. The two results indicate that L_1 distance is the most efficient for active searching.

1pSP1. Frequency domain blind source separation in a noisy environment. Ryo Mukai, Hiroshi Sawada, Shoko Araki, and Shoji Makino (NTT Commun. Sci. Labs., NTT Corp., 2-4 Hikaridai, Seika-cho, Soraku-gun, Kyoto 619-0237, Japan)

A prototype system for blind source separation (BSS) in a reverberant and noisy environment is presented. Our system uses a small three-dimensional array with eight microphones and realizes BSS in various situations such as the separation of many speech signals located in a three-dimensional space, and the extraction of primary sound sources surrounded by many background interferences. The mixed signals observed by the microphone array are processed by independent component analysis (ICA) in the frequency domain. The permutation problem is solved by normalized basis vector clustering, which is a generalized version of directions of arrival (DOA) clustering and has several advantages to the DOA based method. The system estimates the DOA of the source signals as a by-product of the separation process. Moreover, the system has the ability to distinguish primary target signals and ambient noise. Our system performs an on-the-spot BSS of live recorded signals. Live demonstration will be performed at the meeting.

1:25

1pSP2. Beyond the independent component analysis: New blind acoustic sound separation in real world via single-input multiple-output-based independent component analysis. Hiroshi Saruwatari (Nara Inst. of Sci. and Technol., 8916-5 Takayama-cho, Ikoma, Nara, 630-0192 Japan)

This review discusses a new generation of blind acoustic-signal separation in the real world, focusing on a recently proposed ICA method, Single-Input Multiple-Output (SIMO)-signal-based ICA (SIMO-ICA). The term "SIMO" is referred to as a specific transmission system in which the input is a single source signal and the outputs are its transmitted signals observed at multiple microphones. The SIMO-ICA consists of multiple ICA parts and a fidelity controller, and each ICA runs in parallel under the fidelity control of the entire separation system. In the SIMO-ICA scenario, mixed multiple sources detected at the microphones can be separated, not into monaural source signals but into SIMO-model-based contributions from independent sources as they are at the microphones. Thus, the separated signals of the SIMO-ICA can maintain the spatial qualities of each sound source. This attractive feature of the SIMO-ICA shows the promise of applicability and connectability with the other multichannel signal processing for achieving the higher performance beyond the conventional ICA methods. As the successful examples of SIMO-ICA's application, three kinds of systems are described: (*i*) combination with inverse filtering for MIMO decomvolution, *ii*) combination with adaptive beamformer for higher-performance BSS, and *iii* combination with binary masking for real-time processing.

1pSP3. How blind are we in blind signal processing? Walter Kellermann (Univ. Erlangen-Nuremberg, Cauer-str. 7, 91058 Erlangen, Germany, wk@lnt.de)

Blind signal processing algorithms aim at blindly solving classical signal processing problems such as system identification, signal separation, or source localization. Here it is investigated to which extent some of the more popular blind signal processing concepts are really blind when they are used for signal acquisition in the acoustic domain. Blindness regarding the source configuration and the source signal properties, blindness with respect to channel properties, and, finally, blindness regarding the microphone configuration are investigated. It turns out that many algorithms are explicitly nonblind with respect to important properties of the source configuration, such as the number of sources and their pointlike nature. The source signals typically have to fulfill certain statistical properties or have to meet sparseness constraints. Some algorithms rely on a dominant direct acoustic path between sources and sensors, and linearity of the transmission channel model is implied with all convolutive mixture models. Finally, some popular algorithms are actually aiming at direction of arrival estimation, which always requires knowledge on the microphone array geometry. In essence, blind algorithms are wellinformed in many respects and are blind only with regard to a few, although decisive, properties.

1pSP4. Informed acoustic source separation and localization. Kevin H. Knuth (Dept. of Phys., Univ. at Albany, Albany, NY 12222)

Advances in Bayesian computational technology in the last decade have enabled the development of new source separation and source localization algorithms. These algorithms are greatly improved by the encoding of prior information about a specific problem in the form of the chosen relevant model parameters, the assignment of the likelihood functions, and the assignment of the prior probabilities of the model parameter values. I refer to such source separation algorithms as informed source separation for the reason that they are endowed with specific and often vital information about the problem. Furthermore, the Bayesian methodology allows source separation to be united with source localization simply by including the model parameters that are of interest to the researcher. Here, I will discuss the union of source separation and source localization under the Bayesian methodology, the incorporation of prior information, and the construction of an informed algorithm using the new computational technologies that allow us to estimate the values of the parameters that define these high-dimensional problems.

1pSP5. Recovering the quality of speech degraded by reverberations in a room. Masato Miyoshi (NTT Commun. Sci. Labs, 2-4 Hikaridai Seika-cho, Keihanna Sci. City, Kyoto 6190237 Japan, miyo@cslab.kecl.ntt.co.jp)

Speech signals captured by distant microphones in a room are usually reverberated due to wall reflections. Reverberation may seriously deteriorate the signal characteristics, thus damaging the quality of such applications as hands-free telephony or automatic speech recognition. To eliminate such room reverberation effects, the inverse-filtering of the room transfer functions (RTFs) between a speaker and the microphones appears to be a very promising approach. When applied to a microphone system, this processing should work blindly because no explicit information on RTFs or source signals is available. The blind design of an inverse-filter set may be roughly classified into three approaches: (1) calculating an inverse-filter set of RTF estimates obtained from observed reverberant signals based on the ''subspace method,'' (2) calculating the filter set from observed signals and replicas of direct-sound signals using statistical properties inherent in speech signals, and (3) calculating the filter set directly from received signals, by whitening these signals without excessive degradation of the original signal characteristics. This presentation will provide an overview of these three approaches and introduce our speech dereverberation trials.

1pSP6. Blind deconvolution for noisy dynamic channels. Michael J. Roan (Dept. of Mech. Eng., Virginia Tech., Blacksburg, VA 24060)

It is common in acoustics to measure a signal that has been degraded by propagation through an unknown, noisy channel prior to measurement. While only the degraded measured signal is available, the data of interest are the original signal and the channel parameters. Often, it is desirable to reverse the filtering process by application of an inverse filter to recover the original signal. When neither the input signal properties nor the channel properties are known, this process is known as blind deconvolution (BDC). Typically, BDC algorithms assume noiseless, stationary propagation channels and input sources. These assumptions are usually violated in practical applications (e.g., noisy multipath propagation environments with moving source and receiver). To model these effects, predictive techniques are applied to incorporate *a priori* information about the system into the existing blind processing framework. The original contributions of this work follow. First, a novel formulation of the extended Kalman filter (EKF) is proposed. This allows incorporation of *a priori* information into gradient-based blind processing algorithms. This formulation is then applied to the natural gradient (NG) BDC algorithm. Finally, results are presented that suggest significant improvement in signal recovery performance over the NG BDC algorithm for dynamic noisy channels.

1pSP7. Blind dereverberation based on auto-correlation functions of framewise time sequences of frequency components. Kenko Ota and Masuzo Yanagida (Doshisha Univ., 1-3, Tarata-Miyakodani, Kyotanabe, Kyoto, 610-0321, Japan, etf1704@mail4.doshisha.ac.jp)

Proposed is a new blind dereverberation method based on auto-correlation function of framewise time series of each frequency component. Inverse filtering of source-microphone transfer functions is widely employed for suppressing the effects of reflected waves, but this method cannot be employed for cases where source-microphone transfer functions are not available or for time-variant cases. Several methods of spectral subtraction have been proposed to cope with these cases. However, most of them require transfer functions among sources and microphones. The proposed method, however, does not require transfer function inverse filters. Moreover, the method can handle frequency characteristics of sound paths. To realize dereverberation, it is necessary to estimate the delay time and frequency characteristics of reflection, though most conventional methods assume flat frequency characteristics. The proposed method estimates these parameters based on auto-correlation function of each time series of spectral components in frequency spectra obtained every frameshift interval. The proposed method improves dereverberation performance, comparing with methods that assume flat frequency characteristics. The proposed method raises average segmental SNR by 3.4 dB and reduces reverberation time from 390 to 109 ms for a room employed for experiments. [Work supported by Knowledge Cluster Project, MEXT, and by Academic Frontier Project Doshisha University.]

1pSP8. Sparseness-based 2ch blind source separation in reverberant environments based on direction-of-arrival estimation with a reliability measure. Yosuke Izumi, Nobutaka Ono, and Shigeki Sagayama (Dept. of Information Sci. and Technol., The Univ. of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo 113-8656, Japan, izumi@hil.t.u-tokyo.ac.jp)

We present a novel sparseness-based 2ch blind source separation (BSS) method based on robust direction-of-arrival (DOA) estimation that enables reasonable separation of source signals even in a highly reverberant environment. DOA estimation for BSS is not easy in reverberant environments since reflected sound waves behave as coherent interferences in the observed signals and make ambiguous the sound source direction. Our key idea to solve this problem is to find and integrate clean, reliable time-frequency fragments through the observation with a reliability measure. For that, (1) based on a diffused sound field model of reverberation, a theoretical correlation matrix is introduced for whitening the coherent interferences, (2) the DOA of each time-frequency bin is estimated with reliability by utilizing information of neighboring bins, and (3) the reliability-weighted DOAs are integrated over the whole time-frequency bins. After that, separated signals are obtained by time-frequency masking or inverse filtering. Experimental results including comparison with other methods are also reported.

1pSP9. Multilayered spatio-temporal gradient analysis for acoustic blind source separation. Kenbu Teramoto, Md. Tawhidul Islam Khan, Seiichirou Torisu, and Akito Uekihara (Saga Univ., 1-Honjo, Saga-shi, Japan, 8408502, tera@me.saga-u.ac.jp)

A novel blind source separation of a mixture of two or more voice signals has been proposed in the present paper. The separation system has been focused based on the spatio-temporal gradient analysis. The proposed algorithm utilizes the linearity among the signals: sound pressure of source signals, the three-dimensional (x, y, and z directional) particle velocity vector, and its gradient of the observed signals, all of which are governed by the equation of motion. Principally, as the mechanism of blind source separation uses no-*priori* information about the parameters of convolution, filtering as well as mixing of source signals, some simple assumptions such as the statistical independency of the linearly combined (mixed) observed signals containing zero mean as well as unit variance have been implied in the present separation algorithm. Therefore, the proposed method has successfully simplified the convoluted blind source separation problem into an instantaneous blind source separation problem over the spatio-temporal gradient spaces. An acoustic experiment with two female voices has been carried out to compare the simulated data as well. A eight-microphone array system has been adopted to evaluate the voice signals efficiently.

4:05

1pSP10. Study for blind source separation on time-frequency domain considering phase information. Fumio Sasaki, Masahito Yasuoka, and Osamu Tanaka (Dept. of Architecture, Tokyo Univ. of Sci., 1-3 Kagurazaka, Shinjuku-ku, Tokyo 1628601, Japan, fsasaki@rs.kagu.tus.ac.jp)

The methods that can be done for the estimation of the number of source signals and separation of source signals using time-frequency information are proposed as a method of blind source separation. In these methods, some independent conditions are assumed in a time-frequency domain, and observed signals are expanded to time-frequency domain using wavelet analysis. However, these methods are not considered phase differences (difference of distance) between source signals and observed signals. A new method is proposed. The method can be done not only for the source separation but also the specification of the locations of source signals considering phase differences. In this method, it is necessary to assume a rather stronger independent condition than former methods. But, on account of this assumption, a function that becomes a real value only when phase differences are coincidence in time-frequency domain is determined. Using this function, first of all, the number of source signals is calculated, then the locations of source signals and source signals are calculated. The effectiveness of the method is shown using actual synthetic signals.

4:20

1pSP11. Blind spatial subtraction array based on independent component analysis for speech enhancement and recognition. Yu Takahashi, Tomoya Takatani, Hiroshi Saruwatari, and Kiyohiro Shikano (Speech and Acoust. Processing Lab., Nara Inst. of Sci. and Technol., 8916-5 Takayama-cho, Ikoma-shi, Nara, 630-0192 Japan)

We propose a new blind spatial subtraction array (BSSA) that contains an accurate noise estimator based on independent component analysis (ICA) for the realization of noise-robust hands-free speech recognition. Many previous studies on ICA-based blind source separation often dealt with the special case of speech-speech mixing. However, such a sound mixing is not realistic under common acoustic conditions; the target speech can be approximated to a point source but real noises are often not point sources. Under the condition, our preliminary experiment suggests that the conventional ICA is proficient in the noise estimation rather than the direct speech estimation. Based on the above-mentioned findings, we propose a new noise reduction method that is implemented in subtracting the power spectrum of the estimated noise by ICA from the power spectrum of noise-contaminated observations. This architecture provides us a noise-estimation-error robust speech enhancement rather than a simple linear-filtering-based enhancement. Although nonlinear processing often generates an artificial distortion, the so-called musical noise, it is still applicable to the speech recognition system because the speech decoder is not so sensitive to such a distortion. Experimental results reveal that the proposed BSSA can improve the speech recognition rate by 20% compared with the conventional ICA.

1pSP12. Frequency-domain independent component analysis by overlap piecewise integration of separation processing. Tadashige Noguchi, Kenko Ota, Masuzo Yanagida (Doshisha Univ., 1-3 Tatara-Miyakodani, Kyotanabe, Kyoto, 610-0321 Japan, dtg0731@mail4.doshisha.ac.jp), and Leandro Di Persia (Universidad Nacional de Entre Ros Casa de la Universidad, Paran, Entre Ros, Argentina)

Conventional frequency-domain ICA yields the optimal separation for each frequency bin, but it suffers from the permutation problem. The authors have developed permutation-free ICA as a separation scheme by obtaining the separation matrix for a long vector consisting of temporal changes of all frequency components of the received signal. The permutation-free ICA, however, only yields a common separation matrix for all frequency bins. So, the separation matrix obtained in the permutation-free ICA has a common directivity pattern for all frequency bins, though the method can avoid the permutation problem. Proposed in this paper is a scheme of multibin ICA that deconvolves mixed signals into original source signals by shifting piecewise integration of a set of frequency bins consisting of the frequency bin in concern and neighboring frequency bins. The proposed method can yield nearly optimal directivity in the form of the separation matrix for each frequency bin, avoiding the permutation problem. Performance of multibin ICA is compared with those of conventional frequency-domain ICA and permutation-free ICA employing segmental SNR as an evaluation index. TUESDAY AFTERNOON, 28 NOVEMBER 2006　　　　　WAIALUA ROOM, 1:00 TO 5:35 P.M.

Session 1pUW

Underwater Acoustics: Array Processing, Sensors, and Technology

Paul Hursky, Cochair
Heat Light and Sound Research, 12730 High Bluff Dr., San Diego, CA 92130

Hiroyuki Hachiya, Cochair
Chiba Univ., Research Ctr. for Frontier Medical Engineering, 1-33 Yayoi-cho, Inake-ku, Chiba, 263-8522, Japan

Chair's Introduction—1:00

Contributed Papers

1:05

1pUW1. Acoustic seaglider. Bruce M. Howe (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698, howe@apl.washington.edu)

Continually improving acoustics measurements in the ocean is a *sine qua non* for the advancement of ocean acoustics and related fields. Acoustic sensors on mobile platforms will enable basic research topics on temporal and spatial coherence and the description of ambient noise, with direct impact on the applicability of coherent processing with its associated gain to signal detection and acoustic navigation and communications within the context of distributed undersea sensor networks. We describe the integration of acoustic receiving and communication capability in gliders with results from several recent field tests. [Work supported by the ONR.]

1:20

1pUW2. Single element synthetic aperture using an ocean glider. Georges A. Dossot, James H. Miller, Kristy A. Moore (Dept. of Ocean Eng., Univ. of Rhode Island, 217 Sheets Bldg., Narragansett Bay Campus, Narragansett, RI 02882, georges@oce.uri.edu), Steven E. Crocker (Naval Undersea Warfare Ctr., Newport, RI 02871), Jason D. Holmes (Boston Univ., Boston, MA 02215), and Scott Glenn (Rutgers Univeristy, NB, NJ 08901-8521)

The feasibility of using a single transducer element on an ocean glider to create a synthetic aperture is discussed. Acoustic data were collected on two Webb Slocum gliders deployed by Rutgers University during the Shallow Water Experiment (SW06) on the continental shelf off New Jersey. These gliders periodically surfaced for GPS fixes and data transfer via satellite phone. A synthetic aperture is created through coherent processing of the acoustic data as the glider travels through the water. A number of issues including changes in depth, nonsteady motion of the glider, and clock drift can limit the performance of the processing. However, the glider provides a low-noise and low-speed platform, potentially improving the signal-to-noise ratio. The geometry of the experiment provided for near-broadside recording of the 224- and 400-Hz WHOI tomography sources. An acoustic normal mode representation of the field provides the basis for processing of the data similar to the Hankel transform approach of Frisk and Lynch [J. Acoust. Soc. Am. **76**, 205–216 (1984)] and Holmes *et al.* [J. Acoust. Soc. Am. **119**, 3346 (2006)]. Effects of spatial variations in sound speed are examined. [Work sponsored by the Office of Naval Research.]

1:35

1pUW3. Processing data from a low-drag array towed by a glider. Paul Hursky, Michael B. Porter, Martin Siderius (Heat, Light, and Sound Res. Inc., 12730 High Bluff Dr., Ste. 130, San Diego, CA 92130), Vincent K. McDonald, Mark Gillcrist, Brian Granger, Ryan Jones, Aaron Bratten, Andy Huizinga, Peter T. Sullivan, and Susan G. Briest (Space and Naval Warfare Systems Ctr., San Diego, CA 92152)

Small underwater robotic vehicles such as gliders and AUVs have limited capabilities in terms of propulsion, speed, and power consumption, so it takes great care to design suitable sensor systems such as towed arrays for these platforms. Two such arrays were deployed during the Makai experiment, off the coast of Kauai in Hawaii. A 15-element line array with an acoustic aperture of 21 m was towed by a Webb Research Slocum glider. A 40-element line array with an acoustic aperture of 60 m was towed by a small work boat. We will describe the design and construction of these arrays and present results of processing data recorded on these arrays. We will also discuss potential applications for these arrays deployed from gliders and AUVs.

1pUW4. Synthetic stationary array processing for a towed array in maneuver. Yung Lee (Sci. Applications Intl. Corp., 1710 SAIC Dr., McLean VA 22102), William Lee (Duke Univ.), and Andrew Lee (MIT)

When long towed arrays undergo significant maneuvering, the array shape rapidly changes within a processing interval that degrades the array beamforming performance. Towed arrays are known to behave much like pulleys through the water. Thus, hydrophones on the towed array will closely follow the motion of the towed point through the water with a time lag relative to the towing speed. From this concept, it follows that, given an appropriate time alignment, a signal snapshot from the rear section of the array can be interpreted as a signal snapshot from the front section of the array at a later time. This synthetic stationary array processing (SSAP) divides the physical array into highly overlapping sequential segments and, using these segments, forms time-lagged snapshots of a stationary array. As a result, this synthetic stationary array has a reduced size and shape that is defined by the first array segment at the beginning of a processing interval. To demonstrate the effectiveness of this process, real towed array data collected from the MAPEX 2000 experiment conducted by SCALANTCEN were processed. The SSAP results successfully demonstrate processing improvements through turns. A few selected signal tracks were simulated to validate the performance of the SSAP processing.

1pUW5. Experimental results of a fast Fourier transform-based motion compensation of synthetic aperture sonar. Takao Sawa, Taro Aoki, Jyunichirou Tahara (Adv. Marine Technol. Program, JAMSTEC, 2-15 Natsuhima, Yokosuka, Kanagawa 2370061, Japan, sawa@jamstec.go.jp), Tomoo Kamakura, Ryouji Suzuki (Dept. of Elec. Eng., UEC), and Hitoshi Yamaguchi (Nagasaki Prefectural Inst. of Public Health and Environ. Sci.)

Synthetic aperture and its motion compensation technique became available in sonar systems owing to dramatic developments of computer performance. A bottom observation test with synthetic aperture sonar was carried out at the gulf of Katagami in November 2005. The sonar on a tow-fish had detected a bottom and floats at the test. Accelerations and angular velocities of the sonar system had been recorded with external sensors on the tow-fish, too. A relative position and attitude of sonar were calculated from recorded motion data, and a new motion compensation method based on FFT was applied to the synthetic aperture sonar algorithm. In this report, details and capacity of this new method are shown through these experimental results. Sonar images with this new compensation were better than a conventional compensation that uses full bandwidth of motion frequency. Moreover, images were improved by adjusting bandwidth. The authors would like to thank Takeshi Hamazone, a captain of the mother ship, for his maneuvering the ship even in bad weather.

1pUW6. Higher frequency matched-field processing. Claire Debever and William A. Kuperman (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., Mail Code 0238, La Jolla, CA 92093-0238, cdebever@ucsd.edu)

We study matched-field processing (MFP) in the 3.5-kHz shallow water regime at a range of 4 km for which MFP is typically problematic. Data are used to construct both the cross-spectral-density-matrix (CSDM) and the weight vectors for the Bartlett, minimum variance distortionless response (MV), and white noise constraint (WNC) processors. There is sufficient data to construct the weight vectors as a function of time as measured around the CSDM construction time. While the MV processor degrades significantly over a few minutes, the WNC processor remains stable for 15 min or longer. We study these experimentally derived weight vectors to further understand the origin of the increased stability of the WNC over the MV and to gain further insight into how to construct a robust MFP processor. [Work supported by ONR.]

1pUW7. Steering vector sensor array elements with cardioids, hippopedes, and other beam shapes. Kevin B. Smith (Dept. of Phys., Naval Postgrad. School, Monterey, CA 93943) and A. Vincent Van Leijen (Netherlands Defense Acad., Den Helder, Netherlands)

The purpose of this report is to study the impact on linear beamforming due to individual vector sensor element steering patterns. Standard, linear beamformers employ cardioid beampatterns for each vector sensor. In this work, we examine a class of vector sensor element steering patterns beyond the standard cardioid. The element weighting is nonlinear but nonadaptive, making it simple to implement in hardware processing. The new sensor steering patterns, referred to as hippioids, are products of cardioids and various orders of hippopedes. The angular resolution of individual sensors, and the impact on angular resolution from arrays of varying aperture, will serve as the performance measure along with peak-to-sidelobe levels. An example of the differences in vector sensor steering patterns is provided using measured, DIFAR buoy data. [Work supported by the Office of Naval Research, Code 321OA, the Naval Postgraduate School, and the Netherlands Defense Academy.]

1pUW8. Wideband acoustic communication using quadrature-phase shift keying and eight-phase shift keying. Hiroshi Ochi, Yoshitaka Watanabe, and Takuya Shimura (Marine Technol. Ctr., JAMSTEC, 2-15 Natsushima-cho, Yokosuka, 237-0061 Japan, ochi@jamstec.go.jp)

In JAMSTEC, a short-range (up to 500 m) high-speed acoustic communication system for deep sea environment has been investigating. To widen a bandwidth, the new wideband projector was developed. It consists of two transducer elements and has a toroidal beam pattern. To reduce the acoustic radiation pattern of the rear side, the unit, which is like a lampshade, was attached to that projector. Moreover, the beam axis is tilted to the upper side by delayed input signal to the upper transducer element. When this projector is used in the vicinity of the sea bottom, a bottom-reflected wave can be reduced. Carrier frequency of this projector is 80 kHz, and its bandwidth is 40 kHz. The experiment was carried out at the depth of 1000-m area using this projector. Two omni-directional hydrophones were used for receiving. Quadrature phase shift keying (Q-PSK) and 8-PSK were used as its modulation method. The data of several transmission speeds [10 k symbol per second (sps), 12.5, 16, 20, 25, and 40 ksps] were obtained at the transmission range of 200–230 m. Under those conditions, error free communication was carried out for 60 000 bits of data.

1pUW9. The study on data transmission with short positioning pulse in deep sea. Yoshitaka Watanabe, Hiroshi Ochi, and Takuya Shimura (Japan Agency for Marine-Earth Sci. and Technol., 2-15, Natsushima-cho, Yokosuka-shi, Kanagawa pref, Japan, yoshitakaw@jamstec.go.jp)

The ultra short base line (USBL) underwater acoustic positioning in deep sea with digital data transmission is being studied. The goal of this study is improvement of the accuracy and expansion of the functions of the USBL for autonomous underwater vehicles (AUVs) and submersibles due to utilization of the transmitted data. To achieve the goal, the reliable data transmission with short positioning pulse must be ensured. The direct sequence spread spectrum (DSSS) is applied. The frequency band width of signal is 3 kHz with a center focus on 12 kHz for the deep sea use. From the ocean experimental data, it seems that the multipaths from the neighborhood have a dominant effect on the transmission quality. The results of investigation about this matter by experiments and simulations are shown. [This study is supported by a Grants-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology in Japan.]

3:35

1pUW10. Development of a digital 3-D SBL underwater positioning system combined with GNSS compass. Yoshinori Miyamoto, Masahiko Furusawa, Keiichi Uchida, Toshikazu Motoyoshi (Tokyo Univ. of Marine Sci. and Technol., miyamoto@s.kaiyodai.ac.jp), Toshihiro Yamaguchi, Katuji Miwa (Koden Electron. Co., Ltd.), and Toshiharu Kakihara (Tokyo Univ. of Marine Sci. and Technol.)

A highly digitized underwater positioning system using the SBL method was developed. This system can measure highly accurate three-dimensional positions of marine organisms equipped with an ultrasonic transmitter (pinger). This system is combined with a GNSS (GPS) compass that measures the bearing, the location (latitude and longitude), and the commotion (rolling angle and pitching angle) of a boat or a buoy. Then the pinger positions are compensated for the commotion and are translated into the underwater absolute positions. The four arbitrary frequencies of the pingers are received by four wideband hydrophones. The received signals are immediately AD converted in high speed and processed by the quadrature detection and the digital filtering with a bandwidth of 3 kHz using FPGA. Finally, the receiving time differences are measured by the cross correlation, realizing a resolution of 0.01 ms. A position measurement experiment was performed in a water tank (length 15 m, width 10 m, depth 10 m), changing the position of a pinger, and it is confirmed that almost the expected accuracy could be realized. Moreover, this system was installed in a boat and the absolute positions of a fish were pursued to confirm the practicality.

1pUW11. Continued Haro Strait path data processing. A. Tolstoy (ATolstoy Sci., 1538 Hampton Hill Circle, McLean, VA 22101) and Z.-H. Michalopoulou (NJIT, Newark, NJ)

Previous efforts have led to the estimation of candidate source-array (S-R) geometries for some Haro Strait data. In particular, nw014 (one broadband shot to the NW array) has been extensively analyzed with the result that source range, source depth, array phone localizations, water depth at the source (D1), and water depth at the array (D2) can now be restricted to sets based on the time-domain data alone, i.e., on the signal boundary reflections. Most recent efforts include FFTs of the data followed by MFP geoacoustic inversion at multiple high frequencies (480–520 Hz)—using the restricted sets—in order to estimate array depths and shapes as well as some of the bottom properties for the nw014 data. Array shape and phone localizations are extremely important but difficult to attain. This presentation will describe these new efforts.

4:05

1pUW12. Near-orthogonal signals. John Piper (NSWC-PC, 110 Vernon Ave., Panama City, FL 32407)

A least-squares approach was used to construct near-orthogonal signals that can be useful in sonar applications. For the matched-filter case the solution can be written with Lagrange multiplier terms, which reduces to a simple eigenvector problem. Decoding filters are also examined, and these results are compared to the matched-filter case.

4:20

1pUW13. Wave front design by acoustic contrast control. Joung-Woo Choi and Yang-Hann Kim (Ctr. for Noise and Vib. Control(NOVIC), 4114 ME Dept., KAIST, Sci. Town, Daejeon, Korea, jungwoochoi@gmail.com)

A way to design and generate desired wave fronts using multiple sound sources is proposed. In principle, any kind of wave front can be described as a sum of orthogonal basis functions, and the wave front of a specific shape can be generated by focusing multiple sources' energy on a single basis function. Once the sound field is decomposed into a set of orthogonal functions, we can apply a conventional focusing algorithm to generate a desired wave front. Extending the concept of energy focusing, we can also generate a wave front packet, whose energy is concentrated on a group of orthogonal functions rather than single component. This enables us to generate a wave front within a desired bound. For this purpose, we employ acoustic contrast control, which focuses sound energy on a selected group of orthogonal functions by enhancing the energy difference between the focal region and others. Various example cases demonstrate how the proposed method can generate a group of planar and spherical wave fronts propagating to different directions. [Work supported by the NRL project of KISTEP and BK21 project initiated by Ministry of Education and Human Resources Development of Korea.]

1pUW14. Predicted versus measured sensitivities of fiber-optic sensors. Fred C. DeMetz, Sr. (Sabeus, Inc., 26610 Agoura Rd., #100, Calabasas, CA 91302)

Fiber-optic sensors are finding wide use in underwater and seismic applications due to their ease of construction, wide useful acoustic bandwidth, sensor deployment ranges from the light source of 10 km or more, robust temperature and static pressure tolerance, and immunity from requiring supporting electronics near the measurement points. The theoretical sensitivity for a number of optical sensor designs are compared with experimental data. Their signal-to-noise performance is assessed from the standpoint of minimum detectable signal, environmental background, and optical noise source.

4:50

1pUW15. Fiber optic interferometric hydrophone based on fiber Bragg grating with polarization diversity receiver. Chiaki Okawara and Kenji Saijyou (5th Res. Ctr., Tech. R&D Inst., Japan Defense Agency, 3-13-1 Nagase, Yokosuka, Kanagawa, 239-0826 Japan)

The objective of this work is to overcome polarization-induced signal fading (PSF) that occurs in fiber optic interferometric hydrophones based on fiber Bragg grating (FBG). The use of FBGs as reflectors in fiber optic interferometric hydrophones would greatly simplify the construction of the devices' wet-end portion by eliminating couplers, joints, and other connections that are required for other types of fiber optic interferometric hydrophones. Unfortunately, the visibility of the interference signal is reduced by PSF, and the demodulated signal is contaminated greatly by the phase noise. A polarization diversity receiver (PDR) is therefore applied to reduce the PSF influence. We developed a prototype of fiber optic interferometric hydrophone based on FBG with the PDR and demodulate an acoustic signal to confirm the effectiveness of the PDR application. Experimental results described here show that the phase noise is suppressed by selecting an optimum port that has high visibility. Consequently, the effectiveness of the application of the PDR is confirmed.

5:05

1pUW16. A new optical-fiber-based underwater sensor. Francois M. Guillot, D. H. Trivett, and Peter H. Rogers (George W. Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405)

A new type of underwater sensor based on optical fiber Bragg gratings is presented. This transducer can be used in a dipole or a quadrupole (shear sensor) configuration. The sensing principle of the device relies on the interference signal from two Bragg gratings written on the same fiber and illuminated by a tunable, narrow-band light source. The gratings are 5 cm apart, and they each reflect a portion of the incident light. The fiber is epoxied to two spacers separated by a 1-mm gap situated between the gratings. This assembly is then adhered to two plates connected by a hinge, which is located below the gap. One plate is held rigidly and the tip of the other (free) plate experiences transverse vibrations, when ensonified. These vibrations produce periodic gap length changes, which modulate the interference signal from the two gratings. The modulation is related to the amplitude of the sound wave and is monitored with a photodetector. Design optimization to increase the sensitivity and to reduce the noise floor is discussed, and the performance of a practical sensor is presented. [Work supported by ONR.]

1pUW17. Development of an acoustic cloud condensation nuclei counter. Marcellin Zahui, Abhijit Deshpande, and David Delene (Univ. of North Dakota, Grand Forks, ND)

Theoretical development of an acoustic cloud condensation nuclei counter is presented. The proposed instrument will be able to count the number of aerosols present in a sample of air flowing through a growth chamber. The air condenses around aerosols and forms water droplets. The number of aerosols is determined by measuring the sound produced underwater by these droplets when the droplets strike a water surface at the bottom of the growth chamber with an impact velocity equal to either their terminal or maximum velocities. First, the terminal velocities of the droplets are calculated. Then, the maximum velocities that these droplets can sustain without breaking are calculated as a function of droplet diameter. Second, the sound due to droplet impact is estimated and experimentally verified. In this study the bubble sound is not considered because micro droplets falling with terminal velocities do not create bubbles. Also, when accelerated, the velocities are limited such that there is no bubble formation at impact. Finally, two approaches are considered for the instrument. One case uses one hydrophone to measure the total sound radiated by all the droplets. The other case is based on a grid of tiny hydrophones, each measuring a droplet impact sound.

Architectural Acoustics: Acoustics of Large Indoor and Outdoor Performance Spaces I

Daniel R. Raichel, Cochair
2727 Moore Ln., Fort Collins, CO 80526

Toshiki Hanyu, Cochair
Nihon Univ., Narashinodai, Funabashi, Chiba 274-8501, Japan

Chair's Introduction—7:30

Invited Papers

7:35

2aAA1. Differences in dealing with the acoustics of large outdoor and indoor listening spaces. Daniel R. Raichel (Eilar Assoc. and the Graduate Ctr., CUNY, 2727 Moore Ln., Fort Collins, CO 80526, draichel@comcast.net)

It was perhaps fortuitous that Wallace Clement Sabine's first consulting assignment from the Harvard Board of Overseers, the execution of which proved to be seminal in the history of architectural acoustics, entailed an indoor facility. The problems of dealing with outdoor performance areas are considerably greater than those encountered in indoor spaces. Indoor spaces provide surface reflections and absorption of sound, both of which can be manipulated through proper design to yield the desired results with respect to reverberation time and sound dispersion. In the case of outdoor performing areas, there are no reflective surfaces (except in the cases of certain amphitheaters), and the need for sound amplification is often necessitated. A reflective bandshell is generally required to direct the program material toward the audience. The lack of wall reflections tends to result in a lack of musical sonority that is usually present in a well-designed indoor auditorium. A number of specific problems with interior and outdoor spaces and modern approaches toward resolving acoustical problems of large listening areas will be discussed.

7:55

2aAA2. Prediction of reverberation by stochastic processes in a forest: Creation of reverberation in an outdoor performance space. Toshiki Hanyu and Katsuaki Sekiguchi (Nihon Univ., Narashinodai, Funabashi, 274-8501, Chiba, Japan, hanyu@arch.jcn.nihon-u.ac.jp)

A forest is an outdoor space. For that reason, reverberation formulas of indoor spaces cannot be used when predicting forest reverberation. As a matter of fact, because the level decay curve of the reverberant sound produced in a forest is nonlinear, the concept of reverberation time is inapplicable. We clarified that reverberation of a forest is expressible as a Wiener process (Brownian motion), which is a stochastic process, and we derived the formula of reverberation of a forest based on that fact. In this study, Monte Carlo simulation was also carried out. Results clarified the following. (1) The energy decay curve of the reverberation sound of a forest becomes a straight line on the logarithmic scale of time and energy; its line gradient is -2. (2) At a point far from a sound source, the reverberant sound energy increases first and begins to decrease after some period. (3) When the mean-free path is short, the sound level of reverberation becomes high. Furthermore, we devised some methods of generating reverberation in outdoor space using the forest reverberation mechanism. For example, a proposed reverberation wall can produce reverberations using only one wall incorporating sound scatterers.

8:15

2aAA3. Large outdoor performance venues: Acoustical lessons learned. William J. Cavanaugh and K. Anthony Hoover (327F Boston Post Rd., Sudbury, MA 01776)

The Tweeter Center for the Performing Arts (formerly Great Woods) in Mansfield, MA, off Interstate 495, midway between Boston and Providence, accommodates 19 900 patrons and offers 75 to 85 performances each year between 15 May and 15 October. The Pittsburgh Symphony Orchestra inaugurated Tweeter Center's first concert season in June 1986, and The Center hosted the PSO as its summer home for three additional seasons. The Center has hosted performances from solo comedians to symphonic orchestras and rock bands, featuring such diverse acts as the Boston Pops, James Taylor, Phish, and The Kinks. The acoustical lessons learned over two decades of operation are described. The Center has served as a model for the design and operation of facilities in the 20 000-capacity range, including the often difficult issues of controlling excessive amplified sound transmission to residential neighbors, as well as assuring good listening conditions for patrons and performers alike.

2aAA4. Design of public address system for emergency evacuation in a tunnel. Sakae Yokoyama, Hideki Tachibana (Chiba Inst. of Technol., 2-17-1 Tsudanuma, Narashino-city, Chiba, 275-0016, Japan, sakae@iis.u-tokyo.ac.jp), Shinichi Sakamoto (Univ. of Tokyo, Meguro-ku, Tokyo, 153-8505, Japan), and Seiya Tazawa (Metropolitan Expressway Co. Ltd., Chiyoda-ku, Tokyo, 100-8930, Japan)

As a means to improve speech intelligibility of a public address PA system for emergency evacuation announcement in a tunnel, the authors have been investigating the application of the successive time-delay technique and have performed the experiments in an actual tunnel. In the experiments, the effect of the technique has been examined by comparing the difference of speech intelligibility between the conditions with/without time delay. For the design of the PA system in a reverberant tunnel, four kinds of psycho-acoustical experiments on speech intelligibility were performed in an anechoic room using the six-channel recording/reproduction technique and the following results have been obtained: (1) the successive time-delay technique is very effective to improve the speech intelligibility in a tunnel, (2) the system is considerably robust against the error in the delay time, (3) the speech intelligibility improves with the increase of the speech-rate but it should be suitable for such a tense situation as fire emergency, and (4) in order to further improve the speech intelligibility, it is necessary to control the reverberation in the tunnel by any sound absorption treatment. In this paper, the outline of the field experiment and the results of subjective experiments are introduced.

8:55

2aAA5. The Jay Pritzker Music Pavilion at Millennium Park, part 1: Design and construction. Richard Talaske (TALASKE, 105 N. Oak Park Ave., Oak Park, IL 60301)

The acoustic and audio system design for the Pritzker Pavilion represents a leap forward in the outdoor listening experience. The venue offers superior sound experiences to audiences of 11 000 using audio reinforcement and acoustic enhancement systems to support all types of musical performances, particularly for the resident Grant Park Music Festival orchestra. With reliance on the audio systems to project and envelop the audience in sound, the design of the stage enclosure was able to focus on the acoustic quality for the ensemble, a rare opportunity in outdoor facilities. The stage enclosure design includes variable acoustic devices and has an emphasis on intraensemble communication. This presentation will discuss the design of the stage enclosure, the trellis-supported audio systems, and the ways in which the facility is used by resident and visiting musical performers.

9:15

2aAA6. The Jay Pritzker Music Pavilion at Millennium Park, part 2: Research and testing. Gregory Miller, Richard Talaske, Byron Harrison, Evelyn Way (TALASKE, 105 N. Oak Park Ave., Oak Park, IL 60301), Lily Wang, David Bradley, and Craig Johnson (Univ. of Nebraska-Lincoln, Omaha, NE 68182-0681)

The design of the Pritzker Pavilion includes a number of innovative acoustic and audio elements. Two of these elements, the resilient orchestra riser system and the acoustic enhancement system, will be discussed in this presentation. Research previously presented to the ASA [Hoffman *et.al.*, 141st meeting of the ASA) was used in the design of the orchestra riser system at the Pritzker Pavilion. This presentation discusses the field tests that were conducted to assess vibration transfer across the surface of the riser system. Comparison is made to previous research and anticipated results. Subjective evaluations by orchestra members will also be discussed. The acoustic enhancement system is a specialized audio system, separate from the main reinforcement audio system, based on LARES digital signal processing and a distributed loudspeaker approach. Different settings have been developed over time to provide varying decay signatures that are employed on a music-program-dependent basis. Impulse response measurements were taken of unamplified sound, the reinforcement system, and the combination of the reinforcement system with the enhancement system. Testing was conducted with faculty and students from the University of Nebraska.

9:35

2aAA7. Acoustical design of the "Tenseishinbikai Hakko Shinden" Shrine in Shiga. Masayuki Ikegami (Dept. of Acoust Eng., Tech. Res. Inst., Obayashi Corp., 4-640 Simokiyoto, Kiyose City, Tokyo 208-8558, Japan)

A shrine called the "Tenseishinbikai Hakko Shinden" was designed and constructed. It covers a large area and has seating for 3690 people. It is used mainly for religious ceremonies and occasionally for concerts. This report outlines its acoustical design and noise control measures. The acoustics design specifically addressed reverberation control appropriate for its use, in addition to echo-nuisance prevention. The flat fan shape of the building often engenders insufficient initial sound reflection and generates echoes. To avoid these problems, in consultation with the designer, an irregular reflective surface was used for the side walls, a rib-shaped acoustic absorption surface, and a folding-screen shaped diffusion surface was used for the rear wall. In addition to conventional machine room noise control, particular attention had to be devoted to glass walls, rain noise, etc. For the glass walls, the effects on the outside (sound generated in the event room) and the effects on the inside (outdoor traffic noise) had to be controlled. To control rain noise, the sound generated by rain on the metal roof had to be predicted; a suitable roof material was selected.

9:55

2aAA8. Sound around the New England Patriots' stadia. Anthony K. Hoover, Andrew Carballeira, and Matthew Moore (Cavanaugh Tocci Assoc., Inc., 327 F Boston Post Rd., Sudbury, MA 01776)

The New England Patriots wanted to build a new football stadium in Foxboro, MA, adjacent to the old one which would be demolished after the new one was opened. The Environmental Impact Statement (EIS) indicated that one benefit would be a 3.34-dB reduction of stadium noise at the nearest town line because the distance would increase by 980 ft. A procedure to test the resultant noise reduction was developed with keen interest from the Massachusetts Department of Environmental Protection. Touring rock

concert sound systems would output high levels of pink noise, twice during sound-checks in the old stadium and then twice in the new stadium; resultant levels would be measured at several locations around the old stadium and then again around the new stadium. This paper will summarize the results of the measurements and will discuss interesting aspects of a test procedure designed by committee, including the importance of declining to be responsible for certain expectations of an EIS.

2aAA9. Sound system design for acoustically challenging spaces.   Akira Mochimaru and Soichiro Hayashi   (Bose K.K., 28-3-Maruyama-Cho, Shibuya YT Bldg., Shibuya-Ku, Tokyo, Japan)

Sound reinforcement (SR) systems take a critical part in controlling acoustic performance in large venues. Loudspeaker system design including consideration of room acoustics becomes crucial in providing audio information with good intelligibility and natural tonal balance throughout the audience area. There are many elements that can spoil acoustic performance of the sound system in large spaces. Relatively long reverberation time, number of speaker clusters with distances in between, size of each speaker cluster that creates unexpected phase cancellations and so on. Neither the single speaker product nor sound system design based on experiences can provide a perfect solution for these kinds of spaces. On the other hand, an advanced acoustic simulation system including consideration of relative phase between sound sources with capability of listening to the simulated results is now available. By using this technology with academically proven accuracy, speaker array design methodology called bass-array was produced. Bass-array allows the sound system designer to control radiation directivity characteristics of low frequency. Design of custom line-array to suit room configuration of the space is another deliverable of the technology. This technology in association with bass-array or line-array has been successfully applied for providing appropriate acoustic solutions in a number of acoustically difficult spaces.

10:55

2aAA10. Recording in an outdoor performance space.   Pamela Harght   (Berklee College of Music, 150 Massachusetts Ave., Boston, MA 02115)

For both audio engineers and musicians, dealing with indoor and outdoor spaces poses several types of problems for recording and performance purposes. While recording indoors poses many problems, most of them (pertaining to room design, ventilation, placement of musicians) are controllable. However, dealing with outdoor spaces creates many issues entailing uncontrollable situations, specifically those entailing the environment. During the summer of 2006, the author spent 8 weeks at the Tanglewood Music Center in Lenox, MA on an audio engineering fellowship. Tanglewood is the summer home for the Boston Symphony Orchestra; it has both an outdoor performance space and a concert hall that opens for additional lawn seating. This paper discusses and compares the many issues of recording classical music outdoors as well as indoors, based upon experience, research, and interviews with musicians and members of the audio department.

11:15

2aAA11. Acoustics for the one percenter.   Scott Pfeiffer   (Threshold Acoust. LLC, 954 West Washington, 5th Fl., Chicago, IL 60607)

GMC adopted the one percenter from outlaw bikers who took pride in identifying themselves as the 1% of bikers that were making a bad name for the rest of the 99% that were law abiding. GMC and the outlaw bikers had the right idea. We all like to identify ourselves with the few, the proud, those that appreciate the special, the esoteric, the pursuit of greatness. Large venue projects present a special challenge to reaching these goals as the issues of getting 5000 or more people in and out begins to drive the design, natural acoustics become challenging or impossible, and the distribution of audio and video begins to depend on delay clusters and secondary distribution, which all begin as compromises. Doubt enters as the question is raised of how many patrons will notice. It is in these moments when finding the design that serves the one percenter makes all of the difference. Special examples of one percenters will be presented as a retrospective of large venues honoring the most successful projects in this type.

11:35

2aAA12. Improving sound qualities at the seats under deep balcony overhangs.   Wei-hwa Chiang, Wei Lin, and Kun-tai Wu (Dept. of Architecture, Natl. Taiwan Univ. of Sci. and Technol., #43, Sec.4, Keelung Rd., Taipei, 106, Taiwan, edchiang1224@hotmail.com)

Source-receiver distances in a large hall could be reduced by increasing the balcony overhangs, which, however, may cause insufficient acoustical energy for the under-balcony seats. Besides, the reduction in the sense of reverberation cannot be easily mitigated. In this research various design strategies, including utilizing the technique of a flying balcony, were examined in a 1550-seat hall with deep balcony overhangs. Both BEM simulation and scale model measurements were performed. Optimizing the profile of the under-balcony space and utilizing ceiling and side reflectors near the platform were effective in enhancing early reflection. This is especially meaningful for high-frequency string sounds that radiate against the ceiling. Opening the rear part of the balcony that formed a partially flying balcony could compensate late reflections. Preliminary scale modeling results showed that approximately 15% increase in early decay time can be achieved with carefully designed ceiling geometry when the opening area was only 7% of the overhang area.

2aAB1. A tribute to Art Myrberg. John H. Stadler (Natl. Marine Fisheries Service, 801 Lilly Rd. NE, Lacey, WA 98503) and Samuel L. Gruber (Univ. of Miami, Miami, FL 33149)

Arthur A. Myrberg, Jr. passed away in April, 2005, and will be remembered by many as a pioneer in the fields of fish bioacoustics and behavior. His distinguished career spanned more than 40 years, and saw him become a world-recognized expert in these fields, publishing more than 90 peer-reviewed articles, some of which are considered seminal. During more than 35 years as a professor of Marine Science at the Rosenstiel School of Marine and Atmospheric Sciences, University of Miami, he was a well-respected and admired scientist, teacher, lecturer, mentor, and advisor to 24 graduate students. This presentation will trace Art's life from his days as a youth in Lulenecks, Illinois, through his college career and his work with Nobel laureate Konrad Lorenz at the Max Planck Institute, Seiweisen, Germany, culminating in his long career at the University of Miami.

8:25

2aAB2. A history of fish bioacoustic studies. Arthur N. Popper (Dept. of Biol., Univ. of Maryland, College Park, MD 20742, apopper@umd.edu), Richard R. Fay (Loyola Univ. of Chicago, Chicago, IL 60626), and William N. Tavolga (Mote Marine Lab., Sarasota, FL 34236)

Interest in fish sound production and hearing dates back to the writings of Aristotle (384–322 BCE) and Pliny the Elder (23–79 CE), both of whom noted not only that fish make sounds, but also speculated that fish must be able to hear despite their not having apparent ears. The fact that fish could hear was first demonstrated with the work of G. H. Parker in 1903 and later by Karl von Frisch. Studies on sound production were sporadic in the early part of the 20th century and often based on anecdotes until technology derived from antisubmarine warfare became available after World War II. This equipment enabled investigators to listen to fish and correlate sounds with behavior. It was not until the early 1960s that intensive investigations started on fish hearing. This paper will review the history of the study of fish bioacoustics and discuss the contributions of a large number of investigators including those of Arthur Myrberg. Indeed, Art's research stands as a landmark in the field, as well as a fine example of true scholarship. Furthermore, his charismatic presentations of his work were instrumental in stimulating the investigations of other scientists.

8:45

2aAB3. Art Myrberg's contribution to the study of hearing in fishes. Richard R. Fay (Parmly Hearing Inst. and Dept. of Psych., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626, rfay@luc.edu)

Art Myrberg was trained to study behavior from an ethological perspective. When it came to studying the hearing of the vocal and communicating damselfish species of the genus *Eupomacentrus*, he surprisingly decided to use conditioning methods in combination with the best technology then known to produce an excellently designed animal psychoacoustic (laboratory) study that remains today, 26 years later, an exemplary model for students in this field [A. A. Myrberg and J. Y. Spires, J. Comp. Physiol. **140**, 135–144 (1980)]. First, Myrberg well understood that sensitivity to acoustic particle motion was possible for these species, so he produced or simulated sound in the far, free field using a long tube with sound absorbers at the opposite end, and measured both sound pressure and acoustic particle motion. He documented that *Eupomacentrus* was sensitive to particle motion at 100 Hz, but was sound-pressure-sensitive at higher frequencies. He also understood that ambient noise was an important issue in hearing studies, and he did all that he could to measure and reduce it. The result was a "V"-shaped audiogram with greatest sensitivity at 500 Hz, and almost no interspecific variation. We can have great confidence in these audiograms today as valid measurements of hearing ability.

9:05

2aAB4. Art Myrberg's contributions to fish acoustic communication. Michael L. Fine (Dept. Biol., Virginia Commonwealth Univ., Richmond, VA 23284-2012)

Arthur Myrberg was an ichthyologist and ethologist who trained with the Nobel laureate Konrad Lorenz. Art's work exceeded the boundaries of communication (a signal produced by an animal for its own benefit) to include related phenomena such as acoustic attraction and repulsion of sharks, effects of noise, and the creation of the term interception to describe a communication signal picked

up (e.g., intercepted) by another receiver for its own benefit. His work included a wide range of species (sharks, surgeonfish, damselfish, cichlids, gobies, and even invertebrates and marine mammals). He worked at sea and utilized diving for observation and experimental manipulation and then set up lab colonies for further observation and experimentation. What is perhaps his signal contribution to acoustic communication followed this paradigm in an investigation in four related *Eupomacentrus* species that produce similar chirps during a courtship dip. By playbacks of natural and altered sounds he and his students separated the subtle cues used by these fishes to permit intraspecific communication. This rather dry abstract fails to capture Art's love of science, his ability to make outstanding presentations, and my value of his friendship.

9:25

2aAB5. Recent advances in fish acoustic behavior. Timothy Tricas (Dept. of Zoology and Hawaii Inst. of Marine Biol., Univ. of Hawaii at Manoa, Honolulu, HI 96822, tricas@hawaii.edu)

Sounds produced by fish provide important signals or cues in many behavioral contexts. Mechanisms of sound production are diverse and best described in fishes with specialized anatomical structures, but remain tentative for many species. The coproduction of low-frequency hydrodynamic and acoustic stimuli during behavioral interactions can excite the inner ear, lateral line, or both to provide complex acoustico-lateralis information. Recent behavior studies show that acoustic signals function in behavioral displays of aggression, species recognition, courtship, mate attraction, and spawning; in some cases it can function as a single modality signal. Sound stimuli often overlap with the hearing band of highest sensitivity (100–1000 Hz for most species), but in some species these do not match. Much data now exist on the diversity of sounds produced by fishes and environmental acoustic cues, but more evaluation is needed within the context of the animals natural environment. Examples include acoustic cues for recruitment of pelagic fish larvae to reefs, use of ultrasound to avoid predators, and infrasound stimuli. Comparative work on both sound production and sensory reception in fishes can be assessed in relation to their ecology to better understand the evolution of fish acoustic behavior.

9:45

2aAB6. Lateral line research: Recent advances and new opportunities. Sheryl Coombs (Dept. of Biological Sci., Bowling Green State Univ., Bowling Green, OH 43403) and Horst Bleckmann (Univ. of Bonn, 53115 Bonn, Germany)

Computational fluid dynamics, digital particle imaging velocimetry, and engineered micro flow sensors, along with emerging collaborations between neurobiologists and engineers, have opened up new vistas for lateral line research in recent years. Engineering advances have increased our ability to measure the spatiotemporal characteristics of biologically significant, more complex flow signals and how these signals are sensed and processed by the lateral line. Following in the rich tradition of Art Myrberg's work on sound communication in fishes, studies on hydrodynamic signal production and use by fish during interactive social behaviors are now feasible. In addition to these new opportunities, several recent studies have enriched the lateral line landscape. The lateral line sensing and encoding of vortex trails shed by swimming fish or obstacles in a stream have been investigated, along with associated behaviors (e.g., vortex trail following and obstacle entrainment). Blind Mexican cavefish have been shown to form cognitive maps of their surroundings using lateral-line based, hydrodynamic cues. Finally, the responses of goldfish auditory and lateral line systems to the same stimulus source have been documented to reveal how these two closely related systems might work in concert to extract complementary but different types of information from nearby hydroacoustic sources.

2aAB7. Year-round changes of ambient noise in freshwater habitats and temperature effects on hearing in fishes. Sonja Amoser and Friedrich Ladich (Dept. of Neurobiology and Behavioral Sci., Univ. of Vienna, Althanstr. 14, 1090 Vienna, Austria)

Fish get crucial information for their survival from their acoustic environment. Therefore, changes in ambient noise as well as temperature over the year potentially impose great challenges for fishes, especially in freshwater habitats in temperate climates. Noise levels vary more in stagnant habitats such as lakes, backwaters, and streams than in large rivers. The spectral profiles change in stagnant habitats due to biotic noise sources in summer (e.g., stridulating insects), whereas in small streams spectral composition differs due to small changes in water volume, e.g., after snow melt. To investigate possible seasonal effects on fishes, we studied the hearing capabilities of a hearing specialist (Common carp) and a hearing nonspecialist (European perch) at two different temperatures (12 °C and 22 °C) using the AEP recording technique. In the carp the hearing sensitivity decreased up to 12 dB (mean decrease: 4 dB) at 12 °C, whereas no such change was observed in the perch. Latencies of auditory evoked potentials became longer by approximately 0.8 ms at lower temperatures in the carp. The results indicate that auditory sensitivity in hearing specialists is affected by changes in temperature as well as ambient noise throughout the year. [Work supported by FWF.]

2aAB8. The influence of ambient temperature and thermal acclimation on hearing in an eurythermal hearing specialized fish. Lidia E. Wysocki and Arthur N. Popper (Dept. of Biol., Univ. of Maryland, College Park, MD 20742, lwysocki@umd.edu)

Many fish species live in habitats whose water temperature underlies seasonal and diurnal fluctuations. Being ectothermic animals, their body temperature depends on the temperature of the ambient water. Since the speed of all metabolic processes depends on body temperature, the ambient temperature might affect various physiological processes including all sensory systems. However, the maintenance of sensory functions in a changing environment can be crucial for an animal's survival. Several fish species strongly rely on their auditory abilities for acoustic orientation, communication, detecting predators and prey, and finding mates. Channel catfish (*Ictalurus punctatus*) was chosen as a model for an eurytherm species with a relatively high hearing sensitivity and bandwidth to investigate the influence of ambient temperature and thermal acclimation on the auditory system. Hearing sensitivity was measured at different water temperatures to which the animals were either unacclimated or acclimated by recording auditory-evoked potentials. The ambient water temperature significantly influenced hearing thresholds and the shape of the auditory-evoked potentials, especially at higher frequencies. Hearing sensitivity remained decreased at low water temperatures even after an acclimation period of one month, indicating that certain physical limits on sensory processes cannot be compensated for by thermal acclimation.

10:50

2aAB9. Investigating hearing in sturgeon: Getting closer to the origin of hearing in vertebrates. Michaela Meyer, Arthur N. Popper (Dept. of Biol., Univ. of Maryland, College Park, MD 20742), and Richard R. Fay (Loyola Univ. of Chicago, Chicago, IL 60626)

It has been hypothesized that hearing arose early in vertebrate evolution to use sound to glean information about the environment, including the presence of predators and prey. The importance of sound to sense the acoustic scene is especially true underwater where the visual horizon is limited. To create an acoustic scene from sound, an animal needs to localize and identify sound sources. We hypothesize that the sound localization capabilities of primitive bony fishes such as sturgeon are as capable as those of modern bony fishes such as goldfish and, perhaps, many terrestrial vertebrates. We present results from experiments investigating the neural mechanisms of directional hearing and frequency analysis in the auditory periphery of the sturgeon. Extracellular single units were recorded from the eighth nerve during stimulation with a three-axis shaker system that subjects the fish ear to linear accelerations in known directions at various frequencies. This system enables the characterization of both spatial and frequency tuning of the afferents innervating the ear. The results show that similar neural mechanisms for encoding sound direction and frequency exist in the periphery of modern and primitive bony fish, thereby supporting the hypothesis that basic auditory functions arose very early in vertebrate history.

11:05

2aAB10. Recent advances in the fish auditory efferent system. Zhongmin Lu (Dept. of Biol., Univ. of Miami, 1301 Memorial Dr., Coral Gables, FL 33146, zlu@miami.edu) and Seth Tomchik (Univ. of Miami, Miami, FL 33101)

The octavolateral efferent neurons in fish project axons to innervate the ear and lateral line organs. However, the function of the octavolateral efferent system is not well understood. This review focuses on recent progress in structure and function of octavolateral efferent system in a teleost, the sleeper goby (*Dormitator latifrons*). The sleeper goby has a single octavolateral efferent nucleus that is composed of about 19 large, densely packed somata in the medulla. Most efferent neurons have bilateral dendrites and single axons innervating ipsilateral peripheral octavolateral organs. The efferent neurons have distinctive characteristics of frequency, temporal, directional, and dynamic responses, which differ from those of otolithic organ afferents. How efferent stimulation affects afferent response is investigated by electrically stimulating efferent somata and recording compound action potentials from afferents innervating the saccule, the main auditory organ in this species. There are different efferent modulatory effects on afferent response, depending on the level of background noise. Efferent activation inhibits afferent response in quiet conditions but can enhance signal detection in noisy environments. Results of these studies indicate that the fundamental role in efferent modulation of afferent input is likely conserved in both nonmammalian vertebrates and mammals. [Work supported by NIH/NIDCD Grant R01DC003275.]

2aAB11. Flows near model otoliths and their implications for fish hearing. Charlotte W. Kotas, Peter H. Rogers, and Minami Yoda (Mech. Eng. Dept., Georgia Inst. of Technol., Atlanta, GA 30332-0405)

The fish inner ear contains a dense, bony otolith that oscillates in response to acoustic excitation. This relative motion between the otolith and its surrounding fluid generates both steady streaming and unsteady flows in the fluid which in turn displaces the hair cells on the macular membrane. Fish "hear" by interpreting these hair cell displacements. However, most of the hair cells are located near a groove along the otolith (the sulcus), making it likely that the irregular geometric features of the otolith will affect how fish hear by influencing the motions of these hair cells. To understand these acoustically induced flows, magnified otolith models were constructed based upon three-dimensional computer tomography scans of actual otoliths. The model otoliths were sinusoidally oscillated so that steady streaming and unsteady flows could be experimentally studied using particle-image velocimetry. The effect of geometric features like the sulcus was studied near the model surface at various oscillation frequencies, ω, and amplitudes, s. Results will be presented for Reynolds number $Re \equiv \omega L^2/\nu \approx 1 - 10^2$ and amplitude ratios $\epsilon \equiv s/L = 0.05 - -0.2$, where L is a representative otolith length scale and ν is the kinematic viscosity of the fluid. [Work supported by ONR.]

2aAB12. Particle motion perception in cephalopods. Kenzo Kaifu, Susumu Segawa (Tokyo Univ. of Marine Sci. and Technol. 4-5-7, Kounan, Minato-ku, Tokyo, Japan), and Tomonari Akamatsu (Fisheries Res. Agency, Kamisu, Ibaraki, Japan)

In the 1980s, there still had been the argument whether cephalopods could detect sound stimulus or not. The ability of sound detecting (hearing ability or an ability to detect vibration) in cephalopods was proved around 1990, however, there have been few studies about sound detection in cephalopods afterwards. Based on morphological and behavioral studies, it seems that cephalopods do not perceive sound pressure. Provided that compressional waves do not stimulate the nervous systems of the animals, they do response to sound waves due to water particle movement. In this study, the ability to detect sound waves in cephalopods was investigated from the standpoint of water particle movement perception. An object would be well vibrated by sound waves when the length of the object is much smaller relative to the wavelength; consequently, when an animal detects water particle movement, the smaller the animal is, the higher frequency and weaker stimulus it would detect.

2aAOa1. Fish population and behavior revealed by instantaneous continental-shelf scale imaging. Nicholas C. Makris (Dept. of Mech. Eng., MIT, 77 Massachusetts Ave., Cambridge MA 02139), Purnima Ratilal (Dept. of Elec. and Comput. Eng., Northeastern Univ.), Deanelle T. Symonds, Srinivasan Jagannathan, Sunwoong Lee (Dept. of Mech. Eng., MIT, Cambridge, MA), and Redwood W. Nero (Naval Res. Lab., Stennis Space Ctr., MS)

Fish populations in continental shelf environments are instantaneously imaged over thousands of square kilometers and continuously monitored by a remote sensing technique in which the ocean acts as an acoustic waveguide [Science **311**, 660–663 (2006)]. The technique, ocean acoustic waveguide remote sensing (OAWRS), has revealed the instantaneous horizontal structural characteristics and volatile short-term behavior of very large fish shoals, containing tens of millions of fish and stretching for many kilometers. The former follows a fractal or power-law spectral process, indicative of structural similarity at all scales. The latter features compressional waves of fish population density that travel roughly an order of magnitude faster than fish can swim. Here we present an overview of OAWRS imagery documenting fish activity over a 2-week period in the Spring of 2003 at the edge of the continental shelf, roughly 200 km south of Long Island, NY. Until now, continental shelf environments have been monitored with highly localized line-transect methods from slow-moving research vessels. These methods significantly undersample fish populations in time and space, leaving an incomplete and ambiguous record of abundance and behavior.

8:25

2aAOa2. Acoustical imaging of nonbladdered animals using underwater acoustic camera. Kohji Iida, Rika Takahashi, Tohru Mukai (Fac. Fish., Hokkaido Univ., 3-1-1 Minato, Hakodate, Hokkaido, 0418611 Japan, iidacs@fish.hokudai.ac.jp), Yong Tang (Dalian Fish. Univ., Dalian 116023 China), and Masanori Sato (Honda Electron. Co., Ltd., Toyohashi, Aichi, 4413193 Japan)

An underwater acoustic camera using 3.5-MHz ultrasonic waves enclosed in a pressure-resistant case was constructed to observe underwater marine animals. This enabled the measurement of the size, shape, and behavior of living marine animals including internal organs by B-mode images in the detection range up to 240 cm. Observations were conducted for captive animals in a water tank and for natural animals in a field. The captive animals, including fish, squid, and jellyfish, were observed, and a three-dimensional internal structure of animals was reconstructed using multiple acoustical images. The most important contributors of acoustic scattering were the vertebra for nonbladdered fish, and the liver and reproductive organs for invertebrate animals. In a field experiment, the shape, size, and swimming behavior of wild animals were observed. The possibilities and limitations of the underwater acoustic camera for fishery applications were discussed. [Work supported by JSPS Grant-In-Aid for Scientific Research.]

8:45

2aAOa3. Simultaneous observations of zooplankton distribution and density using net sampling, a laser-optical plankton counter, and acoustics. Tohru Mukai, Yasuzumi Fujimori, Jun-ichiro Kishi, and Kohji Iida (Faculty of Fisheries Sci., Hokkaido Univ., 3-1-1 Minato, Hakodate, Hokkaido 0418611, Japan)

Conventional plankton sampling methods are based on net tows, which are often poorly suited to capturing spatiotemporal variability. Various automatic plankton samplers based on optical principles have been developed recently. The laser-optical plankton counter (LOPC) was developed as the next generation OPC. In addition, acoustic technology has been used extensively to survey zooplankton distribution and abundance. This study compared the density and size spectra determined using net contents, LOPC data, and acoustic data. Surveys were conducted for 3 years around Hokkaido, Japan. The sound-scattering layer (SSL) was recorded on the echogram of an echosounder. Biological sampling was conducted using a 1-m^2 frame-type mid-water trawl (FMT; mesh size 1.5 mm) and a NORPAC net (mesh size 500 microns). An LOPC was mounted inside the mouth of these nets. Net sampling was carried out at dusk, when the SSL moves toward the surface (ca. 10–35 m). Acoustic data were derived using a Simrad EK60 echosounder operating at 38, 120, and 200 kHz simultaneously. A comparison of the use of acoustic data, LOPC data, and net contents to assess zooplankton distribution and density will be presented and discussed. [Work supported by JSPS Grants-In-Aid for Scientific Research.]

9:05

2aAOa4. Riding the wave: Scale-dependent descriptions of walleye pollock distributions. Julian M. Burgos, John K. Horne (School of Aquatic and Fishery Sci., Univ. of Washington, 1122 NE Boat St., Seattle, WA 98105, jmburgos@u.washington.edu), and John K. Horne (Natl. Marine Fisheries Service, NOAA, Seattle, WA 98115)

Wavelet analysis was used to describe scale-dependent distributional variability of walleye pollock (*Theragra chalcogramma*) in the eastern Bering Sea shelf between 2000 and 2002. Area backscattering strength (ABC), a measure of acoustic density, was calculated at 20-m horizontal intervals in five echo-integration trawl surveys. The maximum overlap discrete wavelet transform was used to partition the ABC variance into scales ranging from 0.04 to 10.24 km. Wavelet variance was estimated for each transect after denoising with phase plane thresholding. Wavelet spectra can be characterized by large variances at small scales (less than 0.64 km), decreasing when scale increased to 1.28 km, and increasing variance at larger scales. The fraction of the total variance assigned to small scales was negatively correlated with the total acoustic density. This is attributed to the aggregative behavior of walleye pollock. Peaks in wavelet spectra, indicating the presence of coherent features (i.e., schools or shoals), were observed in 48% of the transects at scales ranging from 1.28 to 10.24 km. Peaks at larger scales were more common in winter transects, when walleye pollock form large spawning aggregations.

9:20

2aAOa5. An overview of the theoretical framework for measuring fish swimming speed by a sector-scanning sonar. Akira Hamano (Natl. Fisheries Univ., 2-7-1, Nagata-honmachi, Shimonoseki, Japan 759-6595, ahamano@fish-u.ac.jp), Jennifer Miksis-Olds, Christopher Jakubiak, and Ernest Bernard (Univ. of Massachusetts Dartmouth, New Bedford, MA 02744-1221)

Two identical high-frequency sector-scanning sonars, mounted on a stationary acoustical-optical platform (AOP), were used to study the swimming speed of fishes. The first phase of this study consisted of a motion calibration performed in an acoustic test tank using a standard target sphere (WC 38.1 mm). The sonars are a 200-kHz sector-scanning system employing an 8-element array to receive echo signals over a 90° arc. An overview of the theoretical framework for the motion calibration of the sector-scanning sonar is presented. The second phase of the study related the calibration data to the observed movement of fish. The two-dimensional swimming tracks were identified from the digitized sonar data recorded while the AOP was deployed on the seafloor. These tracks were compared with the movement of the target sphere to make estimates of fish swimming speed. Optical data, when available, were used to confirm the results of acoustic data. The limitations and precision of swimming speed measurements using this system are discussed. The application of this methodology to studies of fine-scale fish behavior has the potential to make previously intractable questions possible. [Work supported by NOAA.]

9:35

2aAOa6. Depth- and size-dependent rhythms of animal emergence in an estuary. Mei Sato and Peter A. Jumars (Darling Marine Ctr., Univ. of Maine, 193 Clark's Cove Rd., Walpole, ME 04573, mei_sato@umit.maine.edu)

Among migrating crustaceans, some species inhabiting shallow waters stay very close to the bottom or burrow into the sediments during the day and come up to the surface at night. This behavior, called emergence, was monitored by the Tracor Acoustic Profiling System (TAPS) with six frequencies (265–3000 kHz) to clarify the mechanisms of benthic-pelagic coupling. Instead of one emergence event up to the surface at night, data with high spatial resolution indicate multiple emergence events varying with both the size of the organisms and distance above the bottom, suggesting that for some species there is a target depth beyond which upward migration is limited. In the Damariscotta River estuary, ME, nocturnal emergence events of mysid shrimp, *Neomysis americana*, occur from late June through early November. Mysid shrimp are known to be important food sources for fishes such as longhorn sculpins, smelt, alewives, and Atlantic cod. The timing of their emergence near the bottom corresponds to the maximum flood tide, suggesting enhancing retention in the estuary. Smaller organisms, on the other hand, emerge primarily during periods of slack tide, but reach the surface only at slack low, also avoiding washout.

9:50

2aAOa7. Combining acoustics and video to image fish in the acoustic dead zone. Jennifer L. Miksis-Olds, Ernest Bernard, Christopher J. Jakubiak, and D. V. Holliday (School for Marine Sci. and Technol., Univ. of Massachusetts, 838 S. Rodney French Blvd., New Bedford, MA 02744, jmiksis@umassd.edu)

A stationary acoustical-optical platform (AOP) has been developed to detect groundfish presence and to estimate biomass. The AOP is a new approach to fisheries science because sampling from a platform on the ocean floor overcomes limitations of traditional surface acoustic surveys, where echoes from groundfish near the seafloor are obscured by stronger reflections from the ocean bottom. The AOP capitalizes on the complementary strengths of acoustical and optical sampling techniques by using acoustics for fish enumeration and optics for species identification and measurements of fish length. Each AOP is equipped with four video cameras, two 200-kHz sonar transducers, and a suite of environmental sensors. One sonar face is mounted in the horizontal direction to image the area directly above the seafloor, whereas the second transducer is oriented vertically to sample the water column above the platform. Acoustic backscatter, target species, size, and observation angle were quantified when fish were simultaneously detected by the sonar and optical sensors. Calculations of target strengths were then related to fish size and orientation, for incorporation into biomass estimates. The AOP is designed to be used in an observation system with multiple platforms elements, so fish populations can be monitored over large spatial scales. [Work supported by NOAA.]

2aAOa8. Acoustic and optic characterization of forage fish distribution in the Bering Sea. Sandra Parker Stetter, John Horne (School of Aquatic and Fishery Sci., Univ. of Washington, Seattle, WA 98195-5020), and James Churnside (Natl. Oceanograph. and Atmospheric Administration Environ. Technol. Lab., Boulder, CO 80305)

Mesopelagic forage fish species are important components of the Bering Sea ecosystem, but information on species distribution and identity is limited. Using acoustics and optics [LIght Detection And Ranging (LIDAR)], this study compared distribution patterns detected by the two gears. Forage species distribution and quantity differed between shelf (6–100 m) and slope (6–100 m, 100–300 m, 300 m to bottom) regions. Acoustic results suggested that shallow and deep depth zones contained dispersed backscatter while the middle slope layer contained patchy schools associated with the shelf break. Variogram results for repeated LIDAR surveys of the shelf and slope regions indicated that backscatter distribution between 6 and 30 m was dynamic at the scale of days. This result was expected given the strong frontal nature of the area. When LIDAR results were compared with coincident acoustic transects on the shelf and slope, differences were found in gear detection of backscatter. Based on acoustic results, 25%–63% of forage fish in the shelf and slope regions were deeper than the LIDAR detection range. Although both LIDAR and acoustics are constrained to portions of the water column, the utility of remote sampling technologies is dependent on survey objectives. [Funding was provided by the North Pacific Research Board.]

2aAOa9. Comparing repeated sidescan sonar measurements of benthic squid egg beds in Monterey Bay, CA. Kenneth G. Foote (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543), Pat J. Iampietro, and Mary Young (California State Univ., Monterey Bay, Seaside, CA 93955)

The squid *Loligo opalescens* lays its eggs in capsules attached to a flat sandy substrate. These capsules are usually clustered in so-called egg beds. Earlier work in Monterey Bay, CA [Foote *et al.*, J. Acoust. Soc. Am. **119**, 844–856 (2006)] established the acoustic detectability of such egg beds. This work has now been extended in a new study performed in June 2006. An EdgeTech sidescan sonar was towed at nominal 5-m height over the bottom. Measurements were made at 400 kHz, horizontal beamwidth 0.5 deg, along six parallel transects, with adjacent centerlines separated by 30 m. The swath width along each transect was 100 m. The transects were repeated on 10, 13, and 14 June. Data from areas where egg beds were densely concentrated, confirmed by drop video camera, have been excerpted. Comparisons of corresponding data, which are generally very strong, are quantified. The question is asked as to whether such sidescan sonar data can be used differentially to measure egg-laying success or hatching over rather short periods of time. If so, this could be a useful tool both in ecological studies and for management purposes. [Work supported by NURP.]

10:50

2aAOa10. Estimating pressure gradients governing fish shoal dynamics over continental-shelf scales. Srinivasan Jagannathan, Sunwoong Lee, Deanelle T. Symonds (Dept. of Mech. Eng., MIT, 77 Massachusetts Ave., Cambridge, MA 02139), Purnima Ratilal (Northeastern Univ.), and Nicholas C. Makris (MIT, Cambridge, MA 02139)

The environmental pressure gradient and stress field on fish shoals spanning more than 10 km is calculated from a sequence of instantaneous continental-shelf scale OAWRS images of areal fish population density [Science **311**, 660–663 (2006)]. The calculation is based on continuum

mechanics and the velocity field of fish groups previously estimated from OAWRS imagery using acoustic flow [Jagannathan *et al.*, J. Acoust. Soc. Am. **119**, 3435 (2006)]. These environmental stress fields describe the driving mechanism behind the dynamic behavior of large fish groups such as expansion, contraction, and translation. Regions of high stress are correlated with regions of high areal fish density. They are also correlated with density waves that convey information across a fish group. Our estimates of environmental stress on fish groups can be correlated with environmetal parameters such as plankton, temperature, and current distributions through physical and biological driving mechanisms.

11:05

2aAOa11. Sonar mapping for coral reef conservation. Lisa Zurk, Joe Lotz, Tim Ellis, James McNames (Elec. and Comput. Eng. Dept., Portland State Univ., P.O. Box 751-ECE, Portland, OR 97207, zurkl@cecs.pdx.edu), and Jean-Louis Ecochard (The Nature Conservancy, Arlington, VA 22203)

Many conservation efforts require an inexpensive and easy-to-use method of mapping and monitoring coral reef structure. A desirable product is a 3D map that effectively portrays the reef relief (and potentially the sub-structure) or features such as fish locations and fish spawning areas. Given field site limitations associated with the reefs, the mapping technique should be portable, rugged, and easy to use. One solution, developed at the Nature Conservancy (TNC), is to utilize a Lowrance fish finding sonar with a GPS system to estimate the top of the coral. This approach has been employed for TNC mapping exercises to generate ArcGIS maps of conservation areas. However, these maps are often negatively affected by sampling and processing artifacts such as sparse collection geometries (causing interpolation errors), distortion due to beam shape, and changes in boat (transducer) position due to wave motion. In this presentation we discuss recent work to address these effects, as well as enhancements to the system by processing acoustic returns from the coral substructure or within the water column for detection of fish populations. The presentation will provide a description of future research, including the intent of making the finished system available as a conservation tool.

2aAOa12. Robust analysis of single echo trace obtained by split beam sounder. Masahiko Furusawa (Tokyo Univ. of Marine Sci. and Technol., 4-5-7 Konan, Minato Tokyo 108-8477 Japan, frsw@s.kaiyodai.ac.jp) and Kazuo Amakasu (Natl. Res. Inst. of Fisheries Eng., Kamisu Ibaraki 314-0408 Japan)

The theory and method of the echo trace analysis of single echoes (ETA), which simultaneously analyze the shape and level of single echoes, are almost established. But, the method has not been extensively used. The major reasons are high-quality echoes with a high signal-to-noise ratio (SNR) necessary for the analysis are some times difficult to obtain; the error introduced by transducer motion is large; and conditions for the theory sometimes could not be fulfilled. Therefore, we apply the ETA to the split beam method, which is most advantageous for the ETA, and make the method robust by introducing the following: careful echo selection considering SNR, correction of the effect of transducer motion, smoothing of the trace by regression analyses, introduction of indexes checking reliability, etc. The useful results of our ETA are the track, the swimming speed and orientation, the target strength as a function of tilt angle, and the estimated size of individual fish. The robust ETA was applied to echoes of fish near a sea bottom and of Antarctic krill to confirm the effectiveness of the method.

11:40

2aAOa13. Comparing acoustic model estimations and *in situ* target strength measurements of juvenile walleye pollock (*Theragra chalcogramma*). Kazuhiro Sadayasu (Natl. Res. Inst. of Fisheries Eng., Fisheries Res. Agency, 7620-7 Hasaki, Kamisu, Ibaraki 314-0408, Japan), Tohru Mukai, and Kohji Iida (Hokkaido Univ., Hakodate, Hokkaido 041-8611, Japan)

Recently, many acoustic surveys for the juvenile walleye pollock have been done around the Hokkaido, Japan. Dependence of target strength on fish length is a most important factor in the conversion of acoustic data to fish biomass. However, the relation between target strength and length of juvenile walleye pollock is not well investigated. This study examined the target strength length relationship (3–10 cm) for the echo integration measurements of the juvenile walleye pollock at 38 kHz from acoustic theoretical model predictions and *in situ* measurements. A prolate spheroid model was used to compute the target strength of the fish relative to its orientation. Swimbladder morphologies of live juvenile walleye pollock caught by set net were obtained from transmission of light or soft x-ray, and converted their morphological parameters. Biological samplings using framed mid-water trawl were carried out near

the spawning area of walleye pollock. During fish samplings, *in situ* target strength measurements were conducted using quantitative echo sounder with split beam transducer. While predicted mean target strengths matched mean *in situ* measurements at small length, there was not agreement at the large length. This discrepancy is a result of avoidance of large fishes from a net mouth.

7:50

2aAOb1. Moving ship thermometry. James A. Mercer, Nick Alger, Bruce M. Howe, Rex K. Andrew (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, mercer@apl.washington.edu), and John A. Colosi (Naval Postgraduate School, Monterey, CA 93943)

The long-range ocean acoustic propagation experiment (LOAPEX), conducted in the NE Pacific Ocean, provided acoustic transmissions from a ship-suspended source at seven stations spanning a near zonal path of 3200 km. The transmissions were received on several bottom-mounted horizontal hydrophone arrays distributed about the NE Pacific Ocean Basin. The experiment and a simple inverse method are described and a preliminary thermal "snapshot" of the ocean basin is presented. [Work supported by ONR.]

8:05

2aAOb2. Anisotropy in the spatial distribution of the arrival points of a ray after a fixed travel time. Stanley M. Flatté (Phys. Dept., Univ. California Santa Cruz, Santa Cruz, CA 95064, sflatte@ucsc.edu) and John A. Colosi (Naval Postgraduate School, Monterey, CA 93943)

An acoustic pulse emitted from a point source arrives on a well-defined wavefront after a fixed travel time. In the geometrical-acoustics approximation, this behavior is understood by following rays. Two simple ray models are presented to treat the scattering of rays by internal waves, and to evaluate the ratio of movements in the ray end points within and perpendicular to the wavefront. Assuming weak forward scattering, and no waveguide, the model predicts that the end points move along the wavefront over much larger distances than perpendicular to the wavefront. [Work supported by ONR.]

8:20

2aAOb3. Fresnel zones in inhomogeneous media. Irina I. Rypina and Michael G. Brown (Univ. of Miami, RSMAS-AMP, 4600 Rickenbacker Cswy., Miami, FL 33149)

A simple general expression for the width of a Fresnel zone in a smooth inhomogeneous environment is derived. In a stratified environment at long range, the general expression is shown to reduce approximately to one that is proportional to $\sqrt{|\alpha| r(R-r)/f}$, where α is the ray stability parameter, f is the acoustic frequency, r is the range to the field point of interest, and R is the source-to-receiver range. In a stratified environment on which a weak perturbation is superimposed, at long range

the width of a bundle of micromultipaths is shown to be approximately proportional to $|\alpha|\sqrt{r(R-r)}$. Thus, at long range both the diffractive and scattering contributions to "the width of a ray" are proportional to $\sqrt{r(R-r)}$ and increase with increasing $|\alpha|$. Theoretical predictions are shown to agree well with travel time sensitivity kernel calculations. [Work supported by ONR.]

8:35

2aAOb4. Moving ship tomography from the Basin Acoustic Seamount Scattering Experiment (BASSEX-04). Kevin D. Heaney (OASIS Inc., 11006 Clara Barton Dr., Fairfax Station, VA 22039), Arthur B. Baggeroer (MIT, Cambridge, MA 02139), Peter F. Worcester, and Matthew A. Dzieciuch (Univ. of California at San Diego, La Jolla, CA 92093)

During the Basin Acoustic Seamount Scattering EXperiment (BASSEX-2004) a set of 32 acoustic transmissions of four moored sources in the central Pacific were made. Broadband transmissions (100 Hz bandwidth, 250 Hz center frequency, 12.276 s period length) from two sources suspended (800 m depth) were received on a towed array (350 m depth, 200 m aperture) as it passed between the two sources at a range of 250 km. This data set provides the opportunity for examining the feasibility of underway moving ship tomography (MST). The primary oceanographic feature is the variability of the mixed layer over a 500×500-km^2 region. Accurate ocean acoustic tomography requires the development of an $N \times 2D$ inversion scheme as well as techniques to perform array element localization to within 10 m. Results on applying a Kalman-filter-based technique to the array sensor data (depth, pitch, roll) and the measured ADCP will be presented. With the receiving ship transecting the path between the two source moorings, each transmission has two paths that pass through different bodies of water.

8:50

2aAOb5. Vertical coherence of low-frequency sound waves propagating through a fluctuating ocean. Alexander G. Voronovich and Vladimir E. Ostashev (NOAA, Earth System Res. Lab., PSD4, 325 Broadway, Boulder, CO 80305)

Low-frequency sound waves propagating over large distances in the ocean exhibit significant scattering due to internal waves. Studies of low-frequency sound propagation through a fluctuating ocean are important for many practical concerns such as communication, acoustic tomography, and source detection, ranging, and recognition. In a recent work [A. G. Voronovich and V. E. Ostashev, J. Acoust. Soc. Am. **63**, 1406–1419

[(2006)] a 3-D modal theory of sound propagation through a fluctuating ocean was developed. Closed equations for the first two statistical moments of a sound field were derived using the Chernov method and assuming that the spectrum of internal waves is given by the Garret-Munk spectrum. In the present paper, we numerically solve the derived equation for the second moment. The results obtained are used to study the dependence of the vertical coherence of a sound field on several parameters of the problem: range, frequency, source and receiver depths, and parameters that characterize the Garret-Munk spectrum. [Work supported by ONR.]

9:05

2aAOb6. A partial theory of phase coherence loss in deep ocean propagation. Francisco J. Beron-Vera and Michael G. Brown (RSMAS-AMP, Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149)

In a fluctuating ocean, coherently adding multiple receptions of repeated transmissions of a signal generally results in a processing gain relative to the background noise only for some finite duration owing to a gradual loss of wave-field phase coherence. In this talk a theoretical framework for understanding some elements of phase coherence loss in transient wave fields in deep ocean environments is presented. The theory predicts that phase coherence loss is pathdependent and very different at short range than at long range. PE simulations of transient wave-field phase coherence loss in an idealized time-varying ocean are presented and shown to be in good qualitative agreement with theoretical predictions. [Work supported by ONR.]

9:20

2aAOb7. Vertical structure and arrival times of the axial wave based upon conductivity, temperature, and depth data acquired during the Long-range Ocean Acoustic Propagation Experiment. Natalie S. Grigorieva and Gregory M. Fridman (Dept. of Appl. Math., St. Petersburg State Marine Tech. Univ., 3 Lotsmanskaya Str., St. Petersburg, 190008, Russia, nsgrig@natalie.spb.su)

In the LOAPEX experiment at some distances from VLA the sound source was deployed to depths quite close to the sound-channel axis. This took place at stations T1000, T500, T250, and T50 where, in particular, the source was deployed to 800 m and the depth of the sound-channel axis at these ranges is about 680 m. The interference of the wave fields corresponding to near-axial rays leads to formation of a complex interference wave ("the axial wave") that propagates along the axis being a component of the axial crescendo. The talk will present the results on simulation of the axial wave as a function of depth of the receiver and the calculation of its arrival time at frequencies 56.25–93.75 Hz. In the time domain the pulse propagation modeling is carried out for the broadband acoustic signals with the pulse center frequency of 75- and 37.5-Hz bandwidth. The obtained results are compared with those for the lowest mode in the adiabatic approximation. Calculations are made for the range-dependent ocean model based upon LOAPEX CTD data and use the integral representation of the axial wave in a local coordinate system introduced in the vicinity of the range-variable sound-channel axis. [Work supported by ONR.]

9:35

2aAOb8. Evolution of a downslope propagating acoustic pulse. Kevin D. Heaney (OASIS, Inc., 11006 Clara Barton Dr., Fairfax Station, VA 22039), Arthur B. Baggeroer (MIT, Cambridge, MA 02139), Peter F. Worcester, Matthew A. Dzieciuch (Univ. of California at San Diego, La Jolla, CA 92093), James A. Mercer, Bruce M. Howe, and Rex K. Andrew (Univ. of Washington, Seattle, WA 98105)

During the North Pacific Acoustics Laboratory (NPAL-04) experiment broadband transmissions (50 Hz bandwidth, 75 Hz center frequency, 27.28 s period length) from a bottom-mounted source off the island of Kauai were received on a towed array (350 m depth, 200 m aperture) near the island and a large aperture vertical line array (VLA) at a range of 2469.5 km. Previous work [Heaney, J. Acoust. Soc. Am. **117**(3), 1635–1642 (2005)] has demonstrated that bottom interaction near the source is a fun-

damental process in the evolution of the wave-train. In this paper results from eight receptions at ranges from 2 to 300 km and the reception on the distant VLA is used to examine the wavefront evolution as it propagates into deep water. Results from a local geo-acoustic inversion will be presented as well as comparison of data with broadband parabolic equation simulations. The initial conclusion is that the first-order bottom bounce, off the seamount near the source, acts as an image source, contributing to a complex arrival pattern even at great distances.

9:50

2aAOb9. Evolution of second-order statistics of low-order acoustic modes. Tarun K. Chandrayadula, Kathleen E. Wage (George Mason Univ., 4400 Univ. Dr., MSN 1G5, Fairfax, VA 22030, tchandra@gmu.edu), James A. Mercer, Bruce M. Howe, Rex K. Andrew (Univ. of Washington, Seattle, WA 98195), Peter F. Worcester, and Matthew A. Dzieciuch (UCSD, La Jolla, CA 92093)

Low-mode signals measured during long range tomography experiments, such as the Acoustic Thermometry of Ocean Climate (ATOC) and the North Pacific Acoustic Laboratory experiments, have a random arrival structure due to internal waves. At megameter ranges, the narrow-band mode amplitude is predicted to be Gaussian and uncorrelated with other modes [Dozier and Tappert, J. Acoust. Soc. Am. **63**, 353–365 (1978)]. Wage et al. measured the centroid, frequency coherence, time spread, and time coherence for the broadband ATOC mode signals received at ranges exceeding 3000 km [Wage et al., J. Acoust. Soc. Am. **117**, 1565–1581 (2005)]. The 2004 Long Range Acoustic Propagation EXperiment (LOAPEX) provided an opportunity to observe how the mode statistics evolves with range. This talk investigates the mean, temporal covariance, and intermodal correlation of the low modes at ranges between 50 and 3200 km using LOAPEX data. Broadband parabolic equation simulations were performed to model internal wave effects on the low-mode signals at the various LOAPEX stations. A kurtosis measure is used to study the amount of cross-modal scattering with respect to range. Statistics of the measured and simulated mode signals are compared. [Work supported by ONR.]

10:05–10:20   Break

10:20

2aAOb10. Modal group time spreads in weakly range-dependent deep ocean. Ilya A Udovydchenkov and Michael G Brown (RSMAS, AMP, Univ. of Miami, 4600 Rickenbacker Cswy., Miami, FL 33149)

Modal group time spreads in deep ocean environments are investigated. The environments considered consist of a range-independent background on which a range-dependent perturbation, due for example to internal waves, is superimposed. Modal group time spreads are defined to be the temporal spread of acoustic energy with a fixed mode number across a nonvanishing frequency band. It is shown that there are three contributions to modal group time spreads that combine approximately in quadrature. These contributions are (1) the reciprocal bandwidth, (2) a deterministic dispersive contribution, and (3) a scattering-induced contribution. Contributions 2 and 3 are shown to be controlled by the waveguide invariant $\beta(m,f)$, a property of the background sound speed structure. Numerical simulations are shown to be in good agreement with theoretical predictions. [Work supported by ONR.]

10:35

2aAOb11. Long-range ocean acoustic propagation experiment (LOAPEX) acoustic modeling analysis using measured environmental data. Michael Wolfson and Frank Henyey (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698)

One objective of LOAPEX concerns the range dependence of multiple forward scattering for broadband, long-range acoustic transmissions. Using environmental data extracted during the experiment, a sound speed field is constructed, which includes sound speed fluctuations due to neu-

trally buoyant intrusions as well as internal waves. This sound speed field is used as input to a full wave simulation model. Range-dependent results from simulations regarding the coherent field and depth scattering below lower turning point caustics are presented.

10:50

2aAOb12. A comparison of experimental and theoretical forward scattering by the Kermit-Roosevelt Seamount. Arthur Baggeroer, Henrik Schmidt, Joseph SikoraIII, Hyun Joe Kim (MIT, 77 Massachusetts Ave., Cambridge, MA 02139), Edward Scheer (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), Peter F. Worcester, Matthew A. Dzieciuch (Univ. of California at San Diego, La Jolla, CA 92093), and Kevin D. Heaney (OASIS Inc., Fairfax Station, VA 22039)

The SPICEX-LOAPEX-BASSEX experiments measured forward scattering from the Kermit-Roosevelt seamounts. LFM and M-sequence signals from 250-Hz moored sources and a 75-Hz ship-deployed source were received with Penn State University's 162-element FORA array. Receptions were obtained from these sources at ranges of hundreds to 1600 km. Previous work [J. Acoust. Soc. Am. **117**, (2549)] discussed the BASSEX forward shadow and patterns of horizontal refraction around the seamount. Additional work [J. Acoust. Soc. Am. **118**, (1936)] compared experimental results with theory using a conical section model of a seamount. This presentation concerns the pulse compressed and array processed time series of M-sequence signals in the forward scattered field of the seamounts. Both travel times and angles of arrival are reconciled with 2-D ray-trace models. Results are comparable to refracted rays, which mainly propagate over the seamount. These, however, do not explain additional echoes, which appear in the experiment, possibly due to reflection and/or diffraction. Normal mode and PE methods are used to confirm ray models and identify additional echoes.

11:05

2aAOb13. On the forward problem of mode coupling through shallow-water nonlinear internal waves. John Colosi and Aaron Young (Dept. of Oceanogr., Naval Posgraduate School, Monterey, CA 93943)

Using the Dyson series, we have developed a 2-D (depth and range) theory to predict the coupling of low-frequency acoustic modes propagating through shallow water nonlinear internal wave fields. Parabolic equation numerical simulations with typical shallow water internal wave fields show that the theory can accurately predict mode coupling up to an acoustic frequency of about 300 Hz. Second-order theory may extend the results to higher frequency and larger amplitude internal waves. Application of the theory to 3-D problems in which azimuthal coupling is weak will be discussed.

11:20

2aAOb14. High-frequency current tomography in coastal regions. Mohsen Badiey and Entin Karjadi (College of Marine and Earth Studies, Ocean Acoust. Lab., Univ. of Delaware, Newark, DE 19716)

In deep-water tomography refracted ray paths can provide accurate account of travel time for the inverse problem. However, in shallow coastal regions, due to the geometry of the source-receiver as well as the waveguide dimensions, most acoustic energy is a multiple reflection from sea surface and sea bottom. This makes the forward problem which deals with resolving the multipath structure of the arriving signals difficult. In this paper, we discuss the limits of reciprocal acoustic transmission as a function of waveguide temporal and spatial parameters for the purpose of

tomography application in coastal regions. Results from a high-frequency (0.5–24 kHz) quasi-reciprocal tomography experiment in a very shallow-water coastal region are presented. Using these data, the accuracy and limit of current tomography for variable sea states are examined for different center frequencies and bandwidths. [Work supported by ONR.]

11:35

2aAOb15. A multistation coastal acoustic tomography system with coherent operation. Hong Zheng (S.E.A. Corp., IU Bldg. 4F, 2-23 Shiohama, Ichikawa, Chiba 272-0127, Japan), Arata Kaneko, and Noriaki Gohda (Hiroshima Univ., Higashi-Hiroshima, Hiroshima 739-8527, Japan)

A multistation coastal ocean acoustic tomography (CAT) system with coherent operation has been developed and applied to field experiments over ten times in the last 8 years. The system is designed to measure both temperature and current velocity fields in the coastal ocean. As is well known, an ocean acoustic tomography is generally based on travel time measurements. In the CAT system, the clock accuracy for travel time measurement is most important to realize coherent transmission from multistations and to measure especially current velocity. For highly accurate coherent transmission from multistations, each station is equipped with a timing module synchronized by the clock signals of global positioning system (GPS). As a result, time error is maintained less than 0.1 μs. In the sound transmission from multistations, the code division multiple access (CDMA) and spread spectrum technology are applied. The coded signals also improved remarkably the signal-to-noise ratio of the CAT system. With detecting not only the amplitude, but also the phase of received signals, the accuracy of travel time measurement is improved within a sampling interval of data. This multistation CAT system served to map 2-D time-varying tidal current structures in Tokyo Bay (Kaneko *et al.*, 2005).

11:50

2aAOb16. Nonlinear optimization for beamforming a geometrically deficient vertical line array: Application to sediment tomography. Steven E. Crocker (Naval Undersea Warfare Ctr., Newport, RI 02841), James H. Miller, Gopu R. Potty (Univ. of Rhode Island, Narragansett, RI 02882), and James F. Lynch (Woods Hole Oceanogr. Inst., Woods Hole, MA 02543)

The 1996 Shelfbreak PRIMER experiment included broadband acoustic transmissions in the vicinity of a shelfbreak front collected using a geometrically deficient vertical line array (VLA). The broadband signals were used to tomographically image sediment sound speed and attenuation. The VLA spanned the lower half of the water column. Hence, the orthonormal properties of the underlying normal modes cannot be guaranteed for any replica vector based on the local modal structure. This produces modal sidelobes in the output of the geometrically deficient VLA. Various methods of extracting the normal modes from VLA data have been developed including a generalized least squares method shown to improve the performance of a geometrically deficient VLA processing phase encoded tomography signals [Chiu *et al.*, IEEE J. Ocean. Eng. **22**, 522–533 (2005)]. The present study seeks to enhance the modal resolution for the reception of high-amplitude, impulsive signals transmitted over a wide variety of source receiver paths in shallow water where ensemble averaging is not an option. The method uses nonlinear optimization techniques to compute a set of array element coefficients that enhance suppression of modal sidelobes, while maintaining adequate spatial matching with the desired mode. [Work supported by Office of Naval Research.]

2aBB1. Extracorporeal cardiac shock wave therapy ameliorates myocardial ischemia in animals and humans. Hiroaki Shimokawa (Grad. School of Medicine, Tohoku Univ., Sendai 980-8574, Japan)

The number of patients with end-stage coronary artery disease without indication of coronary intervention or coronary artery bypass surgery has been increasing. Gene and/or cell angiogenic therapies are currently under investigation for those patients, however, the therapies are invasive in nature and their effectiveness and safety have not been established yet. We here report our successful development of noninvasive extracorporeal cardiac shock wave therapy (CSWT) for the treatment of myocardial ischemia. We first confirmed that endothelial expression of VEGF and its receptor Flt-1 peaks with a low level of SW at 0.09 mJ/mm^2 *in vitro*. We then demonstrated that CSWT effectively ameliorates myocardial ischemia in a porcine model of effort angina without any adverse effects. Finally, we were able to demonstrate that CSWT effectively ameliorates myocardial ischemia and related symptoms in patients with end-stage coronary artery disease without any adverse effects. Myocardial perfusion was improved with CSWT only in the ischemic region where we treated with the therapy. We are currently performing a double-blind clinical study to further confirm the usefulness and safety of our CSWT. [Work supported in part by grants from the Japanese Ministry of Health, Labor and Welfare.]

2aBB2. Various old and new shock-wave applications require different shock-wave beam characteristics. Reiner Schultheiss (Tissue Regeneration Technologies, LLC, 110 Arnold Mill Park, Ste. 400, Woodstock, GA 30188)

Four different medical applications of shock waves and the appropriate pressure field will be discussed. Lithotripsy requires maximum shock-wave energy at the stone. High-pressure amplitudes and the total acoustical energy are the preferable parameters discussed for the disintegration effect. Improved kidney stone disintegration coincident with reduced side effect on the nephritic tissue was realized by a low-angle focusing ellipsoid (LithoGold). In the treatment of soft tissue, unfocused shock waves allow the mechanical parameters like peak pressure and the energy density to be lowered dramatically. Activation of the body's healing mechanisms are found after low pressure/ energy application by the release of growth factors, increased number of blood vessels, and the formation of new true tissue instead of scar tissue. For the treatment of diabetic skin ulcers an unfocused shock head is in controlled clinical studies within the USA. The last application relates to treating open heart muscle and requires a very small shock-wave head. A very short focal distance (11 mm) is used. New blood vessels and the formation of new heart muscle cells are found after treatment. Technical and medical reasons for the different shock-wave beam characteristics are provided.

2aBB3. Shock waves in orthopedics. Takashi Saisu (Div. of Orthopaedic Surgery, Chiba Children's Hospital, 579-1 Heta-chou, Midori-ku, Chiba 266-0007, Japan, h-saisu@dc4.so-net.ne.jp)

Extracorporeal shock wave therapy (ESWT) in the orthopedic field was first reported in 1991 by Valchanou, for the treatment of pseudoarthrosis after fracture. Since 1995, many authors have reported on ESWT for the treatment of painful disease such as calcifying tendinitis of the shoulder, tennis elbow, or planter fasciitis. Now, it has become one of the major treatment methods in orthopedics and veterinary medicine, especially for racehorses. The shock wave research group at Chiba University has been studying ESWT since 1993. We have been elucidating mechanisms of action to the bone and the neural system, performing basic studies using rabbits and rats. A shock wave has three different effects, which are bone induction after multifocal microfracture, perforation of calcified tissue, and induction of degeneration of free nerve ending. Each effect has been utilized for the treatment of pseudoarthrosis, calcifying tendinitis of the shoulder, and enthesopathy such as tennis elbow or planter fasciitis, respectively. Considering our experiences in animal studies, future applications of ESWT would be noninvasive thickening and lengthening of bone and nonsurgical acetabular plasty to prevent osteoarthritis of the hip. Recently, we have been trying nonviral gene transfer assisted by shock waves and we have succeeded in a preliminary animal study.

2aBB4. Influence of focusing and signal shape on the efficiency of stone fragmentation *in vitro* under equal energy conditions.
Rainer E. Riedlinger, Marko Liebler, and Thomas Dreyer (Univ. Karlsruhe, IHE-Akustik, Kaiserstr. 12, D-76131 Karlsruhe, Germany, rainer.riedlinger@ihe.uka.de)

To investigate the mechanisms of fragmentation in lithotripsy, simulations and experiments were performed. Wave shapes deduced from measurements near the focus of a piezoelectric source were used as input signals for finite element calculations of stresses and strains in spherical stones of different sizes. The effects of strongly and weakly focused sound fields were compared to those of a plane wave assumption representing lithotripters with large focal widths. The energies of the fields were matched. In targets with diameters less than 6 mm the simulated tensile stresses induced by strong and weak focusing exceed those of the plane wave assumption. For *in vitro* experiments a double-layered self-focusing piezoelectric source was used. To represent lithotripters with different sound fields the signal shape was varied by changing the interpulse delay but maintaining the energy. The total number of pulses needed for fragmentation into particles smaller than 2 mm diameter was counted. At usually applied energies experimental results show that the numbers of pulses needed for complete fragmentation are almost independent of the signal shape. In conclusion, the results indicate that strongly focused lithotripters are in principle more effective than those with wide focal widths in breakage of small stones.

2aBB5. Using shock waves and micro-nanostructures for gene and drug delivery.
Mark Kendall (Australian Inst. for Bioengineering and Nanotechnology (AIBN), Univ. of Queensland, Level 6, Queensland Bioscience Precinct (Bldg. 80), Brisbane, Brisbane Qd 4072 Australia)

Efficiently and safely delivering biomolecules to the skin's immunologically sensitive cells holds the promise of advancing radical new drugs, vaccines, and immunotherapies for major diseases [D. Chen *et al.*, Expert Rev Vaccines **1**(3): 89–100 (2002)]. Here I present research into using shock waves and micro-nanostructures to meet this goal. First, I analyze the physiology and immunology of the skin target and then introduce current physical approaches for targeting these cells for the immunotherapy [M. A. F. Kendall, Vaccine May 22; **24**(21): 4651–656 (2006)]. Then, I focus on biolistics—accelerating with a helium flow micro-particles coated in DNA to ballistically penetrate the human skin in order to achieve an immunological effect [M.A.F. Kendall, Shock Waves J., **12**(1), 22–30 (2002)]. I present key findings on the engineering of these devices, skin physical interactions induced by micro-particle impact and the resultant local biological responses. Finally, I introduce a micro-nanoprojection array patch technology, highlighting key advantages over biolistics, including the prevention of cell-death from shock impact with key cells.

2aBB6. Measurement of reduced stress in model kidney stones with increased rate of shock wave delivery in lithotripsy.
Teiichiro Ikeda, Michael R. Bailey, Brian MacConaghy, Lawrence A. Crum (Ctr. for Industrial and Med. Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), and Yoichiro Matsumoto (The Univ. of Tokyo, Bunkyo-ku, Tokyo 113-8656, Japan)

Slow clinical shock wave rates more effectively comminute stones. Higher rates create more cavitation bubbles along the focusing axis. Bubble clouds potentially reflect or attenuate the shock wave and also may collapse less energetically. Here, high-speed photo-elastography was used to visualize the dynamic stress distribution inside a transparent model stone. Photo-elastography records constant-stress lines, making quantification possible. PVDF sensors (4 mm diameter) measured force on the proximal face of the stones. The impulsive force of the shock wave and the cloud collapse at various clinical rates (single shocks, 1 Hz, 2 Hz, 3 Hz) in degassed and non-degassed water were calculated from the measurements. Impulse forces from the shock wave and cavitation collapse were comparable in the range $4-7\times10^{-4}$ Ns. At clinical rates in gas-saturated water, the stress fringes of the tensile component of the shock wave were reduced; the observable maximum stress was decreased; and impulsive force from the shock and the cavitation were decreased over single shocks. The results are evidence of reduced stress in the stone at higher rates due to attenuation by bubbles and less so to softened cavitation collapse. [Work supported by Grant Nos. NIH DK43881 and NSBRI SMS00402.]

2aBB7. Numerical study of the collapse of a bubble subjected to a lithotripter pulse.
Eric Johnsen and Tim Colonius (Div. of Eng. and Appl. Sci., California Inst. of Technol., 1200 E. California Blvd., Pasadena, CA 91125, ejohnsen@caltech.edu)

In shock wave lithotripsy, the combined effect of focused shock waves and cavitation pulverizes kidney stones. Although cavitation has been shown to play an important role in the stone comminution process, the underlying mechanism has yet to be fully understood. The goal of the present study is to quantify the potential damage caused by the collapse of a single bubble near a solid surface. Using a high-order accurate quasi-conservative, shock- and interface-capturing scheme [E. Johnsen and T. Colonius, J. Comput. Phys., in press (2006)], the response of an air bubble subjected to a lithotripter pulse is considered. In particular, quantities important in cavitation erosion, such as wall stresses and reentrant jet velocity, are measured as functions of the properties of the pulse (amplitude, wavelength) and the geometry of the problem (stand-off distance from the wall, presence of neighboring bubbles). Preliminary two-dimensional results for a "cylindrical bubble" show that a large water-hammer pressure is measured along the wall. This pressure increases for smaller stand-off distances and longer wavelengths. Further results for spherical bubbles will be presented at the meeting. [This work was supported by NIH Grant PO1 DK043881.]

10:25

2aBB8. The effects of plane shock wave on the endothelial cells *in vitro* and the numerical analysis of pressure wave in the cell. Masaaki Tamagawa, Seiya Iwakura, Shiro Suetsugu, and Jun Fujii (Kyushu Inst. of Technol., Hibikino 2-4, Wakamatsu-ku, Kitakyushu, Fukuoka 808-0196, Japan, tama@life.kyutech.ac.jp)

Shock wave phenomena in living tissues are being applied in the fields of tissue engineering. It is expected that the elastic cells such as endothelial cells and cardio cells have a potential to regenerate or grow quickly by using high pressure wave and short duration time from 1 μs to 100 ms. There are two mechanisms for this, one is the effect of shock waves and the other is the effect of cavitation bubbles. In this paper, to investigate only the effects of plane shock waves on the endothelial cells *in vitro*, the cells worked by shock waves are observed by microscope, and FEM numerical simulation is done to analyze the mechanism. For experiments, the shock tube apparatus is used that makes plane waves and has several tens of ms duration time. After working shock waves (peak pressure 0.4 MPa) on suspended cells, 10% of them are disintegrated, but the others increase faster than control cells *in vitro*. The growth of cells by plane shock waves is also confirmed by the fact that activated gene expression is enhanced. Numerical simulation results show the gradient of the shear stress wave is an important factor.

10:40

2aBB9. Acoustic coupling can be problematic in shock wave lithotripsy. Yuri A. Pishchalnikov, James A. McAteer, Joshua S. Neucks, R. Jason VonDerHaar, Irina V. Pishchalnikova, and James C. Williams, Jr. (Dept. of Anatomy and Cell Biol., School of Medicine, Indiana Univ., 635 Barnhill Dr., Indianapolis, IN 46202-5120, yura@anatomy.iupui.edu)

Research to improve lithotripsy has yielded considerable progress in determining mechanisms of SW-action, has led to development of innovative SW-delivery systems, and has offered practical strategies to enhance stone breakage and minimize renal injury. Little attention has been paid to how SWs are coupled to the body. *In vitro* tests were performed to assess the quality of coupling with a clinical Dornier DoLi-50 lithotripter. A test tank with a Mylar window was coupled to the treatment head using lithotripsy gel. Application of gel as performed in patient treatment always trapped air pockets at the interface, and it took considerable manipulation to eliminate them. Stone breakage was less efficient when air pockets were present, with a linear correlation between percent area of air-pocket coverage and reduction in breakage ($p < 0.001$). Breaking contact and recoupling—as can also occur in patient treatment—reduced stone breakage to ~10% of air-free coupling. Air pockets created when gel was applied to both surfaces, or with coupling and recoupling, reduced the energy density of the pulse to ~30%–50% of air-free. Thus, even under controlled conditions, acoustic coupling in SWL can be inefficient. Poor acoustic coupling could be a significant source of variability in clinical shock wave lithotripsy.

10:55

2aBB10. Experimental application of Holmium:yttrium-aluminum-garnet laser-induced shock wave as a drug delivery system. Tomohiro Ohki, S. H. R. Hosseini, Kazuyoshi Takayama (Biomed. Eng. Res. Organization, Tohoku Univ., Sendai, Japan), Junichi Sato, Atsuhiro Nakagawa, Teiji Tominaga (Tohoku Univ. Grad. School of Medicine, Sendai, Japan), Mariko Kambe (Senseki Hospital, Ishinomaki, Japan), and Mingu Sun (Tohoku Univ., Sendai, Japan)

One of the possible applications of shock waves is enhancement of drug delivery in the central nervous system. To achieve such a goal, it is necessary to develop a suitable shock wave source with the ability to be integrated with an endoscope or a catheter. We have developed a shock wave generator using a pulsed Ho:YAG laser as the energy source; this device is remarkable for its ability to expose shock wave to target tissue in a localized area. The physical feature and characteristics of the generator were clarified. The overpressures of Ho:YAG laser-induced cavitational shock waves were measured by using a PVDF needle hydrophone. Maximum overpressure of 19 MPa at 4-mm distance from tip of the device was

obtained. As a preliminary experiment, the device was applied to evaluate the enhancement of chemotherapeutic effects of shock wave *in vitro*, using human gastric cancer cell (GCIY cell) line and an anticancer drug (Bleomycin: BLM). Proliferation rate of the cells decreased to 90% and 45%, after application of 4000 and 6000 shots of shock waves at the BLM concentration of 1 mic-g/ml. Inhibitions in proliferation rate were observed in accordance with the number of shock wave applications and BLM concentrations.

2aBB11. Experimental study of micro shock wave focusing for precise medical applications. S. H. R. Hosseini, Tomohiro Ohki, and Kazuyoshi Takayama (Biomed. Eng. Res. Organization, Tohoku Univ., 2-1-1 Katahira, Aoba, Sendai 980-8577, Japan)

For applying shock waves to sensitive medical procedures like cranioplasty in a close vicinity of the brain or treatment of myocardial dysfunction, generation of micro underwater shock waves plays an important role. Such delicate applications make limits on usage of conventional shock wave (SW) sources. In the present research a half-ellipsoidal cavity with 20.0-mm minor diameter and the ratio of major to minor diameters of 1.41 was designed as a compact extracorporeal SW source. Silver azide AgN$_3$ pellets ranging from 1.0 to 20 μg with their energy ranging from 1.9 to 38 mJ were used to generate shock waves at the first focal point $F1$ inside the reflector. Irradiation of a Q-switched Nd:YAG laser beam through a 400-μm optical fiber was used to ignite the pellet. The whole sequences of the shock wave generation, propagation, and focusing were visualized by quantitative double pulse holographic interferometry and time-resolved high speed shadowgraph methods. Pressure histories were measured at the shock wave focusing area $F2$ by using a fiber optic probe hydrophone. It is concluded that the compact ESW source has suitable characteristics for medical applications.

11:25

2aBB12. Photo-elastic, high-speed images of stress induced in cylindrical model kidney stones by lithotripsy. Brian MacConaghy, Teiichiro Ikeda, Michael R. Bailey, Adam D. Maxwell (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), and Oleg A. Sapozhnikov (Moscow State Univ., Moscow, 119992, Russia)

Recent experiments and calculations show that a focusing shear wave generated by the shock wave traveling along the length of a cylindrical stone creates the dominant stress and causes fracture of cylindrical model stones. A small disk placed on the proximal face of the stone suppressed the longitudinal wave responsible for spallation in calculations yet had little effect on the number of shock waves required to fracture the stone in experiment. However, a disk placed around the stone blocked the shock wave traveling along the stone in calculations and suppressed fracture in measurements. The conclusion was that so-called dynamic squeezing was a dominant mechanism to spallation. Here, photo-elastic, high-speed imaging was used to observe the suppression of various waves in cylindrical stones made of acrylic. Glycerol was used to avoid artifact from the curvature of the stone. Comparison was made to calculations using the elasticity equations for an isotropic medium. Agreement between measurement and calculation was excellent and supports dynamic squeezing. The results help validate the model, and the technique and modeling may help us understand where and how stress is created in other shock wave therapies. [Work supported by NIH DK43881 and NSBRI SMS00402.]

2aBB13. Shock-wave-based biolistic apparatus. Viren Menezes, S. H. R. Hosseini, Kazuyoshi Takayama (Biomed. Eng. Res. Organization, Tohoku Univ., Sendai, Japan), Mutsumi Nakada, and Akira Kanno (Tohoku Univ., Sendai, Japan)

A shock-wave-based biolistic device has been developed to deliver DNA/drug-coated micro-projectiles into soft living targets. The device consists of an Nd:yttrium aluminum garnet laser, equipped with a suitable

optical setup and a thin aluminum (Al) foil (typically 100-μm thick). The powdered vaccines to be delivered are deposited on the anterior surface of the foil and the posterior surface of the foil is ablated using the laser beam. The ablation launches a shock wave through the foil that imparts an impulse to the foil surface, due to which the deposited particles accelerate to high velocities that are sufficient to enable them to penetrate soft targets.

The device has been tested for *in vivo* DNA delivery by delivering plasmid-coated, 1-μm size, gold (Au) particles into onion and tobacco cells. The GUS activity was detected in the onion and tobacco cells after the addition of an artificial substrate. The present device is totally nonintrusive in nature and has a potential to get miniaturized to suit the existing medical procedures for drug delivery.

2aEA1. Ultrasonic motors—breakthrough trials for the next generation.　Yoshiro Tomikawa, Chiharu Kusakabe, Hideki Tamura, Seiji Hirose　(Dept. of Elec. Eng., Yamagata Univ., Yonezawa, Yamagata 992-8510, Japan, tomikawa@yz.yamagata-u.ac.jp), Takehiro Takano　(Tohoku Inst. of Tech., Sendai, Miyagi 982-8577, Japan), and Manabu Aoyagi　(Muroran Inst. of Tech., Muroran, Hokkaido 050-8585, Japan)

Twenty years and more have passed since real research of ultrasonic motors was started and now their practical applications are performed in some engineering fields. Therefore, such a problem has happened now as to what kinds of breakthrough ultrasonic motors must be researched for the next generation. For this reason, we are challenging the breakthrough research of the ultrasonic motors. This paper deals with such breakthrough motors. In the first part, we deal with thin-form ultrasonic motors of high revolution speed for their use as HDD motors, applying lead-free piezoelectric single crystal of LiNbO$_3$. The second part contains some gyro-moment motors, devised by us originally. The motors can be driven electromagnetically and, moreover, electrostatically in theory. Therefore the motors are suited to ones fabricated by MEMS technology and might be applied as a micro-fun motor for heat radiation in electronic apparatuses, a windmill motor in fuel cells, and so on.

2aEA2. A constant beamwidth transducer for ultrasonic applications.　Kim C. Benjamin, A. Lee Van Buren, Jeffrey A. Szelag, and Sheridan Petrie　(Naval Undersea Warfare Ctr., 1176 Howell St., Newport, RI 02841)

A new class of transducers that produce uniform wide beams ($\sim$20 deg) at ultrasonic frequencies ($\sim$1–2 MHz) is being developed by the US Navy for ultrasonic applications. These transducers will provide a wide insonified field of view for two-dimensional ultrasonic imaging arrays. The design features a larger volume of active material, relative to conventional planar designs, which allows the application of higher drive fields. The prototype described in this article was driven to 200 VRMS and produced a sound pressure of 203 (dB *re* Pa at 1 m) at a frequency of 2.0 MHz. The details of the ultrasonic constant beamwidth transducer (CBT) design, its fabrication, and measured performance are presented. The ultrasonic CBT described in this paper will soon be incorporated into the Navy's Underwater Sound Reference Division (USRD)'s Transducer Standards Loan Program.

2aEA3. Traveling wave power in an energy circulation surface acoustic wave motor stator.　Minoru Kurosawa, Yoshito Miyazaki, and Takashi Shigematsu　(Tokyo Inst. of Technol., G2-32, 4259 Nagatsuta, Midori-ku, Yokohama 226-8502, Japan)

Surface acoustic wave (SAW) motors have been demonstrated their high performance as micro linear motor in speed, thrust, fine stepping motion, and so on. For application of the SAW motor to some equipment, however, the power consumption will be a problem in spite of the superior performance due to the limited power resource of a system. To avoid the large power consumption, an energy circulation driving method has been proposed and tested. The circulation factor will be discussed as concerns the performance at the energy circulation electrode and the phase shift in the system. For example, in case of the 90% circulation coefficient at the circulation electrode, eight times power of the driving power circulates as a traveling wave. But the 45 deg phase shift causes a reduction of one-fourth of the traveling wave. The energy circulation of the SAW motor will be discussed quantitatively. [Research was supported by the Ministry of Education, Culture, Sports, Science and Technology, Grant-in-Aid for Science Research.]

2aEA4. Modeling and performance evaluation of an ultrasonic pump.
Takeshi Hasegawa, Daisuke Koyama, Kentaro Nakamura, and Sadayuki Ueha (P&I Lab., Tokyo Inst. of Technol., 4259-R2-26, Nagatsuta, Midori-ku, Yokohama, 226-8503 Japan, hase@sonic.pi.titech.ac.jp)

This paper describes a low-profile miniature ultrasonic pump consisting of a disk-bending vibrator and a pipe-end located vertically to the disk center via a small gap. First, we explored the relationships between the pump performance and the geometrical conditions of the pump experimentally: the pipe diameter, the gap, and vibration distributions. Based on those results, the thickness distribution of the bending disk was designed using finite-element simulations so that the vibration distribution near the pipe might become uniform. Maximum pump pressure of 20.6 kPa was obtained with a 30-mm-diam bending disk and electrical power consumption of 3.8 W. For optimization, we constructed a model of the pump operation in this study. Nonlinearity in the elastic constant of the working fluid was introduced into the model because the temporal change rate of the gap caused by the ultrasonic vibration of the disk vibrator considerably affects the pump's pressure generation. Results show that the calculated pump pressure well simulates the measured dependence of the gap on the pressure. The acoustic pressure was measured using a fiber optic pressure probe and was compared to the calculated pressure value.

9:10

2aEA5. Methanol sensor using a shear horizontal surface acoustic wave (SH-SAW) device.
Jun Kondoh (Grad. School of Sci. and Technol., Shizuoka Univ., Johoku 3-5-1, Hamamatsu-shi, Shizuoka 432-8561, Japan), Yoshikazu Matsui (Shizuoka Univ., Hamamatsu-shi, Shizuoka 432-8561, Japan), and Showko Shiokawa (SAW&SPR-Tech. Corp., Hamamatsu-shi, Shizuoka 432-8011, Japan)

Measurements of liquid properties are important for industry, environmental issues, and human life. Because a surface acoustic wave on 36YX-LiTaO3 is a shear horizontal (SH) mode, the liquid-phase SAW sensor is realized using a crystal. In this paper, we present a SH-SAW-based methanol sensor that functions at high temperature. The SH-SAW propagation characteristics were calculated using a numerical calculation method considering temperature coefficients of the substrate and liquid. Calculation results indicate that the SH-SAW sensor can detect methanol solutions at temperature greater than 50 °C. Moreover, the calculated results suggest that the sensor sensitivity increases with increasing temperature. The methanol solutions were measured using the SH-SAW sensor. Concentration and temperature of the methanol solution were varied. Linear relationships between sensor responses and concentration were observed at each temperature. As the numerical calculation results suggest, the sensor sensitivity increases with increased temperature. Based on the experimental results, the detection limit of the sensor was estimated as 0.10% by weight at 60 °C.

9:25

2aEA6. An ultrasonic linear motor using traveling waves of twin ridge.
Osamu Koyama, Daisuke Koyama, Kentaro Nakamura, and Sadayuki Ueha (P and I Lab., Tokyo Inst. of Technol, 4259-R2-25 Nagatsutacho, Midori-ku, Yokohama-shi, Kanagawa 226-8503, Japan, shukoyama@sonic.pi.titech.ac.jp)

An ultrasonic linear motor using ridge-mode traveling waves on a substrate is proposed for precision positioning. In our experiments, two parallel ridges are machined on an alumina ceramic substrate with the spacing of 19 mm. The width, height, and length of the ridge are 3 mm, 9 mm, and 186 mm, respectively. Two piezoelectric elements, 19 mm in length and 5×5 mm^2 in cross section, were installed at the position of 15 mm from each end of the ridge, and excited at 87.136 kHz in their fundamental longitudinal mode to stimulate the fundamental ridge mode. Elliptical particle motions are formed, due to traveling waves along the ridge waveguides by the phased drive of the two transducers. An alumina ceramic slider pressed to the two waveguides is moved at 13 mm/s in the opposite direction to the traveling wave through the friction forces. The moving direction can be switched by changing the propagation direction of the traveling wave. The detailed characteristics are experimentally studied.

2aEA7. An application of surface acoustic wave for micro fluid systems.
Hiroki Kuwano, Masato Sato, Jooohyng Bae, and Sumito Nagasawa (Grad. School, Tohoku Univ., 6-6-01 Aza-Aoba, Aramaki Aoba-ku, Sendai, Japan)

This paper describes an application of surface acoustic wave for micro fluid systems. Owing to its high sensitivity, fabrication easiness, and actuation capacity, current SAW devices are widely used as a chemical sensor and linear motor [Takahashi *et al.* IEEE Trans. Ultrason. Ferroelectri. Frequ. Control **43**, 901 (1996)] as well as SAW devices including filters and SAW-Tag in the field of mobile communication. Furthermore, its applications for actuators in liquid such as liquid streaming [Shiokawa *et al.*, Jpn. J. Appl. Phys. **28**(28-1), 126–128 (1989)] and atomizer [Kurosawa *et al.*, Sensors Actuators A **50**, 69 (1995)] are very attractive for micro fluid systems such as a micro injector, a micro total analysis system, and a lab-on-chip. In this paper, we propose and evaluate a novel fluid actuator device for micro fluid systems using Rayleigh waves. One of the important issues is a micro pump and fluidic friction of the micro channel for TAS. The surface acoustic wave is one solution for the issue. Some of the fluid dynamics will be discussed.

2aEA8. Phased arrays and devices for high-intensity focused ultrasound.
Greg T. Clement (Harvard Med. School, 221 Longwood Ave., Boston, MA 02115)

Focused ultrasound (FUS) is rapidly attracting attention as an alternative to surgery for the treatment of tumors and other disorders. Such therapeutic procedures were first proposed over 60 years ago, but have only recently become clinically feasible. These new successes can be attributed primarily to two advances: improvement in noninvasive monitoring techniques and the development of high-power ultrasound arrays. As the field progresses, there is a demand for increased transducer bandwidth, allowing tissue-specific frequency optimization, and even imaging, while maintaining high acoustic power outputs. These arrays have been made possible via dice-and-fill manufactured 1-3 piezocomposite arrays. Transducers with over 500 elements have been tested in the clinic,

and designs have been proposed for at least 5000 elements. Meanwhile, the rapid development of high-power, broadband IC technology has made it possible to build electronic components for amplifiers and switching at a practical cost (under $50/channel). This talk will present several devices being developed in the Harvard/BWH FUS lab, in conjunction with the newly formed National Center for Image Guided Therapy. The challenges and limitations of operating at high driving intensities will also be addressed, with particular attention to nonlinear restoring behaviors of arrays driven off-resonance. [Work supported by NIH Grant U41 RR019703.]

2aEA9. Development of miniature ultrasonic probe with piezoelectric poly-crystalline film deposited by hydrothermal method. Tomohito Hasegawa, Akito Endo, Norimichi Kawashima, Shinichi Takeuchi (Toin Univ. of Yokohama, 1614 Kurogane-cho, Aoba-ku, Yokohama, Kanagawa 225-8502, Japan), Mutsuo Ishikawa, and Minoru Kurosawa (Tokyo Inst. of Technol., 4259 Nagatutamati, Midori-ku, Yokohama, Kanagawa 226-8502, Japan)

Recently, a PZT poly-crystalline film deposited on titanium substrate using the hydrothermal method was studied actively in our laboratory for development of an ultrasonic sensor. These PZT poly-crystalline films can form PZT poly-crystalline films easily on substrates of complex shape using hydrothermal method. We reported a needle-type miniature hydrophone and the ultrasonic transducer with hydrothermally synthesized PZT poly-crystalline films. Results confirmed that the hydrothermally synthesized PZT poly-crystalline films showed wideband frequency characteristics in the megahertz band of sensitivities. A miniature ultrasonic probe with wide frequency band characteristics of sensitivities is thought to be producible using hydrothermally synthesized PZT poly-crystalline films. Miniature ultrasonic probes were fabricated using hydrothermally deposited PZT poly-crystalline film on the end of 0.6-mm-diam titanium wires. Ultrasonic imaging experiments of a target in water were performed using a fabricated ultrasonic probe with hydrothermally synthesized PZT films. Consequently, it was confirmed that this probe has a center frequency of 16 MHz, a bandwidth of 80%, and distance resolution more than 80 μm. We report the structure and performance of fabricated ultrasound probes with hydrothermally synthesized PZT poly-crystalline films, along with results of imaging experiments performed in water.

2aEA10. Study of a micro-tactile sensor with longitudinal vibrator in a smart micro-ultrasonic scalpel. Shunsuke Uchikawa and Minoru K. Kurosawa (Dept. of Information Processing, Tokyo Inst. of Technol., Mailbox: G2-32, 4259 Nagatsuta, Midori-ku, Yokohama, Japan)

A smart micro-ultrasonic scalpel using a hydrothermal PZT film vibrator has been proposed and fabricated. The micro-scalpel has two functions: in addition to a micro-ultrasonic scalpel, a micro-tactile sensor to indentify tumors. The tactile sensor function is studied. The resonance frequency of the vibrator changed when the vibrator tip made contact with a rubber sample. Irrespective of compliance of the sample, the resonance frequency increased up till about tens of micrometer sample. Then, against further sample deformation by the tip, the resonance frequency decreased. From the theoretical analysis using mechanical contact modeling [K. L. Johnson, *Contact Mechanics* (Cambridge University Press, Cambridge, 1985], it was found that the resonance frequency drop was caused by increase of the damping effect of the sample due to deeper stick of the vibrator tip. The Young's modulus of samples is able to be estimated from the resonance frequency curve. From the experimental result, there was a difference in the resonance frequency between a soft rubber sample and a hard one. The elastic characteristic of the sample will be quantified.

11:10

2aEA11. The TDK model for micromachined capacitive Lamb wave transducers. Li-Feng Ge (School of Electron. Sci.e and Technol., Anhui Univ., Hefei 230039, China)

Electrostatic or capacitive ultrasonic transducers (EUTs or CUTs) were originally developed from the condenser transmitters and microphones with grooved and roughened backplates in the 1930s. Significant progress in theoretical and experimental research has been made since the introduction of micromachining techniques at the end of the 1980s. We have seen the advancement not only from the roughened ultrasonic transducers to the 2-D array micromachined capacitive ultrasonic transducers (mCUTs), but also from the grooved ultrasonic transducers to the micromachined capacitive Lamb wave transducers (mCLWTs). Thus, the theoretical TDK model originally developed for grooved ultrasonic transducers [L.-F. Ge, Proceedings 16th Intl. Conf. Acoustics/135th ASA Meeting, l08l–1082, 1998; and Sciences in China (A), (in English), **42**, 1308–1315 (1999)] can be used for mCLWTs. It is most important for a reliable model to be able to predict the transducer's natural frequencies, at which the lowest-order antisymmetric Lamb wave (A_0 wave) is excited. As an example using a typical transducer [M. H. Badi *et al.*, IEEE Trans. Ultrason. Ferroelectr. Freq. Control **50**(9), 1191–1203 (2003)], the fundamental frequency predicted using the TDK model is 2.18 MHz, which agrees well with the measured result of 2.1 MHz. [Work supported by NSFC (60374044).]

Session 2aED

Education in Acoustics: Demonstrations and Tools in Acoustics Education

Uwe J. Hansen, Cochair
64 Heritage Dr., Terre Haute, IN 47803

Fumiaki Satoh, Cochair
Chiba Inst. of Technology, Dept. of Architecture and Civil Engineering, 2-17-1 Tsudanuma, Narashino, Chiba 275-0016, Japan

Chair's Introduction—9:00

After the Chair's Introduction, the authors of each paper will briefly describe their demonstrations (2 minutes each). Authors will then be at their demonstrations to interact with interested participants for the remainder of the session.

Invited Papers

2aED1. Visualization of acoustic resonance phenomena using Kundt's dust figure method. Shinichi Sakamoto, Takumi Asakura, Kanako Ueno (Inst. of Industrial Sci. Univ. of Tokyo, Komaba 4-6-1, Meguro-ku, Tokyo, 153-8505, Japan, sakamo@iis.u-tokyo.ac.jp), Yu Sakimoto, Fumiaki Satoh, and Hideki Tachibana (Chiba Inst. of Technol., Narashino-shi, Chiba, 275-0016, Japan)

It is very effective to visualize a sound field for intuitive understanding of various acoustic phenomena, especially for acoustic education. The most famous and classical visualization technique is the Kundt's dust-tube method contrived by August Adolph Kundt. He devised this experimental technique to determine the sound velocity in the air by observing the mode pattern of a standing wave excited in a glass tube. The technique can be applied to various other acoustic resonance phenomena. In Japan, Sato and Koyasu applied this technique to a two-dimensional room acoustic model experiment in which the effect of the shape of a reverberation room on the normal modes was examined. Referring to these experiments, the authors made experimental equipment to visualize acoustic resonance phenomena for an educational purpose. In our experiment, two types of two-dimensional boxes with hard surface were prepared. In these boxes, normal modes in a closed sound field and the Helmholtz resonance phenomena, which are essential and important for architectural acoustics, can be visualized. These physical experiments are visually impressive on students in architectural courses and therefore the experiment is efficiently used in architectural acoustic courses.

2aED2. Animations of different sound field decomposition methods. U. Peter Svensson and Bård Støfringsdal (Acoust. Group, Dept. of Electron. and Telecommunications, Norwegian Univ. of Sci. and Technol., NO-7491 Trondheim, Norway, svensson@iet.ntnu.no)

Many methods for solving sound-wave propagation problems are based on a decomposition of the sound field. Here, several such decomposition methods will be demonstrated and it will be illustrated how they can give the same final solution even if the partial solutions, or the solutions outside a limited domain, can be very different. Animations of harmonic and transient solutions will be used to illustrate sound-field synthesis based on a decomposition into plane waves, cylindrical harmonics, and geometrical acoustics plus edge-diffraction components. It will also be shown how a sound field that is measured in discrete points can be converted to different representations. These decompositions have pedagogical merits but can also be used in sound-field reproduction techniques. Examples will include free-field situations as well as indoor cases with a multitude of reflections. [This research was supported by the Research Council of Norway.]

2aED3. Introduction of sound material in living environment 2004 (SMILE 2004): A sound source database for educational and practical purposes. Keiji Kawai (Grad. School of Sci. and Technol., Kumamoto Univ. 2-39-1 Kurokami Kumamoto 860-8555, Japan, kawai@arch.kumamoto-u.ac.jp), Kazutoshi Fujimoto (Kyushu Univ.), Teruo Iwase (Niigata Univ.), Tetsuya Sakuma (The Univ. of Tokyo), Yoshito Hidaka (Tohwa Univ.), and Hirohito Yasuoka (The Ctr. for Better Living)

Sound sources are used in various settings of education, research, and business that are related to architectural acoustics. Especially in educational scenarios, they are very effective for students to learn theories together with the experience of listening to actual sounds related to them. Sound Material In Living Environment (SMILE 2004), a sound source database published in 2004 in DVD form (Japanese only), is the culmination of our project. SMILE 2004 is intended as a collection of sample sounds for use in lectures on architectural acoustics at universities or industrial high schools. In addition, it is useful for measurements or demonstrations for academic or practical purposes. The database contains 913 digital sound files of real sounds and impulse responses, which cover the

study fields of acoustics, noise control, and soundscapes. Each sound is accompanied by such information as the 1/1 octave band sound pressure levels and a brief explanation and photographs of the situation in which the sound was recorded. In addition, sample presentations for lectures and practical demonstrations are attached as examples of the use of this database for educational and practical purposes. Details of all the above features will be introduced in a demonstration.

2aED4. A toy using vibrations. Kentaro Nakamura and Sadayuki Ueha (Precision and Intelligence Lab., Tokyo Inst. of Tech., R2-26, 4259 Nagatsuta, Midori-ku, Yokohama 226-8503, Tokyo, Japan)

This study is focused on a toy using vibrations. The toy is composed of a rectangular wooden bar with ten notches and a thin wooden plate at one end of the bar. The plate has a hole at its center and is loosely put at the bar end using a pin. The plate can rotate freely. If notches on the bar are scratched by another bar, the plate begins to rotate due to the vibrations excited on the rectangular bar. The interesting thing is that the rotation direction can be controlled if the way of rubbing is altered. The operation principle of the toy is revealed through experimental observations. The measurements of vibration locus of the pin help us to understand the rotation mechanism. According to these results, the method to control the rotation direction is explained and the analogy to the operation principle of ultrasonic motors is presented.

2aED5. The multimedia simulator of radiation sound field created by a vibration disc. Kohei Michigami, Takahiro Masuda, Hiroshi Suda, and Yoshiro Miida (Chiba Inst. of Technol., 2-17-1 Tsudanuma, Narashino_city, Chiba 275-0016, Japan, kohei@miida.net.it-chiba.ac.jp)

In the field of acoustic education, acoustic phenomena are represented in textbooks as sound models and complex numerical formulas. For that reason, it is difficult for students to visualize, intuitively, the relations between acoustic phenomena and complex numerical formulas. Sufficient understanding was not obtained using static teaching materials, such as sentences and figures in textbooks and notes on a blackboard. Therefore, we have produced multimedia teaching materials that render difficult phenomena as interactively visible. The multimedia teaching materials that have been produced comprise explanatory slides, relation movies, and simulator teaching materials. They show a radiation sound field created by a vibrating disc simulator. It is necessary to calculate many complex series to compute the sound field. Then, the sound field is changed complexly and remarkably by wavelength. Therefore, it is a difficult field to understand for students. Our multimedia teaching material expresses it using 3D-CG. Students can see details of the sound-field changing perspective and the wavelength and disc size ratio. Moreover, students can use it to verify the sound pressure level of a graphically selected point, just as with a measuring instrument.

2aED6. Technical listening training: Systematic training program designed to improve auditory sensitivity. Kazuhiko Kawahara, Masayuki Takada, Shin-ichiro Iwamiya, Yoshitaka Nakajima (Dept. of Acoust. Design, Faculty of Design, Kyushu Univ., 4-9-1 Shiobaru Minami-ku, Fukuoka, 815-8540, Japan, kawahara@design.kyushu-u.ac.jp), and Kazuo Ueda (Kyushu Univ., Fukuoka, 815-8540, Japan)

Technical listening training is a systematic training program designed to improve auditory sensitivity. Through this program, students can obtain the necessary auditory sensitivity before gaining work experience on the job. The type of auditory sensitivity acquired through experience depends of course on the occupation. In contrast, technical listening training provides wide varieties of experiences, so that students can obtain auditory sensitivities associated with various fields and easily adapt to new auditory environments. Technical listening training was developed at the Department of Acoustic Design of the Kyushu Institute of Design. The program has been improved and is still included as part of the curriculum of the Department of Acoustic Design. The present demonstration exhibits the concept of technical listening training as well as its practical application at the School of Design, Kyushu University.

2aED7. An integrated system for learning musical theories from western classical and popular music. Masanobu Miura (Dept. of Media Informatics, Faculty of Sci. and Technol., Ryukoku Univ., Ostu 520-2194, Japan), Norio Emura, and Masuzo Yanagida (Doshisha Univ., Japan)

Presented here is a support system for learning the theory of harmony, one of the main subjects in music education consisting of a set of forbidden progressions. By solving given tasks in the theory of harmony, students can learn forbidden progressions. Shown here is a system that generates all the allowable solutions for given bass tasks within triads, named ''BDS'' (Basse Donnée system), together with a checking system for answers given by students, named ''VISAGE'' (Validity Inspecting System for Answers of Given Exercises). VISAGE is designed to point out note allocations that violate forbidden progressions in an input answer if any. In case an answer of a given exercise does not violate forbidden progressions, the input answer is evaluated from a viewpoint of music. Also presented is ''MAESTRO'' (Musical Aesthetics Evaluation System for Tonal music in Regular and Orthodox style), which evaluates

2aED8. Acoustic demonstrations for education in speech science. Takayuki Arai (Arai Lab., Dept. of Elec. and Electron. Eng., Sophia Univ., 7-1 Kioi-cho, Chiyoda-ku, Tokyo, 102-8554 Japan)

Acoustic demonstrations are highly effective for education in speech science. We recently developed two educational tools for acoustics. The first educational tool is a set of physical models of the human vocal tract and related models. It contains cylinder and plate-type models [T. Arai, J. Phonetic Soc. Jpn., **5**(2), 31–38 (2001)], a sliding three-tube model [T. Arai, Acoust. Sci. Technol., to be published], lung models, an artificial larynx, and head-shaped models [T. Arai, Acoust. Sci. Technol., **27**(2), 111–113 (2006)]. Each model has its own advantages and, if combined effectively, can produce a systematic and comprehensive education in speech production from the lungs to the head. The second educational tool is "Digital Pattern Playback (DPP)" [T. Arai *et al.*, Acoust. Sci. Tech., to be published], which converts a spectrographic image of a speech signal back to sound by digital signal processing. A printed spectrogram on a sheet of paper can also be converted immediately after capturing the image from a camera, and we confirmed that this is more intuitive for learners than converting from an electronic image. [Work partially supported by JSPS.KAKENHI (17500603).]

2aED9. Tools for speech perception, production, and training studies: Web-based second language training system, and a speech resynthesis system. Reiko Akahane-Yamada, Takahiro Adachi (ATR, 2-2-2, Hikaridai, Seika-cho, Soraku-gun, Kyoto, 619-0288 Japan), and Hideki Kawahara (Faculty of Systems Eng., Wakayama Univ. 930 Sakaedani, Wakayama, 640-8510 Japan)

We describe a Web-based instruction system for second language (L2) learners, dubbed ATR CALL. This system is a collection of speech perception, production, and comprehension training tools, designed to examine L2 acquisition mechanisms, especially for native speakers of Japanese who are learning English as L2. Each training component focuses on the acoustic-phonetic, prosodic, lexical, or semantic decoding level of spoken language. The stimuli are selected and presented from a large speech database of 13 000 English words and 6000 English sentences. In the pronunciation training component, learners' productions are scored using HMM-based evaluation algorithms, and automatic and immediate feedback about pronunciation goodness is provided. Speech analysis tools for language learners are also provided. We also describe a speech manipulation system, dubbed STRAIGHT [Kawahara *et al.*, Speech Commun. (1999)]. This system resynthesizes stimuli with quality as high as the original stimulus even after manipulating multiple parameters. A speech morphing algorithm on this system enables us to manipulate various features independently [Kawahara *et al.*, ICCASP 2003]. Thus, it generates stimulus continuum varying in supra-segmental domain and/or segmental domain. [Work supported by JSPS, and e-Society by MEXT.]

2aED10. Vowel synthesis tool based on transmission line model as a web application. Kohichi Ogata, Takuro Masuya, and Yuichiro Shin (Grad. School of Sci. and Technol., Kumamoto Univ., 2-39-1 Kurokami Kumamoto 860-8555, Japan, ogata@cs.kumamoto-u.ac.jp)

This paper introduces a web application for vowel synthesis in acoustics education. Synthesis systems that provide users with interactive operation for determining vocal tract configuration and vocal fold control parameters can be effective tools for intuitive understanding of vowel production for students. For example, differences in the size of the vocal tract and vocal folds between male and female speakers can be recognized as differences in formant and pitch frequencies in speech sounds. The realization of such a system as a web application is suitable for platform independent use, considering the recent progress in information and communication technology. In our developed system, interactive operation for determining vocal tract configuration and vocal fold control parameters is achieved on a web browser by using a Java applet. These articulatory parameters are transferred to a server computer via a client/server connection using socket programming, and synthetic speech is produced using calculation programs on the server computer. The speech synthesizer installed on the server is based on the hybrid speech production model proposed by Sondhi and Schroeter. A preliminary user test showed that the system demonstrated a certain applicability as a teaching tool.

2aED11. WWW-based multilingualized system for technical listening training. Akira Nishimura (Dept. of Media and Cultural Studies, Tokyo Univ. of Information Sci., 1200-2, Yato-cho, Wakaba-ku, Chiba, Japan)

A WWW-based system for technical listening training is proposed. Messages from the system shown in a WWW browser are multilingualized using the GNU gettext mechanism. A system administrator can easily set up the system in a user's language by translating the message catalog. The WWW-based training system is superior to previous training systems in the following respects: (1) software and hardware can be organized more easily; (2) modification and creation of the contents of training are simple; (3) individual training parameters can be set for users; (4) many users can use the system individually or simultaneously; (5) the results of training for users are saved and summed individually; and (6) difficulty of discrimination training is automatically set up individually. Training experiments of intensity discrimination and frequency discrimination were performed using a prototype of the training system for subjects who were naive to auditory experiments. Significant improvements in the abilities of both intensity and frequency

discrimination were observed from results of these experiments. The system is guaranteed to be legal for use, distribution, and modification under the terms of the GNU General Public License. Demonstrations and software packages of the system are distributed at http://adlib.rsch.tuis.ac.jp/~akira/atsdemo/index_en.html.

2aED12. Wonders in perception and manipulation of speech. Makio Kashino (NTT Commun. Sci. Labs./ERATO Shimojo Project, JST/Tokyo Inst. Tech., Atsugi, Kanagawa 243-0198, Japan, kashino@avg.brl.ntt.co.jp), Hideki Kawahara (Wakayama Univ., Wakayama, Wakayama 640-8510, Japan), and Hiroshi Riquimaroux (Doshisha Univ., Kyotanabe, Kyoto 610-0321, Japan)

Under certain conditions, the auditory system can display a number of amazing behaviors. Some of these can be quite unique and may have significant importance for our understanding of the perception of sound. This presentation focuses on behaviors closely related to speech perception. One phenomenon that will be described is termed phonemic restoration. In it, sounds actually missing from a speech signal can be synthesized by the auditory system and clearly heard. Another phenomenon involves noise vocoded speech. In it, speech remains highly intelligible despite the fact that much of its spectral detail is absent. Audio demonstrations will be provided so that the phenomena can be directly experienced. Studying these phenomena will help us understand the function of the central auditory system and develop improved techniques for speech recognition and speech synthesis. This presentation will also contain a demonstration of STRAIGHT, a versatile tool allowing manipulation of various aspects of the speech signal. These demonstrations may be of interest not only to students, but also to teachers in physiology, psychology, and engineering.

2aED13. Amazing features of the auditory system. Kaoru Ashihara (AIST Tsukuba Central 6, 1-1-1 Higashi, Tsukuba, Ibaraki 3058566, Japan, ashihara-k@aist.go.jp), Yukio Iwaya (Tohoku Univ., Aoba-ku, Sendai 9808577, Japan), Kengo Ohgushi (Oheyama-cho Goryo, Nishikyo-ku, Kyoto, 6101102 Japan), and Yoshitaka Nakajima (Kyushu Univ., Minami-ku, Fukuoka 8158540, Japan)

Some audio and audiovisual demonstrations will be presented in order to review the unique nature of the auditory system. The demonstrations cover a wide range of topics: the gap transfer illusion, combination tone, interaction between auditory and visual information, and binaural recording and reproduction. The phenomena to be presented are closely related to the key features of hearing, such as the auditory scene analysis, speech perception, perception of the spatial information, and interaction with other modalities. Because these demonstrations are not only attractive but also of some scientific importance, they can be used as teaching materials in education of physics, physiology, psychology, and engineering. Studying these phenomena will give us insights into the functions of the peripheral and central auditory system.

2aED14. Inexpensive demonstration experiments in acoustics. Andrew Morrison (Dept. of Phys., Illinois Wesleyan Univ., P.O. Box 2900, Bloomington, IL 61702-2900) and Thomas Rossing (Stanford Univ., Stanford CA 94305)

We describe and demonstrate simple classroom demonstration experiments in acoustics using inexpensive equipment.

2aED15. Demonstration of wave synthesis and spectral analysis. Uwe J. Hansen (Dept. of Phys., Indiana State Univ., Terre Haute, IN 47809)

Many inexpensive keyboard synthesizers include a flute sound with overtone levels about 30 dB below the fundamental. Since these wave shapes are nearly perfect sine waves, they are ideally suited to introduce the concept of complex tone synthesis by adding harmonics. Such a keyboard will be available at the station for demonstration purposes and for viewer experimentation. Complex tone synthesis using amplitude control in a Cool-edit program will also be available.

2aED16. Animations, visualizations, and auralizations in architectural acoustics. Ralph T. Muehleisen (Civil and Architectural Eng., Illinois Inst. of Technol., Chicago, IL 60616, muehleisen@iit.edu)

A number of animations, visualizations, and auralizations developed for use in architectural acoustics classes are presented. Animations of plane waves, spherical waves, and standing waves were created using MATLAB software. Visualizations of modes in regular and arbitrary shaped enclosures were created in Comsol Multiphysics software. Auralizations of tonal and broadband noise, hearing loss, transmission loss, and classroom acoustics were created using Adobe Audition software.

Contributed Papers

2aED17. Sonification of sound: Auditory display for acoustics education. Densil Cabrera, Sam Ferguson, and Robert Maria (Faculty of Architecture, Univ. of Sydney, NSW 2006, Australia)

Sonification is concerned with data representation to the ear using nonspeech audio. While auralization is routinely used in architectural acoustics, the broader processes encompassed by sonification are not so commonly applied, but can enhance the appreciation of acoustical proper-

ties of materials and structures, audio signals, and acoustic system measurements. We present examples of sonifications such as (*i*) auditory graphs of reflection and transmission coefficients and reverberation times; (*ii*) auditory graphs of percentiles and moments, applied to time-varying sound levels and to magnitude spectra; (*iii*) conditioning of room impulse responses for sonification using techniques such as time stretching, signal reversal, filtering and auto-convolution/correlation; (*iv*) sonification of complex frequency response or signal spectra; and (*v*) applications of the Hilbert transform for audio signal sonification. Compared to graphic or

numeric representation, such sonifications have the advantage of providing an aural experience of the aspect of sound that is sonified, and so directly convey to a listener something of the meaning of the data.

Furthermore, since it was possible to use it for a hand bell and a musical game mimicking the card game "Concentration," it may be applicable for musical education.

2aED18. Rainfall estimation using SORFED (SOund Recording For EDucation). Lucas B. Lezamiz (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Box 355640, Seattle, WA 98105, lucas@apl.washington.edu)

Underwater sound provides an abundance of information about the environment, both natural and man-made. Using an underwater hydrophone and a webcam above the water's surface, the SORFED website gathers and stores ambient noise from Lake Union 24 hours a day, 30 days at a time. Users can explore the sound signatures of different weather events and human activity on the lake by listening to audio clips side by side with video from the webcam. This website was used as the primary tool for teaching high school students in Seattle how to estimate rainfall by listening to underwater noise. Students worked in teams to calibrate underwater noise to rain rate, then used this relationship to estimate rain rate as a function of time on other days based on the noise level recorded in the lake. Total rainfall was then found by integration. Using similar techniques, students can explore other topics including shipping rate estimation, human behavior and activity, signal-to-noise ratio, and concepts in differentiation and integration.

2aED19. Beamforming with multiple acoustic sources in the classroom. Edward Tucholski (Phys. Dept., Chauvenet Hall, U.S. Naval Acad., 572C Holloway Rd., Annapolis, MD 21402, ejtuchol@usna.edu)

Superposition of multiple sources, constructive and destructive interference, and beamforming are common topics in undergraduate acoustics. While the mathematical models of these topics are fairly easily performed by students, particularly in the far field, the learning experience is enhanced with simple visualizations and by actually building the model with speakers and measuring the resulting amplitude at various angles with a microphone. While this experiment is often performed in an anechoic chamber for best agreement between theory and experiment, the apparatus will work in a typical classroom as a demonstration. The uncomfortable tonal noise in the classroom is eliminated if ultrasonic (30–50-kHz) sources are used. Apparatuses to be demonstrated have been used successfully at the U.S. Naval Academy in both majors and basic physics classrooms, where the professional development of every officer requires an understanding of sensor beamforming.

2aED20. A MIDI (musical instrument digital interface) controller using a mat switch operable by a user in a wheelchair. Takuya Niikawa (Dept. of Biomed. Eng., Osaka Electro-Commun. Univ., 1130-70 Kiyotaki Shijo-Nawate, Osaka 575-0063, Japan), Ryosuke Kawachi, Kotaro Minato (Nara Inst. of Sci. and Technol., Nara 630-0192, Japan), Tatsuo Yoshihara, and Naoya Terayama (Osaka Electro-Commun. Univ., Osaka 575-0063, Japan)

In this study, we devised a MIDI controller that a user with severe physical dysfunction was able to operate by depressing a mat switch with an electric wheelchair, and proposed a new method for musical education and therapy employing the system. This system comprises a mat switch resistant to 100 N of a movement load in a 500×700 mm^2 area, an A/D converter, a PC, and a MIDI device. Signal output from the mat switch is converted to MIDI signals by the PC and transmitted to the MIDI device. By pushing down ten mat switches arranged in a matrix pattern, a user can manipulate all elements necessary to control MIDI signals, such as volume and musical sounds. As a result, it was confirmed that a user in an electric wheelchair was able to control musical notes, volume, tunes, and scales.

2aED21. An online virtual acoustic guitar laboratory. Nelson Lee and Julius O. SmithIII (Ctr. for Comput. Res. in Music and Acoust. (CCRMA), The Knoll, 660 Lomita, Stanford, CA 94305-8180, nalee@stanford.edu)

We present a "virtual acoustic guitar laboratory" in which students can bring in their own acoustic guitars, record several notes, and follow a step-by-step procedure to create their own real-time computational model, suitable for use in a synth plugin in an electronic music studio. The guitar synthesis model is based on the commuted waveguide synthesis technique (http://ccrma.stanford.edu/~jos/cs.html). Online laboratory materials are presently available at (http://ccrma.stanford.edu/~jos), the project website (http://ccrma.stanford.edu/realsimple/), and are also being ported to Connexions (http://www.cnx.org/), an online repository of educational materials freely distributable under a Creative Commons license. Connexion's "modules" and "courses" (which are simply module sequences) are readily and freely accessible and modifiable to allow instructors to adapt the materials as appropriate for their own classroom needs. The online lab materials contain Web pointers to relevant portions of online textbooks covering theoretical aspects of the analysis and synthesis methods used, thereby offering the student a demand-driven deeper understanding within a motivating context. [This work was supported by the Wallenberg Global Learning Network.]

2aED22. Application of speech recognition to teaching English as a foreign language. Hiroyuki Obari (Aoyama Gakuin Univ., 4-4-25, Shibuya-ku, Shibuya-ku, Tokyo, 150-8366 Japan), Hiroaki Kojima, Hiroshi Oomura (Adv. Industrial Sci. and Technol., Tsukuba, Ibaraki, 305-8568 Japan), and Machi Okumura (PRONTEST, Tsukuba, Ibaraki, 305-8568 Japan)

English is considered to be an important common international language; therefore, in Japan English education plays an important role to make Japanese speakers of English intelligible enough to be properly understood for international communication. Intonation and the rhythm of the language and pronunciation of each word are crucial to comprehensive speech. So far the CALL system has not been well equipped with effective software for improving pronunciation. This is why PRONTEST and AIST (National Institute of Advanced Industrial Sciences and Technology) have been jointly developing special software for teaching English pronunciation using the technology of Speech Recognition System integrated into the CALL system. This software can automatically correct the crucial pronunciation of lower Japanese EFL learners and teach them how to improve its pronunciation with a good piece of advice after they pronounce several words with the computer. So far we have successfully developed the CALL system, in which we can deal with the following sounds: [r] [l] [s] [sh] [th] [z] [f] [v] [d] [b]. We carried out an experiment and found out that about 90% of the students were satisfied with correcting their pronunciation using this software at Aoyama Gakuin University.

2aED23. Manuscript preparation with LyXforJASA. John C. Burgess (Dept. of Mech. Eng., Univ. of Hawaii, 2540 Dole St., Honolulu, HI 96822)

LyXforJASA is a graphical software package for creating manuscripts that meet the submission requirements of the Peer-X-Press (PXP) system used by the *Journal of the Acoustical Society of America* (JASA). Its main features are graphical templates for superscript and author-year citation styles and for single figures. It is based on LyX, a screen-based graphical user interface (GUI) to the LaTeX typesetting language. Authors see manuscript content, not LaTeX code. LyX liberates authors from document bookkeeping, such as spacing, font selection, and section, equation,

figure, table, and citation numbering. LyX has a comprehensive, point and click, GUI mathematics editor with an extensive list of symbols. It can export text in LaTeX, PDF, PostScript, and ASCII formats. It has been ported successfully to Linux, Macintosh OSX, and Windows XP. LyXfor-JASA packages can be found at http://ww2.hawaii.edu/~jcb/LyXforJASA/LyXforJASA.html

Musical Acoustics: Comparing Asian and Western Instruments I

Tomoyasu Taguti, Cochair
Konan Univ., 8-9-1 Okamoto, Higashi-ku, Kobe 658-8501, Japan

Thomas D. Rossing, Cochair
Stanford Univ., CCRMA, Dept. of Music, Stanford, CA 94305

Invited Papers

8:20

2aMU1. Acoustics of Eastern and Western bells, gongs, and drums. Thomas Rossing (CCRMA Dept. of Music, Stanford Univ., Stanford, CA 94305)

Bells, gongs, and drums have been part of most Eastern and Western cultures throughout history. We compare the acoustics of some examples of these types of percussion instruments, both contemporary and historical.

8:40

2aMU2. Acoustics of the Korean percussion instruments pyeongyeong and pyeonjong. Junehee Yoo (Dept. of Phys. Education, Seoul Natl. Univ., Seoul 151-742, Republic of Korea, yoo@snu.ac.kr) and Thomas D. Rossing (Stanford Univ., Stanford, CA 94305)

Pyeongyeong is a set of 16 L-shaped chime stones and pyeonjong is a set of 16 oval chime bells. Vibrational mode shapes and mode frequencies of the pyeongyeong determined by holographic interferometry and by experimental modal testing agree very well with those calculated using finite-element methods. A model of the pyeongyeong in which the geometry can be varied shows that the actual shape is probably the one that gave the preferred sound. Vibrational mode shapes and frequencies of the pyeonjong, also determined by holographic interferometry and by experimental modal testing, are split into doublets due to the oval shape of the bells. The splitting is less than in Chinese two-tone bells but it gives rise to audible beats, as in large Korean temple bells.

9:00

2aMU3. Acoustics of the Tibetan long trumpet. Murray Campbell (School of Phys., Univ. of Edinburgh, Edinburgh EH9 3JZ, UK, d.m.campbell@ed.ac.uk) and Arnold Myers (Univ. of Edinburgh, Edinburgh EH8 9AG, UK)

The Tibetan long trumpet, or dung-chen, is a metal horn made in several telescoping conical sections. Dung-chen range in length from around 1.3 to over 3 m; the integral mouthpiece is wide and very shallow. Identical pairs of dung-chen are used in rituals of Tibetan Buddhism, often in combination with other instruments. This paper describes bore profile and input impedance measurements on a number of examples of the dung-chen, and compares the acoustical and musical properties of these Asian brass instruments with those of Western European long trumpets and horns.

9:20

2aMU4. Sound production in Asian and Western free-reed instruments. James P. Cottingham (Phys. Dept., Coe College, Cedar Rapids, IA 52402)

There are two families of free-reed instruments. This paper summarizes some of the research on both done in recent years, with emphasis on differences in history and means of sound production. The Asian mouth-blown instruments are of ancient origin and use a free reed coupled to a pipe resonator. The sheng, sho, khaen, and bawu are typical examples. These reeds are approximately symmetric, typically cut from a single strip of material, and often operate on both directions of air flow. They behave as blown-open or outward-striking reeds, with playing frequency above both the resonant frequency of the pipe and the natural frequency of the reed. The Western free-reed family originated in Europe about 200 years ago and includes the reed organ, harmonium, harmonica, and the accordion-concertina family. In these the reed tongue is offset from the opening in the frame. This permits operation on only one direction of air flow, and pipe resonators are not required and generally not used. The playing frequency of the air-driven reeds is normally below the natural reed frequency and, if the reed is coupled with a pipe, below the resonant frequency of the pipe as well.

2a WED. AM

2aMU5. Comparing the Hawaiian nose flute with the western concert flute. Lydia Ayers and Andrew Horner (Hong Kong Univ. of Sci. and Technol., Clear Water Bay, Kowloon, Hong Kong)

This presentation will compare the spectral and expressive characteristics of the Hawaiian nose flute with the western concert flute. The Hawaiian nose flute is a bamboo courtship flute. This presentation will give live demonstrations on several nose flutes and the western flute, along with brief descriptions of the musical and spectral characteristics of these instruments, and then describe the additive synthesis design template used to capture their subtle timbral characteristics using score data in Csound. In addition, the expressive design successfully uses spectral interpolation for the idiomatic ornamental phrasing for each instrument. A special amplitude/frequency function modulation method simulates the trills, which are also slurred within phrases of varying numbers of notes. [This work was supported by the RGC Competitive Earmarked Research Grant 613505, with special thanks to Rodney ''Kala'' Willis for making the nose flutes.]

2aMU6. Cross-cultural comparison of flute acoustics and playing techniques. Peter L. Hoekje (Dept. of Phys. and Astron., Baldwin-Wallace College, Berea, OH 44017, phoekje@bw.edu) and Pedro Eustache (Castaic, CA 91384)

Examples of flutes from different cultures around the world will be demonstrated, including European flutes, Persian ney, Egyptian kawala, traditional Indian bansuri, custom King bansuri, Japanese shakuhachi, Chinese di, South American kena, and Polynesian nose flutes. The differences among these may in large part be classified according to the details of their sound production mechanism at the mouthpiece, and of the bore and toneholes that form the resonator. These features are closely linked with the sound of the instrument as well as the notes and music played on it, and the playing techniques and styles developed for it. A cross-cultural problem arises when a musician needs to play with the sound and style of a non-Western flute tradition in the context of Western instruments and music. Various solutions to this problem, involving adaptation of either the mouthpiece or the resonator, have been developed.

2aMU7. Tunings of historical Korean pyeongyeong and pyeonjong. Junehee Yoo, Suyoung Jin, Hyunsoo Kim (Dept. of Phys. Education, Seoul Natl. Univ., Seoul 151-742, Republic of Korea, yoo@snu.ac.kr), Koeng-mo Sung, Junguk Noh, and Hyun-woo Ko (Seoul Natl. Univ., Seoul 151-742, Republic of Korea)

In order to reconstruct the *whangjongeum* or scale in Korean traditional instruments, we have measured frequencies of historical pyeongyeong stones and pyeonjong bells mainly from the 14th to 19th centuries. Pyeongyeong consists of 16 chime stones tuned to a scale quite similar to the Western scale beginning with C4. Pyeongjong consists of 16 chime bells, tuned approximately an octave lower than pyeongyeong. We present frequency averages and standard deviations for 124 chime stones and 64 chime bells available in the National Center for Korean Traditional Performing Arts. The spread in frequencies appears to be greater in some periods in history than in others, but the average frequency is quite consistent.

2aMU8. Input impedance of asian free-reed mouth organs. Eric A. Dieckman (Truman State Univ., Kirksville, MO 63501) and James P. Cottingham (Coe College, Cedar Rapids, IA 52402)

The khaen, naw, bawu, and sheng are examples of Asian free-reed mouth organs, which incorporate free reeds coupled to pipe resonators. Previous research has shown that the reeds in these instruments behave as blown-open reeds: the playing frequency is above both the natural frequency of the reed and the first peak of the measured impedance curve. Detailed calculations of input impedance have been made for a variety of these instruments, taking into account the position of the reed along the pipe, tuning slots, finger holes, and noncircular cross sections. The details of these calculations are in good agreement with the measured impedances of the same instruments, even in the higher harmonics. A study of the coupling of the free reed and pipe resonator has provided additional details about the influence of the pipe impedance on the playing frequency and sound spectrum of the reed-pipe combination. 2aPA1. Model experiments to study sonic boom propagation through turbulence.　Philippe Blanc-Benon and Sebastien Ollivier (LMFA, UMR CNRS 5509, Ecole Centrale de Lyon, 69134 Ecully Cedex, France)

The aim of this paper is to present data from laboratory-scale experimental simulations of sonic boom propagation through a turbulent atmosphere. The source used to simulate sonic boom N waves is an electric spark source. In order to model turbulence, two setups have been used: a turbulent jet for kinematic turbulence and a heated grid for thermal turbulence. Acoustic measurements have been conducted for three configurations: free field; close to a plane surface in order to simulate ground effects; and close to a curved surface in order to investigate the propagation into a shadow zone. The surfaces were either smooth or rough. With turbulence, many waveforms have been recorded, then the statistics of various parameters, including the peak pressure and the rise time, have been analyzed. In the free field, data show that the increase of the mean rise time and the decrease of the mean peak pressure are linked to the probability of random focusing. The experiments have enabled separate assessment of the effects of turbulence and roughness in the shadow zone caused by the curved surface. Comparison with numerical simulations will be discussed. [This work was supported by European Commission Contract N:G4RD-CT-2000-00398 and French Ministere de la Recherche (Decision 00T0116).]

2aPA2. Sonic-boom research activities in the Japan Aerospace Exploration Agency (JAXA).　Yoshikazu Makino　(JAXA, 7-44-1 Jindaijihigashi-machi, Chofu, Tokyo 182-8522, Japan, makino.yoshikazu@jaxa.jp)

Some sonic-boom research activities conducted in the Japan Aerospace Exploration Agency (JAXA) are summarized. JAXA started a scaled supersonic experimental airplane program named NEXST-1 in 1996 in order to establish advanced CFD-based design technologies. The flight test of the NEXST-1 was conducted in October, 2005 at Woomera test range in Australia. The sonic-boom signatures of the NEXST-1 were measured on the ground in order to confirm the possibility of demostrating the low sonic-boom design technology with scaled experimental airplanes for a future low-boom demonstrator program. The measured sonic-boom signatures were compared to the signatures extrapolated from the near-field pressure signatures predicted by CFD and panel method or measured in the supersonic wind tunnel. Low-sonic-boom design technology using gradient-based optimization tool with CFD is developed and applied to a non-axisymmetrical fuselage design concept in order to reduce the drag penalty. JAXA works on a human acceptability study in cooperation with Kawasaki Heavy Industries (KHI) using their sonic-boom simulator. Some low-boom signatures in addition to some typical N-shaped signatures with various peak pressure levels were simulated in the boom box and used for subjective test in order to collect the human acceptability data for future sonic-boom acceptability criteria.

2aPA3. Prediction and measurement of a weak sonic boom from an entry vehicle.　Kenneth J. Plotkin　(Wyle Labs., 2001 Jefferson Davis Hwy., Ste. 701, Arlington, VA 22202, kenneth.plotkin@wylelabs.com), Russell J. Franz, and Edward A. Haering, Jr. (NASA Dryden Flight Res. Ctr., Edwards, CA 93523)

There is a current interest in measuring low-amplitude sonic booms in the atmosphere. This interest is related to verifying the predicted loudness and structure of the shock waves. The reentry of the Stardust comet sample probe on 15 January 2006 provided an opportunity for such a measurement. PCBoom4 was used, together with Stardust's projected reentry trajectory, to predict the sonic boom footprint. A theory for the sonic boom of a drag-dominated blunt hypersonic vehicle had been developed by Tiegermann [Ph.D. thesis, Cornell University, 1975]. This theory provides an effective F-function based on energy dissipation, using a blast wave analogy and numeric solution. The inputs to that model are the vehicle drag and flight conditions. Tiegermann's model was implemented in PCBoom4. Drag was obtained by computing deceleration from the expected entry trajectory and multiplying by vehicle weight. A boom with peak overpressure of 0.0524 psf, arriving at 10:00:28.465 UTC, was predicted for a planned measurement site in Ruby Valley, NV, using an atmospheric profile from the upper air reporting station at nearby Elko, NV. The measured sonic boom had a peak overpressure of 0.052 psf and arrived at 10:00:29.719 UTC.

2aPA4. Toward silent supersonic transport—A fundamental study of supersonic biplane. Kazuhiro Kusunose (Tech. Res. and Development Inst., Japan Defense Agency, Sakae-cho 1-2-10, Tachikawa, Japan 190-8533), Daigo Maruyama, Kisa Matsushima, Kazuhiro Nakahashi (Tohoku Univ., Sendai 980-8579, Japan), Hiroshi Yamashita, Masahito Yonezawa, and Shigeru Obayashi (Tohoku Univ., Sendai, Japan 980-8577)

In this research, aerodynamic design of biplane airfoils in supersonic flight is discussed based on computational fluid dynamics (CFD). In supersonic flight, airfoils generate strong sonic booms and wave drags accompanied by shock waves. New airfoil geometries which significantly reduce shock waves using a biplane concept will be proposed. The background of this concept originates from Busemann biplane and Licher type biplane concepts. In order to focus on the shock-wave characteristics around biplane configuration, inviscid flow (Euler) analyses are performed (which are particularly suitable for wave drag analyses). For the evaluation of the reduction level of shock waves, the wave drag coefficient is used. The design Mach number is 1.7. The aerodynamic design is conducted using an iterative inverse design method that is newly implemented. A biplane configuration with a desired performance has been obtained. Having total maximum thickness ratio of 0.10, it has the lift-to-wave-drag ratio of 21.7 at a desired lift condition for supersonic flight. At the range of lift coefficient more than 0.14 this designed biplane has lower wave drag than that of a (zero-thickness) single flat plate airfoil. This result will lead to the realization of silent supersonic transport.

2aPA5. Ballistic range simulation of sonic boom generation. Kazuyoshi Takayama (Biomed. Eng. Res. Organization, Tohoku Univ., Sendai, 980-8577, Japan), Ming-Yu Sun, and Takamasa Kikuchi (Tohoku Univ., Sendai, 980-8579, Japan)

A result of recent ballistic range experiments applied to a sonic boom simulation is reported. For flight simulations at transonic speed ranging from 340 to 400 m/s, we used a 51-mm bore gas gun launching 51-mm-diam sabot and projectile combinations, and for supersonic flight simulations exceeding 400 m/s we used a 15-mm bore two-stage light gas gun. Flow diagnostics were performed mainly by double-exposure holographic interferometry, shadowgraph recorded with a high-speed video camera, and pressure measurements. The present experimental setup is so versatile that we placed a water basin on the recovery tank floor and measured interactions between sonic booms and wavelets in the water basin. As one of the basic research topics related between shock dynamics and aeronautics, we launched 40-mm-diam spheres at high transonic speed of shock Mach number ranging from 1.01 to 1.i at increments of every 0.01, visualized quantitatively flows over spheres, and could determine shock standoff distances over spheres. The speed range we simulated is in the region hardly achievable in existing wind tunnels.

2aPA6. Atmospheric turbulence filter functions derived from high-fidelity measurements. Lance Locey and Victor Sparrow (The Pennyslvania State Univ. Grad. Program in Acoust., State College, PA 16803)

Efforts have been underway to develop filter functions suitable for adding turbulent atmospheric effects to theoretical low-boom waveforms. Filter functions have been created based on a measured input-output relationship. The input is a relatively clean sonic boom waveform measured at altitude by a glider, and the outputs are turbulized' waveforms measured on the ground. One input waveform and multiple output waveforms are used to represent multiple realizations of the atmosphere. Work presented in 2005 [Locey and Sparrow, *Innovations in Nonlinear Acoustics, 17th International Symposium on Nonlinear Acoustics* (American Institute of Physics, Melville, NY, 2006)] yielded an initial set of filter functions using one particular algorithm and data collected during the Shaped Sonic Boom Experiment (SSBE) in January of 2004. In this talk new results will be presented based on high-fidelity measurements made at NASA Dryden Flight Research Center in June of 2006 [T. Gabrielson *et al.*, Proc. Internoise (2006)]. Time permitting, additional methods for obtaining filter functions will be discussed, including the use of existing sonic boom propagation codes modified to include atmospheric turbulence. [Work supported by the FAA/NASA/Transport-Canada PARTNER Center of Excellence for Aircraft Noise and Aviation Emissions Mitigation.]

2aPA7. Atmospheric effects on sonic boom loudness. Anthony R. Pilon (Adv. Development Programs, Lockheed Martin Aeronautics Co., 1011 Lockheed Way, Palmdale, CA 93599, tony.pilon@lmco.com)

The effects of sonic boom propagation through nonstandard atmospheres have been studied. Variations in atmospheric temperature, pressure, humidity, and winds can have significant impact on the structure of the shock waves in the boom signal, as well as the propagation path of the boom. In the study, a hybrid time-frequency domain code was used to calculate finely resolved sonic boom signals for a variety of atmospheric conditions. Idealized near–field signals for low amplitude "N-wave" and "shaped" booms were used to calculate ground level signals. The perceived level metric of Stevens ["Perceived level of noise by Mark VII and decibels (E)," J. Acoust. Soc. Am. **51**, 575–601 (1972)] was used to quantify the loudness of the calculated booms. Results of the study will be used to determine the impact of atmospheric variations on the acceptability of sonic booms from future supersonic cruise aircraft.

2aPA8. Discrete-time modeling of atmospheric turbulence with application to sonic booms. Joe Salamone (Gulfstream Aerosp. Corp., P.O. Box 2206 M/S R–01, Savannah, GA 31402-2206, joe.salamone@gulfstream.com)

A method is presented that computes a discrete-time model of the atmospheric turbulence effects on sonic booms. First, signal processing techniques are applied to sonic booms to extract the shock profiles from N waves measured on the ground. Next, clean shock profiles are estimated from nonlinear acoustics theory using the measured sonic boom ground data as a reference. A discrete-

time model is computed using a Wiener filtering scheme with the "clean" shock profile as the input to the scheme and the measured shock data as the output. The resulting system of equations required to compute a model is ill conditioned. Tikhonov regularization is implemented with the regularization parameter chosen based on inspection of the eigenvalue spectrum of the autocorrelation matrix. Multiple models are obtained for "low" to "high" amounts of turbulence from ground measurements recorded under various atmospheric conditions. Predicted N waves and shaped sonic booms are digitally filtered by the turbulence models. The loudness levels of the sonic booms before and after application of the turbulence models are evaluated.

11:00

2aPA9. Extension of a sonic boom model to ellipsoidal Earth and 3-D atmosphere. Kenneth J. Plotkin (Wyle Labs., 2001 Jefferson Davis Hwy., Ste. 701, Arlington, VA 22202, kenneth.plotkin@wylelabs.com) and Edward A. Haering, Jr. (NASA Dryden Flight Res. Ctr., Edwards, CA 93523-0273)

Sonic boom ray tracing models generally use flat-earth geometry, with 3-D ray propagation through a horizontally stratified atmosphere. There has been recent interest in long-range sonic boom propagation, both for analysis of sonic boom carpet edges from high-altitude flight and for analysis of over-the-top booms. The sonic boom program PCBoom4 has been extended to incorporate ellipsoidal earth and full 3-D ray tracing through a three-dimensional atmosphere. Ellipsoidal geometry of the Earth is handled by the method of Sofair [J. Guidance Control, **23**(2)], which defines a local vertical at given coordinates. A tangent reference plane is defined, and ray tracing is performed using the 3-D formulation of Schulten [NLR TP 97-374], in Cartesian coordinates. Once rays are traced, ray tube areas, signature aging, and focal zones are computed in the traditional manner. When over the top booms are analyzed, a starting signature for propagation after the caustic passage is generated from the recent numeric calculations by Kandil [AIAA Paper No. 2005-0013]. The new program, denoted PCBoom5, is expected to be available in 2007.

11:20

2aPA10. Supersonic aircraft: Shake, rattle and role. Sandy Liu (Federal Aviation Admin., Office of Environment and Energy, (AEE-100) Noise Div., Washington, DC)

There has been a renewed interest worldwide to focus on identifying technological advances that could satisfy the production of a new commercial supersonic aircraft. Although advances have been realized since the Concorde was developed, there is widespread agreement that many challenges remain. At a lesser risk, a supersonic business jet (SBJ) is seen as a technological stepping-stone in the overall tactic of advancing the speed of commercial aircraft. This presentation outlines some of the technological and environmental regulatory challenges facing such an aircraft. This includes a review of the established technical noise working group and activities that address supersonic aircraft environmental matters: sonic boom, aircraft community noise, and aircraft emissions. Federal Aviation Administration (FAA) maintains that a successful supersonic aircraft will depend on its stakeholders' ability to deal with these key issues. FAA finds it beneficial to work within the international arena for addressing these issues to ensure that all stakeholders' concerns are considered. Ultimately, successfully addressing concerns regarding sonic boom is a necessary initial condition for regulatory authorities to reconsider existing restrictions on supersonic operations, *the* key constraint to the business case in the revival to develop a civil supersonic aircraft for the future.

11:40

2aPA11. Flight demonstration project for low-sonic boom design technology. Akira Murakami (6-13-1 Osawa, Mitaka, Tokyo, 181-0015 Japan)

Japan Aerospace Exploration Agency (JAXA) has promoted a supersonic technology research program including flight demonstration since 1997. In this program, JAXA is now planning the new flight demonstration project "Silent Supersonic Technology Demonstrator Project (S3TD)." One of the targets of this project is to demonstrate the low sonic boom aircraft concept to reduce sonic boom intensity by 50% as compared with conventional configuration and to modify the sonic boom signature for not only front shock boom but also the rear shock one. JAXA will develop a new flight demonstrator that is an unmanned vehicle of approximately 3 tons in weight and 13 m in length, and then JAXA will make flight trials by 2012. Now JAXA is designing the base-line configuration, using the CAD-based Automatic Panel Analysis System that we have developed. The shock overpressure of the S3TD base-line configuration is estimated to be about 0.23 psf for front shock and 0.21 psf for rear shock, corresponding to about 50% intensity as compared with those of N-wave signature estimated by the first-cut method. The robustness of the low boom signature is also considered. The rear shock boom signature is so sensitive to flight condition that some small device is installed around the aft deck.

Session 2aPP

Psychological and Physiological Acoustics: Spatial Hearing and Temporal Processing (Poster Session)

Eric W. Healy, Cochair

Univ. of South Carolina, Dept. of Communication Sciences and Disorders, Columbia, SC 29208

Masashi Unoki, Cochair

Contributed Papers

All posters will be on display from 8:30 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:30 a.m. to 10:15 a.m. and contributors of even-numbered papers will be at their posters from 10:15 a.m. to 12:00 noon.

2aPP1. Motion perception of the target sound event under the discriminated two sound events. Tsuruyo Nishida (Gifu Natl. College of Tech., Motosu, Gifu 501-0495, Japan), Kazuhiko Kakehi, and Takamasa Kyutoku (Chukyo Univ., Toyota, Aichi 470-0393, Japan)

The correct percentage of motion direction for one sound event was about 90%. In the case of two sound events, the correct percentage was lower than for one sound event. The sound event was presented through the headphone in these experiments. These two sound events were physically separated both in frequency and in onset time for the two sound events. It might be possible to perceive two sound events separately. The perception of onset time difference and the discrimination of different frequency sound events were investigated to clarify whether the subjects perceived two sound events distinctly. When IEOI (interevent interval) was more than 40 ms, the subjects perceived the onset time difference and the order of two presented sound events. Results clarified that the subjects distinctly perceive two sound events separately with long IEOI. However, the correct percentage for the direction of motion perception of the target in two sound events was significantly lower than for one sound event. The target was strongly affected by the nontarget. Even when two sound events are perceived separately in terms of frequency and temporal order, it is difficult to perceive the motion direction of the target.

2aPP2. Perceptual movement of sounds moved up or down through multiway loudspeakers set up perpendicularly. Yu Agastuma and Eiichi Miyasaka (Musashi Inst. of Technol., 3-3-1 Ushikubo-Nishi, Tsuzuki-ku, Yokohama, Japan)

Perceptual movements of sounds fed through eight loudspeakers perpendicularly set up were investigated. The loudspeakers, which were mutually separated by 30 cm, were set up immediately in front of 15 observers positioned 4.5 m distant from the loudspeakers. They were required to answer the start point of the loudspeaker through which they perceived that the sound was output at the start, and the end point of that loudspeaker. The results show that the ascension or descension of the sound images was perceived when $\frac{1}{3}$ octave bands of noises with center frequencies of 1, 4, and 8 kHz were linearly moved up or down in the range from 60 to 150 cm. The results also show that the perceived moving distance depends on the moving speed, becoming longer than the physical distance at speeds of 10 and 20 cm/s, and converging to the physical distance concomitant with higher moving speed, irrespective of the center frequencies. [Work supported by SCAT.]

2aPP3. Combined manipulations of the perceived location and spatial extent of the speech-target image predominantly affect speech-on-speech masking. Ying Huang, Xihong Wu, Qiang Huang, and Liang Li (Speech and Hearing Res. Ctr., Peking Univ., Beijing, China, 100871, liangli@pku.edu.cn)

Speech maskers contain both informational-masking and energetic-masking components. To fully understand speech masking, it is critical to separate these two types of masking components. This study investigated the effect of the inter-target-source delay (ITSD) on intelligibility of speech when both the speech target and masker were presented by each of the two spatially separated loudspeakers (located at -45 and $+45$ degrees, respectively). The masker was either two-voice speech (different contents between the two loudspeakers) or steady-state speech-spectrum-noise (uncorrelated between the two loudspeakers). The results show that as the ITSD was decreased from 64 to 0 ms, the target image progressively became funneled into the region around the midline, and the intelligibility of the target was monotonically improved by over 40% when the masker was speech, but by only about 10% when the masker was noise. Under the quiet condition, however, the intelligibility was not affected by the change of ITSD. The results suggest that combined manipulations of perceived location and spatial extent of the speech-target image by changing the ITSD predominantly affect informational masking of speech. [Work supported by China NSF and Canadian IHR.]

2aPP4. Free-field sound localization with nonlinear hearing protection devices. Kimberly B. Lukas and William A. Ahroon (U.S. Army Aeromedical Res. Lab., Fort Rucker, AL 3636,)

Hearing enhancement and protection devices are being developed for both civilian and military markets that permit the wearer to maintain an awareness of the ambient sound environment and permit face-to-face communications while still protecting the user from high-level impulse noises or blast waves from, for example, handguns, rifles, and shotguns. The impulse noise protection for these devices can range from less than 9 dB peak pressure reduction to reductions of more than 40 dB peak. There has been little research, however, on the ability to use binaural cues to localize sound with such devices. An experiment to evaluate the ability of normal-hearing listeners to localize broadband noise bursts while wearing various nonlinear hearing enhancement and protection systems was conducted in an anechoic environment. Subjects were asked to localize a 60-dB SPL, 200-ms broadband noise burst from a speaker in 1 of 12 different azimuth locations (0 to 330 deg in 30-deg steps) and five different elevations (0,

± 15, ± 30 deg). The azimuth and elevation errors were measured for each device using circular statistical techniques. Front/back reversals were corrected. The results show a 15- to 20-deg degradation in the wearer's ability to localize sound when using these hearing protectors.

2aPP5. Selection of attractor sounds for an audio-based navigation system for the visually impaired. Brad S. Salisbury, Koorosh Naghshineh (Western Michigan Univ., Kalamazoo, MI 49008-5343), and William Wiener (Marquette Univ., Milwaukee, WI 53233)

Research into human hearing has been very laboratory oriented in the sense that the test environments do not replicate most real world situations [J. C. Middlebrooks and D. M. Green, Annu. Rev. Psychol. **42**, 135–159 (1991)]. While very useful information is gained from these types of tests, it is difficult to see how real world situations affect sound source localization, recognition, and navigation (walking/way finding) performance. Such information is especially important to people who are visually impaired and dependent on prior knowledge of the environment or audio cues for travel. The research reported here was conducted during the development of an audio-based navigation system. The question that arose was, what constitutes good attractor sounds versus bad sounds? A series of physical tests was developed to identify sounds that performed best from within a group of real-world attractor sounds. Testing was conducted with the aid of participants who were blind or visually impaired. Results of the experiments were consistent with those of Landau *et al.* [Asst. Technol. **17**, 133–143 (2005)].

2aPP6. A study of the equivalent perception between a visual stimulus with a feeling of depth and its associated sound. Hiroshi Hasegawa, Akimasa Suzuki, Ichiro Yuyama (Faculty of Eng., Utsunomiya Univ., 7-1-2 Yoto, Utsunomiya-shi, Tochigi-ken 321-8585, Japan), Hirotaka Ono, Masao Kasuga, and Miyoshi Ayama (Utsunomiya Univ., Utsunomiya-shi, Tochigi-ken 321-8585, Japan)

This study investigated the equivalent perception between a visual stimulus and its associated sound. Auditory-visual stimulus presentation experiments were performed using an audio-video clip of a man beating a drum on a road. The visual stimulus, with a perspective view of the road, imparted a depth sensation. Visual stimuli were projected onto a screen of 30.8 (W) (B 16.1 (H) deg. In all, 315 auditory-visual stimuli were produced with combinations of distance between the visual target (the drum) and the observer from (B00 m, the time delay between auditory and visual stimuli from −8F to 8F (1 F=$\frac{1}{30}$ s), and the sound pressure level of the sound stimulus from (B12 dB. The stimuli were presented to six subjects. In each presentation pattern, the sound pressure level to provide a perceptual strength equivalent to that of the visual target was determined: the equivalent sound pressure level (ESPL). Results show that the ESPL increased as the time delay between the auditory and visual stimuli increased, i.e., the ESPL tended to shift in the direction that the event was closer to the observer. The time delay shifted in the direction that the event was distant from the observer.

2aPP7. Localization of text-to-speech voices in a virtual speech display. Gordon Rubin (AT&T Labs, Florham Park, NJ 07932, and Rensselaer Polytechnic Inst., Troy, NY 12180)

An auditory display using high-quality text-to-speech (TTS) voices is presented to a group of individuals. Subjects are asked for their impression of the source direction of a synthesized talker in a nonreverberant environment. Location is coded using a set of nonindividualized head-related transfer functions (HRTFs). Many years of research in binaural technology provide comparative data for the localization ambiguities inherent in such presentation (e.g., front-back confusion). These ambiguities are characterized for stimuli generated by a mature concatenative speech synthesis system. An initial attempt is made to quantify the perceptual significance realized by a binaural-model-motivated speech synthesizer.

2aPP8. Using localization cues to track one of two concurrent sound sequences. Marie Rivenez, Anne Guillaume, Lionel Pellieux, and Christelle Delor (Departement Sci. Cognit. 5 IMASSA, BP 73, 91223 Bretigny sur Orge Cedex, France)

This study examined how localization, via binaural cues, can help the tracking of a sound sequence, interleaved with another sound sequence, across time. The ability to track a sequence was investigated using a temporal irregularity detection task. The temporal irregularity was inserted into a regular isotone sequence (target sequence) interleaved with an irregular sequence of same frequency (masker sequence). Performances were at the chance level when there was no interaural difference between the sequences. In experiment 1, large improvements of performances were found using several interaural level (ILD) or time (ITD) differences between the two sequences. Manipulating the masker sequence ILD and maintaining the signal-to-noise ratio constant in the best ear (experiment 2) or using a monaural presentation of the sequences (experiment 3), data showed that the effect of ILD could not be explained by a monaural processing (best or bad ear listening). Finally, experiment 4 revealed that the effect of binaural cues on tracking a sound sequence was mainly produced by the perceived localisation differences induced by the interaural differences rather than by the physical differences. These results suggested that binaural cues may influence sound sequence tracking via a spatial attention mechanism.

2aPP9. Comparison of pre- and post-cueing in a multiple-source sound localization task. Brian D. Simpson, Douglas S. Brungart (Air Force Res. Lab., 2610 Seventh St., Bldg. 441, Wright-Patterson AFB, OH 45433, brian.simpson@wpafb.af.mil), Robert H. Gilkey (Wright State Univ., Dayton, OH 45435), Nandini Iyer (Air Force Res. Lab., Wright-Patterson AFB, OH 45433), and James T. Hamil (General Dynam., AIS, Dayton, OH 45433)

Although most sound localization research has examined the ability of listeners to determine the location of a single sound presented in a quiet (typically anechoic) environment, most real-world listening situations are more complex, with multiple simultaneous sounds. Here, an initial experiment, designed to examine localization in multisource environments, is described. Listeners judged the location of a target signal (speech or environmental sound, presented normally or time-reversed) masked by up to four simultaneous sounds. In each block of trials, the observation interval was either preceded by, or followed by, a cueing interval, during which the stimulus to be localized was identified. It was expected that these two approaches would lead to different answers, as the associated tasks presumably address different listening strategies (i.e., analytic listening versus monitoring). The results indicate that, in all conditions, localization errors increase as the number of simultaneous sources increases. Moreover, performance degrades more rapidly in the post-cue condition than in the pre-cue condition. Surprisingly, this difference occurs for as few as two simultaneous sources, suggesting that there is a substantial cost when listeners are asked to remember what sounds were present and where those sounds were located in a complex auditory environment. [Work supported by AFOSR.]

2aPP10. Rate limitation and onset dominance in the discrimination of high-frequency click trains with dynamic envelope ITDs. G. Christopher Stecker (Dept. of Speech & Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105, cstecker@u.washington.edu)

Several studies have shown that binaural processing at high carrier frequency is limited to relatively slow modulations, suggesting profound consequences for binaural processing of high-rate electrical stimulation by cochlear implants (CIs). In this study, we measured normal-hearing-envelope ITD thresholds for Gaussian impulses (clicks) with 4000 Hz carrier frequency and 2 ms total duration (BW approximately 900 Hz) and for 16-click trains with rates of 100, 200, or 500 pps. For click trains, right-leading ITDs were static (condition RR), increased linearly from

diotic (condition 0R), or decreased linearly toward diotic (condition R0). Thresholds were calculated from the largest ITD in each stimulus (i.e., the onset of R0 or offset of 0R trains). Consistent with previous results for normal hearing and bilaterally implanted subjects, thresholds were strongly dependent on ICI. Low-rate (100 pps) thresholds improved for 16-click trains relative to single clicks in all conditions, while high-rate (500 pps) thresholds were similar to single clicks for RR and R0 stimuli. In condition 0R, 500 pps ITD thresholds were elevated and comparable to monaural rate discrimination. The results suggest an inability to lateralize high-rate stimuli in the absence of onset ITDs and have important consequences for binaural information processing with cochlear implants.

2aPP11. Evidence for active suppression of masker locations in spatially separated multitalker conditions. Kachina Allen, Simon Carlile, David Alais (Dept. of Physiol., Univ. of Sydney, F13 Univ. of Sydney 2006, NSW Australia, kachina_allen@yahoo.com), and Karen Froud (Columbia Univ., New York, NY 10027)

Three experiments tested active suppression of masker locations. Using a nonword corpus, spatial release from masking (SRfM) of 3.1 dB was calculated using masked thresholds (67%) of colocated and separated (20 deg) masker and target. Mirrored conditions were completed, with results pooled between hemispheres. In experiment 1, 80% of trials were masked 20 deg left of the central target. Random (10%) trials played targets at the expected masker location, and (10%) at the symmetrically opposite side, with maskers 20 deg laterally displaced. Thresholds revealed 2.6-dB reduction at the masker location compared to symmetrically opposite (null) locations. Experiment 2 used a central target with masker played 20 deg to the left in 80% of trials. Random (20%) trials (unexpected) played the masker at the symmetrically opposite side. Target thresholds were reduced by 2.1 dB when masker location was unexpected. Both experiments indicate active suppression of expected masker locations, suggesting masker suppression may contribute to SRfM. Experiment 3 played 80% of trials with maskers 20 deg left of the central target. Random (10%) trials played the target 40 deg to the left of center, and (10%) at the symmetrically opposite side, with the masker 20 deg laterally displaced. Reduced target thresholds (2.0 dB) indicated that masker suppression also extends laterally, beyond the expected masker location.

2aPP12. Lateralization of amplitude-modulated bone-conducted ultrasounds: Discrimination of interaural time and intensity differences. Takuya Hotehama and Seiji Nakagawa (Natl. Inst. of Adv. Industrial Sci. and Technol. (AIST), 1-8-31 Midorigaoka, Ikeda, Osaka 563-8577, Japan, t-hotehama@aist.go.jp)

Ultrasonic vibration generates a sensation of sound via bone conduction; the phenomenon is called bone-conducted ultrasonic (BCU) hearing. Complex sounds also can be perceived by an amplitude-modulated BCU (AM-BCU). In this study, to investigate whether listeners can use an interaural time difference (ITD) in the amplitude envelope and an intensity difference (IID) as cues for lateralization, difference limens for an ITD (ITDL) and an IID (IIDL) for AM-BCU were evaluated. Thirty-kHz sine waves modulated by low-passed noises with cutoff frequencies of 250, 500, 1000, 2000, and 4000 Hz were used as the AM-BCU stimuli. ITDLs and IIDLs for air-conducted (AC) low-passed noises which correspond to modulator of the AM-BCU were also evaluated. Both ITDLs and IIDLs for AM-BCU were observed; AM-BCU was larger in ITDL and smaller in IIDL than AC. The results suggest that it is possible to lateralize AM-BCU using ITD in the envelope and/or IID; however, IID is a more effective cue than ITD.

2aPP13. Modulation masking in monaural and binaural conditions. Monika Kordus (Inst. of Acoust., Adam Mickiewicz Univ., Umultowska 85, 61-614 Poznan, Poland)

The shape of hypothetical modulation filters was measured in monaural and binaural signal presentation. A sinusoidal 4-kHz carrier was amplitude modulated by low-low-noise (LNN) [A. Kohlrausch et al., Acta Acust. **83**, 659–669 (1997)] and a probe tone of a frequency varying from 2 to 256 Hz. Using a three-interval forced-choice (3IFC) procedure the threshold of modulation by the probe tone was determined for the LNN of 16-Hz center frequency and 8-Hz bandwidth, and 64-Hz center frequency and 8-, 16-, or 32-Hz bandwidth. In the monaural condition, signals were presented to the right ear. In the binaural condition, modulation by the LNN was presented to the right ear, and modulation by the probe tone to the left ear. Results showed that masking in the modulation rate domain is characterized by a broad tuning with the highest values of about 17 dB for the monaural condition, and 4 to 9 dB in the binaural condition occurring for probe-tone frequency equal the center frequency of the LNN. The large effect in binaural condition confirms the idea that modulation detection by hypothetical modulation filter bank occurs on a higher level in the auditory system. [Work supported by the Polish Ministry of Education and Science, Grant No. 4T07B03230.]

2aPP14. Frequency dependency of illusory continuity in binaural hearing with respect to interaural time difference. Mamoru Iwaki and Hiroki Kitajima (Grad. School of Sci. and Technol., Niigata Univ., 8050 Ikarashi-2, Niigata, 950-2181, Japan, iwaki@bc.niigata-u.ac.jp)

Illusory continuity is a psychoacoustical phenomenon: when the absence portion of a tone is padded with sufficiently powerful white noise, an intermittent pure tone is perceived as though it were continuous. Many studies have examined this psychoacoustical illusion in monaural hearing, which supports that illusory continuity is observed when no clear evidence of discontinuity exists and when the power of the white noise is sufficiently large to mask the pure tone. In binaural hearing, the authors reported that illusory continuity was observed and that it was related with interaural time difference (ITD) for a single target pure tone of 500 Hz [M. Iwaki and N. Nakamura, INTERSPEECH/EUROSPEECH-2003 (2003) pp. 2065–2068]. This study investigated illusory continuity in binaural hearing for wider frequency ranges of 250–2000 Hz. Results showed that in the lower frequency range, the threshold level of illusory continuity in binaural hearing depended on ITDs between the tone target and noise masker. The increase of the threshold level was minimal when the target and masker have the same ITD. In the higher frequency range, the illusory continuity was independent of differences of ITDs.

2aPP15. Localizing noise in rooms via steady-state interaural time differences. Brad Rakerd (Dept. of Communicative Sci. and Disord., Michigan State Univ., E. Lansing, MI 48824, rakerd@msu.edu), William M. Hartmann, and Eric Pepin (Michigan State Univ., E. Lansing, MI 48824)

Noise lateralization experiments with headphones show that the steady-state interaural time difference (ITD) is, or is not, a valuable cue for sound lateralization depending on the height of the peak of the interaural cross-correlation function (cc). To discover whether these headphone results could be extended to the localization of sound in rooms, binaural recordings were made of one-third-octave noises in diverse environments: a dry classroom, a laboratory, and a reverberation room. Sound sources and a KEMAR recording manikin were moved about in each room to vary the cc from 0.2 to 0.8. The recordings, with ITDs digitally controlled, were presented to five listeners by headphones to measure listener sensitivity to ITD variations. It was found that sensitivity was almost entirely a function of cc with little weight attached to the actual room environment. ITD thresholds decreased monotonically with increasing cc. In agreement with earlier headphone studies using computed noises instead of room record-

ings, typical thresholds were higher by a factor of about 6 for a 2800-Hz band where envelope ITD is used compared to a 700-Hz band where waveform ITD is used. [Work supported by the NIDCD.]

2aPP16. Investigating the buildup of precedence effect using reflection masking. Jess Hartcher-O'Brien, M. Buchholz (Macarthur Auditory Res. Ctr. Sydney (MARCS), Bldg. 5, Bankstown Campus, UWS, Locked Bag, 1797, Penrith South DC), and M. Buchholz (Tech. Univ. of Denmark, DK-2800 Kgs. Lyngby, Denmark)

The auditory processing level involved in the build-up of precedence [Freyman *et al.*, J. Acoust. Soc. Am. **90**, 874–884 (1991)] has been investigated here by employing reflection masked threshold (RMT) techniques. Given that RMT techniques are generally assumed to address lower levels of the auditory signal processing, such an approach represents a bottom-up approach to the buildup of precedence. Three conditioner configurations measuring a possible buildup of reflection suppression were compared to the baseline RMT for four reflection delays ranging from 2.5–15 ms. No buildup of reflection suppression was observed for any of the conditioner configurations. Buildup of template (decrease in RMT for two of the conditioners), on the other hand, was found to be delay dependent. For five of six listeners, with reflection delay=2.5 and 15 ms, RMT decreased relative to the baseline. For 5- and 10-ms delay, no change in threshold was observed. It is concluded that the low-level auditory processing involved in RMT is not sufficient to realize a buildup of reflection suppression. This confirms suggestions that higher level processing is involved in PE buildup. The observed enhancement of reflection detection (RMT) may contribute to active suppression at higher processing levels.

2aPP17. Temporal processes involved in simultaneous reflection masking. Joerg M. Buchholz (CAHR, Acoust. Technol., Tech. Univ. of Denmark, Oersted Plads, Bldg. 352, DK-2800 Kgs. Lyngby, Denmark)

Reflection masking refers to the specific masking condition where a test reflection is masked by the direct sound. Employing reflection masking techniques, Buchholz [J. Acoust. Soc. Am. **117**, 2484 (2005)] provided evidence that the binaural system suppresses the test reflection for very short reflection delays and enhances the test reflection for large delays. Employing a 200-ms-long broadband noise burst as input signal, the critical delay separating these two binaural phenomena was found to be 7–10 ms. It was suggested that the critical delay refers to a temporal window that is employed by the auditory system to analyze the considered stimulus. In the present study, the dependency of this critical delay on the duration of the input signal (i.e., broadband noise) has been investigated. The psychoacoustical results revealed that the critical delay decreases with decreasing stimulus duration, resulting in a critical delay of about 2–3 ms for 20-ms-long stimuli. Hence, for very short stimuli the temporal window or critical delay exhibits values similar to the auditory temporal resolution as, for instance, observed in gap-detection tasks. It is suggested that the larger critical delay observed for longer stimuli is due to the auditory system focusing on lower signal frequencies.

2aPP18. Psychophysical estimates of cochlear tuning using simultaneous and nonsimultaneous masking. Masashi Unoki and Ryota Miyauchi (School of Information and Sci., JAIST, 1-1 Asahidai, Nomi, Ishikawa, 923-1292 Japan, unoki@jaist.ac.jp)

This study attempts to estimate the tuning of an auditory filter, through both simultaneous and forward masking experiments with a notched-noise masker or a sinusoidal masker, to investigate how the effects of suppression affect estimates of frequency selectivity. In these experiments, masked thresholds of the short probe signal (5-ms ramps, no steady state) centered in the masker or delayed from the masker were measured for normal-hearing subjects as a function of the signal frequency (0.5, 1.0, 2.0, and 4.0 kHz), signal level (10, 20, and 30 dB SL), signal delay, and notch-width conditions in the notched-noise masker, or the masker fre-

quency in the sinusoidal masker. ERBs were calculated from derived auditory filters to compare the cochlear tuning. The estimated tunings became much sharper as the center frequency was increased. Moreover, the difference between the tunings of the filter at lower frequencies with either form of masking tended to be smaller than that at higher frequencies. The tuning may be affected by residual effects of suppression due to lower masker components below the signal frequency. [Work supported by special coordination funds for promoting science and technology of young researchers from the Japanese Ministry of Education.]

2aPP19. Practice effects in comodulation masking release. Cynthia M. Zettler and Marsha G. Clarkson (Dept. of Psych., Georgia State Univ., P.O. Box 5010, Atlanta, GA 30302, czettler@student.gsu.edu)

Substantial research has explored the acoustic factors influencing comodulation masking release (CMR), but the impact of practice has not been addressed. The current study evaluated the effect of experience on CMR thresholds. Ninety-eight adults listened to CMR stimuli through headphones once a week for 3 weeks. CMR was measured as the difference in threshold between a reference condition with one 20-Hz-wide amplitude-modulated noise band centered on a 1000-Hz, pure-tone signal, and a modulated masker condition having eight additional noise bands comodulated with the on-signal band. Thresholds were estimated in a single-interval, maximum-likelihood procedure. Hierarchical linear modeling tested the effect of practice on thresholds and CMR. Analyses indicated that thresholds improved significantly with practice ($p < 0.001$) for both masking conditions. On average, reference thresholds improved 5.41 dB per visit (SE=0.703), and modulated masker thresholds improved 3.15 dB per visit (SE=0.495). Total CMR decreased significantly ($p < 0.01$) by 1.98 dB per visit (SE=0.701), most likely because performance in the reference condition improved more than performance in the modulated masker condition. Results indicate that practice improves performance in CMR masking conditions and that total CMR decreases with experience.

2aPP20. Perceptual judgment in synchronization of two complex tones and its relation to the cochlear delays. Eriko Aiba (Grad. School of Music, Kyoto-City Univ. of Arts, 13-6 Oe-kutsukake-cho, Nishikyo-ku, Kyoto, 610-1197 Japan, m06901@kcua.ac.jp) and Minoru Tsuzaki (Kyoto-City Univ. of Arts, Japan)

Onset synchrony of components is widely assumed to be an important cue for perceptual unification as a single tone. However, even if the components begin simultaneously, their temporal relation might not be preserved at the cochlear level. The cochlear delay shifts the arrival of a lower component slightly but systematically behind a higher component. This experiment uses two complex tones as a stimulus to investigate whether the cochlear delay imposes a systematic bias in judging the synchrony of two complex tones. The results are compared with those of our previous experiment using two sinusoidal signals, which indicated that the accuracy of synchrony judgment was worse when the higher component preceded the lower one than in the opposite case. These results will be compared with those of a pioneering study, which indicated that the region of judgment on synchrony of complex tones was greater than 30 ms. [Work supported by the Grant-in-Aid for Scientific Research A, No.16200016, Japan Society for the Promotion of Science.]

2aPP21. Sequential amplitude-modulation interference across auditory channels and across ears. Magdalena Wojtczak, Melanie J. Gregan, and Neal F. Viemeister (Dept. of Psych., Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455)

Forward masking has been demonstrated in the amplitude-modulation (AM) domain [M. Wojtczak and N. F. Viemeister, J. Acoust. Soc. Am. **118**, 3198 (2005)] for masker and signal imposed on the same carrier. This study explores an effect of AM on detection of AM imposed sequentially

on a different carrier. Data show that a 40−Hz AM (interferer) imposed on a 2−kHz carrier affects detection of a 40−Hz AM (signal) imposed on a 5.5−kHz carrier after the offset of the interferer AM. The effect is analogous (and similar in size for the shortest interferer−signal delays) to modulation detection interference for simultaneous interferer AM. In another condition, two independent noise samples were presented to opposite ears. In one ear, a 40−Hz masker AM was imposed on the carrier. In the opposite ear, a 40−Hz signal was imposed on the carrier after the offset of the masker modulation. A forward−masking effect similar to but smaller in size than that in monaural presentation was observed. The data from both experiments suggest that the forward−masking effect in the modulation domain occurs at central stages of processing, where information is combined across peripheral channels and where binaural interactions occur. [Work supported by NIH Grants DC00683 and DC006804.]

2aPP22. The influence of broadened auditory tuning on across-frequency integration of speech. Eric W. Healy and Kimberly A. Carson (Dept. of Commun. Sci. and Disord., Arnold School of Public Health, Univ. of South Carolina, Columbia, SC 29208)

Previous work has suggested that hearing-impaired (HI) listeners may have a deficit in their ability to integrate speech information across different frequencies. Performance of HI listeners was poorer than that of normal-hearing (NH) listeners on across-frequency tasks, and performance dropped more steeply when the signal was degraded through across-frequency asynchrony [E.W. Healy and S.P. Bacon, J. Speech Lang. Hear. Res. **45**, 1262–1275 (2002)]. In the current study, the role of broadened auditory tuning in this deficit was investigated. Broad tuning was simulated in NH listeners using noise-vocoded sentences and manipulating the slopes of the amplitude-modulated carriers. It was found that intelligibility of synchronous carriers was poorest in the broadest slope conditions, suggesting that poor integration of synchronous cues may be at least partially attributable to broad tuning. Performance reductions as a function of asynchrony were also found to be greatest in the broadest conditions, but only when analysis bands matched presentation bands and not when analysis bands were held constant. It is concluded that broadened auditory tuning may account for at least a portion of the across-frequency deficit observed in HI listeners. [Work supported by NIH.]

2aPP23. Effect of flanker band number and excitation pattern symmetry on envelope comparisons in masking release. Ifat Yasin (Dept. of Exp. Psych., South Parks Rd., Univ. of Oxford, Oxford OX1 3UD, UK), Deborah A. Fantini (Univ. of Essex, Colchester CO4 3SQ, UK), and Christopher J. Plack (Lancaster Univ., Lancaster LA1 4YF, UK)

Greater masking release (MR) is observed when narrow-band noise flanker bands (FBs) are lower, rather than higher, than the signal frequency. This may be due to more effective signal coding on the high-frequency side of the excitation pattern (EP) [B. C. J. Moore and U. Jorasz, J. Acoust. Soc. Am. **100**, 2373–2379 (1996)]. If so, masking of a high-frequency signal (asymmetric EP) should lead to a greater MR between FBs below and above the signal frequency than for a lower-frequency signal (symmetrical EP). Masked signal thresholds were compared for pure-tone signals (0.5, 1, or 2 kHz) masked by a narrow-band noise masker centered at the signal frequency [on-frequency band (OFB)] and two (three) FBs at 2-ERB intervals, below (above) the signal frequency. Masked signal thresholds were also measured in the absence of FBs. The OFBs and FBs were modulated at a modulation depth, m, of 0.7. FB envelopes were the same as each other and that of the OFB (comodulated, C), the same as each other but independent of OFB (incoherent, I), or not modulated (unmodulated, U). No clear relationship was found between EP symmetry and MR magnitude. MR is susceptible to the computation used, i.e., $[(I+U)−C]$ or $[I−C]$ as well as level cues.

2aPP24. Timing perception of tonal sequences connected with glides. Satomi Tanaka (Grad. School of Music, Kyoto City Univ. of Arts, 13-6 Kutsukake-chou, Oe, Nishikyo-ku, Kyoto-city, Kyoto 610-1197 Japan, m06902@kcua.ac.jp), Minoru Tsuzaki (Kyoto City Univ. of Arts), and Hiroaki Kato (ATR Cognit. Information Sci. Labs./NICT)

When we hear continuous sound signals, we extract the timing between each segment although each segmental boundary is acoustically unclear. In order to investigate on which points we perceive the temporal structures in sound signals, perceptual experiments were conducted to measure the sensitivity in detecting the temporal deviation by using sound signals containing frequency glides. The following question was raised: What would provide a more effective cue to detect a change in the temporal structures, the starting point or the ending point of glides? Five segments of steady parts, of which high and low were alternated, were connected with four frequency glides, while the amplitude was fixed. By randomizing the duration of glide parts and adjusting the duration of steady parts compemsatively, one can exclusively add a certain degree of fluctuation on the starting point or ending point of glides. The task was to detect a temporal deviation from an isochronous structure. The thresholds of detection were measured within three ranges of the center frequency. The detectability tended to be better under the starting point condition than under the ending point condition. The results were discussed in relation to a computational model of event detection. [Work supported by JSPS.]

2aPP25. Timing perception of sequences with no obvious onset: Isochrony detection in sequences of complex tones connected by formant glides. Minoru Tsuzaki (Kyoto City Univ. of Arts, NICT/ATR Spoken Lang. Commun. Labs., KCUA, 13-6 Kutsukake-cho, Oe, Nishikyo-ku, Kyoto 610-1197, Japan), Satomi Tanaka (Kyoto City Univ. of Arts, Japan), and Hiroaki Kato (ATR Cognit. Information Sci. Labs./ NICT)

To investigate the perceptual cues that detect arrivals of new auditory events, the detectability of deviation applied to an isochronous temporal structure was measured. The stimuli were sequences of complex tones whose formant frequencies alternate between two steady values. Five steady parts were connected by four formant glides. The isochronous structure was introduced exclusively in the intervals between the starting points of the glides or in the intervals between the ending points by adjusting the durations of the glides and the steady parts in a compensatory manner. Since the harmonic components stop and start one after the other during the glides, it is difficult to define the arrival of new events in an entirely physical view. The perceptual difference in detectability between the starting and ending conditions and its dependency on the frequency region could reveal the perceptual cues that are effective in extracting temporal relations of auditory events. The results will be compared with those obtained with sinusoidal stimuli whose frequencies were modulated in a similar way as the formant frequency in this paper, and they will be discussed by reference to a computational model of auditory event detection. [Work supported by JSPS No. 16200016.]

2aPP26. Human performance in detecting audio-visual asynchrony. Armin Kohlrausch, Steven van de Par (Philips Res. Labs. Eindhoven (WO02), HTC 36, NL-5656AE Eindhoven, The Netherlands, armin.kohlrausch@philips.com), Rob van Eijk (Techn. Univ. Eindhoven, NL-5600 MB Eindhoven, The Netherlands), and James F. Juola (Univ. of Kansas, Lawrence, KS 66045)

The perception of audio-visual delays by human observers is typically characterized by two quantities: the point of subjective equality (PSE) and the sensitivity to asynchrony. The PSE can be derived from a temporal order judgment (TOJ) procedure or from the outcomes of a synchronous-successive response paradigm. Sensitivity to asynchrony is derived from the steepness of the response curve in the TOJ paradigm. In this contribution we present data that show that PSE estimates derived from TOJ measurements are much more variable across observers than those based on synchronous-successive data. Two synchronous-successive methods were

used with different response categories: (1) two categories: asynchronous, synchronous, and (2) three categories: audio first, synchronous, video first. Both synchronous-successive methods yielded similar results. A slight influence of stimulus type on PSE estimates derived from synchronous-successive data was observed. To conclude, we analyzed discriminability values obtained with a two-alternative forced-choice procedure. Discriminability is better near the edge than in the middle of the synchronous response category. This suggests that categorical perception might play a role in audio-visual synchrony perception.

2aPP27. The effect of marker duration on time shrinking. Yoko Fujishima and Yoshitaka Nakajima (Faculty of Inst. of Design, Kyushu Univ. 4-9-1 Shiobaru, Minami-ku, Fukuoka, 815-8540, Japan, fujishim@gsd.design.kyushu-u.ac.jp)

Time shrinking is an illusion of time perception. This illusion takes place in stimulus patterns of three successive sound bursts (markers) of equal duration marking two empty time intervals, the preceding time interval (P) and the standard time interval (S). When S is longer than P, S is often underestimated. In this study, we examined whether the duration of the bursts (in this case, pure tones) could affect this illusion. Time shrinking always took place when $S-P$ was less than or equal to 60 ms, and the marker duration did not affect the amount of underestimation of S in this range. However, the illusion took place only for the shortest marker duration of 20 ms when $S-P=80$ ms. The results roughly agreed with previous data. [Work supported by JSPS and 21st Century COE, Kyushu University.]

2aPP28. The role of spectral factors in the occurrence of the gap transfer illusion. Tsuyoshi Kuroda, Yoshitaka Nakajima (Faculty of Design, Dept. of Acoust. Design, Kyushu Univ., 4-9-1 Shiobaru, Minami-ku, Fukuoka 815-8540, Japan, kuroda@gsd.design.kyushu-u.ac.jp), Shimpei Tsunashima, Tatsuro Yasutake, and Shiro Mitsuba (Kyushu Inst. of Design, Minami-ku, Fukuoka 815-8540, Japan)

When a long ascending frequency glide with a gap at the temporal middle and a short continuous descending glide cross at their central position, observers report that the gap belongs to the short glide in spite of the physical position of the gap. This phenomenon is called the gap transfer illusion. We employed multiple-component crossing patterns and systematically varied the spectral slopes or formants of glides. In patterns that contained glides consisting of three harmonic components, the gap transfer illusion occurred when the crossing glides had equal spectral slopes, while the illusion was inhibited when the crossing glides had different spectral slopes. In patterns that contained 25 harmonic components representing formants of Japanese vowels, the gap transfer illusion took place only when the crossing glides had the same formants. Although Nakajima *et al.*

(2000) explained the gap transfer illusion in terms of the proximity of onsets and terminations, the present results show that it is also important to consider the role of spectral factors. [Work supported by JSPS and 21st Century COE, Kyushu University.]

2aPP29. An upper bound on the temporal resolution of human hearing. Milind N. Kunchur (Univ. of South Carolina, Dept. of Phys. & Astron., Columbia, SC 29208, kunchur@sc.edu)

This work obtained an upperbound of about 5 ms for the temporal resolution of hearing by studying human discriminability for bandwidth restriction by low-pass filtering. While low-pass filtering affects both the spectrum and temporal definition of the signal, the spectral changes in this experiment fall below the known just noticeable differences, so that the threshold seems to reflect the neural temporal-discrimination of the auditory system, rather than its ability to distinguish spectral cues based on tonotopic excitation patterns. The present result shows that human temporal resolution extends down to time scales much shorter than found in the past. Rough estimates of the expected resolution, based on convergencies in the cochlear nucleus and subsequent stages, yields values in a range that is consistent with the present experimental result.

2aPP30. Models of musical timbre using cortical spectro-temporal receptive fields and temporal codes. Mounya Elhilali (Inst. for Systems Res., Dept. of Elec. and Comput. Eng., A.V. Williams Bldg., Univ. of Maryland, College Park, MD 20742, mounya@isr.umd.edu), Daniel Pressnitzer (CNRS Université René Descartes Paris, 75005 Paris, France), and Shihab Shamma (Univ. of Maryland, College Park, MD 20742)

It has been customary to propose several "descriptive" definitions to quantify timbre as one of the basic attributes of sound. Multidimensional scaling techniques have proposed several acoustic dimensions to characterize the timbre of subsets of sounds. Yet, in the general case, timbre is an intricate percept difficult to relate to concise acoustic cues. Timbre probably reflects the dynamic interactions between spectral and temporal characteristics of sound that play a crucial role in identifying natural sources and convey a wealth of information about the environment. Recent physiological investigations revealed possible neural mechanisms to extract and represent the spectral and temporal information in complex sounds. At the level of the primary auditory cortex, spectro-temporal receptive fields exhibit a multiscale representation that captures many aspects of dynamic sound spectra. In the current study, we explore the potential correspondence between these cortical properties and the identification of musical instruments. We investigate the use of such representation as a quantitative descriptor of musical timbre, as validated by behavioral data from human subjects. Additionally, we examine biologically plausible coding strategies in this multidimensional cortical mapping involving spike-timing information.

Session 2aSC

Speech Communication: Prosody (Poster Session)

Victoria B. Anderson, Cochair

Univ. of Hawaii, Dept. of Linguistics, 1890 East West Rd., Honolulu, HI 96822

Keikichi Hirose, Cochair

Univ. of Tokyo, Dept. Information and Communication Engineering, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

2aSC1. The effects of speaking rate and tonal contexts on target undershoot of mandarin tone 3. Jia-Shiou Liao (Dept. of Linguist., Univ. of Texas, Calhoun Hall 501, 1 Univ. Station B5100, Austin, TX 78712-0198)

An investigation of the effects of speaking rate and tonal contexts on target undershoot of Mandarin tone 3 (low or low-falling-rising) was conducted. Data were from seven male and eight female subjects, all native speakers of Mandarin. The test phrase comprises three /ma/s in a row, which were put in a sentence to provide a natural context. The second /ma/ was always tone 3, preceded and followed by tone 1 (high-level), tone 2 (mid-rising), tone 3 or tone 4 (high-falling), resulting in 16 distinct combinations. Subjects read sentences at two relatively different rates: slow and fast. The fundamental frequency (F0) and duration of each /ma/ were measured at the onset and offset of its vowel. In addition, the duration of the second /ma/ and F0 at its midpoint were measured. Quantitative analysis of the rate of change in F0 suggests, by and large, that the F0 control systems are not always the same in slow and fast speech within the same tonal contexts. Furthermore, undershoot phenomena occur more often statistically across a syllable boundary than within a syllable boundary. Moreover, the F0 control system produces rates with less random fluctuation across the syllable boundary than within the syllable boundary.

2aSC2. Analysis on the effects of tonal coarticulation at word and nonword syllable boundaries of Mandarin based on the tone nucleus model. Qinghua Sun, Hirose Keikichi, and Minematsu Nobuaki (Univ. of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656 Japan, qinghua@gavo.t.u-tokyo.ac.jp)

As a typical tonal language, Mandarin has four lexical tone types, each of which has its own intrinsic pattern when uttered in isolation. However, when produced in context, the tonal contours present many variations, even if we specifically address the tone nucleus, which is defined as a stable part in a syllable. This study describes how and to what extent the word boundary affects tonal coarticulation in continuous speech. Although several previous works have investigated how the prosodic features of syllables are affected by their surrounding syllable tone types, most of them selected nonsense syllables uttered in a carrier sentence as study targets, which is far from natural situation. In this paper, after preparing a Mandarin speech corpus, in which all tone-type combinations of di-syllables are included with both intraword and interword cases, the degree of concatenation is compared for intraword and interword cases, viewing their tone component's F0 means and ranges of tone nuclei. All target di-syllables are uttered in a phrase. Results indicate that the degree in the intraword and interword cases differ greatly depends on the tone combination. The results were applied into our tone component prediction system, which is based on the tone nucleus model.

2aSC3. The command-response model for F0 contours and its application to phonetics and phonology of tone. Hiroya Fujisaki (Univ. of Tokyo, Tokyo, Japan)

The command-response model for the F0 contours, first proposed for nontone languages such an Japanese and English, has been extended by the author and his co-workers to cover F0 contour of tone languages and has been proved to be applicable to several dialects of Chinese including Mandarin, Cantonese, and Shanghainese, as well as other tone languages including Thai and Vietnamese. Namely, it allows one to approximate F0 contours of these languages/dialects with a very high accuracy using positive and negative tone commands. This paper first presents some results of analysis of F0 contours of these languages/dialects to demonstrate that the model can capture the acoustic-phonetic characteristics of their tones quite well. It then shows that coarse qualitative distinctions in the pattern of tone commands serve to distinguish tones within a language/dialect, as well as to distinguish tone systems of different languages/dialects. Thus the model proves to be a useful tool, not only in the studies of phonetic features of tones, but also in the studies of phonological structure of tone systems.

2aSC4. Tone sandhi effect on Chinese speech perception. Li Hsieh and Ya-Ju Yu (Dept. of Commun. Sci. and Disord., Wayne State Univ., 207 Rackham Hall, 60 Farnsworth, Detroit, MI 48202)

Mandarin Chinese has four tones with various sandhi processes. The third tone sandhi process is when a third tone (T3) becomes a second tone (T2) before another third tone (T3). Previous studies on third tone sandhi used connected speech in their experiments. This study examines the third tone sandhi effect on Chinese listeners in a nonconnected speech condition. Full-tone Chinese syllables were recorded in isolation. Ten Chinese listeners participated in tonal discrimination tasks which consisted of combinations of T2 and T3 (i.e., T22, T23, T32, T33). Three interstimulus intervals (ISIs) (i.e., 50, 250, 500 ms) and three types of pair conditions (minimal-, rhyme-, mixed-pairs) were introduced in the experiments. The findings of this study confirm the phonological hypothesis that the third tone sandhi effect has a great impact across all the pair conditions. When discriminating T23, Chinese listeners had longer response times and more errors than other tone pairs. The phonological phenomenon of third tone

3086   J. Acoust. Soc. Am., Vol. 120, No. 5, Pt. 2, November 2006

Fourth Joint Meeting: ASA and ASJ   **3086**

sandhi persists regardless of connected or nonconnected speech conditions in Chinese spoken language. Differences in processing the tone sandhi pairs (T23) and the nontone sandhi pairs (T32) reveal the psychological reality of the third tone sandhi phonological rule.

2aSC5. A cross-language comparison of the use of stress in word segmentation. Michael D. Tyler (MARCS Auditory Labs., Univ. of Western Sydney, Bldg. 5, Bankstown Campus, Locked Bag 1797, Penrith South DC NSW 1797, Australia), Pierre Perruchet (Université de Bourgogne, Esplanade Erasme, 21000, Dijon, France), and Anne Cutler (Max Planck Inst. for Psycholinguist., 6500 AH Nijmegen, The Netherlands)

In spite of our illusions to the contrary, there are few acoustic cues to word boundaries in spoken language. While statistical probabilities between adjacent speech units provide language-general information for speech segmentation, this study shows that language-specific information may also play an important role. An $f0$ excursion, a correlate of stress, was provided on the first or last syllable of each word in an artificial language. As expected, French listeners succeeded with final-syllable stress but not initial-syllable stress. However, Dutch listeners appeared to benefit from both initial and final stress, rather than initial stress only. When the results were split according to the language background of the talker (French or Dutch), it became clear that the Dutch listeners only benefited from initial stress when the talker was Dutch, but not when the talker was French. Given that the majority of Dutch listeners spoke French, it is suggested that they readily adapted their word segmentation strategies when faced with French-sounding input (i.e., French talker or final stress). In support of this, Australian English listeners with no knowledge of French clearly benefited from initial stress only, consistent with English stress patterning. [Work supported by Conseil Regional de Bourgogne, NWO, CNRS, NIHDC00403.]

2aSC6. Acoustic and spectral correlates of lexical stress. Anthony O. Okobi (Speech and Hearing Bioscience and Technol., Harvard-MIT Div. of Health Sci. and Technol., Cambridge, MA 02139)

Acoustic and spectral parameters that differentiate between primary and nonprimary stressed vowels were determined using two-syllable novel words with identical syllable compositions. The location of the high focal pitch accent within a declarative carrier phrase was varied using an innovative object naming task that allowed for a more natural and spontaneous manipulation of phrase-level accentuation. Results showed that when the high focal pitch accent was on the novel word, vowel differences in pitch prominence, intensity prominence, and vocal tract filter corrected amplitude of the first harmonic ($H1^*$) accurately distinguished primary from nonprimary stressed vowels. Vowel differences in first formant frequency, the spectral approximations of open quotient, $H1^*-H2^*$, and first formant bandwidth, $H1^*-A1^*$, also correlated with lexical stress under this condition. Correlates of lexical stress that were differentiating under all conditions tested were spectral tilt, $H1^*-A3^*$, noise at high frequencies, and duration. Furthermore, results indicated that these lexical stress vowel differences were augmented when the high focal pitch accent was on the novel word. This became apparent after a formula was devised to correct for the masking effect of phrase-level accentuation on the spectral tilt measurement. [Work partially supported by NIH T32-DC00038.]

2aSC7. The acoustic correlates of stress in compounds. Tuuli M. Adams (Linguist. Dept., New York Univ., 719 Broadway, 4th Fl., New York, NY 10003, tuuli.adams@nyu.edu)

The acoustic correlates of linguistic stress are traditionally considered to be intensity, pitch, and segment duration. The current study investigates the correlates of stress in English compounds such as ''blackboard'' by comparing their interaction with different intonational patterns. This study includes an experiment in which participants pronounced compounds in

controlled prosodic and intonational environments and various changes in intensity (dB), pitch (Hz), and duration were recorded for each vowel. Compounds in English are generally said to have a definitive stress pattern that distinguishes them from phrasal sequences; for example, ''greenhouse'' (for plants) would be stressed only on the first syllable, and its counterpart ''green house'' (house that is green) has a more even stress pattern. However, until now there has been no empirical study that successfully identifies the acoustic cues that distinguish compounds from phrasal structures. Results of this experiment show that intensity, pitch, and duration participate in a form of cue trading to signify stress in different contexts. This experiment provides new evidence that the acoustic correlates of stress interact with different intonational environments in a consistent way that distinguishes compounds from phrases.

2aSC8. Second occurrence focus and the acoustics of prominence. Jonathan Howell (Dept. of Linguist., Cornell Univ., 203 Morrill Hall, Ithaca, NY 14850, jah238@cornell.edu)

Partee (1991) challenged the significance of the observation that certain adverbs (e.g., only) reliably associate with phonologically prominent words to truth-conditional effect, noting second occurrence (i.e., repeated or given) focus (SOF) appears to lack a phonological realization. Rooth (1996), Bartels (2004), Beaver *et al*. (2004), Jaeger (2004), and Fry and Ishihara (2005) argued that, while not intonationally prominent, an SOF word can be marked by increased duration and/or increased rms intensity. An acoustic study of verb-noun homophone pairs is reported. Three sophisticated speakers uttered five repetitions of the targets, embedded in discourses, in first occurrence (FOF), SOF, and unfocused (NF) contexts, both pre- and postnuclearly. Syntagmatic comparison shows a durational effect for focus and ordering in the FOF/NF case, yet only an effect of ordering in SOF/NF; similarly, an effect of spectral balance (H1-H3) was found for FOF/NF but none for SOF/NF. Results suggest, contrary to previous assumptions, that simple durational difference is not a straightforward cue of prominence. Sluijter and van Heuven (1996) and Campbell and Beckman (1997) have shown spectral balance calculated by various means is a cue to focus; its absence in these data raises doubts that prominence is reliably produced (let alone perceived) on SOF words.

2aSC9. Intonational distinctions between sentence types in North Kyungsang Korean. Hye-Sook Lee (Cornell Univ., 306 East State St., Apt. 305, Ithaca, NY 14850)

As a lexical pitch accent language, North Kyungsang Korean seems to display a very restricted distribution of intonation. This paper investigates intonational differences between statements and questions in North Kyungsang Korean. In particular, a variety of f0 targets are compared between the sentence types, including pitch accent f0 peak, utterance-final edge, pitch range, and f0 valleys. Besides the acoustic analyses, perceptual identification tests are performed to test whether apparently diverging acoustic cues are perceptually significant. Based on ANOVA tests, it turns out that NK Korean questions can be significantly different from statements with respect to the utterance-final edge f0 and the relative f0 and timing of the rightmost f0 valley. Specifically, questions have higher f0 values at the right edge and higher and earlier occurrences of the rightmost f0 valley. Further, the forced-choice identification tests, whose input materials are manipulated in the similar set of acoustic variables, show that only the utterance-final edge f0 is a strong perceptual cue to distinguish between questions and statements. In the meantime, the comparison of yes/no questions and wh-questions demonstrates that there is no common acoustic factor with which the two types of questions are significantly distinguishable.

2aSC10. The degree of word-initial low tone in Japanese: Syntactic boundaries and speech rate. Hisao Tokizaki (Sapporo Univ., ULS Sumikawa 701, Sumikawa 5-3-8-1, Sapporo, 005-0005 Japan)

This study investigates the nature of word-initial low tone in Japanese. It will be shown that the degree of low tones depends on the speech rate and the number of syntactic boundaries between the word and the immediately preceding word. It will be argued that the phenomena can be explained naturally by boundary mapping from syntax onto phonology (Tokizaki, 1999, 2006). Pierrehumbert and Beckman (1988) and Selkirk and Tateishi (1988) argue that minor phrases are demarcated by initial low tone in unaccented words. Selkirk *et al.* (2003) argue that degree of low tone depends on whether the word is located at the left edge of a maximal projection of the lexical head (XP). The analysis of spoken data will be presented. Radio news and recited sentences are analyzed by Praat. The pitches of the first and the second mora of a word are measured and compared with the pitch of the high tone in the preceding word. The pitch difference of the first mora and the second is calculated. The result shows that our analysis makes a better prediction for the degree of word-initial low tone than previous analyses. [This project is supported by Grant-in-Aid for Scientific Research, JSPS, 2006.]

2aSC11. Variability and mismatch: Speakers' cues and listeners' cues. Yuki Hirose (Dept of Lang. Information Sci., The Univ. of Tokyo, 3-8-1 Komaba, Meguro-ku, Tokyo 153-8902, Japan)

The present study questions the natural assumption that the types of cues speakers use are common to those that listeners utilize. The left-versus right-branching ambiguity (LB/RB) in Japanese complex NPs such as the blue CD-genitive case was the material of interest. In a production study, accompanying visual contexts were manipulated with respect to visual ambiguity: whether there was only one possible target (referent) object corresponding to either RB or LB in each scene, or objects corresponding to both analyses were present in each scene and therefore the ambiguity remains in the visual scene. Phonetic analyses of the collected utterances revealed that when the visual information eliminated the ambiguity, the difference between the LB- and RB-intended utterances was modest and appeared mainly in $F0$ cues; when the ambiguity remained in the visual context, the prosodic manipulation was made mainly on durational cues. Those utterances were then fed to a perception study. A multiple regression analysis indicated that the cues contributing to RB/LB distinctions in listeners mainly showed up on durational cues, suggesting that most types of cues manipulated by speakers who were not aware of the ambiguity did not contribute to listeners' comprehension.

2aSC12. A perception study of syntactic disambiguation using resynthesized speech. Mariko Sugahara (Doshisha Univ., Kyoto, Japan, msugahar@mail.doshisha.ac.jp) and Yuki Hirose (The Univ. of Tokyo, Tokyo, Japan)

It is already well known that when a preceding word (W1) is accented, the following word (W2) is likely to undergo a postaccent downstep. Such a downstep is especially evident in a left-branching structure (henceforth LB) as in [[W1 W2] W3], while it is mitigated in a right-branching structure (henceforth RB) as in [W1 [W2 W3]]. That is, ups and downs of the F0 peak of W2 disambiguate the RB and the LB structure when a postaccent downstep is available (Selkirk and Tateishi, 1991; Kubozono, 1993, Hirose, 2005). Two questions, however, emerge. One is whether or not the magnitude of W3's downstep would ever contribute to the branching disambiguation. The other is what would happen when all words are unaccented, i.e., when no postaccent downstep is available. We carried out a perception study using resynthesized speech as stimuli, to examine those questions. Our results show that neither the W3 peak values of a postaccent environment nor the W2 peak values of an unaccented environment had significant effect on the LB vs. RB disambiguation. Such results will be compared with Hirose's (2005) production and perception study on spontaneous speech.

2aSC13. The effect of segmental structure on the production of Japanese pitch-accent. Irina A. Shport (Linguist. Dept., Univ. of Oregon, 1290 Univ. of Oregon, Eugene, OR 97403, ishport@uoregon.edu)

Japanese pitch-accent is a fall in fundamental frequency ($F0$) after the accented mora. In current models of Japanese pitch-accent contrast, accented and unaccented pitch patterns are predicted to be similar across syllable structure type. This study provides evidence that the segmental make-up of words affects accentual patterns in Tokyo Japanese in terms of their $F0$ contours. Six native speakers produced accented and unaccented words that varied in segmental type of the word-medial mora ($N = 864$). It was found that the pitch-accent contrast was produced differently in words with a short vowel in the first syllable, CVCVCV and CVC:V words (V-group), on one hand, and words with a longer voiced portion of the first syllable, CV:CV and CVNCV words (V:/VN-group), on the other hand, $p > 0.01$. In the accented condition, the average $F0$ fall was 50 Hz for all, but the $F0$ movement within the first syllable was different between the two word groups. In the unaccented condition, word-level, as well as intrasyllabic differences, were observed in $F0$ contours. $F0$ was rising in the V-group, whereas it was flat in the V:/VN-group. These results indicated that pitch patterns varied by segmental structure, more so for unaccented words.

2aSC14. Perception of Japanese pitch accent: Examination of minimal accent pairs. Yukiko Sugiyama (Dept. of Linguist., Univ. at Buffalo, SUNY, 609 Baldy Hall, Buffalo, NY 14260, ys8@buffalo.edu)

Perception of Japanese pitch accent was examined using 20 bimoraic/disyllabic minimal accent pairs. A minimal accent pair refers to a pair of words that is identical except for their accent types. For example, /hana/ "flower" and /hana/ "nose" have the same phonemic sequence and the pitch pattern of low-high yet they differ in that "flower" has accent on the word-final mora while "nose" has no accent (unaccented). A preceding production study that utilized the same 20 pairs of words found that the maximum F0 in the word-final mora was reliably higher for the final-accented words than the unaccented words and the F0 rise from the initial mora to the final mora was reliably larger for the final accented words than the unaccented ones when they were produced sentence-medially followed by a particle. However, the two accent types did not show any reliable difference when they were produced by themselves in isolation. This perception study accesses if the properties found to be related to Japanese pitch accent in production are actually used by listeners when they identify accent types. The relation between the production and perception of Japanese pitch accent will be discussed.

2aSC15. The phonetic and phonological triggers for downstep in Japanese: Evidence from perception. Takahito Shinya (Dept. of Linguist., 226 South College, Univ. of Massachusetts, Amherst, MA 01003, tshinya@linguist.umass.edu)

In Japanese the F0 peak of a word is downstepped after a lexically accented word. Lexical accent can be characterized by its phonological specification in the lexicon or by its phonetic F0 pattern. A perceptual experiment was conducted in order to observe how these two properties interact with each other as downstep triggers. The experiment tested whether listeners compensate for downstep exclusively based on the phonological information of lexical accent or on the phonetic cues available. Participants were asked to judge the relative prominence between two F0 peaks. Results suggest that in order for two words to be perceptually equal in prominence, the second F0 peak must be lower than a given first F0 peak. This difference between the two F0 peaks was significantly greater when the first word was phonetically accented than when it was phonetically unaccented, which suggests that the downstepped F0 peak is perceptually compensated. A similar effect was observed for the phonologically accented first peak, but the effect size was much smaller than the effect observed for the phonetically accented first peak. These results suggest that the primary trigger of downstep in Japanese is the F0 pattern of accented words. Lexical specification plays, at best, a secondary role.

2aSC16. Pitch values in prominent and nonprominent sentence enders in Japanese. Yumiko Enyo (Dept. of Linguist., Univ. of Hawaii at Manoa, 1890 East-West Rd., Honolulu, HI 96822)

This study uses naturally occurring interview data to investigate properties of intonational prominence in Japanese sentence enders (SEs). Since Japanese intonation patterns generally observe downstep (Venditti, 2005), a sentence-ending AP (accentual phrase) is likely to have the lowest F0 in an utterance if it does not receive prominence. Data from one interviewee's responses, SEs in long IPs (more than 5 APs) and short IPs (one or two APs), are used for this analysis. Within the group of 28 short IPs, there were eight cases of the SE nandaroo "what is it, I wonder." Measurements of highest and lowest F0 within nandaroo indicate two distinctive F0 patterns, determined by whether the SE is prominent or nonprominent. (Prominence appears to be placed on an SE when its content is focused.) In prominent SEs, the intonation contour contains peaks that exceed three standard deviations of the speakers F0 average. However, prominent and nonprominent utterances are similar in their F0 minima. As a result, SEs with prominence typically show wider pitch range than those without prominence. Similar results are found for other SEs contained in both long and short IPs.

2aSC17. On the prosody control characteristics of nonverbal utterances and its application to communicative prosody generation. Ke Li, Yoko Greenberg, Nagisa Shibuya, Yoshinori Sagisaka (GITI Waseda Univ. 29-7 Bldg. 1-3-10 Nishi-Waseda, Shinjuku-ku, Tokyo 169-0051, Japan,rikoku@akane.waseda.jp), and Nick Campbell (NiCT/ATR)

In this paper, prosodic characteristics of nonverbal utterances were analyzed using an $F0$ generation model proposed by Fujisaki aiming at communicative speech generation. From the analysis, the different distributions of $F0$ generation parameters have been observed for prototypical four dynamic patterns (rise, gradual fall, fall, and rise&down). Since former works have shown that these differences can correspond to their impressions (such as confident-doubtful, allowable-unacceptable, and positive-negative) expressed by multi-dimensional vectors, we tried to make a computational model from impression vector to $F0$ generation parameters. By employing a statistical optimization technique, we have achieved the mapping from impression vectors to prosody generation parameters. Perceptual evaluation tests using neutral words have confirmed the effectiveness of the mapping to provide communicative speech prosody. [Work supported in part by Waseda Univ. RISE research project of "Analysis and modeling of human mechanism in speech and language processing" and Grant-in-Aid for Scientific Research B-2, No. 18300063 of JSPS.]

2aSC18. Analyses of fundamental frequency contours for Japanese utterances that express several degrees of four emotions—joy, sadness, anger, and fear. Hiromi Kawatsu and Sumio Ohno (Grad. School of Bionics, Comput. and Media Sci., Tokyo Univ. of Technol., 1404-1 Katakura, Hachioji, Tokyo, 192-0982, Japan, kawatsu@so.cs.teu.ac.jp)

To give synthetic speech richer expression, prosodic features of utterances with various kinds of emotions were analyzed. Utterances that express four basic emotions with several degrees were collected as speech material: joy, sadness, anger, and fear. The fundamental frequency contours are analyzed based on a model for the process of generation. Changes in controlling parameters of the model were examined with regard to degrees of emotion. The baseline frequency increases as degrees of emotion increase. Especially for sadness and anger, its tendency is remarkable. Regarding phrase commands, the rate of occurrence increases as the respective degrees of emotion increase. The rates are affected by the kind of branch boundary in the grammatical structure and the number of morae from the immediately preceding phrase command. The change of the amplitude of phrase commands depends on the kind of position of grammatical structure. For the accent commands, timings of their onsets and offsets

are almost constant for degrees of emotion. They depend on the accent types of prosodic words. The magnitude of the accent commands changes as degrees of emotion increase depending on the positions of prosodic words from the beginning of the utterance.

2aSC19. An acoustic functional grammar of English intonation. Hunter B. Hatfield (Univ. of Hawaii, 438 Launiu St., Apt. A, Honolulu, HI 96815, hunterh@hawaii.edu)

There has been a resurgence in recent years of linguistic models that directly embed exact physical and acoustic data right into the formalism. This work attempts to show that many aspects of speech perception and production can only be understood when the acoustic input is fully considered. In the case of speech perception, if there are abstractions, they are abstractions over acoustic input, not based on *a priori* phonological categories. The current paper extends this work into English intonation. The functional phonology of Paul Boersma, which incorporates exact frequency values into an optimality theoretic perception grammar, is extended to explain several basic facts about English intonation, including the derivation of categorical high and low tones from the acoustic signal, the relation of tones to hierarchically adjacent tones, and the affectual aspects of classically paralinguistic intonation. The primary advantage of this approach is that it allows a single model to handle both linguistic and paralinguistic intonation structure, a merger which is only possible due to the use of physical acoustic data in the model.

2aSC20. Does English have accent domains? Molly Shilman (Linguist. Dept., UCLA, Los Angeles CA 90095-1543, mshilman@humnet.ucla.edu)

In ToBI systems, there are languages in which a pitch accent is the head of a particular level of phrase (accentual phrase) (e.g., French, Japanese), and those in which pitch accents are largely independent of phrasing (e.g., English, German). However, some theories of syntax-prosody mapping, such as Truckenbrodt's (1999), assume that a pitch accent is always the head of some prosodic domain. Such theories thus predict that every language with pitch accents should have a prosodic unit that is the domain of pitch accent. Previous work suggests that prosodic boundaries tend to be marked by several types of phonetic cues, including final lengthening (Wightman *et al.*, 1992; Jun, 2005). This study uses a controlled production experiment to determine whether there are accent domains in English: speakers produce near-minimal triplets in which the syntactic relations between words are changed by context but the segmental string, location of word boundaries, and location of the single pitch accent within the target phrase all remain fixed. Productions are then compared for final lengthening at the location of target boundaries. Preliminary results suggest that there is an accent domain in English.

2aSC21. Testing the implicit prosody hypothesis: Data from English. Sun-Ah Jun (Dept. of Linguist., UCLA, Los Angeles, CA 90095-1543, jun@humnet.ucla.edu)

One of the recent theories in sentence processing hypothesized that the prosodic phrasing implicit to a certain syntactic structure determines how speakers interpret the structure. According to this implicit prosody hypothesis (IPH; Fodor, 1998, 2002), in a structure of relative clause (RC) with a complex head noun, speakers/languages tend to prefer low attachment (i.e., an RC is modified by the adjacent head noun) if the prosodic break adjacent to RC is smaller than that between the head nouns. However, speakers/languages tend to prefer high attachment (i.e., an RC is modified by the nonadjacent head noun) if the prosodic break adjacent to RC is greater than that between the head nouns. Jun and Koike (2003) and Jun and Kim (2004) have shown that Japanese and Korean speakers who prefer high attachment produced a bigger prosodic break adjacent to RC than between the head nouns, confirming the IPH. The current study examines the prosodic phrasing of English sentences to investigate whether speakers

of American English, known to prefer low attachment, would produce a larger prosodic break between the two head nouns than that between the RC and the adjacent head noun. Data from 30 speakers will be discussed. [Work supported by UCLA Faculty Grants.]

2aSC22. Phrasal length and complexity effects on interphrase pause duration. Jelena Krivokapic (Dept. of Linguist., Univ. of Southern California, 3601 Watt Way, GFS 301, Los Angeles, CA 90089-1693,krivokap@usc.edu)

This study examines the effect of prosodic structure and phrase length on pause duration and the speech planning processes that such pauses can reveal. Subjects read sentences varying in two ways. First, each sentence included a pause bounded either by long intonational phrases both before and after it, medium phrases before and after, or short phrases before and after. Second, the prosodic complexity of the phrase on each side of the pause, i.e., before it and after it, was varied as to whether it was a branching intonational phrase or a nonbranching intonational phrase. Fourteen speakers read sentences synchronously in dyads so as to minimize variability due to speech rate and individual differences [Cummins, ARLO (2002), Cummins, J. Phonetics: (2003); Zvonik and Cummins, ICSLP (2002)]. The results for the dyads analyzed to date indicate that preboundary branching phrases are followed by longer pauses than nonbranching preboundary phrases. Further, surrounding long phrases lead to longer pauses than surrounding medium phrases, which in turn give rise to longer pauses than surrounding short phrases. Interaction effects of phrasal length and complexity will also be discussed. [Work supported by NIH.]

2aSC23. Speech timing: Final lengthening and syllable reduction in cerebellar pathology. Maureen A. Casper and Jennifer Geibel (State Univ. of New York @ New Paltz; 75 South Manheim Blvd., New Paltz, NY 12561)

The production of prosodic prominence may be considered the hallmark of normal speech motor control. Two theoretical views predict different relations between duration and formant and fundamental frequencies. The dynamic view of coordination predicts a disassociation between time and movement amplitude, while the clock theory of cerebellar movement poses a monotonic relation between duration and frequency. Phrase-final lengthening and syllable reduction each were measured across a prosodic contrast design for the acoustic measures of syllable duration, $F0$, $F1$, and $F2$. The speech characteristics of normal and cerebellar ataxic speakers were compared. In support of gestural dynamics, and following the kinematic findings for normal speakers, the acoustic findings showed longer duration and reduced frequency for phrase-final lengthening, and shorter duration and reduced frequency for syllable reduction. Cerebellar speakers produced longer durations for both events and increased variability for formant and fundamental frequency. This dissimilarity between normal prosodic production and that of cerebellar speakers implies a dynamic relationship between time and articulatory movement. In contrast to normal speech production, cerebellar speech is markedly slow and fails in the rapid adaptation to reduce frequency in phrase-final and reduced syllables.

2aSC24. Voice $F0$ responses to actual versus consciously perceived auditory feedback pitch shifts. Theresa Burnett and Dana Madonia (Dept. of Speech & Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405)

The purpose of this study was to determine the effect of pitch shift discrimination ability on production of voice $F0$ responses to auditory feedback pitch shifts. Subjects repeatedly vocalized /u/ into a microphone while listening to their voice fed back over headphones. During each trial, auditory feedback pitch was experimentally shifted upward or downward (randomly determined) by 50 cents for 100 ms. Subjects subsequently pressed a button labeled up or down to indicate their perceived direction of

voice feedback pitch shift. Voice output was recorded, $F0$ extracted, smoothed, time aligned to the onset of the pitch shift, and averaged. Button response accuracy was found to be at chance expectancy among the majority of subjects. Nevertheless, all subjects responded vocally to the pitch shifts by changing voice $F0$ in the opposite direction, indicating that the direction of the shift was indeed processed by the auditory system. These results are consistent with the existence of preattentive mechanisms of audio-vocal control, and provide evidence for a mismatch between conscious and preattentive auditory processing of voice pitch feedback for the control of voice $F0$. [Work supported by NINDS.]

2aSC25. Correlations between voice $F0$ responses and manual reaction times to auditory feedback pitch shifts. Dana Madonia and Theresa Burnett (Dept. of Speech & Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405)

There appear to be two types of voice $F0$ responses to voice auditory feedback pitch manipulations: early, opposing responses, and later responses that vary across subject and task. The purpose of this study was to determine whether either type correlates with volitional motor abilities. Subjects vocalized /u/ into a microphone while listening to their voice fed back over headphones. Subjects also pressed a joystick button as rapidly as possible upon hearing any experimenter-generated auditory feedback pitch shift. Pitch shift stimuli were 50 cents upward or downward (randomized), and 100-ms duration. Voice was recorded, $F0$ extracted, smoothed, time aligned to the onset of the shift, averaged according to shift direction, and the onset of the first voice $F0$ response was measured. Average manual reaction time was calculated. Findings indicated no significant correlation between manual responses and early voice $F0$ response. However, later voice $F0$ responses and manual reaction times were positively correlated. These results are consistent with the hypothesis that the early voice $F0$ response is automatically generated, and later responses are under voluntary influence. Results also suggest that the variability of later voice $F0$ responses may be a function of individual differences in volitional motor response abilities. [Work supported by NINDS.]

2aSC26. Frequency and amplitude derivatives as syllable-level $F0$ features. Mark Liberman and Jiahong Yuan (Univ. of Pennsylvania, Philadelphia, PA 19104)

Most descriptions of tone and intonation focus on the alignment of $F0$ rises, falls, and inflection points relative to the phonetic unfolding of associated syllables. In this context, it is suggested that the relationship between proportional changes in $F0$ (treated modularly to eliminate the effects of period doubling and halving) and proportional changes in amplitude (within the frequency bands typically dominated by energy from voicing) provides an interesting characterization of $F0$ trajectories in relation to syllabic structure. Using data from conversational and broadcast speech in English and Chinese, parameters of this type (in combination with other acoustic measures) are used in identifying relevant features of tone and intonation.

2aSC27. Declination of subglottal pressure during speech and its relation to tone distribution. Helen M. Hanson, Janet Slifka, Stefanie Shattuck-Hufnagel (Speech Commun. Group, Res. Lab. of Electron., MIT, 77 Massachusetts Ave., Cambridge, MA 02139), and James B. Kobler (Massachusetts General Hospital, Boston, MA 02114)

The subglottal pressure contour P_s for speech is considered to have three phases: initiation (rapid rise), working (level or slightly declining), and termination (rapid fall). The current work focuses on characterization of the working phase in terms of the distribution of pitch accents and of phrase and boundary tones. In particular, the degree of P_s declination is studied. A measure of P_s declination has proven difficult to define [cf. Strik and Boves, J. Phonetics **23**, 203–220 (1995)]. Therefore, in pilot work, subjective ratings of degree of declination are made on a subset of

a corpus in which the tone distribution is controlled. Significant variation in the degree of declination is observed among speakers. For example, P_s for one speaker is relatively constant to slightly declining, while for another it is almost always sharply declining. For some speakers utterances with an early-occurring nuclear pitch accent (NPA) show greater degree of declination than utterances with a late-occurring NPA, as do utterances ending with high tones. Data for additional subjects and objective measures will be presented. The results have implications for models of speech production, and for applications such as computer speech synthesis and recognition. [Work supported by NIH Grants DC00075 and DC04331.]

2aSC28. Comparing methods for measuring pitch "elbows." Ryan Shosted,[a)] Alex Del Giudice, and Amalia Arvaniti (Dept. of Linguist., Univ. of California, San Diego, 9500 Gilman Dr., #0108, La Jolla, CA 92093)

Currently, there is no standard method for determining the location where an F0 curve begins its upward or downward trajectory (sometimes referred to as the pitch "elbow"). It is generally accepted that elbows are hard to measure in a consistent way: some studies have used least-squares fitting methods, others have relied on visual judgments. This study uses a variety of data from English and Greek that exhibit different degrees of difficulty for locating the elbow. Automated results are derived from various implementations of two algorithms. The first algorithm uses linear least-squares fitting, where the intersection of two lines that best approximate the pitch contour denotes the point of the elbow. The second algorithm analyzes point-by-point changes. The results are then compared with those of human labelers. We present results from a series of statistical tests that estimate the robustness of variations on these two algorithms with respect to the performance of the human labelers. Our aim is to provide a method for measuring elbows that is robust and easy to implement and that can be used with different types of pitch contours, in order to improve accuracy of measurements. [a)] Also at Univeristy of California, Berkeley.

2aSC29. Semi-automatic labeling of pitch accents in American English. Diana Stojanovic and Yohei Sakata (Dept. of Linguist., Univ. of Hawaii, 1890 East-West Rd., Honolulu, HI 96822)

This study provides a simple classification of several pitch accents that occur in American English, based on acoustic measurements of F0. Audio samples recorded by a female speaker and transcribed in the ToBI framework (Beckman, 1994) were used to develop five rules to recognize the pitch accents H*, L*, L+H*, and L*+H. Since no information about prosodic phrasing was given to the recognizer, some combinations with phrase accents were considered and contours then grouped into equivalent labels (e.g., %HL* equivalent to H*L−). Based on the rules developed, a semi−automatic process of labeling pitch accents was implemented in Praat. Half of the audio samples were used to train the labeler, the other half to test it. The accuracy level achieved was 69%. When effects of microprosody, creaky voice, or incorrect automatic pitch tracking were removed, the accuracy of classification into equivalent labels increased to 90%. Two types of applications are proposed: semi−automatic computer labeling of intonation for larger quantities of data, and a tool to help human transcribers learn American English ToBI using Praat. In addition, the simple classification is the first step towards looking into speaker variability in realization of different contours, and typology of intonational contours in different languages.

2aSC30. Parametric spectrogram modeling of single and concurrent speech with spline pitch contour. Jonathan Le Roux, Hirokazu Kameoka, Nobutaka Ono, and Shigeki Sagayama (Grad. School of Information, Phys. and Computing, The Univ. of Tokyo. 7-3-1, Hongo, Bunkyo-ku 113-8656 Tokyo, Japan)

This paper proposes a novel general speech analysis framework consisting in a precise and parametric description of speech directly from the power spectrum, resulting in a new efficient pitch estimation method for both single and multiple speaker situations. The speech spectrum is modeled as a sequence of spectral clusters governed by a common pitch contour expressed as a spline curve. These clusters are isolated by an unsupervised 2-D time-frequency categorization of the energy density, and their common pitch contour is estimated simultaneously. A smooth pitch contour can thus be extracted on the whole utterance, linking together its voiced parts, while this is difficult or impossible for frame-by-frame algorithms. The proposed algorithm is compared to several existing methods on a database of single speaker speech, with very good results that place it among the most accurate ones. Moreover, its very high accuracy is shown on the estimation of multi-pitch contours of co-channel concurrent speech.

2aSC31. Robust $F0$ estimation based on complex speech analysis. Tatsuhiko Kinjo and Keiichi Funaki (Univ. of the Ryukyus, Okinawa, Japan)

This paper proposes a novel robust fundamental frequency ($F0$) estimation algorithm based on complex-valued speech analysis for an analytic speech signal. Since the analytic signal provides spectra only over positive frequencies, spectra can be estimated accurately at low frequencies. Consequently, it is considered that $F0$ estimation using the residual signal extracted by complex-valued speech analysis can perform better for $F0$ estimation than that for the residual signal extracted by conventional real-valued LPC analysis. In this paper, the autocorrelation function (AUTOC) weighted by a reciprocal of the AMDF is also adopted for the $F0$ estimation criterion. The proposed $F0$ estimation algorithm is evaluated using three criteria, AUTOC, AMDF, and the weighted AUTOC, with complex-valued residual extracted by complex-valued speech analysis. We also compared the proposed method with those for three signals: the speech signal, analytic speech signal, and LPC residual. Speech signals used in the experiments were corrupted by addition of white Gaussian noise whose noise levels are 10, 5, 0, and −5 [dB]. The performance was evaluated using the gross pitch error (GPE) and fine pitch error (FPE). The results demonstrate that this algorithm based on complex speech analysis can perform better than conventional methods in an extremely noisy environment.

2aSC32. Cross-linguistic examination of listeners frequency thresholds for musical tones and vowels. Daniel Pape (ZAS Berlin, Jgerstrasse 10-11, 10117 Berlin, Germany)

There is clear evidence that musical education increases the discriminability of the frequency threshold (dl). If musical education increases sensitivity, the question arises if listeners of a language that uses F0 for prosody are more sensitive to musical tones and vowels' dl thresholds. A perception experiment was conducted examining the dl of musical tones and vowels for both professional musicians and nonmusicians. The experiment was carried out cross linguistically: The languages include German and English (Germanic languages) and Italian, Portuguese, and Spanish (Romance languages). Results indicate that dl is significantly smaller for musicians compared to nonmusicians for all examined languages. The native vowel dl is significantly smaller for the Germanic languages. This is attributed to the more frequent use of F0 for prosody, thus claiming linguistic reasons. Surprisingly the dl for the musical tone in all languages is smaller for the Germanic musicians compared to the Romance musicians, although musical education and the stimulus were identical for all musically educated musicians. These results indicate an influence of the native language on the pitch accuracy of the listeners. Thus we give evidence that interference of speech pitch and musical pitch processing occurs, which supports the "common processing theory."

2aSC33. Peak alignment in accented Tolowa syllables. Christopher Doty (Dept. of Linguist., Univ. of Oregon, 1290 Univ. of Oregon, Eugene, OR 97403-1290, suomichris@gmail.com)

Tolowa (Athabaskan, Pacific Coast Group) has only three remaining fluent speakers near Crescent City, CA. Tolowa has prominent pitch contours that have been described both as an interaction of stress and vowel length and as lexically specified pitch accent. The present study examined

the phonetic realization of these pitch contours. Fundamental frequency ($F0$) at its highest peak during the rhyme of accented syllables was measured, as was relative duration into the rhyme at which the peak occurred. Preliminary results indicated that a high pitch peak occurred approximately 20%–30% of the way into the rhyme of the syllable. In the case of long vowels in accented syllables, this led to a prominent peak which fell sharply during the second half of the rhyme. A similar peak and fall was seen in accented syllables closed by a voiced sonorant. In the case of accented syllables with short vowels closed by a voiceless consonant, the accent was realized as a rise in pitch leading to the final consonant. These results indicate that the phonetic target is a high peak 20%–30% into the rhyme; the target seems to not include the fall seen in rhymes with long vowels or those closed by voiced sonorants.

2aSC34. Production characteristics of accent in four dialects of Nahuatl. Susan G. Guion (Linguist. Dept., Univ. of Oregon, 1290 Univ. of Oregon, Eugene, OR 97403, guion@uoregon.edu), Jonathan D. Amith (Gettysburg College, Gettysburg, PA 17325), Christopher Doty, and Irina A. Shport (Univ. of Oregon, Eugene, OR 97403)

Most descriptions of Nahuatl (Uto-Aztecan, Mexico) describe regular penultimate accent, although production characteristics are unstudied. Recently, however, dialects from Guerrero state have been described with pitch-accent from historical coda breathy /h/ in nonfinal position [Guion and Amith, J. Acoust. Soc. Am. **117**, S2490 (2005)]. In the current study, the acoustic correlates of this new pitch-accent, as well as penultimate accent, are investigated. Speakers ($n=6$) from four dialects–two with innovated pitch-accent and two with only penultimate accent–were recorded. The production characteristics of fundamental frequency (F0), duration, and voice quality, as indexed by the difference between the first two harmonics (H1-H2), were investigated. Innovated pitch-accent was found to be cued solely by F0. Penultimate accent varied in its production by dialect. In dialects with only penultimate accent, production exhibited characteristics typical of stress-accent: Accented syllables had higher F0, longer durations, and more vocal effort (smaller H1-H2 differences) than unaccented syllables. Dialects with innovated pitch-accent had less stress-like penultimate accents, being cued primarily by F0, or with a relatively small durational difference, but no voice quality difference. This indicates that the innovation of a pitch-accent has changed the formerly stresslike penultimate accent into a more pitch-type accent.

2aSC35. Lexical stress without postlexical head-marking: Evidence from Tagalog. Victoria B. Anderson (Dept. of Linguist., Univ. of Hawaii, 1890 East-West Rd., Honolulu, HI 96822, vanderso@hawaii.edu)

Jun (2005) compares prosodic prominence types in 21 languages representing diverse families (including Australian, Chinese, Germanic, Muskogean, Romance, and Semitic, but none from Austronesian). Jun observes an implicational relationship between the prominence type a language uses at the lexical level (i.e., lexical tone, stress or pitch accent) and the prominence type it uses postlexically (i.e., head-marking or edge-marking). Fourteen languages in the sample employ lexical stress; all use postlexical head-marking (i.e., postlexical pitch accent on a phrases most prominent syllable), and four additionally mark a phrases' edge(s). No stress language in the sample employs postlexical edge-marking alone. However, Tagalog may be such a language. Tagalog uses lexical stress (LAyas "leave;" laYAS "carefree"), but arguably does not use head-marking. This study examined map-task data from four native speakers of Tagalog. Syllables bearing main stress in a phrase, and occurring between zero and three syllables from the end of the phrase, were analyzed for pitch, intensity, and duration. Results show that although syllables with primary stress have increased intensity, and duration, pitch prominences

do not reliably align with these syllables. Instead, low pitch reliably appears on the first syllable in an accentual phrase, while high pitch reliably appears on the last syllable.

2aSC36. Bengali intonational phonology. Sameer ud Dowla Khan (Dept. of Linguist., UC Los Angeles, 3125 Campbell Hall, UCLA, Los Angeles, CA 90095-1543)

Previous studies of Bengali intonation are primarily concerned with the mapping between syntax and intonation, the existence of accentual and phonological phrases, optionality in phrasing, and realization of focus. While these studies have been influential, they shy away from a full description of Bengali intonation, drawing from a small data set produced by a handful of speakers. At present, there is no comprehensive analysis of Bengali intonation that uses data collected from a wide range of speakers. The current study adopts the framework of intonational phonology (Pierrehumbert, 1980; Ladd, 1996) to develop such an analysis based on a large set of data from approximately 25 Bengali speakers. A pilot study measuring pitch and segment durations in 155 sentences suggests the existence of three pitch accent types (low, high, rising) and three levels of prosodic units whose right edges are marked by a boundary tone (intonation, intermediate, accentual). This suggests that Bengali differs from most other languages (Jun, 2005) in having both (1) contrastive pitch accents and (2) a small prosodic unit that is the domain of the pitch accent (i.e., the accentual phrase). Further analyses will illustrate the phonetic realizations of pitch accents and boundary tones in the language.

2aSC37. Prosodic correlates to meaning in infant-directed speech. Debora S. Herold (Dept. of Psych., Indiana Univ. Purdue Univ. at Indianapolis, 402 North Blackford St., Indianapolis, IN 46202, dssasso@iupui.edu), Laura L. Namy, and Lynne C. Nygaard (Emory Univ., Atlanta, GA 30322)

The present investigation examined the extent to which speakers produce reliable prosodic correlates to meaning across a range of semantic domains and whether parents use these kinds of cues to teach word meanings to children. In study 1, acoustic properties including fundamental frequency (F_0), F_0 variation, duration, and amplitude of infant-directed utterances were examined. Speakers were asked to produce question phrases in which novel words were used to convey one of two meanings from a set of antonym pairs (e.g., big/small, yummy/yucky). Herold (2006) has shown that adult listeners can identify word meanings from the prosodic information contained in these utterances. Acoustic analyses revealed that each word meaning had a unique acoustic signature, and that related word meanings such as *big* and *tall* and *small* and *short* had similar acoustic profiles. Study 2 explored whether naturalistic parental speech to young children recruits similar acoustic properties in the service of providing prosodic cues to meaning. Results demonstrated that mothers systematically varied prosodic cues as a function of word meaning when producing speech to their children. These findings suggest that speech directed to infants contains reliable prosodic markers to word meaning and that mothers may use prosodic cues to differentiate word meanings in word learning contexts.

2aSC38. Influence of voice prosody on preferential behaviors. Naoki Hasui and Yugo Takeuchi (1-39-18 Sumiyoshi, Hamamatsu-shi, Shizuoka, 432-8011 Japan, gs06044@s.inf.shizuoka.ac.jp)

In mother-infant interactions, the mother talks in a special voice that is characterized by elevated fundamental frequency (pitch) and exaggerated intonation contours, and the infant turns a face toward the voice and smiles naturally. This case suggests that humans react automatically to the special prosody without understanding of the lexical meaning in the word. We propose a hypothesis that adults react automatically as in the case of the infant by not only a difference of prosody but also the situation that one is in. This study aims to figure out the function of prosody on voice

cognition and utilize these findings for constructing the voice user interface systems with a low cognitive load for users. In this paper, using the virtual maze on a display, we gave the participants a task that they should escape as quickly as possible from the maze. In the situation where the participants choose the route on T-shaped intersection, we gave the participants two leading voices of different prosody, and observed the preferential behavior for the two voices. The experimental results indicate that the voice of the voice user interface systems synthesizing the high pitch or the high rate of speech is naturally accepted and can direct the users.

2aSC39. Utilization of acoustic cues in identifying speech intonation contrasts in cochlear implant recipients and listeners with normal hearing. Shu-Chen Peng (Dept. of Hearing and Speech Sci., Univ. of Maryland, College Park, MD 20742)

This study investigated the utilization of acoustic cues in identifying speech intonation contrasts in adult cochlear implant (CI) recipients and normal-hearing (NH) individuals listening to spectrally and temporally degraded stimuli. Fundamental frequency, intensity, and duration patterns of a disyllabic word, popcorn, were manipulated orthogonally, resulting in 360 resynthesized stimuli. In a two-alternative forced-choice task, CI and NH participants identified whether each stimulus was question-like or statement-like. Each NH listener also identified stimuli that were noise vocoded. Preliminary results from seven CI and four NH listeners indicated that (a) weighting of fundamental frequency in the identification of CI listeners was less pronounced than that of NH listeners, (b) unlike NH listeners who showed little reliance upon intensity or duration patterns in identifying unprocessed stimuli, CI users demonstrated systematic dependence upon intensity and duration cues in identifying the same set of stimuli, and (c) with noise-vocoded (spectrally and temporally degraded) stimuli, NH listeners' identification exhibited weighting patterns for inten-

sity and duration cues in a way similar to that of CI listeners. Implications for the processing of multidimensional acoustic cues for speech intonation in normal and electrical hearing will be discussed. [Work supported by NIDCD-R01DC04786.]

2aSC40. The voices of anger and disgust: Acoustic correlates in three languages. Marc D. Pell, Areej Alasseri (School of Commun. Sci. & Disord., McGill Univ., 1266 Pine Ave. West, Montreal, QC H3G 1A8, Canada, marc.pell@mcgill.ca), Sonja A. Kotz, and Silke Paulmann (Max Planck Inst. for Human Cognit. and Brain Sci., 04103 Leipzig, Germany)

Anger and disgust are believed to represent discrete human emotions with unique vocal signatures in spoken language. However, few investigations describe the acoustic dimensions of these vocal expressions, and some researchers have questioned whether disgust is robustly encoded in the vocal channel. This study sought to isolate acoustic parameters that differentiate utterances identified as sounding angry versus disgusted by listeners based on evidence from three separate languages: English, German, and Arabic. Two male and two female speakers of each language produced a list of pseudo-sentences (e.g., Suh fector egzullin tuh boshent) to convey a set of seven different emotions. The recordings were later judged by a group of native listeners to determine what emotional meaning was perceived from the prosodic features of each pseudo-utterance. Individual sentences identified systematically as conveying either anger or disgust (greater than $3\times$ chance target recognition) were then analyzed acoustically for various parameters of fundamental frequency, amplitude, and duration. Analyses compared which acoustic parameter(s) were dominant for identifying anger versus disgust in each language, and whether these patterns appeared to vary across languages, with implications for understanding the specificity and universality of these emotion expressions in the vocal channel.

WEDNESDAY MORNING, 29 NOVEMBER 2006   HONOLULU ROOM, 8:00 TO 11:55 A.M.

Session 2aSP

Signal Processing in Acoustics, Architectural Acoustics, Engineering Acoustics, Psychological and Physiological Acoustics: Spatial Sound Processing, Control, and Performance Evaluation

William L. Martens, Cochair
McGill Univ., Faculty of Music, 555 Sherbrooke St. W., Montreal, Quebec, H3A 1E3, Canada

Kazuhiro Iida, Cochair

2aSP1. Median plane localization using a parametric model of the head-related transfer function based on spectral cues. Kazuhiro Iida, Motokuni Itoh (AV Core Technol. Development Ctr., Matsushita Electric Ind. Co., Ltd. 600 Saedo, Tsuzuki, Yokohama, 224-8539 Japan, iida.kazuhiro@jp.panasonic.com), Atsue Itagaki, and Masayuki Morimoto (Kobe Univ. Rokko, Kobe, 657-8501 Japan)

The present study has two purposes. One is to examine a simulation method for localizing a sound image. The authors propose a parametric HRTF model to simulate vertical sound localization. The parametric HRTF is recomposed only of the spectral peaks and notches extracted from the measured HRTF, and the spectral peaks and notches are expressed parametrically with center frequency, level, and sharpness. The other purpose is to clarify the contribution of each spectral peak and notch as a spectral cue. Localization tests were carried out in the upper median plane using the subjects' own measured HRTFs and the parametric HRTFs with various combinations of spectral peaks and notches. The results show that the parametric HRTF recomposed using the first and second notches

(N1 and N2) and the first peak (P1) provides almost the same localization accuracy as the measured HRTFs. Observations of the spectral peaks and notches indicate that N1 and N2 change remarkably as the source elevation changes, whereas P1 does not depend on the source elevation. In conclusion, N1 and N2 can be regarded as spectral cues, and the hearing system could utilize P1 as the reference information to analyze N1 and N2 in ear-input signals.

8:25

2aSP2. Evaluation of head-related transfer function on the opposite side to a sound source. Takanori Nishino (Ctr. for Information Media Studies, Nagoya Univ., Nagoya, Aichi, 464-8603 Japan), Takayuki Oda, and Kazuya Takeda (Nagoya Univ., Nagoya, Aichi, 464-8603 Japan)

A head-related transfer function (HRTF) is a complex acoustic transfer function because it includes the effect of reflection and refraction due to the head and ears. The HRTFs on the opposite side to a sound source have more complex characteristics and lower power than HRTFs that are on the same side as a sound source. Moreover, many previous studies about monaural sound localization showed that performances of sound localization on the opposite side were not precise. From these results, it can be assumed that the HRTFs on the opposite side are not necessary to use listener's own. In our experiments, several stimuli that convolved with the HRTFs were presented to evaluate individuality. The left ear HRTF was the subject's own, and the right ear HRTF was the subject's own and others. The differences between the subject's HRTF and others' HRTFs were evaluated using the spectral distortion score. The sound source azimuths were from 0 to 180 deg at intervals of 30 deg; the front was 0 deg, the left side was 90 deg, and the back was 180 deg. The results shows that the right ear HRTFs between 30 and 150 deg azimuth have low individualities.

8:45

2aSP3. Classification head-related transfer functions for an individualization procedure by a tournament-style listening-test. Yukio Iwaya and Yôiti Suzuki (Res. Inst. of Elec. Commun., Tohoku Univ., 2-1-1 Katahira, Aoba-ku, Sendai, 980-8577, Japan)

Individualization of head-related transfer functions (HRTFs) is necessary for high-accuracy sound image localization in three-dimensional spatial rendering by virtual auditory displays (VADs). However, measurement of HRTFs for each listener for all sound-source directions requires a special measuring apparatus and a long measurement time with a listener's physical load. The authors have therefore proposed an individualization method of HRTFs called Determination method of OptimuM Impulse-response by Sound Orientation (DOMISO), in which the best set of HRTFs is selected using a tournament-style listening test without any measurement. In DOMISO, our HRTF corpus, including more than 120 sets of measured HRTFs, is used. In this study, a classification method of these HRIRs is examined to select good seeds for the tournament. First, relationships among various parameters of HRTFs and individualization results by DOMISO are analyzed using multiple-correlation analysis. Second, using promising parameters, all sets of HRTFs in the corpus are classified as a structured tree. Third, using results of classification, listening tests by DOMISO procedure are performed using these HTRFs. Finally, a listening test of sound image localization is conducted with the individualized HRTFs to examine the effectiveness of the classification.

9:05

2aSP4. Development of the fast measurement system for the listener's own head-related impulse responses. Kimitoshi Fukudome (Dept. of Acoust. Design, Faculty of Design, Kyushu Univ., Shiobaru 4-9-1, Minami-ku, Fukuoka, 815 Japan, fukudome@design.kyushu-u.ac.jp), Yusuke Tashiro (Kyushu Inst. of Design, Minami-ku, Fukuoka, 815-8540 Japan), Kazuki Takenouchi, Toshiya Samejima, and Naoki Ono (Kyushu Univ., Minami-ku, Fukuoka, 815-8540 Japan)

Three-dimensional (3-D) spacial sound reproduction through headphones or earphones is best realized for subjects by the use of their own head-related impulse responses (HRIRs). Although HRIR measurements are so extremely time consuming, better externalized HRIRs for subjects must be collected in order to develop future 3-D applications. The fast measurement system for the listener's own HRIRs was constructed based on the continuous measurement method with a subject sitting on a servo-swiveled chair (SSC), and together with a loud speaker elevation arm controlled by a stepping motor. It can greatly reduce the subject burden in HRIR measurements. HRIRs for all azimuthal directions at 29 elevations can be measured in 1 h, constituting a reduction by a factor of 3 of the amount of time required as compared to systems composed of an SSC and a conventional manual elevation system. In the presentation, principles of the fast measurement system and the specifications of the loud speaker elevation arm are described. Performance evaluations are presented in terms of the measurement accuracies by the signal-to-deviation ratio and the spectral distortion, and further the reproducibility in repetitive measurements. [Work supported by the specific project research in the Faculty of Design, 2005.]

9:25

2aSP5. Capture and rendering of spatial sound over headphones. Ramani Duraiswami, Dmitry N. Zotkin, and Adam O'Donovan (Perceptual Interfaces and Reality Lab., Inst. for Adv. Comput. Studies, Univ. of Maryland, College Park, MD 20742)

A theory for capturing an audio scene and then rendering it remotely over headphones is developed. The method relies on capture of a sound field up to a certain order in terms of spherical wave functions. Then, the captured sound field is convolved with the head-related transfer function and rendered to provide presence in the auditory scene. The sound-field representation is then transmitted to a remote location for immediate rendering or stored for later use. A system that implements the capture using a spherical array is developed and tested. Head-related transfer functions are measured using the system described in [D.N. Zotkin *et al.*, J. Acoustic. Soc. Am. (to appear)]. The sound renderer, coupled with the head tracker, reconstructs the acoustic field using individualized head-related transfer functions to preserve the perceptual spatial structure of the audio scene. [Work partially supported by VA.]

2aSP6. Acoustic rendering of a virtual environment based on virtual microphone control and binaural room scanning. Jonas Braasch (School of Architecture, Rensselaer Polytechnic Inst., 110 Eighth St., Troy NY 12180), William L. Martens, and Wieslaw Woszczyk (McGill Univ., Montreal, QC H3A 1E3, Canada)

Binaural room scanning (BRS) is a convolution technique that utilizes a set of spatially indexed impulse responses that are selected in response to listener head movements during virtual acoustic rendering, such that the direction of sonic elements is automatically updated according to the angle determined by a head tracker. Since the room impulse responses have to be measured for only a few loudspeaker positions, a very successful application of BRS is the simulation of a control room. In order to create a flexible headphone-based virtual environment, it is proposed to simulate the input signals for the BRS system using virtual microphone control (ViMiC). ViMiC renders a virtual environment by simulating the output signals of virtual microphones that can be used to address a surround loudspeaker system. The advantages of this approach are twofold. First, the measured impulse responses of the BRS system ensure high spatial density in overall reflection patterns, avoiding the typical gaps in between the early reflections that occur when using solely mirror images or ray tracing. Second, the resulting imaging is closer to common audio engineering practice, where a pleasant but plausible environment is favored over a more purely realistic rendering.

10:05−10:20   Break

10:20

2aSP7. A comparison of listener loudspeaker preference ratings based on *in situ* versus auralized presentations of the loudspeakers. Sean Olive, Todd Welti (Harman Intl. Industries, Inc., 8500 Balboa Blvd., Northridge, CA 91329), and William Martens (McGill Univ., Montreal, PQ, H3A 1E3, Canada)

Auralization methods have several practical and methodological advantages for studying the perception of loudspeaker reproduction in rooms. For subjective measurements of loudspeakers, the auralization should be capable of eliciting the same sound quality ratings as those measured using an original acoustic presentation of a loudspeaker. An experiment was designed to test whether this is possible. Listeners gave preference ratings for both acoustic (*in situ*) and auralized double-blind presentations of four different loudspeakers, and the results were compared. The auralized presentations were generated from binaural room-scanned impulse responses of the loudspeakers convolved with the music test signals and presented over headphones equipped with a head-tracking device. For both *in situ* and auralized methods nine trained listeners gave preference ratings for four different loudspeakers using four different programs with one repeat (eight trials in total). The results show that the auralized and *in situ* presentations generally produced similar loudspeaker preference ratings.

Contributed Papers

2aSP8. Equalization of a one-dimensional sound field with a movable source. Xi Chen, Timothy W. Leishman, Scott D. Sommerfeldt, and Benjamin M. Faber (Acoust. Res. Group, Dept. of Phys. and Astron., Brigham Young Univ., Provo, UT 84602)

An experimental plane-wave tube with a movable side-branch loudspeaker was used to study simultaneous source and sound field equalization. The effects of equalization and inverse filtering were evaluated for different measured field quantities. Parametric equalization filters were designed based on acoustic pressure and total energy density at a point within the tube. An adaptive filter based on total energy density and the filtered-x algorithm was also implemented. The results of the equalization methods are compared and their advantages and disadvantages are explained.

10:55

2aSP9. Numerical calculation method of binaural signals suitable for auralization of a reflective sound field. Makoto Otani (Dept. of Intelligent Systems Design Eng., Toyama PRef. Univ., Imizu, Toyama 939-0398, Japan, otani@pu-toyama.ac.jp) and Shiro Ise (Kyoto Univ., Yoshida-Honmachi, Sakyo-ku, Kyoto City 606-8501, Japan)

Based on the Kirchhoff-Helmholtz integral equation, a numerical calculation method, which enables a wave-theory-based auralization of a sound field inside room, is proposed. Binaural signals are synthesized from pressures and particle velocities on the boundary surface and corresponding head-related transfer functions (HRTF). The proposed method can shorten the extra computation time that is required because of changes in numerical conditions caused by head movement and rotation. The boundary element method (BEM) was used to calculate surface values on sound-reflective objects. In addition, HRTFs for various source positions were calculated using a BEM-based HRTF calculation system [M. Otani and S. Ise, J. Acoust. Soc. Am. **119**, 2589–2598 (2006)]. Results obtained using the proposed method are compared with those of the conventional BEM, whose boundary consists of a head and a wall, and an image source method, which does not incorporate sound wave motion. Those comparisons reveal that the proposed method can accurately simulate binaural signals, including indirect sound from reflective objects. In addition, interactions between the head and wall are discussed, which are omitted in any auralization method using HRTFs to synthesize binaural signals and have not been investigated.

2aSP10. A new digital module for variable acoustics and wave field synthesis. Diemer de Vries, Jasper van Dorp Schuitman (Lab. of Acoust. Imaging and Sound Control, Delft Univ. of Technol., P.O. Box 5046, 2600 GA Delft, The Netherlands), and At van den Heuvel (Acoust. Control Systems B.V., 3886 ZG Garderen, The Netherlands)

In the 1980s, wave field synthesis (WFS) was proposed by Berkhout [J. Audio Eng. Soc., **36**, pp. 977–995 (1988)] as a new and powerful concept for spatial reproduction of sound fields without sweet-spot-limitations. Based on this concept, with implementation of simplifications not deteriorating the perceptual quality, a system for variable acoustics was developed: acoustic control system (ACS). The system has been widely applied as a solution for multipurpose halls. Until now, ACS processors have been built using analog electronic technology. Recently, however, a digital module has been designed that not only enables us to generate the ACS reflection patterns, but also to perform true WFS, e.g., for direct sound reinforcement with preservation of natural spatial properties. In the paper, design and specifications of the module will be discussed. Also, the potentials of integrated application of WFS and variable acoustics will be explained.

2aSP11. Multichannel high sampling rate 1-bit audio with a high definition video recorder system. Jun-ichi Fujimori (Sound and Acoust. Group, Sound Technol. Development Ctr., Yamaha Corp., 203 Matsunokijima, Iwata, Shizuoka, Japan, fujimori-j@beat.yamaha), Yasuhiro Oikawa, and Yoshio Yamasaki (Waseda Univ., Tokyo, Japan)

Ideally, as much audio, video, and metadata information as possible should be acquired to produce archives using the most advanced technology available at the time so that maximum information can be inherited. On the other hand, it is not easy to develop both audio technology and video technology simultaneously or even to integrate them. For example, because we specifically examine audio technology, it is desirable to use video products in the market to achieve the goal. In this sense, we propose the use of IEEE1394 equipment and synchronize their components for integration. We developed a high sampling rate 1-bit audio AD/DA converter that is equipped with IEEE1394 and recording and playback software running on Linux. The software can synchronize a 1-bit audio stream using MPEG-TS of HD video to extend its audio quality using IEEE1394 isochronous streaming with 125-Es resolution. This integration of audio and video is achieved without modifying existing video products. This paper describes the system and the 1-bit audio AD/DA converter (5.6 MHz sampling 8ch in 8ch out or 4.8 MHz sampling 16ch in 16ch out).

2aSP12. Audio noise reduction utilizing inharmonic-frequency analysis of generalized harmonic analysis (GHA). Teruo Muraoka (Res. Ctr. For Adv. Sci. and Technol., The Univ. of Tokyo, 4-6-1, Komaba, Meguro-ku, Tokyo, 153-8904, Japan) and Thoru Ifukube (The Univ. of Tokyo, Tokyo, 153-8904, Japan)

Audio noise reduction is a desired technology for better telecommunications. Currently, the technology is based mostly upon spectral subtraction methods. However, its fundamental problem of musical noise generation remains unsolved. Musical noise is produced by mismatching of instantaneous phases of presampled noise and target noise to be canceled, which causes noise-breathing effects synchronous with the object's intensity variation. Additionally, unnecessary frequency components inherent to Fourier analysis to resynthesis process are mixed in the processed output. For this reason, spectral subtraction is inapplicable to high-fidelity audio. The authors have devoted attention to inharmonic frequency analysis of generalized harmonic analysis (GHA), which was originally proposed by Wiener. The analyses were intended to examine stochastic signals utilizing harmonic frequency analysis. Results clarified that any signal can be represented as an almost periodic function whose frequency components have an inharmonic relationship. In 1993, Dr. Hirata proposed inharmonic frequency analysis based upon successive matching with frequency component templates, which is applicable to high-fidelity audio signal processing. This method came to be called GHA, following Wiener's theory. The authors mostly attempted noise reduction in damaged SP records of historical value, retrieving almost noise-free musical sounds.

WEDNESDAY MORNING, 29 NOVEMBER 2006

MAUI ROOM, 7:50 A.M. TO 12:00 NOON

Session 2aUW

Underwater Acoustics and Acoustical Oceanography: Sediment Acoustic Processes: Quantifying the Effects of Sediment Properties on Dispersion, Attenuation, Reflection, Scattering, and Buried Target Detection I

Eric I. Thorsos, Cochair
Univ. of Washington, Applied Physics Lab., 1013 NE 40th St., Seattle, WA 98105-6606

Masao Kimura, Cochair
Tokai Univ., Dept. of Geo-Environmental Technology, 3-20-1 Shimizu-Orido, Shizuoka 424-8610, Japan

Chair's Introduction—7:50

Invited Papers

7:55

2aUW1. The Sediment Acoustics Experiment in 2004 (SAX04). Eric I. Thorsos, Kevin L. Williams, Dajun Tang, Steven G. Kargl Darrell R. Jackson, and Brian T. Hefner (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698, eit@apl.washington.edu)

A major sediment acoustics experiment (SAX04) was conducted near the coast of northwestern Florida, USA during September–November 2004. In addition to our laboratory, a number of other institutions participated, principally from the USA and Canada. SAX04 addressed sound penetration into, propagation within, and scattering from the shallow-water seafloor, as well as scattering from proud and buried targets. The sandy sediment at the experiment site has a critical angle of nearly 30 deg, convenient for study of acoustic penetration into sediments at grazing angles below the critical angle. A shallow-water depth of about 17 m allowed divers to be utilized in many aspects of the experimental work. In particular, divers deployed a 30-m rail system on the bottom for synthetic aperture sonar and other acoustic measurements. SAX99, conducted at a site nearby, showed the importance of scattering from ripples on high-frequency acoustic penetration at subcritical grazing angles. In part because of these findings, a new research initiative on sediment ripple formation, evolution, and decay was begun by ONR, and investigators from this program carried out studies at the SAX04 site. An overview will be given of the SAX04 measurement program. [Work supported by ONR.]

2aUW2. Observations of seafloor ripples and a time-dependent ripple geometry model. Peter Traykovski (Appl. Ocean Phys. Dept., Woods Hole Oceanogr. Inst., Woods Hole, MA, 02543)

Recent seafloor acoustic scattering experiments and theoretical developments have shown that the presence of ripples on the seafloor can increase the amount of subcritical angle acoustic penetration into the seafloor. A ripple observation and acoustic scattering experiment (SAX04) was recently conducted near Fort Walton Beach, Florida. During this experiment a sidescan sonar on an REMUS AUV was used to observe ripple geometry from the nearshore (5-m depth) to the shelf break (50-m depth). The ripples were found to increase in wavelength from 20 cm in the nearshore to 1.2 m at the shelf break. The offshore ripples were a product of Hurricane Ivan, which had passed the site 2 weeks prior. Time series of ripple geometry, measured with a tripod-mounted rotary sidescan sonar and a two-axis rotary pencil beam sonar, from a coarse sand site at the Martha's Vineyard Coastal Observatory, also revealed long-wavelength (0.6 to 1.2 m) relict ripples after wave events. Ripple geometry models that assume the ripples are in equilibrium with hydrodynamic forcing underpredict the wavelength of the relict ripples at both sites; thus a new model that allows for a time delay between ripple adjustment and forcing was developed. [Work supported by ONR.]

2aUW3. Biodegradation of wave-formed sand ripples during SAX04 (Sediment Acoustics Experiment 2004). Alex E. Hay (Dept. of Oceanogr., Dalhousie Univ., Halifax, NS B3H 4JI, Canada)

The gradual decay of 50- to 70-cm-wavelength sand ripples over a 20-day period of continuous *in situ* observations is presented. The ripples formed midway through the SAX04 experiment during Tropical Storm Matthew, and the observation period began immediately following this event. Bed elevation profiles and planform images of the ripple field were obtained at centimeter-scale resolution using rotary sonars, and at millimeter-scale resolution using a laser-video bed profiling system. Low-frequency currents, wave orbital velocities, and near-bed turbulence were monitored simultaneously with colocated instruments. The observed rates of change of the principal components of the bed elevation spectrum and of the spatially integrated backscatter intensity differences are presented and compared to predictions made with a diffusivity-based model of the ripple decay process. The model-data comparisons yield values for the horizontal sediment diffusivity which are consistent with previous measurements using particle-counting techniques.

2aUW4. Velocity dispersion in water-saturated granular marine sediments. Masao Kimura (School of Marine Sci. and Technol., Tokai Univ., 3-20-1 Orido, Shimizu-ku, Shizuoka, Shizuoka 424-8610, Japan, mkimura@scc.u-tokai.ac.jp)

The velocity dispersion in water-saturated granular marine sediments is an important subject that has remained unresolved in the community of sediment acoustics. Reported velocity dispersion results cannot be explained using the Biot model with the constant frame bulk modulus. The author showed that the values of the frame bulk modulus of water-saturated glass beads and beach sands are approximately 10^9 Pa at a frequency of 500 kHz and about ten times greater than those used typically in the community. Moreover, the author proposed a modified gap stiffness model incorporated into the Biot model (BIMGS model). Using this model, the author demonstrated that the frame bulk modulus has frequency dependence [M. Kimura, J. Acoust. Soc. Am. **1205** (2006)]. In this study, the BIMGS model is established using the measured results of the longitudinal wave velocities in glass beads saturated with alcohol-water mixed liquids. Then the velocity dispersion in glass beads and beach sands with different grain sizes are analyzed using the measured results of the longitudinal wave velocity at a much higher frequency and in the region of relaxation frequency. Finally, it is shown that the reported velocity dispersion can be explained using the BIMGS model.

Contributed Papers

2aUW5. Sound waves and shear waves in saturated unconsolidated sediments. Michael J. Buckingham (Marine Physical Lab., Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., La Jolla, CA 92093-0238)

A recent, continuum-mechanics theory of compressional and shear wave propagation in saturated unconsolidated sediments relies on grain-to-grain interactions as the sole source of internal stress in the porous medium. On the basis of a statistical argument, nonlinear microscopic processes occurring at grain boundaries are incorporated into the intrinsically linear grain-shearing theory. The result is two sets of algebraic dispersion relationships, one of which represents a compressional wave and the other a shear wave. The shear wave is predicted to exist even in the absence of an elastic "frame." For both types of wave, the theory predicts logarithmic dispersion and a near-linear dependence of attenuation on frequency. The grain-shearing dispersion relations, which are functions not only of frequency but also of the geophysical parameters of the sediment (porosity, bulk density, grain size, and overburden pressure), show excellent agreement with multiple data sets that have appeared in the literature over the past half century. Since the physical mechanisms behind the grain-shearing theory and Biot's classical theory of wave propagation in porous media are quite different, some comments will be offered in an attempt to clarify the circumstances in which the respective theoretical approaches might be valid. [Research supported by ONR.]

2aUW6. Frame virtual mass for unconsolidated granular media with slippage. Nicholas P. Chotiros and Marcia J. Isakson (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029)

A model of the grain contact physics in the presence of a propagating wave is extended to included losses due to slippage. Mechanical coupling between grains in a randomly packed unconsolidated granular medium is inherently stochastic. Grain-to-grain contact asymmetry leads to coupling of kinetic energy into orthogonal linear and rotational motion at the grain level, and partitioning of the energy. The result is an increase in inertia, which may be treated as an additional or virtual mass term for both shear and compressional waves. The virtual mass term can be evaluated, given the scintillation index of the compressional and shear contact stiffness, Poisson's ratio, and the average number of contact points at each grain. The effect of slippage at the grain-to-grain contact is examined. [Work supported by Office of Naval Research, Ocean Acoustics.]

2aUW7. A comparison of two observations of compressional wave velocity dispersion in marine sediments. Charles W. Holland (Appl. Res. Lab., The Penn State Univ., State College, PA), Altan Turgut (Naval Res. Lab., Washington, DC), Jan Dettmer, and Stan Dosso (Univ. of Victoria, Victoria, BC, Canada)

Compressional velocity dispersion exists in all marine sediments. If the dispersion is great enough, it may play a significant role in acoustic interaction with the seabed. On the other hand, if dispersion is weak, seabed models and databases can be substantially simpler. The ocean acoustics community is divided on this issue, in part because of the lack of observations. Here we compare two recent methods for measuring dispersion. One technique measures the broadband reflection coefficient (frequency dependence of the critical angle) and thus infers the velocity dispersion. The other technique measures time of flight in an *in situ* probe over a broadband of frequencies. Measurements on New Jersey Shelf (STRATAFORM area) are compared and implications for the frequency dependence of the compressional wave attenuation are discussed. [Work supported by the Office of Naval Research and NATO Undersea Research Centre.]

2aUW8. Low-frequency laboratory measurements of sound speed in water-saturated granular sediments. Theodore F. ArgoIV (Appl. Res. Labs., Univ. of Texas, P.O. Box 8029, Austin, TX 78713-8029) and Preston S. Wilson (Univ. of Texas, Austin, TX 78712-0292)

Accurate knowledge of the acoustic behavior of water-saturated granular sediments is required for effective sonar operation in certain environments. Acoustic dispersion at frequencies below about 20 kHz has been the topic of much recent study and debate. While the understanding of real ocean-bottom sediments in their full complexity is the ultimate goal, laboratory measurements are significantly less difficult and subject to less uncertainty. This plays an important role in sediment acoustics since the difference between the predictions of competing propagation models is only a few percent. A new laboratory impedance tube apparatus, which operates in the 0.5–10-kHz frequency range, has been developed to address this issue. The device can be operated as a traditional acoustical impedance tube, in which water-borne sound waves interact with the water-saturated sediment. The device can also be operated as a driving-point impedance instrument, in which the mechanical input impedance of a column of water-saturated sediment is investigated. The effective-fluid sound speed is then inferred from the impedance measurements. Preliminary measurements of the sound speed in reconstituted natural sand sediments and artificial granular sediments obtained with the new apparatus will be presented and compared to existing theory. [Work supported by ONR.]

10:30

2aUW9. *In situ* acoustic scattering, attenuation, and dispersion measurements in marine sediments. Altan Turgut, Roger Gauss (Naval Res. Lab., Washington, DC 20375), Charles Holand (The Penn State Univ., State College, PA 16804), and Lisa Zurk (Portland State Univ., Portland, OR 97207)

The degree of acoustic velocity dispersion and nonlinear frequency dependency of attenuation in various types of sediments is investigated. A down-looking chirp sonar and a wideband acoustic probe system are used to measure compressional wave speed and attenuation within 2–150-kHz frequency band. Measurements indicate slight velocity dispersion and nonlinear frequency dependency of attenuation in silty and sandy sediments that can be effectively modeled by an extended Biot theory (Yamamoto and Turgut, J. Acoust. Soc. Am. **83**, 1744–1751 (1988)]. The degree of acoustic scattering due to volume inhomogeneities and surface roughness is also estimated from the incoherent components of the measured signals. Acoustic scattering results are favorably compared with those predicted by pseudospectral FDTD simulations that used colocated vibracore data as input. Robustness of the attenuation and dispersion measurements by using chirp sonar and acoustic probe systems is also verified by the FDTD simulations [Work supported by the ONR.]

10:45

2aUW10. Weak consolidation model for wave propagation in ocean sediments. James Berryman (Lawrence Berkeley Natl. Lab., 1 Cyclotron Rd., Berkeley, CA 94720)

Within the context of Biot's theory of poroelasticity, both effective density approximations and grain-to-grain elastic and inelastic effects are incoporated into a complete theory of acoustic propagation through ocean-bottom sands. The sedimentary material is assumed to be at best weakly consolidated. A variety of possible attenuation mechanisms are considered in order to explain ultrasonic data for both laboratory studies on glass beads saturated with water and silicon oil, as well as *in situ* data from the SAX99 experiment. An effective medium model is introduced to treat the weakly consolidated frame constants. Wave speeds and attenuations are explained to first order by the effective density approximation alone, but the remaining small discrepancies in velocity can be modeled successfully using the consolidation constants. Remaining attenuation discrepancies can then be fit using several methods including (a) increase of viscosity in fluid trapped between grains, (b) increase of viscosity due to high frequencies alone, and also (c) a new approach that specifically takes dynamic— but small amplitude—grain rearrangements into account. None of these mechanisms was taken into account in Biot's original low-frequency theory.

11:00

2aUW11. Frequency dependences of absorption and scattering components of attenuation for water-saturated sands. Keiichi Ohkawa (Tech. R&D Inst., JDA, 5-2 Ichigayahonmuracho Shinjuku-ku, Tokyo, Japan)

Frequency dependences of attenuation of sound waves in water-saturated marine sands are discussed. Measured attenuation includes a scattering component, and this makes it difficult to understand the frequency dependences of attenuation. By removing the scattering component from the measured attenuation, the Kramers-Kronig (K-K) relationship gives the correct sound speed dispersion. Consequently, the intrinsic attenuation extracted from the data collected during SAX99 experiments follows the Biot theory for overall frequencies. This suggests that the attenuation coefficient of sound waves for water-saturated sands is not linear in f. The sound speeds recalculated via the K-K relationship are also in excellent agreement with the Biot theory at high frequencies.

11:15

2aUW12. Dispersion and attenuation due to scattering from heterogeneities in the porosity of sand sediments. Brian T. Hefner, Darrell R. Jackson (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698), Joseph Calantoni, and Allen H. Reed (Naval Res. Lab., Stennis Space Ctr., MS 39529)

Close packed granular materials are inherently heterogeneous at small length scales due to the random packing of the grains. These heterogeneities should manifest themselves in the frame moduli and the porosity of the medium. For sound propagation through fluid-saturated granular materials, the small scale of the heterogeneities may lead to scattering from the fast compressional wave into the slow compressional wave, increasing the attenuation of sound in the medium. This mechanism may account for the increase in high-frequency attenuation relative to expectations based upon Biot theory observed in recent measurements in sand and glass-bead sediments. Previously, we presented the results of a perturbation theory of sound propagation that accounted for losses due to scattering from heterogenieties in the bulk frame modulus [B. T. Hefner *et al.*, J. Acoust. Soc. Am. **119**, 3447 (2006)] and showed that the losses due to this mechanism were not enough to account for the measured attenuations. The theory has since been expanded to account for heterogeneities in the porosity. This

theory relies on knowledge of the spatial statistics of the porosity and efforts are underway to measure these spatial variations in both simulations of glass beads and through CT scans of sand sediments. [Work supported by ONR.]

11:30

2aUW13. Measurements of the frequency dependence of sound speed and attenuation in a sandy sediment. Brian T. Hefner, Darrell R. Jackson, Kevin L. Williams, and Eric I. Thorsos (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698)

Among the systems deployed during the sediment acoustics experiments, SAX99 and SAX04, were a fixed buried hydrophone array and a diver-deployed mobile array. The buried hydrophone array was used to measure the sound penetration into the sediment from a mobile source tower over a frequency range of 11–50 kHz during SAX99. For very steep incident grazing angles well above the critical angle, the penetrating field is only weakly influenced by the surface roughness and can be used to determine the sound speed and attenuation in the sediment. For SAX04, the frequency range was extended such that the new range covered 2–50 kHz. The diver-deployed array consisted of two sources and two receivers, which could be inserted into the sediment to a depth of 10 cm to measure sound speed and attenuation from 100–260 kHz during SAX99. For SAX04, the frequency range was increased to 40–260 kHz such that the measurements overlapped those made using the buried array. The sound speeds measured during both experiments using these systems are consistent with the predictions of Biot theory while the attenuation follows a linear frequency dependence at high frequencies. [Work supported by ONR.]

11:45

2aUW14. Frequency dependence of sound speed and attenuation in marine sediments. William M. Carey (Boston Univ., Boston, MA 02215), Ji-Xun Zhou (Georgia Inst. of Technol., Atlanta, GA 30332), and Allan D. Pierce (Boston Univ., Boston, MA 02215)

Zhou and Zhang [J. Acoust. Soc. Am. (2005) (2006)] have reviewed diverse data for propagation in sandy sediments. Attenuation for frequencies below 1 kHz corresponds roughly to $\alpha = 0.34(f/f_o)^2$ dB/m with the reference frequency being 1 kHz. The best-fit exponent is slightly less than 2. Their review of results for frequencies above 10 kHz suggests a substantially different frequency dependence. They considered two explicit models, the Biot model as parametrized and extended by Stoll and the BICSQS model of Chotiros and Isakson [J. Acoust. Soc. Am. (2004)]. In either case the fit of parameters to match sound speed dispersion resulted in an unsatisfactory fit of attenuation versus frequency, and conversely. The present paper reexamines this and contends that, while Biot's formulation is intrinsically correct at low frequencies, Stoll's parametrization is noncausal: Chotiros' model more nearly captures the correct physics in that it is intrinsically causal and includes relaxation processes. A considered extension is to include a continuous smear of relaxation processes (rather than just two) within the basic context of the original Biot model. This is shown to be wholly consistent with Kramers-Kronig relations and to have sufficient flexibility to fit the overall data set.

WEDNESDAY AFTERNOON, 29 NOVEMBER 2006   LANAI ROOM, 1:00 TO 5:20 P.M.

2pAA1. Manfred R. Schroeder's life in acoustics: Phases, reflections, and other contributions of a "perfect number." Birger Kollmeier (Medizinische Physik, Universitaet Oldenburg, D-26111 Oldenburg, Germany)

Number theory such as the rules to compose a perfect number (which is the sum of all its divisors, e.g., 6, 28, 496, 8128) constitutes only a small part of the many fields of research Manfred R. Schroeder mastered in his scientific life. After finishing his Ph.D. with Erwin Meyer in Goettingen in 1954, Schroeder joined Bell Labs where he eventually became director of acoustics and mechanics research. In 1969 he was also appointed professor of physics and director of the Drittes Physikalisches Institut in Goettingen. He contributed to many seminal publications and inventions in the areas of room acoustics, speech coding, physiological and psychological acoustics, and computer graphics. The Schroeder phases describe the quadratic initial phase relation of the harmonics in a tone complex to produce a maximum flat (speech) waveform. The Schroeder diffusors are reflection gratings based on his number theoretic considerations that suppress the specular reflections while distributing scattered sound into all different directions. The current talk will give an overview of Manfred Schroeder's life in acoustics and his various contributions, including some stories about his unique character. A special focus will be placed on the Schroeder phases and their current use in hearing research.

<center>1:25</center>

2pAA2. Modification of time and frequency dimensions of speech. James L. Flanagan (Rutgers Univ., 26 Wolf Hill Dr., Warren, NJ 07059)

Vocal and auditory mechanisms impose constraints on speech signals. These constraints are central to techniques for coding and bandwidth compression, and hence to efficient transmission and storage. A key representation is the short-time Fourier transform, describing the signal in terms of two variables—time and frequency. This separation affords opportunity, within limits, to scale these information-descriptive parameters. This report recollects efforts (incentivized by bandwidth conservation) to modify speech in time and frequency. The ''Analytic Rooter'' [Schroeder *et al.*, Proc. IEEE **55**, 396–401 (1967)] divides bandwidth by a factor of 2, keeping temporal characacteristics intact. The ''Phase Vocoder'' [J. Flanagan and R. Golden, Bell Syst. Tech. J. **45**, 1493–1509 (1966)] allows nonrational manipulations in both time and frequency. And, ''Silence Detection,'' based upon automatic step-size adjustment in adaptive differential PCM coding [Flanagan *et al.*, IEEE Trans. Commun. **COM-30**, 336–345 (1982)], permits speed variations with constant bandwidth. Recordings illustrate the effects.

<center>1:45</center>

2pAA3. Early linear predictive speech coding at Bell Telephone Laboratories and Electrical Communication Laboratory. Fumitada Itakura (Meijo Univ., Shiogamaguchi 1-501, Tempaku-ku, Nagoya 468-8502, Japan)

At the 6th ICA in Tokyo (1968), two papers on the linear predictive coding of speech were presented by Manfred Schroeder and by me in the same session. The first paper was on the adaptive linear predictive waveform coding for medium band coding (time domain modeling) and the latter was on the LPC vocoder based on the autoregressive spectral estimation for narrow-band coding (frequency domain modeling). Although their approaches were very different in both concept and scope, there were dramatic common points: the covariance and autocorrelation methods were used to solve normal equation to determine the LPC parameters and also the pitch period was extracted to reproduce speech periodicity in both systems. Subsequently the multipulse (1982), stochastic (1984), and code (1985) excitation LP were proposed at AT&T BTL, whereas the transformation of LPC parameters to PARCOR (1969) and LSP (1975) and their efficient quantization were intensively studied at ECL of NTT. These efforts were eventually combined for practical implementations in the secure, cellular, and IP telephone in the 1980s. The brilliant ideas by Manfred Schroeder and his associates at BTL, in particular Bishnu Atal, have always been a helpful lighthouse to navigate the world-wide speech coding research in the right direction since 1980s.

<center>2:05</center>

2pAA4. Personal reflections on 20 years of research with Manfred R. Schroeder: From concert hall acoustics to code-excited linear prediction. Bishnu S. Atal (Dept. of Elec. Eng., Univ. of Washington, Seattle, WA 98185)

I joined Bell Laboratories, Murray Hill in 1961. Bell Labs then had an excellent environment for challenging researchers to find creative solutions to difficult problems in telecommunication. Coming from India, I was fortunate to have Manfred as my mentor. He and I collaborated on many interesting problems. Stereo sound systems in those days kept the sound confined between two speakers, and we wondered why we could not spread the sound beyond the speakers. We invented a system for creating signals at the human ears that removed this limitation, producing the beginning of surround sound. Vocoders could not synthesize natural-sounding speech, and Manfred always felt that the speech synthesis models used in vocoders were too rigid and inflexible. This kind of thinking led us to the path of adaptive predictive coding and we presented a paper on this topic at the first IEEE meeting on speech communication in Boston in 1967. We continued working together producing better and better speech quality on predictive coders. Our research led to the approach of code-excited linear prediction, which forms the basis of world-wide digital cellular standards.

<center>2:25</center>

2pAA5. The roles of models in speech communication research. Hiroya Fujisaki (Univ. of Tokyo, Tokyo, Japan)

The use of models is a key to development of science and technology. Only through modeling can one test various ideas, hypotheses, and theories against what one observes in nature. This paper first gives a systematic review of models that have been developed in the past on various aspects of speech communication, both between humans and between human and machine. These include speech production models, speech acoustics models, speech perception models, as well as language models and dialogue models. It will then describe briefly some of the models developed by the current author. Finally, it will discuss those aspects that have not been modeled so far, and present the author's prospects on how to model them. This paper is dedicated to Manfred Schroeder, whose distinguished contributions in many areas of acoustics were enlightening to a large number of fellow researchers.

<center>2:45</center>

2pAA6. Progress in electroacoustic transducer research. Gerhard M. Sessler (Darmstadt Univ. of Technol., Merckstrasse 25, 64283 Darmstadt, Germany, g.sessler@nt.tu-darmstadt.de)

Manfred Schroeder always had a vivid interest in the field of electroacoustic transducers. During his time as Director of Acoustics Research at Bell Laboratories, work on electret transducers was started by Jim West and the author in 1962 and the activities were extended over the years to electret materials, directional microphones, and microphone signal processing. Schroeder himself made some interesting contributions to this field, such as the design of directional microphones based on gradients of various orders with toroidal and unidirectional directivity patterns. Some of these devices were implemented with electret transducers. Work on directional microphones at Bell Labs continued as the author went to the Darmstadt University of Technology. There, studies on silicon transducers were initiated, with the first silicon condenser microphone described in 1983. Recently, a completely new and promising variety of piezoelectric transducers was implemented, consisting of charged cellular polymers. This is a new modification of the electret transducer principle developed in the 1960s at Bell Laboratories.

3:20

2pAA7. Application of digital signal processing to architectural acoustics in the 1960s. James E. West (Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218)

Digital signal processing techniques in architectural acoustics were first used to investigate the acoustical properties of Philharmonic Hall at Lincoln Center for the Performing Arts in New York City in the early 1960s. The management of Lincoln Center invited the Acoustics Research Department of Bell Labs, headed by Manfred Schroeder, to assist in an evaluation of the Hall because conventional measurement methods were unable to explain its subjective performance. Computer-generated specially shaped tone bursts were played and the sound pressures at different locations in the Hall were recorded and later converted into digital form for evaluation. Special filters were programmed to evaluate reverberation times based on different portions of the decay, and energy distribution in time, space, and frequency domains. Better insights into the relationships between subjective and physical measurements were made possible utilizing the power in digital signal processing.

2pAA8. New directions in room acoustics: Probabilities, computer simulation, number theory. Heinrich Kuttruff (RWTH Aachen Univ., D52066 Aachen, Germany, hku@akustik.rwth-aachen.de)

This paper highlights just a few of M. R. Schroeder's major contributions to room acoustics. In his first investigations Schroeder presented a new approach to the frequency response of rooms by recognizing its random character, at least in the range above a critical frequency limit (today known as the Schroeder frequency). Soon afterwards he began employing the then-new digital computer as a research tool. Together with B. S. Atal he simulated the sound transmission in rooms, and in 1961 both authors demonstrated what nowadays is known as auralization and cancellation of acoustical cross-talk between two loudspeakers. In 1967 they published probably the first paper on ray tracing. Furthermore, Schroeder contributed to measuring techniques, for instance by introducing the integrated impulse response method of recording sound decay. Another astounding achievement is Schroeder's invention of pseudo-random surface structures based upon number-theoretical schemes (Schroeder diffusers). Such devices may be used to scatter sound waves into all directions and hence to improve the acoustics of concert halls by creating lateral sound reflections. By his unconventional ideas and numerous innovations Manfred R. Schroeder has changed our understanding of sound transmission in rooms and initiated many new research activities.

4:00

2pAA9. Acoustic contribution to travel comfort in airplanes— insight delivered from room acoustics. Volker Mellert (Inst. f. Phys., Oldenburg Univ., 26111 Oldenburg, Germany)

Travel comfort in airplanes is affected by numerous parameters from which the acoustic environment provides a major contribution, as revealed in measurements of various symptoms of passenger and crew in long-haul flights. Tools known from room acoustics are useful to calculate and estimate an optimal acoustic design of the cabin interior, e.g., background noise levels must match the demand for privacy, or an appropriate STI ensures good public address and communication between the passenger and crew member. Many measures assume a statistical description of the acoustic field. But the strong frequency-dependant absorption leads to different Schroeder frequencies f_s, which indicate the transition from well-separated resonances to many overlapping normal modes. In consideration of the extended noise sources as boundary conditions it is useful to determine with f_s the regimes of analytical solutions of the wave field within the cabin from a more costly numerical (FEM/BEM) approach.

4:20

2pAA10. Are concert halls random number generators? Jean-Dominique Polack (UPMC, CNRS, MCC, LAM, 11 rue de Lourmel, F-75011 Paris, France)

In 1954, Manfred Schroeder proved that sound fields in rooms are statistical in nature. Based on his subsequent work, several models of sound fields were derived, both in the frequency and the time domain, that make it possible to predict most of the properties of sound fields in rooms, including the major room-acoustical indices. One of these models, derived by the author, is based on random number generation, another field to which Manfred Schroeder contributed. This model is presented, and its predictions compared to measurements by A. C. Gade and G. W. Siebein in US concert halls (see Gade's presentation at Sabine Centennial symposium in June 1994). Predictions are also compared with current theories of reverberation. However, the model is not able to predict the modal behavior below the Schroeder frequency yet. The solution lays in the so-called semiclassical approximation, which is briefly presented. The case of rectangular halls, where the semiclassical approach is no longer an approximation, but is exact, illustrates how to reconcile Monte Carlo approaches, ray theory, and mode distribution.

4:40

2pAA11. Schroeder's phase in psychoacoustics. Armin Kohlrausch (Philips Res. Labs. Eindhoven (WO02), HTC 36, NL-5656AE Eindhoven, The Netherlands, armin.kohlrausch@philips.com)

I want to address Manfred Schroeder's contributions to psychoacoustics with a special emphasis on the period 1980 to 1990, when I worked with him at the Third Physical Institute in Goettingen. Among the psychoacoustic topics Schroeder worked on were binaural hearing, often in relation to room acoustics and stereophony, and monaural phase perception. The latter topic was first addressed in an ASA conference abstract from 1959, in which Schroeder emphasized the role of the signal's peak factor for the perceived timbre. This theme was taken up in the famous mathematical paper in 1970, in which Schroeder demonstrated that a quadratic relation between frequency and phase in a (flat-spectrum) harmonic complex allows one to synthesize a periodic signal with a flat temporal envelope

2p WED. PM

and a quasilinear frequency modulation. Quite accidentally, it was found out in Bennett Smith's master thesis in 1984 that under specific circumstances, the input phase of the stimulus and the phase characteristic of a fixed point on the basilar membrane can nearly compensate each other. This interpretation, published in 1986 in J. Acoust. Soc. Am. with Schroeder as senior author, initiated a great number of perceptual and physiological studies on the phase characteristics of the inner ear.

5:00

2pAA12. Sequences and their consequences. Michael Vorlaender (Inst. fuer Technische Akustik, RWTH Aachen Univ., D-52056 Aachen, Germany)

Number theory is an inspiration for application in science and engineering. In acoustics, correlation sequences for measurement signals and for diffusors became famous, mainly due to innovative ideas of Professor Manfred Schroeder. [Number Theory in Science and Communication, 3rd ed. (Springer, Berlin, 1999).] Maximum-length sequences were implemented in many real-time analyzers for measuring impulse responses. Their autocorrelation properties are almost ideal and they are widely in use today. Benefits and limitations due to hardware constraints are briefly discussed. Another particular interesting sequence is the Fibonacci sequence. It can be created from a simple loop algorithm as a binary sequence. [H., Schmidt, ''Eigenschaften und Realisierung von Fibonacci-Folgen.,'' Proc. DAGA88, Braunschweig, p. 621]. The ratio of zeros and ones is converging to the golden ratio, 1.6180 . . . . Its spectrum consists of peaks at frequencies and with amplitudes corresponding to the golden ratio, too. When playing such sequences with certain clock frequency, a strange tonal sound can be heard. In psychoacoustic listening tests the pitch perception and pitch strength were investigated. Moreover, intervals and melodies were played by using a midi interface and new melodic and rhythmic pieces of Fibonacci music were created and checked in listening tests.

2pAB1. Recent discoveries and continuing mysteries in the auditory systems of bony fishes. Peggy L. Edds Walton (Parmly Hearing Inst., Loyola Univ. Chicago, Chicago, IL 60626, peddswa@phi.luc.edu)

Recent research has revealed aspects of the auditory system that reflect the diversity of bony fishes as a group. This presentation will review some of the more exciting finds. For example, the long-standing classification of the hair-cell orientation patterns in saccules may require revision given the diversity of hair-cell orientations documented in closely related fishes recently. Hearing studies have shown that, although auditory specialist fishes (otophysines, with auditory accessories for detection of the pressure component of a sound wave) hear higher frequencies than auditory generalists (those that respond primarily to the particle motion component of a sound wave), work on the toadfish has shown that sensitivity at their best frequencies is not as different as once believed. However, a new kind of auditory specialist has emerged within the herrings. Some herring species respond to ultrasonic frequencies (¿20 kHz), apparently via a specialized region of the utricle. The utricle may be the rising star of the fish auditory periphery as physiological and anatomical-projection studies in nonherring species indicate that the endorgan may serve both the vestibular and the auditory systems. Emerging insights into auditory processing among fishes will be discussed. [Research supported by the NIH.]

2pAB2. Recent advances in hearing and sound communication by fishes. Friedrich Ladich (Dept. of Neurobiology and Behavior, Univ. of Vienna, 1090 Vienna, Althanstr. 14, Austria)

Acoustic displays have been observed in representatives of 30 or more families of bony fishes. Thanks to Art Myrberg's ground-breaking work, we have insights into the multitude of functions of acoustic signalling in fishes including mate choice, individual and species recognition, reduction of territory intrusions, and interception. Recent studies, many of which have arisen from Art's work, focus on ontogenetic and seasonal changes, female vocalizations, and effects of ambient and anthropogenic noise in hearing and sound communication. In croaking gouramis (labyrinth fishes), for example, ontogenetic development of acoustic communication depends on changes in sound parameters, increases in sound levels, and auditory sensitivities. The importance of seasonal changes in hearing was recently uncovered in toadfish and cyprinids. Generally male fish display acoustically to attract females, but the opposite may

occur. Only female croaking gouramis vocalize during mating. Ecoacoustical investigations reveal that hearing specialists (cyprinids) are well adapted to the low ambient noise levels of standing freshwaters. They are heavily masked in flowing waters, unlike generalists, which are merely affected by ambient noise. Gaussian and ship noise diminishes a fish's ability to detect sounds and resolve temporal patterns, indicating that human-made noise affects acoustic orientation and communication in fishes. [Work supported by FWF.]

1:45

2pAB3. Seasonal variation in the frequency response of the ear: Implications for communication. Joseph Sisneros (Dept. of Psych., Univ. of Washington, Seattle, WA 98195)

Seasonal variation in vocal-acoustic behavior is well known among nonmammalian vertebrates; however, studies of the neural mechanisms underlying such seasonal variation have focused mainly on the anatomical rather than the neurophysiological correlates of seasonal reproductive periodicity. In this talk, I present the neurophysiological evidence for seasonal variation in the frequency response of the ear in the plainfin midshipman fish (*Porichthys notatus*). Vocal communication is essential to the reproductive success of the seasonally breeding midshipman fish, which migrates during the late spring and summer from deep ocean sites into the shallow intertidal zone to breed. Female midshipman fish use the auditory sense to detect and locate males that are singing from their nests. The seasonal onset of male mate calling in the midshipman fish coincides with a dramatic increase in the range of frequency sensitivity of the female's saccule, the midshipman's main organ of hearing, thus leading to increased encoding of the male's mate call. I will present evidence for a steroid-dependent mechanism that leads to this form of auditory plasticity and discuss why this plasticity of peripheral auditory frequency sensitivity may represent an adaptation to enhance the acquisition of auditory information needed for mate identification and localization during the breeding season.

2:05

2pAB4. Directional hearing in sharks and other fishes. Anthony Hawkins (Loughine, Kincraig, Blairs, Aberdeen AB12 5YT, UK)

Art Myrberg and his co-workers were among the first biologists to obtain clear evidence that predatory sharks are able to locate sound sources at long distances. Previous experiments had shown that elasmobranches were relatively insensitive to sounds, and it had been suggested that fish were incapable of determining the direction of a sound source in the far field. It was subsequently shown that fish could discriminate between sounds from spatially separated sources in the horizontal and median vertical planes. They could even distinguish between identical sound sources at differing distances. It has been suggested that fish determine direction using particle motion detectors, the otolith organs of the inner ear. An array of vector detectors is capable of detecting the axis of propagation, but as they are inherently bidirectional there remains a problem in detecting the actual direction of the source. This paper considers the proposal that the ambiguities are resolved by phase comparison between the vector detectors and other detectors responding to the sound pressure incident upon the gas-filled swimbladde.

2pAB5. Sound production in two loricariid catfishes. Amanda L. Webb and Michael E. Smith (Dept. of Biol., Western Kentucky Univ., Bowling Green, KY 42101)

Many families of catfishes produce sounds via pectoral spine stridulation and/or swim bladder compression using sonic muscles linked to the swimbladder. Sound production capabilities in the catfish family Loricariidae has not yet been examined. We recorded sounds produced by two species of loricariid catfish, *Otocinclus affinis* and *Pterygoplichthys gibbiceps*. Both species produced short, broadband clicks via pectoral spine stridulation. Mean fundamental and dominant frequencies for *O. affinis* and *P. gibbiceps* were approximately 4000 and 8000, and 600 and 1200 Hz, respectively. Durations of sound pulses were generally shorter in *O. affinis* (2–12 ms) compared to *P. gibbiceps* (20–100 ms). Scanning electron microscopy was used to examine the dorsal process of the base of the pectoral spines of each species. Sound is produced as the ridges of the pectoral spine base slides past the channel of the pectoral girdle. Distances between dorsal process ridges of *O. affinis* and *P. gibbiceps* were approximately 50 and 160 microns, respectively, with the ratio of this distance to

the fish total length being comparable between species. Relationships between spine interridge distance, pulse duration, and spectrum of the sounds produced will be discussed. [We thank John Andersland for SEM assistance.]

2:40

2pAB6. Sound production and hearing ability in the Hawaiian sergeant fish. Karen P. Maruska, Kelly S. Boyle, Laura R. Dewan, and Timothy C. Tricas (Dept. of Zoology, Univ. of Hawaii and Hawaii Inst. of Marine Biol., 46-007 Lilipuna Rd., Kaneohe, HI 96744, maruska@hawaii.edu)

Sounds provide important signals for inter- and intraspecific communication in fishes, but few studies examine behavioral contexts of sound production and hearing ability within a single species. This study characterized the sounds and their behavioral contexts in a wild population of Hawaiian sergeant damselfishes (*Abudefduf abdominalis*), and compared

their features to hearing sensitivity measured by both auditory-evoked potentials (AEP) and single-cell recordings in the auditory midbrain. The sergeant fish produces low intensity ($\sim$85–115 dB rms re: 1 μPa), low-frequency ($\sim$100–400 Hz) sounds during nest preparation, courtship an agonistic interactions. Both AEP and single-cell recordings show that fish are most sensitive to these frequencies (80–300 Hz) with best frequency at 100 Hz. However, auditory thresholds to tonal stimuli were approximately 20 dB lower for single-cell recordings than those measured by AEP experiments. Further, midbrain auditory neurons were on average more sensitive to playbacks of conspecific sounds than to pure tones. These experiments show that the hearing ability of this damselfish closely matches the intensity and spectral characteristics of sounds produced in the wild. Multidimensional studies that incorporate analyses of and responses to biologically relevant natural sounds are necessary to understand acoustic processing and the evolution of acoustic communication in fishes.

3:10

2pAB7. Sound production mechanism in carapid fish: First example with a slow muscle. Eric Parmentier, Jean Paul Lagardere, Pierre Vanderwalle, Jean-Baptiste Braquegnier (Lab de Morphologie Fonctionnnelle et Evolutive, Univ of Liege, Belgium), and Michael L. Fine (Virginia Commonwealth Univ., Richmond, VA 23284-2012)

Fish sonic swimbladder muscles are the fastest muscles in vertebrates and have fibers with numerous biochemical and structural adaptations for speed. Carapid fishes produce sounds with a complex swimbladder mechanism including skeletal components and extrinsic sonic muscle fibers with an exceptional helical myofibrillar structure. To study this system we stimulated the sonic muscles, described their insertion and action, and generated sounds by slowly pulling the sonic muscles. We find the sonic muscles contract slowly, pulling the anterior bladder and thereby stretching a thin fenestra. Sound is generated when the tension trips a release system that causes the fenestra to snap back to its resting position. The sound frequency does not correspond to the calculated resonant frequency of the bladder, and we hypothesize that it is determined by the snapping fenestra interacting with an overlying bony swimbladder plate. To our knowledge this tension release mechanism is unique in animal sound generation.

3:25

2pAB8. Sound communication by the forceps fish, *Forcipiger flavissimus* (Chaetodontidae). Kelly S. Boyle and Timothy C. Tricas (Dept. of Zoology, Univ. of Hawaii at Manoa, 2538 McCarthy Mall, Edmondson 152, Honolulu, HI 96822)

The forceps fish, *Forcipiger flavissimus* (family Chaetodontidae), lacks the anterior swim bladder horns and laterophysic connection that are proposed to improve processing of acoustic signals in the genus *Chaetodon*. Despite the lack of hearing specializations, laboratory experiments using hydrophones synchronized to video revealed the forceps fish produce at least three sounds: (1) a pulse (21-ms duration, peak frequency=318 Hz) associated with rapid cranial elevation, (2) a low-frequency pulse (9-ms duration, peak frequency=41 Hz) associated with anal fin retraction and elevation, and (3) a high-frequency broadband click (3-ms duration, peak frequency=7924 Hz) associated with tail slap behavior. Auditory evoked potential experiments demonstrate that hearing thresholds for this species are 10–21 dB higher than *Chaetodon* in the 200–600-Hz band. High-speed kinematic analyses show that motor movements associated with some acoustic behaviors are different than those in *Chaetodon*, thus the presence of sound production may be the ancestral state for the family but the mechanisms are divergent. Field observations on Hawaiian reefs reveal that forceps fish occur in pairs and trios that may be haremic, and use acoustic communication among group members.[Work supported by NSF IBN0137883 to TT.]

3:40

2pAB9. Acoustico-lateralis communication in coral reef butterflyfishes. Timothy C. Tricas and Kelly S. Boyle (Dept. of Zoology and Hawaii Inst. of Marine Biol., Univ. of Hawaii at Manoa, Honolulu, HI 96822, tricas@hawaii.edu)

Butterflyfishes are conspicuous members of coral reefs and well known for their pairing behavior and visual displays during social interactions. Members of the genus *Chaetodon* have a unique arrangement of the anterior swim bladder horns that connect with the lateral line (the laterophysic connection) and also project towards the inner ear, but functions for this putative acoustico-lateralis adaptation were not known. Field experiments demonstrate that the monogamous multiband butterflyfish, *C. multicinctus*, produces hydrodynamic pulses and sounds during territorial defense, and pulse trains that may be an alert call to the mate. In field choice tests, individuals could distinguish mates from nonmates and produced different calls to each, thus demonstrating the existence of mate recognition and context-specific sound production. Laboratory experiments show that sound production differs among sexes, hydrodynamic pulses are of low frequency ($<$100 Hz), and sounds have peak energy from 100–500 Hz. Auditory evoked potential experiments demonstrate that the auditory system has best sensitivity from 200–600 Hz and that the swim bladder horns provide a 10–20-dB gain within this band. These social sounds produced by *Chaetodon* can provide relevant stimuli to the auditory, vestibular, lateral line and possibly the laterophysic systems.

3:55

2pAB10. Ultrasound hearing and response in alosine herrings: A short history of the pure and applied research to date. Carl R. Schilt (LGL Ltd., P.O. Box 416, North Bonneville, WA 98639)

In the early 1990s it was reported that downstream-migrating American shad (*Alosa sapidissima*) avoided a sonar-sampling beam with fundamental frequency over 150 kHz. Since then there has been a considerable body of laboratory and field work to determine which fishes have such hearing capacity, what the hearing limits are, what the hearing mechanisms may be, what might have led to selection for such capacity, and the utility of such stimuli to control the local distributions of fishes with such ultrasonic hearing. So far it seems that ultrasonic click aversion is limited to one subfamily of primarily anadromous herrings (family *Clupeidae*; subfamily *Alosinae*). The capacity to hear very high clicks and the propensity to swim away from the stimulus direction has led to experiments in shad protection, especially in hydropower and other industrial environments, which have been promising. This talk will review the history of both the pure and applied science on alosine herring ultrasound response and suggest possible research and application strategies for the future.

4:10

2pAB11. Continental shelf fish choruses in Australian waters. Robert D. McCauley (CMST Curtin Univ., G.P.O. Box U 1987, Perth 6845 Australia) and Douglas H. Cato (Defence Sci. & Technol. Org., NSW)

Almost everywhere the authors have sampled ambient noise on Australia's continental shelves, in tropical and temperate waters, evening choruses have been recorded. Chorus maximum frequency varies from a few hundred Hz to a few kHz and may result from different species, but the consistency of the timing and similar chorus nature suggests that different source species are following similar behavior. Individual chorus signals are comprised of single pops or clicks of $<$200-ms duration, similar to those described from fish. We hypothesize that these chorus sources are nocturnally active fishes that mainly forage in the water column at night. In the Perth Canyon, Western Australia, shelf break choruses centered at 2 kHz have been measured since 1992. Here each evening the chorus begins shortly after dusk, reaches a maximum around 2 hours post dusk, drops to a lower level, rises again predawn, and then disappears during the day. Canyon net sampling through the water column has only recovered fish of the family Myctophidae as potential chorus sources. Long sea-noise time series records from the Canyon indicate significant seasonal trends in chorus levels and differences between years, possibly indicating that chorus activity reflects secondary productivity.

2pAB12. Transmission of air gun array signals in Australian waters.
Robert D. McCauley, Susan J. Rennie (Curtin Univ. of Technol., G.P.O. Box U 1987, Perth 6845, Australia), and John R. Hughes (Santos Ltd., Adelaide SA 5000, Australia)

Received air gun array signal parameters from 15 seismic surveys in Australian waters have been analyzed. Measurements include sources from 1115 to 4900 cui (18.3 to 80.3 L), ranges of hundreds of meters to thousands of kilometers along travel paths of 15 m to full ocean depth. For any array there may be large (± 9 dB) difference in received level between consecutive signals, especially if two 3-D arrays are operated alternatively. All arrays demonstrate horizontal directivity, being typically omnidirectional below nominally 50 Hz but focusing higher frequency energy about their longer axis. Three-dimensional arrays tend to be square and 2-D arrays rectangular with the long axis across track; thus 2-D arrays are more focused. At a nominal range, differences of up to 40 dB were found when comparing small arrays operating in shallow water with large arrays in deeper water. For example, a 2500-cui array transmitting in 70 m water had no waterborne energy at 20-km range whereas a 4900-cui array operating on the shelf slope was detectable via a deep sound channel path at 2000-km. This large variation in received levels under different scenarios implies similar differences in environmental implications.

2pAB13. Distribution of static pressures on the skin surface of parallely swimming fish.
Kazuhiko Anraku, Tatsuro Matsuoka, and Kenji Watanabe (Faculty of Fisheries, Kagoshima Univ., 4-50-20 Shimoarata, Kagoshima 890-0056, Japan, anraku@fish.kagoshima-u.ac.jp)

Hydrodynamic static pressures on the body surface of fish generated by conspecifics parallely swimming were measured in a flume tank, and they were compared with those generated by changing the position of two individuals under different flow velocities. Two dead common carp (BL = 20 cm), fixed in 20% of formalin, were used. Pressure was measured by a manometer connected to the ends of three aluminum pipes (inner diameter = 3 mm), which were inserted perpendicularly to the body axis from right to left in the control fish. The openings of the pipes were located on head, trunk, and caudal regions, and each was on the infraorbital or trunk canal lateral lines. The target fish was moved on the horizontal XY plane using a traverse device. Although pressures changed depending on the regions measured, changes of pressure according to position and current velocity were relatively low in the caudal region. The absolute values of the pressure increased as flow velocity increased, and decreased with an increase in the distance between individuals. Relative positions when the maximum pressure changes were observed at each flow velocity did not change, indicating that pressures were largest when the maximum body width of the conspecific is closest.

2pAO1. Swimbladders under pressure: Anatomical and acoustic responses by walleye pollock.
John K. Horne, David Barbee (School of Aquatic and Fishery Sci., Univ. of Washingtons Box 355020, Seattle, WA 98195), Kouchi Sawada, Koki Abe, Kazuhiro Sadayasu, and Yoshimi Takao (Natl. Res. Inst. of Fisheries Eng., Kamisu-city, Ibaraki 314-0408, Japan)

Pressure influences echo intensities of swimbladdered fish through changes in swimbladder volumes and surface areas. Volume reduction is expected to correspond to Boyle's law (volume $\propto$ pressure^{-1}) but the resulting deformation in swimbladder surface area will largely determine target strength at geometric scattering frequencies. Dorsal and lateral radiographs of juvenile walleye pollock (*Theragra chalcogramma*) in a pressure chamber were used to image swimbladders from ambient to a maximum of 5-atm pressure. As pressure increased, dorsal swimbladder surface areas decreased at a constant rate among the three individuals. Swimbladder volume reduction rates were similar among individuals but less than that predicted by Boyle's law. Compression of swimbladders occurred dorsal-ventral, anterior-posterior, and laterally. Resulting swimbladder shapes became more spindlelike as pressure increased. KRM predicted target strengths at 38 and 120 kHz decreased more rapidly at 3 atm above ambient than at lower pressures. [Work supported by ONR and NRIFE.]

2pAO2. Modeling of the backscattering by swimbladder-bearing fish.
Dezhang Chu, Timothy K. Stanton (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), J. Michael Jech (NOAA/Northeast Fisheries Sci. Ctr., Woods Hole, MA 02543), and D. Benjamin Reeder (Naval Postgraduate School, Monterey, CA 93943)

A composite scattering model has been developed to describe the backscattering by swimbladder-bearing fish. This model includes the influence of elongation of the swim-bladder not only on the resonance frequency, as do most of the existing scattering models, but also on the quality factor Q and the overall scattering level. In addition, within the region covering the transition from resonance scattering to geometric scattering, the effect of asymmetric cross section of the swimbladder has also been included to represent a more realistic shape of fish swimbladder. The model was compared with other scattering models, such as Kirchhoff ray mode (KRM) and Fourier matching method (FMM). Model predictions were then compared with field data collected with a new broadband towed system. For a single-species Atlantic herring school (*Clupea harengus*) with a measured length distribution, the predicted resonance scattering including resonance peak location and overall level matched the broadband acoustic data reasonably well. Some modeling issues will also be discussed.

1:35

2pAO3. Target strength and behavior of swimming juvenile southern bluefin tuna in a cage estimated by echo-trace analysis. Koki Abe, Yoshimi Takao, Kazuhiro Sadayasu, Kouichi Sawada, and Kazuo Amakasu (Nat. Res. Inst. Fish. Eng., 7620-7 Hasaki, Kamisu, Ibaraki, 314-0408, Japan)

Echo-trace analysis (ETA) was applied to echoes from juvenile southern bluefin tuna (*Thunnus maccoyii*, SBT) swimming in a cage. The experiments were conducted offshore Esperance in Western Australia, using a split-beam echosounder operating at 70 kHz. The dimensions of a cylindrical cage were 7 m in diameter, 20 m in depth, and 8.5 cm mesh size of a net. A transducer was set at the center of a cage. The samples of SBT were caught by trolling near the study site. The age classes were 1 or 2 years old that were ranging 45 to 82 cm in fork length. Only one SBT was put into a cage at a time in order to obtain single echoes from one fish. As the swimbladder of juvenile SBT was not gas-filled in this stage, its target strength (TS) was much lower than TS of a same-size fish with gas-filled swimbladder. Because of low TS values, there were some difficulties to obtain high quality echo-traces continuously. So, preselections of high signal-to-noise and noninterference echoes from the echogram were needed before applying ETA. Swimming velocities and TS patterns in dorsal aspect were estimated by ETA.

1:50

2pAO4. An advanced 3-D scattering model for squid. Benjamin A. Jones, Andone C. Lavery, and Timothy K. Stanton (WHOI, Woods Hole, MA 02543-1050)

A three-dimensional, acoustic scattering model for squid has been developed that incorporates high-resolution, spiral computerized tomography (SCT) scans of squid morphology. This model numerically implements the distorted wave Born approximation (DWBA) for an inhomogeneous body using a combined ray trace and volume integration approach. SCT scans of squid, taken in air, revealed detailed morphology of the animal including the interior cavity of the mantle. The model accounts for these features with volume elements that are small (less than 1/20 the wavelength) for the frequencies of interest (0–120 kHz). Target strength predictions are compared with published data from live, freely swimming squid. Although only two materials, mantle tissue and seawater, are used to represent squid in this study, our model can be easily generalized to include many distinct, weakly scattering regions within a volume. Ranges of validity with respect to material properties and numerical considerations are explored using benchmark computations with such simpler geometries as spherical and cylindrical shells.

2:05

2pAO5. Target strength estimation of the large jellyfish *Nemopilema nomurai*. Miyuki Hirose (Grad. School of Fisheries Sci., Hokkaido Univ., 3-1-1, Minato Hakodate Hokkaido, 041-8611, Japan), Tohru Mukai, Kohji Iida (Hokkaido Univ., Hakodate Hokkaido, 041-8611, Japan), and Doojin Hwang (Chonnam Nat. Univ., Dundeok-dong, Yeosu Jeollanam-do 550-749, Korea)

The jellyfish *Nemopilema nomurai*, which reaches up to 2 m in diameter and 200 kg in weight, has occurred in large numbers in the Sea of Japan during the last several years and has had a negative effect on coastal fisheries in this region. Data on the abundance and distribution of jellyfish

are needed to forecast when and where they will occur in coastal areas. Acoustic techniques are commonly used to study the distribution and abundance of fish and zooplankton because these techniques can survey large areas relatively quickly. However, before such surveys can be conducted, the acoustic characteristics of the target species must be known. In this study, the density of and speed-of-sound in live jellyfish were measured to clarify their acoustic characteristics using a theoretical scattering model. Jellyfish density was measured using the dual-density method, while the speed of sound was measured using the time-of-flight method. The acoustic characteristics were estimated with the distorted-wave Born approximation (DWBA) model using these material properties and the shape of free-swimming jellyfish. The results demonstrate the feasibility of investigating the abundance and distribution of jellyfish using acoustic methods. [Work supported by JSPS and KOSEF Core University Program on Fisheries Science (FiSCUP).]

2:20

2pAO6. Predictions of acoustic scattering by a fish school. Charles F. Gaumond and Ralph N. Baer (Naval Res. Lab., Washington, DC 20375)

A theory originally developed by Richard Love [J. Acoust. Soc. Am. **64**, 571–580 (1978)] is used to model scattering by a school of fish. In order to incorporate propagation effects, this model has been integrated into a modified version of the RAM acoustic propagation model developed by Michael Collins. Running the integrated model over a sequence of frequencies results in predictions of the time and frequency response of broadband signals scattered by fish schools. Using an ensemble of fish school realizations lets us develop features that describe the response of a fish school to the acoustic signals. These features in turn allow separation of returns from a target from those from interfering schools. [Work supported by the Office of Naval Research.]

2pAO7. Using acoustic backscatter to determine the size distribution of channel catfish in a commercial pond. John Heffington, James Chambers (Natl. Ctr. for Physical Acoust., The Univ. of Mississippi, 1 Coliseum Dr., Univ., MS 38677), David Heikes, Steve Pomerleau, and Eric Stone (The Univ. of Arkansas at Pine Bluff, Pine Bluff, AR 71601)

With increasing seafood demand, aquaculture is poised to become a major growth industry in the United States. In particular, channel catfish represents an approximately $400 million industry. Pond management strategies, however, are compromised by high fish densities with large size distributions that result from years of continuous culture without a total harvest. Recent work has been presented on the Aquascanner SONAR system, which evaluates the total biomass of the pond but is less effective in determining the size distribution. To address this shortcoming, research colleagues at the University of Arkansas Pine Bluff are using a subsample seine net. Their method involves pulling a trawl across the pond to obtain a sample of the fish and manually weighing the fish in a time-consuming process to provide the size distribution. The work presented here attempts to use acoustic backscatter to determine the size distribution of the fish in lieu of the manual weight measurements. After being seined, the fish are allowed to swim back into the pond through a restrictive pipe and are pinged acoustically to determine their target strength and thus size. The experimental design of the system and results will be discussed. [Work Supported by the USDA.]

2pAO8. Swimbladder morphology and target strength of myctophid fish of the northwestern Pacific. Hiroki Yasuma, Kazushi Miyashita (Field Sci. Ctr. for the Northern Biosphere, Hokkaido Univ., 3-1-1, Minato, Hakodate, Hokkaido, 041-8611 Japan), Kouichi Sawada (Natl. Res. Inst. of Fisheries Eng., Hasaki, Kashima, Ibaraki, 314-0421 Japan), and Ichiro Aoki (Univ. of Tokyo, Bunkyo, Tokyo, Japan)

Swimbladder shapes of fish from 14 myctophid species captured around Japan were measured using an x-ray method to estimate the theoretical target strength. Using those x-ray images, the fish were classified into bladder species and nonbladder species according to the presence of the gas. Five species had no swimbladder in any body size range examined. Others contained bladder and nonbladder fishes in relation to growth. The growth of swimbladder length was not proportional to that of body length (allometric growth) in some bladder fishes. Based on morphological parameters of the body and swimbladder, the relationships between body length and target strength from 38 to 200 kHz were estimated using theoretical acoustical backscattering models. Estimated values of target strength showed greater than 10-dB differences between bladder and nonbladder fishes, even when the fish were of equivalent size. Because of the allometric growth of the swimbladder, values of the target strength were not proportional to the square of the body length in most bladder species. In addition, larger fishes (over 60 mm) of Myctophum asperum showed regressive growth of the swimbladder (or target strength), suggesting that the use of the 20 log relationship is inappropriate for bladder species of myctophid.

2pAO9. *In situ* **measurement of target strength, tilt angle, and swimming speed of Boreopacific gonate squid (*Gonatopsis borealis*).** Kouichi Sawada, Hideyuki Takahashi, Koki Abe, and Yoshimi Takao (Natl. Res. Inst. of Fisheries Eng., Fisheries Res. Agency, 7620-7 Hasaki, Kamisu, Ibaraki, 314-0408, Japan)

Target strength (TS), mantle length (ML), swimming speed, and tilt angle of Boreopacific gonate squid *Gonatopsis borealis* were measured using an acoustical-optical composite system (J-QUEST) in the North Pacific Ocean. The J-QUEST consists of a quantitative echosounder operating at 70 kHz and a high-sensitivity stereo video camera system installed in a housing resistant to pressure at the depth of 300 m. In the daytime, Boreopacific gonate squids were seen at the J-QUEST depth of 230 m by the stereo video camera. Swift vertical movements were also observed on the echogram at the same time. Swimming speeds and tilt angles were estimated by tracking echoes from the same squid. Estimated average swimming speed was over 1 m/s and tilt angles were almost vertical. Average TS calculated from squidlike echoes was -54.1 dB and average ML calculated from the stereo video images was 23.9 cm with standard deviation of 5.9 cm. Standardized TS by the squared ML was -81.9 dB. In the nighttime, a Boreopacific gonate squid (estimated ML 37 cm) at the J-QUEST depth of 25 m was observed preying on one Japanese anchovy, *Engraulis japonicus*, in an aggregation with estimated average length of 12.3 cm.

2pAO10. Target strength of *Sargassum* plant with vesicles containing gas. Kenji Minami (Hokkaido Univ., 3-1-1 Minato-cho, Hakodate, Hokkaido, 041-8611, Japan), Akira Hamano, Takeshi Nakamura (Natl. Fisheries Univ., Shimonoseki, Yamaguchi 759-6595, Japan), Yoshimi Takao (Fisheries Res. Agency, Kamisu, Ibaraki, 314-0408, Japan), and Kazushi Miyashita (Hokkaido Univ., Hakodate, Hokkaido, 041-8611, Japan)

Information about the target strength (TS) of a vesicle is important to estimate the acoustic scattering of *Sargassum* plants. Experimental TS (TSe) of a vesicle was obtained at 70 and 200 kHz using quantitative echo sounders in a freshwater tank ($10 \times 10 \times 15$ m). The TSe of ten vesicles examined here were -56.88–51.68 dB at 70 kHz and -60.30–-50.90 dB at 200 kHz. The TSe's of small vesicles were 2.56–-3.70 dB higher at 70 kHz than at 200 kHz, suggesting that these small vesicles were affected by the airbladder resonance. Theoretical TS (TSt) was estimated by airbladder−scattering models to confirm this effect. The gas radii of 418 vesicles (containing the experimented ten vesicles) were measured using a soft x−ray system and applied to the theoretical models. Their radii were 0.52–-6.00 mm; calculated TSt matched with TSe. According to the theoretical model, the vesicles were not affected by the resonance when argument ka is $ka > 1$ (where k is the wave number and a is the radius). However, the vesicles were affected by the resonance when $ka < 1$. That fact indicates that small vesicles (a is 1.22–-2.38 mm) at 70 kHz were affected by the resonance.

2pAO11. Target strength of a mesopelagic fish *Maurolicus japonicus* at 38 and 120 kHz. Tadanori Fujino, Hiroki Yasuma, Kazushi Miyashita (Hokkaido Univ., 3-1-1, Minato-cho, Hakodate, Hokkaido, 041-8611, Japan, fnori@fish.hokudai.ac.jp), Kazuhiro Sadayasu, and Koki Abe (Fisheries Res. Agency, Hasaki, Kamisu, Ibaraki, 314-0408, Japan)

Target strength (TS) of *Maurolicus japonicus* was examined at 38 and 120 kHz using experimental measurements (at 38 kHz) and theoretical swimbladder scattering models. Experimental measurements showed that the average TS for dominant size (32.1 to 34.8 mm standard length) were -60.5 to -56.7 dB, and the effect of the fish orientation on TS was slight. These results coincided with the model estimation, proving that swimbladder models are valid to estimate the TS of *M. japonicus*. The slight effect of the fish orientation on TS was presumed due to the oval shaped swimbladder with high aspect ratio, which is relatively little to the wavelength. This is a merit because tilt angle is usually a major source of TS variation. However, a little swimbladder would cause acoustic resonance at low frequencies, which leads to insatiability on TS according to depth change. Using the resonant model, relationships of the TS and standard length were estimated for depth 50, 100, 150, 200, and 250 m at 38 and 120 kHz, respectively. While TS at 120 kHz showed little change according to depth, TS at 38 kHz changed with depth and showed larger TS than 120 kHz for each size.

2pAO12. Target strength pattern measurement of krill (*Euphausia pacifica*) and measuring limits in a small tank. Kouichi Sawada (Natl. Res. Inst. of Fisheries Eng., Fisheries Res. Agency, 7620-7, Hasaki, Kamisu, Ibaraki, 314-0408, Japan), Tohru Mukai (Hokkaido Univ., Hakodate, 041-8611, Japan), Kazuo Amakasu, Koki Abe, and Ken Ishii (Fisheries Res. Agency, Kamisu, Ibaraki, 314-0408, Japan)

Euphausia pacifica is an extremely important species for Japanfs northeast coastal fisheries and a key species for ecosystems in the northwest Pacific Ocean. Target strength (TS) of krill information have been required for acoustic surveys; they constitute a scale factor that is used to convert acoustic estimates of abundance. A precise TS pattern measurement system was constructed in a small tank. Target strength patterns of a target are measurable in the angle range of 60 deg at 1-deg steps. First, TS values of the thinnest fishing line with 53-mm diameter were measured as it was planned for use in tethering krill. TS measurement limits were also confirmed by measuring echo signals and noise signals. Maximum TS of the fishing line was -95 dB and the measurement limit was -98 dB at the frequency of 200 kHz with 10 dB of signal-to-noise ratio (SNR). Second, we confirmed the validity of the target suspension method. The thinnest fishing line was penetrated into the krill body to tether it between two vertical fishing lines. Finally, TS patterns of 12 live krill were measured and compared with theoretical calculations using distorted wave Born approximation. Both agreed well.

2pAO13. Estimation of swimming behavior and backscattering pattern of Antarctic krill using echo-trace-analysis. Kazuo Amakasu (Natl. Res. Inst. of Fisheries Eng., Fisheries Res. Agency, 7620-7 Hasaki, Kamisu, Ibaraki, 314-0408, Japan, soundproc@yahoo.co.jp), Masahiko Furusawa (Tokyo Univ. of Marine Sci. and Technol., Minato-ku, Tokyo, 108-8477, Japan), and Sakiko Ando (Ocean High Technol. Inst. Inc., Nakano-ku, Tokyo, 164-0012, Japan)

Echo-trace-analysis was applied to single echo-traces of Antarctic krill to estimate *in situ* swimming orientation, swimming speed, and backscattering pattern. Acoustic data were collected with a split-beam echosounder operating at 70 kHz on 11 January 2005 during the Southern Ocean survey by the training vessel *Umitaka-maru* of Tokyo University of Marine Science and Technology. While the acoustic data were collecting, the ship speed was 2 knots. A pulsewidth and a pulse-repetition-period of the echosounder were 0.6 ms and 0.27 s, respectively. Krill aggregations were observed at the depth range 15–30 m from the hull-mounted transducer and at upper and lower edges of them some single echo-traces were visually recognized on echograms. In this work, these echo traces were analyzed. As preliminary results, the average swimming orientation was 4.0 deg with a standard deviation of 14.2 deg and the average swimming speed was 0.33 m/s with a standard deviation of 0.16 m/s. The average swimming orientation was close to the orientation observed with a video plankton recorder by Lawson *et al.* [J. Acoust. Soc. Am. **119**(1), 232–242 (2006)]. The estimated backscattering patterns showed peaks at incident angles around -10 to 10 deg and were similar to the patterns predicted by theoretical models.

2pAO14. Development and application of multifrequency acoustic techniques to the study of Antarctic krill distribution. Gareth L. Lawson, Peter H. Wiebe, Timothy K. Stanton, and Carin J. Ashjian (Woods Hole Oceanog. Inst., Woods Hole, MA 02543)

Multifrequency acoustic techniques were refined and applied in a study of the distribution of Antarctic krill. Acoustic, video, and net data were collected in a continental shelf region west of the Antarctic Peninsula in the falls and winters of 2001 and 2002. Improved parametrization of a theoretical model of krill target strength was achieved through direct measurement of all model parameters. Krill visual acuity was used to determine a threshold level of volume backscattering strength for identifying krill aggregations. Differences in mean volume backscattering strength at 120 and 43 kHz further served to distinguish krill from other sources of scattering. Inversions were performed of mean volume backscattering strength (43, 120, 200, and 420 kHz) in these acoustically identified ag-

gregations to estimate the weighted mean length and density of krill. Inversion results were comparable to net samples for estimated length, but acoustic estimates of krill density exceeded those from nets by one to two orders of magnitude, likely due to avoidance and differences in the volumes sampled by the two systems. Application of these methods to survey data demonstrated strong spatial and temporal variability in the horizontal and vertical distribution of krill aggregations, consistently associated with food availability, temperature, and predators.

2pAO15. Acoustic studies investigating the distribution and abundance of krill in critical blue whale habitat in the Monterey Bay submarine canyon. Louise P. McGarry, Charles H. Greene (Cornell Univ., Snee Hall, Ithaca, NY 14853), Peter H. Wiebe (Woods Hole Oceanog. Inst., Woods Hole, MA 02543), and Donald A. Croll (Univ. of California, 100 Shaffer Rd., Santa Cruz, CA 95060)

Blue whales, the largest animal on the planet, are frequently found in concentrations at the ocean surface in areas over thick sound-scattering layers of krill. In this study, the dive behavior of a blue whale was investigated in the context of zooplankton acoustic backscatter data concurrently collected in the Monterey Bay submarine canyon. The whale dive behavior revealed that the whale spent greater than 50 percent of its time in the region of the most intense backscatter, suggesting threshold foraging behavior. In order to describe the prey field within the canyon, additional day and night acoustic surveys with MOCNESS net tows in the canyon and along its perimeter were collected. Here, a three-dimensional characterization of the prey field is developed using the acoustic data. Further work will be undertaken to estimate the relative biomass of the zooplankton taxa generating the acoustic backscatter within and without the intense sound-scattering layer, and to model the acoustic backscatter that would be expected to be generated from the zooplankton specimens collected: the forward problem. [This work is supported by the ONR.]

2pAO16. Multiple-angle acoustic scattering and classification of zooplankton. Paul L. D. Roberts and Jules S. Jaffe (Marine Physical Lab, Scripps Inst. of Oceanogr., La Jolla, CA 92093-0238)

The use of multiple-angle acoustic scattering to discriminate between two ecologically important classes of zooplankton' copepods and euphausiids, is proposed. The distorted wave Born approximation is used to model the multiple-angle scatter from a linear array of transducers designed to be practical for field deployment. Using a large set of noisy training and test data generated from uniformly random length and three-dimensional orientation distributions from each class of scatterers, the

performance of classification algorithms in several feature spaces is evaluated. The results show a marked improvement in classification performance as additional angles, and larger angular separations, are included in the classifier. Interestingly, even in the case of uniformly random three-dimensional scatterer orientation, low classification error (~5%) can be obtained. These results hold promise for substantially improving the classification of fluidlike zooplankton *in situ* using multiple angle scatter obtained with a simple collection geometry.

2pBBa1. Radiation force imparted on a kidney stone by a Doppler-mode diagnostic pulse. Oleg A. Sapozhnikov (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA, 98105), Leonid A. Trusov (Moscow State Univ., Moscow 119992, Russia), Alexander I. Gromov (Mandryka 2nd Central Clinical Military Hospital, Moscow 107014, Russia), Neil R. Owen, Michael R. Bailey, and Lawrence A. Crum (Univ. of Washington, Seattle, WA, 98105)

Detection of kidney stones and estimation of their sizes is an important part of the lithotripsy treatment. Fluoroscopy is often used to target stones, but not every stone is radio-opaque and, in addition, fluoroscopy produces ionizing radiation. Acoustic waves offer an alternative way to visualize stones. The acoustic impedance of kidney stones typically differs significantly from that of surrounding tissue. A useful consequence of the impedance mismatch is the possibility to target stones with diagnostic mode ultrasound. Another consequence is that radiation force pushes the stone. Stone displacement may be responsible for the twinkling artifact that has been observed by several authors in color Doppler mode of ultrasound imaging. This effect can be used to detect not only renal and ureteral stones, but also calcifications in other organs (e.g., breast). In this paper we model the radiation force associated with the Doppler diagnostic pulse. The problem is divided into three parts: (1) acoustic scattering; it is solved in finite differences; (2) radiation force calculation; (3) stone velocity estimation supposing the stone sits in soft tissue. 2pBBa2. Numerical solutions of the Khokhlov-Zabolotskaya-Kuznetsov (KZK) equation satisfying the Rankine-Hugoniot condition. Gianmarco Pinton and Gregg Trahey (Duke Univ., 136 Hudson Hall, Box 90281, Durham, NC 27708, gfp@duke.edu)

A numerical method that solves the KZK equation and satisfies the Rankine-Hugoniot relation for shock-wave propagation is described and characterized. By comparison with a known planar solution, it is demonstrated that current numerical methods in both the time and frequency domains predict a shock front that is stationary relative to the propagation phase and that the proposed method predicts the correct speed. These methods are then compared in the context of shock-wave lithotripsy and high intensity focused ultrasound. At the focus, axisymmetric shock-wave lithotripter simulations show that the Rankine-Hugoniot method predicts peak positive pressures that are 20% smaller, peak negative pressures that are 10% larger, and a full width at half maximum that is 45% larger.

High-intensity focused ultrasound simulations for an axisymmetric transducer in water have even larger variations in peak positive pressures and intensity but smaller variations in peak negative pressure. Simulations for a rectangular transducer in tissue, where absorption is more prominent, exhibit smaller but significant variations in peak pressures and intensity. Satisfying the Rankine-Hugoniot condition plays an important role in numerical simulations of the KZK equation. [This work was supported by NIH Grants R01-HL075485 and 1R01-CA114093-02.]

2pBBa3. Shock-wave energy deflection due to the presence of bone. Thomas Matula, Juan Tu, Michael Bailey (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), Kirsten Fagnan, and Randy LeVeque (Univ. of Washington, Seattle, WA 98105)

The physical interaction of shock waves with musculoskeletal tissues is inherently different from other high-pressure acoustic therapies. Whereas high-intensity focused ultrasound and lithotripsy focus their energy in regions of soft tissue, musculoskeletal shock-wave therapy (SWT) involves focusing shock waves (SWs) near or at bones. The presence of bones will cause reflection, refraction, and diffraction of acoustic energy. In our analysis of cavitation generated during clinical SWT treatment, we noticed that the cavitation was occurring away from the SW focus. We confirmed this by performing an *in-vitro* experiment on a bone embedded in gel. We also quantified the deflection angle as a function position near a bone in water: A talus was manufactured using rapid prototyping. It was placed near the focus of an electrohydraulic SW device. To visualize the pressure field, a high-speed camera imaged the cavitation field generated around the focus. As the bone was moved closer to the focus, the cavitation field (and thus, the pressure field) deflected away from the bone. The deflection angle was measured as a function of relative distance between the bone and focus. Numerical simulations were performed to model the deflection of energy away from the bone.

1:45

2pBBa4. A sensitive, broadband polyvinylidine difluoride (PVDF) hydrophone for accurate characterization of shock waves. Adam D. Maxwell, Brian E. MacConaghy (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA), Oleg A. Sapozhnikov (Moscow State Univ., Moscow, 119992, Russia), and Michael R. Bailey (Univ. of Washington, Seattle, WA)

Few hydrophones are capable of measuring high-intensity fields such as shock waves accurately. One of the more reliable is the fiber-optic probe hydrophone. However, this system is expensive and insensitive. We

2p WED. PM

created a new PVDF hydrophone and compared it with a fiber-optic system. The hydrophone consisted of a 25-μm-thick PVDF membrane with a 0.5-mm active element and a preamplifier, which were each held in separate attached polycarbonate housings. The amplifier had adjustable gain and could account for membrane resonance to flatten the frequency response. A model of the frequency response for the system was developed, which agreed well with the measured response. Shock waves were measured in two Dornier HM-3 clones and an electromagnetic lithotripter. Measurements were also recorded using a 2-MHz focused piezoceramic source and a broadband PVDF source. Shock-wave measurements closely matched those recorded by the fiber-optic hydrophone and calculations made with a KZK-type model. Very little damage to the membrane was found after applying several thousand shock waves. This new membrane hydrophone is robust and sufficiently accurate to measure high-intensity fields, while greatly reducing cost, increasing sensitivity, and simplifying measurements of shock waves. [Work supported by NIH DK43881, DK55674, and NSBRI SMS00402.]

2pBBa5. Calculation and measurement of acoustic scatter to assess fragmentation in shock wave lithotripsy. Neil R. Owen (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), Oleg A. Sapoznikov, Michael R. Bailey, and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

Shock wave lithotripsy (SWL) is currently conducted with little feedback on whether kidney stones are breaking. To determine if fragmentation could be assessed, acoustic scatter from intact and fractured stone models was calculated numerically and measured *in vitro*. Acoustic scatter from the stones, which were modeled with glass spheres, was calculated numerically using a linear elastic model, initialized with known elastic constants, and propagated from the stone model surface using the Helmholtz-Kirchhoff integral. Experimentally, shock waves were generated with a research lithotripter and scatter was measured with a broadband, spherically focused receiver. Calculated and measured results agreed well in the time domain. In frequency, power spectra were integrated to find energy and showed that scatter from the fractured stone model had higher energy in specific frequency bands that were related to the reverberation period. High-speed photography indicated that cavitation did not adversely affect the analysis of scatter. In this work it was possible to distinguish between the intact and fractured stone models. This method could be applied to stones that fragment gradually under the application of shock waves and potentially be used to estimate fragment size, and therefore the endpoint of therapy. [Work supported by NSBRI SMS00402 and NIH DK43881.]

2pBBa6. Bubble responses to lithotripsy shock waves. Wayne Kreider, Michael R. Bailey (Ctr. for Industrial and Medical Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105), Oleg A. Sapozhnikov (Moscow State Univ., Moscow 119992, Russia), and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

The responses of bubbles subjected to a lithotripsy shock wave have been investigated numerically and experimentally to elucidate the role of heat and mass transfer in the underlying dynamics of strongly excited bubbles. Single spherical bubbles were modeled as gas-vapor bubbles by accounting for liquid compressibility, heat transfer, vapor transport, vapor trapping by noncondensable gases, diffusion of noncondensable gases, and heating of the liquid at the bubble wall. For shock-wave excitations, the model predicts bubble growth and collapse, followed by rebounds whose durations are significantly affected by vapor trapping. To experimentally test these predictions, bubble rebound durations were measured using passive cavitation detectors, while high-speed photographs were captured to evaluate the local cavitation field and to estimate radius-time curves for individual bubbles. Data were acquired for bubbles in water with varying temperature and dissolved gas content. Measurements verify that vapor trapping is an important mechanism that is sensitive to both temperature and dissolved gas content. While this work focuses primarily on individual

bubbles, some bubble cloud effects were observed. Analysis with a simple multibubble model provides noteworthy insights. [Work supported by NIH T32-EB001650, NIH DK43881, and NSBRI SMS00402.]

2:30

2pBBa7. Millisecond initiation of boiling by high-intensity focused ultrasound in tissue-mimicking phantoms. Michael S. Canney, Michael R. Bailey (Ctr. for Industrial and Medical Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698), Vera A. Khokhlova (Moscow State Univ., Moscow 119992, Russia), and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105-6698)

Nonlinear propagation effects leading to shock formation at the focus of high-intensity focused ultrasound (HIFU) treatments can accelerate heating and cause rapid boiling in tissue. Boiling can be utilized for targeting the treatment with B-mode ultrasound and should be taken into account when planning the treatment, because bubbles reflect ultrasound and thereby displace and distort the lesion shape. In these experiments, an HIFU transducer of 2-MHz frequency, 4-cm aperture, and 4.5-cm focal length was used to investigate heating effects from shock formation in tissue-mimicking phantoms. The time required to attain 100 °C at the focus was calculated with weak shock theory from the peak amplitudes calculated with a KZK-type model, and time to boiling was measured by high-speed video and a 20–MHz passive cavitation detector (PCD) for different values of phantom absorption (both lower than tissue absorption) and HIFU power (100–200 W). Boiling was observed in 3 ms at the highest power level used by the observation of visible bubbles and by a significant change in the PCD time signal and spectrum. [Work supported by NIH DK43881, NSBRI SMS00402, and RFBR.]

2:45

2pBBa8. Characterization of the YDME FEP-BY02 tumor therapy system. Bryan Cunitz (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105), Stuart Mitchell, Yak-Nam Wang, Barbrina Dunmire, and Peter Kaczkowski (Univ. of Washington, Seattle, WA 98105)

The YDME FEP-BY02 is an extracorporeal tumor therapy device that has been in clinical use in China for several years. In the USA, this device is currently under investigation for the treatment of pancreatic cancer. Prior to being submitted for an application for an Investigation Device Exemption (IDE) with the FDA, the device will be required to undergo a thorough characterization of all systems involved in patient treatment. The purpose of this research is to characterize the FEP-BY02 and obtain data for an IDE application to the FDA for the treatment of pancreatic cancer using the FEP-BY02. A series of acoustical characterization, *in vitro*, and *ex vivo* tests are being conducted to validate the company's preclinical and clinical experience in China. Comparisons between three methods (radiation force balance, fiber-optic hydrophone, and scattering hydrophone) for measuring/determining focal intensities will be used to assess the validity of the measurement techniques and evaluate acoustic output over the functional input range of the FEP-BY02. Transparent gels impregnated with thermally sensitive markers will be used to visualize lesion formation and evaluate lesion characteristics with respect to input parameters. Thermocouples implanted in tissue mimicking thermal gels and *ex vivo* tissue will be use to evaluate the thermal response with respect to input parameters. Preliminary data indicate that the therapeutic ultrasound treatment system forms consistent lesions at the desired target.

3:00

2pBBa9. Acoustic virtual laboratory: A modeling tool for high-intensity focused ultrasound applications. Francesco P. Curra, Steven G. Kargl, and Lawrence A. Crum (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA)

The field of high-intensity focused ultrasound (HIFU) is emerging with strong potential and broad medical applications. Characterized by its ability to penetrate at depth inside the body without harming intervening tissue, therapeutic ultrasound has posed the basis for a new array of nonin-

vasive therapies. However, the inherent complexity of biological media and the nonlinear nature of ultrasound propagation at HIFU regimes make optimization and control of the therapy still a challenging task. In this respect, an accurate modeling tool, the Acoustic Virtual Laboratory (AVL), will be presented for solving multidimensional HIFU problems in complex geometries that can greatly assists in predicting HIFU applications effects and, therefore, help in the optimization and control of the treatment. AVL consists of 2-D, 2.5-D (cylindrical symmetry), and 3-D coupled solutions for acoustic and elastic wave propagation in heterogeneous, lossy, bubbly, and porous media with the bioheat equation for temperature estimation. It includes linear and nonlinear wave propagation, arbitrary frequency power law for attenuation, and can account for multiple reflections and backscattered fields. Sample results for tumor ablation, acoustic hemostasis, and propagation through porous bones will be illustrated. [Work supported by US Army Medical Research Acquisition Activity and NIH NCRR Grant R21 RR 21472.]

2pBBb1. Temperature dependence of acoustic properties of human tissues with a high-resolution ultrasound backscatter microscope. Jee Woo Park (Acoust. Res. Lab., Dept. of Phys., SungKyunKwan Univ., Suwon 440-746, Republic of Korea), Jiehui Liu, Byoung Nam Kim, and Suk Wang Yoon (SungKyunKwan Univ., Suwon 440-746, Republic of Korea)

The B-mode *in vitro* images of human skin and ocular tissues are obtained using a high-resolution ultrasound backscatter microscope (UBM) at the frequencies of 40, 80, and 100 MHz. It shows that a high-resolution UBM can visualize more detailed superficial microstructures of skin and eye at higher frequencies. In order to improve high-frequency ultrasound images, we have investigated the acoustic properties, such as sound velocity, sound attenuation, and backscatter coefficient, of human tissues with this UBM system over the frequency range from 25 to 110 MHz. Their acoustic properties are also investigated as a function of temperature in the range from 20 °C to 65 °C, which may provide bases for ultrasound image monitoring of thermal therapy. [Work supported by Strategic National R&D Program of Ministry of Commerce, Industry and Energy (MOCIE), Republic of Korea.]

2pBBb2. Calibration for biological acoustic impedance microscope. Naohiro Hozumi (Aichi Inst. of Technol. 1247 Yakusa-cho, Toyota, 470-0392 Japan), Satoshi Terauchi, Ayumi Kimura, Masayuki Nagao, Sachiko Yoshida (Toyohashi Univ. of Technol.), Kazuto Kobayashi (Honda Electron.), and Yoshifumi Saijo (Tohoku Univ.)

The presentation deals with the calibration for a biological acoustic impedance microscope. A block of tissue was placed on a plastic substrate, and an acoustic pulse focused on the interface was transmitted from the rear side of the substrate. The reflection was received by the same transducer and interpreted into local acoustic impedance. An acoustic impedance image was obtained by mechanically scanning the transducer. A reference material was simultaneously observed in order to perform calibration. A water droplet was employed as a reference material, however, it often entered into the interface between the substrate and tissue, leading to the reduction of the image quality. Therefore, several kinds of compounds were investigated. Silicone rubber was relatively homogeneous and stable in acoustic impedance, after a certain period of curing time. However, its dispersion with the scale of focal spot size was as large

as 0.02 Ns/cm^3, suggesting that a sufficient number of points should be measured and averaged in order to obtain a precise reference signal. Finally, change in local acoustic impedance of cerebella tissue of a rat as a function of postnatal days was quantitatively assessed for each independent layer like molecular layer, granular layer, and white matter.

4:00

2pBBb3. Ultrasonic evaluation of blood coagulation from stroke patients. Ying Li, Dong-Guk Paeng (Oceanic Information and System Eng., Ocean College, Cheju Natl. Univ., JEJU, Korea, 690-756), Sitaramanjaneya Anjaneya Reddy Guntur, Min Joo Choi, Young Ree Kim, and Jae-Chul Choi (Cheju Natl. Univ., JEJU, Korea, 690-756)

It is already known that the ultrasound speed and attenuation coefficient are increasing during the blood clotting process. A pulse echo system was set up to measure the sound speed and attenuation coefficient of human blood at 37 C. From ten healthy volunteers, the blood was taken to measure sound speed and attenuation coefficient during blood coagulation without and with heparin. For ten stroke patients, sound speed and attenuation were measured with aPTT or PT for comparison. The variation of sound speed and attenuation coefficient of blood after adding heparin was small. Sound speed of plasma from healthy volunteers was increased to 7 from 1535 m/s over 50 min without heparin, but to 1 m/s during the first 5 min for heparin-added blood. Sound speed of plasma from stroke patients was changed little compared to that from healthy volunteers without heparin. Attenuation coefficient was increased linearly during plasma coagulation for both volunteers and stroke patients, but its temporal slopes were much smaller for stroke patients. The blood samples from the stroke patients that investigated how heparin affects sound speed and attenuation as a function of time before and after taking the heparin and the results will be discussed.

4:15

2pBBb4. Correlation between the degree of hemolysis and acoustic impedance, speed of sound, and attenuation in flowing whole blood. Adam White and Constantin-C. Coussios (Inst. of Biomed. Eng., Dept. of Eng. Sci., Univ. of Oxford, 17 Parks Rd., Oxford OX1 3PJ, UK, constantin.coussios@eng.ox.ac.uk)

The effect of increasing levels of mechanical hemolysis on the propagation of 15-MHz ultrasound in flowing whole blood at 37 °C was investigated. An experimental setup was developed, which enabled the continuous measurement of attenuation, speed of sound, and acoustic impedance

in porcine whole blood under conditions of laminar flow and mean shear rates well above the threshold for red cell aggregation. Starting with an initial hematocrit of 35%, an increasing volume fraction of the blood in the flow loop was hemolyzed by exposure to very high shear stresses. The attenuation coefficient at 15 MHz was found to vary between 1 dB/cm for 0% hemolysis (no red cell damage) to 5 dB/cm for 75% hemolysis, remaining approximately constant for higher hemolysis levels. Speed of sound decreases from 1561 m/s for healthy blood to 1545 m/s for 80% hemolysis. Finally, acoustic impedance was also found to vary from a minimum of 1575 Kg/m^2 to 1589 Kg/m^2 between 15% and 90% hemolysis. These results show great promise towards solving the inverse problem, namely developing a technique capable of deducing the degree of hemolysis noninvasively and in real time based on measured changes in ultrasound parameters.

4:30

2pBBb5. Multimodality tissue-type imaging of prostate cancer. Ernest Feleppa, Shreedevi Dasgupta, Sarayu Ramachandran (Riverside Res. Inst., 156 William St., New York, NY 10038, feleppa@rrinyc.org), Christopher Porter, David Dail, and Marc Lacrampe (Virginia Mason Medical Ctr., Seattle, WA 98101)

Unlike many tumors, prostate cancer cannot be imaged reliably by any single, existing, conventional modality. This makes guiding biopsies, targeting therapy, and monitoring effects problematic. Therefore, our objective is to improve significantly the depiction of prostate cancers using multimodality, multifeature techniques combined with nonlinear classifiers such as artificial neural networks (ANNs) and support vector machines (SVMs). Our previous studies show encouraging potential for tissue typing and imaging based on ultrasound spectrum analysis using ANNs and SVMs that produce ROC-curve areas of 0.84 to 0.88 compared to 0.64 for conventional ultrasound imaging. Similar studies by others have shown that magnetic-resonance spectroscopy can produce comparable ROC-curve areas based on the ratio of choline and creatine to citrate. Because these two modalities sense entirely distinct properties of tissue, i.e., microscopic mechanical properties by ultrasound and chemical properties by magnetic resonance, their combination should markedly improve classification performance in distinguishing between cancerous and noncancerous prostate tissue. We have undertaken preliminary studies incorporating these two modalities. These studies demonstrate the feasibility of coregistering features from each modality and generating new, combined-modality images that exploit the attributes of both modalities.

4:45

2pBBb6. Validating the theoretical framework relating ultrasonic spectrum-analysis parameters to scatterer properties. Shreedevi Dasgupta, Ernest Feleppa, Jonathan Mamou (Riverside Res. Inst. 156 William St., NY 10038), and Mark Rondeau (Cornell Univ., Ithaca, NY)

Existing theoretical frameworks for ultrasound spectrum analysis relate properties of backscattered echo signals from tissues to scatterer properties. However, the reliance of these frameworks on numerous key assumptions may not be appropriate for evaluating tissue properties. The objective of our studies is to validate those assumptions or reduce dependence on them so that estimates of scatterer properties can be made with greater confidence. Ultrasound rf data were acquired from isolated, uveal melanoma cells suspended in liquid media using center frequencies of 10 and 35 MHz. Average cell size was 12 μm and concentrations ranged from 1.3×10^8 cells/ml to 2.0×10^6 cells/ml. Theoretical spectral-parameter values predicted by the Lizzi framework were calculated using known values for size and concentration and published values for sound propagation velocity and acoustic impedance. Normalized spectral parameters were computed from the experimental rf data using standard Fourier methods. Predicted and experimental values for the slope, midband, and intercept parameters agreed to within 11%. Initial results tend to validate the theory at these scatterer concentrations. Future work will provide more insight into scattering behavior under a greater variety of conditions, e.g., scatterer sizes and concentrations.

5:00

2pBBb7. Alias-free estimation of blood velocity using wideband pulse transmission. Naohiko Tanaka (Faculty of Systems Eng., Shibaura Inst. of Technol., 307 Fukasaku, Saitana 337-8570, Japan, tanaka@se.shibaura-it.ac.jp)

Blood velocity information that is obtained from a pulsed Doppler system is applied to clinical diagnoses of the circulatory system. However, the conventional pulsed Doppler technique has a fundamental limitation on Doppler velocities: blood velocity is measured erroneously when it is greater than the Nyquist limit. This phenomenon is called aliasing. This study is aimed at expanding the range of measurable blood velocities while avoiding aliasing. A new technique proposed here is based on wideband pulse transmission and phase correction. A series of short pulses with a wide frequency band is transmitted in this technique. Received echoes are Fourier transformed and converted to the cross spectrum. The phase of the cross spectrum is proportional to the frequency and the blood velocity. When the blood velocity is greater than the Nyquist limit, a part of the phase of the cross spectrum is larger than $\pm \pi$ and is wrapped in $\pm \pi$. The wrapped phase data are corrected using wideband echo information to avoid aliasing. Then the gradient of the corrected phase is estimated and converted to the blood velocity. Simulation results show that the proposed technique triples the velocity range.

5:15

2pBBb8. Continuous delay estimation with polynomial splines. Gianmarco Pinton and Gregg Trahey (Duke Univ., 136 Hudson Hall, Box 90281, Durham, NC 27708, gfp@duke.edu)

Delay estimation is used in biomedical ultrasonics to determine blood flow, phase aberration corrections, and elastographic images. The accuracy of the algorithms developed to determine these delays depends on noise, bandwidth, and delay range. Subsample delay resolution is required in most cases. Two new algorithms that use cubic polynomial splines to continuously represent the delay and the apply pattern matching functions are introduced. The continuous analytic expressions for the pattern matching functions are used to calculate the delay. Normalized cross correlation and the sum of the squared error are implemented. These algorithms are compared to conventional delay estimators, such as discrete normalized cross correlation, autocorrelation, and to another spline-based method. Simulations compare the performance across noise, delay, and bandwidth. The proposed algorithms perform better, in terms of bias and jitter. For example, the jitter at a 0.5 subsample shift is 2.3×10^{-3} subsample shifts for interpolated normalized cross correlation, and 3.5×10^{-4} and 4.0×10^{-4} for the two proposed algorithms. The computational requirements of the new algorithms are also considered and are shown to be competitive with the interpolated normalized cross correlation at low interpolation values and smaller at large interpolation values. [This work was supported by NIH grants R01-HL075485 and 1R01-CA114093-02.]

5:30

2pBBb9. Erythrocyte aggregability from human, horse, and rat blood by ultrasound backscattering measurements. Kwon-Ho Nam (Interdisciplinary Postgraduate Program in Biomed. Eng., Cheju Natl. Univ., 66 Jejudaehakno, Jeju-si Jeju-do, South Korea, 690-756), Dong-Guk Paeng, Tae-Hoon Bok, and Min Joo Choi (Cheju Natl. Univ., 66 Jeju-si Jeju-do, South Korea, 690-756)

A pulse-echo system was used in a cylindrical chamber with a stirring magnet and a 5-MHz focused transducer for studying erythrocyte aggregation from human, horse, and rat blood. The highest backscattering power was measured from horse blood and followed by human and rat blood both at stasis and under shear forces. In human and horse blood, the backscattered power (BP) was decreased with stirring speed and saturated within 1 min. The BP was increased to 20 dB when blood flow was stopped. Since the aggregation of rat erythrocytes in autologous plasma is very low and barely detectable by the ultrasound BP, rat plasma was

replaced by phosphate buffered saline containing polyvinylpyrrolidone 360 in order to enhance the aggregation. In conclusion, this simple *in vitro* ultrasound measurement system requires a small amount of blood, which may provide an alternative method to investigate the mechanisms and

physiological roles of erythrocyte aggregation. Furthermore, the rat erythrocytes in polymer solution may be useful for an automatic measurement system to examine the bioactive materials that affect aggregation in preclinical studies.

2pEA1. Development of shear-horizontal–surface-acoustic wave (SH-SAW) sensor for liquids. Jun Kondoh (Grad. School of Sci. and Technol., Shizuoka Univ., Johoku 3-5-1, Hamamatsu-shi, Shizuoka 432-8561, Japan) and Showko Shiokawa (SAW&SPR-Tech. Corp., Hamamatsu-shi, Shizuoka 432-8011, Japan)

Acoustic-wave devices have been applied as chemical and physical sensors for gas and liquid phases. Since the surface acoustic wave (SAW) on a 36°-rotated Y-cut X-propagating LiTaO$_3$ single crystal (36YX.LT) is in the shear horizontal (SH) mode, SH-SAW devices have been applied as liquid-phase sensor. In this paper, we present fundamental properties of the SH-SAW sensor and its applications. When a liquid is loaded on the SH-SAW propagation surface, evanescent fields of the SH displacement and piezoelectric potential penetrate into the liquid. Evanescent fields are influenced from the liquid, so phase velocity and amplitude of the SH-SAW are perturbed. By detecting the change, liquid-phase sensor is realized. Based on the theoretical calculation, the SH-SAW sensor is influenced by liquid properties, i.e., density and viscosity products, relative permittivity, and conductivity. For simultaneous detection of these properties, a three-channel SH-SAW sensor is fabricated. Evaluation of mixed solutions of glucose and ethanol is carried out using the sensor. The results indicate that the three-channel SH-SAW sensor can be applied to a fermentation monitoring system.

2pEA2. Lead zirconate titanate thick-film ultrasonic transducer for 1- to 50-MHz frequency bands fabricated by hydrothermal method. Mutsuo Ishikawa, Minoru Kurosawa (Interdisciplinary Grad. School of Sci. and Eng. Tokyo Inst. of Technol. Kurosawa lab. G2-32, 4259 Nagatutamati, Midori-ku, Yokohama, Kanagawa 226-8502), Tomohito Hasegawa, Hiroshi Kitsunai, Akito Endoh, Shinichi Takeuchi (Toin Univ. of Yokohama), Takeyoshi Uchida, and Tsuneo Kikuchi (Natl. Inst. of Adv. Industrial Sci. and Technol.)

This prototype ultrasonic transducer had about a 30-μm thick hydrothermal PZT layer on a 50-μm thick titanium substrate. An active area of this transducer was 3.5 mm in diameter. Material constants of this hydrothermal PZT thick film were measured. Electromechanical coupling coefficient kt was over 0.25 and acoustic impedance was 6 Mrayl. A mechanical resonance frequency in the thickness mode of the prototype ultrasonic transducer was approximated by a mason's equivalent circuit using the thickness and the material constants of the hydrothermal PZT film and the Ti substrate. The prototype ultrasonic transducer had a double broad peak spectrum of about 15 and 30 MHz in simulation. Also, these broad peaks were a half wavelength and a quarter wavelength resonance frequency in a combined structure of the hydrothermal PZT thick film and the Ti substrate. The prototype ultrasonic transducer transmitted ultrasound in water. Experimental results were the prototype ultrasonic transducer radiated ultrasound at the frequency range from 1 to 50 MHz as wideband using respective resonance frequency. A reason for the wideband characteristics radiation of ultrasound was the prototype ultrasonic transducer has low acoustic impedance and double broad peak.

2pEA3. Equivalent network representation for length-extensional vibration modes in a side-plated piezoelectric bar with a varying parameter. Ken Yamada (Dept. of Electron. Eng., Faculty of Eng., Tohoku Gakuin Univ., 1-13-1 Chuo, Tagajo 985-8537, Japan)

Equivalent network representation is derived for length-extensional vibration modes in a side-plated piezoelectric bar with varying parameters along it. In contrast to findings of a former report [Yamada *et al.*, IEEE Trans. UFFC **48**(2), 613–616 (2001)], which dealt with the longitudinal

piezoelectric effect, the bar in this study is presumed to be excited through a transverse piezoelectric effect. The network comprises an electrical transmission line of length corresponding to the bar length and an electrical port with a capacitor that is linked to the line at both its ends via two ideal transformers. Frequency characteristics of the input electric admittance of the bar with a sinusoidally varying piezoelectric parameter, which shows the unique feature of the vibrator, is demonstrated using equivalent network analysis. The possibility of applying this network for modeling the interdigital transducer for excitation and detection of surface acoustic waves (SAWs) is discussed.

2pEA4. Measuring micro liquid volume by acoustic resonant technique. Makoto Wakabayashi, Daisuke Koyama, Kentaro Nakamura, and Sadayuki Ueha (P&I Lab. Tokyo Technol., 4259-R2-26, Midori-ku, Yokohama, Kanagawa 226-8503, Japan)

A method to measure micro liquid volume less than 300 ln with the accuracy of 0.1% is highly needed in biogenetic and biochemical industries. The authors propose a novel method to estimate micro liquid volume in a small well using acoustic resonance. In our experiments, liquid is in a container 6.5 mm in inner diameter and 9 mm in height, and the sound pressure near the well is measured by sweeping the illuminating sound field from 6 to 11 kHz. According to the relationship between the resonance frequency and the volume, we can successfully estimate the small volume with the accuracy of 0.1% and an excellent repeatability. For simultaneous multipoint measurements, we experimentally investigate the effect of adjacent wells on resonant frequency of the target well. It is revealed that the resonance frequency shift due to the mutual coupling between the adjacent wells is negligible if the well interval is less than 5 mm.

2:10

2pEA5. A multidimensional overview for ultrasonic motor driven loudspeaker development. Hirokazu Negishi, Juro Ohga (Dept. of Electron. Systems Eng., Essex Univ., 1-37-14 Koyabe Yokosuka 238-0026, Japan, hiro.note@jcom.home.ne.jp), and Juro Ohga (Shibaura Inst. of Technol., Tokyo 108-8548, Japan)

Twelve years of history for the development activity of the ultrasonic motor driven loudspeaker show a multidimensional aspect. Three main axes are geography, frequency, and mechanical impedance. Geography came first since initial conception was in the UK, yet the prototyping was in Japan. The origin was an idea for a stepping motor driven digital loudspeaker that was to address improving abnormalities coming from the fundamental resonant frequency, the so-called "F0." Consultation revealed the idea was weak but unexpectedly "ultrasonic motor" was recommended. This led the prototyping to be in Japan, where the invention and development of the motor took place. The second is frequency. For audible sound reproduction, inaudible ultrasonic frequency is employed. Although combination of these two regions in frequency is not new for sound reproduction, a couple between the bottom end of the audible sound reproduction and the ultrasonic motor is completely new for this arena. The third is mechanical impedance since convention is low whereas this one is high. Actually, this is the core of the attempt as most abnormalities around "F0" stem from weak mechanical impedance. Other axes also exhibit contrast against conventions such as linearity, controlling, driving, and lifetime of the motor itself, as well as configuration of the sounding mechanism.

2:25

2pEA6. Loudspeaker using continuous revolution of a piezoelectric ultrasonic motor. Yuta Ohnuma, Yusuke Iwaki, Juro Ohga (Shibaura Inst. of Technol., 3-7-5, Toyosu, Koto-ku, Tokyo 135-8548, Japan, m106020@sic.shibaura-it.ac.jp), Hirokazu Negishi (Essex Univ., Yokosuka 238-0026, Japan), and Kazuaki Maeda (TOA Corp., Japan)

Volume displacement of a direct radiator loudspeaker diaphragm is inversely proportional to the square of its signal frequency. The lowest frequency of a flat response is restricted by the diaphragmfs fundamental resonance frequency. Therefore, a loudspeaker diaphragm for radiation of a low-frequency signal shall have large amplitude and low resonant frequency. The authors propose the application of a piezoelectric ultrasonic motor for this purpose. It produces a completely controlled large output force because its output mechanical impedance is much greater than any conventional transducer or motor. An ultrasonic motor whose stator is connected to a direct-radiator loudspeaker cone diaphragm by a rod and whose rotor is loaded by a heavy metal ring rotates with a constant veloc-

ity. Modulation of the velocity by the audio signal causes driving force to the diaphragm because a heavy ring with large inertia tends to rotate with constant velocity. This paper reports construction of a practical experimental model and its output sound pressure characteristics.

3:00

2pEA7. Removal of thin hard coating on glass substrate by collision of nanometer-sized particles accelerated in high-intensity ultrasonic field. Naoya Kudo and Kazunari Adachi (Faculty of Eng., Yamagata Univ., 4-3-16 Jounan, Yonezawa, Yamagata, 992-8510 Japan, ere69123@dip.yz.yamagata-u.ac.jp)

The aim of this study is to establish a fundamental recycling technology for optical lenses. In industry, a common conventional technique for cleaning the surface of a small object such as an optical lens is through the use of ultrasonic cavitation. However, the intensity of shock waves caused by the cavitation is difficult to control. The authors have considered that the substances that adhere to lens surfaces, such as hard optical coatings and stains, are removable using collisions, against the lens surface, of many tiny particles that are accelerated by a high-intensity ultrasonic field. Some physical parameters that dominate the removal effect have been changed systematically to illustrate the surface-refreshing process for lenses in the experiments. The authors worked to experimentally clarify the particle collision effect on the removal. In addition, the acoustic field was analyzed using finite-element method. The authors have also attempted to elucidate the principle of the removal technique through comparison of experimental results with those obtained through numerical simulation. A precise elucidation, however, remains as an important problem to be solved.

3:15

2pEA8. Atomization of high-viscosity materials by one-point convergence of sound waves radiated from an aerial ultrasonic source using a square transverse vibrating plate. Hikaru Miura (Dept. of Elec. Eng., College of Sci. and Technol., Nihon Univ., 1-8-14, Kanda Surugadai, Chiyoda-ku, Tokyo 1018308, Japan)

It is difficult to atomize high-viscosity materials such as oil without contact; however, it is possible to do so using intense aerial ultrasonic waves. As a sound source for that purpose, an aerial ultrasonic source with 20-kHz resonance frequency was used along with a square transverse vibrating plate that has the nodal mode of vibration amplitude in the shape of a lattice. The source radiates four-directional sound waves in the far field. To obtain high sound pressure in the near field, radiated sound waves were converged using several flat boards and four parabolic reflective boards placed near the source. Sound pressure reaches 6.5 kPa (S.P.L. 170 dB), a very high level, at the convergent point. Scattering and atomization of the high-viscosity materials were examined at the point of convergence. Results show the following. Atomization by a sound wave is possible in the case of high-viscosity materials. The higher the sound pressure, the shorter the beginning time of atomization becomes. The distribution of the atomized particles diameter is 0.05–0.22 mm at the movement viscosity of 10 000 cSt.

3:30

2pEA9. Ultrasonic complex vibration converters using different sound velocity metal ring pairs with slanted thickness. Jiromaru Tsujino, Tetsugi Ueoka, Goh Kishimoto, and Rohei Karatsu (Kanagawa Univ., 3-27-1 Rokkakubashi, Kanagawa-ku, Yokohama 221-8686, Japan)

The ultrasonic complex vibration systems are effective for various high power applications. New complex vibration converters using different sound velocity metal ring pairs with slanted thickness are proposed and studied. Two different sound velocity rings with a slanted surface along the diameter are superimposed. The converter ring pair may be installed in any place of a longitudinal vibration system and driven by a longitudinal vibration source. The system is driven transversally according

to traveling time difference between both sides of the converter. The vibration rod vibrates in elliptical to circular locus in the case where these two natural frequencies are adjusted as phase difference is near to 90 deg. Thus, various one-dimensional complex vibration systems are obtained. Piezo-ceramics cut or polarized slanted may be used. The 18-mm-diam converter for 27-kHz system consists of a phosphor bronze and stainless steel rings. The rings are cut slanted, 1.5 to 6.5 mm in thickness at outer diameter, and superimposed to an 8-mm-thick ring. Two or three converters are available for more complicated vibration modes. Using 27- and 150-kHz complex vibration systems, 1.0-mm-thick aluminum plates and coated thin copper wires for IC cards were welded directly with material strength.

3:45

2pEA10. Nondestructive inspection system for corrosion detection in fuel tank liners. John W. Doane, Michael D. Gray, and Jayme J. Caspall (Georgia Inst. of Technol., 771 Ferst Dr., Atlanta, GA 30332, jd37@mail.gatech.edu)

An ultrasonic, nondestructive inspection system for the early detection of corrosion in fuel tank aluminum liners was developed and tested. A Labview-controlled scanner, which rode on the tank's resident rib braces, housed a 10-MHz transducer and a miniature video camera. The bidirectional (axial, azimuthal) scan resolution was controlled by adjusting the surface standoff distance of the focused transducer to produce variable-area interrogation sites. The phenomenon of increased backscatter from corrosion-roughened surfaces was exploited to detect the presence of corrosion in its early stages. The transducer acted as both transmitter and receiver, capturing the echoes from the subject surface while the video camera captured an image of the surface under acoustic inspection. The acoustic and visual data were overlayed to form a composite image of the entire inspection surface. The system was field-tested using two tanks pulled from active duty at the Marine Corps maintenance facility in Cherry Point, NC. [Work supported by JCAA.]

4:00

2pEA11. Evaluation of the static stress exerted on the clamping bolt in the structure of a bolt-clamped Langevin-type transducer. Toru Takahashi and Kazunari Adachi (Adachi Lab., 8-312, Faculty of Eng., Yamagata Univ., 4-3-16 Jonan, Yonezawa, Yamagata, 992-8510, Japan, g02239@dipfr.dip.yz.yamagata-u.ac.jp)

Bolt-clamped Langevin-type transducers (BLTs) must possess various characteristics depending on the field in which they are used. It has already been clarified by the authors that prestress or bearing stress imposed on piezoelectric elements in a transducer should be sufficiently large to compensate for their low tensile strength. For this study, we measured the strain on the clamping bolt surface using strain gauges pasted on it to evaluate the static prestress that changes with the turning angle of the metal block in clamping. We calculated the strain for some BLTs of identical shape using the finite-element method (FEM) and measured it to

confirm the validity of the prestress calculation that was achieved previously by the authors. Unfortunately, a large difference in the strain between the calculated and measured results was observed. We cited three possible reasons for that huge discrepancy. Among them, plastic deformation of the screw thread might most influence the result. As long as the design problem of BLTs pertaining to the prestress remains unresolved, we cannot take full advantage of the excellent electromechanical transduction efficiency of BLTs for high-power ultrasonic applications.

4:15

2pEA12. Multilayered high-performance transducer using polyurea thin film. Marie Nakazawa, Masaya Tabaru, Daisuke Koyama, Kentaro Nakamura, Sadayuki Ueha (Tokyo Tech., 4259 R2-25, Nagatsuta, Midori-ku, Yokohama, Kanagawa 226-8503, Japan, nakazawa@sonic.pi.titech.ac.jp), and Akihiro Maezawa (Konica Minolta M.G. INC., Tokyo, Japan)

Polyurea thin film exhibits useful characteristics as a high-frequency ultrasonic transducer such as a low acoustic impedance of 70% of that of PVDF, considerably high piezoelectric constants compatible with conventional piezoelectric polymers, and a higher Curie temperature. A polyurea thin film transducer working at over 100 MHz can be made on any surfaces through vapor deposition polymerization with a high controllability of thickness. To enhance the transducer performance, a multilayered configuration is studied in this study. A special twin-vacuum-chamber is used for laminating the polyurea layers and the aluminum electrodes alternately. We fabricate two- and three-layered transducers with 1.5-μm polyurea thin films as well as single-layer transducers. To evaluate the transducer performances, we measure the capacitances, the electrical admittances, the coupling factors, and the Q values. The pulse/echo measurements are also conducted to determine the transmission and receiving characteristics of the transducers using a glass plate as a reflector. The results of the pulse/echo experiments show that the received voltage amplitude of the multilayered transducer is higher than that of the single-layer transducer.

4:30

2pEA13. Analysis of fluid-borne coupling in transducer arrays. Kassiani Kotsidou and Charles Thompson (Ctr. for Adv. Computation and Telecommunications, Univ. of Massachusetts Lowell, 1 Univ. Ave, Lowell, MA 01854)

In this work, we will analyze fluid-borne coupling between adjacent elements of a transducer array. In the case of a transducer having low inertia mass, such coupling can result in a reduction in the radiation efficiency and the directional fidelity of the array. The coupling factor and the mutual radiation impedance have been investigated by Lord Rayleigh (1903), Wolff and Malter (1929), and R. I. Pritchard (1960) for the case of an array comprised of ideal piston radiators. These results will be used as a starting point for our work. The effect of the inertia impedance of the transducer and the control of the special distribution of the radiated field is considered.

2pEDa1. Sound education in urban environment. Yoshio Tsuchida (Kanazawa Inst. of Technol., 7-1 Ohgigaoka, Nonoichi, Ishikawa, 921-8501, Japan)

There are various viewpoints for education and there are various levels for a sound. We have some cases to teach a ''sound.'' A certain person teaches a sound as music, another person teaches it as physics. But education is not teaching. It is more important to feel and enjoy. Then, one's sensitivity for a sound will be nourished. Experimental listening is called Sound Education based on soundscape. The case of a workshop on Sound Education is addressed in this paper. Sound Education finally aims at improvement of our environment. Many activities of Sound Education were devised by R. Murray Schafer [A Sound Education, 100 Exercises in Listening and Soundmaking, Arcana Editions]. Some activities were devised by Joseph Bharat Cornell as Nature Game [Sharing Nature With Children (Sharing Nature Series), Dawn Publications.] Sound Education has several aims. It differs according to the group that sponsors it. Here are the workshops executed by me. One aim for environmental preservation, and another one aim for community design.

1:25

2pEDa2. Music as a vehicle to do science in the elementary classroom. Uwe J. Hansen (Dept. of Phys., Indiana State Univ., Terre Haute, IN 47809)

During the past several years, a number of workshops were conducted for public school teachers at the elementary levels. Training and materials were provided to help teachers use music as a vehicle to introduce science concepts. Tools used in these workshops include a long spring to introduce standing waves and the concept of harmonics, a monochord to relate frequency ratios to musical intervals, and simple computer software to introduce wave addition and spectral analysis. All of these will be demonstrated and ways of introducing them in the elementary classroom will be discussed. [These workshops were supported with ASA and Eisenhower funds.]

1:45

2pEDa3. Exciting demonstration in acoustics by high-school teachers' group: "Stray Cats." Kanako Ueno (Inst. of Industrial Sci., Univ. of Tokyo and Tech. Committee on Education in Acoust. of ASJ, Komaba 4-6-1, Meguroku, Tokyo, 153-8505, Japan), Takayuki Arai, Fumiaki Satoh, Akira Nishimura, and Koichi Yoshihisa (Tech. Committee on Education in Acoust. of ASJ, Meguroku, Tokyo, 153-8505, Japan)

In Japan, to get students interested in a subject, high-school teachers often form a group to share their ideas and inventions on education. ''Stray Cats'' is one of the most active groups in physics. The group has been proposing many exciting demonstrations, which were contrived to support students' learning process with intuitive understanding of physics. Here, instead of using commercial equipment, they developed simple teaching tools that show physical phenomena in an exciting and attractive way, using quite common materials and daily goods. For example, the velocity of sound is measured by a pipe filled with a gas (air, CO_2, helium, etc), setting a loudspeaker and two microphones in the pipe. Interference of sounds is demonstrated by two pipes with attached cone-shaped horns at one end, which collect a source sound in different phase, and merging them into one at the other end, which produce louder or quieter sound as a result of interference. Hitting or rubbing different length of aluminum rods aids students' understanding of longitudinal waves and transverse wave with the relationship between rod's length and pitch, as well as a pleasant experience with beautiful tones. These educational tools will be presented with videos taken with the Stray Cats group.

2pEDa4. An acoustics education outreach program for young children. Ralph T. Muehleisen (Civil and Architectural Eng., Illinois Inst. of Technol., Chicago, IL 60616, muehleisen@iit.edu)

With limited time for science in the preschool and primary classroom, and limited science education of many preschool and primary school educators, the need for science professionals to engage in outreach education is ever increasing. Additionally, there is an increasing need for children to be aware of the problems of noise exposure, especially with regard personal sound systems. In this talk, a one-hour acoustics education outreach program developed for preschool and early primary school children is presented. In the program, children are involved in a discussion of the human auditory system and the dangers of noise exposure, engage in listening exercises using a keyboard synthesizer, construct a small musical instrument, and finally play the musical instrument with the rest of the class in a marching band.

2pEDa5. Let children experience speech science. Takayuki Arai (Dept. of Elec. and Electron. Eng., Sophia Univ., 7-1 Kioi-cho, Chiyoda-ku, Tokyo, 102-8554 Japan)

An education in acoustics is important for students of different ages: college, high school, middle school, and potentially even elementary school students, for whom such hands-on models are the most important. Because speech communication is a basic human activity, even for children, we expect that even the youngest students to be interested in speech science. With this in mind, we were motivated to develop intuitive and effective models for teaching speech science to all types of students. Our physical models of the human vocal tract [T. Arai, J. Phonetic Soc. Jpn., **5**(2), 31–38 (2001)] have recently been installed in an exhibition in a museum in Japan. Children can watch, listen to, and touch the models. Our recent head-shaped and lung models [T. Arai, Acoust. Sci. Technol. **27**(2), 111–113 (2006)] are also useful for educating students, because they are intuitive to produce a systematic and comprehensive education from the lungs to the head. Furthermore, we recently designed a sliding three-tube (S3T) model that has a simple mechanism for producing several different vowels [T. Arai, Acoust. Sci. Technol (to be published)]. This model is being used for an activity at a science workshop for children. [Work partially supported by JSPS.KAKENHI (17500603).]

2pEDa6. Development of educational software that supports study of sound environment for children. Hiroyuki Sakai (Ctr. for Promotion of Excellence in Higher Education, Kyoto Univ., Yoshida-Nihonmatsu, Sakyo, Kyoto 606-8501, Japan), Tadashi Shirakawa (NPO Onbunken, Tokyo, Japan), and Munetaka Tanaka (Sound Process Design, Inc., Tokyo, Japan)

A sound map, on which observed sounds are drawn as visual symbols, is well known as one of the nature games. Sound educational software, cultivating children's ecological view through their daily experiences focusing on sounds, was developed by using the sound map concept. Children record observed sounds through a sound-walk in outdoors into PC, and learn the sound environment through their collaborative work including classification, analysis, and group discussions in a workshop or a class. In a traditional approach on the field of educational technology, a lot of teaching materials introducing novel ICTs (information and communication technologies) are developed, but it is rather important to support usefulness for users (children and teachers), promote motivations for their learning, and support the smooth learning progressive process. In this presentation, the development concept of the software for the sound environment study based on socio-cultural approach is discussed, while an actual use example of this software is demonstrated.

2pEDa7. Stimulating children's interest in acoustics using models and toys. M. G. Prasad (Dept. of Mech. Eng., Stevens Inst. of Technol., Hoboken, NJ 07030)

Sound is an important means for sensory perception. Children, being naturally curious and sensitive, respond very well to sound. Simple acoustical toys attract their curiosity and attention. The use of simple sound- or music-producing tools draws their attention and then they ask questions. In answering their questions simple principles of acoustics and scientific reasoning can be taught to them. Simple principles such as tone change due to change of volume in a resonator, the role of length in the sound produced by a tube, the role of damping in cutting down vibration and sound, etc. can be taught to the children. Also, the description of noise being unwanted sound can be demonstrated using simple mechanical models with comparison to desirable sound as music through instruments such as the flute. A model of the human ear can be used to describe the way the sound is perceived. The use of models and encouraging children to ask questions will further enhance their curiosity. The author will share his experiences gained through making presentations for elementary school children.

2pEDa8. Re-equipping the University of Sydney's acoustics laboratory for teaching after a fire. Ken Stewart and Densil Cabrera (Faculty of Architecture, Univ. of Sydney, NSW 2006, Australia)

For some decades, the University of Sydney has taught and conducted research in architectural and audio acoustics from the Faculty of Architecture's acoustics laboratory. In October 2005, a fire in the anechoic room destroyed the laboratory mainly through heat and smoke damage. Recovery has involved a reconsideration of the systems used for teaching and research, and this presentation outlines our approach to this. One consideration is that measurement systems should be relatively self-contained, so that setup time for measurements is minimized, and several setups can be used simultaneously for hands-on teaching. New equipment tends to be computer based, which has the advantages of much greater measurement power, automation, recording, and interfacing, but can be less intuitive for students to understand than individual analog components. This presentation compares the preexisting and renovated laboratory, especially in terms of teaching strategies in audio and acoustics using technical equipment. We present examples of previous and envisaged student projects to illustrate how such infrastructure can support learning.

2pMU1. Acoustical characteristics of Chinese stringed instruments and their Asian relatives. Akiko Odaka (Dept. of Musicology, Tokyo Natl. Univ. of Fine Arts and Music, 10-8 Uenokoen, Taito, Tokyo 110-8714, Japan) and Shigeru Yoshikawa (Kyushu Univ., Fukuoka 815-8540, Japan)

In Asia, there are many relative musical instruments that derive from the same origin or share a similar structure. In spite of their similarities, they show distinct differences from each other in terms of their musical usages, playing techniques, and acoustic effects. This varies with each musical genre, musical structure, social background, and acoustic taste swayed by those elements. People often add special devices to musical instrument or improve them so as to realize their acoustical ideas. For example, the shamisen and biwa, Japanese plucked lutes, have devices to allow strings to vibrate against the neck-wood, creating a reverberant high-frequency emphasis called sawari, which is of special value in each performance. A device that creates a similar effect, called jawari in Hindi, is also found in the sitar, a traditional stringed instrument of India. On the other hand, the Chinese sanxian, one of the relatives of the Japanese shamisen lacks this device. In this presentation, specific features of various musical instruments are introduced from both musicological and acoustical viewpoints. In particular, Chinese stringed instruments are focused on and compared with those of Japan, Korea, and India for investigation of their acoustical effects.

1:40

2pMU2. Vibro-acoustic measurement of several biwas. Tomoyasu Taguti (Konan Univ., 8-9-1 Okamoto, Higashinada, Kobe, Japan) and Kakuryo Tohnai (Nerima, Tokyo, Japan)

The biwa is a family of Japanese lutes that have been played for more than 1000 years. This paper reports some measurements on the vibro-acoustic characteristics of several biwas of different types. The main concern is the similarity and difference of the fukuju-to-table transfer mobilities among the individual biwas. Here, the fukuju is a kind of bridge whose shape and way of

installation differ distictively from those common to the majority of other lute families found in many countries in the past as well as in the present time. The measurement revealed that in most cases the fukujus have two major vibration modes, to be labeled the ''twist'' and ''flap'' modes, with the corresponding resonance frequencies in the regions of about 0.9 to 1.2 kHz and of 1.4 to 1.6 kHz, respectively, though the exact figures depend on the physical size and shape. Their resonance property takes an important roll to determine the fukuju-to-table transfer mobility as the coupled vibroacoustic system with the table. The fukuju-to-table mobilities were compared with the spectra of the corresponding plucked sounds.

2:00

2pMU3. The acoustics of the hammered dulcimer and similar instruments. David Peterson (Univ. of Central Arkansas, Conway, AR 72032)

The hammered dulcimer, an antecedent of the piano, apparently originated in the Middle East sometime around the 14th century. A typical instrument has 23 to 30 courses of strings, two to four strings per course, and is played with two wooden hammers. As in the yang qin and other Asian dulcimers, bridges separate some string courses into two notes. In American instruments the treble bridge creates a musical fifth, which facilitates the speedy playing of diatonic scales and also creates a strong harmonic structure to the tone. In response to player demand, modern builders have used improved or new materials (glues, woods, composites, plastic) and better design to create a lighter and less resonant instrument with a greater musical range. Dr. Peterson will demonstrate various playing styles.

2:20

2pMU4. Development of a carbon-fiber-reinforced composite for guitar soundboards: Investigation of bracing effect by experiment and simulation. Akira Okuda and Teruaki Ono (Faculty of Engineeing, Gifu Univ., Yanagido Gifu-City, Japan 501-1193, ono@cc.gifu-u.ac.jp)

A carbon-fiber-reinforced polyurethane foam composite whose physical and acoustic properties closely resemble those of wood for stringed-instrument soundboards was developed. A guitar with such a composite-made soundboard produced an almost identical tone to that produced with a wooden soundboard. The procurement of wood for soundboards, however, has not yet become very difficult. To accelerate the production and use of guitars with composite soundboards, it is necessary to create an attractive guitar that has characteristic and unique tones that cannot be realized on a wooden soundboard, making use of composite characteristics of design freedom. Wooden top boards, soundboards, have bracing that has traditionally and experientially been glued; however, the effects of bracing have never been clarified. In this study, the bracing effect on the frequency response and vibration mode in a guitar top board was investigated using experimentation and simulation. From the results obtained, a composite-made soundboard with no bracing, which produces more harmonics than a wooden one with bracing, was simulated as an example.

2pMU5. On the factors for detecting mistuned conditions and guiding their corrections for the Koto tuning. Tamaki Ando (Tokyo Natl. Univ. of Fine Arts and Music, 12-8 Ueno Park, Taitou-ku Tokyo, Japan 110-8714, an_tamaki@yahoo.co.jp)

By observations at the Koto tuning practice, it is realized that the bridge is moved in the period of about 400 ms, which is too short to feel the sensation of beat. Then, two kinds of listening tests were planned. The test sounds composed of two Koto sounds which should be tuned in one octave interval were presented at the same time like a part of actual Koto tuning process. The lower tone was at 196.9 Hz, the pitch of the higher one was varied in the range of 20 cents. Their length from the beginning was varied from 50 to 500 ms. The first experiment is for the judgment of the right or wrong tuning (higher or lower). The second one is for the tone color impression using 13 pairs of adjectives. The results of these experiments show that reasonable pitch judgments can be done for the test sounds longer than 200 ms by well-experienced Koto players, and the test sounds are clearly distinguished from each other by their tone color difference, whereupon in the Koto tuning by expert players, the direction and degree of mistuning are found to be judged at the initial stage of Koto sounds by the tone color impression.

2pMU6. Acoustics of the *haegeum*, a Korean string instrument. Junehee Yoo (Dept. of Phys. Education, Seoul Natl. Univ., Seoul 151-742, Republic of Korea, yoo@snu.ac.kr) and Thomas D. Rossing (Stanford Univ., Stanford, CA 94305)

The Korean *haegeum*, closely related to the Chinese *erhu* and Japanese *kokyo*, dates back to the Goryeo Dynasty. It is played with a horsehair bow that is inserted between two strings attached to a small barrel-shaped resonator. A bow made up of a bamboo stick with lengths of horsehair is held by the right hand of the performer. The two strings are generally tuned to A3♭ and E4♭ and the resonator is tuned to about 300 Hz. The resonator has a paulownia wood plate at one end on which the bridge rests. By means of holographic interferometry, we compare modes of vibration in resonators of bamboo, ailanthus, birch, and ash.

3:30

2pMU7. Inharmonic sounds of bowed strings in Western music and Beijing opera. Chen-Gia Tsai (Grad. Inst. of Musicology, Natl. Taiwan Univ., No. 1, Sec. 4, Roosevelt Rd., Taipei 106, Taiwan, tsaichengia@ntu.edu.tw)

Due to the nonlinear bow-string interaction, inharmonic sounds can be produced by bowed strings. Such sounds are characterized by subharmonics, sidebands, and noises. Bow location, bow speed, and bow pressure on the string have been found critical to producing inharmonic sounds on the violin or the cello. In the accompaniment music of Beijing opera singing,

inharmonic sounds produced by the major bowed-string instrument (the jinghu) are sometimes called ''blossoming tones.'' They are played with a special touch technique of the left hand, and a chaotic behavior of string vibration arises from a nonlinear boundary condition with unilateral con-straints. The spectra of blossoming tones can be viewed as high-pass noises, with the cutoff frequency of about 1.6 kHz. Blossoming tones are sophisticatedly used for emotional expressions in Beijing opera. Their harsh quality recalls some pathological human voices.

2pPA1. Realism assessment of sonic boom simulators. Brenda M. Sullivan (NASA Langley Res. Ctr., M.S. 463, Hampton, VA 23681, brenda.m.sullivan@nasa.gov), Patricia Davies (Purdue Univ., West Lafayette, IN 47907-2031), Kathleen K. Hodgdon (Penn State Univ., State College, PA 16804-0030), Joseph Salamone (Gulfstream Aerosp. Corp., Savannah, GA 31407), and Anthony Pilon (Lockheed Martin Aeronautics Co., Palmdale, CA 93599)

The perceived realism of booms reproduced in three simulators, at NASA, Lockheed Martin, and Gulfstream Aerospace, was studied. The NASA and Lockheed facilities are loudspeaker-driven, airtight concrete structures that enable reproduction of the entire spectrum, including the very lowest frequencies. The Gulfstream facility is enclosed within a trailer and consists of a folded horn as well as loudspeakers. This creates the sonic boom waveform as a traveling wave but is unable to reproduce the lowest frequencies. In the tests, subjects experienced in listening critically to real sonic booms heard reproductions in the simulators of sonic booms recorded outdoors. Tests comparing the NASA/Gulfstream simulators and the Lockheed/Gulfstream simulators used the same outdoor sonic boom waveforms, though each simulator uses its own preprocessing to equalize the waveforms for presentation. The tests showed that the presence of ground reflections, very low frequencies, or recording hiss were not factors in realism ratings. However, the inclusion of some of the postboom noise heard after the boom itself was found to be extremely important for a realistic boom simulation.

1:20

2pPA2. Sonic boom perception: Live versus simulator playback. Kathleen Hodgdon, Tom Gabrielson (Appl. Res. Lab., Penn State, University Park, PA 16802), Anthony Atchley (Penn State University Park, PA), Brenda Sullivan (NASA Langley Res. Ctr., Hampton, VA 23681), Joe Salamone, and Chris Babcock (Gulfstream Aerosp. Corp., Savannah, GA 31407)

A research team conducted a study at NASA Dryden Flight Research Center to compare the perception of real versus simulated booms. The field test included an assessment of noise measurement systems and a subjective jury trial on perception of sonic booms heard outdoors. Seventeen sonic booms were recorded under the flight path of four separate flights of three F-18s, using various microphones and recorders at multiple ground and ear level locations. Waveform analysis was conducted comparing the recordings as a function of location and measurement system. Eighteen subjects listened to live sonic booms, then rated the realism of the playback of a selection of those booms reproduced in the Gulfstream Supersonic Acoustic Signature Simulator II several hours later. The subjects also provided adjective descriptors of boom perceptions. The booms selected for the jury trial presented a variety of boom characteristics that included postboom noise. The subjects rated the playback as realistic, contributing to the validation of the simulator for use in future testing. Waveform comparisons and results from the field measurements and jury trial will be presented. [Work sponsored by FAA/NASA/TC PARTNER Center of Excellence.]

1:40

2pPA3. Preliminary work on the development of a lexicon for supersonic aircraft sound. Andrew Marshall, Patricia Davies (Purdue Univ., 140 S. Intramural Dr., West Lafayette, IN 47907-2031, aimarsha@purdue.edu), Brenda Sullivan (NASA Langley Res. Ctr., Hampton, VA 23681), and Anthony Pilon (Lockheed Martin Aeronautics Co., Palmdale, CA 93599)

A series of tests was conducted in three sonic boom simulators to test how expert subjects perceived the realism of the sound playback. Subjects heard sounds (recorded sonic booms) in two simulators and rated them on a realism scale. On completion of this realism test, subjects were asked to write down descriptions of the sounds and also of real booms (indoor and outdoor) that they had heard in the past. They then listened to 14 sounds and, after each sound, wrote down adjectives and phrases describing the sound

characteristics. The 14 sounds were also analyzed and sound attribute metrics calculated for the main part of the boom as well as for the after-boom noise. The results of this analysis were compared to the words used to describe the sounds, and a preliminary set of words is proposed for inclusion in a lexicon for supersonic aircraft sound.

2:00

2pPA4. Human response to low-intensity sonic booms heard indoors and outdoors. Brenda M. Sullivan, Jacob Klos, Ralph D. Buehrle, David A. McCurdy (Structural Acoust. Branch, NASA Langley Res. Ctr., Hampton, VA 23681, brenda.m.sullivan@nasa.gov), and Edward A. Haering, Jr. (NASA Dryden Flight Res. Ctr., Edwards, CA 93523-0273)

A house on Edwards Air Force Base, CA, was exposed to low-intensity N-wave sonic booms during a 3-week test period in June 2006. The house was instrumented to measure the booms both inside and out. F-18 aircraft were flown to achieve a variety of boom overpressures from approximately 0.01 to 0.06 psf. During 4 test days, 77 test subjects heard the booms while seated inside and outside the house. Using the Magnitude Estimation methodology and artificial reference sounds, the subjects rated the annoyance of the booms. Since the same subjects heard similar booms both inside and outside the house, comparative ratings of indoor and outdoor annoyance were obtained. Preliminary results from this test will be presented.

2:20

2pPA5. Building structural acoustic response to aircraft sonic booms. Ralph D. Buehrle, Jacob Klos, Brenda M. Sullivan (Structural Acoust. Branch, NASA Langley Res. Ctr., Hampton, VA 23681), and Edward A. Haering, Jr. (NASA Dryden Flight Res. Ctr.)

As part of the NASA Low Boom/No Boom flight test project, a series of low-amplitude sonic-boom tests was completed over a 3-week period in June of 2006. This series of flight tests was designed to evaluate indoor/outdoor human subjective response, structural acoustic building response, and the effects of atmospheric turbulence for low-amplitude sonic booms characterized by overpressures in the nominal range of 0.1 to 0.6 pounds per square foot (psf). Low-amplitude sonic booms were generated by F-18 aircraft using dive trajectories to produce a range of overpressures at the Edwards Air Force Base housing area. In addition, straight and level supersonic flights were used to generate normal level (nominally 1.4 psf) sonic-boom overpressures at the housing area. This report will describe the structural acoustic building response measurements obtained during this flight test project. A single-family ranch-style home was instrumented with nearly 300 microphone and accelerometer sensors to determine the incident pressure and the building's structural acoustic response. Data were acquired for over 100 sonic-boom events. The test setup will be described and analysis of the measurements will be presented.

2:40

2pPA6. Modifications to the Gulfstream sonic boom simulator for the enhancement of low-boom simulations. Chris Babcock and Joe Salamone (Gulfstream Aerosp. Corp., P.O. Box 2206, Savannah, GA 31402)

A procedure is presented to enhance the simulation of measured low booms. Qualitative results show the SASSII, as originally designed, successfully reproduced the realism of full scale N waves. The simulator did not meet the realism level of the full-scale N waves when trying to reproduce the realism of lower amplitude sonic booms referred to as low booms. Data acquisition hardware was upgraded. Time alignment of each driver was performed with a different technique. Equalizer and amplifier programming was modified for each driver to provide a higher signal-to-noise ratio necessary to increase the realism of measured low booms in the simulator. A multipoint equalization was performed with a modified listening area. An iterative method rather than direct method was used to solve for the system of equations generated by the Weiner filtering scheme. The results are evaluated quantitatively by comparing the perceived loudness, A-weighted, and C-weighted sound-exposure levels of the full-fidelity waveform compared with the system output in the listening area.

2pPA7. Prediction and measurement of sonic booms generated by the launch of a Minuteman II missile. Steven D. Pettyjohn (The Acoustcs & Vib.. Group, 5700 Broadway, Sacramento, CA 95820-1852)

The Air Force wanted to launch a Minute II missile full range. Predictions were 15.9 psf of over pressure at the sonic boom focus using similitude based on Saturn 5 data. Since this is at the threshold where single strength glass could break, a decision was made to predict over pressure using a NASA program. This program predicted a level of 16.1 psf over pressure, just 1.3% greater than the original estimate. Confirmation was made by measuring the sonic boom from the launch out of Vandenberg Air Force Base. Seven small boats equipped with sound-activated tape recorders were placed along the flight path with some boats placed at the predicted focus point based on the weather forecast provided by the Air Force. Based on work by A.D. Pierce, two distinct N-wave types were expected. One would represent the path from where the missile first reached sonic speeds and would propagate along a fairly shallow path with

respect to the earth's surface. The second wave type would arrive from a much higher elevation in the flight path and would propagate through many atmospheric layers. Weather forecasts were incorrect, but the results show the two shock wave types.

3:30

2pPA8. Modeling and measurements of nonlinear spherically divergent N waves in air. Vera A. Khokhlova, Mikhail V. Averiyanov, Petr V. Yuldashev (Dept. of Acoust., Faculty of Phys., Moscow State Univ., Moscow 119992, Russia, vera@acs366.phys.msu.ru), Sebastien Ollivier, and Philippe Blanc-Benon (LMFA, Ecole Centrale de Lyon, 69134 Ecully Cedex, France)

Propagation of nonlinear N pulses in relaxing medium was studied experimentally and numerically. An electric spark source was used in laboratory-scale experiments in ambient air to obtain spherically divergent shock pulses of 30-s duration and 1000-Pa peak pressure at 15-cm distance from the source. Pressure waveforms were measured by the broad-

band $\frac{1}{8}$-in. microphone at the distances varying from 15 cm to 2 m from the spark source. A numerical solution was obtained for an initial analytic N waveform at the same distances based on the modified Burger's equation for nonlinear spherical waves in dissipative medium with relaxation. The duration of the initial N wave was defined by matching the zero values of the corresponding analytic measured spectra; the amplitude was obtained by matching the experimental and theoretical nonlinear propaga- tion curves for the N-wave duration. The results of modeling were found to be in good agreement with the experimental data. A frequency response of the microphone was obtained at various distances as a ratio between the measured and modeled spectra and showed a good reproducibility. The relative effects of relaxation, nonlinearity, and microphone filtering on the N-waveform parameters are discussed. [Work is supported by RFBR and INTAS grants.]

2pPP1. Umbo vibration in response to two-tone stimuli measured in human subjects. Diana Turcanu, Ernst Dalhoff, and Anthony W. Gummer (Univ. Tuebingen, HNO-Klinik, Elfriede-Aulhorn-Str. 5, 72076 Tuebingen, Germany)

The aim of these experiments was to noninvasively investigate cochlear mechanics near auditory threshold in human subjects by measuring the vibration response of the umbo. The vibration measurement setup consists of a custom-built laser Doppler vibrometer (LDV), employing a conventional heterodyne interferometer, for which all optical and electronic parts were tailored to the problem of measuring picometer-sized vibrations in the presence of large, extraneous movements in the order of 0.1 mm (e.g., heart beat, breathing, or swallowing). The cubic distortion product (DP) of the otoacoustic emissions (OAEs) in response to sound stimulation with two tones was measured as vibration on the umbo. For stimulus frequencies, f1 and f2, with f2/f1 = 1.2 and f2 = 4–9.5 kHz, and intensities L1 and L2, with L1 = 0.4L2 + 39 dB and L2 = 20–65 dB SPL, the vibration amplitudes were 1–8 pm in subjects ($N = 20$) with hearing loss no more than 25 dB SPL. Application of this vibration technique to a recently proposed method [P. Boege and T. Janssen, J. Acoust. Soc. Am. **111**, 1810–1818 (2002)] of objectively estimating hearing threshold by means of extrapolating DPOAE growth functions showed a standard deviation of the estimate of only 8.6 dB.

2pPP2. Optical imaging of neural activity to vocalized sounds in the guinea-pig auditory cortex. Junsei Horikawa, Takashi Hatta, Shunji Sugimoto (Toyohashi Univ. of Technol., Toyohashi 441-8580, Japan), Yutaka Hosokawa (Ryukyu Univ., Okinawa 903-0215, Japan), and Michinori Kubota (Tokyo Med. & Dental Univ., Tokyo 101-0062, Japan)

Spatiotemporal neural activity in response to vocalized sounds (calls) was investigated in the auditory cortex of anesthetized guinea pigs using an optical imaging technique with a voltage-sensitive dye (RH795). Guinea-pig calls were recorded digitally and presented to the ear from a loudspeaker located contralaterally to the recording cortex. Pure tone (PT), click (CLK), and white noise (WN) stimuli were used for comparison. The response in the primary (AI) and dorsocaudal (DC) fields of the auditory cortex to a PT appeared at the stimulus onset and in the corresponding frequency band, followed by nonsimultaneous lateral inhibition in the adjacent frequency bands. The responses to CLK and WN stimuli appeared in a wide area of the fields corresponding to the wide frequency components of the stimuli. The response to calls changed spatially and temporally because the components' frequencies changed over time. Strong responses occurred in the frequency bands corresponding to prominent instantaneous frequency components. These results suggest that activity to calls in AI and DC fields is formed by spatiotemporal excitatory and inhibitory interactions between the frequency bands responding to instantaneous frequency components in the calls. [Work supported in part by the 21st century COE program ''Intelligent Human Sensing'' from the MESSC, Japan.]

2pPP3. Extraction of sounds' time-frequency features in the auditory cortex. Shunji Sugimoto, Yuuta Suzuki, Hiroyuki Tanaka (Toyohashi Univ. of Technol., Toyohashi 441-8580, Japan, sugimoto@tutkie.tut.ac.jp), Michinori Kubota (Tokyo Med. & Dent. Univ., Tokyo 101-0062, Japan), and Junsei Horikawa (Toyohashi Univ. of Technol., Toyohashi 441-8580, Japan)

Although ''time-frequency feature extraction'' is a fundamental cue that is used to recognize speech sounds, its physiological mechanisms remain largely unknown. This research is aimed at understanding what time-frequency features of sounds are extracted by auditory cortical neurons. We investigated spatiotemporal response patterns in the guinea-pig auditory cortex, using an optical recording method (MiCAM Ultima; Brain Vision) with a voltage-sensitive dye (RH795). Experiments were performed under anesthesia (ketamine, 100 mg/kg, and xylazine, 25 mg/ kg). Pure tones (PTs), frequency-modulated (FM) sounds with various modulation rates, and their combinations were presented to the animals. Cortical activation was induced at the onset and offset of PTs along the

3122   J. Acoust. Soc. Am., Vol. 120, No. 5, Pt. 2, November 2006

Fourth Joint Meeting: ASA and ASJ   **3122**

isofrequency contours. The onset response was followed by strong inhibition. In contrast, FM sounds evoked an additional activation moving across the isofrequency contours in the cortex, with locations corresponding to the instantaneous frequency input of the FM sweep. Such a response became more evident when the FM sweep rate increased. Based on these results, we discuss physiological mechanisms by which sounds with a rapid frequency modulation lead to "time-frequency feature extraction" in cortical neurons. [Work supported in part by the 21st century COE program "Intelligent Human Sensing" from the MESSC, Japan.]

2pPP4. An attempt to measure the hearing thresholds for high-frequency sounds by using the auditory brain-stem response.

Kazumasa Hosokawa (Musashi Inst. of Technol., 1-28-1 Tamatsutsumi, Setagaya-ku, Tokyo, 105-8557 Japan), Kaoru Ashihara (AIST, Tsukuba, Ibaraki, 305-8566 Japan), and Shogo Kiryu (Musashi Inst. of Technol., Setagaya-ku, Tokyo, 105-8557 Japan)

Recently, devices using high-power ultrasounds are increasing. However, influences of high level ultrasounds on human are not fully understood. Psychophysical studies show that the hearing thresholds exceed 80 dB SPL at a frequency above 20 kHz. It is reported that high frequency sounds above 20 kHz affect activities in the human nervous system. In order to examine whether the peripheral auditory system can be activated by high-frequency sounds, an attempt is made to measure the auditory brainstem response (ABR) for the frequency range between 4 and 20 kHz. In preliminary experiments, the ABR was measured for a tone pip with the center frequency of 14 kHz. However, the ABR was not clearly observed above 16 kHz. The thresholds determined by the ABR were approximately 40 dB larger than the psychophysical thresholds. The ABR was evoked by low-frequency components of the tone pip at the high presentation levels.

2pPP5. Distortion product otoacoustic emission fine structure as an early hearing loss predictor.

Karen Reuter and Dorte Hammershøi (Dept. of Acoust., Aalborg Univ., Fredrik Bajers Vej 7, B5, 9220 Aalborg Øst, Denmark, kr@acoustics.aau.dk)

Otoacoustic emissions (OAEs) are a promising method to monitor early noise-induced hearing losses. When distortion product otoacoustic emissions (DPOAEs) are obtained with a high-frequency resolution, a ripple structure across frequency can be seen, called DPOAE fine structure. In this study DPOAE fine structures are obtained from 74 normal-hearing humans using primary levels of L1/L2 = 65/45 dB. The subjects belong to groups with different ages and exposure histories. A classification algorithm is developed, which quantifies the fine structure by the parameter's ripple place, ripple width, ripple height, and ripple prevalence. Temporary changes of the DPOAE fine structure are analyzed by measuring DPOAE both before and after exposing some of the subjects to an intense sound. The characteristic patterns of fine structure can be found in the DPOAE of all subjects, though they are individual and vary from subject to subject within groups. The results do not indicate that the DPOAE fine structure alters with the state of hearing, as it is suggested in the literature. The data analysis is still in process at this stage.

2pPP6. The behavior of the distortion product otoacoustic emissions in response to contralateral stimulation by stationary and nonstationary signals.

Olimpia Szczepaniak (Div. of Rm. Acoust. and Psychoacoustics, Adam Mickiewicz Univ., Umultowska 85, 61-614 Poznan, Poland, oli0809@interia.pl)

The main aim of the study was to determine the DPOAE of the cochlea in the case of contralateral stimulation by stationary and nonstationary signals. The analysis was performed for $3f_1 - 2f_2$, $2f_1 - f_2$, $2f_2 - f_1$ intermodulation distortion products on a group of 20 normal hearing subjects (NH) and ten patients with low UCL (uncomfortable loudness level). The optimized primary tone level setting ($L_1 = 0.4L_2 + 39$ dB) was used. Each NH subject was characterized by the I/O function of otoacoustic emission (40–90 dB SPL) and dp-grams for the three levels of two-tone (85/75, 75/65, and 65/55 dB SPL) for frequencies between 1 and 12 kHz. Parameters for subjects with UCL were individually selected. The suppression of otoacoustic distortion products and the intergroup correlation of the slopes of I/O function with various contralateral stimulators were discussed. Results obtained from the experiment were compared between the two groups studied.

2pPP7. A functional MRI study on auditory feedback control of pitch.

Akira Toyomura (RIES, Hokkaido Univ., Sapporo 060-0812 Japan /JST, toyomu@es.hokudai.ac.jp), Sachiko Koyama, Tamaki Miyamoto, Atsushi Terao (Hokkaido Univ., Sapporo 060-0812, Japan), Takashi Omori (Tamagawa Univ., Tamagawa 194-8610, Japan), Harumitsu Murohashi, and Shinya Kuriki (Hokkaido Univ., Sapporo 060-0812, Japan)

Perception of one's own speech plays an important role in fluent speech production. In this study, we conducted a functional magnetic resonance imaging (fMRI) experiment to delineate the neural mechanism for auditory feedback control of pitch, using a transformed auditory feedback (TAF) method. Subjects ($n = 12$, right handed) were required to vocalize /a/ for 5 s while hearing their voice through a headphone. In the TAF condition, the feedback voice pitch was shifted randomly up or down from the original pitch two or three times. The subjects were required to hold the pitch of the feedback voice constant by changing the pitch of the original voice. In the non-TAF condition, the pitch of feedback voice was not modulated and the subjects merely vocalized /a/ continuously. A contrast between TAF and non-TAF conditions showed some significantly greater activations in the TAF condition ($p < 0.05$ corrected). In the right hemisphere, the supramarginal gyrus, the prefrontal area, the anterior insula, and the superior temporal gyrus showed greater activation. In the left hemisphere, only the premotor area showed greater activation. This result suggests that auditory feedback of pitch is controlled mainly by the right hemispheric network. [Work supported by JST.]

2pPP8. Mechanisms of bone-conducted ultrasonic perception assessed by electrophysiological measurements in human.

Seiji Nakagawa (Natl. Inst. of Adv. Industrial Sci. and Technol. (AIST), 1-8-31 Midorigaoka, Ikeda, Osaka 563-8577, Japan, s-nakagawa@aist.go.jp) and Aya Nakagawa (Natl. Inst. of Adv. Industrial Sci. and Technol. (AIST)/ Suita Municipal Hospital, Osaka, Japan)

Several studies have reported that bone-conducted ultrasound (BCU) is perceived even by the profoundly sensorineural deaf; however, the mechanisms involved remain unclear. We previously reported some unique characteristics of BCU perception: (1) the pitch of BCU is about ten-odd kHz and is independent of its frequency, (2) the dynamic range of BCU is narrow, less than 20 dB, and (3) BCU mask 10–15-kHz air-conducted sounds. In this study, cortical magnetic field (N1m), middle latency (MLRs) and auditory brainstem responses (ABRs) and electrocochleogram (EcochG) evoked by BCU in human were recorded to clarify the neural pathway for BCU. Substantial MLRs and ABRs (wave-I–V) were evoked by BCU as well as by air-conducted sound. Although a clear N1m response was elicited by BCU and its equivalent current dipoles (ECDs) were estimated in the auditory cortices, ECD locations for BCU did not follow the tonotopic organization at the cortical level. Both wave I of ABRs and AP of EcochG were observed clearly, indicating that the auditory nerve was substantially activated. These results suggest that BCU goes through the normal auditory pathway—there are no special organs for BCU perception; however, unique processes may exist in the cochlea.

2pPP9. Interaction between the tonotopic and periodic information in recognition of "melodic" contours. Toshie Matsui, Chihiro Takeshima (Kyoto City Univ. of Arts, Grad. School of Music, 13-6, Kutsukake-cho, Oe, Nishikyo-ku, Kyoto 610-1197, Japan, m04905@kcua.ac.jp), and Minoru Tsuzaki (Kyoto City Univ. of Arts, Kyoto 610-1197, Japan)

It is known that the tonotopic and periodic aspects of sounds are separated in the auditory sense. To investigate the manner of representing these two aspects, a psychological experiment was designed. The stimuli are sequences of vowels, each of which changes its fundamental frequency and "size," i.e., the centroid of its formants, using a STRAIGHT vocoder. Participants are asked to respond if the transient patterns of the stimuli are "clockwise" or "counterclockwise" in a two-dimensional space, one of whose coordinates is the periodicity and the other of which is the size. Results indicate that the judgment was not so easy as in the case in which one would judge the transition patterns of points in a two-dimensional visual space. This inference implies that the two attributes might be represented as values on two completely independent scales, but not like the values in two coordinates of a single point.

2pPP10. A preliminary study of construction of a musical mood scale. Junko Matsumoto (Nagano College of Nursing, 1694, Akaho, Komagane, Nagano, 399-4117, Japan, matsumoto@nagano-nurs.ac.jp)

In this study to construct a mood scale that was specific to listening to music, appropriate items were selected preliminarily. Three hundred three university students were presented 70 adjectives by a questionnaire and asked to rate how frequent they feel each mood after listening to music in their daily lives on a four-point scale. A factor analysis were completed on the mood items and yielded five factors indicating suffering, comfortableness, solemnness and aggression, calmness, and sadness, respectively. Items with high loading on these factors were selected to construct a musical mood scale and any of them were modified because they might have an obscure meaning.

2pPP11. Sensitivity analysis to evaluate the benefits and risks of using prior information in adaptive psychometric procedures. Jeremiah Remus and Leslie Collins (Dept. of Elec. and Comput. Eng., Duke Univ., Box 90291, Durham, NC 27708)

Numerous adaptive psychometric procedures have been developed based on a Bayesian framework. In these procedures, a key component for estimating the targeted parameter and determining the next stimulus value is the parameter probability distribution. The presence of a parameter probability distribution introduces the opportunity to include prior information via initialization of the parameter probabilities. However, differences in the techniques for parameter estimation and stimulus selection may determine how various psychometric procedures benefit from accurate prior information or recover from inaccurate prior information. In this study, several adaptive psychometric procedures using a Bayesian framework were investigated through simulation of a psychophysical task. The simulations included prior information with varying degrees of accuracy and varying levels of initial confidence. Results suggest that the benefits of prior information are dependent on the specific psychometric procedure and the inclusion of prior information may influence the final choice of an appropriate psychometric procedure.

2pPP12. Observed variability in d' for yes-no and two-interval forced choice procedures. Walt Jesteadt, Lori Leibold, Samar Khaddam, Jessica Messersmith, and Melissa Krivohlavek (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

The sampling distribution of d' estimates can be determined from knowledge of the true d' and the number of trials per estimate [J. Miller, Percept. Psychophys. **58**, 65–72 (1996)]. Five subjects were tested in a fixed-level intensity discrimination task to obtain estimates of the observed variance of d' for both the yes-no and two-interval forced-choice (2IFC) procedures over a wide range of d' values. The stimuli were 2-kHz sinusoids, 300 ms in duration with 10-ms ramps, with differences in intensity ranging from 0.1 to 4.9 dB, centered on 70 dB SPL. An estimate of d' was computed for each of ten 100-trial blocks at each intensity difference for each procedure. Psychometric functions, based on 14 000 trials per function, were well fitted using intensity differences expressed in units of ΔL and were steeper for 2IFC than for yes-no. The variance of d' estimates exceeded the variance of the sampling distribution by a factor of 2.1 for yes-no and a factor of 3.1 for 2IFC, with learning effects contributing to the additional variance in some subjects. For a given value of d', the variance of d' estimates was approximately equal in yes-no and 2IFC. [Work supported by NIH/NIDCD.]

2pPP13. Neural correlates of psychometric functions for auditory detection. Huanping Dai (Div. of Commun. Disord., College of Health Sci., Univ. of Wyoming, Laramie, WY 82071)

The psychometric function in a 2IFC task, which describes the relation between the percentage of correct responses (pc) and the signal strength (x), can be expressed using the Gaussian probability function (ϕ) with a threshold (α) and a slope (β) parameter, $pc = \phi[(x/\alpha)^{\beta}/2^{1/2}]$. For auditory detection, the psychometric functions exhibited a wide range of slopes in different conditions, such as tone in noise [$\beta \approx 1$, D. M. Green, M. J. McKey, and J. C. R. Licklider, J. Acoust. Soc. Am. **31**, 1446–1452 (1959)] and tone in quiet [$\beta \approx 2$, C. S. Watson, J. R. Franks, and D. C. Hood, J. Acoust. Soc. Am. **52**, 633–643 (1972)] by listeners with acoustic hearing, and detection by listeners with electrical hearing [$\beta_{max} \approx 10$, G. S. Donaldson, N. F. Viemeister, and D. A. Nelson, J. Acoust. Soc. Am. **101**, 3706–3721 (1997)]. To understand the mechanisms underlying the change in the slope of the psychometric function, the performance of a neural detector engaged in the same tasks as the listeners was analyzed, and the neural correlates of the psychometric function, the neurometric function, was derived. Under the assumption that the detection was based on spike counts of the neuron(s) tuned to the signal frequency, the derived neurometric function showed slope values in good agreement with those obtained from the listeners.

2pPP14. Perceptual organization in loudness enhancement and decrement. Deborah A. Fantini (Dept. of Psych., Univ. of Essex, Wivenhoe Park, Colchester, CO4 3SQ, England) and Christopher J. Plack (Lancaster Univ., Lancaster, LA1 4YF, England)

Loudness enhancement is an increase in the loudness of a target tone that occurs when a more intense inducer tone either precedes or follows the target. Loudness decrement is a similar effect in the opposite direction. The present work investigates the role of perceptual organization in this paradigm by employing a capture tone presented simultaneously with the inducer. In a pair of experiments, the inducer, target, and comparison tone were always 1 kHz. The capture tone, when present, was either 2.0 or 0.5 kHz (an octave above or below the target). A 10-ms inducer tone immediately preceded a 10-ms target, with a 10-ms comparison tone presented 850 ms later. Listeners were instructed to ignore the inducer and to judge whether the target or comparison tone was louder. Equal-loudness matches were estimated using two randomly interleaved adaptive tracks, one converging on the just-louder threshold and the other on the just-quieter threshold. Results from both enhancement and decrement experiments indicate that the addition of a capture tone significantly reduces the magnitude of the effect, however it does not eliminate the effect completely. These findings indicate that perceptual organization does play a role in the effects of an inducer tone on loudness judgments.

2pPP15. Determining the area of the sweet spot in a surround loudspeaker setup for various microphone techniques. Nils Peters (Music Technol. Area, Schulich School of Music, McGill Univ., 555 Sherbrooke St. West, Montreal, PQ H3A 1E3, Canada, nils.peters@mcgill.ca) and Jonas Braasch (Rensselaer Polytechnic Inst., Troy, NY 12180-3590)

Several types of microphone techniques exist to record music performances for surround-sound reproduction. Variations between different techniques are found in the distance and angle between the microphones, and the choice of directivity patterns. All the arrays are targeted to produce an accurate spatial impression at the sweet spot. The aim of this investigation is to determine how different microphone techniques affect the size of the sweet spot, the area in which the spatial cues are reproduced with sufficient accuracy. In particular, the common belief that spaced techniques lead to larger sweet-spot areas than coincidence and near-coincident techniques is investigated. For this purpose, impulse responses (IR) of different microphone arrays are measured in a concert hall. Afterwards, test sounds are convolved with the measured IRs and presented through a surround loudspeaker setup in a control room. A dummy head is used to record the reproduced sound fields at different positions inside the listening area. In a psychoacoustic experiment, listeners are asked to rate the different recordings according to the spatial impression provided by different recording techniques. The results of the listening test will be presented and compared to signal analyzes of a binaural model.

2pPP16. Perceptual dimensions of impulsive-source active sonar echoes. Jason E. Summers, Derek Brock, Brian McClimens, Charles F. Gaumond, and Ralph N. Baer (Naval Res. Lab., Washington, DC 20375-5350)

Recent findings [J. Pitton *et al.*, J. Acoust. Soc. Am. **119**, 3395(A) (2006)] have joined anecdotal evidence to suggest that human listeners are able to discriminate target from clutter in cases for which automatic classifiers fail. To uncover the dimensions of the perceptual space in which listeners perform classification, a multidimensional scaling (MDS) experiment was performed. Subjects rated the aural similarity between ordered pairs of stimuli drawn from a set of 100 operationally measured sonar signals, comprising 50 target echoes and 50 false-alarm clutter echoes. Experimental controls were employed to evaluate consistency in judgments within and between subjects. To ensure that dimensions were discovered rather than imposed [Allen and Scollie, J. Acoust. Soc. Am. **112**, 211–218 (2002)], subjects were neither trained in classification nor made aware of the underlying two-class structure of the signal set. While training improves classification performance, prior work suggests that both expert and nave listeners use the same perceptual space [R. Mackie *et al.*, ONR Tech. Rep. 2723-1, NR 197-060/4-18-79 (1981)]. Results of the MDS study are presented, including an evaluation of the number of perceptual dimensions and their interpretation in terms of perceptual and physical attributes of the signals. [Work supported by ONR.]

2pPP17. Remote psychoacoustic testing using the Internet. Alastair C. Disley, David M. Howard, and Andrew D. Hunt (Dept. of Electron., Univ. of York, Heslington, York, YO10 5DD, UK)

A number of recent listening tests by the authors and others have begun to use the Internet as a medium for remotely conducting psychoacoustic listening tests. While this offers a solution to the problem of gathering enough highly trained listeners in one geographic location, it results in a reduction in control of factors such as the listener's immediate environment. A recent experiment by the authors [A. C. Disley, *et al.*, "Spectral correlations of timbral adjectives used by musicians," J. Acoust. Soc. Am. **119**, 3333 abstract only (2006)] offered the opportunity to examine and quantify the effect of remote testing via the Internet. Twenty four listeners took an Internet-based listening test on ten separate occasions, alternating between a controlled environment and an uncontrolled environment. Listeners were given instructions about their uncontrolled listening environments, and data subsequently collected demonstrate good but

not universal compliance with those instructions. Comparison of experimental results between the different test environments shows very little difference, with a slight reduction in the controlled environment to the listeners' self-assessed confidence in their judgments. The techniques, advantages, and disadvantages of the Internet as a medium for remote psychoacoustic testing are discussed.

2pPP18. +Gz acceleration modifies low-frequency perception. Patrick M. B. Sandor, Lionel Pellieux (IMASSA-SC, F91223, Bretigny-sur-Orge, France), and Christophe Dehlinger (LEGTP Stanislas, F67160 Wissembourg, France)

Hypergravity is associated with maneuvering acceleration (+Gz) in fighter aircraft and can be simulated in a human centrifuge, two noisy environments where classical audiometric data in silence cannot be obtained. Yet under +4-Gz acceleration, with masking noise, the hearing threshold just superior to the masking noise upper limit frequency was reported to be slightly reduced and therefore hearing paradoxically enhanced [Sandor *et al.*, Aviat. Space Environ. Med. **75**, 9525 (2004)]. It was analyzed as an indirect evidence of attenuation of low-frequency perception in relation with the shape of the masking noise and the alteration of associated upwards spread of masking effect. A pressure modification in cochlea was supposed to occur under +Gz, due to transmission of intracranial pressure through the cochlear duct, as observed in a clinical case [Portier *et al.*, Ann. Otol. Rhinol. Laryngol. **111**, 817–820 (2002)]. We developed a finite element model of cochlear mechanics revealing a shape modification of the apical side of cochlea under the pressure modification compatible with +4-Gz acceleration. Manoussaki and colleagues [Phys. Rev. Lett. **96**(8), 088701 (2006)] emphasize the role of cochlea curvature in low frequency perception. Our experimental and computational results reinforce this role of cochlea curvature in low frequency perception.

2pPP19. Predictors of auditory performance in hearing-aid users: The role of cognitive function and auditory lifestyle. Martin D. Vestergaard[a] (Ørsted-DTU Acoust. Technol., Tech. Univ. of Denmark, DK-2800 Lyngby, and Res. Ctr. Eriksholm, Kongevejen 243, DK-3070 Snekkersten)

Within clinical audiology, it is often observed that patients who are expected to perform the same differ in auditory performance. Hearing-aid users may be dissatisfied with their instruments while they score satisfactorily in objective tests, or they may be satisfied with their instruments while no objective benefit can be measured. It has been suggested that lack of agreement between various hearing-aid outcome components can be explained by individual differences in cognitive function and auditory lifestyle. We measured speech identification, self-report outcome, spectral and temporal resolution of hearing, cognitive skills, and auditory lifestyle in 25 new hearing-aid users. The purpose was to assess the predictive power of the nonauditory measures while looking at the relationships between measures from various auditory-performance domains. The results showed that only moderate correlation exists between objective and subjective hearing-aid outcome. Different self-report outcome measures showed a different amount of correlation with objective auditory performance. Cognitive skills were found to play a role in explaining speech performance and spectral and temporal abilities, and auditory lifestyle was correlated with self-report outcome. However, overall the predictive leverage of the various measures was moderate, with single predictors explaining only up to 19 percent of the variance in the auditory-performance measures. [a] Now at CNBH, Department of Physiology, Development and Neuroscience, University of Cambridge, UK.

2pPP20. Perception and production of virtual pitch by absolute-pitch musicians. I-Hui Hsieh and Kourosh Saberi (Dept. of Cognit. Sci., Univ. of California at Irvine., Irvine, CA 92697, ihsieh@uci.edu)

The ability of absolute pitch (AP) and control (non-AP) musicians to identify and produce musical pitch from long-term memory was investigated in three experiments. In experiment 1, subjects identified the pitch of either a missing-fundamental complex or a highpass-filtered piano note. Unlike control subjects, AP subjects were highly accurate (¿85%) in identifying virtual pitch even when cues were restricted to the 4th and 5th harmonics. In a second experiment, subjects produced, within 3 s, the pitch of a randomly selected musical note without an external acoustic reference through either (1) adjusting a octave-range slider or (2) voicing/singing the target note. AP subjects, but not controls, were highly accurate (0.3 semitone) in the adjustment task. However, both AP and non-AP subjects were extremely accurate (i.e., SD=0.97, 0.90 semitone error, respectively) in voicing the required pitches as determined from FFTs of the recorded voiced notes. In experiment 3, subjects identified pitch of solfeggio syllables at mismatched note frequencies, created by altering the sampling rate of digitally recorded voiced labels. Identification accuracy by AP subjects declined to 65%, supporting a cognitive/linguistic interference model. Implications of these findings for models of absolute pitch encoding will be discussed. [Work supported by NSF.]

2pPP21. Pitch estimation of bone-conducted ultrasound. Kazuhito Ito and Seiji Nakagawa (Natl. Inst. of Adv. Industrial Sci. and Technol., 1-8-31 Midorigaoka, Ikeda, Osaka 563-8577, Japan, keith.ito@aist.go.jp)

Although ultrasound is perceptible through bone conduction, its perception mechanism has been clarified only slightly. The subjective pitch of bone-conducted ultrasound (BCU) sounds like a tone or harmonic sound of ten-odd kilohertz, independent of its own frequency. It has been difficult to determine the frequency of the pitch precisely because the pitch varies among listeners and with the position and strength of BCU stimulation, moreover; BCU hearing is not masked well by air-conducted (AC) band-pass noise. In this study, the BCU pitch-perception mechanism was investigated using beats with AC tones. The AC tones of 10–17 kHz, for which the presence of the pitch of BCU had been expected, were presented sequentially together with BCU (30 kHz) stimulation. Listeners were asked whether or not they were able to hear beats. For comparison, bone-conducted (BC) harmonic sounds of audible frequency components (e.g., 11–16 kHz, 1-kHz step) were also investigated. Results showed that no beat was heard between the AC tones and the BCU, whereas beats between the AC tones and the BC harmonic sounds were heard, suggesting the possibility that the pitch-perception mechanism of BCU is different from those of AC and BC sounds in this audible frequency area.

2pPP22. Off-frequency listening in a pitch matching experiment. Veronica Eckstein and Bruce G. Berg (Dept. of Cognit. Sci., Univ. of California Irvine, 3151 Social Sci. Plaza, Irvine, CA 92697)

A pitch-matching paradigm was used to investigate the pitch of three-tone complexes. For different conditions, the central tone was 200, 1000, or 2000 Hz with the side tones spaced by either 30 or 45 Hz. The tones were of equal intensity or a signal was added in phase to the central tone with a level of 5, 0, or 5 dB relative to the side tones. Listeners adjusted the frequency of a pure tone to match the pitch of the complex. According to a model known as the envelope weighted average of the instantaneous frequency (EWAIF) [L. Feth, Percept. Psychophys. **15**, 375–378 (1974)], the pitch should be approximately equal to the center frequency for all conditions. Contrary to this prediction, increasing the bandwidth or decreasing the signal level systematically lowered the pitch. However, the results are consistent with EWAIF calculations if the stimuli are first passed through the skirt of an auditory filter. This method may provide an alternative technique for estimating the filtering properties of the auditory system. [Work supported by Center for Hearing Research, UCI.]

2pPP23. Sample discrimination of frequency differences with ipsilateral and contralateral distracters. Donna L. Neff, Walt Jesteadt, and Lori J. Leibold (Boys Town Natl. Res. Hospital, 555 N 30th St., Omaha, NE 68131)

This experiment examined the effect of ipsilateral and contralateral tonal distracters on sample discrimination of frequency differences. In the 2AFC baseline task, four listeners indicated which of two intervals, each containing a two-tone target complex, was higher in pitch. The pairs of target tones were drawn from Gaussian frequency distributions centered at low-, middle-, and high-frequency regions. Two distracter tones were then added, one from each of the two nontarget frequency regions (e.g., low targets, middle and high distracters). Distracter tones were either randomly drawn from a Gaussian frequency distribution or fixed in frequency at the mean of the distribution. Across conditions, targets were in the left or right ears, with distracters in the ipsilateral or contralateral ear. There was little effect of target ear or effect of adding fixed-frequency distracters in either ear. Effects of random-frequency distracters varied across subjects and frequency regions, with both ipsilateral and contralateral distracters showing large effects for some subjects and conditions. Distracters were least effective with middle-frequency targets. The ability to use the ear as a channel appears to depend on both the relative variability and relative frequency regions of the targets compared to the distracters. [Work supported by NIDCD.]

2pPP24. Dynamic center of gravity effects: Matching virtual frequency glides. Evelyn M. Hoglund, Lawrence L. Feth (Dept. of Speech and Hearing Sci., The Ohio State Univ., Columbus, OH 43210), and Ashok K. Krishnamurthy (The Ohio State Univ., Columbus, OH 43210)

Lublinskaja (1996) demonstrated that changing the amplitudes of two-resonance Russian vowels over time leads listeners to hear a glidelike transition that follows the dynamic center of gravity (COG). Ananthara-man (1998) investigated COG transitions for sinusoidal signals by asking subjects to match frequency-modulated (FM) to virtual frequency (VF) glides. The amplitudes of two tones were simultaneously modulated to produce a percept of a glide with rising pitch, similar to that of an FM sweep, although the frequencies remained fixed. However, listeners might perform Anantharaman's task by simply attending to the location of one of the anchor tones without perceiving the virtual glide, as the frequencies of the two component tones were changed to alter the frequency span of the VF glide. This study modified that work by fixing the anchor frequencies, but confirmed the potential for procedural artifacts. Two additional experiments eliminated FM signals altogether and asked listeners to match VF glides to VF glides. Even with anchor frequency roving, subjects were able to match the VF glide trajectories for frequency separations up to 6 to 8 ERB. Results were compared with predictions from the perceptual spectral centroid model. [Research supported by a grant from NIH/NIDCD R01-DC006879.]

2pPP25. Spectrotemporal structure influences spatial release from informational masking in reverberant settings. Erol Ozmeral, Priyanka Zutshi, Virginia Best, and Barbara Shinn-Cunningham (Dept. of Cognit. and Neural Systems, Boston Univ., 677 Beacon St., Boston, MA 02215, ozmeral@cns.bu.edu)

Spatial separation between target and masking sources improves target identification due to both changes in energy (acoustic benefit) and the ability to focus attention on the target (spatial benefit). Studies of speech intelligibility show that while acoustic benefits are reduced by reverberation, spatial benefits remain robust [Kidd *et al.*, Acustica **114**, 526–536 (2005)]. The current study extends a previous study of nonspeech communication calls [birdsong; Best *et al.*, J. Acoust. Soc. Am **118**, 3766–3773 (2005)] to explore whether, like speech, the spatial benefit for these signals is robust in reverberation. It was found, however, that reverberation decreased both acoustic and spatial benefits for birdsong identification. To examine whether the decrease in the spatial benefit was due to spectrotem-

poral differences between speech and birdsong, songs were slowed down to half the original rate (making them more similar to speech). For these songs, the spatial benefit was preserved in reverberation. These results suggest that spatial benefits in reverberation are less effective for rapidly fluctuating signals, presumably because reverberation smears their temporal structure, impairing segregation of competing syllables. Thus, the relatively slow fluctuations in speech may be important for its resilience to interference from other talkers in reverberant environments. [Work support by Grants AFOSR-FA9550-04-1-0260 and NIDCD (P30) DC04663.]

2pPP26. Effect of number of masking talkers on masking of Chinese speech.

Xihong Wu, Jing Chen, Zhigang Yang, and Liang Li (Speech and Hearing Res. Ctr., Peking Univ., Beijing, China, 100871, wxh@cis.pku.edu.cn)

In this study, speech targets were nonsense sentences spoken by a Chinese female, and speech maskers were nonsense sentences spoken by other one, two, three, or four Chinese females. All stimuli were presented by two spatially separated loudspeakers. Using the precedence effect, manipulation of the delay between the two loudspeakers for the masker determined whether the target and masker were perceived as coming from the same or different locations. The results show that the one-talker masker produced the lowest masking effect on Chinese speech. When the number of masking talkers increased progressively to 2, 3, and 4, even though informational masking progressively decreased, energetic masking progressively increased, leading to an increased total masking effect on targets. A new form of calculation of the speech intelligibility index confirmed an increase of energetic masking as the masking-talker number increased, even when the long-term average signal-to-noise ratio was unchanged. Some differences between Chinese speech masking and English speech masking were revealed by this study. [Work supported by China NSF and Canadian IHR.]

2pPP27. The role of fundamental frequency and target segregation in the presence of same-band and different-band maskers.

Nandini Iyer, Douglas Brungart, and Brian Simpson (Air Force Res. Lab., 2610 Seventh St., Bldg 441, Area B, WPAFB, OH 45431, nandini.iyer@wpafb.af.mil)

A number of recent studies on multitalker speech perception have been based on envelope-modulated, sine-wave-excited speech similar to the kind used to simulate the processing used in cochlear implants. Although these modulated sine-band signals are highly intelligible in isolation, they are typically much harder to segregate in multitalker listening tasks than normal speech. In this experiment, we examined the extent to which the difficulty in segregating these signals could be attributed to the absence of the fundamental frequency $F0$ that is present in natural speech. Psychometric functions were measured with speech and noise maskers for three types of signals: (1) natural speech; (2) sine-excited cochlear implant speech (CIS); and (3) $F0$-excited CIS, which was generated in the same way as the CIS but with a simulated glottal pulse train as an excitation source. The results show that performance was better with the $F0$-excited CIS than with the sine-excited CIS in all conditions, including those where the target and masking talkers overlapped in frequency. Performance was also generally better when the $F0$-excited CIS was generated with $F0$ values from different-sex rather than same-sex talkers. The results confirm the importance of $F0$ cues in the segregation of competing speech signals.

2pPP28. Effect of peripheral interference and attentional loss on divided listening to multiple simultaneous talkers.

Takayuki Kawashima (Dept. of Cognit. and Behavioral Sci., Univ. of Tokyo, 3-8-1 Komaba, Meguro-ku, Tokyo, 153-8902 Japan, ckawa@mail.ecc.u-tokyo.ac.jp) and Takao Sato (Univ. of Tokyo, Bunkyo-ku, Tokyo, 113-0033 Japan)

Effects of two factors, peripheral interference (masking) and attentional loss, that may impose restriction on divided listening were investigated using Japanese words. In each trial in the divided listening task, simultaneous multiple voices were presented first, then followed by a target voice produced by one speaker. Participants reported whether the target was included in the multiple voices or not. When the number of talkers (manipulated from one to six) was more than three, the estimated hit ratio was lower than unity, and decreased monotonically as the number of talkers increased. To investigate factors inducing the decrement, participants were also tested when the target was presented before the multiple voices. In this condition, decrement of the performance as a function of the number of talkers was gradual, compared to that in the divided listening condition. Decrement of the performance in the pretarget condition was thought to come mainly from peripheral interference, and the difference between the two tested conditions was interpreted as representing the cost in dividing attention. The result suggests that failure in divided listening to three or four talkers largely comes from the attentional factor, although the role of peripheral interference becomes larger when there are more talkers.

2pPP29. Change deafness and how the auditory system organizes sounds.

Melissa K. Gregg and Arthur G. Samuel (Dept. of Psych., State Univ. of New York, Stony Brook, Stony Brook, NY 11794-2500, mgregg@ic.sunysb.edu)

Change blindness, or the failure to detect changes to a visual scene that seem blatantly obvious after the fact, has been demonstrated in a variety of different situations. Exploration of auditory failures to detect change has been far less studied, even though demonstrations of change deafness could have important theoretical implications. Four experiments were conducted to explore the processes involved in change deafness by measuring explicit change detection as well as auditory object encoding of natural auditory scenes. Considerable change deafness occurred, even though auditory objects were encoded quite well. Change detection performance was better when stimuli were not presented at distinct spatial locations (experiment 1) than when they were presented with spatial cues (experiment 2). Familiarity with the objects did not affect detection or recognition performance. In order to establish an effective cue for auditory detection and recognition, performance was assessed when auditory stimuli were presented in distinct regions of perceptual space based on fundamental frequency and harmonicity (experiments 3 and 4). Implications for the mechanisms responsible for change deafness and auditory sound organization are discussed.

2pPP30. Sensitivity to increments analyzed separately for each level in a roving paradigm.

Anne-Marie Bonnel and Ervin Hafter (Dept of Psych., Univ. of California at Berkeley, 3210 Tolman Hall, Berkeley, CA 94720-1650)

Studies of level discrimination using a dual-task paradigm have shown no cost of shared attention when levels were roved, so that comparisons between targets and standards were in sensory-trace memory, but clear evidence of a cost when levels were fixed, and comparisons seemed based on context-coded memory. Interest in the effects of these two types of memory led here to an auditory single-task in which a trial consisted of a standard tone set to level (I), followed by a target that was (I) alone or (I+ΔI). Durations were 50 or 200 ms; standards ranged from 50 to 70 dB SPL. In line with the view that the near miss to Weber's Law is negligible over this range, fixed standards provided constant thresholds (log ΔI/I). As typical, overall performance was reduced by roving, but a surprising result was that the magnitude of this loss depended on (I). Thus, roving had the least effect with the highest value of (I); then thresholds rose steeply as (I) was reduced. Independent of this slope, a wider range of roving produced a greater overall loss. This is discussed in terms of an additive noise, possibly connected to the use of trace memory.

2pPP31. Factors influencing the auditory and cross-modal attentional blink. Adelbert W. Bronkhorst, Marieke van der Hoeven (TNO Human Factors, Kampweg 5, 3769 DE Soesterberg, The Netherlands, adelbert.bronkhorst@tno.nl), Jan Theeuwes, Erik van der Burg, and Thomas Koelewijn (Vrije Univ., 1081 BT Amsterdam, The Netherlands)

When an observer has to report two targets (T1 and T2) embedded in a stream of distracters, an attentional blink can occur. This is the degradation in performance for T2 when T1 and T2 are presented sufficiently close in time (within about 500 ms). The attentional blink paradigm has been extensively used within the visual domain as a tool to study bottlenecks in the processing of sensory information. Several studies have shown that an attentional blink can also occur during auditory or cross-modal presentation. However, these blinks are smaller and more stimulus dependent than visual blinks. In our research we have found a robust blink when T1 and T2 are tones embedded in distracters tones, but no blink when T2 is replaced by a visually presented letter among different distractor letters. The cross-modal blink is also absent when both T1 and T2 are digits. We do find a clear cross-modal blink when a visual T1 with increased difficulty (three letters or a word) is combined with a T2 consisting of a spoken letter. Our results indicate that there are modality-specific as well as amodal bottlenecks and that the latter occur when stimuli are processed on a verbal or semantic level.

2pPP32. Reproducible maskers reveal similar mechanisms predicting multiple-burst-same and multiple-burst-different informational masking conditions. Robert H. Gilkey (Wright State Univ., Dayton, OH 45435), Christine R. Mason, and Gerald Kidd, Jr. (Boston Univ., Boston, MA 02215)

Gilkey, Mason, and Kidd [J. Acoust. Soc. Am. **109**, 2468 (2001)] found that although informational masking has typically been thought to depend more strongly on the variability in the ensemble of masking stimuli presented across trials, trial-by-trial performance was strongly related to the specific masker waveform presented on each trial. Moreover, hit and false-alarm rates to individual masker stimuli under multiple-burst-same (MBS) conditions were well predicted by the patterns of energy in those stimuli. Hit and false-alarm rates under the multiple-burst-different (MBD) condition were more difficult to predict. This paper reports on further efforts to model those data. The results indicate that performance under both MBS and MBD conditions can be predicted using a linear combination of envelope statistics computed from seven narrow frequency bands surrounding the 1000-Hz signal frequency. MBS responses are related to the average height of the envelope in these bands and MBD responses are related to the standard deviations of the envelopes. [Work supported by NIH/NIDCD.]

2pPP33. The application of the equal energy hypothesis (EEH) to interrupted, intermittent, and time-varying non-Gaussian noise exposures. Roger P. Hamernik, Wei Qiu, and Robert I. Davis (Auditory Res. Lab., State Univ. of New York at Plattsburgh, 101 Broad St., Plattsburgh, NY 12901)

Industrial data and animal research show that non-Gaussian (nonG) noise exposures are more hazardous to hearing than energy equivalent Gaussian (G) exposures. A statistical metric, kurtosis $[b(t)]$, was shown to order the severity of noise-induced trauma following a nonG exposure relative to an energy and spectrally equivalent G exposure. Four groups of chinchillas were exposed to one of four different nonG interrupted, intermittent, and time-varying (IITV) noise paradigms over 19 days at an Leq= 103 dB(A) SPL, with $b(t)$= 25 or 50. Each daily exposure consisted of two 4.25-h periods with an hour break. Each 4.25-h exposure was interrupted for 15 min and each 5-day sequence was separated by a 2-day break. Each daily IITV exposure followed one of two different SPL temporal patterns that varied between 90 and 108 dB(A). All IITV exposures produced a toughening effect that did not alter the degree of noise-induced trauma. NonG noise produced as much trauma as a G exposure at 110 dB.

Despite very different temporal paterrns for the $b(t)$= 50 exposures, trauma was the same. Thus within a common class [i.e., the same Leq and $b(t)$] of nonG, IITV exposure, the EEH may apply. [Work supported by NIOSH.]

2pPP34. The application of statistical learning models to the prediction of noise-induced hearing loss. Wei Qiu, Jun Ye, and Roger P. Hamernik (Auditory Res. Lab., State Univ. of New York at Plattsburgh, 101 Broad St., Plattsburgh, NY 12901)

Three powerful nonlinear statistical algorithms [a support vector machine (SVM), radial basis function network (RBFN), and regression tree] were used to build prediction models for noise-induced hearing loss (NIHL). The models were developed from an animal (chinchilla) database consisting of 322 animals exposed to 30 Gaussian and non-Gaussian noise conditions. The inputs for the models were either energy or energy plus kurtosis. The models predict inner hair cell (IHC) loss, outer hair cell (OHC) loss, and postexposure threshold shift (PTS) at 0.5, 1, 2, 4, and 8 kHz. The models incorporating both energy and kurtosis improved the prediction performance significantly. The average performance improvement for the prediction of IHC loss was as much as 55%, for OHC loss it was 66% and for PTS, 61%. The prediction accuracy of SVM and RBFN with energy plus kurtosis for all three outputs (predictions) was more than 90% while for the regression tree model it was more than 85%. Energy is not a sufficient metric to predict hearing trauma from complex (non-Gaussian) noise exposure. A kurtosis metric may be necessary for the prediction of NIHL. [Research supported by NIOSH.]

2pPP35. The development of models for the prediction of noise-induced hearing loss. Wei Qiu, Jun Ye, and Roger P. Hamernik (Auditory Res. Lab., State Univ. of New York at Plattsburgh, 101 Broad St., Plattsburgh, NY 12901)

Three statistical learning models were developed to predict noise-induced hearing loss (NIHL) from an archive of animal noise exposure data, which contains 936 chinchillas exposed to various noise environments. The following models were constructed: (*i*) A support vector machine model with a nonlinear radial basis function kernel. (*ii*) A multilayer perceptron network model and (*iii*) a radial basis function network model. In addition to frequency-specific energy metrics, noise exposure parameters and biological metrics such as kurtosis, noise type, and pre/postexposure hearing thresholds were used as inputs to the model. There were several indices of auditory trauma at specific audiometric test frequencies that were to be predicted by the models: e.g., noise-induced permanent threshold shift, percent outer hair cell loss, and percent inner hair cell loss. The average prediction accuracy for the three models was better than 80%. These results demonstrate the feasibility of developing such models for the prediction of NIHL in humans. [Research supported by NIOSH.]

2pPP36. Noise-induced hearing loss from non-Gaussian equal energy exposures. Robert I. Davis, Wei Qiu, and Roger P. Hamernik (Auditory Res. Lab., State Univ. of New York at Plattsburgh, 101 Broad St., Plattsburgh, NY 12901)

Data from several different exposures [Hamernik *et al.*, J. Acoust. Soc. Am. **114**, 386–395 (2003)] showed that, for equivalent energy [Leq = 100 dB(A)] and spectra, exposure to a continuous, non-Gaussian (nonG) noise produces greater hearing and sensory cell loss in the chinchilla than a Gaussian (G) noise. The statistical metric, kurtosis, could order the extent of the trauma. We extend these results to Leq= 90 and 110 dB(A), non-Gaussian noises generated using broadband noise bursts, and band-limited impacts within a continuous G background noise. Data from nine new experimental groups with 11 or 12 chinchillas/group will be presented. Evoked response audiometry established hearing thresholds and surface preparation histology quantified sensory cell loss. There were clear

intensity-related effects. At the lowest levels there were no differences in the trauma produced by G and nonG exposures. At Leq=90 dB(A), nonG exposures produced increased trauma relative to equivalent G exposures. By removing energy from the impulsive transients by limiting their bandwidth, trauma could be reduced. The use of noise bursts to produce the nonG noise also reduced the amount of trauma. A metric based on kurtosis and energy may be useful in modifying existing exposure criteria. [Work supported by NIOSH.]

2pPP37. The application of the equal energy hypothesis (EEH) to interrupted, intermittent and time-varying Gaussian noise exposures. Wei Qiu, Roger P. Hamernik, and Robert I. Davis (Auditory Res. Lab., State Univ. of New York at Plattsburgh, 101 Broad St., Plattsburgh, NY 12901)

Interrupted, intermittent, time-varying (IITV) noise exposures may reduce the susceptibility of the cochlea to hearing loss through toughening or conditioning effects. Six groups of chinchillas were exposed to a broadband Gaussian IITV noise over the course of 19 days at an Leq=101 or 106 dB(A) SPL. All exposures at a given Leq had the same total energy. Each daily exposure consisted of two 4.25-h periods with an hour break in between. Each 4.25-h exposure was interrupted for 15 min and each 5-day sequence was separated by a 2-day break. Daily IITV exposures at 101 dB varied between 90 and 108 dB(A), while those at 106 dB(A) varied between 80 and 115 dB(A). For the IITV exposures three different variations in the SPL temporal profile were used. Five-day continuous, equal energy exposures at 100 or 106 dB(A) SPL served as control conditions. The IITV exposures produced up to 40 dB toughening that did not have any effect on thresholds or sensory cell losses. There were some differences in the permanent threshold shift and cell loss across equal energy exposures but the differences were small. The EEH may be valid for Gaussian IITV exposures. [Work supported by NIOSH.]

2pPP38. Temporal characteristics of extraction of size information in speech sounds. Chihiro Takeshima (Grad. School of Music, Kyoto City Univ. of Arts, Kyoto 610-1197, Japan, ctakeshima@yahoo.co.jp), Minoru Tsuzaki (Kyoto City Univ. of Arts, Kyoto 610-1197, Japan), and Toshio Irino (Wakayama Univ., Wakayama 640-8510 Japan)

We can identify vowels pronounced by speakers with any size vocal tract. Together, we can discriminate the different sizes of vocal tracts. To simulate these abilities, a computational model has been proposed in which size information is extracted and separated from the shape information. It is important to investigate temporal characteristics of the size extraction process. Experiments were performed for listeners to detect the size modulation in vowel sequences. All the sequences had six segments. Each segment contained one of three Japanese vowels: "a," "i," and "u." Size modulation was applied by dilating or compressing the frequency axis of continuous, STRAIGHT spectra. Modulation was achieved by changing the dilation/compression factor in sinusoidal functions. The original $F0$ pattern of the base sequence, except for warping of the time axis, was used for all stimuli. The minimum modulation depth at which listeners were able to detect the existence of modulation was measured as a function of the modulation frequency. The results will be compared with low-pass characteristics in a temporal modulation transfer function obtained with the amplitude-modulated noise. They will be discussed in relation to a computational model based on the Mellin transformation.

2pPP39. She hears seashells: Detection of small resonant cavities via ambient sound. Ethan J. Chamberlain, Lawrence D. Rosenblum, and Ryan L. Robart (Dept. of Psych., Univ. of California, Riverside, Riverside, CA 92521)

There is evidence that blind listeners can detect the presence of obstacles based on how the obstacles structure the ambient sound in a quiet room [Ashmead *et al.*, J. Vis. Impair. Blindn. **9**, 615 (1998)]. Potentially,

this ability is based on auditory sensitivity to the buildup of ambient wave interference patterns in front of the obstacle. This effect is not unlike how the internal structure of a seashell amplifies a room's ambient sound to emulate the sound of the ocean. Experiments were conducted to determine whether unpracticed, sighted listeners were sensitive to this information. Blindfolded listeners were placed in a quiet room and were asked to determine the location of a small resonant cavity placed next to either their left or right ear. Results revealed that listeners were very accurate at this task. Follow-up experiments examined the limits of this sensitivity as well as its acoustical support. These findings suggest that unpracticed listeners might be sensitive to subtle changes in the ambient acoustic structure of a quiet environment.

2pPP40. Effects of listening environment on speech recognition in noise. Linda Thibodeau and Tina Keene (Univ. of Texas at Dallas, 1966 Inwood Rd., Dallas, TX 75235)

The ability to recognize speech in noisy situations varies among individuals despite normal hearing. Although some of the variation may be related to physiological differences, some may be attributed to environmental experiences. The purpose of this investigation was to examine how everyday listening experiences were related to speech recognition in noise abilities. Using the Hearing in Noise Test, reception thresholds for speech were compared for listener groups who differed in their preferred listening levels for music and signal-to-noise ratios for daily communication. Results suggested that speech recognition in noise was related to listening levels. These results have implications for the use of assistive devices to improve the signal-to-noise ratio in adverse communication situations.

2pPP41. Comparing vowel formant thresholds from two tasks: Classification versus 2-alternative forced choice (2AFC) adaptive tracking. Eric Oglesbee (Dept. of Linguist., Indiana Univ., Bloomington, IN 47405, eoglesbe@indiana.edu) and Diane Kewley-Port (Indiana Univ., Bloomington, IN 47405)

Accurate classification of vowels in American English is difficult because of the number of acoustically similar vowels. Previous experiments in our lab [Kewley-Port *et al.*, J. Acoust. Soc. Am. **118**, 1929–1930 (2005)] described a new method to obtain formant thresholds using a classification task rather than the more typical 2AFC task. The goal of the present experiment was to directly compare formant thresholds estimated from a classification task with a modified 2AFC paradigm using adaptive tracking. Stimuli, generated by STRAIGHT, consisted of separate continua for formants F1 and F2 based on natural productions of "bid" shifted to "bed," and "cut" shifted to "cot." Separate 7- and 14-step continua were created for the classification and 2AFC tasks, respectively. Eight subjects participated first in the classification task, followed by the 2AFC task. Classification threshold results here replicated those observed in our previous experiments. Within-subject comparisons of the classification and 2AFC data refined our method for calculating a classification threshold from logistic psychometric functions. Individual thresholds calculated using this refined method were very similar to those from the 2AFC task. Results demonstrate the viability of using a more natural, single-interval classification task to estimate formant discrimination thresholds. [Work supported by Grant NIHDCD-02229.]

2pPP42. Cochlear and cognitive models for speech enhancement. Melissa Dominguez (DBK Acoust., 110 Village Station Ln., Grayslake, IL, 60030), Jeff Bondy, and Andrew Dittberner (GN Resound, Glenview, IL, 60026)

There has been a long running interest in using cochlear models for audio processing. Psychophysical masking stemming from normal cochlear operation is used as the basis for most audio compression circuits, while the cochleas mel-frequency response is mimicked by most automatic speech recognition circuits. An area that has been less well explored

in audio processing is the auditory brain. Recent research shows that cognitive abilities are a good predictor of peformance on many hearing tasks, especially those which are more complex and realistic. By extending a nonlinear, adaptive cochlear model with cognitive modules a novel tool for sound assessment is made that allows an estimate of cognitive load. Quantitative offline benefit has never been modeled before. We test the new predictor on noise reduction circuits in hearing aids. This family of algorithms is well known to not increase intelligibility but has been shown to reduce perceived noisiness. This reduction is proposed as equivalent to reducing cognitive load. The elderly, with their heavier reliance on high level processing, could greatly benefit from the reduction in cognitive load. A new algorithm for reducing cognitive load is compared to spectral subtraction algorithms.

2pPP43. Cross-modal plasticity and the sensitive period for cochlear implantation. Kristi A. Buckley, Emily A. Tobey (The Univ. of Texas at Dallas, 1966 Inwood Rd. Dallas, TX 75235), and Anu Sharma (The Univ. of Colorado at Boulder)

Previous research suggests prelingually deaf individuals who receive a cochlear implant early in childhood develop better oral communication skills than those who receive their implant later. However, the mechanisms influencing this sensitive period are not well understood. This investigation explores one possible mechanism limiting the sensitive period for cochlear implantation, cross-modal plasticity. Cross-modal plasticity occurs when one sensory system recruits cortical processing resources of another absent or damaged sensory system. This reallocation of cortical processing resources may influence the ability of the auditory system to respond to restored auditory sensation through the electrical stimulation of a cochlear implant. In order to investigate the possible relationship between cross-modal plasticity and the sensitive period for cochlear implantation, we examined the visual evoked potential (VEP) to peripheral motion in prelingually deaf children and adults, and normal-hearing children and adults. The VEP response source is compared across ages and groups. Preliminary data from adults indicate the source of the VEP response in deaf individuals originates from the temporal lobe, compared to the parietal lobe in normal hearing individuals, suggesting evidence of cortical reorganization in deafness. [Work funded by NIH F31DC007007 (K. Buckley, P.I.), R01DC04558 (E. Tobey, P.I.), and R01DC006257 (A. Sharma P.I.).]

2pPP44. Predictions of Mandarin Chinese tone identification in cochlear implants using particle filters. Kenneth D. Morton, Jr., and Leslie M. Collins (Dept. of Elec. and Comput. Eng., Duke Univ., 130 Hudson Hall, Box 90291, Duke Univ., NC 27708)

The spectral information provided in current cochlear implants is inadequate for reliable speech perception in tonal languages. Speech comprehension in a tonal language, such as Mandarin Chinese, requires recognition of lexical tones. New strategies for sound processing may allow the transmission of more spectral information and may therefore improve Mandarin Chinese tone recognition. Four cochlear implant speech processing strategies were examined in this study. Each provides a different amount of spectral information. Automated pattern recognition of Mandarin Chinese tones processed using cochlear implant acoustic models can be used as a means of testing the abilities of each of the algorithms to transmit the necessary spectral information for accurate tone perception and may be used to focus future Mandarin Chinese tone recognition studies in cochlear implant subjects on the most promising speech processing strategies. Classification based on spectral features derived from particle filtering is compared to classification derived from other features in an effort to determine the necessary spectral information for accurate tone classification in both quiet and noisy conditions. Automated classification results will be compared to the results of a listening experiment using normal-hearing subjects and acoustic models.

2pPP45. Simulating the effect binaural (electric and acoustic) hearing on Mandarin speech recognition under background noise for patients with cochlear implant (CI). Chao-Min Wu and Wei Jen Cheng (Dept. of Elec. Engr., Natl. Central Univ., 300, Chung-Da Rd., Chung-Li, Taiwan 320)

This study evaluated the effects of binaurally combined electric and acoustic hearing on Mandarin speech recognition under simulated background noise for normal-hearing (NH) listeners and CI recipients of the Nucleus-24 device with contralateral hearing aid (HA). Chinese word and tone recognition were measured in seven NH subjects using simulated four-channel continuous interleaved sampler (CIS) type speech processing strategy under three different conditions, namely, (1) only simulated (CI) signals with modulated Gaussian white noise for monaural stimulation, (2) simulated (CI) signals with modulated Gaussian white noise and simulated HA signals (low-pass speech signals with cutoff frequency of 500 Hz) for monaural stimulation, and (3) simulated (CI) signals with modulated Gaussian white noise to one ear and simulated hearing aid (HA) signals to the other ear for dichotic stimulation. For comparison purposes, Chinese word and tone recognition were also measured in three CI users using advanced combination encoding (ACE) strategy. Preliminary results showed that the Chinese word and tone recognition rates of the NH listeners and CI recipients are statistically significantly improved (word and tone recognition rates were improved from 3.85% to 60.86% and 40.14% to 97.43% for NH listeners and 20% to 37.5% and 50% to 90% for CI recipients).

2pPP46. Pitch discrimination in children using cochlear implants. Amy McKinnon and Michael Kiefte (School of Human Commun. Disord., Dalhousie Univ., 5599 Fenwick St., Halifax, NS, B3H 1R2 Canada)

Research in pitch perception by cochlear implant users has focused primarily on postlingually deafened adults. Little is currently known regarding the pitch perception abilities of those who are implanted at a very early age, yet many children receive cochlear implants when they are less than 2 years old. Given the effects of brain plasticity, it is conceivable that pitch perception by early cochlear implant users may be much better than that of their older counterparts. This study examines pitch discrimination thresholds in young cochlear-implant users between the ages of 4 and 16. A computer game was developed to determine difference limens for fundamental frequency in vowellike stimuli at three referent frequencies: 100, 200, and 400 Hz. Two different tasks were employed: pitchdiscrimination, in which subjects were asked whether two stimuli are same or different, and pitch ranking, in which participants determine which of two stimuli is higher in pitch. Normal-hearing matches were tested to control for maturational effects, and adult cochlear implant users were also tested to compare findings with other studies. [Work supported by the Nova Scotia Health Research Foundation.]

2pPP47. Improving the voice pitch discrimination threshold through cochlear implants. Shizuo Hiki (Waseda Univ., Tokorozawa, Japan, hiki@waseda.jp) and Masae Shiroma (Natl. Univ. of Health and Welfare, Ohtawara, Japan)

Aiming at the maximum use of linguistic information conveyed by the periodicity pitch of speech sound through cochlear implants, the possibility of improving the voice pitch discrimination threshold was examined for cochlear implantees: three acquired deaf adults and four congenitally deaf children. Female and male adult speech samples of vowel /a/ were analyzed and resynthesized using the STRAIGHT computer program to shift the original voice pitch (c1 and c) one octave upward and downward with a half-step interval on the musical scale. By presenting those synthetic speech samples in pairs, the discrimination threshold of the voice pitch interval was observed. Association of the speech samples to the picture of a piano keyboard was helpful for conceptualizing the voice pitch change, especially for children. Preliminary observation results suggested that the discrimination threshold can be improved by less than one

whole step by adults and two whole steps by children. Those figures were promising because, even for Japanese word accent and Chinese tones, which were conveyed by the precise changes in voice pitch, it was ascertained by acoustical analyses of both their production and perception that discrimination of a half-step difference was small enough to recognize their pitch patterns.

2pPP48. Implementing a psychophysical interface for the sound processor for electrical and acoustic research version 3 (SPEAR3). Joshua S. Stohl, Chandra S. Throckmorton, and Leslie Collins (Duke Univ., 130 Hudson Hall, Box 90291, Durham, NC 27708; lcollins@ee.duke.edu)

Current speech processing strategies use amplitude-modulated fixed rate pulse trains to communicate information. Using acoustic models, researchers have recently demonstrated that variable stimulation rate strategies may provide an improvement of speech perception in noise and music perception [Nie *et al.*, 2005; Stohl and Collins, 2006; Throckmorton *et al.* (2006) (in press)]. It has been hypothesized that successful implementation of these strategies will require psychophysics-based tuning. An experimental interface is needed to implement such psychophysical experiments, and most interfaces provided by implant manufacturers do not provide the stimulus design flexibility necessary. HearWorks provides the SPEAR3 developmental sound processor, which is capable of dynamically updating the stimulation rate and offers bimodal and bilateral configurations. Assembly and Visual Basic code is included with the SPEAR3, but must be modified and expanded to implement dynamic stimulus presentation and graphical user interfaces for specific psychophysical tasks. Using data collected from Nucleus CI 24 implant users, we will demonstrate that the SPEAR3 may be used to implement general psychophysical experiments. The ability of the SPEAR3 speech processor to implement variable stimulation rates is critical to future psychophysical testing of variable stimulation rate processing strategies.

WEDNESDAY AFTERNOON, 29 NOVEMBER 2006

REGENCY BALLROOM (ROYAL HAWAIIAN), 2:00 TO 4:45 P.M.

Session 2pSA

Structural Acoustics and Vibration: Scattering, Diffraction, Radiation, and Damping

2pSA1. Phased array steering of structure-borne sound radiated from a flexible beam by active modal control. Alfred Tan (Dept. of Aerosp. Eng., Tokyo Metropolitan Univ., 6-6 Asahigaoka, Hino-shi, Tokyo, 191-0065, Japan), Dunant Halim (The Univ. of Adelaide, SA 5005, Australia), and Nobuo Tanaka (Tokyo Metropolitan Univ., Hino-shi, Tokyo, 191-0065, Japan)

This paper analytically demonstrates the implementation of a control strategy to actively steer the structure-borne sound radiated from a simply supported beam structure, which is excited by an arbitrary mono-frequency force. The surface of the beam is discretized into many finite elemental sound radiators that correspond to their respective nodal points. The dynamics of the beam structure are identified in order to modify the modal vibration characteristic for beamsteering purpose. The acoustic power is formulated in terms of its velocity according to the Rayleigh expression. The key to the control strategy is to combine the *a priori* knowledge of the structural modal characteristic with the sensors measurements. As a result, this is used to control the normal surface vibration velocity profile of the beam structure into a set of congruent elemental sound radiators, each differing only by successive delayed phase in order to steer the radiated sound beam pattern into a desired far field direction. The arrangement of the sensors/actuators on the beam structure is designed to instill such a unique set of elemental sound radiators. Numerical studies are performed to evaluate the effectiveness of the proposed sound steering concept into the far-field hemisphere. [Work supported by JSPS.]

2pSA2. Effects of material orientation on the radiation efficiency of baffled plates. J. Gregory McDaniel (Dept. of Aerosp. and Mech Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, jgm@bu.edu)

The orientation of an anisotropic material may have profound effects on acoustic radiation from the structure. The present work explores these effects for the case of a thin anisotropic plate in an infinite rigid baffle. An understanding of the acoustic radiation, in terms of the radiation efficiency, is begun by considering two effects. The first is that of wave steering, in which the direction of structural wave propagation is changed by the material orientation. The second is that of wave mixing, in which the the relative mixture of propagating and evanescent waves is changed by the material orientation. The effect on radiation follows from the fact that radiation from propagating and evanescent waves is known to be dramatically different. The relative importance of frequency and excitation is also explored in the context of these two effects. These results are expected to lead to improved designs of composite structures at no additional cost—simply by changing the orientation of the material. [Work supported by ONR.]

2pSA3. A method to measure the equivalent acoustic impedance of a scatterer. Seung-ha Lee (Ctr. for Noise and Vib. Control, Dept., of Mech. Eng., KAIST, Sci. Town, Daejeon, 305-701, Korea, seung-habird@kaist.ac.kr)

The procedures of simplifying scatterers' geometry and finding its equivalent acoustic impedance are proposed by using scattering holography and multiple multipole expansions. The scattered sound field depends on the incident field, the geometry, and the physical property of the scatterer, which can be measured by using tools such as a set of microphones and a 3-D scanner. Once the sound field over a surface is measured, the whole sound field of 3-D space can be reconstructed by acoustic holography. However, predicting near-field sound by holography is inefficient in practice, because huge numbers of measurement points are required to describe the complex sound field in the vicinity of a scatterer. With this regard, multiple multipole expansions are employed to reduce the number and the size of elements of a scatterer necessary to express the measured scattered field. Therefore it is equivalent to simplifying the geometry of a scatterer, and enables us to predict the sound pressure and velocity, as well as acoustic impedance, on the scatterers' surface. Using the proposed method, it is demonstrated that the equivalent acoustic impedance can be obtained. 2pSA4. Acoustic backscattering from fluid-filled submerged prolate spheroidal shells. Jeffrey E. Boisvert (NAVSEA Newport, Newport, RI 02841) and Sabih I. Hayek (Penn State Univ., University Park, PA 16802)

The equations of motion for nonaxisymmetric vibration of prolate spheroidal shells of constant thickness were derived using Hamilton's principle [S. I. Hayek and J. E. Boisvert, J. Acoust. Soc. Am. **114**, 2799–2811 (2003)]. The shell theory used in this derivation includes shear deformations and rotatory inertias. The shell displacements and rotations were expanded in infinite series of comparison functions. These include associated Legendre functions in terms of the prolate spheroidal angular coordinate and circular functions in the azimuthal angle coordinate. The fluid-filled shell is insonified by a plane wave with an arbitrary angle of incidence. The external and internal fluid loading impedances were computed using an eigenfunction expansion of prolate spheroidal wavefunctions. Far-field backscattered acoustic pressure spectra are presented as a function of the angle of incidence for several shell thickness-to-half-length ratios ranging from 0.005 to 0.1, and for various shape parameters, a, ranging from an elongated spheroidal shell ($a = 1.01$) to a spherical shell ($a \sim 100$). A comparison of the backscattering from fluid-filled and empty shells is presented at selected plane wave incident angles. [Work supported by the ONR/ASEE Summer Faculty Research Program and the NAVSEA Newport ILIR Program.]

2pSA5. Modeling a magnetorheological elastomer's transient stiffness parameters. Anne-Marie Lerner and Ken Cunefare (Georgia Tech., ken.cunefare@me.gatech.edu)

Semiactive vibration absorbers are tunable vibration absorbers whose natural frequencies can change controllably to minimize vibration better than their passive counterparts, which can be used to reduce occupant vibration in cars. The variable natural frequency is achieved by using a dynamically tunable spring. In order to use a material as a dynamically tunable spring, its transient parameters must be understood and controlled, so as not to lead to instability. This work characterizes the behavior of magnetorheological elastomers (MREs), which are a type of ferromagnetic-elastomer composites whose tensile/compressional stiffness increases as an applied magnetic field is increased. If the transition from one stiffness state to another is too slow, the MRE can have a detrimental effect on vibration control. Transient behavior of MREs with different concentrations of ferromagnetic material and different geometric shapes was recorded empirically, and the MRE stiffness change in response to a change in magnetic field was modeled as a function of ferromagnetic

content, MRE geometric shape, and the change in magnetic field strength. MREs in this configuration exhibited natural frequencies in the 30–65-Hz range, where MREs were able to change their natural frequency by up to 17%.

2pSA6. Vibration absorption by an undamped beam element. Ilker Murat Koc, Adnan Akay (Dept. of Mech. Eng., Carnegie Mellon Univ., Pittsburgh, PA 15213), and Antonio Carcaterra (Univ. of Rome, La Sapienza, 00184, Rome, Italy)

Through two complementary approaches, using modal response and wave propagation, this presentation will show the conditions under which a decaying impulse response, or a nearly irreversible energy trapping, takes place in a linear conservative continuous system. The results show that the basic foundation of near-irreversibility or pseudo-damping rests upon the presence of singularity points in the modal density of the systems. To illustrate the concept of pseudo-damping in detail, a simple undamped beam is modified to introduce a singularity point in its modal density distribution. Simulations show that by a suitable application of a compressive axial force to an undamped beam on an elastic foundation, the impulse response of a beam shows the characteristics of a nearly irreversible energy trap and a decaying impulse response. Attaching such a modified beam to a single degree of freedom oscillator shows energy trapping by the beam producing pseudo damping. [Research carried out while AA served at NSF.]

<center>3:45</center>

2pSA7. Pseudo-damping in undamped plates and shells. Antonio Carcaterra (Dept. of Mech. and Aeronautics, Univ. of Rome, La Sapienza Via Eudossiana, 18, 00184, Rome, Italy) and Adnan Akay (Carnegie Mellon Univ., Pittsburgh, PA 15213)

Pseudo-damping is a counter-intuitive phenomenon observed in a special class of linear structures that exhibit an impulse response characterized by a decaying amplitude, even in the absence of any dissipation mechanism. The conserved energy remains within but designated parts of the system. Pseudo-damping develops when the natural frequency distribution of the system includes condensation points. The recently formulated theoretical foundation of this phenomenon, based on mathematical properties of special trigonometric series, makes it possible to describe a class of mechanical systems capable of displaying pseudo-damping characteristics. They include systems with discrete oscillators and one-dimensional continuous beamlike structures already reported by the authors in recent studies. This paper examines development of pseudo-damping phenomenon in two-dimensional structures, using plates and shells as examples, and shows how a preloaded plate on an elastic foundation can lead to pseudo-damping. Moreover, in the case of curved shell elements examined here, pseudo-damping can result due to the curvature of the structure, which naturally introduces condensation points in the modal density. [Research carried out while AA served at NSF.]

<center>4:00</center>

2pSA8. Fundamentals of apparent damping phenomena in linear conservative systems. Antonio Carcaterra (Dept. of Mech. and Aeronautics, Univ. of Rome, La Sapienza Via Eudossiana, 18, 00184, Rome, Italy) and Adnan Akay (Carnegie Mellon Univ., Pittsburgh, PA 15213)

This presentation addresses a class of irreversible phenomena that can develop in linear conservative systems and provides a theoretical foundation to explain the underlying principles. Recent studies have shown that energy can be introduced to a linear system with near irreversibility, or energy within a system can migrate to a subsystem nearly irreversibly, even in the absence of dissipation. Inspired by the properties of probability distribution functions, the general formulation developed here is based on particular properties of harmonic series, which form the common basis of

linear dynamic system models. The results demonstrate the existence of a special class of linear nondissipative dynamic systems that exhibit nearly irreversible energy exchange and possess a decaying impulse response. The formulation and its results also support the recent studies that observed near irreversibility and apparent damping in several dynamic systems and provide a common theoretical foundation for such behavior. [Research carried out while AA served at NSF.]

2pSA9. Using an enhanced constrained layer damping model to assess relative damping contributions. Zhengchao Xie and W. Steve Shepard , Jr. (Dept. of Mech. Eng., The Univ. of Alabama, Box 870276, Tuscaloosa, AL 35487, sshepard@eng.ua.edu)

Constrained layer damping (CLD) is an effective passive vibration control approach in which damping comes from the core layer's deformation. In the most general sense, this deformation will include shear, longitudinal extension, and transverse compression deformations. In this work, new analytical models and their single-layer finite-element (FE) implementations are used to examine the dependence of these types of damping on the frequency and the core layer's thickness for different boundary conditions. This information can be important in cases where a simplified model is needed with an acceptable error. The sandwich beam's response is examined by using various tools in order to determine the important aspects of the model, with particular emphasis on the relative importance of each of the three types of damping. Then, frequency responses found

using different single-layer finite elements are compared for different boundary conditions. By using both the analytical models and FE method results, guidance is provided on how to choose an appropriately simplified model or finite element for more practical analyses.

2pSA10. Effect of burst-modulated sinusoidal dither waveforms on the effectiveness of dither forces to eliminate friction-induced oscillations. Jeff W. Badertscher, Kenneth A. Cunefare, Al A. Ferri, and Michael M. Michaux (771 Ferst Dr., Rm. 205, Altanta, GA 30332)

This paper examines the effectiveness of high-frequency dither-cancellation techniques using burst-modulated signals. The classic single-degree-of-freedom (SDOF), mass on moving belt, model is analyzed using the method of averaging and numerical integration of system dynamics. Two different friction laws are used to model the contact point, both exhibiting a negative friction coefficient-velocity relationship. Recent results [M. Michaux and A. Ferri, Proceedings of IDETC05 Paper no. DETC2005-84491 (2005)] found that sinusoidal dither forces could stabilize or destabilize such a system, depending on the system and frictional characteristics as well as the dither signal amplitude and frequency. This paper extends this previous analysis to burst-modulated sinusoidal dither signals. Earlier experimental research has shown burst-modulated dither signals to be an effective method of suppressing automotive brake squeal. It is found that, for a given amplitude and frequency, burst signals are also capable of stabilizing the system. Individual effects of each burst parameter on system stability are established.

2pSCa1. When is a phonological rule acquired? A look at children's production on syllable-final nasals in Taiwan Mandarin. Renee Hung (Dept. of English, Natl. Taiwan Normal Univ., 162 Hoping E. Rd., Sec. 1, Taipei, Taiwan 106, reneejh@hotmail.com) and Janice Fon (Natl. Taiwan Univ. Taipei, Taiwan 106)

Syllable-final nasals, /n/ and /N/, tend to be merged when they are after /i/ and ə in Taiwan Mandarin, but in different directions. For /i/, /n/ is merged with /N/, while for ə, /N/ is merged with /n/ (Chen, 1991; Tse, 1992; Hsu, 2005). This study thus aims to examine whether children in Taiwan merge syllable-final nasals in Mandarin the way adults do. Fifty Grade-2 and Grade-6 students would read monosyllabic words, containing 3 [vowels (/i/, ə, /a/)] ×4 (tones) =12 minimal pairs differing only in nasal endings. They would repeat the words twice, once in Zhuyinfuhao, a local phonetic system, and once in traditional Chinese characters. Preliminary results indicated that Grade-2 children treated the /eN/ words very similarly to adults, although the occurrences of nasal merge were less

frequent in the Zhuyinfuhao set than in the character set. For vowel /i/, however, merging of both directions could be found in both Mandarin characters and Zhuyinfuhao.

2pSCa2. Phonetic development of word-initial Korean stops in young Korean children. Minjung Kim and Carol Stoel-Gammon (Dept. of Speech & Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105-6246, minjungk@u.washington.edu)

A number of studies have investigated developmental patterns of stops in various languages through the instrumental analysis; however, very little is known about phonetic characteristics of Korean stops in speech of young Korean children. In Korean, stops are produced at three places of articulation (labial, alveolar, velar); at each place, there is a three-way contrast, yielding nine stops in word-initial position. All stops are voiceless and are differentiated by several acoustic parameters including VOT, f0 of the following vowel, and the amplitude difference of the first and

second harmonics (H1−H2) at the voice onset of the following vowel. The present study examines developmental aspects of word-initial Korean stops by measuring values of VOT, f0, and H1−H2 at the onset of the following vowel in words produced by Korean children aged 30, 36, 42, and 48 months. Findings will focus on the phonetic features used by Korean children to contrast the three-way stops and on comparisons between the phonetic patterns of stops produced by Korean children and Korean adults.

2pSCa3. Patterns of anticipatory lingual coarticulation in typically developing children.

Shawn Nissen, Kurtt Boucher, and Mathew Parson (Dept. of Commun. Disord., Brigham Young Univ., Provo, UT 84602)

Many studies have examined the patterns of speech coarticulation in adults and younger speakers; however previous findings have not established a consistent developmental perspective. There are contrasting views on whether children at early stages of development demonstrate more, less, or about the same amount of anticipatory coarticulation than adults. This study will focus on describing the patterns of anticipatory lingual coarticulation in the obstruent productions of three groups of children between 3 and 6 years of age ($N=42$) and one comparison group of adults ($N=14$). Frequency measures for the first and second formants were extracted from multiple tokens of a centralized and unstressed vowel (schwa) spoken prior to two different sets of productions. The first set of productions consisted of the target vowel followed by a series of real words containing an initial CV(C) syllable, while the second set consisted of nonword productions with a relatively constrained phonetic context. Formant values were transformed to a perceptually normalized scale (ERB) prior to statistical analysis. Analysis of variance was utilized to determine if the formant frequencies varied systematically as a function of age, gender, and phonetic context. [Work supported by research funding from Brigham Young University.]

2pSCa4. Developmental vowel acquisition data obtained by a band-filtering analysis method: Results from Hungarian children.

Krisztina Zajdó (Div. of Commun. Disord., Univ. of Wyoming, Dept. 3311, 1000 E. Univ. Ave., Laramie, WY 82071, kzajdo@uwyo.edu)

A recently developed band-filtering analysis method (van der Stelt *et al.*, 2003, 2005; Zajdó *et al.*, 2004) that minimizes the dependence of the results on fundamental frequency allows for a dependable identification of spectral measures in children's vowels. In the scripts, selection of segments with certain acoustic features (e.g., sound quality, $F0$) is followed by the calculation of spectral envelopes between 0–7 kHz, resulting in 40 filter values per spectrum. An intensity matrix is produced with data from each 40 filters. Data reduction is achieved through prinicipal component analysis. Results indicate that the first two principal components are related to the $F1$ and $F2$ of vowels, both in adults (Pols, 1977) and children (Zajdó *et al.*, 2005). Analyses of unlabeled vowel productions in Hungarian-speaking children at 2; 0, 3; 0 and 4; 0 years show that the first two eigenvectors account for $>50\%$ of the variability in all age groups. By using these eigenvectors, age-specific reference planes are created. Mapping phonemically labeled vowel measures onto the 4; 0-year-old's plane from each age group suggests that children produce decreasingly overlapping vowel categories as they age. With development, vowel categories are increasingly specified, covering more distinct areas of the acoustic vowel space. [Work supported by UW.]

2pSCa5. The acquisition of speech rhythm by bilingual Spanish- and English-speaking four- and five-year-old children.

Ferenc Bunta (Dept. of Commun. Sci., Temple Univ., Weiss Hall, 1701 North 13th St., Philadelphia, PA 19122, fbunta@temple.edu) and David Ingram (Arizona State Univ., Tempe, AZ 85287)

This study investigates the acquisition of speech rhythm by bilingual Spanish- and English-speaking children, comparing their performance to that of monolingual age-matched peers in both languages, and to monolingual and bilingual adults. Participants included younger children (between 3 years, 9 months and 4 years, 5 months, 15 days), older children (between 4 years, 6 months, 18 days and 5 years, 2 months), and adults (over 18 years). A sentence elicitation task of 26 sentences per language was used to obtain 64 samples that yielded over 15 000 duration measurements of vocalic and intervocalic intervals. The duration measurements were entered into the normalized vocalic and intervocalic pairwise variability index (PVI) measures based on Grabe and Low (2002). The results indicated that younger bilingual children displayed distinct speech rhythm patterns for their target languages and deviated from their monolingual English-speaking peers. Older bilingual children also produced significant separation of speech rhythm, and differences between older bilingual children and their monolingual peers speaking English were also found. Comparisons between younger and older bilingual children indicated an effect for the vocalic PVI measure, but not for the intervocalic PVI, providing partial support for age differences for bilingual children. Bilingual adults showed separation of their languages and performed similarly to their monolingual peers, overall.

2pSCa6. Comparative study of perception of Japanese dialectal accent in children.

Ayako Shirose (Waseda Univ., Mikajima 257915, Tokorozawa 3591129, Japan) and Kazuhiko Kakehi (Chukyo Univ., Tokodachi 101, Toyota 4700393, Japan)

This paper reports the acquisition course of perception of Japanese dialectal accent. We carried out an experiment of accent perception for native speakers of Japanese dialects, namely, Tokyo dialect (Standard Japanese) and Kagoshima dialect. Then we compared results between the two dialects. Experimental stimuli were real words with several types of synthesized accent patterns. Results revealed that the Kagoshima children and adults accepted both the native Kagoshima accent and the Tokyo accent, whereas the Tokyo children and adults accepted only the native Tokyo accent. These results suggest that the Kagoshima speakers had insensitivity to the perception of accent. In our previous studies, the Kagoshima children showed different characteristics of accent production from the Tokyo and Kyoto children: the Tokyo and Kyoto children acquired their native accent correctly, whereas the Kagoshima children failed to produce it. [Shirose *et al.*, J. Cognit. Sci. **2**(1), 33–44 (2001)]. The insensitivity of accent perception of both Kagoshima adults and children might be one factor contributing to results of accent production. These intriguing parallels of accent perception and production will be discussed inclusively.

2pSCa7. Infants' attention to repeated speech and musical patterns.

Gerald W. McRoberts (Haskins Labs., 300 George St., Ste. 900, New Haven, CT 06511, mcroberts@haskins.yale.edu) and Colin Dawson (Dept. of Psych., 1503 E Univ. Blvd., Univ. of Arizona, Tucson, AZ 85721)

Previous investigations have shown that infants older than 5 months listen longer to speech with repeated utterances than to speech without utterance repetition. The present studies investigated whether infants also attend preferentially to repeated musical patterns. Musical phrases of four and five notes and ending with a rest were composed using several pitch contours and rhythmic patterns. Experiments 1 and 2 compared trials in which phrases were immediately repeated (AABBCC), to trials in which the same phrases occurred without repetition (ABCDE). In the first experiment, no listening preference for either trial type was found for 6- or 9-month-old infants. In experiment 2, silence was added after each phrase to assist infants in parsing the phrases. Infants again failed to show a listening preference. In experiment 3, trials of speech, half with repeated utterances and half without repeated utterances (from previous experiments), were interspersed with trials of repeated and nonrepeated music. Nine-month-olds demonstrated a preference for the repeated trials of both speech and music over nonrepeated trials of the same type. The fact that a preference for musical repetition is only obtained through induction (from verbal repetition) suggests that repeated speech may hold a special attentional status for infants. [Work was supported by Grants NIH_R15/DC005947 and NIH_R01/DC00403.]

2pSCa8. Infants listening to songs: Exploring a processing trade-off between phonetic and pitch patterns. Gina C. Cardillo and Patricia K. Kuhl (Inst. for Learning and Brain Sci., Box 357988, Univ. of Washington, Seattle, WA 98195, ginacc@u.washington.edu)

This investigation explored 11-month-olds' responses to changes in the phonetic (lyric) and pitch (melody) content of songs. Sixty infants were tested using a between-subjects auditory preference paradigm. After being familiarized with a four-note song, infants were presented with both the familiar song and a new song that contained either a novel syllable or pitch order. In experiment 1, infants preferred listening to a novel melody when the phonetic content was redundant, but showed no preference when the identical melody change occurred in the presence of variegated phonetic content. In experiment 2, we tested the hypothesis that infants presented with songs containing variegated phonetic information would attend to changes in words but not melodies. Infants marginally preferred listening to novel songs when only the lyrics changed, but did not show a preference when only the melodies changed. Taken together, the results are consistent with *a priori* predictions, and suggest that even though infants can recognize melodic changes when they are presented in isolation, identical changes become more difficult to detect when more complex phonetic information is introduced. Thus, neural resources at this age may be more heavily committed to processing phonetic information than pitch information when both are present. [Work supported by the J.S.McDonnell Foundation, NIH.]

2pSCa9. Cognitive influences in infant speech perception. Barbara T. Conboy, Jessica Sommerville, Josie Randles, Caryn Deskines, and Patricia K. Kuhl (Inst. for Learning and Brain Sci., Univ. of Washington, UW Box 357988, Seattle, WA 98195-7988)

Speech perception during the first year reflects increasing attunement to native language phonetic features, but the mechanisms underlying this development are not well understood. Reductions in non-native phonetic discrimination have been linked to improvement in native phonetic discrimination and later vocabulary growth (Kuhl *et al.*, 2005), and performance on nonlinguistic tasks (Lalonde and Werker, 1995). The present study examined links between native and non-native voice onset time discrimination, receptive vocabulary (MacArthur-Bates CDI), and cognitive control abilities at 11 months. Infants ($n = 18$) completed a double-target conditioned head turn task and two nonlinguistic tasks requiring attentional control and resistance to irrelevant cues (means-end and detour-reaching object retrieval). Infants with CDI scores above the median showed higher native discrimination scores, $t(16) = 2.15$ 0.05, but no group differences for the nonnative contrast. Infants with scores above the median on either cognitive task showed worse discrimination of the nonnative contrast (means-end, $t(15) = 2.27 p 0.04$; detour-reaching, $t(15) = 3.49$, $p .01$), but no group differences for the native contrast. These results suggest that cognitive control plays a role in infants' ability to ignore acoustic cues that are irrelevant to their native languages phonemic categories. [Work supported by NICHD (Grant HD37954) and a UW NSF Science of Learning Center Grant (LIFE).]

2pSCa10. Distinguishing voices: Are infants' abilities affected by age or language experience? Megha Sundara and Patricia K. Kuhl (Inst. for Learning & Brain Sci., Univ. of Washington, Box 357988, Seattle, WA 98195-7988)

We know surprisingly little about infants' ability to encode voice information when listening to speech. Research with infants has focused on their ability to recognize their mother or fathers' voice and distinguish it from an unfamiliar voice. However, communication consists of interactions with unfamiliar speakers as well. Adults are well able to extract information about the speakers gender, size, age, dialect, etc., even from short samples of an unfamiliar persons voice. In experiment 1, we tested 4- and 12-month-old English-learning infants on their ability to distinguish an unfamiliar male and female voice when listening to Hindi monosyllabic words. Results indicate that the 12-, but not the 4-month-olds can distin-guish an unfamiliar male and female voice when listening to Hindi words. In experiment 2, we tested 4- and 12-month-old English-learning infants on their ability to distinguish an unfamiliar male and female voice when listening to English monosyllabic words. Now, both 12- and 4-month-olds are able to distinguish the voices. Together, these results indicate that infants' ability to distinguish voices is affected by age as well as their language experience. We are now testing adults to determine if the effects of language experience on the ability to distinguish voices persists even after development.

2pSCa11. The bilingual brain: A comparison of native and non-native speech perception in monolingual and bilingual infants. Patricia K. Kuhl, Sharon Coffey-Corina, Denise Padden, and Maritza Rivera-Gaxiola (Inst. for Learning & Brain Sci., Univ. of Washington, Seattle, WA 98195, pkkuhl@u.washington.edu)

Infants raised in monolingual families are equally good at native and non-native speech discrimination early in life. By 12 months, performance on native speech has significantly improved while non-native performance declines. We tested bilingual American infants at 7 and 11 months of age on native (/ta-pa/) and non-native (Mandarin affricate-fricative) contrasts used in the monolingual tests. Phonetic discrimination was assessed using behavioral (conditioned head-turn) and brain (event-related potential) measures. The MacArthur Communicative Development Inventory estimated infants developing language skills at 14, 18, 24, and 30 months of age. The monolingual data [Kuhl *et al.*, *Language Learning and Development* (2005)] demonstrated that at 7 months of age, infants native and non-native speech perception skills predicted their later language development, but differentially. Better *native* phonetic perception predicted more rapid language development between 14 and 30 months, whereas better *non-native* phonetic perception predicted slower language development over the same time period. Performance of bilingual infants on the same speech perception tasks, and their patterns of language growth between 14 and 30 months, will be compared to those of the monolingual infants, and a model that accounts for the results will be described. [Work supported by NSF, NIH, and the Human Frontiers Science Program.]

2pSCa12. Aussie, Aussie, Aussie, Oi-Oi-Oi: Infants love an Australian accent. Christine Kitamura (MARCS Auditory Labs., Univ. of Western Sydney, Locked Bag 1797, Penrith South DC NSW 1797, Australia, c.kitamura@uws.edu.au), Robin Panneton (Virginia Tech, Blacksburgm, VA 24061-0436), Anna Notley, and Catherine Best (Univ. of Western Sydney, Penrith South DC NSW 1797, Australia)

This study examines infant's attention to dialect differences following Nazzi *et al.*'s [J. Mem. Lang., **43**, 1–19 (2000)] finding that American 5-month-olds can discriminate British- and American-English. Using a serial preference task, 48 6-month-old Australian and American infants heard sentence sets spoken in Australian- and American-English. Results showed that at 6 months, American infants listen longer to Australian than American sentences, but Australian infants show no preference. By 8 months, American infants also show no preference. The developmental lag suggests Australian infants have more exposure to the American dialect (e.g., television programs) than American infants to the Australian dialect. Thus, it is predicted, with less linguistic experience, Australian 3-month-olds will show a dialect preference comparable to American 6-month-olds. Data from 14 3-month-olds support this hypothesis; moreover, they also listen longer to Australian than American sentences. Together the results imply that the ability to generalize across two dialects is a function of experience, and that, with age, infants filter out irrelevant phonetic information and cluster American and Australian dialects into the same group. Future directions of this study are discussed as are the reasons why Australian English is the dialect of preference for infants from both dialect environments.

2pSCa13. Word extraction in adult-directed and infant-directed speech in African-American-English-learning infants. Shiri Katz-Gershon and Jean Andruski (Dept. of Audiol. Speech Lang. Pathol., Wayne State Univ., 207 Rackham, 60 Farnsworth St., Detroit, MI 48202)

Although there is evidence that infant-directed speech (IDS) facilitates word extraction in Standard-American-English (SAE)-learning infants, this effect has not been tested in African-American-English (AAE)-learning infants. An important question that remains unaddressed is whether infants are better tuned to word boundary cues in their native dialect than a non-native dialect. Specifically, do infants extract words more efficiently from IDS in their native dialect than from IDS in a non-native dialect. This study compares the ability of eight-month-old AAE-learning infants to extract words from AAE and SAE IDS. The head-turn preference procedure was used to measure infants' memory for nonsense words embedded in sentences in AAE versus SAE. Infants were familiarized for 2 min with six sentences containing nonsense words and were then presented with both familiar and unfamiliar nonsense words carrying matching prosodic features. The difference in looking times between the familiar and unfamiliar nonsense words was used as a measure of word extraction. Results so far demonstrate an advantage of IDS over adult-directed speech in SAE. IDS in AAE is less advantageous than IDS in SAE. Acoustic analysis shows that the prosodic features of target nonsense words in SAE may make them more salient to infants than target words in the AAE sample.

2pSCa14. Exploring and learning the consequences of vocalizations in early infancy. Francisco Lacerda and Lisa Gustavsson (Dept. of Linguist. Stockholm Univ., SE-106 91 Stockholm, Sweden)

The ability to discover and learn about the consequences of own vocalizations is currently being studied in three groups of infants, 3–5-, 6–8-, and 9–11-month olds, exploring a situation that resembles an audiovisual memory game. The infants are tested individually, in a quiet and dimmed studio. They sit in front of a black computer monitor connected to an eye-tracking system. At randomly selected intervals, a circle appears in the center of the screen and expands and shrinks rapidly to a bright circle to signal that an observation trial is in progress. If the infant vocalizes during the trial, an animated actor emerges after about 200-ms delay at screen coordinates that are contingent on spectral characteristics of the initial part of the infant's vocalization. The actors brightness and time on display is controlled by the vocalizations overall intensity. By analyzing the changes in predictive looking behavior that probably occur during the session, we expect to gather valuable information on the infant's capacity to learn about consequences of their vocalizations at different ages. [Work supported by grants from the Bank of Sweden Tercentenary Foundation (MILLE, K2003-0867) and EU NEST program (CONTACT, 5010).]

2pSCa15. The acoustic characteristics of infant cries. Naoto Yamane and Yoko Shimura (The United Grad. School of Education, Tokyo Gakugei Univ., 4-1-1 Nukuikitamachi, Koganei, Tokyo, 184-8501, Japan, r052004s@u-gakugei.ac.jp)

The present study measured the acoustic characteristics of infant cries. Twenty-eight infants participated, ranging from 2 to 23 months of age. Crying was elicited when their mother moved to a distance, leaving them in the lap of unknown person. The cries were recorded with a microphone placed 1 m from the infant's mouth in an anechoic room. Analysis of the recorded cries revealed four patterns: cries were classified as either voiced or breathy, and as higher or lower than 7 kHz. Certain cry characteristics were later rated as more stress-causing, suggesting they could potentially elicit more abuse reactions. The recorded cries were presented to adults and breathy cries with a high-frequency component were labeled as emergency cries and as likely to cause high stress levels in parents and caregivers. In Japan, living spaces have recently begun changing such that environments are more echoic, perhaps exacerbating negative reactions to high-frequency components of infant cries.

2pSCa16. Discovering place and manner features—What can be learned from acoustic and articulatory data? Ying Lin (Dept. of Linguist, Univ. of Arizona, Tucson, AZ 85721) and Jeff Mielke (Univ. of Ottawa, Ottawa)

Theories of phonological acquisition often assume that features are innate and universal, and establishing distinctive features requires the availability of minimal pairs. In this study, we explore an inductive approach to feature discovery without resorting to minimal pairs. Our basic assumption is that learners have access to a wide variety of phonetic information, and so feature induction can proceed through recursive clustering of the data. To test our hypothesis, we used as our data acoustic and articulatory measurements made simultaneously from a set of CVC syllables. The articulatory data are obtained with ultrasound imaging, and the vocal tract is characterized by a vector of cross distances from the tongue body to a reconstructed palate. The raw articulatory data are then mapped to a lower dimensional space using principle components, on which clustering is carried out. Experiments using acoustic and articulatory data suggest that these two sources of information lead to the discovery of place and manner features, respectively, thus bringing support to an alternative theory of feature learning.

2pSCb1. Second-language speech perception: The modification of automatic selective perceptual routines. Winifred Strange (Ph.D. Program in Speech and Hearing Sci., City Univ. of New York Grad. School, 365 Fifth Ave., New York, NY 10016, strangepin@aol.com)

It is well established that late second language (L2) learners show significant difficulties in categorizing L2 consonants and vowels that do not occur in the native language (L1), or that occur, but differ in their phonetic realization in L1 and L2. These perceptual problems underlie (some) L2 production difficulties (accented L2 speech); lead to L2 comprehension difficulties, especially in nonoptimal listening environments; and may persist even after years of immersion in the L2 environment. However, it has been shown that intensive laboratory training (listening with feedback) can lead to improved perception of difficult non-native contrasts that: (a) generalizes to novel speakers and stimulus materials, (b) persists over months, and (c) produces improvements in production of trained segments. In the model presented here, changes with experience in patterns of phonetic perception are conceived of as reflecting the modification of language-specific (L1) selective-perceptual routines used to extract phonologically relevant information efficiently from continuous speech input. Theoretical and methodological issues will be discussed regarding (a) the conceptualization of (changes in) the structure of phonetic/phonological categories, (b) empirical assessment of phonetic perceptual learning, (c) operational definitions of mastery of L2 phonological categorization, and (d) implications for improving phonetic perceptual training techniques. [Work supported by NIDCD.]

2:40

2pSCb2. STRAIGHT as a research tool for L2 study: How to manipulate segmental and supra-segmental features. Hideki Kawahara (Faculty of Systems Eng., Wakayama Univ., 930 Sakaedani, Wakayama 640-8510, Japan) and Reiko Akahane-Yamada (ATR, Sorakugun, Kyoto 619-0288, Japan)

A morphing algorithm based on STRAIGHT speech manipulation system [Kawahara *et. al.*, ICASSP (2003)] has a potential importance in L2 study, since it generates stimulus continuum with quality close to natural speech. The morphing procedure yields an equally spaced continuum in an abstract parameter domain, which is spanned by fundamental frequency, STRAIGHT's time-frequency representation (a variant of smoothed spectrogram), the periodicity map, and the time-frequency coordinate. Instead of manipulating all these parameters at once, it is useful to manipulate each parameter independently. This individual parameter manipulation can also be generalized to coupled manipulation by introducing new parameters defined using a set of parameters. This extension enables us to manipulate segmental and supra-segmental features instead of manipulating abstract physical parameters. For example, coupling energy envelope, fundamental frequency, and temporal axis stretching factor yield access to a prosodic feature that is basically supra-segmental. Manipulation of spectral landmark positions yields access to a phonological feature that is basically segmental. A preliminary test results using the right-light continuum sets generated using a STRAIGHT-based method and the Klatt synthesizer will also be presented.

2pSCb3. Structural representation of the pronunciation and its application to computer-aided language learning. Nobuaki Minematsu (Grad. School of Frontier Sci., The Univ. of Tokyo, 5-1-5, Kashiwanowa, Kashiwa-shi, Chiba, 277-8562, Japan)

The conventional speech applications have been developed by looking at sound substances of speech and this strategy is derived from acoustic phonetics. However, the speech representation of this framework, e.g., spectrogram, is inevitably with nonlinguistic factors such as speakers and microphones. Then, all the developed systems come to select users, where the systems may work fine with a major part of the users but still work poorly with the others. The author believes that this situation should be avoided for educational applications because users don't know whether they are outliers or not. Recently, the author proposed another framework of developing speech applications by looking at only sound contrasts and this strategy is derived from physically and mathematically interpreting structural phonology. On this new framework, nonlinguistic factors such as speakers and microphones are mathematically

2p WED. PM

removed from speech as pitch information can be removed by smoothing the spectrogram. This talk shows what is possible by the new framework, which completely discards the absolute acoustic properties such as formants and spectral envelopes. In other words, in the new framework, an utterance is modeled as organized pattern of sounds although it has been modeled just as a linear string of sounds in the conventional framework.

3:20

2pSCb4. Using speech recognition for just-in-time language learning. Maxine Eskenazi, Antoine Raux, and Elizabeth Harris (Carnegie Mellon Univ., 4619 Newell Simon Hall, 5000 Forbes Ave., Pittsburgh, PA 15213)

While many language learning systems rely on the student to be a dedicated learner, the opportunity to teach language is present outside the classic teaching situation, in all everyday oral and text-related activities. Teaching language in real situations, where the new knowledge is needed and used immediately, has great potential for robust learning: items are retained over a long period of time, make learning other items easier, and are generalized to other situations. Giving immediate and effective error detection and corrective feedback is a technical challenge for language modeling, spoken dialogue structure, and targeted speech synthesis. We will discuss just-in-time language learning and then present one type of just-in-time learning, lexical entrainment, where the automatic system detects an oral error and then respeaks the utterance that contained the error in corrected form, emphasizing the corrected portion. To test the effectiveness of this approach, the Lets Go spoken dialogue system that furnishes bus information to Pittsburghers was modified to predict errors from a variety of non-native speakers of English. A study of the effectiveness of lexical entrainment for a group of non-native users will be described. [This work is sponsored by NSF Grants 0208835 and IIS0096139.]

3:40

2pSCb5. Theory and method in automatic evaluation of spoken language proficiency. Jared Bernstein (Ordinate Corp., 800 El Camino Real, Menlo Park, CA 94025)

Several kinds of theory (linguistic, psycholinguistic, and sociolinguistic) have been used to justify different methods of language proficiency assessment or to explain patterns of performance observed in proficiency tests. After reviewing some traditional methods of testing spoken language performance (e.g., structured interviews, listening comprehension, word identification in noise, and elicited imitation), the assumptions underlying these methods are compared. When the practicality, reliability, and validity of assessment methods are evaluated, differences in the associated theories become clearer. A low perplexity testing method is presented that scores a set of context-free speech-interactive tasks using speech recognition and analysis techniques to measure aspects of the linguistic and phonetic content of spoken responses. Data from several experiments comparing interview testing with low-perplexity testing on populations of second language speakers (of English, Spanish, and Dutch) suggest that nearly all the information that expert judges extract about levels of communicative competence can be accounted for in terms of automaticity of spoken language processing. Furthermore, measurement techniques that are feasible in low-perplexity testing provide much greater precision in the spoken language proficiency reporting scale than was previously feasible, opening up a range of new applications.

2pSP1. Evaluation of spatial impression of sound in horizontal and depth directions for the purpose of developing an advanced multichannel live sound reproduction system. Hiroyuki Okubo, Toshiyuki Nishiguchi, Reiko Okumura, and Kimio Hamasaki (Human & Information Sci., NHK Sci. & Tech. Res. Labs., 1-10-11 Kinuta Setagaya, Tokyo 157-8510 Japan)

A prototype of an advanced multichannel live sound reproduction system was developed. In this system, multiple loudspeakers are arranged in the horizontal and depth directions in front of listeners to reproduce a sense of sound depth and width [K. Hamasaki *et al.*, Proc. 119th AES Convention, (2005) p. 6559]. Using this prototype, a number of subjective

tests were conducted to evaluate the listeners sense of sound depth and width. The results revealed that while the direct sound source was perceived near the predicted horizontal location, the sense of depth varied largely from subject to subject. Another listening test was conducted in which reflections from the upper-front of the listeners were reproduced. Simulated reflections of a virtual space were divided into 11 directional room impulse responses (RIRs). The RIRs were convoluted with individual sound sources (male vocals), and subjects compared their spatial impressions of the sound sources reproduced with and without such reflections. The results of this listening test revealed that the feeling of sound depth was one of the factors of spatial impressions and it increased when the reflections from the upper-frontal direction were reproduced.

2pSP2. Precise position measurement of objects using a coded acoustic signal in an indoor environment. Kuramitsu Nishihara (Grad. School of Sci. and Technol., Chiba Univ., 1-33 Yayoi-cho Inage-ku, Chiba, 263-8522 Japan), Tadashi Yamaguchi, and Hiroyuki Hachiya (Chiba Univ., Chiba, Japan)

Acoustic sensing in the air might serve as an effective technique for acquiring information about an object, such as its distance, shape, and surface configuration. Nevertheless, it is difficult to identify acoustic waves clearly because many mirror reflections or environmental noises exist in the air. In addition, acoustic measurement requires a longer time than measurements using lasers or electromagnetic waves because sound propagates much more slowly than light. For this study, we attempted highly precise position measurement using an M-sequence signal in an indoor environment. The degrees of M-sequence were 7–14; the transmitting frequency was 25 kHz. A signal reflected from various angles was received by moving the receiving unit, which contained three microphones. Measurement results with the M-sequence signal showed that the signal-to-noise ratio (S/N) improved 20–40 dB compared with a burst wave. Furthermore, the distance resolution improved when the M-sequence degree was changed. The distance and the angle of multiple objects installed indoors or in walls were detectable as a result of construction of a two-dimensional plane based on received signals.

1:30

2pSP3. Self-similar analysis of the room impulse response. Yong Tang, Hideo Shibayam, Wakako Tanaka, and Tooru Itakura (Dept. of Commun. Eng., Shibaura Inst. of Technol., 3-7-5 Toyosu Koutou-ku, Tokyo, 135-8548 Japan, m603101@sic.shibaura-it.ac.jp)

Important information of the room acoustic characteristics is contained in the room impulse response. We analyze the time-space correlation of the impulse response by the self-similarity method. The room impulse response is divided into the frame of the length of the fixed time. Attractors are composed by affine transformation of each frame. The attractors that make the Hausdorff distance become the shortest between the standard frame and attractors are decided. The impulse response is reconstructed by using these attractors. In the self-similar analysis, the frame length is decided from the period of the Hausdorff distance between the initial sound and the reflection sound. We show results for the relation between the room acoustic characteristics and the attractors calculated from the self-similar analysis.

1:45

2pSP4. Application of dynamic synapse neural networks on gunshot recognition. Alireza A. Dibazar, Hyung Ook Park, Walter M. Yamada, and Theodore W. Berger (Dept. of Biomed. Eng., Univ. of Southern California, 1042 Downey Way, DRB140, Los Angeles, CA 90089-1111, dibazar@usc.edu)

Identification of acoustic signals in noisy environments remains one of the most difficult of signal processing problems, and is a major obstacle to the high degree of accuracy and speed needed to identify suspicious sounds in high-security, high-safety environments. We have previously developed an acoustic recognition capability using a novel, biologically based Dynamic Synapse Neural Network (DSNN) technology. The DSNN-based technology has been demonstrated to classify target sounds with a high degree of accuracy, even in high noise conditions. In this paper we focus on extending the acoustic recognition capability of DSNNs to the problem of gunshot recognition. In order to recognize and localize the event, an array of four microphones is used for sound input. For localization purpose, time-delay estimation algorithm (TDE) is employed for triangulation. We have developed stand-alone, portable, and cost-efficient hardware with which both recognition and localization can be performed. In field-testing, the system classifies and localizes over 90% of the trained-for sounds. Performance for firecracker, starter pistol, 9-mm, and 44-caliber, explosion/firing sounds was also tested.

2:00

2pSP5. Effects of reproduction methods and audio coding on word intelligibility with competing talkers. Kenji Ozawa and Junichi Nakagai (Interdisciplinary Grad. Sch. of Med. and Eng., Univ. of Yamanashi, 4-3-11 Takeda, Kofu, 400-8511 Japan, ozawa@yamanashi.ac.jp)

Effects of reproduction methods and high-efficiency audio coding on word intelligibility were examined in a tele-collaboration system. Monaural, stereophonic, and binaural methods were studied. Transform domain weighted interleave vector quantization (TwinVQ) [Iwakami *et al.*, Proc. ICASSP'95, pp. 937–940 (1995)] was used as the audio coding method. Intelligibility tests using word lists, in which word familiarity was controlled, were conducted under six conditions combining three reproduction methods with two conditions, i.e., with or without audio coding. In the experiments, three talkers pronounced different words simultaneously; a listener was then asked to selectively hear the word of a designated talker. Analyses of variance of the experimental results showed that intelligibility for the binaural method was higher than for the other two reproduction methods in both conditions with or without audio coding. Moreover, the benefit of the binaural method was demonstrated because intelligibility for the method with audio coding was higher than that for the stereophonic method without coding, whereas the amount of audio data in the former method was much smaller than in the latter, indicating that the binaural method with high-efficiency audio coding is useful for a tele-collaboration system. 2pSP6. Environmental adaptation of hidden Markov models in an automatic sounds recognition system used for surveillance applications. Asma Rabaoui, Zied Lachiri, and Noureddine Ellouze (ENIT (Ecole Nationale des Ingenieurs de Tunis) Rue Ibn Mandhour, Residence Sana, Bloc Yasmine, App10, ARIANA 2080 Tunisie)

Generally, the main goal of an automatic sound recognition system is to analyze in real time the sound environment of a habitat and to detect the abnormal sounds that could indicate a distress situation. In a surveillance application, the most encountered problem is the background noise that can be captured with the sounds to be identified. Thus, we propose to use a multistyle training system based on HMMs: one recognizer is trained on a database including different levels of background noises and is used as a universal recognizer for every environment. In order to enhance the system robustness, we will explore different adaptation algorithms that reduce the environmental variability. The algorithms closely examined are maximum likelihood linear regression (MLLR), maximum *a posteriori* (MAP), and the MAP/MLLR algorithm that combines MAP and MLLR. Experimental evaluation illustrates a recognition improvement over the baseline system (i.e., none adapted system) results. By using 156 adaptation scenes, the error rate of the adapted recognizer improves over the baseline system by more than 30% for rather all the considered algorithms, even under important noise degradation conditions.

2:30

2pSP7. Passive acoustic fiber Bragg grating sensor measurements of Green function in an instrumented part. Karl A. Fisher, Sean K. Lehman, and David H. Chambers (Lawrence Livermore Natl. Lab., L-333, 7000 East Ave., Livermore, CA 94550)

The development of fiber Bragg grating (FBG) sensors for acoustic measurements permits the instrumentation of manufactured composite parts for the purposes of nondestructive evaluation (NDE) and lifetime monitoring. The parts can be designed from conception with an array of FBG acoustic receivers integrated into its internal structure for the purpose of multistatic data collection for NDE and monitoring of internal changes. The FBG array is accessed via a port on the outer surface and requires no additional power demands on the operation of the part. Data collection is accomplished by activating sources on the surface of the part and measuring the fields along the FBG array. We are particularly interested in Green function (GF) estimation of a FBG instrumented composite structure. By

passively measuring diffuse acoustic fields throughout the volume, we use a technique developed by Lobkis and Weaver [J. Acoust. Soc. Am. **110**(6), 3011–3017 (2001)] to estimate the GF within the part and monitor it over time. We describe FBG sensor array operation, review the theory of diffuse field GF estimation, and present examples in heterogeneous multilayered structures. [This work was performed under the auspices of the U.S. DOE by University of California Lawrence Livermore National Laboratory under Contract No. W-7405-Eng-48.]

2:45

2pSP8. Super-resolution algorithms for ultrasonic nondestructive evaluation imagery. Grace Clark (Univ. of California Lawrence Livermore Natl. Lab., 7000 East Ave., L-130, Livermore, CA 94550, clark9@llnl.gov) and Jessie Jackson (Univ. of California Lawrence Livermore Natl. Lab., Livermore, CA 94550)

The spatio-temporal range resolution of ultrasonic measurements is often severely limited by the inherent band-limited spectral transfer function of ultrasonic transducers. This is manifested as ringing in the time domain. Super-resolution algorithms and a new MATLAB-based software system are presented for improving spatial resolution in one-dimensional (1-D) pulse-echo signals (A-scans). Two-dimensional (2-D) images (B-scans) and 3-D volumes are formed from suites of processed 1-D signals. The algorithms solve two inverse problems that are ill-posed and ill-conditioned. Regularization techniques and prior constraints are used to ensure useful results in practice. Given a noisy reflection signal (A-scan) $u(t)$ and an associated reference signal $x(t)$, the algorithms first solve the system identification problem to produce an optimal least-squares band-limited estimate $\hat{h}(t)$ of the impulse response of the material under test. Next, an algorithm based upon the method of alternating orthogonal projections produces a spectrum−extrapolated version $\hat{h}_e(t)$ of the impulse response estimate. This estimate, when used in place of the raw reflection signal $u(t)$, enhances the spatio−temporal resolution by mitigating the transducer distortion. The efficacy of the algorithms is demonstrated on real data from controlled experiments. Three different practical applications are presented, showing improved location of material interface boundaries. [Work supported by Grant UCRL−ABS−222494.]

2pSP9. Nondestructive technique to detect a crack in a concrete block by precise estimation of the surface wave. Takeshi Murakami, Toyota Fujioka, Yoshifumi Nagata, and Masato Abe (Dept. of Comput. and Information Sci., Faculty of Eng., Iwate Univ., Ueda 4-3-5, Morioka City, Iwate, Japan)

This paper describes a method to estimate a crack's position in a concrete block using several accelerometers. An array of accelerometers is attached to the concrete block and an impact is made on the concrete surface with a small hammer. If a crack exists, a reflection wave is generated at the crack position. Conventional methods to estimate the reflection point may seem to be useful for detection. Since the concrete block is elastic, however, it has three wave propagation modes: the surface wave mode, the primary wave mode, and the secondary wave mode. We cannot estimate the position using conventional methods because the necessary primary wave mode is weaker than the surface wave mode. To estimate the crack position precisely, we have already proposed two methods to eliminate the surface wave and side wall reflections. However, since the elimination is insufficient, they sometimes yield a peak at a position where there is no crack. Therefore, this paper proposes a method to estimate the surface wave more precisely to suppress such a peak. Some experiments were carried out, yielding better results.

3:30

2pSP10. Applying broadband beam-based decomposition of the time reversal operator (BBDORT) to midfrequency active sonar systems. David M. Fromm (Naval Res. Lab., 4555 Overlook Ave. SW, Washington, DC 20375-5350)

This paper reports on progress developing broadband beam-based decomposition of the time-reversal operator (BBDORT) for midfrequency hull-mounted active sonar systems. BBDORT combined with backpropagation has been previously demonstrated to localize a mid-water-column target in shallow water using a vertical source-receiver array [Fromm and Gaumond, J. Acous. Soc. Am. **118**, 2039]. However, the array spanned the water column, and choosing an optimal beam set (to scan for targets in a short period of time) can make as much as 30-dB target improvement over nonoptimal beam sets. Current research efforts will address: source-receiver array configurations and tactical frequencies of Navy operational interest, evaluating performance in different environments, and determining efficient algorithms to optimize beam sets. [Work supported by the Office of Naval Research.]

3:45

2pSP11. Properties of focused time reversal operator in random media. Jean-Luc Robert (Philips Res. North America, 345 Scarborough Rd., Briarcliff Manor, NY 10510, jean-luc.robert@philips.com) and Mathias Fink (Universite Paris 7, 75005 Paris, France)

FDORT (focused DORT) is an alternative of the DORT method using focused transmits instead of single-element transmits. In the case of well-resolved point scatterers, the FDORT eigenvectors may be understood as invariants of the time reversal operator. However, if the medium is a collection of many subresolution scatterers (speckle), a different interpretation is more helpful. It is shown that, in speckle, the FDORT matrix may be interpreted statistically as a spatial correlation matrix, whose coefficients are the correlation between signals received by pairs of elements. The matrix is fully described by the Van Cittert Zernike theorem. The first eigenvector still has focusing properties, and the eigenvalues can be related to the so-called focusing criterion. Applications to aberration estimation in medical ultrasound are presented.

4:00

2pSP12. Spatio-temporal invariants of the time-reversal operator. Jean-Luc Robert (Philips Res. North America, 345 Scarborough Rd., Briarcliff Manor, NY 10510, jean-luc.robert@philips.com) and Mathias Fink (Universite Paris7/ESPCI, 75005 Paris, France)

The DORT method gives the spatial invariants of the monochromatic time-reversal operator, at a given temporal frequency. It allows the monochromatic Green functions of point scatterers to be extracted from a data set. However, in acoustics, broadband signals are usually used and thus, it is often interesting to have the invariants in the time domain, or to know the evolution of the monochromatic Green function with frequency. It is not always easy, especially in complex media, because the sequence of the DORT eigenvectors (the invariants) changes as a function of the frequency. Thus, an invariant corresponding to a given scatterer may be the first at low frequencies, but the second at higher frequencies. Therefore, it is difficult to reconstruct a spatio-temporal Green function from monochromatic invariants. We introduce here the spatio-temporal time-reversal operator as a linear operator described by a fourth-order tensor, and deduce a method to obtain its spatio-temporal invariants. The method reduces to a more straightforward matrix decomposition, and thus can be easily implemented. Properties of the invariants are described, and applications to focusing in complex media are presented.

4:15

2pSP13. Semiautomatic inverse filtering of vowels with differing degrees of nasality. Michelle Tooher and Christer Gobl (Phonet. and Speech Lab., School of Linguistic Speech and Commun. Sci., Trinity College Dublin, Dublin 2, Ireland, mtooher@tcd.ie)

Most approaches to inverse filtering are either manual or automatic. Manual methods, while providing high-quality fine-grained analysis, require user expertise and manpower to analyze even small amounts of data. Automatic methods allow large-scale analysis, but lack the precision required to capture non-neutral voice dynamics as present in, for example, expressive speech. This paper reports on development of a semiautomatic inverse-filtering toolkit, focusing on an adaptive nasal/non-nasal vowel inverse filter. For vowels with differing degrees of nasality (from not nasalized to heavily nasalized), each frame is analyzed using machine learning techniques to assess the degree of nasality. Based on this assessment, the inverse filter is adapted according to acoustic theory, to best analyze each frame of the data, employing either all-pole or pole-zero analysis where necessary. User intervention is possible, in both specifying analysis frames and fine-tuning of pole and zero number and location. Training data for machine learning are selected on the basis of auditory and acoustic analysis. This semiautomatic approach allows analysis of large-scale corpora while retaining the robustness and fine-grained analysis of manual methods. Results from analysing both non-nasalized and nasalized vowels from a corpus of Irish are presented. [This work is funded by the IRCSET Embark Initiative.]

4:30

2pSP14. Ambiguity analysis of matched-field source localization under spatially correlated noise field. Wen Xu (Teledyne RD Instruments, 14020 Stowe Dr., Poway, CA 92064)

Matched-field processing (MFP) concerns estimation of source location by exploiting full-wave modeling of acoustic waveguide propagation. The ambiguity output in MFP relies on the correlation between the signal field at the true source position and the signal field at each scanning source position. This correlation often shows a multimodal structure due to the nonlinear parameter dependence: in addition to a mainlobe around the true source position, there are unpredictable prominent high sidelobes elsewhere. For a well-conditioned problem, in the absence of noise the peak output is guaranteed to occur at the true source position. In the presence of noise, we will probably have some peak outputs around the sidelobes, introducing a large localization error. Therefore, output ambiguity structure is a very important factor in the development of any matched-field algorithm operated in low-SNR scenarios. To analyze the ambiguity behavior, a quantitative approach for error analysis has previously been developed in the context of the maximum likelihood estimate (MLE) with spatially white noise. In this talk, generalization to including spatially correlated noise field introduced by discrete interferences and/or surface distribution sources is discussed.

4:45

2pSP15. Multiuser communications using passive time reversal. Heechun Song, William S. Hodgkiss, William A. Kuperman, Tuncay Akal (MPL/SIO, UCSD, La Jolla, CA 92093-0238), and Mark Stevenson (NATO Undersea Res. Ctr., La Spezia, Italy)

A recent paper [Song *et al.*, IEEE J. Ocean. Eng. **31**, 165–173 (2006)] demonstrated multipleinput/multiple-output (MIMO) multi user communications in shallow water using active time reversal where the time reversal array (i.e., base station) sent different messages to multiple users simultaneously over a common bandwidth channel. Passive time reversal essentially is equivalent to active time reversal with the communications link being in the opposite direction. This paper describes MIMO passive time reversal communications, which enables multiple users to send information simultaneously to the time reversal array. Experimental results at 3.5 kHz with a 1-kHz bandwidth demonstrate that as many as six users can transmit information over a 4-km range in 120-m-deep shallow water using QPSK modulation, achieving an aggregate data rate of 6 kbits/s. Moreover, the same data rate has been achieved at 20 km range by three users using 16-QAM modulation.

2pUW1. Concerning the sediment volume contribution to scattering in SAX04 (Sediment Acoustics Experiment 2004) sediment: Sound speed and bulk density fluctuations. Kevin Briggs (Seafloor Sci. Branch, Naval Res. Lab., Stennis Space Ctr., MS 39529-5004)

Sound speed and bulk density profiles measured from SAX04 sediment cores are used to estimate correlation lengths of fluctuations in the sound speed and the bulk density. Sound speed is measured from 5.9-cm-diameter cores at 1-cm intervals and bulk density is measured at 2-cm intervals from the same cores. Previous estimates of these parameters from experimental data involved fewer realizations (cores), limited sampling areas, and samples without mud flasers within the sand sediment. Values of correlation length may vary according to location within the SAX04 site. Correlation length values estimated with Burg's algorithm from sediment sound-speed fluctuations averaged 2.24 cm, from sediment bulk density fluctuations averaged 2.53 cm. Ranges of values of correlation length estimated from bulk density fluctuations from locations inside the experiment site are used to present a range of volume scattering strength predictions, given the other parameters of sediment sound speed, sound attenuation, density ratio variance, and ratio of sound speed to density fluctuations used by the perturbation approximation to the composite roughness model for each location. At the SAX04 site, interface scattering

dominated over volume scattering, despite the presence of mud inclusions with strong sound speed and bulk density contrasts. [Work sponsored by ONR.]

2pUW2. The effects of layering on reflection coefficient and transmission measurements from a sand/water interface at the Sediment Acoustics Experiment 2004 (SAX04). Marcia Isakson (Appl. Res. Labs., Univ. of Texas, Austin, TX 78713)

During the Sediment Acoustics Experiment 2004 (SAX04), transmission measurements from 4.5 to 50 kHz were taken on an eight-transducer array buried at an angle of 15 deg using a source mounted on a remotely operated vehicle (ROV). Simultaneously, the reflection coefficient was measured using a three-receiver vertical line array (VLA). Reflection coefficient measurements at angles from 10 to 70 deg were obtained. Environmental characterization of the area has revealed layering effects such as a surficial mud layer, mud inclusions, and depth-dependent sediment properties such as porosity. The consequence of this layering on the variability of the amplitude of reflection coefficient measurements and the time of arrival of transmission measurements will be investigated. [Work supported by ONR, Ocean Acoustics.]

2pUW3. Measurement and modeling of elliptical particle motion in the seabed. John C. Osler, David M. F. Chapman, Paul C. Hines, Jeffrey Scrutton (DRDC Atlantic, P.O. Box 1012, Dartmouth, NS B2Y 3Z7, Canada, john.osler@drdc-rddc.gc.ca), and Anthony P. Lyons (The Penn State Univ., State College, PA 16804)

As part of the SAX04 experiment conducted off the coast of Florida in the Gulf of Mexico, four vector sensors containing three-axis accelerometers and pressure sensors were buried in the seabed. These served as the receivers to measure sediment sound-speed dispersion using a variety of techniques. One technique involved the generation of spherical waves from a point source in water and transmitted into the seabed in the frequency band 800 to 3000 Hz. In this geometry, the contribution of inhomogeneous waves to the field results in elliptical—rather than longitudinal—particle motion. The orientation of the elliptical orbit varies with the source-receiver geometry, frequency, and the sediment sound speed, thereby allowing measurements of sediment sound-speed dispersion. However, the orientation of the ellipse major axis is not always aligned with the direction of wave propagation suggested by Snell's law. Measurements were made at several angles approaching the nominal critical angle in order to address the trade-off between increased sensitivity of the measurement versus greater departure from Snell's law. Measurements and modeling of the elliptical particle motion are compared to ensure that the sediment sound-speed estimates account for any bias created by the inhomogeneous waves. [Work partially supported by ONR.]

2pUW4. Characterization and modeling of synthetic aperture sonar image statistics. Anthony P. Lyons, Shawn F. Johnson, Douglas A. Abraham (The Penn State Univ., Appl. Res. Lab., State College, PA 16804, apl2@psu.edu), and Kevin L. Williams (Univ. of Washington, Seattle, WA 98105)

Interest in the application of synthetic aperture sonar (SAS) to seafloor mapping and object detection has been increasing in recent years. Because images of the seafloor obtained with SAS systems can sometimes exhibit large pixel-to-pixel fluctuations, robust seafloor segmentation or target detection still requires a thorough understanding of the SAS image statistics and their relation to seafloor parameters. As part of the SAX04 sediment acoustics experiment, acoustic data suitable for SAS processing were collected using a bottom-mounted rail system off the coast of Florida in the Gulf of Mexico in October, 2004. This unique data set has been used to explore several important aspects of SAS image statistics including their dependence on system resolution and on the correlation structure of SAS reverberation due to ripples that were present at the study site. Models of

the reverberation envelope probability distribution function (pdf) based on the K-distribution have been found to well describe the reverberation environment for systems with lower resolutions than possible with broadband SAS systems. Characterization and modeling of SAS image statistics based on the K-distribution and using ground truth collected during SAX04 will be presented. [Work performed under ONR Grants N00014-04-1-0013 and N00014-06-1-0245.]

2:00

2pUW5. Modeling the effect of multipath on high-resolution synthetic aperture sonar image statistics. Shawn F. Johnson, Anthony P. Lyons, Douglas A. Abraham (Appl. Res. Lab., The Penn State Univ., State College, PA 16804, sfjohnson@psu.edu), and Kevin Williams (Univ. of Washington, Seattle, WA 98105)

Recent analysis of Synthetic Aperture Sonar data collected during the Office of Naval Research sponsored SAX04 experiment in the Gulf of Mexico during October 2004 has shown that the processed image has varying amplitude statistics as a function of range. Since synthetic-aperture sonar maintains a constant range-independent resolution cell size, unlike traditional sonar systems, one would expect that the statistics of the image would be based solely on the seafloor properties. The K-distribution shape parameter was estimated as a function of range and increases at discrete ranges corresponding to the onset of multi-path propagation (low shape parameter values represent a heavy tailed distribution). At these points of increase in shape parameter, scattered returns arising from additional propagation paths arrive with the result that two or more parts of the seafloor are contributing to the same sonar resolution cell, which leads to a larger K-distribution shape parameter than would be expected when only the direct path contributes. Model results using the sonar system geometry and interface scattering theory will be used to illustrate this effect. [Work supported by ONR Codes 321 and 333. First author supported by a National Defense Science and Engineering Graduate Fellowship.]

2pUW6. Synthetic aperture sonar imaging of buried spheres and cylinders. Steven G. Kargl and Kevin L. Williams (Appl. Phys. Lab., 1013 NE 40th St., Seattle, WA 98105)

During SAX04, synthetic aperture sonar (SAS) was used to detect buried spheres where the nominal grazing angle of incidence from the SAS to the point above a sphere was well below the sediment's critical grazing angle. SAS images from other measurements below the critical angle on buried spheres and finite cylinders in the NSWC-PC test pond facility have also produced target detections. Numerical simulations will be discussed that accurately predict the observed signal to noise (SNR). Simulations include estimates of reverberation from the rough seafloor, and the subcritical penetration through the seafloor, scattering from a target, and propagation back to the SAS. Required material parameters were obtained from environmental measurements including profiles of the small-scale surface roughness and the superimposed ripple structure. These simulations, the sonar equation results, and the model/measurement comparisons over the frequency range of 10–50 kHz further support sediment ripple structure as the dominant mechanism for subcritical penetration in this range. [Work supported by ONR.]

2pUW7. Measurement of scattering wave from a buried object using an underwater vehicle. Koichiro Tanaka, Taku Suto, and Takahiro Fukai (Ishikawajima-Harima Heavy Industries Co., Ltd., 1, Shin-Nakahara-Cho, Isogo-Ku, Yokohama 235-8501, Japan, kouichirou_tanaka@ihi.co.jp)

Measurements of a scattering wave from a buried object were carried out at a site in Tokyo Bay. The buried object was set below the bottom with about 10-m water depth. A crane suspended a subbottom profiler to insonify the object. In these measurements, the medium frequency (less than 10 kHz) was used to penetrate near the critical angle. Also, when the object shape is a cylinder and so on, the scattering wave appears strongly

in the specific direction, which is with the shape of the object and the physical relationship of the source and the object. The direction where this scattering wave appears is strongly different from the source position, and it is difficult to catch in the mono-static position. Especially, because the level of the scattering wave becomes low in the case of the scattering from the object under the seafloor, it is favorable if the scattering wave can be measured in the direction with this strong level. Therefore, to catch this strong scattering wave, an underwater vehicle was used. A hydrophone array was attached at the head of the underwater vehicle to accumulate over a series of pings. This report deals with the way and results of these measurements.

2:45

2pUW8. Buried target detection with a synthetic aperture sonar. John Piper (NSWC-PC, 110 Vernon Ave., Panama City, FL 32407)

During SAX04 the NSWC-PC dual-frequency synthetic aperture sonar collected data from a buried target field. Detections of a buried fluid-filled sphere from above critical angle averaged 34 dB and from below critical angle averaged 24 dB with a ripple field with predominant 42-cm spacing. These results are compared to simulated PCSWAT results.

3:15

2pUW9. Using a dual-band synthetic aperture sonar for imaging various seafloor compositions. John S. Stroud, Daniel Brown, Jr., Daniel Cook, Jose Fernandez (NSWC-PC Code HS11, 110 Vernon Ave., Panama City, FL 32407), Kerry Commander (Office of Naval Res., Arlington, VA 22203), David Kolesar, and Tom Montgomery (Appl. Res. Lab, State College, PA 16804)

The Small Synthetic Aperture Minehunter (SSAM) is a synthetic aperture sonar mounted aboard a 12.75-in. REMUS600 unmanned underwater vehicle transmitting both low (10–50 kHz) and high (105–135 kHz) frequency bands. The sonar and the vehicle are highly integrated, which allows precise pulse timing, attitude correction, and object geolocation. Operating simultaneously in both bands produces two independent images of each scene. The upper band is capable of 2.5- by 2.5-cm resolution that provides high-fidelity images of proud targets. The lower band, processed to 7.5- by 7.5-cm resolution, adds clutter reduction as well as capabilities against buried targets. The dual bands of this sonar have proved to be a robust solution for minehunting in the littorals. In the past 18 months, SSAM has been deployed nine times. In these tests, the system has operated against bottom types including mud, sand, rippled sand, layered mud and sand, posidonia, and coral. Imagery from sea tests showing all of these bottom types will be presented. [The authors would like to acknowledge support from the ONR, Code 32.]

3:30

2pUW10. Performance of a buried object scanning sonar against targets buried in sand at the SAX-04 (Sediment Acoustics Experiment 2004) site. Steven Schock (Dept. of Ocean Eng., Florida Atlantic Univ., 777 Glades Rd., Boca Raton, FL 33431, schock@oe.fau.edu)

The performance of synthetic aperture processing for imaging buried targets in the band of 3 to 20 kHz is quantified by measuring the SNR of 3-D acoustic images of targets buried in sand at the SAX-04 site. A buried object scanning sonar consisting of an omnidirectional projector and a 40-channel hydrophone line array is towed within 10 m of the seabed at various horizontal offsets to buried targets to measure the SNR of target echoes as a function of grazing angle. Detections of the targets occurring at grazing angles smaller than the critical angle suggest that buried targets can be detected using the evanescent boundary wave thereby improving the range of the sonar for detecting shallow-buried targets. Acoustic images of buried targets also show that backscattering from sand ripples, sediment variability, and sediment layer interfaces limit the performance of the sonar for detecting and imaging buried objects.

3:45

2pUW11. The design of a boundary element package for treating acoustic scattering from buried objects. Ralf Burgschweiger, Martin Ochmann (Univ. of Appl. Sci., Dept. of Mathematics, Phys., Chemistry, TFH Berlin Luxemburger Strasse 10, D-13353 Berlin, Germany), and Bodo Nolte (Federal Armed Forces Underwater Acoust. and Marine Geophys. Res. Inst. (FWG), D-24148 Kiel, Germany)

The target strength of objects placed in water and partially buried in the sediment are calculated by means of a boundary element solver. For this reason, a boundary element code with suitable pre- and postprocessor is developed. With the help of the preprocessor, the scattering objects within the transition range between fluid and sediment can be modeled. The preprocessor can manage large and complex meshes (more than 100 000 elements) and is able to import NASTRAN and ANSYS mesh-files. It automatically generates closed geometric meshes. These meshes are used as database for the BEM calculations. For reducing computing time, the boundary element solver runs on a high number of personal computers in parallel equipped with Windows- or Linux-operating systems. These calculator hosts will receive their task from the preprocessor using TCP/IP-based interprocess communication. The parallel calculations can be performed as a service in the background and remotely administrated by the postprocessor. The postprocessor polls the results from the calculator hosts, delivers them to the appropriate projects, and provides visualization and analysis of the results. The efficiency of such a parallel processing boundary element package will be demonstrated for the acoustic scattering at simple test objects consisting of a high number of surface elements.

4:00

2pUW12. Subcritical grazing angle detection of targets buried under a rippled sand interface. Joseph L. Lopes, Carrie L. Dowdy, Raymond Lim (Naval Surface Warfare Ctr., Code HS11, 110 Vernon Ave., Panama City, FL 32444), Dajun Tang, Kevin L. Williams, and Eric I. Thorsos (Univ. of Washington, Seattle, WA 98105-6698)

Controlled acoustic measurements were conducted to investigate subcritical detection of targets buried in sand having a rippled sediment-water interface. The measurements were performed in a freshwater test-pond with a 1.5-m layer of sand on the bottom. Bottom ripple was formed by scraping the sand with a machined rake. Broadband (10 to 50 kHz) transducers were placed onto an elevated rail that translated horizontally permitting data to be processed using synthetic aperture sonar (SAS) techniques. Targets included silicone oil-filled spheres and flat-endcapped, solid aluminum cylinders. Data were acquired for various ripple wavelengths, heights, and orientations. For each bottom configuration, the seabed roughness over the buried target was measured to verify the ripple parameters and to estimate the small-scale roughness spectrum. This information was used in models predicting backscatter signal levels from the target and bottom. Results for spherical targets have generally been good. However, when cylindrical targets were inspected, model agreement was variable for reasons not fully understood. Characteristics of the target return are found to depend sensitively on ripple height and wavelength, and bottom parameters. Results are discussed with an eye towards understanding previously unexplained field test detections of buried cylindrical targets. [Work supported by ONR and SERDP.]

4:15

2pUW13. Scattering of evanescent waves incident on targets in a simulated sediment. Curtis F. Osterhoudt and Philip L. Marston (Dept. of Phys. and Astron., Washington State Univ., Pullman, WA 99163)

When a sound beam in water is incident on a sediment at a sufficiently small grazing angle, the resulting wave field in the sediment is complicated, even for the case of flat, fluidlike sediments. The wave field in the sediment for a sound beam from a simple transducer has an evanescent component and diffractive components. This situation has been experimentally simulated by using a combination of previously described immiscible liquids [Osterhoudt *et al.*, J. Acoust. Soc. Am. **117**, 2483 (2005)]. Measured wave-field features are similar to those seen in a wave-number-

integration-based synthesis (using OASES) for a related problem. Targets are placed in the evanescent wave field to simulate scattering by targets buried in marine sediments. Features of the observed backscattering are relevant to detecting and clarifying objects in sediments. Measurements include the resonant excitation of the organ-pipe mode of open water-filled cylinders previously studied with free-field illumination [Osterhoudt and Marston, J. Acoust. Soc. Am. **113**, 2334 (2003)]. The degradation of the backscattering with increasing target depth and with target tilt were measured and modeled. Simple approximate models of these properties are facilitated by the localized coupling processes for the excitation of (and radiation by) organ-pipe modes. [Work supported by ONR.]

4:30

2pUW14. Observations of subcritical acoustic penetration of a sandy seafloor. Darrell R. Jackson, Brian T. Hefner, Kevin L. Williams, and Eric I. Thorsos (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698, drj@apl.washington.edu)

During the sediment acoustic experiments, SAX99 and SAX04, buried hydrophone arrays were used in conjunction with sources mounted on a movable tower to study subcritical acoustic penetration. The seafloor at the SAX99 site displayed prominent, regular sand ripples of 48-cm wavelength. These caused downward diffraction of sound incident below the critical angle, resulting in elevated sound-pressure fields in the sediment. These measurements were made over the frequency range 11–50 kHz and were in substantial agreement with a first-order perturbation model. For SAX04, the frequency range was extended down to 2 kHz, but the site had weaker, more disorganized ripples. As expected, this resulted in weak acoustic penetration, with the pressure field primarily due to the evanescent wave. To further test the penetration model, artificial ripples of wavelength 50 and 75 cm were created by divers. These ripples increased sound penetration levels by 5–10 dB when the incidence azimuthal direction was normal to the ripple crests. The diffraction angles of the penetrating sound were found to be consistent with the predictions of the perturbation model. [Work supported by ONR.]

4:45

2pUW15. Backscattering from sediments: Comparison of scattering strengths from a simple sand and from a sand/mud environment. Kevin Williams, Eric Thorsos, Dajun Tang, and Darrell Jackson (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105-6698, williams@apl.washington.edu)

Two sediment acoustics experiments were carried out within 1 km of each other off the coast of Florida, the first in 1999 and the second in 2004. Though close in space the sediment was very different due to the effects of Hurricane Ivan in 2004. Hurricane Ivan resulted in the deposition of mud patches on top of the medium sand. Subsequent weather events deposited sand on top of these patches. The backscattering at each site will be presented for frequencies from 20 to 1000 kHz and grazing angles from 20 to 45 deg. At angles below the critical angle (30 deg) and frequencies below 150 kHz the backscattering measured in the two experiments is consistent given the difference in the sediment roughness spectra.

Above the critical angle, however, the backscattering measured in the 2004 experiment is several dB higher than in the 1999 experiment and increases immediately above the critical angle instead of decreasing. This difference is attributed to an increase in sediment volume scattering in 2004. From 150 to 1000 kHz the data from both years indicate a change in scattering mechanism below the critical angle to a mechanism differing from sediment interface roughness scattering. [Work supported by ONR.]

5:00

2pUW16. Measurements of interface roughness and examination of near bottom interface properties. Dajun Tang, Brian Hefner, Kevin Williams, and Eric Thorsos (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

A series of measurements was made of sediment properties during SAX04 over a 40-day period using IMP2, a sediment conductivity system; a stereo camera system made fine-scale interface roughness measurements toward the end of this period. During this period, several weather events (including Hurricane Ivan and a subsequent tropical storm) altered the sediment properties. The large, nonsymmetric ripples resulting from the hurricane decayed to a more symmetric form over time, while mud suspended in the water column was found first on top of the sand and then trapped just beneath the interface. Comparison of the interface roughness power spectra from IMP2 and the stereo camera shows good agreement at overlapping spatial scales and the stereo measurements extend the IMP2 estimation of the power spectra to a much higher spatial frequency. Complementary cores taken by a team from the Naval Research Laboratory at the same sites where IMP2 was deployed confirmed the depth and location of the imbedded mud found by IMP2. The implications of these environmental measurements to acoustic backscattering will be discussed. [Work supported by the ONR.]

5:15

2pUW17. Laboratory study of high-frequency scattering from water-saturated granular sediments. Anatoliy Ivakin (APL-UW, 1013 NE 40th St., Seattle WA 98105), Jean-Pierre Sessarego, and Regine Guillermin (CNRS/LMA, 13402 Marseille cedex 20, France)

Sound backscattering and reflection from water-saturated granular sediments at frequencies from 200 kHz to 7 MHz were studied in controlled laboratory conditions. Two kinds of well-sorted sandy sediments, fine and coarse sands, and two kinds of glass beads with corresponding sizes were chosen for the study. The two types of sand had narrow log-normal size distributions of particles with the mean diameters 0.25 and 1.5 mm for fine and coarse sand, respectively. The sediments were degassed and their surface was flattened carefully. In these conditions, the grain-scattering mechanism can be considered as a dominating factor controlling incoherent component of the field scattered from the sediment. Frequency dependencies for the backscattering strength at various grazing angles and the reflection coefficient at normal incidence were measured. The effects related to the sediment grain size are analyzed and their possible applications to remote sensing of marine sediments are discussed. [Work supported by ONR and CNRS.]

Chair's Introduction—7:30
Invited Papers

7:35

3aAAa1. Characterizing viscoelastic and anisotropic porous materials. Laurens Boeckx, Poonam Khurana, Gerrit Vermeir, Walter Lauriks (Laboratorium voor Akoestiek en Thermische Fysica, Celestijnenlaan 200D, BE-3001, Leuven, Belgium, laurens.boeckx@fys.kuleuven.be), and Wim Desmet (Katholieke Universiteit Leuven, BE-3001, Belgium)

A wide range of commercial applications (building acoustics, food industry, automotive industry) can be found for porous materials. Accurate material characterization and modeling is vital for the use of these materials in multilayered systems due to increasing demands in acoustic comfort, noise legislation, and quality control during production. There is, however, a distressing lack in raw, accurate material data and measurement methods concerning the characterization of these materials. Measuring and modeling methods for the characterization of these materials will be presented. The experimental technique for the determination of the elastic properties is based upon the excitation of waveguides in porous materials. The other parameters of the Biot-Allard model are predicted using ultrasound. Acoustical properties can be predicted by using the measured structural material properties and incorporating them into a transfer-matrix-based multilayered model.

7:55

3aAAa2. Linking microstructure and acoustic properties of open-cell foams. Camille Perrot, Raymond Panneton (GAUS, Dept. of Mech. Eng., Universite de Sherbrooke, QC, Canada, J1K 2R1, camille.perrot@usherbrooke.ca), and Xavier Olny (ENTPE DGCB URA CRNS, Audin 69518, Vaulx en Velin, France)

A research program has been initiated in 2002 in order to link microstructure of high porosity open-cell foams to their acoustic properties. This paper is intended to highlight the main results of this study. The general objective of the research program is the determination of the acoustical macro-behavior from the physics at the local scale. A real rigid-framed porous media is studied. To this end, one needs first to determine the local geometry of the media, and second to solve over this geometry the partial differential equations that govern dissipation phenomena by thermal and viscous effects. The first step has been overcome by the technique of computed microtomography. This leads to experimental identification of the parameters of an idealized periodic unit-cell. The second step, solving harmonic heat and viscous fluid equations, is performed using Brownian motion and finite element simulations, respectively. Then, macroscopic behavior is obtained by spatial averaging of the local and frequency-dependent thermal and velocity fields. Results are presented in terms of two dynamic characteristic functions (viscous and thermal permeabilities) compared to impedance tube measurements. This computational methodology may be seen as a first step to optimize the microstructure of foams from a bottom-up approach for better sound proofing.

8:15

3aAAa3. Interlaboratory experiments on the characterization of the acoustical and related nonacoustical properties of porous media. Kirill Horoshenkov, Amir Khan (Univ. of Bradford, Bradford, UK), Frank Sgard, Francois Xavier, BecoLuc Jaouen, Amlie Renault, Nesrine Amirouche (Ecole Nationale des Travaux, Lyon, France), Jorn Hubelt (Gesellschaft fr Akustikforschung Dresden mbH (AFD), Germany), Francesco Pompoli, Nicola Prodi, Paolo Bonfiglio (Universita di Ferrara, Ferrara, Italy), Walter Lauriks, Laurens Boeckx (Katholieke Universiteit Leuven, Belgium), Giulio Pispola, Francesco Asdrubali (Univ. of Perugia, Perugia, Italy), Noureddine Atalla, Celse Amdin (Univ. of Sherbrooke, Sherbrooke, Canada), K. Mark Gmerek, and Adam Weston (The Boeing Co., Chicago, IL)

A series of reproducibility experiments on the characterization of acoustical parameters of selected samples of porous media is carried out on a range of porous samples in several independent laboratories in Europe and North America. The data on the characteristic acoustic impedance and complex propagation constant are presented in this work. In addition, the assessment of the related geometrical parameters required for modeling the acoustic performance of porous media, namely the steady-state flow resistivity, porosity, tortuosity, viscous and thermal characteristic lengths, and thermal permeability, is carried out. Detailed procedures related to sample preparation, and installation are discussed together with data on the material property variation observed between individual material samples and laboratories.

3aAAa4. Sound absorption characteristics of a honeycomb-backed microperforated panel (MPP) absorber. Kimihiro Sakagami, Kosuke Nakajima, Masayuki Morimoto (Environ. Acoust. Lab., Faculty of Eng., Kobe Univ., Rokkodai, Nada, Kobe, 657-8501, Japan), Motoki Yairi, and Atsuo Minemura (Kajima Corp., Chofu, Tokyo, 182-0036, Japan)

Microperforated panels (MPPs) are typically made of a thin metal or plastic panel and are often unsuitable for an interior finish because thin limp panels do not have enough strength. In particular, an interior finish of room walls requires appropriate strength. In order to solve this problem, a honeycomb structure is attached behind MPPs to stiffen the construction. Thus, it is possible to stiffen an MPP without increasing its thickness, which is important to keep MPPs at their best absorption performance. Furthermore, a honeycomb can increase MPPs' absorption coefficient in a similar way as a porous layer backed by a honeycomb. In this study, an experiment was performed to gain insight into the acoustical effect of a honeycomb structure behind MPPs and a simple theoretical model to interpret the experimental effects is presented. The experimental results show that the honeycomb affects the absorption characteristics of MPPs: the absorption peak increases and shifts to lower frequencies. This effect becomes more significant as the thickness of the honeycomb increases. The results from the theoretical model show the same tendency. This is attributed to the fact that the honeycomb makes a similar condition to local reaction in the back cavity.

3aAAa5. Development of new sound insulators with perforated board and honeycomb layer systems. Masahiro Toyoda and Daiji Takahashi (U. and E. Eng., Grad. School of Eng., Kyoto Univ., Katsura C1-4-392, Nishigyo-ku, Kyoto 615-8540, Japan, ae.toyoda@archi.kyoto-u.ac.jp)

Two newly developed types of sound insulators are introduced in this study. The first type is derived from an analytical model of a vibrating surface with an impedance facing. The model is investigated theoretically; the results indicate the possibility of reducing radiation from the vibrating surface by giving appropriate impedance. To realize this effect, a model using a perforated board with a subdivided air cavity is proposed. It is shown theoretically and experimentally that this insulator can achieve radiation reduction at an arbitrary frequency. The second type is proposed from the viewpoint of the subdivision strategy. It presents the possibility of improving insulation by restricting the air-particle motion at the interface between the vibrating surface and air. This method for noise control has an attractive simplicity and considerable practical benefit. The attenuation mechanism is discussed theoretically and experimentally. Results of this investigation show that the effect of this insulator is characterized by reduction of acoustic radiation at low frequencies near and below the critical frequency of coincidence. Wide use of these two insulators in many fields is anticipated.

3aAAa6. The effects of damped panels on sound transmission loss through lightweight framed construction. Brandon Tinianov (Quiet Solution, 1250 Elko Dr., Sunnyvale, CA 94089)

The incorporation of damping into the design of materials has been long understood as an effective method for improving the transmission loss of undamped, lightweight structures. Classic examples of its application include marine vessels, aircraft, and ground transportation such as trains, trucks, and buses. However, damping has rarely been incorporated into the materials used for the lightweight construction techniques found in modern buildings. This paper will review the basic principles of designing improved damping into construction materials using the well-known RKU model. The presentation will also review the mechanisms of energy transfer through lightweight building systems and present the improvements in acoustical performance due to damped materials. Typical gains are from 3–18 points in single number ratings (STC, Rw) and greater than 20 dB in some 1/3-octave bands. Extensive laboratory transmission loss data will be presented.

Contributed Papers

3aAAa7. Resilient ceiling construction in residential buildings. Anthony Nash (Charles M. Salter Assoc., 130 Sutter St., San Francisco, CA 94104, anthony.nash@cmsalter.com)

In multifamily buildings, the floor/ceiling assembly between living units needs to be sound rated. In North America, a common light-frame floor construction involves wood or cold-formed metal joists spaced at 400 mm. The typical practice is to attach a gypsum board ceiling to the underside of the floor framing using narrow strips of "Z"-shaped thin metal called "resilient channels." If the resilient channels or the ceiling are installed incorrectly, the low-frequency sound insulation of the assembly can be seriously degraded. Based on our experience with resilient ceiling construction, there are two significant factors that have not yet been documented in an acoustical laboratory. One factor is to maintain a small separation around the entire perimeter of the ceiling where it intersects vertical wall surfaces (this void is later sealed airtight with a flexible caulking material). A second is the particular design of the Z-shaped resilient channel. The paper will discuss findings from two acoustical test series of floor/ceiling assemblies in wood-frame buildings. In both cases, the assembly was tested before and after modifications to the perimeter of the existing resilient ceiling. Each of the series also included tests of a complete ceiling reconstruction using an improved resilient channel design.

3aAAa8. The effect of damping materials on heavy-weight floor impact in apartment buildings. Jin Yong Jeon, Seung Yup Yoo, and Pyoung Jik Lee (School of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea, jyjeon@hanyang.ac.kr)

Floating floors, in which resilient isolators are inserted between the structural slab and the upper layer of the floor, are generally used because of their effectiveness in controlling structure-borne and airborne noise. However, these isolators amplify low-frequency noises below 100 Hz that are generally produced by heavyweight impacts. Viscoelastic damping materials are widely used to reduce noise in settings such as vehicles, ships, and machinery; however, there has been no report of their use in apartment building structures for reducing floor impact sounds. The addition of damping can be embodied using viscoelastic liquid such as silicone gasoline; energy is absorbed with superior characteristics being a solid matter of viscoelastic materials. In this study, optimized thickness of the damping layer was investigated for the efficient reduction of low-frequency noise generated by heavy-weight floor impact. Effects of temperature variations on the characteristics of storage modulus and loss factor of the material were also investigated.

10:15

3aAAa9. Sound absorbing material made of polyester nonwovens.
Shin-ichi Koga   (Fukoku Co., Ltd., 254 Nakayama, Mitsuhashi-machi, Yanagawa, 832-0811 Japan), Kazutoshi Fujimoto, and Ken Anai   (Kyushu Univ., Hakozaki, Higashi-ku, Fukuoka 812-8581 Japan)

Polyester nonwovens (PW) comprise fine fibers, similarly to glass wool (GW). Therefore, PW is expected to have high sound-absorption capabilities. In recent years, application of PW, an entirely recyclable material, as an absorbent material has attracted much attention from the viewpoints of resource recycling and waste reduction. In some cases, manufactured PW has been used as an interior material in an actual acoustic laboratory. Reportedly, however, PW has slightly inferior sound absorption capabilities compared to GW. For wider use as a sound-absorbing material, PW must have better sound absorption. In this study, sound absorptions of PW were measured for various fiber compositions. Specifications that engender high sound absorption capabilities were examined. Results revealed PW specifications that provide similar sound absorption as GW with similar thickness and density. The PW presented in this paper has both high sound absorption and good environmental properties. Therefore, it is useful as a sound absorbing material not only for architectural use, but also in various other fields. Finally, two examples are introduced of an actual anechoic chamber that was finished using PW.

10:30

3aAAa10. Sound-absorbing material made of recycled polyester nonwovens using scrapped pieces.   Kazutoshi Fujimoto, Ken Anai, Tatsurari Nakano   (Faculty of Human-Environment Studies, Kyushu Univ., 6-10-1 Hakozaki, Higashi-ku, Fukuoka 812-8581 Japan), and Shin-ichi Koga   (Fukoku Co., Ltd., Mitsuhashi-machi, Yanagawa, 832-0811 Japan)

The authors developed polyester nonwovens (PW) that have nearly equivalent sound absorption to glass wool with similar thickness and density. Unfortunately, scraps amounting to 20% of crude polyester are generated during PW manufacturing and cutting. They must be discarded as waste materials. Therefore, the authors contrived an original recycling technique to use such scrap pieces. Sound absorption characteristics of recycled materials manufactured using this method (RPW) are inferred to differ from those of PW because of their different fiber compositions. In this study, sound absorption of RPW is measured and the following points are examined experimentally: the relationship between manufacturing processes and sound absorption of RPW; sound absorption of RPW when two kinds of scrap pieces are mixed; and effects of mixing crude materials on RPW sound absorption. Results indicate that RPW has sufficient sound absorption for practical use. Comprising scrapped pieces that have been discarded as waste, RPW addresses the social importance of good resources usage and waste reduction; it also offers advantages of lower cost than PW. This RPW material is anticipated for use in various fields as a sound-absorbing material.

10:45

3aAAa11. Propagation characteristics of airborne ultrasonic wave in porous materials.   Kenichi Aoki and Tomoo Kamakura   (The Univ. of Electro-Commun., 1-5-1 Chofugaoka, Chofu-shi, Tokyo 182-8585, Japan, aoki@ee.uec.ac.jp)

The attenuation coefficient and propagation speed of airborne ultrasound are measured for highly porous open-cell polyurethane foams and fibers at frequencies of 1 kHz to 1.7 MHz. A theoretical model is proposed to explain the frequency responses of the transmission loss and speed of an air coupled wave physically in porous materials. The model is derived from Biot's flow resistance and density [M. A. Biot, J. Acoust. Soc. Am. **28**, 179–191 (1956)], Lambert's bulk modulus of fluids in pores [R. F. Lambert, J. Acoust. Soc. Am. **72**, 879–887 (1982)], and Zwikker and Kosten's concept for compliance of the side holes with entrance resistance [*Sound Absorbing Materials* (Elsevier, Amsterdam, 1949)]. Using measured data of static flow resistance to determine the mean pore size and the proposed model, theoretical prediction is made for the transmission losses and sound speeds in porous materials. Good agreement of theory and results of experiments in the whole frequency range supports the usefulness of the present model. Additionally, the model provides some findings for the extra attenuation coefficient of a slow wave in cemented glass bead specimens and sandstone for high-frequency ranges [P. B. Nagy, J. Acoust. Soc. Am. **93**, 3224–3234 (1993)].

11:00

3aAAa12. Comparative results of field impact isolation testing of numerous resilient underlayment systems for hard-surfaced flooring.
Marlund Hale   (Advance Eng. Acoust., 663 Bristol Ave., Simi Valley, CA 93065, mehale@aol.com)

There is a strong ongoing interest in replacing carpet and pad flooring in existing multi-family residences and during apartment conversions to condominiums with hard surface flooring. Installing such flooring often results in a significant decrease in the impact isolation performance of the floor/ceiling assembly. Some municipalities and/or homeowners associations have enacted regulations requiring that floor/ceiling assemblies meet specific minimum laboratory and/or field acoustical performance standards. This paper presents published vendor data and field performance test results for two condominiums in a multi-family residential complex for which both the city and the homeowners association have such performance requirements. A series of field tests was undertaken to assist the homeowners in selecting qualifying underlayment systems for their preferred hard surface flooring replacement of their existing quality carpet and pad flooring. The test flooring systems were each installed by a flooring contractor. All aspects of these field tests were maintained as identical as possible, with the only variable being the different commercial resilient underlayment products. Published vendor data of certified laboratory IIC test results are compared with the FIIC field test results.

11:15

3aAAa13. Reflectivity of absorptive surfaces.   Jonathan Rathsam and Peter D'Antonio   (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774)

The random incidence absorption coefficient is a very coarse metric. In many small and large room applications, a directional absorption coefficient more accurately describes potential problems from first-bounce specular reflections. An impedance tube is useful for evaluating normal incidence absorption, but a more general approach to determining a material's specular reflectivity or first-bound attenuation is needed. The AES-4id-2001 information document describes such a method. This study compares the "first-bounce specular attenuation" of 1 ft (H) $\times$ 3 ft (W) and 4 ft (H) $\times$ 8 ft (W) samples of 2-in.-thick, 6 pcf fiberglass absorbers (with and without fabric covering) with that of a rigid reflector, using a 2D boundary method goniometer. The boundary wave's arrival is calculated and identified in the impulse response measurements. The use of small and large samples allows evaluation of both the fabric covering and boundary wave effects on the specular attenuation, for normal and 45-deg incidence. Time and frequency domain results are presented.

3aAAb1. Acoustics of ancient Greek and Roman theaters in use today. Anders Christian Gade and Konstantinos Angelakis (Acoust. Technol., Tech. Univ. of Denmark, Bldg. 352, DK 2800 Lyngby, Denmark, acg@oersted.dtu.dk)

In the Mediteranan area a large number of open, ancient Greek and Roman theatres are still today facing a busy schedule of performances including both classical and contemporary works of dance, drama, concerts, and opera. During the EU funded ''Erato'' project and a subsequent master thesis project, extensive measurement data have been collected from three well-preserved theatres, which represent three different stages of enclosing the audience in an open-air environment: (1) the Epidaurus Theatre in Greece without skenae wall or columnade behind the cavea; (2) the Jerash South theatre in Jordan with skenae wall but no columnade; and (3) the Aspendos Theatre in Turkey having both a full skenae building and a columnade around the cavea. In the paper the acoustic characteristics of these theatres will be compared and discussed in the light of acoustic performance requirements for modern use.

8:15

3aAAb2. Acoustical design issues for contemporary places of worship. Jason R. Duty and David R. Schwind (Charles M. Salter Assoc., Inc., 130 Sutter St., Ste. 500, San Francisco, CA 94104, jason.duty@cmsalter.com)

This presentation intends to discuss the acoustical design of contemporary places of worship in the range of 500 to 3000 seats. The wide variety of programming requirements, concurrent uses, space constraints, and undesirable adjacencies in contemporary churches can be a similar challenge to many performing arts spaces. Many contemporary churches have loud, amplified music in their services and children's classrooms. In addition, religious study courses in adjacent classrooms are being held at the same time as the main worship service. During off-hours the spaces are used concurrently for teaching, conferences, weddings, prayer, and rehearsals. In many cases, the rooms outside of the main worship space are undersized and have undesirable adjacencies to each other as well as the main worship space. Using case studies we will discuss sound isolation design to reduce interference between concurrent unrelated uses, as well as room shaping and room finish treatments (including variable acoustics) to address room acoustics and the large sound systems.

8:30

3aAAb3. Acoustical design of Sejong Performing Arts Center recital hall. Jin Yong Jeon and Yong Hee Kim (School of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea, jyjeon@hanyang.ac.kr)

Acoustical design of a convention center into a recital hall of Sejong Performing Arts Center located in Seoul, Korea was carried out to renovate its function. The area of the convention space is about 612 m^2 and it is mainly used for meetings, symposia, and so on. The volume of the existing hall is limited to 3100 m^3, which causes lack of late reflections, due to its structural limitations. Therefore, the existing ceiling slab was designed to be pulled up so that a new ceiling can create extra volume of 1000 m^3. A leaf-shaped floor plan and tilted side balconies within 16-m width between side walls were designed to adequately increase enough lateral reflection and spatial impression. The inclined side wall of 1:10 slope was proposed through the comparison with different angles of walls. The saw-tooth-shaped GFRC (glass fiber reinforced concrete) wall reflectors and center protruded stage rear wall are designed for sound diffusion. From the results of computer and scale modeling, it was predicted that the new space will have adequate reverberation time of 1.5 s and a uniform distribution of sound-pressure levels within 3 dB.

8:45

3aAAb4. A study on the influence of geometrical characters to the acoustical performance in vineyard terraced concert halls. Yi-run Chen and Wei-hwa Chiang (Dept. of Architecture, Natl. Taiwan Univ. of Sci. and Technol., #43, Sec.4, Keelung Rd., Taipei, 106, Taiwan, d9413002@mail.ntust.edu.tw)

There are two distinctive features defining vineyard terraced concert hall: audiences surrounding the stage and vineyardlike seating arrangement. Besides that, people may find more differences than similarities within those limited built cases. This paper investigated the influence of geometrical characters to acoustical performance in vineyard halls using computer simulation. Through case studies of nine vineyard terraced halls, some geometrical characters were selected as research variables, namely volume, overall proportion, dimensions of key elements, seating capacity, arrangement of vineyard terraces, terraced side box shaping, and ceiling shaping. Acoustical parameters EDT, LF, C80, and G were analyzed by varying architectural features of a prototype developed based on the main geometrical characters of the nine halls. It has been found that raising terraced side boxes would help increase G and LF. For a constant room volume, increasing the number of terraces with sufficient height would raise the LF value in the nearby area mostly. Changing ceiling shape only had influence on the rear part of the front terrace.

3aAAb5. Alternatives to the traditional concert hall experience.
Bobby GibbsII, Jonas Braasch, and Ted Krueger (Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180)

As relates to live performance, the purview of sound quality in architectural acoustics is mostly limited to concert halls. While the concert hall is perhaps the most common setting in which to hear live Western classical music in our present day, this was not always the case historically. As will be shown from analysis of published text as well as interviews with music critics, artists, and concert-goers, a variety of alternatives to the concert hall exists currently in the form of domestic settings, casual settings like coffee shops, as well as large outdoor settings like farms and parks. The advantages and disadvantages of such alternative venues, as concerns the overall concert experience and the quality metric of intimacy particularly, will be discussed. Moreover, design issues relating to the acoustical environment as well as the social environment in these venues will be discussed based on the data. This paper will ideally foster discussion in the acoustical and the architectural community on ways to expand the traditional concert hall experience as well as address design issues in alternative venues. [Work supported by ASA Minority Fellowship and RPI Humanities, Arts, Architecture, and Social Sciences Fellowship.]

3aAAb6. New approach of the model experiment in room acoustics—advantage of $\frac{1}{16}$ scale model. Hidemaro Shimoda (Shimizu Corp., 3-4-17 Etchujima, Koto-Ku, Tokyo, 135-8530 Japan) and Yasuhiko Tahara (Tohoku Bunka Gakuen Univ., Aoba-Ku, Sendai, 981-8551 Japan)

In the construction of the auditoria, the examination by the acoustic model experiment has been often performed. This paper describes the outline of the result of investigating various features of the method of the experiment by $\frac{1}{16}$ scale models compared with models of $\frac{1}{10}$ and $\frac{1}{20}$ scales that have been generally adopted up to now. That is, the following advantages are found in the case study of the $\frac{1}{16}$ scale model experiment, and the new approach to the model experiment method is proposed here. (1) full cover of the band to 4 kHz enables the quantification of a practical physical acoustic parameters. (2) The parameter as the air absorption coefficient in the supersonic wave band by $\frac{1}{10}$ scale models can be used. (3) Cheap digital sound recording system can be used considering the microphone characteristics. (4) The model construction cost can be largely saved compared with $\frac{1}{10}$ models.

3aAAc1. Quantitative evaluation of characteristics of an auditorium shape in horizontal cross section. Kazuma Hoshi (Grad. School of Sci. and Technol., Nihon Univ., 1-8-14, Kandasurugadai, Chiyoda-ku, 101-8308, Tokyo, Japan, hoshi@arch.jcn.nihon-u.ac.jp), Toshiki Hanyu, and Katsuaki Sekiguchi (Nihon Univ., Chiyoda-ku, 101-8308, Tokyo, Japan)

The room shape of an auditorium is often classified as a "shoe-box type," "fan-shape type," "round type," "surrounding (vineyard) type," or other shape. The surface diffusivity index (SDI), which is an evaluation index of surface irregularities, has been proposed by Haan and Fricke, but the SDI is based on visual surveys of photographs or drawings [Appl. Acoust. **51**(1), 53–69 (1997)]. Clarification of the relationship between an auditorium's shape and its acoustic characteristics would be simplified if the auditorium shape were understood objectively rather than subjectively. Therefore, in this study, we tried to objectively obtain characteristics of a room shape in horizontal cross section using an elliptic Fourier descriptor, which can detect the periodicity of a two-dimensional contour. Room shapes were expressed as spatial frequency characteristics calculated from their Fourier descriptors. Based on them, we can understand the amplitude of irregularities and their scale. In addition, by using principal component analysis, it is possible to understand, quantitatively, the main differences of room shapes in horizontal cross section.

3aAAc2. Design and construction of a small sound testing room in an office building. Edward C. Duncan and Kenneth Kaliski (Resource Systems Group, Inc. 55 Railroad Row, White River Junction, VT 05001)

A small sound-testing room has been constructed in the basement of an office building located within 50 ft. of railroad tracks. The room was designed to be multifunctional with both reverberant and semianechoic settings. The sound isolation of the room was designed with the expectation of conducting active noise reduction tests with sound-pressure levels of 120 dB and higher. The room is also being used to roughly estimate absorption coefficients of various materials. The room is $10.5 \times 9.75 \times 7.5$ ft. with a volume of 768 ft^3. It is composed of a concrete floor and gypsum walls and ceiling. The walls are isolated from the floor with rubber isolation pads. The ceiling is constructed of 5/8-in. gypsum, 1/2-in. plywood, and a 2-in. layer of sand. The wall construction is 2×4 wood studs, two layers of 5/8-in. gypsum resiliently attached, and 3 in. of fiberglass. The entrance to the room is made of double solid core wood doors with a composite isolation and absorption layer in between both doors. Other design components, actual sound transmission testing results, reverberation times, modal issues, and uses for the room are discussed.

10:20

3aAc3. Introduction of auditory filter into evaluation of characteristics of small enclosures. Saori Shimada, Hisaharu Suzuki, and Akira Omoto (Omoto Lab., Dept. of Acoust. Design, Faculty of Design, Kyushu Univ., Shiobaru 4-9-1, Minami, Fukuoka 815-8540, Japan)

Physical measures, which are useful for evaluating small enclosures such as studios and car cabins, are examined. Especially, auditory filtering using Zwicker's loudness model is introduced for calculating the measures. Most current measures used in evaluating the large sound field such as concert halls are based on measured or calculated impulse responses. Instead, the music signals of some genres are used in this study. Using the auditory model, the amount of information can be reduced, even when complicated signals are used as stimuli: the signals are convertible to information in 25-bark bands. Correspondence of such physical quantities and subjective judgments are considered from the viewpoint of sound-field similarity. Subjects are asked to judge the similarity of two successive sounds whose frequency characteristics are modified artificially using the equalizer. The analysis results obtained using the auditory filter were compared with the subjective evaluation. Results indicate that analysis using the auditory filter can yield fairly good correspondence with the subjective evaluation, especially in a middle frequency band. Regarding the low-frequency band, the degree of correspondence depends on the musical genre. Expanding the effective frequency bands is an important theme of our ongoing research.

10:35

3aAc4. Cross-modal perception of room acoustics. Anthony McCreery and Paul Calamia (Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, mccrea@rpi.edu)

The development of perceptually accurate audio-visual systems has been hindered by the fact that traditional scientific investigations into auditory and visual perception in humans have separated the two senses into separate and distinct modalities. It is important to consider the perception of these modalities as critically linked and ultimately inseparable. Research investigating expected levels of reverberance given 2-D visual representations of several environments shows that perception of reverberation is heavily dependent on the visual appearance of a room. For the experiments to be discussed here, subjects were asked to adjust the level of reverberant sound that accompanied video of a person speaking in three different rooms: a library, a playhouse, and a cathedral. The results show that reverberance levels chosen by subjects rarely match those measured from impulse responses recorded in the rooms being presented. Experimental methodology and results as well as implications for the development of future audiovisual systems will be discussed.

10:50

3aAc5. Considering source directivity in a recital hall with seats surrounding the platform. Wei Lin, Weihwa Chiang, and Yi-run Chen (Dept. of Architecture, Natl. Taiwan Univ. of Sci. and Technol., #43, Sec.4, Keelung Rd., Taipei, 106, Taiwan, d9313001@mail.ntust.edu.tw)

The impact of source directivity can be significant for chamber music performances, in particular for arena-type halls that have visual intimacy. This study has been carried out to understand the physical and perceptual aspects of the seats surrounding the platform in recital halls. Effects of architectural features were evaluated using computer simulations that accounted for source directivity and diffusive reflections. Both live and recorded subjective evaluations of chamber music performances were made in an actual hall while acoustical measurements were also taken. As a result, computer simulations using a singer source showed significant decrease in both clarity and strength in the 2-kHz band for the seats surrounding a centered platform. A wall 6 m in front of the platform was effective in mitigating the problems. Sound levels calculated from the recordings taken from various viewing angles were correlated with subjective evaluations, especially in the high frequencies. Timbre appeared to be the principal factor influencing solo performances and balance was the most important in judging ensembles. Nevertheless, live evaluation showed no significant difference among the listening positions.

Contributed Poster Paper

Poster paper 3aAc6 will be on display from 8:00 a.m. to 11:30 a.m. The author will be at the poster from 11:05 a.m. to 11:30 a.m.

3aAc6. Acoustic design of studio to record effect sounds in. Shinichi Oda, Junko Yokoyama, and Junichi Mikami (Dept. of Eng. Administration, Japan Broadcasting Corp. (NHK), 2-2-1 Jinnan, Shibuya-ku, Tokyo 150-8001, Japan)

We reconstructed a studio that has a space in which to record effect sounds. In this space, we record walking sounds on wooden floors, tile floors, sand, grass, and so on. This studio was planned on a floor with a light allowable load because the floor was formerly the roof of the building. A recording studio is usually constructed with a floating structure. The thin floating floor causes vibration of floorboards. A thick floor is heavy. In addition, we recorded the sound when we jumped on the floor. The noise from the structure disturbs the effect sounds that we need if the vibration caused by jumping stimulates the studio structure. For those reasons, we planned the following design to record pure effect sounds: The effect sound space is insulated from other spaces with the room structure. A floating ceiling is hung from the fixed ceiling, and parts of floating walls are hung from overhead beams. Only the floating floor and the other parts of floating walls are set upon the fixed floor. Consequently, the floating floor in the effect sound space was made thicker than would be possible otherwise.

3aAB1. Auditory streaming and the spectrotemporal analysis of sound in the cortex. Shihab Shamma and Mounya Elhilali (Elec. and Comput. Eng. & Inst. for Systems Res., Univ. of Maryland, College Park, MD 20742)

Auditory streaming is a phenomenon that manifests itself in the everyday ability of humans and animals to parse complex acoustic information arising from multiple sound sources into meaningful auditory streams. For instance, the ability to follow a conversation at a noisy cocktail party or hear the violin in the orchestra both rely on the formation of auditory streams. While seemingly effortless, the neural mechanisms underlying auditory streaming remain a mystery. In this talk, we shall discuss how this perceptual ability may emerge as a consequence of the multiscale spectrotemporal analysis of sound in the auditory cortex. A simplified model of this process is developed to demonstrate how auditory streaming could underlie the separation of complex sounds from two sources (e.g., speech or music). The model reveals that certain perceptual attributes are critical for the simultaneous separation of sounds (pitch and onset sensiticity), whereas others are important for the sequential binding of the segregated sound features (timbre and location).

8:05

3aAB2. Time-sharing acoustic stream analysis to recognize multiple objects in space by echolocating bats. Hiroshi Riquimaroux (Doshisha Univ., 1-3 Tatara Miyakotani, Kyotanabe, Kyoto 610-0321, Japan)

Echolocating bats need to catch prey while they have to avoid obstacles and escape from their predators at the same time. Therefore, they have to perceive precise information about multiple objects from their surrounding space while they are flying. However, there are strong restrictions in the system; the neural system is too slow to perform real-time processing, and the bat has only one sound source emission and only two ears to receive echoes. The purpose of the present study was to investigate how echolocating bats perceive important information about different objects in space during their flight by analyzing acoustic characteristics of emitted pulses and returning echoes. Pulses and echoes of CF-FM and FM bats were recorded by a wireless telemetry microphone system (Telemike) on their head. In order to reconstruct their flight trajectory, a dual high speech video camera system was used. Obtained data showed multiple streams for temporal change in echo delay, Doppler-shift compensation, and echo intensity compensation. The present findings indicate that echolocating bats may adopt a time-sharing analysis, which is practically fast enough to recognize multiple objects in space during flight. [Work partly supported by the Innovative Cluster Creation Project promoted by MEXT and by a grant to RCAST at Doshisha University from MEXT.]

8:25

3aAB3. Echolocating bats control the directionality of sonar signals to sort out the auditory scene. Annemarie Surlykke (Inst. of Biol., Univ. of Southern Denmark, DK-5230 Odense M., Denmark) and Cynthia F. Moss (Univ. of Maryland, College Park, MD 20742)

A primary function of hearing is the localization and identification of sound sources in the auditory scene. Results from humans and other animals have shown that spectral and temporal features, as well as source direction, are important parameters used for organizing acoustic sources. Echolocating bats control the features of vocalizations to shape information carried by echoes from auditory objects. Our research on big brown bats, *Eptesicus fuscus*, suggests the importance of vocal control for scene analysis: When a bat performs a dual task, requiring both obstacle avoidance and prey capture, it solves the task sequentially, adapting the temporal pattern of its cries to produce sonar strobe groups, strobing first the obstacle and then the prey. Directional control over the sonar beam pattern confirms this sequential processing: The bat alternates fixation of the beam axis on the obstacle and prey. The importance of directionality is corroborated by studies in another bat, Trachops cirrhosus, where behavior and morphology optimize sonar directionality for different tasks. When hanging from a perch *T. cirrhosus* emits sounds for general orientation with limited demands for directionality. When hunting, prey localization necessitates high directionality associated with sound emission through the nostrils surrounded by the moveable nose leaf.

3a THU. AM

3aAB4. Wild dugongs' vocal responses to conspecific calls. Kotaro Ichikawa, Nobuaki Arai (Biosphere Informatics, Grad. School of Kyoto Univ., Yoshida-honmachi, Sakyo-ku, Kyoto, 606-8501, Japan, ichikawa@bre.soc.i.kyoto-u.ac.jp), Tomonari Akamatsu (Natl. Res. Inst. of Fisheries Eng., Kamisu, Ibaraki, 314-0408, Japan), Tomio Shinke (System Intech Co., Ltd., Shizuoka, Shizuoka, 424-8610, Japan), and Kanjana Adulyanukosol (Phuket Marine Biological Ctr., 83000, Phuket, Thailand)

Wild dugongs were found to call back more to conspecific calls than to artificially synthesized sounds. The population was exposed to four different playback stimulii a wild dugong chirp, a synthesized down-sweep sound similar to the dugong chirp, a synthesized constant-frequency sound, and no sound as a control. Vocalizing dugongs were localized using an array of stereo-underwater-recording systems. Wild dugongs vocalized more frequently after the playback of dugong chirps (2.8 calls/min) than those of constant-frequency (0.55 calls/min) and control (0.2 calls/min), ($p > 0.01$, Kruskal-Wallis test). Dominant frequencies of response calls were 4810 Hz to dugong chirps and 4470 Hz to down-sweep sounds. These were higher than those to other stimuli (3794 and 4044 Hz). Distances of calling-back dugongs from the playback speaker were significantly shorter for dugong chirps (10.19 m) and down-sweep (19.02 m) than that for constant frequency (105.84 m) ($p > 0.001$). The observed dominant frequencies of response calls (4510 Hz) were above the cutoff frequency of Lloyd's mirror effect in shallow waters of the present study. Frequency-modulated narrow-band sounds like chirps travel longer and enable accurate measurements of source directions by binaural receivers. These suggest that chirps could be used for conspecific recognition in noisy acoustic scenes in tropical shallow waters.

3aAB5. How does a green leafhopper male induce a female's willingness to mate? Masao Fukui (Lab. of Insect Physiol.., Grad. School of Agriculture, Kyoto Univ., Sakyo-ku, 606-8502, Japan)

When on their host plants, male leafhopper *Nephotettix nigropictus* (Insecta; Hemiptera) produces substrate-borne signals of two kinds, which are associated with different behavioral activities: (*i*) a calling signal and (*ii*) a duetting signal in response to a female. These signals both influence pair formation and the female's willingness to mate. After receiving a vibrational reply from a female responding to the calling signal, the calling male increases the first component of the calling signal from one trill to two or more trills, then continues in a duet with the female. During more duets, males wanting females to mate increase the number of chirps that compose a buzz as the second component of the calling signal. This increment of the first component is almost always one stable trill, but the increment of the second component apparently depends on the strength of the female's reply. This paper presents discussion of the biological significance and role of male signals to induce females to mate.

3aAB6. An avian cocktail party: Masking and unmasking in birds. Micheal Dent, Elizabeth McClaine (Dept. of Pyschology, B76 Park Hall, Unversity at Buffalo, Buffalo, NY 14260, mdent@buffalo.edu), Barbara Shinn-Cunningham, Virginia Best, Erol Ozmeral, Frederick Gallun, Kamal Sen, and Rajiv Narayan (Boston Univ., Boston, MA 02215)

The ability to effectively communicate in a noisy environment is an auditory skin that all animals must develop for basic survival. Birds are one group of animals that use auditory communication for everything from mating to prey capture. In general, how well humans and other animals are able to hear signals in their environment is a function of the properties of the signal and the properties of the noise, and include spatial, temporal, and spectral characteristics. Here, the abilities of birds to correctly identify zebra finch songs embedded in different types of maskers that were emitted from the same location or from separate locations (and presented at different signal to noise ratios) were measured using operant conditioning techniques. In general, zebra finches and budgerigars showed very small differences in thresholds between songs embedded in the three types of maskers: broadband noise, modulated noise, and choruses of zebra finch songs. When the calls were emitted from one location and the maskers from another, a condition that elicits spatial unmasking in humans (Best *et al.*, 2005), zebra finches had lower thresholds while budgerigars generally did not. These results suggest some species-specific advantages to listening in noisy environments.

3aAB7. Assessing the relative importance of source distance determined by acoustic cues and noise level as predictors of disturbance in a study of the Mexican spotted owl. Ann E. Bowles, Stefanie K. Moffat, Samuel L. Denes (Hubbs-SeaWorld Res. Inst., 2595 Ingraham St., San Diego, CA 92109, abowles@hswri.com), Christopher M. Hobbs (Wyle Labs., Arlington, VA 22202), and Dana H. Banwart (GeoMarine, Inc., Hampton, VA 23666)

In forested areas, acoustic localization of source distance and noise level are potentially reliable indicators of an approaching source. The relative importance of these cues was examined during a study of Mexican spotted owl responses to human-made noise. The study was conducted in mixed-conifer forest on steep northeast facing slopes. Owls had no or limited experience with the experimental paradigm. Shaped noise bursts were projected from a Sound Projections portable stereo speaker system with line of sight to the target owl(s). Signals were shaped noise bursts with 10–15-dB/s onset rate projected to produce received maximum A-weighted levels in two ranges, 55–65 dB and 75–85 dB, at distances of 20, 40, and 80 m. Levels were measured a short distance from the target owl(s) using a calibrated recording system (DAT or digital recorder equipped with an ACO 7013 microphone, 20 Hz to 20 kHz). They were also estimated using a single-event sound propagation model (NMSIM,Wyle Laboratories). Preliminary analysis showed that both source level and distance were significantly related to owl response, but that distance explained twice as much variance in behavior as level. 3aAB8. Comparisons of song perception in male and female songbirds utilizing cardiac responses. Maki Ikebuchi (Human Information System Labs., Kanazawa Inst. of Technol., Hakusan, Ishikawa 924-0893, Japan, mikebuch@his.kanazawa-it.ac.jp) and Kazuo Okanoya (RIKEN Brain Sci. Inst., Wako, Saitama 351-0198, Japan)

In most songbirds, males sing to defend territories and to attract females, and females evaluate the quality of males based on songs. This should lead to differences in song perception between the sexes, but it has been difficult to devise an assay that can evaluate song perception without introducing motivational bias. For example, the copulation solicitation assay is useful for evaluating female perception of songs, but this assay cannot be utilized for males. We found that birds react to a sound of interest by increasing the heart rate, and this response was used to compare song perception in Bengalese and zebra finches. We used conspecific and hetero-specific songs as stimuli and these were presented in a planned order. In Bengalese finches, only females responded to the changes in conspecific song repertoire. In zebra finches, both males and females reacted to such changes. Bengalese finches are a domesticated species and males do not establish breeding territories. Conversely, male zebra finches establish a small territory when breeding. In both species, songs are an important trait by which females select males. These ecological differences concur with the species and sex differences in the cardiac response. [Work supported by JSPS and JST.]

3aAB9. Detection of objects in complex environments by echolocating big brown bats. Caroline M. DeLong, Sarah A. Stamper, and James A. Simmons (Dept of Neurosci., Brown Univ., Box 1953, Providence, RI 02912)

In previous psychophysical experiments, big brown bats detected or discriminated objects (monopole and dipole targets comprised of 15 mm diameter cylinders) presented standing on smooth surfaces with little clutter. Performance was determined by mutual masking of echoes from the targets themselves. In new experiments, bats did two-alternative (left/right) forced choice tasks to detect a two-cylinder dipole target in complex, cluttered environments. In experiment 1, the targets were set inside 14-mm-deep, 20-mm-diam holes in a layer of foam 25 mm thick. Cylinders of different heights protruded 13, 5, or 2 mm above the surface of the foam, or were recessed 1 mm below the surface. The bats performance varied as a function of protruding height. In experiment 2, the dipole target was embedded within arrays of distractor objects that varied in shape, size, orientation, and material. Both experiments explore how bats isolate the echoes from the dipole target from the mixture of echoes returning from the clutter—whether distractor objects or echoes from the sides of the holes. Big brown bats must engage in this acoustic scene analysis when catching insects, such as beetles, against a backdrop of foliage.

10:40

3aAB10. The sonar beam of big brown bats (*Eptesicus fuscus*) during landing. Jens C. Koblitz, Peter Stilz, Wiebke Pflästerer, Mariana Melcon, and Hans-Ulrich Schnitzler (Tierphysiologie, Universität Tübingen, Auf der Morgenstelle 28, 72076 Tübingen, Germany, jens.koblitz@web.de)

The parameters signal duration, pulse interval, and frequency have previously been used to describe the approach behavior of landing bats. An array with 16 microphones was used to investigate additional parameters during the approach flight of landing big brown bats (*Eptesicus fuscus*). For each signal emitted the position of the landing bat in relation to the microphone array was determined using a 3-D video system, and the width, maximum intensity, and aiming direction of the sonar beam were calculated. The approach to the landing site begins at a distance of about 1.4 m when the bats pick up the landing site with their sonar beam. This focusing on the landing site is indicated by a clear decrease of the deviation between beam aiming and direction to the landing position. The maximum intensity of the sonar beam is reduced by about 6 dB per half distance during the last 2 m of the approach, which indicates a gain control mechanism. The width of the sonar beam remains constant throughout the whole approach.

10:55

3aAB11. Spatial release from masking of aerial tones in a California sea lion (*Zalophys californianus*). Marla M. Holt and Ronald J. Schusterman (UCSC Long Marine Lab., 100 Shaffer Rd., Santa Cruz, CA 95060)

Spatial release from masking (SRM) occurs when a signal and masker are spatially separated, resulting in improvement of signal detection relative to when they are spatially co-located. Sea lions forage in the water, breed on land, produce airborne vocalizations that are associated with social and reproductive activities, and possess highly reduced pinnae. In this study, SRM was measured at 1, 8, and 16 kHz in a California sea lion who had to detect an aerial tone in the presence of an octave band of white noise centered at the tone frequency. Testing was conducted in a hemi-anechoic chamber. While the masker always occurred in front of the subject (0 deg), the tone occurred at 0, 45, or 90 deg in the horizontal plane. Absolute thresholds were also measured at these angles to account for differences in hearing sensitivity based on source azimuth. Masked thresholds were lower by as much as 12 dB at 1 kHz when the signal and masker were separated by 90 deg. These results were compared with those of a harbor seal who, like all true seals, naturally lacks pinnae. Performance differences between the two subjects at the highest frequency likely reflect variations in pinna anatomy.

11:10

3aAB12. Underwater noise and zones of masking with respect to hopper dredging and manatees in the St. Johns River in Jacksonville, FL. Edmund R. Gerstein, Joseph E. Blue (Leviathan Legacy Inc., 1318 SW 14th St., Boca Raton, FL 33486), Gerard F. Pinto, and Seth Barr (Jacksonville Univerisity, Jacksonville, FL 32211)

Underwater noise radiating from dredging can effectively obscure or mask biological and other important sounds. This study recorded underwater acoustic characteristics of hopper dredging in the St. Johns River, Jacksonville, FL, to evaluate noise impacts in the waterway with respect to the endangered West Indian manatee. Of particular interest was the extent and range that dredging noise may mask the sounds of approaching commercial and recreational vessels. Vertical hydrophone arrays and a multichannel PC-based recording system were used to measure dredging noise at various distances. Ambient noise surveys, active propagation of calibrated sources, and controlled boat noise measurements were conducted along the waterway. These data were integrated with behavioral hearing data to estimate zones of masking surrounding dredging. Three discernable noise sources that masked boat noise were (1) cavitation from dredge propellers, (2) draghead vacuuming, and (3) noise from submerged slurry pipelines. Sustained high ambient noise levels from dredging can significantly increase the risk of manatee-boat collisions by masking the sounds of approaching vessels over large radii (up to 2.5 miles). Mitigations suggested include ship quieting, reducing propeller cavitation, insulating or elevating slurry pipelines, and minimizing transects to pump out stations. [Work funded by the City of Jacksonville Waterways Commission.]

3aAB13. "Vocal grooming" in an eusocial subterranean rodent: The naked mole-rat (*Heterocephalus glaber*). Shigeto Yosida, Kazuo Okanoya (Grad. School of Sci. & Technol., Chiba U., 1-33 Yayoi-Cho, Inage, Chiba, 263-8522 Japan), Chizuko Suzuki, Sanae Nanvuh, and Kazuo Okanoya (RIKEN BSI., Wako, Saitama, 351-0198 Japan)

The naked mole-rat is a unique communal-living rodent of east Africa. In a subterranean environment, this small rodent species has a complex hierarchical society with labor division that is comparable to those of bees and ants. They are also known for their extensive vocal repertory of more than 17 sounds, which might have evolved as an alternative to visual cues, and which contributes to maintaining its society. We showed that their most frequent vocalization, the soft-chirp (SC), has an antiphonal nature, and it might function for rank-identification and reconciliation purposes. The SC is elicited either by another's SC or physical touch. We analyzed acoustic properties of SC elicited by touching the animals, and found that it varies according to the body mass. The emission rate was highest among larger (superior) animals, but the smaller (inferior) of the two emitted SCs more frequently when observing behavior of two interacting animals. Playback experiments revealed that the use of SC generally follows these two rules: smaller animals vocalize more often than larger ones, and larger ones respond only to smaller animals' SCs. These features of SC resemble grooming behavior among primates.

3aAB14. Neural responses to communication sound in the inferior colliculus of the naked mole-rat. Shizuka Tokin, Kohichi Tanaka (Lab. for Molecular Neurosci., Sch. of Biomed. Sci., Tokyo Med. and Dent. Univ., 1-5-45 Yushima, Bunkyo-ku, Tokyo 113-0034 Japan), Shizuka Tokin, and Kazuo Okanoya (RIKEN BSI., Wako, Saitama, 351-0198 Japan)

The naked mole-rat (*Heterocephalus glaber*) is a highly social subterranean rodent that lives in Eastern Africa. Because they a dig burrow system and spend most of their lives underground, they are functionally blind and rely heavily on auditory information. They have at least 17 different vocalizations, which are associated with specific behavioral contexts. In this study, we focused on the soft chirp (SC), which is one of the most frequent vocalizations in this species, and recorded neural responses to synthesized SCs in the inferior colliculus. We found that the responses could be divided into three groups based on their response patterns. These response patterns represented the duration or frequency of stimuli. In addition, we also found that the number of spikes changed with the degree of frequency modulation. From these results, we hypothesized that the vocalizations of naked mole-rats can be represented by integrating the activity of such neurons that respond to a specific feature of sound.

Biomedical Ultrasound/Bioresponse to Vibration and Physical Acoustics: Celebration of Floyd Dunn I

William D. O'Brien, Cochair

Univ. of Illinois, Dept. Electrical and Computer Engineering, 405 N. Mathews, Urbana, IL 61801

Junichi Kushibiki, Cochair

Tohoku Univ., Dept. of Electrical Engineering, 6-6-05 Aoba, Aramaki-Aza, Aoba-ku, Sendai 980-8579, Japan

Chair's Introduction—8:00

Invited Papers

8:05

3aBB1. Celebration of Floyd Dunn: Some remarks about his life, career, and accomplishments. William D. O'Brien, Jr. (Bioacoustics Res. Lab., Dept of Elec. and Comput. Eng., Univ. of Illinois, 405 N. Mathews Ave., Urbana, IL 61801)

No celebration of Floyd Dunn would be complete without some remarks about the life, career, and accomplishments of this remarkable scientist/engineer. Floyd had made significant scholarly contributions in six general themes, and you will hear about their impact to our welfare during the celebration. The six ultrasonic biophysics themes include absorptive processes, nonlinear phenomena, application in living systems, toxicity, measurement techniques, and ultrasonic microscopy. Floyd has been recognized for his accomplishments by being the recipient of most of the important national and international awards including National Academy of Sciences, National Academy of Engineering, ASA's Gold Medal and Silver Medal in Bioresponse to Vibration, Acoustical Society of Japan's Medal of Special Merit, IEEE's Edison Medal, and election to Fellowship in six professional societies.

8:25

3aBB2. Imaging propagation speed of pulsive vibration in the heart wall for healthy subjects and patients with old myocardial infarction. Hiroshi Kanai (Dept. of Electron. Eng., Tohoku Univ., Aramaki-aza-Aoba 6-6-05, Sendai 980-8579, Japan), Sachiko Watanabe (Miyagi Shakaihoken Hospital, Sendai, Japan), Yoshifumi Saijo, and Motonao Tanaka (Tohoku Univ., Sendai, Japan)

This study presents a novel method that noninvasively visualizes myocardial heterogeneity for healthy subjects and patients with old myocardial infarction. By a sparse sector scan, the myocardial minute motions were measured simultaneously at about 1000 points in the heart wall at a high frame rate. We have found that a pulsive vibration is excited by aortic-valve closure [H. Kanai and Y. Koiwa, Ultrasound Med. Biol. **27**, 481–498 (2001)]. The consecutive spatial distributions of the vibrations reveal that the vibration propagates from the root of the aortic valve to the apex [H. Kanai, IEEE Trans. UFFC. **51**, 1931–1942 (2005)]. In this study, the

method was applied to seven healthy subjects and five patients, and the spatial distribution of the propagation speed of the vibration is also visualized. For all healthy subjects, the propagation of the pulsive vibration was visible both in longitudinal-axis and apical views, and there is spatial difference in the propagation speed; 4.3 ± 0.5 m/s for the high echo area and 2.9 ± 0.4 m/s for the low echo area, for a 60-Hz component. For patients, the propagation speed in the diseased area is about 30% lower than the normal area. These preliminary results indicate that the method has a potential for revealing myocardial heterogeneity.

8:45

3aBB3. Ultrasound stimulated vibroacoustography and vibrometry for measuring tissue properties.   James F. Greenleaf and Chen Shigao   (Mayo Clinic College of Medicine, Rochester, MN 55901)

Ultrasound stimulated vibroacoustography has been used to image tissues using the acoustic response of tissues to localized harmonic radiation pressure. The method provides high resolution and high dynamic range images of tissues. The parameter being imaged is a complex combination of scattering, attenuation, and nonlinearity. However, specific use of harmonic or pulsed radiation pressure and subsequent measurement of the tissue response can be used to measure fundamental material properties of tissue. The measurement of shear wave dispersion can be used to estimate elastic shear moduli of tissue. Fundamental model free properties such as elastic storage and loss constants can also be measured. Ultrasound radiation pressure is used to induce free propagating shear waves. The measurable properties of the shear waves are sensitive to only the material properties of the tissue under certain circumstances. Shear moduli in tissue are measured with high accuracy and precision given appropriate models of wave propagation within the geometry of the tissue. Careful use of shear wave propagation and subsequent measurements can provide fundamental measurements of tissue mechanical properties if models are accurate.

9:05

3aBB4. Evaluation of liver fibrosis using the acoustic characteristic and statistical signal processing of echo.   Tadashi Yamaguchi   (Faculty of Eng., Chiba Univ., 1-33 Yayoi-cho, Inage-ku, Chiba, 263-8522 Japan) and Hiroyuki Hachiya   (Chiba Univ., Inage-ku, Chiba, 263-8522 Japan)

We evaluate the relationship between changes in acoustic properties accompanying change of a tissue and echo information using human liver specimens *in vitro*. The rf echo signals of a 20-mm-thick human liver specimen (200 frames) were acquired continuously using a probe using 2.0-MHz transmission frequency and 4.0-MHz receiving frequency. The signals were processed using statistical signal processing to extract abnormal echo information. After ultrasonic scanning, 50×50-mm^2 sections were cut from the liver specimens for microscopy and acoustic microscope measurement. The liver fiber structure was extracted from 20 4-μm-thick Masson's trichrome stained microsections. The speed of sound and the attenuation of 2-mm-thick cut specimens were measured using 25-MHz ultrasound. Results of comparing 3-D structures of abnormal information extracted from echo signals and the 3D fiber structures extracted from microsections showed that both structures were clearly in agreement. Furthermore, it was confirmed that the speed of sound of fibers measured using an acoustic microscope was faster than that for normal liver tissue.

9:25

3aBB5. The importance of cells and arrangement of cells to ultrasound backscatter.   Michael Oelze   (Dept. of Elect. & Comput. Eng., Univ. of Illinois at Urbana-Champaign, 405 N. Mathews, Urbana, IL 61801, oelze@uiuc.edu)

The early work of Professor Floyd Dunn identified the importance of collagen structures and globular protein to ultrasound backscatter [Fields and Dunn, J. Acoust. Soc. Am. **54**, 809–812 (1973)]. Recent advances in tissue characterization through ultrasound backscatter have again focused on determination of the underlying microstructures responsible for scattering. The focus of new models for ultrasound backscattering has been on the contribution of cells. Specifically, new models have sought to address the ultrasound backscatter from single cells and from different arrangement of cells. The importance of cells and their arrangements in tissues to classification of disease, i.e., cancer, through ultrasound was also noted by Professor Dunn [Saijo *et al.*, Ultrasound Med. Biol. **17**, 709–714 (1991)]. In the present work, the construction of a new cell model of scattering was made from measurements of acoustic properties of cells. Different arrangements of cells, i.e., uniform distribution of cells and cells arranged in groups, were examined in simulation using the new cell model. Finally, the new cell model and simulations were compared to ultrasound backscatter measurements from different kinds of cancer. The arrangement of cells within a cancerous region was observed to be significant for diagnostically differentiating between cancers using ultrasound backscatter.

9:45

3aBB6. Evaluation of blood flow velocity vector measurement accuracy: Numerical simulation and flow phantom studies of Rankine's vortex.   Takashi Okada, Teruyuki Sonoyama, Akimitsu Harada   (Aloka Co., Ltd., 3-7-19, Imai, Ohme, Tokyo, 198-8577, Japan), Shigeo Ohtsuki   (Tokyo Inst. of Technol., Nagat-suda, Midori-ku, Yokohama, 226-8503, Japan), and Motonao Tanaka   (Tohoku Employee's Pension Welfare Hospital, Hukumuro, Miyagino-ku, Sendai, 983-8512, Japan)

A new method to measure the velocity vector of blood flow on the observation plane was recently developed [Ohtsuki and Tanaka, J. Visuali. **9**, 69–82 (2006)]. The method is based on the calculation of stream functions. To evaluate the accuracy of this method, we have studied the velocity distribution of Rankine's vortex in numerical simulation and experiments. The vortex of the simulation model was 50 mm in radius, the forced vortex was 20 mm in radius, and the maximum velocity of the vortex was 50 cm/s. The differences between the velocity profiles of the vortex obtained by this method and by simulation were less than 10%, although the accuracy depended on the angle of the observation plane. Furthermore, we conducted phantom experiments in which the vortex was created in degassed water by using a magnetic stirrer. Color Doppler data of the vortex flow were acquired using a ultrasonic diagnostic system (SSD-6500, Aloka, Japan) and the velocity vector distribution was calculated. The experimental results were in good agreement with the simulation model. We conclude that the reliability of this method is very high. The results suggest great potential of the new velocity vector method for quantitative diagnosis of cardiac functions.

10:20

3aBB7. Professor Floyd Dunn's contribution to understanding the biological effects of ultrasound. Mel E. Stratmeyer   (Food and Drug Administration/CDRH, 9200 Corporate Blvd. (HFZ-120), Rockville, MD 20850, melvin.stratmeyer@fda.hhs.gov)

During Professor Dunn's career, ultrasound exposure has evolved from being used to induce dramatic tissue effects in animals to routine diagnostic fetal imaging in humans. An understanding of the fundamental mechanisms and dosimetric parameters involved in ultrasound-induced biological effects was essential to allow ultrasound to be clinically used for tissue destruction, physical therapy, and routine diagnostic imaging. Professor Dunn's early research and the research of other prominent scientists, many of them trained by Professor Dunn, will be discussed to demonstrate advancements in our understanding of the biological effects of ultrasound.

10:40

3aBB8. Reduction of cavitation threshold by second-harmonic superimposition and its potential application to sonodynamic therapy. Shin-ichiro Umemura   (School of Health Sci., Kyoto Univ., Kyoto, 607-8507 Japan, sumemura@hs.med.kyoto-u.ac.jp), Ken-ichi Kawabata, Kazuaki Sasaki, and Nami Sugita   (Hitachi Central Res. Lab., Tokyo, 185-0043 Japan)

Acoustic cavitation is known to induce bioeffects under certain conditions. Cavitation threshold, the acoustic strength needed to induce such cavitation, in various biological systems was intensively studied by Dr. Dunn's group. Their results have significantly contributed to the safety concerns of diagnostic and therapeutic uses of ultrasound. Acoustic cavitation is also known to be the primary cause of sonochemical reactions. Chemical compounds such as hematoporphyrin were found to be activated by acoustic cavitation and induce *in vitro* and *in vivo* antitumor effects thereby. In order to make use of this effect in therapeutic practice, cavitation must be generated reproducibly without depending on standing waves at acoustic power inducing no significant heating. It was also found that the cavitation threshold can be significantly reduced by superimposing the second harmonic onto the fundamental in insonation. The threshold was reduced by more than an order of magnitude, especially in the presence of a certain compound such as Rose Bengal (RB). An amphiphilic derivatives of RB, selectively accumulating in tumor tissues, was synthesized and used in combination with focused ultrasound with second-harmonic superimposition to treat experimental murine tumors, resulting in significant reduction of their sizes. A hypothesis on the mechanism behind this will also be discussed.

11:00

3aBB9. Exposure estimation and dosimetry for ultrasound thermal therapies. Gail ter Haar   (Joint Dept. of Phys., Inst. of Cancer Res., Royal Marsden Hospital, Sutton, Surrey, SM2 5PT, UK)

The success of ultrasound thermal therapies relies on achieving a predetermined temperature rise in a specified tissue volume. If these treatments are to be used in clinical application, it is important to be able to estimate the required exposure parameters and to undertake appropriate dosimetry. Floyd Dunn and his co-workers were pioneers in this field for high-intensity focused ultrasound (HIFU). In early papers they addressed the problem of ultrasonic dosage and dose rate. This remains a topic of active discussion. A major part of these investigations relies on accurate temperature measurement in ultrasonic fields in tissue. The viscous heating artifact that occurs when thermocouples are used was first recognized by the Illinois group in the 1950s. Effective ways of estimating this component of the measured temperature rise are still being sought. Investigation of the dependence of HIFU lesion size on *in situ* ultrasound intensity, exposure time, and frequency will be described, and the importance of acoustic cavitation and boiling for the definition of an ultrasound dose parameter will be discussed.

11:20

3aBB10. Numerical analysis of temperature in tissue radiated by focused ultrasound. Nobuyuki Endoh and Takenobu Tsuchiya (Dept. of Eng., Kanagawa Univ., Yokohama 221-8686, Japan)

Higher power ultrasonic equipment is recently extending not only into therapy but also into diagnosis because newer diagnostic systems such as harmonic imaging require higher ultrasound than conventional imaging systems. It is very important to assure the safety in the use of diagnostic equipment, especially for prevention of burns caused by radiation from ultrasonic imaging systems. In this two-dimensional FDTD-HCE study, temperature increases in tissue were simulated at the focal point of a phased array transducer like a common B-mode imagine system. A center frequency of radiated pulse is assumed to be 2.5 MHz and ISTPA = 0.72 W/cm^2. Results show that the temperature in tissue at the focal point is proportional to the pulse repetition frequency (PRF) when the PRF is changed from 100 to 400 kHz. It is also shown that common equipment is safe because the maximum temperature rise in tissue is only 0.0004 °C at the focal point of the transducer even though the PRF is 400 kHz. [Work supported by High-Tech Research Center Project from the Ministry of ECSST.]

11:40

3aBB11. Professor Floyd Dunn's contributions to ultrasound metrology. Gerald R. Harris   (U.S. Food and Drug Administration, 12725 Twinbrook Pkwy., Mail Code HFZ-170, Rockville, MD 20852-1719, gerald.harris@fda.hhs.gov)

A half-century ago the applications of ultrasound in medicine were, apart from physiotherapy, mostly experimental, and the related bioeffects and toxicity studies were in their infancy. Progress in both of these areas was hampered in part by the lack of acceptable tools for measuring the exposure levels, especially for the intense fields then being used in ultrasound surgical studies. Professor Floyd Dunn's advancements in ultrasound measurement techniques at the University of Illinois Bioacoustics Research Laboratory afforded accurate means for quantifying these exposures and laid the groundwork for subsequent developments in ultrasound measurement and calibration. In this presentation Professor Dunn's early work in thermal and radiation force techniques will be described and some recent methods that are being investigated to characterize ultrasound fields, particularly at high intensities, will be reviewed.

Session 3aEA

Engineering Acoustics, ASA Committee on Standards, and Psychological and Physiological Acoustics: Hearing Aids

Invited Papers

8:00

3aEA1. Digital hearing aids: A brief history.　Harry Levitt　(P.O. Box 610, Bodega Bay, CA 94923)

The journey leading to the development of digital hearing aids began at Bell Laboratories in the mid 1960s when a digital computer was used to simulate an experimental high gain telephone with frequency shaping for people with hearing loss. The simulation was off-line at about 100 times real time. About 20 years later, a digital master hearing aid operating in real time was developed using a high speed array processor. The development of wearable digital hearing aids followed soon after as high speed digital signal processing (DSP) chips were developed. The first wearable digital hearing aid was a body worn instrument and was not a commercial success. At this stage, digitally controlled analog hearing aids could be made small enough to be worn on the ear and these instruments were widely used by the end of the decade. During the 1990s, low-power DSP chips were developed that were small enough to allow for all-digital ear-worn hearing aids to be developed. The challenge today is to tap the tremendous potential of digital signal processing techniques within the power and size constraints of a practical, wearable instrument.

8:20

3aEA2. A new speech enhancement method for two-input two-output hearing aids.　Junfeng Li, Shuichi Sakamoto, Yo-iti Suzuki　(R. I. E. C., Tohoku Univ., 2-1-1, Katahira, Sendai, 980-8577, Japan, junfeng@ais.riec.tohoku.ac.jp), and Satoshi Hongo (Miyagi Natl. College of Tech., Medeshima-Shiote, Natori-shi, Miyagi, 981-1239, Japan)

Human beings have the ability to pick up a speech signal in noisy environments, which is known as the cocktail-party effect. This phenomenon is, however, often degraded in persons with impaired hearing. Therefore, a good method to enhance this phenomenon must be very useful to improve speech intelligibility in ambient noise for hearing-impaired persons. In this lecture, multi-input two-output speech enhancement techniques are first summarized. Subsequently, a new two-input two-output speech enhancement method is proposed that is based on the frequency domain binaural model (FDBM) [Nakashima *et al.*, Acoust. Sci. Technol. **24**, 172–178 (2003)]. In the proposed method, the interaural differences are first calculated from the noisy observations and employed to determine the sound-source locations. A speech absence probability (SAP) estimator is then developed using knowledge of estimated source locations. It is further integrated into the original FDBM to improve the interference-suppression capability. Effectiveness and superiority of the proposed speech enhancement method with respect to the original FDBM are validated through comprehensive experiments in terms of objective and subjective speech-quality measures. [Work supported by Sendai Intelligent Knowledge Cluster.]

8:40

3aEA3. Utilizing the auditory systems processing capabilities in the development of methods to auto-steer signal processing strategies in hearing instruments.　Andrew B. Dittberner, Jeff Bondy, Maureen Coughlin, Bill Whitmer　(GN Auditory Res. Lab., 2601 Patriot Blvd., Glenview IL 60026), and Melissa Dominguez　(DBK Acoust., Grayslake IL, 60030)

Hearing instruments have evolved in both the hardware and signal processing domains, providing more computational capabilities and sophisticated sound processing strategies. Static or adaptive methods are employed by these sound processing strategies to achieve a desired output. Due to the adaptive nature of some of these processing strategies and the continual increase in the number of parameters that can interact negatively with each other, there is a need to provide some method of global control over the parameter states. In addition, due to individual needs of the end user, parameter states in a hearing instrument may not satisfy the broad range of acoustic environments that a listener encounters, so identification of particular acoustic environment characteristics is also important. The purpose of this work is to introduce and discuss these problems and some of the current research efforts addressing environmental classification and global control of a hearing instrument's parameter states. The scope of this discussion will be on strategies employed to meet the needs of the end user in reference to the acoustic environment they identify as having a negative impact on their auditory experience and the desired performance they expect from the hearing instrument in that environment.

3aEA4. A study of signal-to-noise ratio conditions for measuring the intelligibility of hearing aids in noisy live environments.
Yasuhiko Arai (Kanazawa Inst. of Technol., 7-1 Ohgigaoka, Nonoichi, Ishikawa 921-8501, Japan, araiyasu@neptune.kanazawa-it.ac.jp) and Yoshiyuki Yoshizumi (Matsushita Electric Ind. Co., Ltd., Tsuzuki-ku, Yokohama 224-8539, Japan)

The authors studied a method to measure the intelligibility of directional hearing aids using a dummy head in noisy environments. The method is based on ISO recommendations (ISO 8353-2, ISO 8353-3). However, it is sometimes difficult to meet the quasi-free-field conditions. Therefore, a method for approximate measurement of intelligibility, by which the equivalent results are obtained in noisy live environments, is recommended. To simulate noisy environments, a multitalker (MULT) noise or a simulated multitalker noise was simultaneously and noncorrelatively put out through four loudspeakers in the live testing room. The MULT noise was composed of eight voices (four males and four females). The experiment showed that mixed voices of eight to ten persons were adequate for interference of the test speech words. The 50% SNR specification, meaning signal-to-noise ratio that gives intelligibility of 50% correct, was introduced into the measurement system. Intelligibility was measured under various SNR conditions. It was expressed approximately by the sigmoid function of SNR. The 50% SNR was estimated from the experimental equation. The intelligibility was measured adequately in the range between 0% and 100% by using the 50% SNR specification. The system configuration, measuring conditions, and measured samples are discussed.

3aEA5. Perception-model-based sound quality prediction for hearing aids: Big effect, small effect, and the optimization of noise reduction algorithms.
Birger Kollmeier, Rainer Huber, Thomas Rohdenburg, and Volker Hohmann (Medizinische Physik, Universitaet Oldenburg and Kompetenzzentrum HoerTech, D-26111 Oldenburg, Germany)

Objective sound quality models can be used to optimize hearing aid algorithms and their respective parameter settings by numerically predicting the subjective sound quality assessed by humans without having to perform quality measurements with humans concurrently. The big effect prediction considers how the (individual) hearing loss affects the aided or unaided perceived sound quality. The small effect prediction aims at subtle differences at a given amplification level of the hearing aid in order to compare processing parameters. This talk will concentrate on benchmarking different types of objective prediction methods both for big effect and small effect conditions using a wide range of signals and processing conditions, respectively. In addition, the performance of PEMO_Q, an auditory-model-based quality prediction scheme developed at Oldenburg University will be discussed, which has been modified to include the effect of hearing impairment and the adaptation to different kinds of test data sets. We will also demonstrate the degree to which PEMO_Q is beneficial for optimizing noise reduction algorithms that are suitable for hearing aids. The objective measure helps to efficiently scan the multidimensional parameter space for an optimum parameter set of the noise reduction algorithm. [Work supported by BMBF and by HoerTech.]

3aEA6. The design and evaluation of a noise suppression system for custom-made digital hearing aids.
Yoshiyuki Yoshizumi and Shigekiyo Fujii (Matsushita Electric Industrial Co., Ltd., 600, Saedo-cho, Tsuzuki-ku, Yokohama, 224-8539 Japan, yoshizumi.yoshiyuki@jp.panasonic.com)

A noise suppression system, which has the inbuilt feature to adapt to the local environment, for custom-made digital hearing aids has been developed. The signal process is based on spectral subtraction technology with 32 bands in the frequency domain. The signal-to-noise ratio was improved by an average of 7.5 dB in rms level. Its effectiveness was evaluated using the seven-point rating scale method for nine normal-hearing subjects and six hearing impaired subjects. Test speech is presented under three different environments, which consist of a car, a duct, and a crowded place. As a result of the assessment, the same tendency is observed between normal and hearing-impaired subjects and there were two good points that were found. First, the noise suppression system makes them more comfortable to listen to speech with the statistical significance of $p = 0.05$. Second, the noisiness is reduced with the statistical significance of $p = 0.01$. It should be noted that there is a scattering of the plotted data; however, statistically, the data result is quite acceptable.

3aEA7. Development of novel biologically inspired directional microphones.
Ronald N. Miles, Weili Cui, Quang Su, Rui Wu, Lin Tan, Yang Liu, Stephen A. Jones, Venkatesh Mohnankrishnaswami, Thomas Strait, William Butler, David DiBernardo (Dept. of Mech. Eng., State Univ. of New York, Binghamton, NY 13902-6000, miles@binghamton.edu), F. Levent Degertekin, Baris Bicen, Wook Lee, and Kamran Jeelani (Georgia Inst. of Technol., Atlanta, GA 30332-0405)

The development of novel directional microphones for hearing aids is described. The mechanisms underlying the design of these unusual microphones were inspired by our earlier study of the ears of the parasitoid fly *Ormia ochracea* [Miles, *et al.*, J. Acoust. Soc. Am. **98**, 3059–3070 (1995)]. The structure of *Ormia's* ears inspired new approaches to the design of directional microphones that have the potential to be more sensitive and have lower thermal noise than typical miniature microphones. The mechanisms for directional hearing in this animal are discussed along with the engineering design concepts that they have inspired. Microphones have been fabricated out of silicon that employ either capacitive sensing or optical sensing to convert the diaphragm motion into an electronic signal. Measured results indicate that the directivity of these microphones is very similar to that of an ideal first-order differential microphone. In addition, novel microphone diaphragms have been fabricated that posses a second-order directional response. These can be used to achieve a significant reduction of unwanted background acoustic noise in hearing aid applications. 3aEA8. Binaural speech enhancement by complex wavelet transform based on interaural level and argument differences. Satoshi Hongo (Dept. of Design and Comput. Applications, Miyagi Natl. College of Technol., 48 Nodayama, Medeshima-Shiote, Natori, Japan, hongo@miyagi-ct.ac.jp) and Yôiti Suzuki (Res. Inst. of Elec. Commun., Tohoku Univ., Japan)

Binaural information might enhance speech signals in noisy environments. Most precedent studies in this area have implemented signal processing in time and frequency domains. For this study, an enhancement method using complex wavelet transform (CWT) was proposed. The CWT has a scale domain whose bandwidth is inversely proportional to the scale level and may therefore be well compared to auditory filters. The proposed processing procedure is the following: (1) By computing CWT for a sound signal at every direction of arrival (DOA), a database (DB) of the scale domain wavelet coefficients is prepared for every DOA. (2) For binaural input signals from an unknown direction, the scale domain wavelet coefficients are calculated using CWT. (3) The DOA of the input signal is estimated as the direction for which interaural level and argument differences calculated from wavelet coefficients are the most similar to those in the DB. (4) The input signal is segregated similarly to FDBM (Nakashima *et al.*, 2003) based on the estimated DOA. Experiments with a directional target signal and an interference sound source calculated from real HRTFs were conducted to show the effectiveness of the proposed algorithm. [This research was partially supported by Sendai Intelligent Knowledge Cluster.]

3aEA9. Study of the multimicrophone composed of unidirectional microphones for glasses-type hearing aids. Kenzo Miura (Panasonic MCE Co., Ltd., 4-3-1, Tsunashima-higashi, Kohoku-ku, Yokohama 223-8639, Japan) and Yasuhiko Arai (Kanazawa Inst. of Technol., Nonoichi, Ishikawa 921-8501, Japan)

That multiunit microphones (MUMs) using unidirectional units offer high sensitivity, low electronic noise, and low wind noise for the binaural hearing aids of glasses type is a fact that has already been reported. [K. Miura and Y. Arai, Th.2.D.4, 18th ICA, Kyoto, Japan (April, 2004)]. Two types of MUM are proposed herein for glasses-type hearing aids that have an array of three units positioned over the front frame for each channel. One type is the parallel front-direction array type (PA-MUM). The other type has a twisted direction array (TA-MUM). Performances of these MUMs were compared with that of a bigradient (BG) microphone positioned on the side frame. Results show that the PA-MUM has very narrow directivity; TA-MUM showed moderate directivity. The electronic noise and the wind noise of these MUMs were at a very low level. On the other hand, the BG microphone showed rather sharp directivity, but the electronic noise from the signal conditioner and the wind noise were both of a high level. These results show that PA-MUM is suitable for listening to speech in very noisy environments and that TA-MUM is suitable for general use for glasses-type hearing aids.

3aEA10. A model of own-voice perception with hearing aid usage. Stefan Stenfelt (Dept of Neurosci. and Locomotion/Div. of Tech. Audiol., Linkping Univ., SE-58185 Linkping, Sweden) and Sabine Reinfeldt (Chalmers Univ. of Technol., SE-41296 Göteborg, Sweden)

Until recently, own-voice issues for hearing aid users were dominated by the occlusion effect. However, with the so-called open fittings, the occlusion-related own-voice problems have been significantly reduced. There are groups of hearing-aid users, though, for whom open fittings are unavailable, either because of high-frequency gain requirements or because of ear geometry. Of even bigger importance is the fact that hearing-aid users still have own voice issues, even when their occlusion problems have essentially been solved. A model is presented for perception of the own voice comprising an estimation of the own voice transmission by airborne and structure borne sound. Parameters of the model are the occlusion effect from the ear mould and ventilation tubes, gain settings of the hearing aid, and transmission properties of the middle ear during vocalization. The results show that both the airborne and structure borne sound transmission depend on both amplifier and acoustical parameters. A ventilation tube in the ear-mould may introduce a resonance that causes extreme alterations of the own voice spectral content. Although the model is far from complete, it can provide useful insights on own-voice related issues and give design directions to alleviate, at least partly, own-voice problems related to hearing aid usage.

3aEA11. Transverse variations of sound pressure in an ear canal occluded by a hearing aid. Michael R. Stinson and Gilles A. Daigle (Inst. for Microstructural Sci., Natl. Res. Council, Ottawa, ON, Canada K1A 0R6)

The sound field in a model ear canal has been investigated experimentally and theoretically. The canal was cylindrical, 7.5-mm diameter, and terminated with a Zwislocki coupler to represent absorption by the human middle ear. The outer end of the canal was driven by a test hearing aid, with the acoustic output from a receiver entering the canal through a 1-mm port. The hearing aid was provided with a 20-mm-long vent, either 1 or 2 mm in diameter. The sound field inside the canal was measured using a specially designed 0.2-mm-diam probe microphone [Daigle and Stinson, J. Acoust. Soc. Am. **116**, 2618 (2004)]. In parallel, calculations of the interior sound field were performed using a boundary element technique. Both calculations and experiment reveal large transverse variations of sound pressure level, as much as 25 dB at 8 kHz, near the inner face of the hearing aid. Variations are greatest near the outlet port of the receiver and the vent hole. Deeper into the canal, the transverse variations are less significant and, at depths greater than 5 mm, only a longitudinal variation remains. [Work supported by Gennum Corp.]

3aNS1. Results from the National Institute for Occupational Safety and Health Administration/Environmental Protection Agency (NIOSH/EPA) interlaboratory comparison of American National Standards Institute (ANSI) S12.6-1997 Methods A and B. William J. Murphy (Hearing Loss Prevention Team, NIOSH, MS C-27, 4676 Columbia Pkwy., Cincinnati, OH 45226-1998, wjm4@cdc.gov), Elliott Berger (Aearo/E-A-R Corp., Indianapolis, IN 46268-1657), Dan Gauger (Bose Corp. Framingham MA 01701-9168), Brad Witt (Howard Leight Industries, San Diego, CA 92154), Rich McKinley (U.S. Air Force Res. Labs., Dayton, OH 45433), Samir Gerges (Laboratório de Vibraçöes e Acústica, Florianópolis, SC, Brazil), and William Ahroon (U.S. Army Aeromedical Res. Lab., Fort Rucker, AL 36362-0577)

The Environmental Protection Agency and the National Institute for Occupational Safety and Health sponsored the completion of an interlaboratory study (E-A-RCal[SM] Laboratory, Howard Leight Industries, Brazil Acoustics and Vibration Laboratory, NIOSH Robert Taft Laboratories, US Air Force Research Laboratory, and US Army Aeromedical Research Laboratory) to compare two fitting protocols described in ANSI S12.6-1997 (R2002). Method A (informed user fit) and Method B (naive subject fit) were implemented according to the standard. Six models of hearing protection were tested in the study: two earmuffs, foam, premolded, and custom-molded earplugs, and canal caps. The muffs were counterbalanced both in testing order and the occluded and unoccluded conditions. The earplugs were counterbalanced across testing order and occlusion. Each laboratory tested 24 subjects for both methods and each protector. This paper reports on the results from this study. Particularly, the comparison of the statistical errors for each method and protector will be evaluated. In general the lower, 80th percentile, estimates of the expected protection were quite similar. The upper, 20th percentile, tended to exhibit effects that were dependent upon the method and the laboratory. [Work supported by EPA interagency agreement DW75921973-01-0.]

3aNS2. Methods of measuring the insertion loss of active noise reduction devices. Dan Gauger (Bose Corp., M.S. 271E, 145 Pennsylvania Ave., Framingham, MA 01701, dan_gauger@bose.com), Elliott Berger, Ronald Kieper (E-A-R/Aearo Technologies, Indianapolis IN 46268), John Casali, and Chuck Perala (Virginia Tech, Blacksburg VA 24061)

As active noise reduction (ANR) becomes more common, the need has developed for the measurement of device attenuation, passive and active combined, for use in noise protection calculations. An experiment was conducted involving both REAT and MIRE measurements on five circumaural and two supra-aural ANR devices in two different laboratories. Subject selection and instruction were consistent with the ANSI S12.6-1997 Method B fitting paradigm for all measurements. MIRE was measured both using microphones mounted on canal-occluding plugs near the entrance of the canal ("shallow MIRE") and using concha-mounted microphones with probe tubes extending near to the tympanic membrane and an unoccluded canal ("deep MIRE"); the latter measurements were done with the same device fitting trials as the REAT measurements. The two MIRE measurements were quite similar, with the shallow MIRE values typically better by margins of only 0.5 to 1.0 dB at all frequencies. A positive REAT minus MIRE difference at the lower frequencies consistent with the effects of physiological noise masking was observed. Various analyses of the data are presented and a recommendation is made for how ANR device total attenuation might be measured in a future standard as part of a hearing protector rating regime encompassing both passive and active devices.

8:15

3aNS3. Variability of field-based hearing protection device attenuation measurements. Richard Neitzel, Sebrina Somers, and Noah Seixas (Univ. of Washington, DEOHS, 4225 Roosevelt Way, NE #100, Seattle, WA 98105)

HPD attenuation is highly dependent on individual-specific fit. Prediction of an individual's attenuation depends on measurement system accuracy and attenuation variability due to HPD refitting. This study compared attenuation measurements from two systems [one real-ear-attenuation-at-threshold (REAT) and the other microphone-in-real-ear (MIRE)] on workers using two earplugs (foam and custom-molded). Workers' perceptions of the earplugs were also evaluated. Individual's attenuation results were summarized as personal attenuation ratings (PARs). Variability in PARs from between-subject, between-day, and within-day differences was used to

determine the lower confidence limit, or uncertainty factor (UF), of an individual's attenuation. The custom-molded earplug PARs achieved a higher percentage of labeled attenuation than did the foam earplug with both test systems, and also had higher overall acceptance among workers. MIRE PAR levels were lower than REAT levels for both earplugs, but the relationship between the two test systems was highly variable. The MIRE system had lower within-day variability than the REAT system. One individual's MIRE results were highly influential; removal of these results greatly reduced the UF for the custom-molded earplug/MIRE combination. UFs ranged from 8.8 to 13.5 dB. These findings highlight the importance of evaluating variability in individuals' HPD attenuation, rather than relying on single measurements.

8:35

3aNS4. Has the Occupational Safety and Health Administration record-keeping rule changed hearing loss prevention programs? Laurie Wells (Assoc. in Acoust., Inc., 2283 Danielle Court, Loveland, CO 80537, lwellshear@cs.com)

The Occupational Safety and Health Administration (OSHA) record-keeping rule 29 CFR part 1904.10, changed the definition of recordable hearing loss and created a separate column on the OSHA 300 form to record noise-induced hearing loss (NIHL). In an effort to identify possible effects of the record-keeping rule change, an informal written survey was distributed at the National Hearing Conservation Association (NHCA) annual conference in February, 2006. NHCA conference attendees, because they specialize in hearing loss prevention, are likely to be familiar with hearing conservation issues so their perceptions are of particular interest. A total of 36 attendees, including audiologists, audiometric technicians (OHC), industrial hygienists (IH), mobile test company owners, occupational medicine physicians (OMP), and occupational health nurses (OHN) completed the ten-question survey. In summary, there appears to be a consensus that the everyday practice of hearing loss prevention has been affected by the record-keeping rule change, with both positive and negative influences. Employers seem to be paying more attention to HLPPs, which is, by itself, a positive outcome. Somewhat alarming however, is the finding suggesting that recordable STSs may be being ''lined-out'' or ''denied'' inappropriately in order to keep recordable rates artificially low.

8:55

3aNS5. Hearing effects of nonoccupational sound exposure evaluated by temporary threshold shift. Hiroaki Takinami (RION Co., Ltd., 3-20-41 Higashimotomachi, Kokubunji Tokyo 185-8533 Japan, hiro@rion.co.jp) and Shoji Aono (Osaka Univ., 1-2 Yamadaoka, Suita, Osaka 565-0871, Japan)

In the 1960s, the relation between the acoustical characteristics of sound exposure and the sound-induced temporal threshold shift (TTS) of people were carefully investigated by Shoji $et\ al.$ [J. Acoust Soc. Am. **48** 978−987 (1970); 6th ICAA−2−8, pp. A9−A12 (1968)]. Based on these studies, an equation that estimates TTS at various test frequencies was proposed as a function of the TTS−critical−band levels. In this presentation, therelation between the sound exposure and the TTS will be reviewed, and a prototype TTS meter that estimates TTS in real time operation will be introduced. The hearing effects of some nonoccupational sounds at different places (Pachinkoparlor, disco, and livehouse) were evaluated with the TTS levels as the indicator. The sounds from portable musicplayers and music instruments of or chestra were also evaluated. The TTS levels were measured for shorttime sound exposure and compared to long−term estimates using the TTS meter. In some cases, after 2− or 4−h sound exposure, the estimated TTS levels at the test frequency of 4 kHz reached almost 20 dB.

9:15

3aNS6. Japanese young people's recreational sound environment and hearing protection. Yôiti Suzuki and Fumitaka Saito (Res. Inst. of Electr. Commun., Tohoku Univ., Katahira 2-1-1, Aobaku, Sendai 980-8577, Japan)

Intense sound may damage hearing even if the listeners are willing to listen to it. Risk of hearing disorders due to leisure time sound is an important problem in hearing conservation. A questionnaire survey of Japanese young people's leisure time activities showed that in Japan concerts rather than discos seemed more influential and in comparison with the results in Finland, the awareness of the danger of intense sound was much less. The sound levels while listening to music with loudspeakers and at pop-music concerts were measured. While listening levels with loudspeakers were quite modest (avg.: $L_{Aeq}=65$ dB for favorite music pieces), at the two concerts the L_{Aeq}'s at audience positions ranged from 95 to 105 dB. Since the pop music performed at the concerts was mild relative to typical values in the present Japanese music scenes, this level may be regarded as near the minimum that could be expected for such activities. Additionally, L_{Aeq} while playing one of ten kinds of musical instruments at the player's ear was measured. The results ranged from 76 (viola) to 110 dB (trombone). Consideration of hearing protection at music scenes and education regarding its value seem very important.

3aNS7. Variability in real-ear attenuation at threshold evaluations of hearing protection devices. William A. Ahroon, Melinda E. Hill, and Kimberly B. Lukas (U.S. Army Aeromedical Res. Lab., Fort Rucker, AL 36362)

The American National Standard Method for the Measurement of the Real-Ear Attenuation of Hearing Protectors (ANSI S12.6-1997 [R2002]) contains explicit requirements for the physical parameters of the test facility used in measuring the performance of hearing protection devices and in subject selection and device fitting. However, the standard curiously does not provide a similar level of detail when considering the psychophysical procedure used to define ''threshold'' other than when an automatic recording audiometer is used. Most facilities conducting ANSI-based measurements of hearing protector performance appear to use a Bekesy tracking procedure, but other methods such as a modified method of limits or a method of adjustment procedure are implemented as well by some facilities. Following several tests of hearing protection over the past year, several examples of large variability caused by very low attenuation results in one or both runs in a few subjects have been noted. The data from these unusual subjects are analyzed and presented along with recommendations for the psychophysical procedures to be included in future versions of the standard.

3aNS8. Comparison of passive versus active noise reduction headsets in light aircraft cockpit noise: Communications intelligibility and workload. John Casali, Brian Valimont, Jeffrey Lancaster (Auditory Systems Lab., Virginia Tech, 250 Durham Hall, Blacksburg, VA 24061, jcasali@vt.edu), and Dan Gauger (Bose Corp., Framingham, MA, 01701)

Under instrument flight rules (IFR) conditions in Cessna 172R (95 dBA) cockpit noise, eight IFR-licensed pilots flew four 3.5-h nonstop flights in an FAA-certified, single-engine flight simulator, while wearing one of four communications headsets in each flight. All flights imposed an equivalently high level of air traffic control communications, at three Speech Transmission Index (STI) values: 0.30, 0.50, and 0.70. Perceptual and psychomotor workload were also controlled. In addition to a battery of flight-related metrics (some reported elsewhere), an objective, flight-embedded measure of communications intelligibility was obtained—the number of readbacks required of the pilot to attain 100% intelligibility on each command. An ANOVA revealed that as a group, the ANR headsets (Sennheiser HMEC300, Bose Aviation X, LightSPEED Thirty3G) required significantly fewer readbacks (averaging 1.2–1.3) than did the passive David Clark H-10-13.4 (averaging 1.5). Flight control performance, as reflected by deviations in assigned magnetic heading, altitude, and airspeed, was highest during flights with the Bose headset. Pilots' workload estimates were measured using the modified Cooper-Harper scale, with 1 representing lowest workload and 9 representing highest. The three ANR headsets were associated with average workload ratings of 3.4–3.5, while the passive headset yielded a higher average workload of 4.4.

10:05–10:15   Break

3aNS9. An evaluation of the acoustic properties of an improved combat arms earplug. Mary S. Binseel and Tomasz R. Letowski (U.S. Army Res. Lab., AMSRD-ARL-HR-SD, Aberdeen Proving Ground, MD 21005, mary@arl.army.mil)

This study investigates the performance of an improved version of the combat arms earplug (CAE). U.S. Army soldiers must operate in environments which can go from quiet to noisy in a moment. They also operate in environments where the predominant noise hazard can be either continuous or impulse noise. The current earplug of choice to address these varying protection needs is the CAE. The CAE is a two-sided earplug which provides linear attenuation for steady-state noise exposure on one side and nonlinear protection for impulse noise protection on the other. Although feedback from the field has been favorable regarding the functioning of the CAE, other concerns such as fit, comfort, size, and the need to remove, turn, and reinsert the earplug to change the modality have been raised. In order to address these concerns, the Army Research Laboratory provided funding for the development of an improved CAE. The improved CAE was evaluated for attenuation of continuous and impulse noise, soldier performance in localization and speech intelligibility tasks, and soldier acceptance on issues such as ease of use, perceived protection, equipment compatibility, sizing, and comfort. Results of these experiments will be discussed.

3aNS10. Design of linear time-domain filters for hearing protector modeling. Jeffrey S. Vipperman (Dept. of Mech. Eng., Univ. of Pittsburgh, 648 Benedum Hall, Pittsburgh, PA 15261) and William J. Murphy (Natl. Inst. for Occupational Safety and Health, Cincinnati, OH 45226-1998)

Accurately modeling hearing protectors for predicting the hazard underneath them is of interest to many. This project modeled the single transfer path through the hearing protector from the free field to the ear drum, as an extension to the frequency-domain modeling method presented by Price and Kalb [J. Acoust. Soc. Am. **103**, 2878 (1998)]. First, the real ear attenuation at threshold (REAT) data from the hearing protectors (muff and plugs) were converted to linear quantities and curve fit to form

a continuous function of frequency, while preserving the low-pass characteristic. The resulting magnitude was combined with the head-related transfer function (HRTF) to form the magnitude of the total transfer function. Using complex cepstrum, a stable, complex frequency response function (FRF) was created by assuming a minimum phase transfer path. System identification methods were used to fit the FRF data to a parametric model that was converted to an infinite impulse response (IIR) digital filter. Subject-fit REAT data were used in order to represent real-world usage. Imperfect usage was modeled by derating the subject fit data by 1 standard deviation (SD). Tests on an artificial head are conducted to evaluate the filters in the time and frequency domains. [This research was supported wholly by NIOSH.]

3aNS11. A source of high-level acoustic impulses for the measurement of hearing protectors. Jan Zera and Rafal Mlynski (Central Inst. for Labour Protection, Natl. Res. Inst., Czerniakowska 16, 00-701 Warsaw, Poland)

The paper describes a laboratory source for generating high-level, A-type acoustic impulses. The basic part of the source is a steel cylinder closed at one end with elastic foil. The blast is produced by an abrupt break of the foil caused by an increased pressure of air compressed inside the cylinder. By adjusting the air pressure inside the cylinder the impulses peak SPL may be set within a range of 150–170 dB. As the peak SPL is increased from 150 to 170 dB, the rise time and A duration of impulses decrease respectively from 350 to 14 s and from 1.1 to 0.4 ms. An advantage of the source is that it produces impulses with highly repeatable parameters; for a given value of air pressure inside the cylinder, standard deviation of peak SPL distribution is only 1.3 dB. The source is omnidirectional in the horizontal plane and has a nearly circular directional pattern in the vertical plane. The source is a good alternative for generating impulses with the use of explosives and is particularly useful for measurements made indoors, in the laboratory. [Work supported by the Polish Ministry of Science and Education, Grants T07B00428 and SP03.1].

3aNS12. Applicability of impulse noise hearing damage risk criteria (DRCs) to hearing protectors. Jan Zera and Rafal Mlynski (Central Inst. for Labour Protection, Natl. Res. Inst., Czerniakowska 16, 00-701 Warsaw, Poland)

Hearing damage risk criteria, DRC, concerning exposure to impulse noise, developed by CHABA [Ward CHABA Report (1968)], Pfander [J. Acoust. Soc. Am. **67**, 628–633 (1980)], Smoorenburg [*New Perspectives on Noise*] (Raven, New York, 1982), pp. 471–490], and Dancer [Acust. Acta Acust. **3**, 539–547 (1995)], have been destined for impulses encountered in open space, in free-field conditions. To adapt these criteria for conditions in which hearing protective devices (HPDs) are used, a standard procedure was proposed in the literature (e.g., by Pfander) that consists in subtracting the attenuation of the HPD, typically 25 dB, from the impulse's peak SPL. Such a simple method does not take into account the change of the signal waveform under the HPD, usually resulting in increased A, C, or D duration. In this study, the subtraction method was verified by a comparison of impulse noise DRC with the parameters of acoustic impulses measured under the earmuff: peak SPL, rise time, and A, C, and D duration. Results show that the subtraction method underestimates the possible hearing damage risk posed by exposure to impulse noise when a hearing protector is used. [Work supported by the Polish Ministry of Science and Education, Grants T07B00428 and SP03.1].

3aNS13. Performance of sound restoration hearing protection in impulsive noise. William J. Murphy (Hearing Loss Prevention Team, Natl. Inst. for Occupational Safety and Health, 4676 Columbia Pkwy., MS C-27, Cincinnati OH 45226-1998)

Hearing protection devices (HPDs) are the principal means of protecting the hearing of a person against harmful levels of noise in highly impulsive noise environments. New HPDs which utilize sound restoration circuitry were measured using a mannequin to assess the performance of

these protectors in response to small-arms weapons fire. The results for the peak reduction and attenuation were analyzed for both indoor and outdoor measurements. The performance of the protectors exhibited little dependence with level for impulses between 150 and 170 decibels. The passive performance for a single protector characterized the active performance for these high-intensity impulses. The results were also evaluated using the US Army AHAAH cochlear model. As the peak sound-pressure level underneath the different models of protectors increased, the estimated risk of hearing loss increased. [Work supported by EPA Interagency Agreement DW75921973-01-0.]

11:30

3aNS14. Criteria levels for nonoccupational noise exposure. Leslie Blomberg (Noise Pollution Clearinghouse, Box 1137, Montpelier, VT 05601)

Selecting criteria levels for nonoccupational noise exposure requires consideration of several factors. These include: (1) the need to protect public health and safety; (2) the diverse sources of nonoccupational noise exposure; (3) the inconsistent patterns of exposure, for example, the potential for multiple exposures in 1 day, or none; (4) complications caused by workplace exposure; (5) the fact that those exposed include children and minors; (6) the inability of the general public, without training or equipment, to understand traditional means of expressing noise exposure; (7) difficulties educating the public about nonoccupational noise; and (8) complications that may arise if levels are mandated or adopted by government bodies. Given these considerations, the paper argues there are actu-ally three criteria levels needed: (1) one that delimits safe noise exposure; (2) one that reflects increased levels of risk and the need for increased vigilance in protecting hearing; and (3) one that indicates unsafe exposure, for which hearing conservation should be practiced. Moreover, new and simpler ways of determining these levels are needed. Specific levels are recommended, and a method developed by the Noise Pollution Clearing-house for use by the general public to determine if a sound is too loud is presented.

11:45

3aNS15. Dosimeter measures of sound exposure experienced by university students. William A. Yost, Noorah Koita, Robert Maslo, Prasad Patel, Ruchita Patel, and Brendan Ringhouse (Parmly Hearing Inst., Loyola Univ. Chicago, 6525 N. Sheridan Rd., Chicago, IL 60626)

There is increased concern about excessive sound exposure, especially in students, resulting from the use of Ipods and similar devices. Such exposure needs to be considered in light of the daily noise dose such users experience. In this study five university students wore noise dosimeters for 10 h per day for 5 days, and noise levels were recorded every minute. The students also maintained a diary of their activities (activities were noted at least every half hour) during the time they wore the noise dosimeters. The diary was standardized so that each student used the same diary format. Results indicating the noise levels, noise dose, and the relationship of the levels to the students activities will be presented and discussed. In general the noise exposure experienced by these students was usually mild (less than 60 dBA) to moderate (between 60 and 75 dBA).

Contributed Poster Paper

Poster paper 3aNS16 will be on display from 7:30 a.m. to 12:00 noon. The author will be at the poster from 12:00 noon to 12:15 p.m.

3aNS16. Review of literature on hearing damage by personal stereo. Dorte Hammershøi and Rodrigo Ordoñez (Dept. of Acoust., Aalborg Univ., Fredrik Bajers Vej 7-B5, DK-9220 Aalborg Ø, Denmark, dh@acoustics.aau.dk)

In the 1980s and 1990s there was a general concern for the high levels that personal stereo systems were capable of producing. At that time no standardized method for the determination of exposure levels existed, which could have contributed to overly conservative conclusions. With the publication of ISO 11904-1:2002 and 11904-2:2004, previous studies can be viewed in a different light, and the results point, in our opinion, at levels and listening habits that are of hazard to the hearing. The present paper will review previous studies that may shed light over the levels and habits of contemporary personal stereo systems, which can produce even higher levels and are of even wider use.

3aPA1. Attempts to observe bubble fusion in deuterated acetone.　Carlos G. Camara, Seth J. Putterman, Brian Naranjo　(Phys. Dept., UCLA, 2-202 Knudsen Hall, Los Angeles, CA, 90095, camara@physics.ucla.edu), Stephen D. Hopkins　(Intel Corp. Portland, OR, 97205), and Kenneth S. Suslick　(Univ. of Illinois, Urbana, IL 61801)

A pulsed neutron generator (PNG) and a radioactive source have been used to seed cavitation at dynamic pressures ranging up to 35 atm. No fusion signal above background has been observed. Our upper bound is less than $1E-4$ of the signal claimed by R. P. Taleyarkhan *et al.* [Phys. Rev. Lett. **96**, (2006)]. Reasons for the failure of bubble fusion in acetone and future directions will be discussed. [Research funded by DARPA. We thank Brian Kappus for valuable discussions.]

8:55

3aPA2. Influence of ultrasonic frequency on sonochemical reactions.　Kyuichi Yasui, Toru Tuziuti, Teruyuki Kozuka, Atsuya Towata, and Yasuo Iida　(Natl. Inst. of Adv. Industrial Sci. and Technol. (AIST), Moriyama-ku, Nagoya 463-8560, Japan, k.yasui@aist.go.jp)

Numerical simulations of the pulsation of an air bubble have been performed for various ultrasonic frequencies (20 kHz to 1 MHz) and pressure amplitude taking into account the effect of nonequilibrium chemical reactions inside a bubble and that of nonequilibrium evaporation and condensation of water vapor at the bubble wall. The calculated results have revealed that as ultrasonic frequency decreases, the mole fraction of water vapor inside a bubble increases at the end of the bubble collapse. While the main oxidant created inside a vaporous bubble, which is defined as a bubble consisting mostly of water vapor at the end of the bubble collapse, is OH radical, that inside a gaseous bubble, which is defined as a bubble consisting mostly of noncondensable gas (air) at the end of the bubble collapse, is H_2O_2 or O atom when the bubble temperature is less than or more than 7000 K, respectively. Although the optimum acoustic amplitude for the oxidant's creation inside a bubble increases as the ultrasonic frequency increases, the range of the suitable acoustic amplitude for the oxidants creation becomes wider. It possibly results in the optimum ultrasonic frequency for the oxidant's creation reported in the literatures (200–600 kHz).

9:15

3aPA3. Comparison of sonoluminescence and water vapor plasma spectra.　Masanori Sato, Nagaya Okada　(Honda Electron. Co., Ltd., 20 Oyamazuka, Oiwa-cho, Toyohashi, Aichi 441-3193, Japan), Hideo Sugai, Tatsuo Ishijima, and Hirotaka Hotta　(Nagoya Univ., Nagoya, Aichi 464-8603, Japan)

An experimental study was carried out to find the mechanism of OH spectra generation through sonoluminescence. Line spectra of OH, H, and O were observed very clearly in water vapor plasma generated by 2.45-GHz microwave irradiation under the pressure of 40 hPa; however, broadband continua were not detected. Multibubble sonoluminescence (MBSL) and single-bubble sonolumines- cence (SBSL) have continua, and OH spectra were detected occasionally in MBSL. However, OH spectra were not detected in SBSL and higher temperature MBSL. The sources of emission in MBSL and SBSL were considered to be identical and differences in spectra of OH bands were attributable to the higher temperature. Experimental results obtained using low temperature water vapor plasma confirm that OH spectra depend on the bubble's interior plasma temperature: that is, at low temperatures, spectra of OH (308 nm), Ha, Hb, and O are clearly visible in water vapor plasma.

9:35

3aPA4. Molecular dynamics study on the nucleation and growth of cavitation bubbles.　Shu Takagi　(Dept. of Mech. Eng., Univ. of Tokyo, Bunkyo Ku, 7-3-1 Hongo, Tokyo 113-8656, Japan, takagi@mech.t.u-tokyo.ac.jp) and Shinichi Tsuda　(Univ. of Tokyo, Tokyo 113-8656, Japan)

Molecular dynamics simulations have been conducted for the nucleation and growth processes of cavitation bubbles in a decom- pressed liquid. To investigate the effects of noncondensable gas, the comparison between one-component liquid argon and two- component liquid argon, which includes helium gas molecules as impurities, was made. As a result, we observed that a competing coarsening similar to Ostwald ripening occurs in the one-component liquid argon, while coalescence of bubble nuclei frequently

occurs in the two-component case. In spite of the different growth patterns between the two cases, the values of the growth exponent are close to 1/2 in both cases. However, it has been found that the scaling components that constitute the growth exponent, i.e., the scaling exponent for the total radius of all nuclei and that for the number of nuclei, are different between the two cases. These scaling components are discussed in relation to a driving force for bubble nuclei to grow. In addition, the asymptotic behavior of the size distribution function of bubble nuclei is also discussed using these scaling parameters.

3aPA5. Frequency effects on intense sonoluminescence and bubble dynamics in sulfuric acid. Shin-ichi Hatanaka and Shigeo Hayashi (Univ. of Electro-Commun., 1-5-1 Chofugaoka, Chofu, Tokyo 182-8585 Japan, hatanaka@pc.uec.ac.jp)

Emission intensity increased remarkably with decreasing frequency for both multibubble sonoluminescence (MBSL) and single-bubble sonoluminescence (SBSL) in a concentrated sulfuric acid solution dissolving xenon gas. The spectrum of MBSL in the sulfuric acid showed the emission bands of a large peak at 388 nm and small peaks at 360 and 418 nm. The increase of MBSL intensity at lower frequency was responsible for the increase of the band peak at 388 nm in addition to the increase in continuous spectrum. The bubble dynamics in the sulfuric acid was different from that in water. The intense SBSL was emitted when the bubble was moving on an ellipselike trajectory. The intense MBSL was emitted even when multiple bubbles formed bubble clusters, which could not emit light in the water case.

10:30

3aPA6. Experimental analysis of blackbody emission from sonoluminescence in sulfuric acid. Stephen D. Hopkins, Carlos G. Camara, and Seth J. Putterman (Phys. Dept., UCLA, 2-202 Knudsen Hall, Los Angeles, CA 90095)

The spectrum of emission from a single xenon bubble in concentrated sulfuric acid driven at 30 kHz is an excellent fit to Planck's law with a surface temperature of 8000 K. The measured flash width and emission radius are also consistent with blackbody emission. In this study the only fitting parameter available is the temperature [Phys. Rev. Lett. **95**, (2005)]. [Research funded by DARPA.]

10:45

3aPA7. Drop tube generates 10-W flashes of sonoluminescence. Brian A. Kappus, Avic Chakravarty,[a] , and Seth J. Putterman (Phys. Dept., UCLA, 1-129 Knudsen Hall, Los Angeles, CA 90095)

Use of a low vapor pressure liquid such as phosphoric acid, with dissolved xenon in a vertically exited tube, generates ~200-ns flashes of sonoluminescence with a peak power of 10 W. We are in the process of characterizing the bubble motion by use of backlighting, stroboscopic, and streak photography. We will also broach the topic of disequilibrium between atom and electron temperatures. [Research funded by DARPA. We thank Carlos Camara and Shahzad Khalid for valuable discussions.]
[a] Deceased.

11:00

3aPA8. Attempts to observe sonoluminescence from a single bubble driven at 10 MHz. Shahzad Khalid, Carlos G. Camara, and Seth J. Putterman (Phys. Dept., UCLA, 2-202 Knudsen Hall, Los Angeles, CA 90095)

A 10-MHz spherical transducer array is used to generate cavitation at its focus with a field of ~100 atm. Sonoluminescence as well as light-scattering measurements will be discussed. [Research funded by DARPA.]

11:15

3aPA9. Unidentified energy conversions in an oscillating bubble. Karel Vokurka (Phys. Dept., Tech. Univ. of Liberec, 46117 Liberec, Czech Republic) and Silvano Buogo (CNR IDAC, 00133 Roma, Italy)

Acoustic radiation of freely oscillating bubbles has been studied experimentally. The oscillating bubbles have been generated by underwater spark discharges. Recorded pressure waves made it possible to determine the acoustic energy radiated by the oscillating bubbles and the potential energy of the bubbles when attaining the first and second maximum volumes. Comparison of the potential and acoustic energies revealed that about 70% of the potential energy of the bubble available at the first maximum volume has been converted into an unidentified energy. A possible candidate for the energy conversion mechanism seems to be internal converging shock wave in the bubble interior. The presence of this wave can be observed indirectly in a radiated pressure wave. The measured energies are compared with energies computed using a suitable model. This comparison shows that the theoretical values agree with experimental data until the bubble attains the first minimum volume. However, at later times discrepancies are observed. [Work has been partly supported (K.V.) by the Czech Ministry of Education as the research project MSM 46747878501.]

11:30

3aPA10. Optical observation of collapses of two bubbles adhered to the quartz wall under ultrasound irradiation with high-speed video camera: Micro-jet arising from two collapsing bubbles. Kenji Yoshida, Shintaro Nakatani, and Yoshiaki Watanabe (Faculty of Eng., Doshisha Univ., 1-3 Tataramiyakotani, Kyotanabe, Kyoto, Japan, etf1103@mail4.doshisha.ac.jp)

The mechanical action of a micro-jet, which arises from the collapse of bubbles, has been widely used for ultrasonic cleaning and sonoporation in medical field. The generation mechanism of a micro-jet induced by the ultrasound irradiation is focused on. In previous theoretical and experimental researches, the generation mechanism is well known when a single bubble is adhered to a rigid wall. However, its mechanism is not understood in detail when multiple bubbles exist on rigid wall. The optical observation of multi-bubble collapse greatly contributes to the development of micro-jet applications. It was observed that the collapses of two bubbles adhered to the quartz wall in an ultrasound field with high speed video camera (HPV-1, SHIMADZU). Maximum recording rate of this high speed video camera is 1 000 000 frames/second. The emitted ultrasound frequency is 27 kHz. From the observation, one of two bubbles was deformed after these bubbles vibrate. The micro-jet was generated to the opposite side against the deformed bubble when the deformed one touches the other. Then, the direction of the micro-jet to the quartz wall was almost horizontal. The number of micro-jets increased every time the distorted bubble touched the other. Finally, five micro-jets to the various directions were observed at the same instant.

3aPP1. Speech perception: Development from general mechanisms to modules. Patricia K. Kuhl (Inst. for Learning & Brain Sci. and Dept. of Speech and Hearing Sci., Univ. of Washington, Seattle, WA 98195)

Are the mechanisms subserving speech perception modular or general process in nature? I will adopt a developmental perspective to address this question. Using data from cross-cultural, cross-species, and developmental experiments, I will argue that, early in infancy, the mechanisms underlying speech perception are domain general and rely on processing that is not exclusive to speech signals. Language evolved to capitalize on general mechanisms of perception and action, and this ensures that all infants, regardless of the culture in which they are born, initially respond to and learn from exposure to language. As experience with language ensues, neural commitment to the properties of the language to which an infant is exposed results in dedicated neural networks and speech perception becomes more specialized. Finally, I will suggest that adult members of the culture help instill language in the child by adjusting the language they use when addressing infants and children (motherese), a speech style that exhibits interesting acoustic properties. Language input to the child enhances its learnability. A model of the developmental process will be described. [Research supported by NSF and NIH.]

8:55

3aPP2. Auditory events in language and music. Yoshitaka Nakajima and Kazuo Ueda (Faculty of Design, Kyushu Univ., 4-9-1 Shiobaru, Minami-ku, Fukuoka 815-8540, Japan, nakajima@design.kyushu-u.ac.jp)

Perceptual organization of both language and music is based on temporal units that can be called auditory events. Speech syllables and musical notes correspond typically to auditory events. The listener categorizes these events in various ways in order to extract information. We are at a preliminary stage of searching for acoustic cues that the auditory system can utilize to determine auditory events. Averaged intensity of a speech signal within a moving Gaussian temporal window of 15 ms gives cues of syllable boundaries, especially when this averaged intensity is compared with the intensity change obtained with a Gaussian temporal window of 200 ms. The change of intensity obtained through a filter of about 600–2200 Hz compared with the intensity change obtained through an almost flat filter also gives cues of syllable boundaries. Thus, intensity cues and spectral cues both work to mark syllables. This holds both in Japanese and in English. Such intensity cues may work when applied to monophonic or homophonic music, but spectral changes do not correspond clearly to musical notes. Thus, the perceptual mechanisms that determine speech syllables and musical notes can be different. [Work supported by JSPS and 21st Century COE, Kyushu University.]

9:15

3aPP3. Music and language in deaf children with cochlear implants. Takayuki Nakata, Sandra E. Trehub, Yukihiko Kanda, and Haruo Takahashi (Dept of Psych., Nagasaki Junshin Catholic Univ., 235 Mitsuyama-machi, Nagasaki-shi, Nagasaki-ken 852-8558, Japan, Dept. of Psych., Univ. of Toronto, Nagasaki Bell Hearing Ctr., Nagasaki Univ. Grad School of Biomed. Sci.)

Congenitally deaf children with cochlear implants successfully perceive speech in quiet environments, and many produce intelligible speech with normal voice quality. Because implants were designed to optimize speech rather than music perception, timing cues are preserved at the expense of pitch cues. Consequently, adult implant users tend to discontinue musical activities that were enjoyable prior to the onset of deafness. By contrast, congenitally deaf children enjoy a variety of musical activities including listening, singing, and playing instruments. Research in our laboratory suggests that musical activities may enhance child implant users' speech perception skills. For example, initiation of music listening at home by children with cochlear implants predicted their success on a word recognition task. Moreover, earlier ages of implantation were positively associated with enhanced motivation for listening to music. In addition, child implant users were able to identify musical themes that accompanied their favorite television programs. Unlike hearing children, however, they could not recognize the music from the melody (i.e., pitch patterning) alone. Analyses of these children's singing revealed rhythmic patterning similar to that of hearing children but pitch patterning that was grossly distorted. In short, rhythm plays a central role in child implant users' musical experience.

3aPP4. Dissociation of music and speech: Evidence from statistical learning in congenital amusia. Isabelle Peretz (Dept. of Psych., Univ. of Montreal, B.O. 6128, Succ. Ctr. ville, Montreal, QC, Canada H3C 3J7, isabelle.peretz@umontreal.ca) and Jenny Saffran (Univ. of Wisconsin—Madison, Madison, WI 53706)

Individuals who suffer from congenital amusia (commonly called tone-deafness) have experienced life-long difficulties in processing of music. The deficit can be traced down to an impairment in fine-grained pitch discrimination [Hyde and Peretz, Psychol. Sci., (2004)]. Their language abilities appear intact. One possible account for this dissociation between music and speech is that amusics lack normal exposure to music because of their lifelong history of musical failures. In other words, amusics might be able to acquire basic musical abilities if given appropriate exposure. To test this possibility, a group of 11 adults with congenital amusia, and their matched controls, were exposed to a continuous stream of syllables or tones for at least 21 min. Their task was to try to identify words or motifs, defined by transitional probabilities, following the procedure used by Saffran and collaborators [Cognition, (1999) (2001)]. The results show that amusics can learn novel words as easily as controls whereas they systematically fail on musical materials. Thus, limited exposure cannot fully account for the musical disorder. Implications for the domain specificity/generality debate of statistical learning will be discussed.

3aPP5. Nonlinguistic rhythm perception depends on culture and reflects the rhythms of speech: Evidence from English and Japanese. Aniruddh D. Patel, John R. Iversen (The Neurosci. Inst., 10640 John Jay Hopkins Dr., San Diego, CA 92121), and Kengo Ohgushi (Kyoto City Univ. of Arts, Kyoto, Japan)

Does a listener's native language influence the perception of nonverbal rhythms? One way to address this question is to examine the perception of rhythmic grouping, as suggested by Jakobson, Fant, and Halle in *Preliminaries to Speech Analysis*. Grouping refers to the perceptual clustering of events into higher level units such as phrases. Several principles of grouping of auditory patterns, established a century ago, have come to be thought of as innate properties of perception. The supporting data have come entirely from Western cultures, however. In this study, native English and Japanese speakers were tested for their perception of grouping in simple rhythmic sequences of tones. Members of the two cultures showed different patterns of perceptual grouping, demonstrating that basic auditory processes are shaped by culture. Furthermore, measurements of the temporal structure of English versus Japanese speech and music suggest that the observed differences reflect the rhythms of the two languages, rather than rhythmic differences between American and Japanese music. While it has long been known that a listener's native language influences the perception of speech, these results suggest that native language can also exert an influence on general auditory perception at a basic level. [Supported by Neurosciences Research Foundation and by JSPS.]

3aPP6. Two issues at the interface between speech and music. Diana Deutsch (Dept. of Psych., Univ. of California, San Diego, La Jolla, CA 92093) and Trevor Henthorn (Univ. of California, San Diego, La Jolla, CA 92093)

In what ways are speech and music subserved by domain-specific mechanisms, and in what ways by common neural substrates? This issue is addressed with respect to absolute pitch, which has generally been considered to be a musical faculty accessible only to rare individuals. Based on several findings obtained from speakers of tone languages, it is argued that absolute pitch originally evolved to subserve speech, and that it may be acquired readily during the first year of life, if infants are given the opportunity to associate pitches with verbal labels. It is further conjectured, based on other findings, that the early acquisition of pitch accent languages, such as the Tokyo and Osaka dialects of Japanese and the Hamkyeng and Kyengsang dialects of Korean, might also be conducive to the acquisition of absolute pitch. Perceptual relationships between speech and song are next considered. These generally differ in their features; however, a spoken phrase can be perceptually transformed to appear as song rather than speech, simply by repeating it several times over without any alteration in the signal (Deutsch, 2003). This phenomenon is demonstrated, its parameters are explored, and its implications for the mechanisms underlying perception of speech and song are discussed.

Contributed Papers

3aPP7. Training musicians and nonmusicians to discriminate Mandarin tones. Terry L. Gottfried and Grace Y.-H. Ouyang (Dept. of Psych., Lawrence Univ., Appleton, WI 54912-0599, rewgottt@lawrence.edu)

Musicians and nonmusicians were compared in their ability to learn Mandarin tone contrasts. Participants were pretested to assess their accuracy in tone discrimination. Some were then given six sessions of articulatory and acoustic training over 3 weeks; others were given no training. At the end of 3 weeks, participants were again tested on their discrimination accuracy. Listeners judged whether the tones (tone 1, high level; tone 2, mid rising; tone 3, low dipping; tone 4, high falling) of two different Mandarin syllables were the same or different. In some trials, listeners discriminated tones in words spoken by two speakers; in other trials, they discriminated tones in words spoken by one speaker only. The pretest revealed that musicians are significantly more accurate in discriminating Mandarin tones than nonmusicians. Musicians and nonmusicians who received the training regimen performed more accurately than untrained listeners on the posttest discrimination. Musicians showed significantly less improvement than nonmusicians with training, probably due to ceiling effects (their posttest accuracy was over 95%). Two-speaker discrimination trials were significantly more difficult for all listeners, but especially for nonmusicians. Discrimination of tones 2 and 3 was most difficult for all listeners, but showed considerable improvement after training.

3aPP8. The effects of musical experience on linguistic pitch perception: A comparison of Norwegian professional singers and instrumentalists. Maren Helene Rø, Dawn Behne (Dept. of Psych., Norwegian Univ. of Sci. and Technol., N-7491 Trondheim, marenhel@stud.ntnu.no), and Yue Wang (Simon Fraser Univ.)

Speech prosody and music share tonal attributes well suited for studying cross-domain transfer effects. The present study investigates whether the specific pitch experience acquired by professional singers and instrumentalists transfers to the perception of corresponding prosodic elements in a native and non-native language. Norwegian and Mandarin words with tonal distinctions, together with corresponding hummed tones, were presented dichotically in a forced attention listening test to three groups of native Norwegian listeners: professional singers, professional instrumentalists, and nonmusicians. While instrumentalists and singers were both more accurate (higher percent correct for both ears) than nonmusicians for Mandarin linguistic and hummed tones, only instrumentalists showed positive transfer to corresponding native Norwegian stimuli. Results indicate a pattern of perceiving tonal distinctions that mirrors the pitch experience acquired through professional vocal and instrumental training: Instrumentalists generally appear to rely on an autonomous, categorical pitch strategy, consistent with their primary training with discrete, fixed intervals. Singers, on the other hand, tend to use a similar strategy for nonlinguistic pitch perception, but not in processing native tonal contrasts. Overall, pitch experience acquired through musical training appears to have a positive transfer to non-native speech perception.

3aPP9. Effects of musical experience on linguistic pitch perception training. Dawn Behne (Psych., Norwegian Univ. of Sci. and Technol., 7491 Trondheim, Norway), Yue Wang (Simon Fraser Univ., Burnaby, BC V5A 1S6, Canada), Maren Helene Rø, Ann-Karin Hoff, Hans Andreas Knutsen, and Marianne Schmidt (Norwegian Univ. of Sci. and Technol., 7491 Trondheim, Norway)

Research continues to address the extent to which music ability transfers to other tasks and processes, among them speech perception. The current study examines the transfer of music experience to native and non-native linguistic pitch perception and tracks this process during training. Participants were nonmusicians (NMs) and music conservatory students (CMs), all of whom were native Norwegian listeners. Participants were tested with Norwegian and Mandarin materials in a tone-based and intonation-based directed attention dichotic listening task, administered five times during 2 weeks. Results show that training generally leads to increased accuracy in linguistic pitch perception. CMs are more accurate than NM in both tasks, and maintain this advantage throughout training. For both groups, training led to a decreased difference in performance between ears, with notably different patterns of ear improvement between NMs and CMs. Across languages, whereas CMs had improved accuracy in both tasks, NM showed no improvement in the tone task for either language. Findings indicate that musically trained listeners' experience positively transfers to native and non-native linguistic pitch perception, an advantage which, in training, affords them more extensive improvement across linguistic pitch tasks and in particular for a non-native pitch task where the native linguistic system does not interfere.

3aSC1. A computer-assisted instruction system for self-teaching of discriminating Chinese tones based on their acoustical properties. Shizuo Hiki, Kazuko Sunaoka, and Song Liu (Waseda Univ., 2-579-15 Mikajima, Tokorozawa, 359-1192 Japan, hiki@waseda.jp)

A computer-assisted instruction (CAI) system for self-teaching to discriminate Chinese tones was developed, and provided through the internet to Japanese college students of Chinese language class. The data of acoustical analysis and perceptual judgment on the Chinese tones played an important role in designing the system. The result of observation on characteristic errors in discriminating Chinese tones by the Japanese students was also utilized. This system offered three kinds of use for self-teaching:

testing, training, and reviewing. The original word lists consisted of 15 bisyllabic words with every combination of the four tones of Standard Chinese, involving different rates of unvoiced consonants, which disturbed the tone discrimination. In the partial word lists, only words having tone 2 and/or tone 3, which were difficult for the beginners, were excerpted from the original lists. Their speech samples with both female and male voices were accommodated. Temporal changes in fundamental frequency were extracted from the speech samples and displayed as visual cues in the training. It was also possible in the training to present only the words answered incorrectly in the preceding testing. By selecting suitable uses and word lists with the progress of self-teaching, the required time for achieving the goal was reduced.

3aSC2. Providing new methods for teaching Japanese speech communication for learners of Japanese as L2: Developing teaching materials using MRI-movies and natural speech data. Ryoko Hayashi, Chunyue Zhu, Toshiyuki Sadanobu, Jumpei Kaneda (Grad. School of Cultural Studies and Human Sci., Kobe Univ., Nada-ku Tsurukabuto 1-2-1, Kobe 657-8501, Japan, rhayashi@kobe-u.ac.jp), Donna Erickson (Showa Music Univ., Kanagawa 243-8521, Japan), Nick Campbell (ATR, Hikaridai 2-2-2, 619-0288, Japan), and Miyoko Sugito (Inst. for Speech Commun. Res., Nara 631-0014, Japan)

It is critical to provide people learning Japanese as a second language information about natural speech, since there is wide variability of articulation and speaking styles associated with various social attitudes and/or expressions in Japanese. For developing teaching materials for English and Chinese learners of Japanese as a second language, two new methods are demonstrated. One utilizes MRI-movies that dynamically demonstrate differences among vowel articulations in Japanese, English, and Chinese. This approach is effective for teaching good pronunciation, especially with regard to consonant cluster production, since the timing of the articulation for consonant clusters is visibly presented. The other is audio-visual data of natural speech in Japanese that demonstrate several typical expressions, e.g., wry face and strained (laryngealized) voice for asking favors politely. This type of material shows not only variations of speech communication in Japanese but also cultural differences among native speakers of Japanese, English, and Chinese. [Work supported by MEXT.]

3aSC3. Effects of training with sentences at varied speaking rates on native English speakers' perception of Japanese vowel length. Yukari Hirata, Emily Cullings, Elizabeth Whitehurst, Jacob Whiton (Dept. of East Asian Lang. and Lit., Colgate Univ., 13 Oak Dr., Hamilton, NY 13346), and Stephen Lambacher, G. (Univ. of Aizu, Aizu-Wakamatsu, Fukushima 965-8580, Japan)

In training non-native speakers to perceive difficult second language (L2) phonetic contrasts, providing variation in speakers and phonetic contexts helps the formation of L2 categories [Pisoni and Lively, in *Speech Perception and Linguistic Experience* (1995), pp. 433–459. The present study tested the hypothesis that high stimulus variability in speaking rate would have positive effects for L2 learners. Native English speakers' ability to identify Japanese vowel length was examined with three types of training: slow-only, fast-only, and slow-fast. Their perceptual abilities were measured with a pretest and posttest and compared with a control group that was not trained. Test stimuli were sentences containing Japanese disyllables spoken at three rates (slow, normal, fast). Participants were trained to identify the length of the second vowel of disyllables embedded in a sentence and they received immediate feedback. The pretest to posttest improvement of the slow-only (8.2%) and slow-fast (8.7%) training groups was significantly greater than the control group's improvement (3.9%). However, the fast-only (7.7%) training group's improvement did not significantly differ from the control group's improvement. In addition, slow-fast training, unlike other training, had an advantage in performance on the fast rate stimuli. Implications for the variability theory will be discussed. 3aSC4. Factors affecting the success of non-native vowel perception training. Kanae Nishi and Diane Kewley-Port (Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405)

Previously, Nishi and Kewley-Port [J. Acoust. Soc. Am. **118**, 1900 (2005)] reported the successful outcomes of an intensive vowel perception training protocol for Japanese and Korean learners of English. Their results indicated that vowel training worked best when large numbers of vowels in nonsense words were presented within the training blocks. In this report, additional analyses were performed in order to explore the generalization of training from nonsense to real words that were presented only during pre- and post-training tests. Results showed that, although both groups showed steady and substantial improvement for all vowels in nonsense words, generalization to real words was inconsistent across lis-

tener groups, different vowels, and talkers. These results indicated that: (1) native vowel phonology had a considerable influence on the success of our structured, intensive identification training protocol using many vowels; (2) nonsense word training incorporating high natural variability across phonetic contexts and talkers may not be sufficient to achieve the desired generalization to real words. These results are explained in part by the vowel acoustics (formant frequencies and vocalic duration) of the stimulus materials used for training and tests. 3aSC5. An analysis of the factors reading rate, vocabulary ability, and speaking proficiency in relation to the test of English for international communication (TOEIC) scores of Japanese learners of English. Keiko Asano and Michiko Mochizuki Sudo (Juntendo Univ., 1-1 Hiragagakuendai Inbamura, Inbagun, Chiba 270-1695, Japan, keiko_asano@sakura.juntendo.ac.jp)

This study investigated the relationships between the TOEIC scores and the two factors of the reading rates and vocabulary abilities of Japanese learners of English. Also studied are the relationships between the scores of the two TOEIC sections and the learners' speaking proficiencies. Applying the Rauding theory, which reported the same comprehension processes underlying reading and listening, to second language acquisition, this study tested the hypothesis that the processing time for reading had an effect on that for listening. The Japanese subjects in this study took TOEIC and standardized tests of reading rates and vocabulary abilities, and also participated in a production experiment. The results showed high correlations between the TOEIC scores and the two factors of reading rates and vocabulary abilities. They also showed the tendency that the improvement of reading rates and vocabulary abilities contributed to the improvement of not only the scores of the TOEIC Reading Section, but also those of the TOEIC Listening Section. In addition, this study clarified the degree to which the speaking proficiency measured by naturalness judgments of native speakers of English corresponded to the proficiency indirectly measured by the TOEIC Listening Section.
