As discussed above, two metrics have been found to be particularly useful (White and Mattys, 2007a, 2007b): VarcoV, the coefficient of variation of vowel interval duration, and %V, the proportion of utterance duration that is vocalic. The focus of the present study is therefore on these two metrics, together with the widely used nPVI-V (normalized pairwise variability index of vowel interval duration), which we found previously to be highly correlated with VarcoV, while being somewhat less discriminative. As a matter of record, however, the primary analyses were carried out for all rhythm metrics listed in Table I, and are reported in the Appendix. We include the results for nPVI-VC, a metric not utilized by White and Mattys (2007a, 2007b), but subsequently found useful in the classification of dysarthric speech by Liss *et al.* (2009).

II. METHOD

A. Participants and measurers

Six speakers, three females and three males, of Standard Southern British English were recorded. None reported any speech or hearing problems. The measurers were all trained phoneticians.

B. Materials

The five English sentences were the same as those used by White and Mattys (2007a) and are listed here in Appendix A. The sentences were constructed to avoid the approximants /l/, /r/, /j/, and /w/, for reasons discussed in Sec. I B.

C. Recordings

The sentences were recorded at the University of Bristol as part of a longer session comprising (1) short story reading, (2) map description, and (3) sentence reading (the five sentences in the present study preceded by five others). Participants were given time to rehearse the sentences silently before reading them aloud and were instructed to speak in their normal conversational voice at a rate that felt natural and comfortable. Sentence readings that contained errors or disfluencies were repeated. Recordings, direct to disk at a sampling rate of 32 kHz, were made in a sound-attenuated room using a high-quality microphone.

D. Measurements

The boundaries between vocalic and consonantal intervals of the Standard Southern British English sentences were labeled by five phonetically trained measurers (M1–M5). Prior to labeling, the measurers agreed to follow the criteria adopted by White and Mattys (2007a). (Note that the results for measurer M1 are those originally reported in White and Mattys, 2007a.) As these criteria were the sole common guide for the measurers in this study, they are reproduced verbatim.

"This procedure was carried out with reference to standard criteria (e.g., Peterson and Lehiste, 1960); where labels were associated with the start or end of pitch periods, they were placed at the point of zero crossing on the waveform.

The primary determiner of the placement of a vowel-consonant boundary was the end of the pitch period preceding a break in formant structure associated with a significant drop in waveform amplitude. Additional criteria which facilitated the location of the boundary in certain contexts included:

- Where the vowel offset was glottalized, a change in the shape of successive pitch periods, for example, lengthening or doubling.
- Before fricatives, the onset of visible frication.
- Before nasals, the appearance of nasal formant structure and a waveform amplitude minimum.

The consonant-vowel boundary was the beginning of the pitch period at the onset of vocalic formant structure, where this was associated with the appearance of pitch periods consistent with the body of the vowel (e.g., unfricated and of comparable amplitude). Aspiration following stop release was therefore included within the consonantal interval." (White and Mattys, 2007a, pp. 506–507).

Following the practice in White and Mattys, 2007a, pauses and disfluencies within utterances were excluded and vowel-vowel or consonant-consonant intervals on either side of the pause were combined. The measurers did not discuss specific labeling criteria, nor did they examine each other's measurements at any stage prior to extraction and analysis of the resulting durational data. These precautions were intended to ensure that the labeling differences between measurers can be regarded as representative of the differences that occur when independent studies use comparable labeling criteria, but different measurers.

The recorded utterances were also subjected to an automatic phone alignment process. Based on an orthographic transcription of each sentence, a forced alignment was carried out with the open-source speech recognition tool SPRAAK (Demuynck *et al.*, 2008). Forty-one tri-state monophonic Gaussian mixture models were trained on the British English SpeechDat FDB telephone speech database (Draxler *et al.*, 1998), separately for male and female speakers. As a 32 ms Hamming window with a step size of 10 ms was used, the duration of the aligned segments is in multiples of 10 ms with a minimum duration of 30 ms. The lexicon used in the forced alignment process was derived from the orthographic transcription using the CELEX lexical database (Baayen *et al.*, 1995). The resulting phone alignments were then transformed into alternations of vocalic and intervocalic intervals, in order to bring them into the same format as the segmentations by the human measurers.

Scores for the metrics %V, ΔV, ΔC, VarcoV, VarcoC, nPVI-V, rPVI-C, and nPVI-VC (see Table I) were then computed, separately for the five read sentences produced by each of the six speakers. For the sake of consistency, utterance-initial consonants, where they occurred, were excluded from the measurements.

E. Statistical analysis

We report on the variability in contrastive rhythm scores according to speaker, sentence materials, and measurers. For the analysis of the variability due to speakers, each speaker contributed 30 scores to each rhythm metric (five sentences and six measurers). For the analysis of the variability due to sentence materials, each sentence contributed 36 scores to each rhythm metric (six speakers and six measurers). For the analysis of the variability due to measurers, each measurer produced 30 scores per rhythm metric (six speakers and five sentences). The intraclass correlation coefficients (ICCs) were computed with the R environment's IRR package (Gamer *et al.*, 2007). We used a two-way model, which treats both raters and items as randomly sampled from a population (Shrout and Fleiss, 1979). Intraclass correlation coefficients of 0.40–0.59 are commonly regarded as indicating moderate inter-rater reliability, values of 0.60–0.79 as substantial, and values of 0.80 or larger as outstanding (Garson, 2009). In addition, in order to provide some sense of whether differences between speakers, sentences, and measurers are potentially problematic for interpretation, we compared the size of those differences to the largest difference reported between languages in White and Mattys (2007a) as a benchmark, namely, the difference between scores for Castilian Spanish and Standard Southern British English (see Fig. 1 for VarcoV and %V values).

III. RESULTS AND DISCUSSION

As discussed above, we focus on the rhythm metrics found by previous studies (White and Mattys, 2007a, 2007b) to be the most discriminative between and within languages: VarcoV, the coefficient of variation of vocalic interval duration (standard deviation divided by the mean); nPVI, the normalized pairwise variability index of vocalic interval duration (see Table I for fuller definition); and %V, the proportion of total utterance duration made up of vocalic rather than consonantal intervals.

A. Effect of speaker on %V, VarcoV, and nPVI-V scores

Figure 2 shows the mean %V, VarcoV, and nPVI-V scores of the six Standard Southern British English speakers averaged across sentences and measurers. The means for the other rhythm metrics can be found in Appendix B.

A one-way repeated measures analysis of variance (ANOVA) for %V showed a main effect of Speaker, $F(5,145)=15.53$, $p<0.001$. Values for ICCs and 95% con-

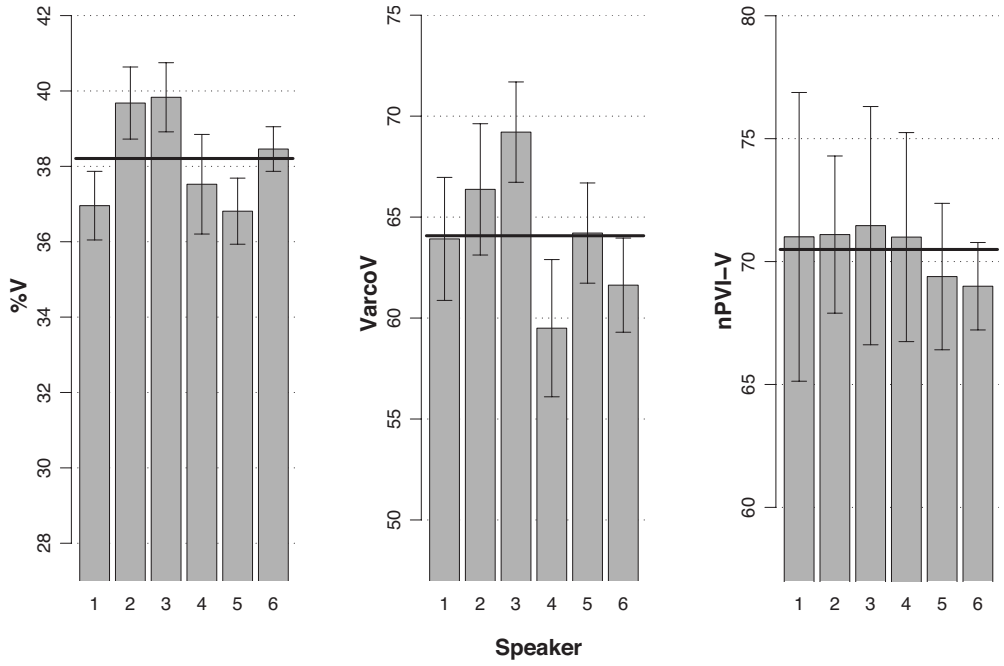

FIG. 2. Means and standard errors of the rhythm metrics %V, VarcoV, and nPVI-V for the six SSBE speakers. The solid horizontal bars indicate the pooled means.

fidence intervals for all metrics and conditions are summarized in Table II. As can be seen, consistency among speakers for %V was moderate. The largest difference in mean %V was 3.0 or 30% of the Spanish-English difference and the mean difference was 1.6 or 16% of Spanish-English. For VarcoV, there was also a main effect of speaker, $F(5,145)=13.47$, $p<0.001$. Consistency among speakers was moderate (Table II). The largest difference in mean VarcoV was 9.7 or 42% of Spanish-English, and the mean difference was 4.2 or 18% of Spanish-English. For nPVI-V, we found no main effect of speaker, $F(5,145)<1$. Consistency among speakers was again moderate (Table II), but here the actual differences between the speakers' mean scores were very low: The largest difference in mean nPVI-V was 2.5 or only 7% of Spanish-English, and the mean difference was 1.2 or 3% of Spanish-English.

TABLE II. Intraclass correlation coefficients, among speakers, sentences, and measurers, for the rhythm metrics %V, VarcoV, and nPVI-V (with 95% confidence intervals). Values of 0.40–0.59 are commonly regarded as indicating moderate inter-rater reliability, values of 0.60–0.79 as substantial, and values of 0.80 or larger as outstanding (Garson, 2009).

	%V	VarcoV	nPVI-V
1. Speakers	0.53 [0.38,0.70]	0.56 [0.41,0.72]	0.52 [0.36,0.68]
2. Sentences	0.38 [0.23,0.55]	0.32 [0.17,0.49]	0.01 [−0.08,0.15]
3a. Measurers (including automatic alignment)	0.64 [0.49,0.77]	0.64 [0.49,0.77]	0.52 [0.36,0.68]
3b. Measurers (excluding automatic alignment)	0.67 [0.52,0.80]	0.71 [0.57,0.82]	0.62 [0.47,0.76]

All other rhythm metrics also showed a main effect of speaker (Appendix B). The ICCs of ΔV and nPVI-VC were in the range of those for %V, VarcoV, and nPVI-V; the ICCs for the consonantal interval metrics were lower.

B. Effect of sentence on %V, VarcoV, and nPVI-V scores

Figure 3 shows the mean %V, VarcoV, and nPVI-V scores of the five English sentences averaged across speakers and measurers. The means for the other rhythm metrics can be found in Appendix C.

For %V, a one-way repeated measures ANOVA showed a main effect of sentence, $F(4,140)=27.10$, $p<0.001$. Consistency between sentences, as measured by the ICC, was low (Table II). The largest difference in mean %V between sentences was 4.9 or 49% of Spanish-English and the mean difference was 2.0 or 20% of Spanish-English. For VarcoV, there was also a main effect of sentence, $F(4,140)=35.38$, $p<0.001$. Consistency between sentences was low (Table II). The largest difference in mean VarcoV was 13.0 or 57% of Spanish-English, and the mean difference was 6.5 or 28% of Spanish-English. For nPVI-V, we also found a main effect of sentence, $F(4,140)=35.49$, $p<0.001$. Consistency between sentences was very low (Table II). The largest difference in mean nPVI-V was 15.5 or 42% of Spanish-English, and the mean difference was 9.0 or 25% of Spanish-English.

All other rhythm metrics also showed a main effect of Sentence (Appendix C). The ICCs likewise all indicated a low consistency between sentences. As with the analysis of speaker differences above, the ICCs of the consonantal interval metrics were generally lower than those of the vocalic metrics, with the exception of a very low value for nPVI-V.

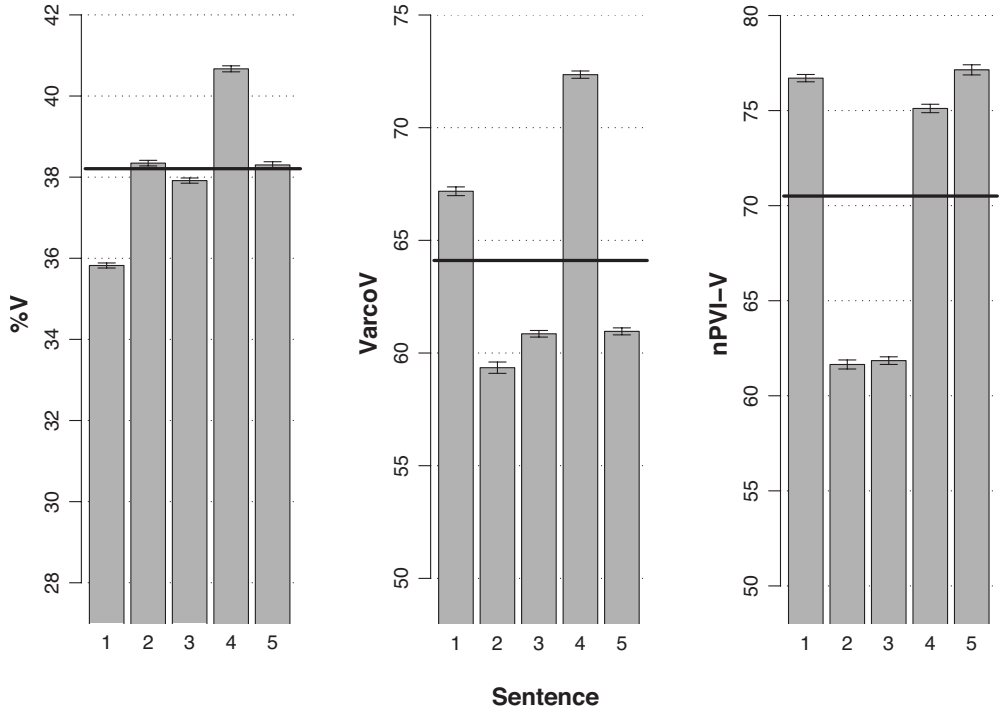

FIG. 3. Means and standard errors of the rhythm metrics %V, VarcoV, and nPVI-V for the five English sentences as read by the SSBE speakers. The solid horizontal bars indicate the pooled means.

C. Effect of measurer on %V, VarcoV, and nPVI-V scores

Figure 4 shows the mean %V, VarcoV, and nPVI-V scores of the five human measurers (M1–M5) and the automatic phone alignment (A) averaged across speakers and sentences. The means for the other rhythm metrics can be found in Appendix D.

For %V, a one-way repeated measures ANOVA showed a main effect of measurer, $F(5,145)=15.85$, $p<0.001$. Consistency among measurers, as measured by the ICC, was, however, substantial (Table II). The largest difference in mean %V was 3.7, or 37% of Spanish-English, and the mean difference was 1.4 or 14% of Spanish-English. For VarcoV, we also found a main effect of measurer, $F(5,145)=10.06$, $p<0.001$. Consistency among measurers was substantial (Table II). The largest difference in mean VarcoV was 6.4 or 28% of Spanish-English, and the mean difference was 3.4 or 15% of Spanish-English. For nPVI-V, there was a main effect of measurer, $F(5,145)=2.46$, $p<0.05$. Consistency among measurers was moderate (Table II). The largest dif-

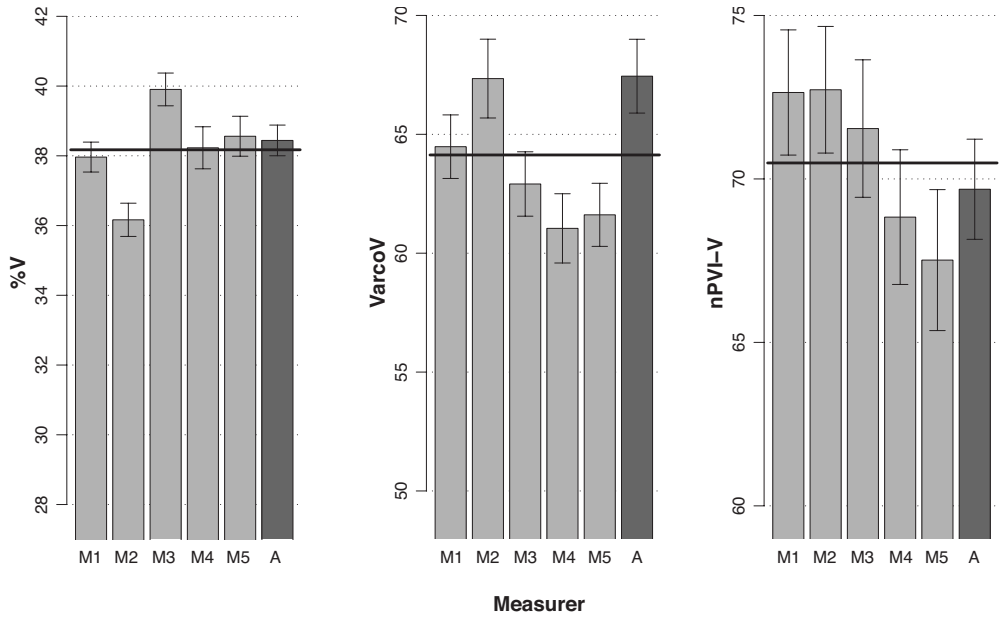

FIG. 4. Means and standard errors of the rhythm metrics %V, VarcoV, and nPVI-V (for SSBE) for the five human measurers (M1–M5) and the automatic phone alignment (A). The solid horizontal bars indicate the pooled means.

ference in mean nPVI-V was 5.2 or 14% of Spanish-English difference, and the mean difference was 2.6 or 7% of Spanish-English.

All other rhythm metrics also showed a main effect of measurer (Appendix D), with the exception of ΔV, where the effect approached significance. The consonantal interval metrics were again generally less consistent across measurers than the vocalic interval metrics.

As for the performance of the automatic phone alignment, Fig. 4 shows that the mean %V and nPVI-V scores were well within the range of the human measurers, and for VarcoV were just outside the human measurers' range. This observation was confirmed by pairwise comparisons between the automatic alignment and mean values for the five human measurers. There was no difference in mean for %V, $t(29)=0.08$, $p=0.44$, and nPVI-V, $t(29)=-0.51$, $p=0.61$. For VarcoV, the mean score of the automatic alignment was higher than that of the human measurers, $t(29)=3.02$, $p=0.005$. When we compared the consistency among human measurers with that among all measurers (i.e., including the automatic alignment) we found that the ICCs among the human measurers alone are somewhat higher (Table II); however, the overlapping confidence intervals indicate that these differences were not significant.

D. Discussion

The analyses show that variation between speakers, sentences, and measurers all contribute to variability in rhythm metric scores. Sentences produced the largest variation in scores, with, for example, the mean difference in VarcoV between sentences being 28% of the Spanish-English difference. The differences due to speakers and measurers were generally smaller. In addition, consistency was highest among measurers (generally with an ICC of above 0.60) and lowest between sentences (ICC below 0.40). Between speakers, the ICC was around 0.50. The confidence intervals for sentence ICC and measurer ICC did not overlap for either %V or VarcoV, indicating that, for these two metrics, consistency among sentences was significantly lower than consistency among measurers. With regard to individual rhythm metrics, differences were generally smallest for nPVI-V and largest for VarcoV. Consistency, on the other hand, was slightly lower for nPVI-V than for the other two metrics: This likely to be in part the result of the lack of variation in nPVI-V between speakers; with little variation in the other two variables, there is little scope for sentences to show consistency in their patterns of scores.

How relevant are these differences to the comparison of results between studies? The largest difference between the English sentences examined here, for example, was more than half the size (57%) of the mean English-Spanish difference, which can be considered the archetypal poles of the contrastive rhythm space, at least among languages studied so far. Thus, a small unrepresentative set of sentences could easily alter the position of the language measured within the rhythm space, as also demonstrated by Prieto *et al.* (2009).

What then are "representative" sentences for the purpose of rhythm analysis? At the segmental level, Prieto *et al.* (2009) clearly showed that the phonological structure of syllables has an impact on rhythm scores, with untypical patterns (such as sentences comprised of a succession of open syllables for English) producing misleading results. At the suprasegmental level, one critical factor is clearly the relative numbers and distribution of strong and weak syllables. Low *et al.* (2000) constructed sentences containing only strong syllables and showed that nPVI-V scores were much lower than those for sentences containing an alternating pattern of strong and weak syllables.

TABLE III. The number of syllable transitions without a change in stress (weak-weak or strong-strong), the number of total transitions, and the CRI for the English sentences.

Sentence	Constant transitions	Total transitions	Constant regularity index
1	4	14	0.71
2	6	16	0.63
3	5	14	0.64
4	4	16	0.75
5	2	16	0.88

As a further test of the effect of suprasegmental structure on rhythm measures, we introduce the contrast regularity index (CRI), a measure of the regularity of sentence stress patterns. We calculated CRI as $1-(c/t)$, where c stands for the number of syllable transitions in which the stress remains constant (a weak syllable followed by a weak syllable or a strong syllable followed by another strong syllable), and t for the total number of syllable transitions. The lower the number of syllable-to-syllable transitions where stress is unaltered, the higher the CRI, with a CRI of 1 indicating a strict alternation of strong and weak syllables.

The CRIs for the five English sentences used in this study are listed in Table III. Given that the PVI was devised to reflect the strength of the alternation between successive syllables, it is reassuring that patterns of CRI values quite closely correspond to the nPVI-V values, with the two sentences lowest in CRI (sentences 2 and 3) also having the lowest nPVI-V scores, and the sentences with a high CRI (sentences 1, 4, and 5) having the highest nPVI-V scores.

It is worth noting that, although VarcoV scores were generally highly correlated with nPVI scores, the pattern of scores was very different for sentence 5, which had a low VarcoV score and yet the highest nPVI-V score. This was also the sentence that had the highest CRI value, reflecting its regularly alternating strong-weak pattern, only disrupted by two weak-weak transitions. The ordering of strong and weak syllables is thus critical for nPVI-V, and irrelevant for simple global measures of interval duration variation such as VarcoV, as discussed in Low *et al.*, 2000. This sensitivity to the rhythmic structure of utterances could be seen as a strength of the PVI, but could also be a weakness in studies that lack a sufficiently large and language-typical range of metrical structure.

In summary, it is clear that all three factors—speakers, sentences, and measurers—need to be considered when developing studies and comparing results. We found that the largest source of variation in rhythm scores was the sentences selected for the study: These can either be randomly

sampled or specifically designed to be representative of the language in terms of phonological and suprasegmental structures, as discussed above. Speakers—a moderate source of variation in rhythm scores—can be naturally treated as a random factor and so the usual caveat regarding low speaker numbers applies. There is little corrective action available, however, regarding idiosyncratic differences between measurers apart from the obvious step of ensuring that all measurers conform to an agreed protocol for the identification of segment boundaries. Given that, it is reassuring to note that differences in rhythm scores between measurers are relatively small compared to those arising from speakers and, in particular, sentences, and that consistency between measurers—as indexed by intraclass correlation coefficients—is relatively high.

IV. GENERAL DISCUSSION

In an attempt to assess the reliability of contrastive rhythm metrics used routinely in phonetic research, we examined how such metrics are affected by variation between measurers, sentences, and speakers. We analyzed five English sentences spoken by six speakers of Standard Southern British English, with segmentation into vocalic and intervocalic intervals carried out by five phoneticians, together with an automated alignment using speech recognition software.

The results clearly demonstrate that the nature of the sentence materials recorded is the most important source of variation in rhythm scores. Consistency of scores between sentences was low for all metrics, even those metrics—%V, VarcoV, and nPVI-V—previously found to be most discriminative between language groups and robust to variation in articulation rate (White and Mattys, 2007a, 2007b). Mean differences between SSBE sentences for these three metrics were equivalent to 20%–28% of the differences between Castilian Spanish and Standard Southern British English, which were the largest cross-linguistic differences found in our previous study (White and Mattys, 2007a), with %V the most consistent and nPVI-V the least consistent between sentences. Such differences raise potentially serious problems of interpretation of rhythm scores given the underlying assumption that they should reflect stable rhythmical properties of languages. One solution to this problem is to record a sufficiently large number of randomly sampled sentences to provide a representative selection. Alternatively, materials may be constructed to accurately represent the phonological and metrical structures encountered in the natural speech of the languages under investigation. We have proposed a contrast regularity index as a simple statistical measure of metrical structure; other measures would be required to assess phonological patterns such as the clustering of consonants in onsets and codas. Analyzing recordings of natural spontaneous speech represents a third approach to the problem.

Variation in rhythm scores between speakers was not as marked as between sentences, with mean differences for the three metrics less than 18% of the Spanish-English difference, and particularly low for nPVI-V. Consistency between speakers was nevertheless only moderate and provides a strong indication against taking single-speaker studies to be in any way representative of population means. Of course, rhythm metrics may be efficacious for comparing scores within a single speaker under different speaking conditions or assessing changes over time, for example, regarding the deterioration in a speaker's prosody due to speech pathology (e.g., Liss *et al.*, 2009), the efficacy of ameliorative speech therapy, or progress to proficiency in second language acquisition. Assuming that the caveats regarding materials are heeded, the use of rhythm metrics in longitudinal studies such as these is one of the potentially most productive areas of their application.

Inter-measurer reliability was relatively good, with mean differences for %V, VarcoV, and nPVI-V between 7% and 15% of the Spanish-English difference. As with speakers, nPVI-V showed the smallest mean difference between measurers, although intraclass correlation coefficients showed that consistency was numerically somewhat lower than for %V and VarcoV.

A practical implication of these findings is that it should be possible to use several measurers within one study without substantial loss of reliability. Our measurers provided segmentations based on their own interpretation of a set of written instructions without consulting each other. By ensuring that measurers discuss problem cases and update their joint segmentation protocol accordingly, we expect that differences between measurers could be reducible to a nonsignificant level. In addition, of particular practical interest is our finding that the automatic phone alignment produced rhythm metric scores that were comparable to those of the human measurers. Of the three metrics examined here, only for VarcoV was the score of the automatic alignment different from the mean score of the human measurers, although the automatic alignment still performed within the range of the human measurers. Automatic phone alignment could, therefore, be used in future studies of contrastive speech rhythm, assuming an adequate supply of training data for the languages under investigation.

Finally, as this paper is essentially a methodological study, we present some recommendations for researchers intending to utilize contrastive rhythm metrics. The first two recapitulate what we have learnt from our previous work (White and Mattys, 2007a, 2007b); the others summarize the findings of the present study.

(1) %V, VarcoV, and nPVI-V are robust to variation in articulation rate and are effective at discriminating between language varieties previously held to differ in terms of contrastive rhythm. However, as all rhythm metrics have limitations, it is safest to use %V in combination with either VarcoV or nPVI-V rather than rely on a single metric.
(2) Results for non-rate-normalized metrics (ΔV, ΔC, and rPVI-C) are difficult to interpret and not reliably discriminative, likewise all metrics of consonantal interval variation (VarcoC, in addition to the non-rate-normalized ΔC and rPVI-C). Furthermore, they show relatively poor consistency between speakers, sentences, and measurers.
(3) Single-speaker or low-N studies should absolutely be avoided where speakers are intended to be representative

of a particular linguistic group. Contrastive rhythm metrics may be useful in single-speaker longitudinal studies, however.

(4) Rhythm scores are strongly affected by the particular linguistic materials used. Either a large sample of sentences should be used or materials should be constructed to be representative of the relevant phonological and metrical properties of the language under study.
(5) Where several measurers are used, they should work according to an agreed protocol for the identification of segment boundaries. Furthermore, discussion and comparison of difficult cases between measurers, which were avoided in the current study, should help minimize variation in rhythm scores.
(6) Contrastive rhythm scores obtained through automatic alignment show good agreement with those obtained from human measurers, assuming sufficient training data are available for the language in question. Of course, use of automated methods would allow much larger sampling of speakers and sentences.
(7) Do not rely too heavily on contrastive rhythm metrics or over-interpret the results of studies that use them. They merely provide an approximate indication of the degree of temporal stress contrast in a language and are susceptible to extraneous variation from multiple sources.

ACKNOWLEDGMENTS

This research was supported by a grant from the Leverhulme Trust (United Kingdom) to S. L. Mattys (Grant No. F/00182/BG) and a Research Training Network grant from the Marie Curie Foundation (Grant No. MRTN-CT-2006-035561). We thank Esther de Leeuw for help with segmentation.

APPENDIX A: THE SENTENCES READ BY THE SSBE SPEAKERS IN THIS STUDY

The following are the sentences read by the SSBE speakers.

(1) The supermarket chain shut down because of poor management.
(2) Much more money must be donated to make this department succeed.
(3) In this famous coffee shop they serve the best doughnuts in town.
(4) The chairman decided to pave over the shopping center garden.
(5) The standards committee met this afternoon in an open meeting.

APPENDIX B: SPEAKER COMPARISONS

Means (and standard errors) of the rhythm metrics ΔV, ΔC, VarcoC, rPVI-C, and nPVI-VC according to speaker; the ICC among speakers (with 95% confidence intervals); and the *F*-test for a main effect of speaker.

	Sp 1	Sp 2	Sp 3	Sp 4	Sp 5	Sp 6	ICC	*F*-test
ΔV	53.8 (1.4)	55.7 (1.3)	55.5 (0.6)	45.0 (1.3)	42.9 (0.6)	46.4 (1.1)	0.45 [0.29,0.62]	$F(5,145)=48.06$, $p<0.001$
ΔC	69.3 (2.5)	55.1 (2.0)	58.8 (2.4)	60.4 (2.1)	54.0 (2.2)	57.7 (1.4)	0.26 [0.12,0.45]	$F(5,145)=8.94$, $p<0.001$
VarcoC	48.2 (1.6)	42.8 (1.2)	47.8 (1.4)	47.6 (1.1)	46.4 (1.2)	48.2 (1.5)	0.25 [0.12,0.44]	$F(5,145)=3.21$, $p=0.009$

(Received 23 April 2008; revised 15 December 2009; accepted 17 December 2009)

The speech intelligibility index (SII) is an often used calculation method for estimating the proportion of audible speech in noise. For speech reception thresholds (SRTs), measured in normally hearing listeners using various types of stationary noise, this model predicts a fairly constant speech proportion of about 0.33, necessary for Dutch sentence intelligibility. However, when the SII model is applied for SRTs in quiet, the estimated speech proportions are often higher, and show a larger inter-subject variability, than found for speech in noise near normal speech levels [65 dB sound pressure level (SPL)]. The present model attempts to alleviate this problem by including cochlear compression. It is based on a loudness model for normally hearing and hearing-impaired listeners of Moore and Glasberg [(2004). Hear. Res. **188**, 70–88]. It estimates internal excitation levels for speech and noise and then calculates the proportion of speech above noise and threshold using similar spectral weighting as used in the SII. The present model and the standard SII were used to predict SII values in quiet and in stationary noise for normally hearing and hearing-impaired listeners. The present model predicted SIIs for three listener types (normal hearing, noise-induced, and age-induced hearing loss) with markedly less variability than the standard SII.

I. INTRODUCTION

One of the first studies on modeling speech intelligibility was started at AT&T Bell Laboratories in the 1920s. The aim of these studies was to analyze speech quality, telephone quality, and speech transmission. The work was published internationally only shortly after World War II (French and Steinberg, 1947; Fletcher and Galt, 1950; Fletcher, 1953), and formed the basis of the "articulation theory" (Allen, 1996). The principle of the articulation scheme was to calculate the available speech information at the receiver's ear (listener), and the outcome was a number between zero and unity, called the articulation index (AI). An AI of zero meant that no information was present at the receiver's ear, whereas an AI of unity meant that all the information was transmitted properly. Unfortunately, the AI method was hardly used after its publication (Müsch, 2001), which may well have been due to its complex calculations. To overcome this problem, Kryter (1962) introduced a calculation scheme that was based on the articulation theory, but much simpler to use. Eventually, his method led to the standard ANSI S3.5 (1969) AI calculation method. The AI model kept on evolving, and today a revised version, named the speech intelligibility index (SII) (ANSI S3.5-1997, 1997), is commonly used (e.g., Noordhoek *et al.*, 2000; Hornsby and Ricketts, 2003; Kates and Arehart, 2005; Dubno *et al.*, 2002; Woods *et al.*, 2006). The SII model was designed to predict speech intelligibility for conditions with noise and through communication channels. Nevertheless, it is often used for hearing aid settings and adjustments, and for the evaluation of hearing aid benefit.

The basic principle of the SII model is as follows: For a given condition where speech is embedded in noise at a given signal-to-noise ratio (SNR), the SII is calculated using the average noise spectrum, the average speech spectrum, and the listener's hearing threshold. By calculating the SNR in different frequency bands, and by assigning a weight to each band (the so-called band-importance function, e.g., Pavlovic, 1994, the SII is finally composed by adding the frac-

a)Author to whom correspondence should be addressed. Electronic mail: k.s.rhebergen@amc.uva.nl

tions of available speech in each band (e.g., Studebaker *et al.*, 1993), while accounting for distorted speech at higher levels [>73 dB sound pressure level (SPL)] with aid of a level distortion factor (e.g., Hou and Thornton, 1994; Sherbecoe and Studebaker, 2003). As with the AI, the SII is a number between zero and unity and can been interpreted as the proportion of audible speech that is available to the listener. The articulation theory assumes a fixed relation between the proportion of audible speech and the observed performance for normal-hearing (NH) listeners in their native language, regardless of the type of listening condition (i.e., in quiet or in background noise). The shape of the appropriate transfer function (e.g., Sherbecoe and Studebaker, 1990, 2003, 2002) depends on the speech material (e.g., words and sentences) and the measurement method used (word score, sentence score, up-down procedure, and fixed levels). Such transfer functions can be used in corresponding listening conditions to predict speech intelligibility as a function of speech level in quiet or in noise, or conversely, to describe the observed performance [e.g., the speech reception threshold (SRT); Plomp and Mimpen, 1979] for a chosen proportion of audible speech (i.e., a chosen SII). For example, the proportion of audible speech required to understand about half of a list of short, everyday, Dutch sentences presented in stationary noise is about one-third (SII=0.33). This is true in native normally hearing listeners for their SRT for Dutch sentences (Noordhoek *et al.*, 2000, 2001; van Schijndel *et al.*, 2001; Versfeld and Dreschler, 2002; Rhebergen and Versfeld, 2005). In addition, when using the extended SII (ESII) model (Rhebergen and Versfeld, 2005; Rhebergen *et al.*, 2006) the same proportion is predicted for sentences in fluctuating noise. The extended SII predicts speech intelligibility for sentences in fluctuating (real-life) noise with reasonably good accuracy (Rhebergen and Versfeld, 2005; Rhebergen *et al.*, 2006, 2008; George *et al.*, 2006, 2007). The relationship between the SII value and the SRT for hearing-impaired (HI) listeners is less clear. Some hearing-impaired listeners have SII values of about one-third at the observed SRTs whereas others have marked higher SII values at the SRT. Apparently, this latter group of hearing-impaired listeners require more audible speech (i.e., SII >0.33) at the SRT than do normally hearing listeners. An elevated SII associated with an observed SRT is often associated with a supra-threshold deficit in such listeners (e.g., Noordhoek *et al.*, 2000, 2001; van Schijndel *et al.*, 2001; Versfeld and Dreschler, 2002; Festen and Plomp, 1990; George *et al.*, 2006). For such listeners the SII model is not able to explain the observed SRTs on the basis of audibility alone. Factors other than raised hearing levels likely contribute to the observed SRTs (e.g., decreased temporal and spectral resolution).

Unfortunately, the SII model is less successful in predicting the SRT in quiet (e.g., Holube and Kollmeier, 1996; Peters *et al.*, 1998; Noordhoek *et al.*, 2000, 2001). For normally hearing listeners, SII values for the SRT in quiet (SRTq) are often found to be higher than for the SRT in stationary noise (SRTn) (e.g., Noordhoek *et al.*, 2000, 2001). As the performance (number of sentences repeated correctly) is the same for the SRTq and the SRTn, this implies that the SII model predicts that a larger proportion of audible speech (i.e., a higher SII) is required to understand half of the sentences in quiet relative to in noise. Apart from possible effects of phonemic restoration in noise, this is rather unlikely because the absolute threshold is often considered to be an internal noise floor (French and Steinberg, 1947; ANSI S3.5-1997, 1997; ANSI S3.4-2007, 2007). Furthermore, the variance across listeners of the calculated SIIs for SRTq data is often larger than found for SRTn data (e.g., Noordhoek *et al.*, 2001), which, on the other hand, may also be partly attributed to measurement errors and variability of the individual hearing thresholds. Lastly, the SII differences between SRTq data for normally hearing and hearing-impaired listeners were larger than found between those groups for SRTn data (e.g., Noordhoek *et al.*, 2001). A preliminary study concerning this phenomenon using two large data sets (Lyzenga and Rhebergen, 2007) showed the counter intuitive effect of higher SII values in quiet for normally hearing listeners as compared to hearing-impaired listeners. There is no simple explanation for these differences in predicted speech intelligibility. Both in noise and in quiet, the SII model calculates the effective proportion of speech available to the listener. In stationary noise, the SRTn is generally measured well above the listeners' hearing threshold; in most studies the noise level is between 60 and 80 dBA. The average observed SRTn (i.e., the SNR for speech) is about −5 dB for normally hearing listeners (Plomp and Mimpen, 1979). So, for SRT measurements in stationary noise, the speech levels usually vary from about 55 to about 75 dBA. In quiet, the SRTq is expressed in speech level (dBA), and is highly dependent on the listeners' hearing threshold. The speech level at the SRTq is about 15–20 dBA for normally hearing listeners (for a Dutch corpus, see Plomp and Mimpen, 1979; for a review, see Plomp, 1986). Because in these studies the SRT always represents 50% correct performance, a performance intensity (PI) function (e.g., Sherbecoe and Studebaker, 1990, 2002; Dubno *et al.*, 2002) is not needed to transform SII values and speech levels (or SNRs) into performance correct scores, or visa versa. Therefore, it is not likely that the variance in the SII is due to a flaw in a PI function, it is probably the result of a shortcoming of the SII model calculation.

In general, all of the articulation schemes [i.e., AI, SII, and the speech transmission index (STI) of Houtgast and Steeneken, 1985] were designed to predict speech intelligibility for speech presented at a normal speech-spectrum level (62.35 dB SPL, ANSI S3.5-1997, 1997) to normally hearing listeners. Many listeners with sensorineural hearing impairment not only exhibit increased absolute thresholds (which all articulation schemes take into account), but also suffer from a deterioration of supra-threshold sounds and speech processing capabilities at higher speech levels (Pavlovic, 1989). Pavlovic *et al.* (1986), Studebaker *et al.* (1997), and Ching *et al.* (2001) developed a method to incorporate this supra-threshold deterioration into the AI model, and in the SII (ANSI S3.5-1997, 1997) it has been taken into account by means of a general "hearing loss desensitization" factor. This addition to the articulation theory improved the speech intelligibility predictions for the *average* mild to moderate hearing-impaired listener at higher speech levels (>73 dB

SPL), but it is still difficult to accurately predict the performance of individual hearing-impaired listeners (Ching *et al.*, 1998, 2001; Hogan and Turner, 1998; Studebaker *et al.*, 1999b; Sherbecoe and Studebaker, 2003). Since this hearing loss desensitization only comes into play for large hearing losses, and the level distortion factor for relatively high speech levels, SII calculations for SRTq data (<73 dB SPL), measured in listeners with normal and moderate impaired hearing, will hardly be influenced by this correction. Next to raised thresholds, no further auditory differences between normally hearing and hearing-impaired listeners, such as a loss of compression, are taken into account in the SII.

Contrary to the standardized loudness model (ANSI S3.4-2007, 2007), the SII model does not incorporate an auditory filterbank in its calculations to account for hearing loss dependent changes in spectral resolution. The addition of the upward spread of masking function proposed by Ludvigsen (1987) in the SII model improved to some extent the effect of spectral masking in normally hearing listeners, but is still not sufficient to account for masking as a function of frequency (Noordhoek *et al.*, 1999), as a function of level (e.g., Studebaker *et al.*, 1999), or as a function of hearing impairment (Noordhoek *et al.*, 2000; Hornsby and Ricketts, 2006). Furthermore, the SII model does not account for changes in cochlear compression as a function of level and hearing loss. In the SII, the effective proportion of audible speech is calculated with the aid of an intensity importance function (IIF). In the IIF, the speech dynamic range is assumed to be fixed at 30 dB for all speech levels. Since cochlear compression influences the dynamics of perceived sounds, and is much larger near normal speech levels than near threshold (Glasberg and Moore, 2000; Oxenham and Bacon, 2003; Oxenham and Plack, 1997; Plack and Oxenham, 1998; Plack *et al.*, 2007), it presumably affects the internal dynamics of speech signals as well. As a result, for normally hearing listeners, the internal effective dynamic range of speech presented at a normal speech level is more compressed (smaller) than at relatively low levels. This effect, and its possible interactions with the absolute threshold, are not included in the SII model. Compared to listeners with normal hearing, who may have strong cochlear compression at speech levels (about 65 dB SPL), the effective internal dynamic range of the speech signal for listeners with cochlear hearing loss is less compressed at such levels (giving a larger speech dynamics, i.e., larger vowel to consonant ratios). At lower levels, normally hearing listeners have less compression, which reduces the differences in speech dynamic range between these two groups. Since the articulation theory assumes that the proportion of speech (i.e., audibility for speech presented in quiet) is related to the dynamics of the speech signal, the SII model may be improved by introducing a cochlear compression parameter (in combination with an auditory filterbank: ANSI S3.4-2007, 2007) in the calculations. In a sense, we introduce compression in the present model by introducing cochlear amplification. Cochlear amplification (gain) is highest and approximately linear at very low levels (roughly below 30-dB SPL, e.g., Oxenham, 1995; Glasberg and Moore, 2000). It diminishes for intermediate levels, which result in compression when its effectiveness diminishes and eventually the transduction returns to linear (no gain) for very high levels (roughly higher than 100 dB SPL). Varying this compression parameter (i.e., gain) as a function of hearing loss will affect the internal representation of the speech effective dynamic range (i.e., the IIF). Therefore, the calculation scheme is non-linear for normally hearing listeners and becomes more and more linear with increasing hearing loss. Because of cochlear compression, the amount of audible speech may change less as a function of input level for normally hearing listeners as for hearing-impaired listeners. As a result the SII variance at the SRT in quiet may be reduced for normally hearing listeners. Furthermore, the differences between the SII values in quiet and noise might be smaller when accounting for the IIF as a function of level and hearing loss. In addition, reducing the compression when modeling hearing-impaired listeners will give rise to a more realistic model. Both these adaptations may increase the predictive power of the model and to lead to a better description of SRTq data for normally hearing and hearing-impaired listeners.

This paper describes a novel speech intelligibility approach to model SRTs for sentences presented in quiet and in noise, for normally hearing and hearing-impaired listeners. With the aid of the ANSI loudness model (ANSI S3.4-2007, 2007; Moore and Glasberg, 2004) and a cochlear compression function (Oxenham, 1995), expected excitation levels are calculated for speech and for noise, in which the applied compression function is varied with level and hearing loss. First, the assumed dynamic range of speech is converted to excitation patterns. Next, SII values for presented speech levels are calculated by comparing those levels with the excitation levels demarking the dynamic range of speech, the absolute threshold, and, when present, the noise. The inclusion of compression in the SII model is expected to decrease the observed differences between estimated SII values for SRTs in quiet and in stationary noise, especially for normally hearing listeners (see Sec. II B for how introducing compression in the model might alleviate this problem). In addition, if it is a better model, the variance in SII values within and between groups of normally hearing and hearing-impaired listeners should decrease. In addition to compression, there are other factors, both cochlear and central, that can affect speech intelligibility. In the present approach we start by incorporating just cochlear compression in the model, which may be extended with more cochlear factors in later studies (e.g., forward masking). When all cochlear factors are accounted for, investigations concerning more central aspects of speech perception, such as across-channel interactions and phonemic restoration, can be considered.

II. MODEL DESCRIPTIONS

A. The standard SII model

A detailed description of the SII model is given in the standard ANSI S3.5-1997, 1997 or alternatively in Amlani *et al.*, 2002. In short, the SII model calculates the average proportion of speech information available to a listener. As input, it uses the long-term average spectra of the presented speech and noise, and the listener's pure-tone hearing levels.

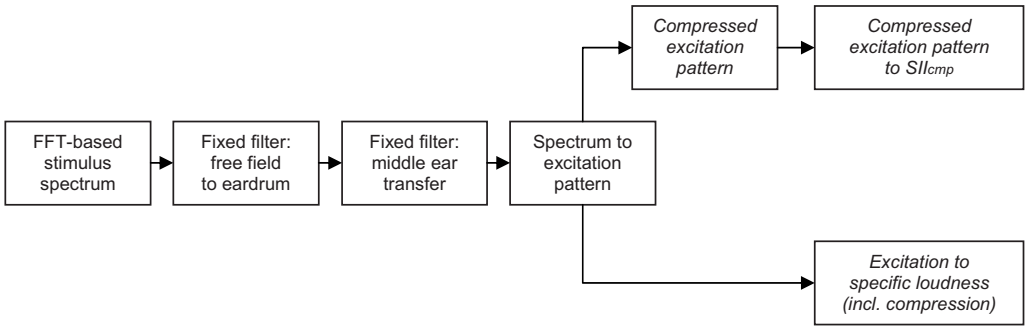

FIG. 1. Schematics of the models. The loudness model of Moore and Glasberg (2004) is depicted in the lower branch. The branching of to the top depicts the SIIcmp model.

Speech and noise are filtered into a number of frequency bands. Within each band, spectrum levels of speech and noise are determined separately, including correction factors for audibility in relation to the absolute threshold for pure tones, for self-masking of speech, and for upward spread of masking. Next, the signal-to-noise ratio is calculated in each band (SNR^i). These SNR^i values are used to calculate the proportion of audible speech (A^i) with aid of an IIF that assumes linearly increasing importance of speech levels from −15 to +15 dB relative to the rms of the speech

$$A^i = (SNR^i + 15)/30;$$

$$\text{when } A^i > 1 \text{ then } A^i = 1,$$

$$\text{when } A^i < 0 \text{ then } A^i = 0. \quad (1)$$

Subsequently, the audibility within each frequency band (A^i) is multiplied with a band-importance function (I^i) to account for the type of speech material (e.g., Studebaker *et al.*, 1993; Pavlovic, 1984, 1987), and with a level distortion factor (D^i) to account for very high speech levels, to yield the effective audibility within a frequency band. Last, the SII is the sum of the effective audibility in each band

$$SII = \sum_i A^i \times I^i \times D^i. \quad (2)$$

B. SIIcmp model with cochlear compression

The present model attempts to alleviate the discrepancy between SII estimates in noise and in quiet by including cochlear compression in the "inner-ear" part of the model. We refer to this model as the SIIcmp model. In the ANSI SII model, compression is not included explicitly in the calculations. However, because this model was designed to work well at normal speech levels (around 65 dB SPL), the effects of compression were included implicitly by using data collected for such levels to calibrate the model. Introducing cochlear compression explicitly into the SIIcmp model allows the possibility of reducing the amount of compression for lower stimulus levels, in accordance with many findings in humans and animal models (Ruggero *et al.*, 1997; Russell and Nilsen, 1997; Rhode and Cooper, 1996). When reducing the compression for low levels, the internal dynamic range of speech at low levels will increase. Estimated excitation levels for the softer speech parts will then benefit less from cochlear amplification, which will reduce their levels, possibly below the absolute threshold. As a consequence, less speech information will be assumed to be available to normally hearing listeners, which will counteract the relatively high standard SII values estimated for those conditions.

The SIIcmp model is based on a series of loudness models for normally hearing and hearing-impaired listeners (Glasberg and Moore, 2002; Moore and Glasberg, 2004; Glasberg and Moore, 2006), which provided the basis for ANSI S3.4-2007, 2007 (middle and lower branches of Fig. 1). Using these models, they were able to predict loudness values for a large variety of conditions and sounds for both normally hearing and hearing-impaired listeners. For the present calculation of SII values, we use the loudness-model stages up to the calculation of the short-term excitation patterns for fluctuating sounds (middle branch of Fig. 1). The model starts with two filter stages to account for the free-field to eardrum sound pressure transformation, and the middle-ear conversion of sound pressure at the eardrum to sound pressure at the oval window of the cochlea. To generate an excitation pattern on an effective equivalent-rectangular bandwidth (ERB) scale, the initial filter stages are FFT (fast Fourier transform) spectral decomposition. To facilitate predictions for fluctuating sounds, a series of short-term excitation patterns is calculated with a 1-ms step, from the consecutive short-term spectra in 64-, 32-, 16-, 8-, 4-, or 2-ms temporal windows, depending on the frequency range of the analysis band (see Table I or Glasberg and Moore, 2002). Normal perceptual sensitivity or spectral resolution is assumed to be accounted for in the calculation of these excitation patterns. In the original model, specific loudness values were calculated next, as a function of frequency, from these un-compressed excitation patterns. In the present

TABLE I. Frequency regions of the FFTs and the corresponding temporal windows.

F_{low} (Hz)	F_{high} (Hz)	Window size (ms)	Window size (samples)
31.25	78.125	64	2048
93.75	468.75	32	1024
500	1 187.5	16	512
1250	2 375	8	256
2500	3 750	4	128
4000	15 000	2	64

model, when calculating the excitation patterns from the 64- to 2-ms short-term spectra, we have explicitly incorporated a compression function (after Oxenham, 1995), as given in the following (left-hand box in the top row of Fig. 1):

$$L < 0: \; L_c = L + G, \tag{3}$$

$$0 <= L < 100: \; L_c = 0.9L + A + B\left(1 - \frac{1}{1 + e^{(50-L)/20}}\right), \tag{4}$$

$$L >= 100: \; L_c = L, \tag{5}$$

where L is the input level, G is the cochlear gain, A is $-0.0894G + 10.894$, and B is $1.1789G - 11.789$. This equation was suggested by Oxenham (1995), and was used subsequently by Moore *et al.* (1996), Oxenham and Moore (1997), Glasberg, *et al.* (1999), Glasberg and Moore (2000), Wojtczak *et al.* (2001), and Bacon and Oxenham (2004). The functions have shapes closely resembling those measured on the basilar membrane in animal models (Robles *et al.*, 1986; Ruggero, 1992; Ruggero *et al.*, 1997).

To produce SII values for the present SRTs in quiet and in stationary noise, we first generated an excitation pattern for the absolute threshold (for normally hearing listeners resulting in excitation levels near 0 dB), and in each temporal window we generated excitation patterns representing the noise (when present) and representing the width of the IIF dynamic range (upper and lower boundaries). By comparing the excitations for the lower and upper boundaries of the speech with the higher one of the internal (absolute threshold) and external noise, signal-above-noise ratios can be calculated. This procedure generates a series of internal signal-above-noise ratio as a function of frequency (ERB scale) and time (1-ms step). In each temporal window, short-term SII values are calculated from these ratios using similar spectral weighting as used in the standard SII. For this step, the spectral weights of the standard SII were recalculated for the ERB scale. At the moment no self-masking of speech is included in these calculation stages. In the standard SII, the self-masking of speech is assumed to lie at a level of 24 dB below the speech rms. This function has only a very limited effect on the estimated SII values, as it falls outside of the dynamic range of speech assumed in the IIF of the ANSI standard. The self-masking of speech in the ANSI SII appears to originate from the earlier version of French and Steinberg (1947) in which the dynamic range of speech was assumed to stretch from 12 dB above rms to 24 dB below. In addition, no level distortion factor is included in the present model, as such a factor is not expected to play a large role in SRTs for sentences in quiet, nor can it be properly calibrated using the data set available for this study (see below). So, at present, any loss of perceptual sensitivity is only modeled in the estimation of the excitation patterns. Finally, the predicted SII is generated by averaging the short-term SII values.

To model hearing impairment, the function of the model is altered in a number of ways. First, the audiogram is assumed to be composed of a degree of inner and a degree of outer-hair-cell loss in a fixed ratio. Moore and Glasberg (2004) found an outer-hair-cell loss versus inner-hair-cell loss ratio of 0.9 to correspond best with their loudness data for hearing-impaired listeners. The outer-hair-cell loss is used to broaden the auditory filters as in Moore and Glasberg, 2004, and to set a loss of cochlear compression by reducing the cochlear amplification G in Eqs. (3)–(5). This reduction in cochlear amplification results in a reduction in excitation level. The inner-hair-cell loss modeled as a further reduction in excitation level. Together, these two reductions in excitation level represent a loss of pure-tone sensitivity in the excitation pattern in accordance with the audiogram.

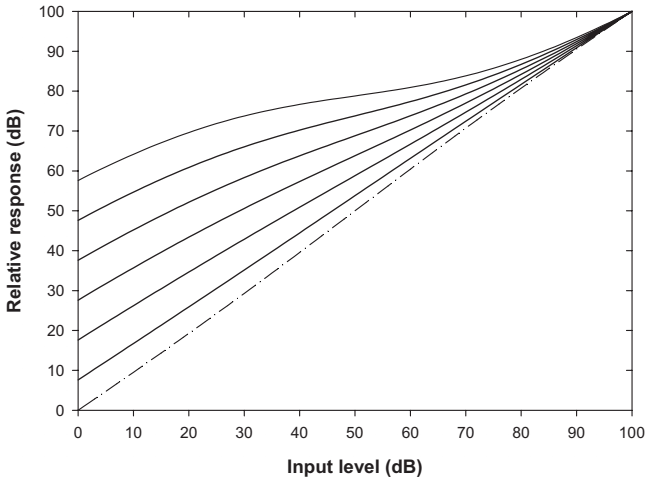

FIG. 2. Schematic input-output cochlear compression function for several values of the cochlear gain G (from bottom to top): 0, 7.6, 17.6, 27.6, 37.6, 47.6, and 57.6 dB.

C. Settings of the SIIcmp model

The SIIcmp model was used to predict SRTs in quiet and in stationary noise for both normally hearing and hearing-impaired listeners for comparison with the standard SII. We used a default outer-hair-cell loss versus inner-hair-cell loss ratio of 0.9. The amount of compression was set from the listeners' audiograms, and the signal levels in the experiments were passed into the model in the same way as done by Moore and Glasberg (2004). The maximum amount of gain G in Eqs. (3)–(5) was set to 57.6 dB (as shown in Fig. 2). For all the calculations, we used stationary speech-shaped noise fragments as stimuli for both the speech and, when present, the noise, as in the ANSI SII model. These fragments were 3661 samples long, sampled at 44.1 kHz, and they were resampled to 2656 samples at a sample rate of 32 kHz (after Moore and Glasberg, 2004). For the present stationary-noise fragments, this resulted in 20 time frames of 64 ms (maximum length of 2048 samples) with a 1-ms (32 samples) step. The resultant 20 short-term SIIcmp values were averaged together to produce a long-term SIIcmp estimate. This procedure was followed to allow modeling of speech reception in fluctuating noise in later studies (for which more time frames will need to be averaged together than for the present stationary stimuli), for the present stationary stimuli it did not affect outcomes.

To model the width of the IIF dynamic range of speech in the excitation patterns, we chose different speech levels and calculated excitation patterns for them. We assume that the effective, perceptual, dynamic range of the speech is defined at the eardrum, and that the dynamic range in the internal representation is compressed depending on presentation level and hearing loss. The SII model assumes a fixed speech dynamic range dynamic range of 30 dB at the eardrum. In a number of studies (Cox *et al.*, 1988; Rankovic, 1997, 1998; Boothroyd, 1990, 2000; van Tasell, 1993; Byrne *et al.*, 1994; Drullman, 1995a; Zeng *et al.*, 2002; Studebaker and Sherbecoe, 2002; Molis and Summers, 2003; Lobdell and Allen, 2007; Hilkhuysen, 2007), dynamic ranges larger than 30 dB were found for a range of speech materials [mean 45 dB, standard deviation (SD)=5 dB across these studies]. To investigate the effects of change in the dynamic range of speech, we used six IIFs with assumed different widths of the IIF dynamic range (30, 35, 40, 45, 50, and 55 dB). The physical speech peaks lie at 12 dB above the rms level (Cox *et al.*, 1988; Byrne *et al.*, 1994). However, we chose the effective speech peaks at 15 dB (Sherbecoe *et al.*, 1993; Studebaker *et al.*, 1999; Sherbecoe and Studebaker, 2002; Studebaker and Sherbecoe, 2002) to account for the notion that listeners are able to listen about 3 dB "into" the noise (Scharf, 1970; Drullman, 1995a, 1995b; Moore, 1997; Studebaker *et al.*, 1999; Sherbecoe and Studebaker, 2002). Thus, the IIFs ranged from +12 dB down to −18, −23, −28, −33, −38, and −43 dB relative to the rms level, respectively. The results for these six different IIFs as function of hearing loss and speech level in quiet and noise were analyzed statistically to help in selecting the appropriate effective IIF dynamic range. This will be discussed further in Sec. VI.

III. METHODS

In a preliminary study (Lyzenga and Rhebergen, 2007), SRT data were used from two studies that measured SRTs for male (Smoorenburg, 1992) or female (Festen and Smits, 2007) speech. In both studies, SRTs were measured in quiet and in noise according to the method of Plomp and Mimpen (1979). An extensive description of this method is described in the review of Plomp (1986). The SRT estimates the SNR at which 50% of presented sentences are repeated entirely correctly. Unlike the Smoorenburg data,[1] the Festen and Smits (2007) data were measured at a single clinic using a constant method, and the speech used was the high-quality female material (Plomp and Mimpen, 1979). Therefore, it was decided to concentrate on that study to evaluate the SII-cmp model settings.

The data set of Festen and Smits (2007) comprises 402 ears. The subjects were all working in airplane maintenance under noisy conditions. Their ages ranged from 18 to 62 years (average of 31 years with a SD of 7). All subjects were native speakers of Dutch. Their tone-audiometric thresholds were recorded at one-third octave frequencies: 0.25, 0.5, 0.8, 1, 1.25, 1.6, 2, 2.5, 3.15, 4, 5, 6.3, and 8 kHz (with the help of continuous audiometry: Peekel D4/6631). The distribution of their thresholds is presented in Fig. 3. In the present paper, the ears were split into three categories: 323 normally hearing denoted as NH, 65 with a dip presumably resulting from noise exposure (a dip of more than 15 dB hearing loss between 2 and 6 kHz relative to 1 and 8 kHz, Smoorenburg, 1992; Bosman and Smoorenburg, 1995) denoted as noise-induced hearing loss (NIHL), and 14 hearing-impaired ears (on average more than 20 dB hearing loss) denoted as HI. Monaural SRTs[2] were measured for the better ear in quiet (SRTq) and in stationary speech-shaped noise (SRTn) presented at four fixed levels: 35, 50, 65, and 80 dBA. Signals were mixed and played out using a PC. The sample rate of all stimuli was 15.625 kHz.

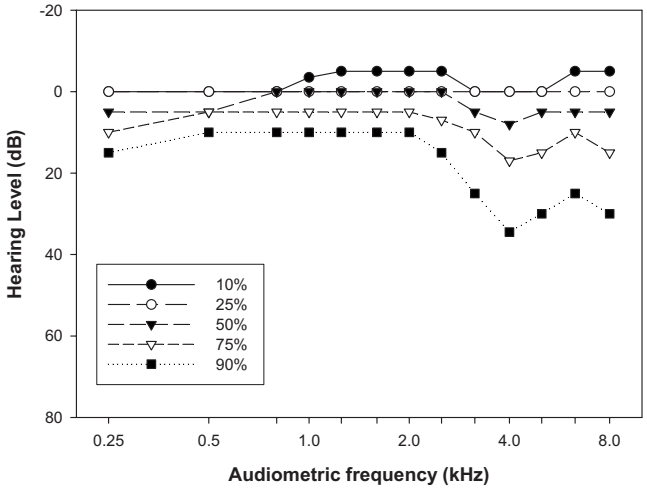

FIG. 3. Distribution of pure-tone thresholds in the set of 402 ears of the Festen and Smits (2007) set. The percentages indicated represent the fraction of ears at a certain frequency with higher tone thresholds than the plotted value.

IV. MODELING RESULTS

A. The data set

Table II shows the distribution of the SRTq (noise level=−∞ dBA) and SRTn (in dB SNR) values, for all listeners' groups of the Festen and Smits (2007) data set. To examine the effects within the SRTn data set, a four [noise level: 35, 50, 65, and 80 dBA] × three [listener group: NH, NIHL, HI] analysis of variance (ANOVA) was performed. As expected, the effects of "noise level" ($F[3,1596]=98.2$, $p<0.001$) and "listener group" ($F[2,1596]=99.9$, $p<0.001$) were both significant, as was the interaction between them ($F[6,1596]=26.2$, $p<0.001$). Bonferroni *post-hoc* tests showed significant differences between all three listener groups ($p<0.01$), and between the SRTs for all noise levels ($p<0.01$) except for the levels 50 and 65 dBA ($p=0.3$), and the levels 35 and 80 dBA ($p=1.0$). To examine the effects within the SRTq data set, an ANOVA was performed on the three listener groups. As expected, listener group ($F[2,399]=81.5$, $p<0.001$) was significant. Bonferroni *post-hoc* tests showed significant differences between all three listener groups ($p<0.01$). Table III shows the average SRTs for the subgroups.

TABLE II. (a) Distribution of SRTs of the Festen and Smits (2007) data set, measured in quiet, expressed in dBA, and the SRTs measured in noise at 35, 50, 65, and 80 dBA, expressed in dB SNR. Data are shown for the 323 normally hearing listeners in (a), for the 65 listeners with noise-induced hearing losses in (b), and for the 14 hearing-impaired group in (c).

Percentiles	5	10	25	50	75	90	95
SRTq (dBA)	11.8	13.0	15.0	17.4	20.2	24.9	27.3
SRTn (35 dB)	−6.5	−5.8	−5.0	−4.2	−3.0	−2.2	−1.0
SRTn (50 dB)	−7.4	−6.8	−5.8	−5.0	−4.2	−3.4	−3.0
SRTn (65 dB)	−7.0	−6.6	−5.8	−5.0	−4.6	−3.8	−3.4
SRTn (80 dB)	−5.8	−5.4	−4.6	−4.2	−3.4	−2.6	−2.6
SRTq (dBA)	13.0	14.4	16.0	19.2	22.8	27.0	27.8
SRTn (35 dB)	−5.6	−4.8	−4.2	−3.0	−2.0	−1.0	−1.0
SRTn (50 dB)	−7.4	−6.8	−5.8	−5.0	−3.8	−2.4	−1.8
SRTn (65 dB)	−6.9	−6.4	−5.8	−5.0	−4.2	−3.0	−2.3
SRTn (80 dB)	−5.7	−5.0	−4.2	−3.8	−3.0	−2.4	−1.4
SRTq (dBA)	17.4	17.6	25.2	31.6	40.9	52.6	56.2
SRTn (35 dB)	−4.6	−4.4	−2.0	1.2	5.9	16.2	19.0
SRTn (50 dB)	−5.4	−5.4	−4.7	−3.6	−2.4	3.8	8.2
SRTn (65 dB)	−5.4	−5.4	−5	−4.6	−3.3	−1.2	−0.6
SRTn (80 dB)	−5.0	−4.8	−4.6	−4.0	−2.5	−1.8	−1.4

B. The standard SII model

For comparison to the SIIcmp approach with compression, speech intelligibility was also predicted with the standard SII model (ANSI S3.5-1997, 1997). The standard SII calculations were conducted using the long-term speech spectrum of the female speaker. In order to approximate sound levels at the ear drum (as required by the SII model), speech and noises were filtered with a 400th point finite impulse response (FIR) filter with the characteristics of the Beyer Dynamic DT48 headphones used in the study. Absolute thresholds at each 1/3-octave frequency were used as input to the SII model. The standard SII predictions are calculated with a fixed IIF of 30 dB (+15 to −15 dB ref rms) speech dynamic range. For the NH listener group, we assume that no supra-threshold deficits played a role in the recorded SRTn and SRTq values. So, the effective audibility (i.e., the SII) should be similar for SRTs in quiet and in noise. The SII values corresponding to SRTs for listeners with NIHL and HI listeners are often found to be higher (i.e., worse) than those of NH listeners (e.g., Plomp, 1986; Festen and Plomp, 1990; Peters *et al.*, 1998; Versfeld and Dreschler, 2002). This is often attributed to the fact that listeners with cochlear hearing loss need more speech information to reach the same "effective" speech audibility as normally hearing listeners. The SII model does not account for hearing loss in a completely realistic manner, and calculates audibility in stead of effective audibility. As a consequence, the SII values at the SRT may be higher when cochlear impairments are involved.

The boxes in Fig. 4 show the SII values for the three groups of listeners for noise levels of $-\infty$ (quiet), 35, 50, 65, and 80 dBA. In each box triplet, the boxes on the left, in the middle, and on the right represent the groups NH (n=323), NIHL (n=65), and HI (n=14), respectively. As expected, the ANSI S3.5 predicts different SIIs for speech intelligibility in quiet and in noise: For NH listeners, the average predicted SII in quiet (0.39) is about 0.10 higher than the SII for a stationary-noise level of 80 dBA (0.29). In quiet and for low noise levels (35 and 50 dBA), the SII values are highest for the NH listeners, followed by the NIHL listeners, and lowest for the HI listeners. These SII results suggest that normally hearing rather than listeners with a cochlear deficit have supra-threshold deficits in quiet and in low noise conditions. In higher noise conditions (65 and 80 dBA), the SII values for the three listeners' groups are rather similar and show no consistent trends. When concentrating on the spread in the data, it can be seen that the variance in the SIIs in quiet is relatively large (NH: 0.011), even though we used individual 1/3-octave audiograms, and that the spread goes down with increasing stationary-noise levels (NH: from 0.003 at 35 dBA down to 0.001 at 80 dBA).

C. The SIIcmp model

For the SIIcmp approach, SIIs' predictions are calculated assuming six different widths of dynamic range of speech (IIFs stretching over 30, 35, 40, 45, 50, and 55 dB,

TABLE III. SRTs measured in the quiet, expressed in dBA, and the SRTs measured in noise at 35, 50, 65, and 80 dBA, expressed in dB SNR for NH, NIHL, and HI. Standard deviations are given between parentheses.

	NH	(n=323)	NIHL	(n=65)	HI	(n=14)
SRTq (dBA)	17.5	(4.1)	19.6	(4.9)	33.4	(11.3)
SRTn (dB 35)	−4.0	(1.7)	−3.1	(1.5)	3	(6.8)
SRTn (dB 50)	−5.2	(1.3)	−4.7	(1.7)	−2.8	(3.5)
SRTn (dB 65)	−5.2	(1.2)	−4.8	(1.3)	−4	(1.4)
SRTn (dB 80)	−4.1	(1)	−3.7	(1.1)	−3.6	(1.1)

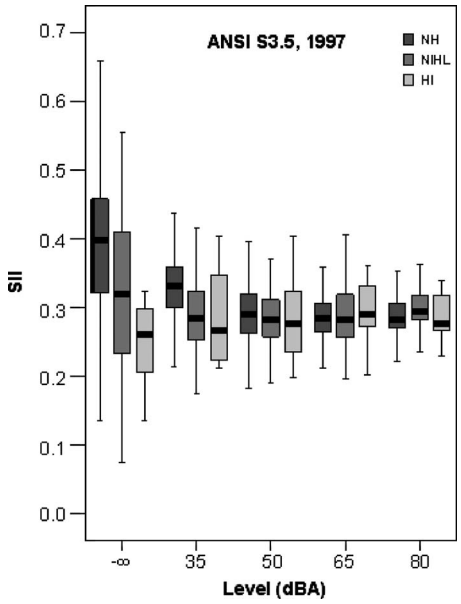

FIG. 4. Predicted ANSI SII values for the Festen and Smits (2007) data set. In each box triplet, the boxes on the left, in the middle, and on the right represent the groups NH, NIHL, and HI, respectively. From left to right, the triplets show the predictions for the SRTq and for four SRTns at noise levels of 35, 50, 65, and 80 dBA, respectively.

respectively). The speech peaks are assumed to be 12 dB for all six IIFs, representing the physical peaks above the rms. The box triplets in the six panels of Fig. 5 show the resulting of six sets of SII predictions, from left to right in each panel for the SRTs in quiet ($-\infty$) and in stationary noises at 35, 50, 65, and 80 dBA, respectively. In quiet, the SIIcmps show a large effect of the chosen IIF dynamic range, for the NH group (left-most boxes of each triplet) the predictions go down from 0.40 at a 30-dB range to 0.18 at a 55-dB range, while their variances decrease from 0.011 to 0.002 with increased IIF dynamic range. So, depending on the chosen dynamic range, the present model improves intelligibility predictions in comparison to the standard SII. In stationary noise, the predictions go down from around 0.3 at the 30-dB range to just under 0.2 at the 55-dB range, while their variances are very small (between 0.001 and 0.002) for all IIF dynamic ranges. It is interesting to compare the SIIcmp results in Fig. 5 to the standard SII results in Fig. 4. In Fig. 4, it can be seen for quiet and for the 35-dBA noise level that the amount of speech needed for comprehension is smaller for larger hearing losses. This is inconsistent with the idea that hearing-impaired listeners have supra-threshold deficits further reducing intelligibility, and it is not seen in the panels of Fig. 5 for the SIIcmp. Figure 5 shows for all three groups that the variances in the predictions are much higher for the SRTq than for the SRTn, which may well be related to relatively high uncertainty in the audiogram data. For all three groups, the predicted SIIcmps for the SRTq and the SRTn are closest in value for the IIF dynamic range of 45 dB. For this dynamic range, the variances for the SRTq are smaller for the SIIcmp (NH: 0.004; NIHL: 0.005; HI: 0.010) than for the standard SII prediction (NH: 0.011; NIHL: 0.015; HI: 0.017). This is illustrated in the bottom panel of Fig. 6, which shows the average SII values in noise per listener group compared to the average SII in quiet for the ANSI SII and the SIIcmp for the chosen IIF dynamic ranges. The average SII in quiet lies within the spread of the SII values in noise for dynamic ranges between about 45 and 50 dB. In Fig. 6, the left-most values are those for the ANSI SII. The top panel of Fig. 6 illustrates the reduced spread between groups for the SIIcmp in quiet compared to the ANSI SII in quiet. When the dynamic range in the standard SII calculation was increased in a similar manner as was done for the SIIcmp, then the SII values decreased, but the relative distance between the expectations in quiet and in noise did not decrease (not shown in Fig. 6), as can be expected for a linear model.

D. Analysis of variance

To test whether the noise level affected the audibility calculations, a 4 [noise level(35,50,65, and 80 dBA] $\times 3$ [group: NH, NIHL, and HI] multivariate analysis of variance (MANOVA) was performed on the 7 SII data sets [SII model calculations: SIIcmp for 6 IIF dynamic ranges and the standard SII] for listeners shown in Figs. 4 and 5. Of the main effects, noise level and group were significant. This indicates that the dynamic models were unable to produce consistent SII values as function of noise level and listeners' group. However, the interaction noise level $\times$ group was only significant for the ANSI SII predictions ($F[6,1596]=7.2$, $p<0.0001$). This indicates that the ANSI S3.5 model was not able to produce consistent predictions for the SRTn across noise levels and groups, while the SIIcmp approach managed to do so. As noted before, the ANSI SII values for lower noise levels are higher for NH compared to NIHL and HI listeners, while the opposite is true for higher noise levels. This may be explained by interactions, between the varying amounts of compression and the absolute threshold that can occur for the lower noise levels in the SIIcmp calculations.

One of the aims of our investigation was to bring predicted SII values for different hearing losses and for conditions in quiet and in noise closer together than they are for the standard SII. To test this, a 2 [listening condition: quiet and pooled noise conditions] $\times 3$ [listener group] MANOVA was performed on the 7 SII data sets [SII model calculations: SIIcmp for 6 IIF dynamic ranges and the standard SII]. Of the main effects, the effect of group was significant only for the ANSI SII predictions ($F[2,2004]=47.9$, $p<0.0001$). The main effect of "listening condition" was only significant for the ANSI SII and for the SIIcmp at 30–40 dB IIF dynamic ranges. So, for larger dynamic ranges, the SIIcmp showed no significant effects of group. In addition, no significant interactions were found for the SIIcmp results for IIF dynamic ranges of 35 and 40 dB. However, the articulation theory assumes that the presentation level has no effect on the speech intelligibility around normal speech levels, whereas for higher levels a level distortion effect occurs (>73 dB SPL). When the 80 dBA noise level is excluded from the pooled SRTn data, to eliminate any possible effects of level distortions, a significant main effect for the factor group is still only shown for the ANSI SII calculations ($F[2,1604]=42.7$, $p<0.0001$). The main effect of listening condition was only significant for the ANSI SII and the SIIcmp for 30-

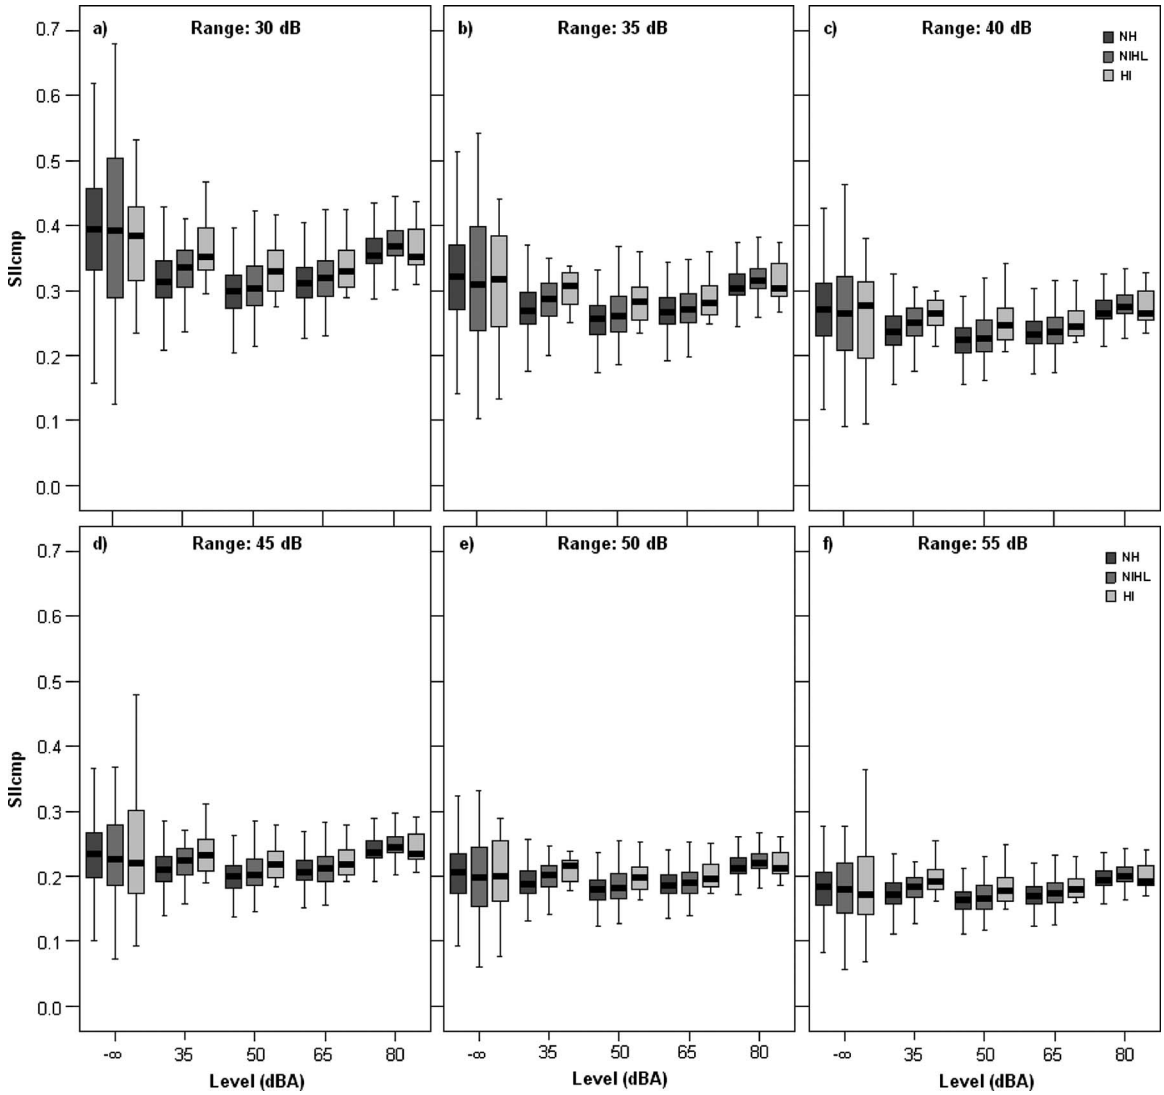

FIG. 5. Predicted SIIcmp values for the Festen and Smits (2007) data set for the chosen IFF dynamic ranges of 30, 35, 40, 45, 50, and 55 dB. The layout of each panel is the same as in Fig. 4.

to 45-dB IIF dynamic ranges. No significant interactions were found for the SIIcmp calculated for an IIF dynamic range of 40 dB.

E. The role of supra-threshold problems in hearing-impaired listeners

For hearing-impaired listeners, SII values above 0.33 at the SRT have often been interpreted as indication of supra-threshold problems (e.g., Noordhoek *et al.*, 2000, 2001; van Schijndel *et al.*, 2001; George *et al.*, 2006). Correcting for their loss of compression may be expected to affect the corresponding speech intelligibility estimations, and therefore could influence the estimated magnitudes of the supra-threshold problems. Since soft sounds will become even harder to perceive without cochlear amplification, it can be expected that including cochlear amplification and compression into the SII calculations will reduce the estimated degree of supra-threshold problems. The model predictions in Secs. IV B and IV C were conducted on a large group of NH subjects (323), but only for relatively small groups of NIHL subjects (64) and HI subjects (14). To further examine the responses of hearing-impaired listeners, SIIcmp values were predicted for SRTs measured in several other studies in literature, with ears classified as NH, NIHL, or HI using the same criteria as were used for the Festen and Smits (2007) data set. Additional data came from the following studies: from Smoorenburg (1992): 400 ears classified into 228 NH, 130 NIHI, and 42 HI; from de Laat and Plomp (1983): 10 young NH and 20 young HI listeners; from Festen and Plomp (1990): 20 HI listeners; and from Bosman and Smoorenburg (1995): 19 NIHL (with very similar audiograms compared to the other NIHL groups), 20 NH, and 14 elderly HI listeners. Female speech (Plomp and Mimpen, 1979) was used to measure the monaural SRT, and all subjects were tested in a sound treated booth with headphones in all studies but Smoorenburg (1992), who used male speech and different measurement rooms not all of which were sound treated. Figure 7 shows the distribution of the standard SII and SIIcmp predictions derived from the data of these studies. For the hearing-impaired listener groups, this figure does not show a clear decrease in the estimates for the SIIcmp as compared to the standard SII. So, for the present sets

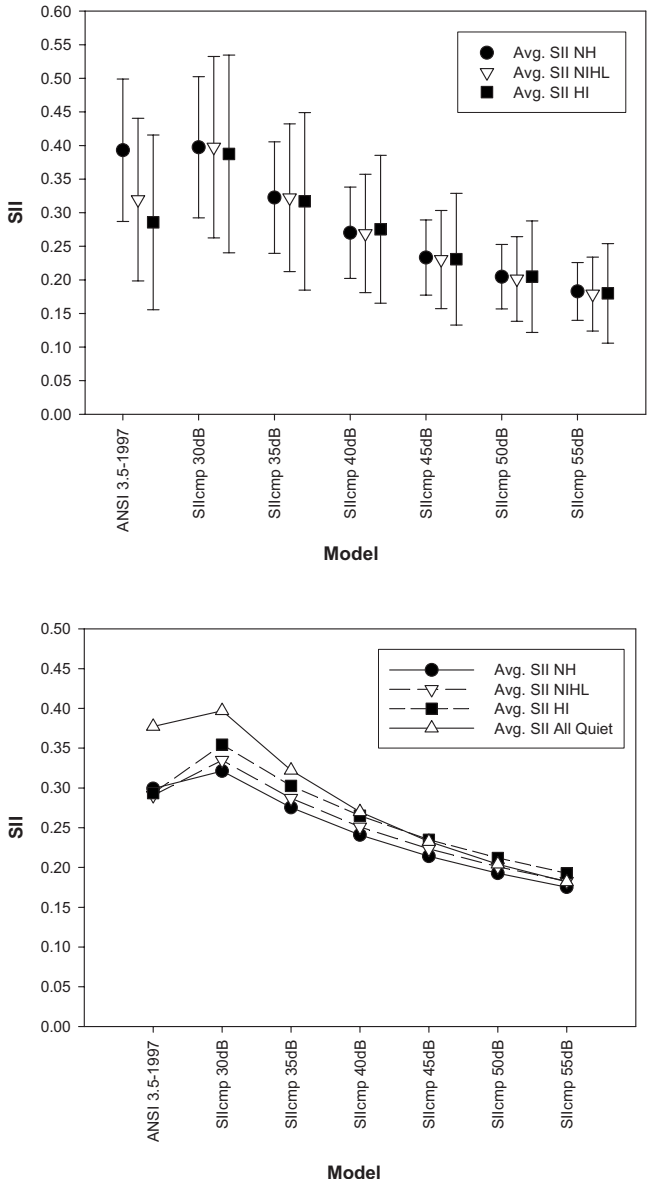

FIG. 6. The top panel shows the average SII values as a function of model (ANSI SII and SIIcmp for the chosen six IFF dynamic ranges) for the SRTq in NH, NIHL, and HI listeners. The results for the listener groups NH, NIHL, and HI are displayed as circles, triangles, and squares, respectively. Error bars indicate the standard deviations between subjects. The bottom panel shows for the corresponding SII values for the SRTn, supplemented with the overall averaged results for the listener groups in quiet (up-side down triangles).

of data, the aforementioned hypothesis of reduced measures of supra-threshold problems by including auditory compression in the speech intelligibility estimations is not confirmed. A more decisive test of this hypothesis will probably require audiograms taken at 1/3-octave frequencies rather than the octave frequencies used in the studies included above.

V. GENERAL DISCUSSION

A. SII predictions

Model predictions with the SIIcmp approach show a significant improvement for the NH and NIHL listener groups of the Festen and Smits (2007) data set. The SIIs for the SRT in quiet and stationary noise are about the same with assumed IIF dynamic ranges of 35, 40, and 45 dB. Furthermore, for the SRTq data, the variance of the predicted SIIcmps is smaller than that of the predicted ANSI SIIs. So, the predictive power for individual SRTs has improved by introducing cochlear compression into the SII model. This may be somewhat surprising, as cochlear compression, or rather cochlear amplification, brings many benefits. Nevertheless, it is not always advantageous. For example, the detection of level increments shows a "mid-level hump" where performance is worse than at other levels (e.g., Carlyon and Moore, 1984). This is being attributed to compression. In addition, there is a body of work arguing that compression reduces modulations, which may be detrimental for speech reception (e.g., Plomp, 1988). In the present paper, we introduced compression into the SIIcmp model, and for the SRTq it pushed a portion of the speech signal below the absolute threshold. So here, it is primarily an interaction between the amount of cochlear compression as a function of level and the absolute threshold that affects SII values for speech perception measurements.

The modified SII approach shows much less improvement for listeners with moderate to severe hearing loss than for normally hearing listeners. It is likely that other factors than audibility have an effect on the speech intelligibility for these listeners. The ANSI SII and the SIIcmp models account for different aspects of hearing loss, and so leave different "remainders" that might be classified as supra-threshold deficits. The SIIcmp model attempts to account for cochlear compression as a function of hearing loss, but it does not account for other factors such as degraded temporal resolution. Furthermore, while the model does take some cochlear factors into account, it does not account for factors that have more central causes (e.g., cognition deficits), or factors related to Tinitus, Hyperacusis, or Menière's disease. Such problem can affect the robustness of the measured speech reception levels. Therefore, model predictions for these types of hearing loss are likely to be less reliable than those for listeners with a more simple cochlear hearing loss. To account for other factors that may play a role in speech intelligibility, one should not just rely on the listener's hearing levels. Additional aspects of the listeners' performance (i.e., a full auditory profile) might also need to be taken into account (Dreschler *et al.*, 2007).

B. Effective speech dynamic range

At normal speech levels, it can be assumed that cochlear compression will "squeeze" the speech dynamic range together in a more or less uniform way. So, adding compression to the SII model does not directly change the estimated SII values, as they are calculated from ratios of available speech information in the dynamic range. That is, unless there is a knee-point of the compression function in the dynamic range of the speech, or unless there is an interaction with the absolute threshold. The effects of compression for the SRTq in the current study probably arise from an interaction between compression and absolute thresholds. In a previous study presented at the ASA meeting in Salt Lake City (Lyzenga and Rhebergen, 2007) we have looked into the

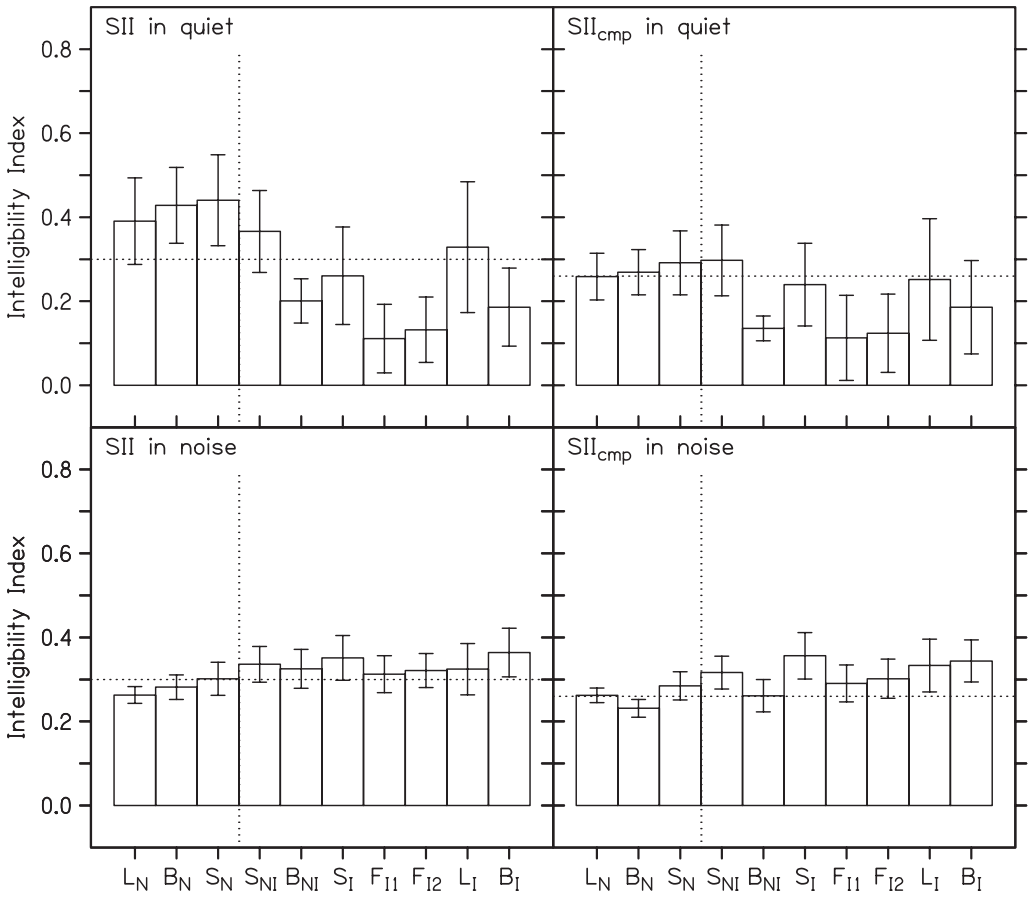

FIG. 7. Predicted SII and SIIcmp values, for an IIF dynamic range of 40 dB, for the data from Smoorenburg (1992), denoted as S_N, S_{NI}, and S_I; from Bosman and Smoorenburg (1995), denoted as B_N, B_{NI}, and B_I; from de Laat and Plomp (1983), denoted as L_N and L_I; and for the set of 20 hearing-impaired ears of the data from Festen and Plomp (1990), denoted as F_{I1} and F_{I2} for two types of used speech material, where the subscripts N, NI, and I stand for normal hearing (to the left of the vertical dotted line), noise-induced hearing loss, and hearing impaired, respectively. Note that the average values for the SII and the SIIcmp are not the same (horizontal dotted lines).

difference in SIIcmp predictions between the following two assumptions: (1) The effective (perceptual) dynamic range of the speech is 30 dB, is constant at the eardrum, and is compressed depending on presentation level and hearing loss, and (2) the effective dynamic range of the speech is fixed at 15 dB in the excitation (after compression with a ratio of 2 at the "normal" speech level). The second assumption did not lead to any systematic and understandable results. So, in the present study, we dropped that assumption and continued on with the assumption that the dynamic range of speech is defined at the eardrum and is affected by cochlear compression before it expresses itself in the excitation.

The effective speech dynamic range is assumed to be 30 dB in the SII model (ANSI S3.5-1997, 1997), with the speech peaks at 15 dB above the rms. The latter assumption is based on a range of speech perception experiments (e.g., Studebaker *et al.*, 1993, 1999; Studebaker and Sherbecoe, 2002). The 30-dB effective speech dynamic range is based on a "best fit" of the data of Studebaker *et al.*, 1993 (Sherbecoe and Studebaker, 2002). Recently, some studies have been published where the effective speech dynamic range was measured in intelligibility experiments using words (Studebaker *et al.*, 1999; Sherbecoe and Studebaker, 2002) or sentences (Drullman, 1995a; Hilkhuysen, 2007). The results of these studies suggest that the effective dynamic range of the speech is likely to be larger than the originally assumed 30 dB, and it is probably closer to a value between 40 and 45 dB. Based on these perceptual experiments, model predictions with such assumed dynamic ranges offer plausible alternatives. In the present study, SIIcmp predictions for larger assumed dynamic ranges (>30 dB) reduced the variance in the predictions for the SRTq, whereas the variances in SIIcmp predictions for the SRTn data remain fixed at very low values. In contrast, the predictions of the standard SII did not improve when the dynamic range in that model was increased (Sec. IV C). The effects of hearing threshold are clearly smaller for the SRTn measurements, which were performed at relatively high presentation levels. Under such conditions, the noise level is well above the SRTq ($\geq$20 dB), and consequently the noise level will be the main factor limiting speech audibility.

For lower speech levels, and for listeners with hearing losses at levels near the noise levels, the audibility of the speech will be dominated by the either the noise or the absolute threshold, whichever has the higher level. For the SRTq, intelligibility primarily depends on the speech levels relative to the absolute threshold, which is reflected in the SII models. Since the absolute thresholds are often measured at octave frequencies, and with an accuracy of about $\pm$ 5 dB,

the reliability of the absolute-threshold estimate is a major factor in the variance of SII predictions in quiet. A 5-dB error per octave frequency may lead to approximately a 16.7% audibility difference compared to an ideal prediction. As a consequence, the variance in SII predictions can be expected to be larger for SRTq data than for SRTn data. The advantage of the Festen and Smits (2007) data set was that hearing thresholds were measured at 1/3-octave intervals, which gives a better spectral sampling of the actual absolute-threshold profile than octave frequencies. Using absolute thresholds recorded at 1/3-octave frequencies would likely lead to more reliable results than using just the octave frequencies for which the audiogram is routinely measured.

VI. CONCLUSIONS

Introducing compression in speech intelligibility calculations increased the predictive power of the model: For normally hearing listeners, the SII values for SRTs in quiet and in stationary noise were brought closer together and the spread in the data was reduced. This can probably be attributed to interaction effects between compression and absolute thresholds. For hearing-impaired listeners no clear decrease in estimated supra-threshold deficits was observed. In the future, more cochlear effects such as forward masking will need to be included in the model. When the function of the cochlea is modeled with greater precision, the amount of supra-threshold deficits in hearing-impaired listeners might need to be re-evaluated.

ACKNOWLEDGMENTS

K.S.R. was financially supported by the Dutch Foundation "Heinsius Houbolt Fonds." The authors like to thank Guido Smoorenburg, Arjan Bosman, and Jan de Laat for making their SRT data sets available to them. They also want to thank Brian Moore for the MATLAB® code of the loudness model. The constructive comments of the two anonymous reviewers and the editor Ken Grant are gratefully acknowledged.

[1]The Smoorenburg (1992) data were collected at five different clinics with slightly different methods, and they show an effect of location.

[2]The speech reception threshold should not be confused with the speech recognition threshold, which is defined as the level at which 50% of spondee words are repeated correctly.

A reanalysis of McGurk data suggests that audiovisual fusion in speech perception is subject-dependent

Jean-Luc Schwartz[a)]
Department of Speech and Cognition/Institut de la Communication Parlée, GIPSA-Lab, UMR 5216, CNRS, Grenoble University, 38402 Saint Martin d'Hères Cedex, France

(Received 21 November 2008; revised 21 December 2009; accepted 22 December 2009)

Audiovisual perception of conflicting stimuli displays a large level of intersubject variability, generally larger than pure auditory or visual data. However, it is not clear whether this actually reflects differences in integration per se or just the consequence of slight differences in unisensory perception. It is argued that the debate has been blurred by methodological problems in the analysis of experimental data, particularly when using the fuzzy-logical model of perception (FLMP) [Massaro, D. W. (1987). *Speech Perception by Ear and Eye: A Paradigm for Psychological Inquiry* (Laurence Erlbaum Associates, London)] shown to display overfitting abilities with McGurk stimuli [Schwartz, J. L. (2006). J. Acoust. Soc. Am. **120**, 1795–1798]. A large corpus of McGurk data is reanalyzed, using a methodology based on (1) comparison of FLMP and a variant with subject-dependent weights of the auditory and visual inputs in the fusion process, weighted FLMP (WFLMP); (2) use of a Bayesian selection model criterion instead of a root mean square error fit in model assessment; and (3) systematic exploration of the number of useful parameters in the models to compare, attempting to discard poorly explicative parameters. It is shown that WFLMP performs significantly better than FLMP, suggesting that audiovisual fusion is indeed subject-dependent, some subjects being more "auditory," and others more "visual." Intersubject variability has important consequences for theoretical understanding of the fusion process, and re-education of hearing impaired people. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3293001]

I. INTRODUCTION

When a public demonstration of the McGurk effect (McGurk and MacDonald, 1976) is presented to visitors or students, there appears a large variability in the subjects' audiovisual (AV) responses, some seeming focused on the auditory (A) input, others more sensitive to the visual (V) component and to the McGurk illusion. The existence of possible differences in fusion would have important consequences in both theoretical and practical terms. However, it stays hotly debated, considering that subjects could actually differ in pure auditory and visual performance rather than in fusion per se. In the following, the major elements of discussion and disagreement will be reviewed. Then it will be suggested that the debate has been largely blurred by methodological problems. A way out of these problems will be proposed, which will constitute the core of the present paper. The objective is actually twofold: present a methodological framework for analysis of audiovisual speech perception data and show that this framework confirms that there are indeed interindividual differences in the fusion process.

A. Interindividual differences in audiovisual fusion in the speech perception literature

The possibility that subjects could put more or less "weight" on the auditory or visual inputs is certainly not new. It was, for example, the focus of a paper by Seewald *et al.* (1985), suggesting that there was a "primary modality for speech perception," either auditory or visual. This hypothesis has received less attention since the work by Massaro and colleagues in the framework of the development of the "fuzzy-logical model of perception" (FLMP). Indeed, a central assumption of the model is that, apart from possible differences in auditory or visual perception, the fusion mechanism per se is exactly the same for all subjects (Massaro, 1987, 1998). The mechanism, actually a multiplicative process applied to fuzzy-logical levels of confidence provided by audition and vision on all possible answers, is considered as being an optimal process, in the sense that "all sources contribute to a decision but more ambiguous sources are given less of a say in the decision" (Massaro, 1998, p. 115).

A repeated claim by Massaro and colleagues is hence that all subjects are "optimal integrators" and combine auditory and visual evidence for available categories all exactly in the same multiplicative way. Any difference in the output of the audiovisual speech perception process would be only due to differences in auditory and visual processing and unisensory category tuning between subjects.

The hypothesis of a universal and optimal fusion mechanism remains controversial, and was the object of a series of experimental and modeling work by Grant and Seitz (1998), who claimed that, even when unimodal skill levels are taken into account, large differences in individuals' AV recognition scores persist which "might be attributable to differing efficiency in the operation of a perceptual process that *integrates* auditory and visual speech information" (p. 2438). The debate further continued between Massaro and Cohen (2000) and Grant (2002). Actually, the question of possible intersubject differences in AV integration, apart from being theoreti-

a)Author to whom correspondence should be addressed. Electronic mail: jean-luc.schwartz@gipsa-lab.inpg.fr

cally challenging, has important potential practical applications. Indeed, if some subjects integrate the audio and visual information less efficiently than others, the focus in a rehabilitation process (in case of hearing impairment for example) should be put on the training of integration, rather than just the training of auditory or visual abilities (Grant and Seitz, 1998). Incidentally, Rouger *et al.* (2007) claim to have found that cochlear implanted subjects are better at integrating the sound and face of a speaker's utterances than normal hearing subjects.

In the last 15 years, a number of studies have shown substantial individual variability in AV speech recognition. Sekiyama and Tokhura (1991) showed that McGurk fusion illusions were reduced in Japanese compared with English participants. Since then, several studies have investigated comparative language effects for audiovisual speech integration: English vs Japanese (Sekiyama and Tokhura, 1993; Kuhl *et al.*, 1994), English vs Japanese vs Spanish (Massaro *et al.*, 1993), Spanish vs German (Fuster-Duran, 1995), or German vs Hungarian (Grassegger, 1995). A number of differences have been reported. Some of them come from the nature of the stimuli, differing from language to language. However, there remain differences between linguistic groups perceiving the same stimuli. Sekiyama and Tokhura (1993) claimed that they reflect variations in the *weight* different linguistic communities would attribute to the visual input in the integration process. They suggested that the Japanese community could make less use of the visual input because of a cultural difference, namely, that "it may be regarded as impolite in Japan to look at someone's face" (p. 442). On the other hand, Massaro *et al.* (1993) and Kuhl *et al.* (1994) interpreted these differences as coming from variations in the inventory of linguistic prototypes rather than from social or cultural variations in the tuning of the audiovisual process. Indeed, Massaro *et al.* (1993) showed that their own data displaying different audiovisual perception of conflicting AV stimuli by English, Spanish, and Japanese subjects, could be perfectly fitted by FLMP. In the FLMP fit, the differences between English, Spanish, and Japanese subjects cannot be due to differences in fusion: they are totally due to differences in the unimodal categorization responses.

More recently, Sekiyama *et al.* (2003) showed that the very early ability to fuse auditory and visual inputs, displayed by a McGurk effect appearing as soon as 4 months in infants' speech perception (Burnham and Dodd, 1996, 2004; Rosenblum *et al.*, 1997), was followed by a developmental evolution of AV fusion after 6 years, and largely between 6 and 8 (Sekiyama and Burnham, 2004) for English children. This increase could be the result of a learning process, and it seems to be blocked in Japanese children, hence resulting in the smaller role of the visual input in AV perception previously described. Once again, however, it could be argued that this developmental pattern is just indicative of a development of *unimodal* auditory and visual categories rather than of integration per se. Basically, children (and particularly English ones) would be progressively more and more accurate in their perception of visual categories, hence the increase in AV performance. In this reasoning, fusion would stay perfectly stable whatever the age, i.e., multiplicative and optimal, in Massaro's sense.

Finally, gender differences in audiovisual fusion have been suggested in various papers, female subjects presenting a higher level of audiovisual performance and a greater level of visual influence on auditory speech (Irwin *et al.*, 2006; Strelnikov *et al.*, 2009), possibly linked to differences in the cortical networks involved, with less left lateralization in females compared with males (Pugh *et al.*, 1996; Jaeger *et al.*, 1998).

B. A methodological caveat: the 0/0 problem in FLMP testing

In a recent paper, Schwartz (2006) displayed a severe technical problem in the comparison of FLMP with other models when using corpora containing McGurk data. Indeed, in the case of conflicting inputs, the audio and visual stimuli provide at least one quasinull probability in each possible category, and the multiplicative process implied by the FLMP leads to AV predictions equal to 0/0, which is indeterminate. Therefore, any audiovisual response can be fitted by the FLMP. The consequence is double. First, since FLMP may predict any pattern of response in the McGurk case, fitting McGurk data with FLMP cannot help determine if variation in AV perception is actually due to differences in unimodal behavior or in AV fusion. Second, the overfitting ability of the FLMP with discrepant A and V stimuli might well contaminate the global root mean squared error (RMSE) criterion systematically used when FLMP is compared with other models. For these reasons, it seems more appropriate to use a Bayesian model selection (BMS) criterion, which intrinsically accounts for any overfitting problem (MacKay, 1992; Pitt and Myung, 2002; Schwartz, 2006).

In this context, the present paper aims at reconsidering the invariant vs subject-dependent audiovisual fusion problem, in a sound BMS framework. A classical test corpus of audiovisual consonant-vowel stimuli extensively studied by Massaro (1998) will provide a basis for assessing possible discrepancies in audiovisual fusion between subjects, independent of any linguistic or developmental effect. For this aim, weighted FLMP (WFLMP), a variant of FLMP explicitly incorporating subject-dependent weights of the audio and visual inputs in integration, will be compared with FLMP. This will provide the opportunity to use both BMS and RMSE criteria on these two models. This will also lead to a principled methodology for comparing audiovisual speech perception models on a given set of data. This methodology uses a so-called Laplace approximation of BMS, called BMSL, together with a systematic assessment of the number of really useful parameters in the models to compare, relying on the BMS ability to deal with variations in the number of degrees of freedom in these models.

Section II will recall the experimental material and provide a detailed description of the proposed methodology, together with the models to compare, and the assessment criteria. In Sec. III, the obtained results will be presented, before a discussion in Sec. IV.

II. METHODOLOGY

A. Experimental material: The UCSC corpus of CV audiovisual discrepant stimuli

The corpus considered here has been extensively used for comparing audiovisual fusion models in speech perception (Massaro, 1998). This corpus crosses a synthetic five-level audio /ba/-/da/ continuum with a synthetic video similar continuum. The 10 unimodal (5A, 5V) and 25 bimodal (AV) stimuli were presented for /ba/ vs /da/ identification to 82 subjects, with 24 observations per subject. The responses are kindly made available by Massaro and colleagues on their website (http://mambo.ucsc.edu/ps1/8236/).

B. Model comparison

1. RMSE and corrected RMSE

Let us consider a given speech perception experiment consisting in the categorization of speech stimuli involving n_E experimental conditions Ej, and in each condition, n_C possible responses corresponding to different phonetic categories C_i. In most papers comparing models in the field of speech perception, the tool used to compare models is the "fit" estimated by the RMSE, computed by taking the squared distances between observed and predicted probabilities of responses, averaging them over all categories C_i and all experimental conditions Ej, and taking the square root of the result

$$\mathrm{RMSE} = \left[\left(\sum_{\mathrm{Ej},C_i} (P_{\mathrm{Ej}}(C_i) - p_{\mathrm{Ej}}(C_i))^2\right)/(n_E n_C)\right]^{1/2} \quad (1)$$

(observed probabilities are in lower case and predicted probabilities in upper case throughout this paper).

Considering that two models M_A and M_B might differ in their number of degrees of freedom, Massaro (1998) proposed to apply a correction factor $k/(k-f)$ to RMSE, with k the number of data and f the number of degrees of freedom of the model (p. 301). This provides a second criterion:

$$\mathrm{RMSEcor} = k/(k-f)\left[\left(\sum_{\mathrm{Ej},C_i} (P_{\mathrm{Ej}}(C_i) - p_{\mathrm{Ej}}(C_i))^2\right)/(n_E n_C)\right]^{1/2}. \quad (2)$$

2. BMSL

If $\mathbf{D}$ is a set of k data d_i, and M a model with parameters $\boldsymbol{\Theta}$, the fit may be derived from the logarithm of the *maximum likelihood of the model* considering the data set, that is the value of $\boldsymbol{\Theta}$ maximizing $L(\boldsymbol{\Theta}|M) = p(\mathbf{D}|\boldsymbol{\Theta},M)$. However, comparing two models by comparing their best fits means that there is a first step of estimation of these best fits, and it must be acknowledged that the estimation process is not error-free. Therefore, the comparison must account for this error-prone process, which is done in Bayesian model selection by computing the total likelihood of the model knowing the data. This results in integrating likelihood over all model parameter values. Taking the opposite of the logarithm of total likelihood leads to the so-called BMS criterion that should be minimized for model evaluation (MacKay, 1992; Pitt and Myung, 2002):[1]

$$\mathrm{BMS} = -\log \int L(\boldsymbol{\Theta}|M)p(\boldsymbol{\Theta}|M)d\boldsymbol{\Theta}. \quad (3)$$

The computation of BMS through Eq. (3) is complex. It involves the estimation of an integral, which generally requires use of numerical integration techniques, typically Monte Carlo methods (e.g., Gilks *et al.*, 1996). However, Jaynes (1995) (Chap. 24) proposed an approximation of the total likelihood in Eq. (9), based on an expansion of log(L) around the maximum likelihood point $\boldsymbol{\theta}$:

$$\log(L(\boldsymbol{\Theta})) \cong \log(L(\boldsymbol{\theta})) + 1/2(\boldsymbol{\Theta} - \boldsymbol{\theta})'[\partial^2 \log(L)/\partial\boldsymbol{\Theta}^2]_{\boldsymbol{\theta}}(\boldsymbol{\Theta} - \boldsymbol{\theta}), \quad (4)$$

where $[\partial^2 \log(L)/\partial\boldsymbol{\Theta}^2]_{\boldsymbol{\theta}}$ is the Hessian matrix of the function log(L) computed at the position of the parameter set $\boldsymbol{\theta}$ providing the maximal likelihood L_{max} of the considered model. This leads to the so-called Laplace approximation of the BMS criterion (Kass and Raftery, 1995):

$$\mathrm{BMSL} = -\log(L_{max}) - m/2\log(2\pi) + \log(V) - 1/2\log(\det(\boldsymbol{\Sigma})), \quad (5)$$

where V is the total volume of the space occupied by parameters $\boldsymbol{\Theta}$, m is its dimension, which is the number of free parameters in the considered model, and $\boldsymbol{\Sigma}$ is defined by

$$\boldsymbol{\Sigma}^{-1} = -[\partial^2 \log(L)/\partial\boldsymbol{\Theta}^2]_{\boldsymbol{\theta}}. \quad (6)$$

The preferred model considering the data $\mathbf{D}$ should *minimize* the BMSL criterion. There are, in fact, three kinds of terms in Eq. (5). First, the term $-\log(L_{max})$ is directly linked to the maximum likelihood of the model, more or less accurately estimated by RMSE in Eq. (1): the larger the maximum likelihood, the smaller the BMSL criterion. Then, the two following terms are linked to the dimensionality and volume of the considered model. Altogether, they result in handicapping models that are too "large" (that is, models with a too high number of free parameters) by increasing BMSL.[2] Finally, the fourth term provides a term favoring models with a large value of $\det(\boldsymbol{\Sigma})$. Indeed, if $\det(\boldsymbol{\Sigma})$ is large, the determinant of the Hessian matrix of log(L) is small, which expresses the fact that the likelihood L does not vary too quickly around its maximum value L_{max}. This means that the fit provided by the model around its maximum likelihood point is stable: exactly the contrary of FLMP with McGurk data, since its overfitting abilities result in very rapid modifications of the prediction even for very small changes in the unimodal values, making the integration process quite unstable and oversensitive to the tuning of free parameters in the model. Derivation of the exact formula in Eq. (5), together with a practical implementation of BMSL, can be found in http://www.icp.inpg.fr/~schwartz/fichiers_pdf/BMSL_tutorial.pdf.

Bayesian model selection has already been applied to the comparison of AV speech perception models, including FLMP (see Myung and Pitt, 1997; Massaro *et al.*, 2001; Pitt *et al.*, 2003). However, this involved heavy computations of integrals in Eq. (3) through Monte Carlo techniques, which would be difficult to apply systematically in model compari-

sons. BMSL has the advantage of being easy to compute and to interpret in terms of fit and stability. Furthermore, if the amount of available data is much higher than the number of parameters involved in the models to compare (that is, the dimension m of the Θ space), the probability distributions become highly peaked around their maxima, and the central limit theorem shows that the approximation in Eqs. (4) and (5) becomes quite reasonable (Walker, 1967). Kass and Raftery (1995) suggested that the approximation should work well for a sample size greater than 20 times the parameter size m (see Slate, 1999, for further discussions about assessing non-normality).

3. Estimating the "true" number of degrees of freedom in a model

The number of model parameters in most model comparison studies in AV speech perception is generally kept fixed to the "natural number of degrees of freedom" of the model, that is, the number of free parameters necessary to implement the model in its most extensive definition. Care is generally taken to check that the models have basically the same number of degrees of freedom; otherwise the RMSE correction described previously could be applied. Notice that this correction loses some sense if a parameter is introduced with no effect on the model likelihood (a "useless parameter") while BMSL naturally discards useless parameters through the integration in formula (3).

Of course, completely useless parameters generally do not exist, since this would correspond to some kind of misconception of the model. However, it is important to assess the possibility that some parameters are not really useful in the model behavior. For example, while all model comparisons generally involve a subject-by-subject assessment—and it will also be the case here—it could be interesting to test if some parameters could not, in fact, be similar from one subject to the other. The same could be done from one experimental condition to the other. Therefore, various implementations of the models to compare will be systematically tested, with a progressively increasing number of fixed parameters and thus a decreasing number of free parameters, in order to attempt to determine the *true* number of degrees of freedom of the model, that is, the number of free parameters really useful, and providing the highest global likelihood of the model knowing the data. Our basic assumption is that it is under the condition of true number of degree of freedom that models can be really assessed and compared in sound conditions.

Decreasing the number of free parameters raises two problems. First, the parameters to fix must be adequately selected. This may be done on a statistical objective basis, for example, through principal component analysis techniques, but this results in combinations of parameters difficult to interpret. A heuristic approach was preferred in which the observation of experimental data guided the selection of possible parameters to be kept fixed from one subject to another. The second problem is to estimate the value of the parameters being kept fixed. This was done through a Round Robin technique, in which a given parameter for one subject is estimated from the mean value taken by the parameter in the whole corpus excluding the current subject from the computation. This technique, classical and computationally simple, prevents from any artifactual introduction of the current data to model inside the "fixed" parameter used to model the data in a circular approach, which would be inappropriate.

C. Models

Two models were compared, FLMP and a variant with weighted contribution of the auditory and visual inputs in the integration, WFLMP. For each corpus, each model (including the variants associated with the decrease in the number of degrees of freedom) was fitted to the data separately for each subject. This enabled us to compute both mean values of the selected criteria, averaged over all subjects, and to assess differences between models by applying Wilcoxon signed-rank tests over the compared criteria for each subject.

1. FLMP

In a speech perception task consisting in the categorization of auditory, visual, and audiovisual stimuli, the FLMP may be defined as a Bayesian fusion model with independence between modalities, and the basic FLMP equation is

$$P_{AV}(C_i) = P_A(C_i)P_V(C_i)/\sum_j P_A(C_j)P_V(C_j), \quad (7)$$

C_i and C_j being phonetic categories involved in the experiment, and P_A, P_V, and P_{AV} the model probability of responses respectively in the A, V, and AV conditions.

2. WFLMP

The weighted FLMP model, called WFLMP, is defined by

$$P_{AV}(C_i) = P_A^{\lambda_A}(C_i)P_V^{\lambda_V}(C_i)/\sum_j P_A^{\lambda_A}(C_j)P_V^{\lambda_V}(C_j), \quad (8)$$

where λ_A and λ_V are subject-dependent factors used to weight the A and V inputs in the computation of the audiovisual responses estimated by $P_{AV}(C_i)$ (see other introductions of weights inside FLMP in Schwarzer and Massaro, 2001; or for a similar kind of weighted fusion model applied to speech recognition, in various implementations since Adjoudani and Benoît, 1996: see a review in Teissier *et al.*, 1999). For each subject, a lambda value is defined between 0 and 1, and λ_A and λ_V are computed from lambda by: $\lambda_A = \text{lambda}/(1-\text{lambda})$ and $\lambda_V = (1-\text{lambda})/\text{lambda}$, with thresholds maintaining λ_A and λ_V between 0 and 1. Figure 1 shows how lambda controls the weights λ_A and λ_V and how this results in varying P_{AV} from a value close to P_A when lambda is close to 0, to a value close to P_V when lambda is close to 1, passing by a value identical to the FLMP prediction when lambda is set at 0.5, with λ_A and λ_V both equal to 1.

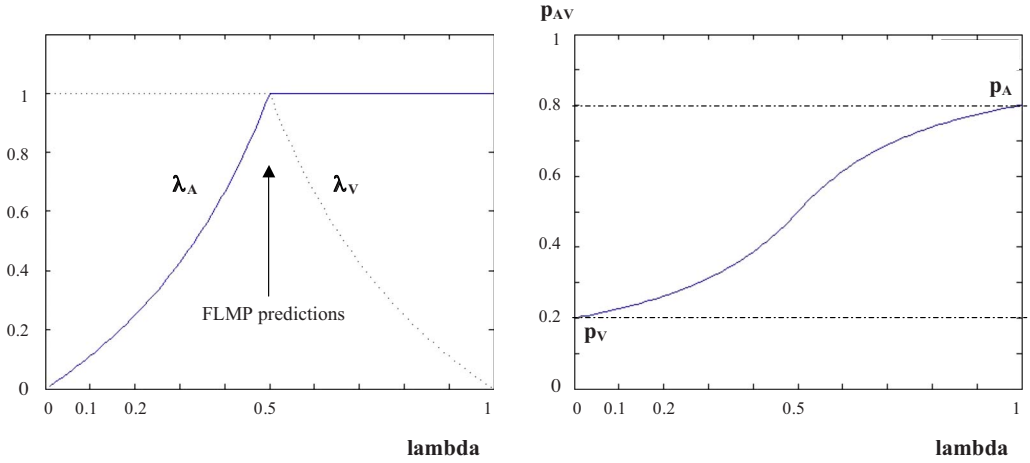

FIG. 1. (Color online) Variations in weighting coefficients λ_A and λ_V (left) and predicted p_{AV} (right) as a function of the lambda parameter tuning fusion in WFLMP. When lambda is close to 0, the audio weight decreases toward zero, the video weight increases toward 1, and the modeled p_{AV} reaches a value close to p_V. Conversely, when lambda is close to 1, the audio weight increases toward 1, the video weight decreases toward zero, and the modeled p_{AV} reaches a value close to p_A. Notice that for a lambda value at 0.5, both audio and video weights are set to 1, which provides exactly the FLMP predictions. In this example, p_V is set to 0.2 and p_A to 0.8.

III. RESULTS

A. Analysis of individual experimental data

The UCSC corpus has been extensively used in AV speech perception model assessment, generally with a good fit using the FLMP and RMSE criterion (Massaro, 1998; see also Massaro *et al.*, 2001, for an assessment of FLMP with a BMS criterion on this corpus). However, looking at the data, there seems to appear an effect not predicted by the FLMP, that is, interindividual differences in AV interaction. This is displayed in Fig. 2, showing two subjects with very close auditory and visual performances, although with quite different audiovisual responses. It seems that the weight of the visual modality is, respectively, high for the first one [Fig. 2(a)] and low for the second one [Fig. 2(b)]. Though the FLMP does not incorporate A and V weights, the fit is, however, quite acceptable (with RMSE values, respectively, 0.04 and 0.02 for these two subjects). This good fit is actually obtained because of the 0/0 instability: indeed, the FLMP simulation of unimodal data for the first subject is drawn toward slightly more ambiguous values for A responses and less ambiguous values for V responses [see Fig. 2(a)], while the inverse is done for the second subject [see Fig. 2(b)]. This is the indirect way the FLMP may decrease the importance of a modality in fusion, by slightly but consistently misfitting the unimodal data without introducing subject-specific weights, and while keeping a very low RMSE value (a very good fit) because of the 0/0 problem (Schwartz, 2006). Such consistent misfits of unimodal data, if they happen in a significant number of cases, would indicate a problem in modeling. They should be taken into account in a BMS criterion, although they are almost undetectable in a RMSE criterion.

B. Selected degrees of freedom for FLMP and WFLMP

The first implementation of FLMP needs ten parameters for each subject, that is five values $Ai=P_{Ai}(/da/)$ and five values $Vj=P_{Vj}$ (/da/) for the five stimuli of each continuum. Since the WFLMP model needs one more parameter per sub-

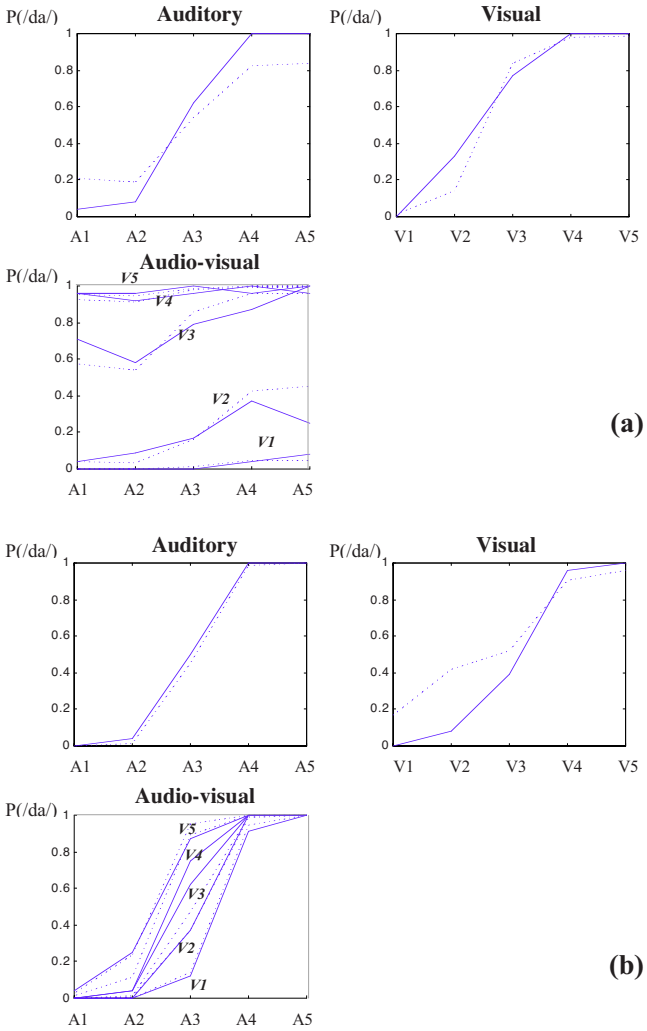

FIG. 2. (Color online) (a) Audio (top left), visual (top right), and audiovisual (bottom) data for subject 3 in UCSC corpus: data in solid lines and FLMP predictions in dotted lines. (b) Same as Fig. 2(a) for subject 18 in UCSC corpus.

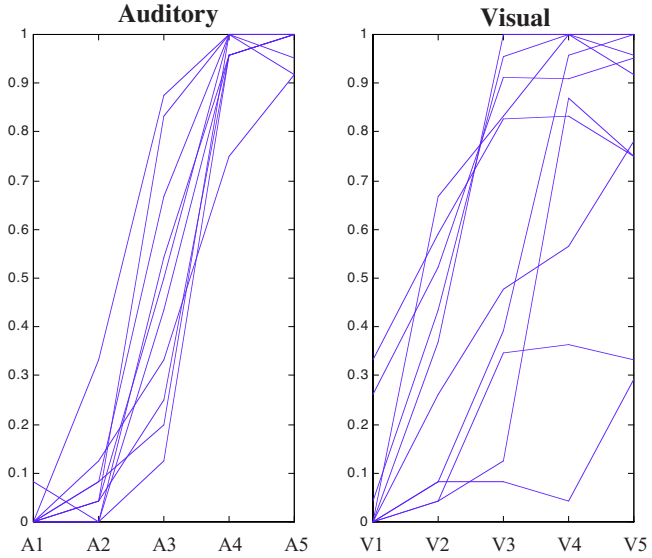

FIG. 3. (Color online) Left: audio identification for ten subjects. Right: visual identification for ten subjects.

ject, one parameter was removed by fixing the value of the parameter A5 (audio response for the fifth audio stimuli, higher than 0.99 in average) at a value equal to the mean of the value it takes for the other subjects.

To explain how the number of parameters was decreased, on Fig. 3 a sample of auditory and visual identification curves is displayed for 10 of the 82 subjects. In the audio results [Fig. 3(a)], the curves are all S-shaped from a value close to 0 to a value close to 1, with less variation on the sides (for A5, A1, and to a lesser extent A4 and A2). Therefore, it was attempted to fix these parameters, in this order, with the Round Robin procedure. In the visual curves [Fig. 3(b)], the configuration is different and suggests that it should be possible to describe these curves by estimating some values by a linear regression prediction on logit values of Vi, that is, $\log(Vi/(1-Vi))$. For this aim, two linear regression predictions on logit values were defined, one predicting V2 and V4 from the parameters V1, V3, and V5, and the other predicting V2, V4, and V5 from the parameters V1 and V3. Altogether, this lead to five variants of the FLMP and WFLMP models, respectively, with 10, 6, 5, 4, and 3 free parameters per subject (Table I).[3]

C. Modeling results

Figure 4 shows the results for the two models with their five free-parameter variants. For each case, means and standard deviations computed on the modeling results for the 82 subjects are presented.

With ten parameters per subject, the FLMP fit is good, with an average RMSE value at 0.051 (see Massaro, 1998, p. 64). Interestingly, the fit is significantly better for the WFLMP with the same number of free parameters, with an average RMSE value at 0.0445 (since $N=82$ is higher than 20, z-ratios are used following a unit normal distribution, $u=4.92$, $p<0.001$). RMSE then logically increases when the number of parameters decreases [Fig. 4(a)]. The portrait for RMSEcor is the same [Fig. 4(b)]. However, BMSL reaches a minimum for six parameters, both for FLMP and WFLMP [Fig. 4(c)]. In this variant of both models, A1 and A5 are fixed, together with A4 for WFLMP. V2 and V4 are estimated from V1, V3, and V5 by logit linear regression. For this optimal six-parameter implementation, there is a significant gain of WFLMP over FLMP ($u=4.77$, $p<0.001$).

TABLE I. The five variants of FLMP and WFLMP. All fixed parameters are estimated by the Round Robin technique.

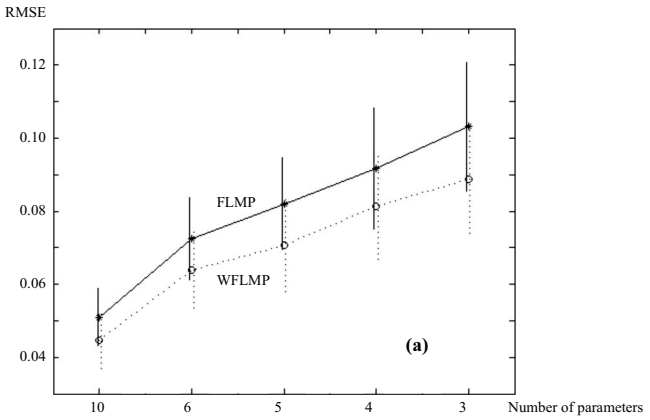
No. of parameters per subject	Parameters for FLMP	Parameters for WFLMP
10	V1–V5, A1–A5	+lambda A5 fixed
6	V1, V3, V5, A2, A3, A4 V2, V4 estimated by linear regression A1, A5 fixed	+lambda A4 fixed
5	V1, V3, A2, A3, A4 V2, V4, V5 estimated by linear regression A1, A5 fixed	+lambda A4 fixed
4	V1, V3, A2, A3 V2, V4, V5 estimated by linear regression A1, A4, A5 fixed	+lambda A2 fixed
3	V1, V3, A3 V2, V4, V5 estimated by linear regression A1, A2, A4, A5 fixed	+lambda V1 fixed

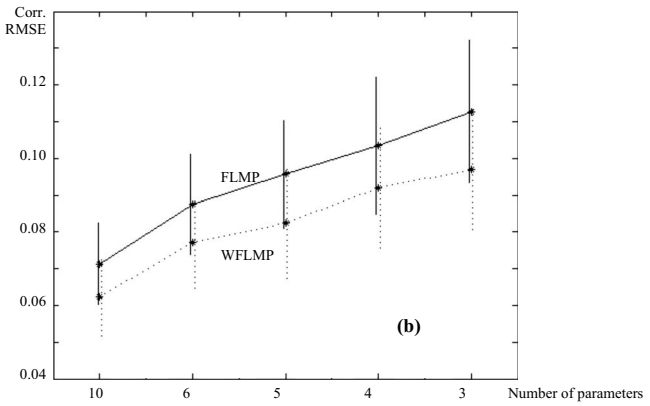
In Fig. 5, the histogram of logarithms of estimated lambda values are plotted for all subjects for WFLMP with six parameters. It appears that the range is indeed large, with auditory subjects on the right of the 1-value and visual subjects on the left. Under a criterion of λ_A/λ_V values, respectively, higher than 1.5 or lower than 0.67 (1/1.5), there are 33 "audio" and 14 "visual" subjects, the remaining 35 being intermediary.

Figure 6 shows how WFLMP models the two subjects compared in Fig. 2. Typically, the auditory and visual fits are similar between subjects—as in the experimental data themselves—while the good fit of the differences between subjects in audiovisual values is due to large differences in the lambda values, as shown on Fig. 5. This confirms that subject (a) is rather visual (with a λ_A/λ_V ratio at 0.23) and subject (b) is rather auditory (with a λ_A/λ_V ratio at 3.89), as suggested by the data themselves.

IV. GENERAL DISCUSSION

Two topics are addressed in the present work. One concerns methodology for model comparison, which is of particular importance in audiovisual fusion, as evidenced by the very large number of controversies regularly arising in the domain. This also has implications for designing models for audiovisual fusion in speech perception. The second one concerns the invariant vs subject-dependent nature of audiovisual fusion and more generally the parameters able to intervene in fusion. These topics will be addressed one after the other.





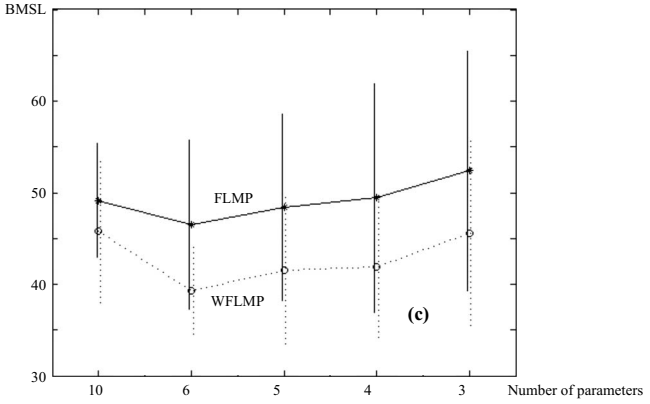


FIG. 4. (a) Compared RMSE values for FLMP vs WFLMP simulations with three to ten free parameters per subject. (b) Compared corrected RMSE values for FLMP vs WFLMP simulations with three to ten free parameters per subject. (c) Compared BMSL values for FLMP vs WFLMP simulations with three to ten free parameters per subject.

A. An adequate methodology for comparing models

There are two important claims in our methodological approach. First, a local criterion such as RMSE, or its quasi-equivalent maximum likelihood criterion, can be inappropriate, particularly in cases involving models which have a tendency to overfit the data, e.g., with FLMP and McGurk data. A global BMS criterion is theoretically sounder, as has been discussed in a large number of papers, unfortunately not much acknowledged in the speech perception community. The local approximation provided by BMSL is simple to compute, easy to interpret, and efficient assuming that the number of experimental data points is sufficient. In the present paper, it appears that RMSE and BMSL converge on showing the superiority of WFLMP over FLMP for the McGurk data. But this is not systematically the case (see,

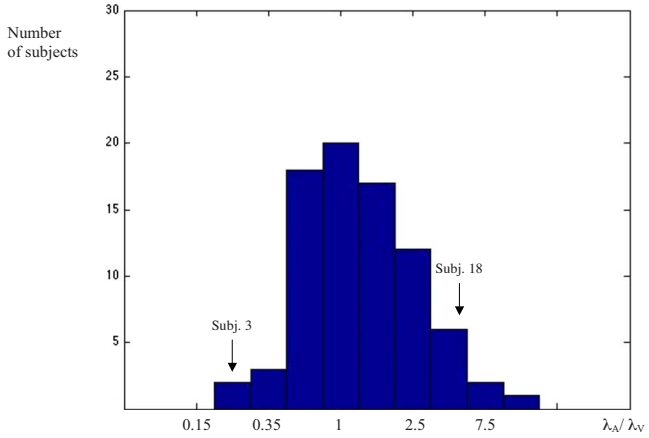

FIG. 5. (Color online) Histogram of λ_A/λ_V values controlling the fusion process for the 82 subjects in the WFLMP model with six parameters. Values for subject 3 [data displayed in Fig. 1(a)] and subject 18 [data displayed in Fig. 1(b)] are superimposed on the figure.

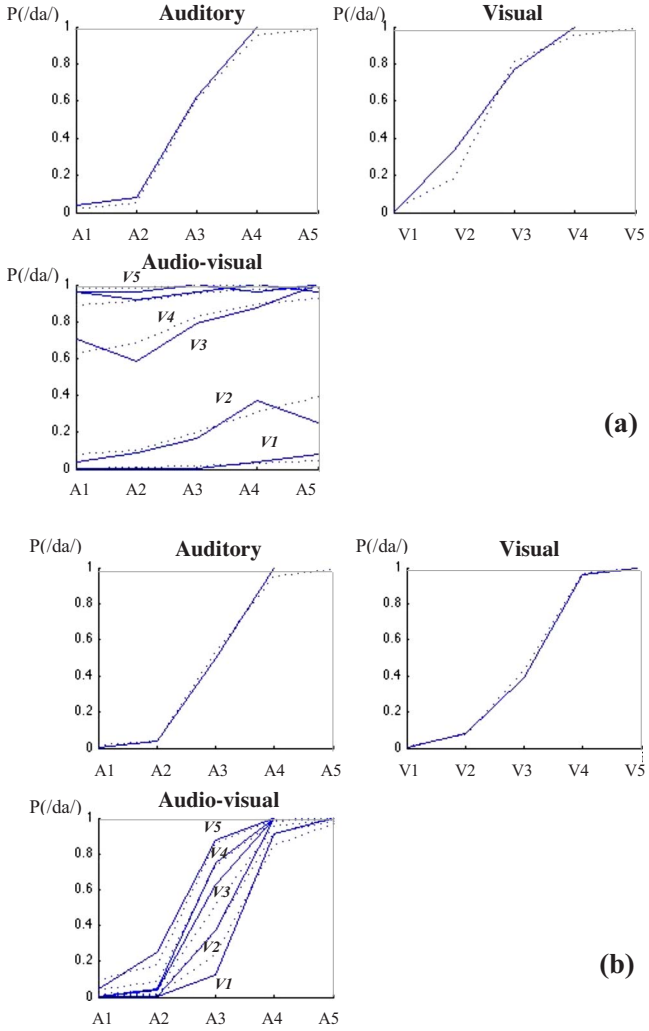

FIG. 6. (Color online) (a) Audio (top left), visual (top right), and audiovisual (bottom) data for subject 3 in UCSC corpus: data in solid lines and predictions with WFLMP with six parameters in dotted lines. (b) Same as Fig. 6(a) for subject 18 in UCSC corpus.

e.g., Schwartz and Cathiard, 2004; Schwartz, 2006). Therefore, we suggest that any model comparison involving FLMP based on a RMSE criterion should be taken cautiously, and its conclusions should be considered as probably arguable unless a new evaluation based on Bayesian model selection is undertaken.

Second, varying the number of parameters in model assessment is very important. Of course, the difficulty is that there is much freedom in the strategies that can be proposed for this principled reduction. This should involve both a simple and intuitive approach, and a substantial number of variants to be able to assess the approximate number of really meaningful parameters for comparing models.

In fact, these two claims are related. Decreasing the number of parameters *forces* one to use a criterion able to take the size of the model parameter set into account. This is the case of BMS and its BMSL approximation, and *not* the case of RMSE, in which any correction is largely arbitrary. Variation in the number of parameters showed that there was indeed some redundancy in the ten free parameters per subject involved in FLMP for the present corpus, six appearing as a more plausible number of degrees of freedom (three for the visual input, three for the audio input). It is interesting to note that a reduced number of degrees of freedom provided a much larger difference in favor of WFLMP, compared with the complete set of ten parameters.

B. Audiovisual fusion models

The present paper is focused on FLMP for methodological reasons associated with its very frequent use in publications, and its excessive adaptability to McGurk data leading in several cases to inappropriate or mistaken analyses of experimental results. However, FLMP is actually neither weakened nor strengthened by the present paper.

It is not weakened since we proposed both an adequate method for testing it in safer conditions—through the BMS framework—and a possible variant with subject-specific modulation—WFLMP—which could provide the route for new developments more in line with evidence that fusion is subject-dependent. Massaro and colleagues already introduced both ingredients in some of their work, but the present paper shows that they are actually *required* in any further use of FLMP in speech perception, particularly (but not exclusively) in experiments involving incongruent stimuli, as in the McGurk effect.

It is not strengthened either, since the present analysis could have been applied to other fusion models, such as Braida's pre- and postlabeling models (Braida, 1991; see also Grant and Seitz, 1998; Grant, 2002), with quite probably the same conclusions. Actually, a number of models have been recently developed explicitly taking into account the possibility that one modality could be favored in the fusion process. This is the point addressed by Ernst and colleagues with their maximum likelihood framework according to which integration would be "optimal" in leading to the largest possible reduction in the variance of the multisensory output. This is achieved by adaptively weighting modalities in relation to their reliability (or variance) for the considered task (Ernst and Banks, 2002; Ernst and Bulthoff, 2004; Denève and Pouget, 2004; Körding *et al.*, 2007 and a precursor use of this concept in audiovisual speech perception models in Robert-Ribes *et al.*, 1995). This "optimal integration" view is different from the optimal Bayesian fusion of decisions implemented in FLMP, since it occurs at a precategorical level.

C. What drives audiovisual fusion in speech perception?

The major theoretical output of the present paper is that it clearly shows that fusion is subject-dependent. There are indeed large intersubject differences in audiovisual fusion for speech perception, with various groups of subjects, some being more auditory, and others more visual. Many papers mention such a large variability in audiovisual performance. However, it was always unclear whether this was due to differences in unisensory performance or multisensory integration. The present analysis strongly reinforces the second view.

This opens the route to a number of questions about the fusion mechanism itself. Differences between subjects in the McGurk paradigm could result from a general "orientation" of a given subject toward one or the other modality for individual reasons (specific or related to, e.g., culture, language, sex, or age). They could also be the consequence of properties of the task or the experimental situation, which could have driven the subject toward one rather than the other stimulus input in a bimodal task.

1. Interindividual factors

It could well be the case that some subjects rely more on audition and others more on vision, and that they weight audiovisual fusion accordingly (see Giard and Peronnet, 1999). Hence, it could be assumed that there is for a given subject a general trend to favor one modality over another one, whatever the task. This should result in future studies comparing audiovisual fusion in various speech and nonspeech tasks, searching for individual portraits stable from one task to the other. These different behaviors could also be associated with differences in neuroimagery experiments, in terms of the involved cortical networks and of the quantitative role of each part in the global portrait.

We have already discussed in the Introduction possible factors that likely to play a role in sensor fusion: some languages could use the visual input more than others (e.g., English more than Japanese), female subjects could use it more than males, and adults more than children. Notice that the methodology employed here could be used to reanalyze all data relevant for these claims, in order to carefully disentangle the role of unimodal and multimodal factors in the corresponding studies.

This opens an important question, which is to know to what extent the weighting process can be dynamically modified during the subject's life. We have already mentioned the developmental evolution leading to an increase in the role of the visual input (see e.g., Sekiyama *et al.*, 2003; Sekiyama and Burnham, 2004). Recent data by Schorr *et al.* (2005)

suggested that there is a critical period for the development of audiovisual fusion in speech perception, before 2.5 years. In the case of a perturbation of one or the other modality, related to age or handicap, the question becomes to know if a subject can, voluntarily or through any reeducation means, selectively reinforce the weight of the most efficient modality.

In a recent study, Rouger *et al.* (2007) claimed that this could indeed be the case, hearing impaired subjects equipped with cochlear implants displaying, in their terms, "a greater capacity to integrate visual input with the distorted speech signal" (p. 7295). Actually, these data should be considered with caution, being a possible case of unimodal effects interpreted as bimodal. Indeed, Rouger *et al.* compared three populations of subjects: hearing impaired subjects equipped with cochlear implants (CIs), normal hearing subjects with audition degraded by noise (NHN), and normal hearing subjects presented with noise-band vocoder speech degrading audition in a way supposed to mimic the cochlear implant (NHV). They showed that for a similar level of audio performance, the audiovisual recognition is larger for CI than for NHV, NHN being in the middle. Two factors could be, in their view, responsible for this pattern: differences in the visual performance and in integration per se. A modeling approach leads them to claim that while the global visual scores are actually better in CI compared with NHN and NHV, there would be an additional gain in CH compared with NHV, hence the claim about a "greater capacity to integrate visual input with the distorted speech signal." Notice that integration efficiency would be as high in NHN as in CH according to their analysis. However, careful inspection of auditory confusion matrices for NHV and NHN, available in Rouger, 2007, shows that the structure of these matrices is quite different. Importantly, the transmission of the voicing mode was poorer in speech degraded with noise-band vocoder (NHV) than with white noise (NHN), suggesting that there could be a poorer complementarity in the audio and visual inputs in NHV, logically resulting in lower audiovisual scores. Differences in audiovisual performance would hence result from the structure of the unimodal inputs (being less complementary for normal hearing subjects presented with noise-band vocoder speech) rather than from integration per se. Actually, in this case, a study based on WFLMP and BMS would probably *not* reveal any discrepancy in integration between impaired subjects equipped with cochlear implants (CI) and normal hearing subjects (NHV and NHN).

2. Intraindividual factors

Finally, it is quite possible that the weight of one modality depends on the experimental situation per se. First, stimuli themselves could possibly drive the weighting factor. In a review of intersensory interactions, Welch and Warren (1986) proposed "modality precision" or "modality appropriateness" as a key factor in explaining which modality should dominate intersensory judgments. Evidence for the role of reliability in audiovisual fusion for speech perception can be found in the study by Lisker and Rossi, 1992 on the auditory, visual, and audiovisual identification of vocalic rounding. Careful inspection of their data shows that although auditory identification seems in some cases quite accurate, there is a systematic trend for putting more weight in the visual modality within audiovisual data, as if the subjects "knew" that their eye was better than their ear at this particular task. Conversely, Robert-Ribes *et al.* (1998) on their study of audiovisual vowel perception in noise reported that with a very high level of noise, some subjects consistently select a given response (e.g., [ø]) for all vowels in noise in the auditory modality, which could lead in a model as FLMP to a large probability of response of this category in the audiovisual modality. However, this is not the case, showing that subjects know that the auditory modality is not reliable at high levels of noise and hence discards it almost completely from the fusion process.

Second, the experimental conditions could lead to enhance or decrease the role of one modality in the fusion process. Attentional mechanisms should play a role at this level. Actually, while it had been initially claimed since McGurk and MacDonald, 1976 that the McGurk effect was automatic and not under the control of attention, it appeared later that the instruction to attend more to audition or to vision might bias the response (Massaro, 1998). A recent set of experiments by Tiippana *et al.* (2004) showed that if the attention is distracted from the visual flow, the role of the visual input seems to decrease in fusion, with less McGurk effect. Notice that the authors themselves attempted to simulate their data with FLMP and argued that the good fit of their data by a model claiming that fusion is automatic appeared as "a paradox" (p. 458). Actually, reanalysis of their data in a BMS framework with a weighted FLMP suggests that there are indeed attentional factors intervening in fusion itself, independent of unimodal effects (Schwartz and Tiippana, in preparation). This is confirmed by a number of recent experiments showing the possibility to modulate the McGurk effect based on manipulations of attention (e.g., Alsius *et al.*, 2005, 2007), although here again, a precise analysis of experimental results in a BMS framework could provide an adequate control for disentangling unimodal from multimodal factors.

V. CONCLUSION

The present work proposed a new methodology for comparatively assessing models of audiovisual speech perception. This methodology is based on both the use of a Bayesian model selection criterion approximated in a computationally simple way (BMSL) and on a systematic variation in the number of degrees of freedom of the models to assess, in order to reveal the "true" number of parameters in a given model for a given task. The comparison of FLMP with a variant with auditory and visual weights varying from one subject to another (WFLMP) leads to the conclusion that weights are indeed variable, and hence that audiovisual integration seems subject-dependent.

This could have important consequences in future studies about audiovisual speech perception. First, from a methodological point of view, it suggests that studies on audiovisual speech perception should consider these differences and possibly separate experimental groups into "auditory" or "vi-

sual" subgroups based on such criteria such as McGurk performance. Second, from an audiological point of view, this indicates that subjects should be assessed based on their audiovisual fusion abilities, and considered differently—in terms of reeducation and practice—depending on whether they are more auditory or more visual in their behavior.

[1]In the following, bold symbols deal with vectors or matrices, and all optimizations are computed on the model parameter set $\boldsymbol{\Theta}$.

[2]The interpretation of the term log(V) is straightforward and results in handicapping large models by increasing BMSL. The term $m/2\log(\pi)$ comes more indirectly from the analysis and could seem to *favor large models*. In fact, it can only decrease the trend to favor small models over large ones.

[3]It could seem paradoxical to maintain the number of free parameters similar for each subject, while attempting to show interindividual differences. This is not the case actually. The principle is to freeze as much as possible the structure of the model for all subjects, in order to let the differences appear in an objective way.

The importance of temporal fine structure information in speech at different spectral regions for normal-hearing and hearing-impaired subjects

Kathryn Hopkins[a] and Brian C. J. Moore
Department of Experimental Psychology, University of Cambridge, Downing Street, Cambridge CB2 3EB, England

(Received 13 February 2009; revised 4 December 2009; accepted 22 December 2009)

Speech reception thresholds (SRTs) were measured for target and competing-speech signals, processed to contain variable amounts of temporal fine structure (TFS) information. Signals were filtered into 30 1-ERB_N wide channels (where ERB_N refers to the bandwidth of normal auditory filters), which were either tone vocoded, preserving temporal envelope information (extracted using the Hilbert transform), or left unprocessed, containing both TFS and envelope information. Improvements in SRT were compared when TFS was progressively introduced, starting with the high- or low-frequency channels. The results suggest some redundancy in the TFS information across frequency regions. In a second experiment, the signal was divided into five, 6-ERB_N-wide spectral regions, four of which were tone vocoded. The remaining region was either absent (creating a spectral notch) or was present and unprocessed. SRTs were measured for normal-hearing and hearing-impaired subjects. Conditions where all channels were vocoded or unprocessed were also included. Normal-hearing subjects benefited similarly when TFS information was added to each region, suggesting that TFS information is important over a wide frequency range. Hearing-impaired subjects benefited less, although the benefit varied across subjects. Benefit from TFS information in speech was correlated with a psychophysical measure of TFS sensitivity obtained at two center frequencies. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3293003]

I. INTRODUCTION

Processing using a noise or tone vocoder can be used to remove temporal fine structure (TFS) information (the rapid fluctuations in amplitude close to the center frequency of a narrow-band signal) and to preserve, as far as possible, temporal envelope information (slower fluctuations in amplitude that are superimposed on this TFS). Speech reception thresholds (SRTs) for a target talker with a competing-talker or noise background are higher when the combined signal is noise or tone vocoded than when it is unprocessed. This is true even when such processing uses similar analysis bandwidths to those of the peripheral auditory filters, so that the spectral information available to the central auditory system is similar to that for unprocessed speech (Gnansia *et al.*, 2008; Hopkins *et al.*, 2008). This suggests that TFS information improves speech intelligibility for normal-hearing subjects when listening in background noise. Nonsense syllables processed to preserve TFS information and to remove temporal envelope information as far as possible are highly intelligible to normal-hearing subjects, following some training, suggesting that TFS may also play a role in speech intelligibility in quiet (Lorenzi *et al.*, 2006).

Recent studies suggest that subjects with moderate cochlear hearing loss have a reduced ability to use TFS information in psychophysical tasks (Buss *et al.*, 2004; Lacher-Fougère and Demany, 2005; Moore *et al.*, 2006a; Hopkins and Moore, 2007) and for the perception of speech (Buss *et al.*, 2004; Lorenzi *et al.*, 2006; Hopkins *et al.*, 2008). Hopkins and Moore (2007) measured the ability of normal-hearing and hearing-impaired subjects to discriminate harmonic and frequency-shifted tones, where each component was shifted upwards by the same amount in Hz. Such stimuli have the same envelope repetition rate, but different TFS. The harmonic and frequency-shifted tones were filtered into the same spectral region to prevent discrimination based on excitation-pattern cues, provided that components falling within the filter passband were unresolved. Normal-hearing subjects could discriminate such stimuli well when the filter was centered on the 11th component in the complex (and so all components within the passband were unresolved). For the same condition, hearing-impaired subjects performed very poorly, most scoring no better than chance. The authors interpreted this result as providing evidence that subjects with moderate cochlear hearing loss have a reduced ability to use TFS information.

Hopkins *et al.* (2008) measured the SRT as a function of the frequency range over which TFS information was available for a combined target and competing-talker signal. The signal was split into 32 channels, each of which was 1-ERB_N wide, where ERB_N refers to the equivalent rectangular bandwidth of the auditory filter for young, normal-hearing subjects, when measured at moderate sound levels (Glasberg and Moore, 1990). Above a cut-off channel, CO, channels were noise vocoded, and so contained only temporal enve-

[a]Author to whom correspondence should be addressed. Electronic mail: kh311@cam.ac.uk

lope information. For channels up to and including CO, channels were not processed, and so contained both TFS and envelope information. SRTs for normal-hearing subjects decreased as CO was increased, and more TFS information was included in the signal. As a group, the hearing-impaired subjects improved much less than the normal-hearing subjects as CO was increased, suggesting that they were less able to use TFS information in speech when listening in a competing-talker background. However, the individual results for the hearing-impaired subjects were rather variable, with some subjects showing no benefit at all from the added TFS information, and one subject benefiting almost as much as the normal-hearing subjects. The authors suggested that the reduced ability of hearing-impaired subjects to use TFS information could contribute to the speech perception problems reported by hearing-impaired subjects, and that the variability in the ability to benefit from TFS information could account for some of the variability in speech perception reported for subjects with similar audiometric configurations. However, the exact way in which TFS information contributes to speech intelligibility for normal-hearing subjects remains uncertain. A number of possibilities have been suggested, and these are described in Secs. I A–I C.

A. Fundamental frequency (F0) coding

Considerable research has addressed the importance of TFS information in pitch perception, particularly for coding the frequencies of pure tones and resolved harmonics in complex tones. Psychophysical data support the hypothesis that TFS information is important for the perception of pure tones for frequencies up to at least 5000 Hz. For example, Moore (1973) measured frequency difference limens (DLFs) for short-duration pure tones, which had a broader frequency spectrum than longer tones of the same frequency. DLFs were better than predicted by a model that assumed that discrimination of pure tones was based on detection of a difference in the excitation pattern (Zwicker, 1970), although others found smaller discrepancies between the predictions of Zwicker's model and DLFs as a function of duration (Freyman and Nelson, 1986). TFS information has also been suggested as a possible cue for coding F0 information for complex tones with components that are unresolved but intermediate in harmonic number (harmonic ranks 8–14) (Moore and Moore, 2003; Moore *et al.*, 2006b). However, this role remains uncertain, with other researchers suggesting that F0 coding for such stimuli can be accounted for by coding the repetition rate of the waveform using envelope information rather than TFS, or on the basis of partially resolved harmonics (Bernstein and Oxenham, 2006; Oxenham *et al.*, 2009). In the presence of a background sound, F0 information may be important for segregating sound sources into separate auditory streams, particularly when the background is a competing talker (Brokx and Nooteboom, 1982; Scheffers, 1983; Bregman *et al.*, 1990).

B. Coding the frequencies of peaks in the short-term speech spectrum

The coding of formant frequencies is important for vowel and consonant identification. Some animal studies have shown that a rate-place code may not carry sufficient information to account for psychophysical measures of vowel discrimination at all sound levels. At high levels, auditory filters broaden and the responses of many neurons saturate, so that peaks in the rate-place profile at the vowel formant frequencies become indistinct (Sachs and Young, 1979). However, Young and Sachs (1979) described representations of vowel formants using rate, place, and temporal information that were stable for levels up to at least 80 dB sound pressure level (SPL). These results suggest that temporal information may play some role in coding the frequencies of peaks in the spectra of speech signals.

C. Listening in the dips

It has been proposed that TFS information is important when listening to target speech in a background that is modulated in amplitude. In such a background, subjects can take advantage of a short-term improvement in signal-to-background ratio (SBR) to "glimpse" information about the target. Normal-hearing subjects have lower SRTs in modulated noise than steady noise (Duquesnoy, 1983; Peters *et al.*, 1998), and for a fixed overall SBR, they show better word and syllable identification for signals in modulated noise than in steady noise (Festen and Plomp, 1990). This improvement in performance has been termed "masking release." Hopkins and Moore (2009) measured SRTs for a target speaker in amplitude-modulated and steady noise. The target and background signals were mixed and then filtered into 32 1-ERB_N-wide channels. Channels up to and including a cut-off (CO) channel were not processed further, and so contained both envelope and TFS information, while channels above CO were tone vocoded to preserve only envelope information, which was extracted using the Hilbert transform. They found that normal-hearing subjects improved more when CO was increased (and so more TFS information was included) when listening in a modulated-noise background than in a steady-noise background. They suggested that subjects could use a change in TFS information in the dips of a modulated background to identify the presence of a signal and to code its properties. The idea that TFS information is important for masking release is supported by the positive correlation found by Lorenzi *et al.* (2006) between the ability of young hearing-impaired subjects to understand speech processed to contain primarily TFS information and masking release for intact speech in noise. However, it is known that, for stimuli processed to remove envelope cues, envelope information is partly reconstructed in the auditory system (Ghitza, 2001; Zeng *et al.*, 2004), and such reconstruction is greater when the filters in the peripheral auditory system are sharper. Hence, the correlation found by Lorenzi *et al.* (2006) might have occurred because frequency selectivity varied across subjects, and because frequency selectiv-

ity influences both masking release (Gnansia *et al.*, 2008) and the recovery of envelope cues from speech processed to contain primarily TFS information.

The interpretation of experiments on masking release has recently been addressed by Bernstein and Grant (2009). They showed that the amount of masking release depended on the SRT for steady noise; masking release was greater for conditions when the SRT for steady noise was more negative. This could partially explain the results of Lorenzi *et al.* (2006) and Hopkins and Moore (2009), as they measured masking release in terms of a reduction in SRT, and the SRT for steady noise was different across subjects (in the study of Lorenzi *et al.*) or conditions (in the study of Hopkins and Moore).

It has also been suggested that the coding of F0 information may be important for masking release (Summers and Leek, 1998; Stickney *et al.*, 2004). If this were the case, TFS information could be indirectly important for masking release because of its likely importance in coding F0 information (as discussed earlier). However, Oxenham and Simonson (2009) showed that masking release was similar for speech stimuli that were low-pass filtered at 1200 Hz or high-pass filtered at 1500 Hz. If accurate coding of F0 information was important for masking release, more masking release would be expected for the low-pass filtered condition, where resolved harmonics were present, allowing more accurate coding of the F0. Thus, these results suggest that F0 information may not be as important for masking release, as was previously thought.

D. Rationale for the present study

Measuring the importance of TFS in different spectral regions may provide information about the possible role of TFS information in speech perception, and the problems that may be encountered by people who are relatively insensitive to TFS, such as hearing-impaired people and cochlear-implant users. If TFS information is mainly important for coding the frequencies of resolved harmonics (which dominate the perception of F0 information), then a benefit from TFS information would only be expected for frequencies below about 1000 Hz. If, however, TFS information is also important for coding peaks in the short-term spectrum of speech, or for listening in the dips of a fluctuating background, then benefit from TFS information should occur for higher frequencies, provided that the listener has the ability to extract the TFS information.

Hopkins *et al.* (2008) found that, when TFS information was added starting from the low-frequency channels, the biggest improvement in performance occurred when CO was increased from 0 to 4, and the improvement as CO was raised further was gradual. No significant improvement in performance occurred when CO was increased beyond 24 (equivalent to a frequency of 4102 Hz). It may initially appear that this supports the hypothesis that TFS information is mainly important at low frequencies, and that TFS information is not at all important for frequencies above about 4000 Hz. However, this result could be influenced by redundancy in the TFS information that was added to the signal as CO was increased. If there was redundancy in the TFS information in different spectral regions, adding more TFS information would not necessarily result in an improvement in performance.

This hypothesis was tested in experiment 1. A similar method to that of Hopkins *et al.* (2008) was used, but in addition to the TFS information being added starting with the low-frequency channels (TFS-low conditions), TFS information was added starting with the high-frequency channels (TFS-high conditions). If the benefit from adding TFS information in a particular spectral region is reduced by the presence of TFS information in other spectral regions (because of redundancy in the TFS information), then the changes in performance between the same values of CO for the TFS-low and TFS-high conditions may be different. Only normal-hearing subjects were tested.

In experiment 2, the importance of TFS information in different spectral regions was assessed in more detail by measuring the benefit of adding TFS information to single isolated spectral regions to reduce the effects of redundancy in the TFS. Normal-hearing and hearing-impaired subjects were tested.

In experiment 3, a psychophysical measure of TFS sensitivity developed by Moore and Sek (2009a) was used for the same hearing-impaired subjects who took part in experiment 2 and for a different group of normal-hearing subjects. Subjects were required to discriminate harmonic complex tones from frequency-shifted tones, in which all of the components were shifted up by the same amount in Hz. The stimuli were centered on either 1419 or 2904 Hz, which corresponded to the third and fourth frequency regions in experiment 2. It was assessed whether the results of this measure of sensitivity to TFS were correlated with the benefit obtained from TFS information in speech. If this were the case, it would lend weight to the test as a measure of sensitivity to TFS, and also to the idea that the ability to use TFS is an important predictor of the ability of hearing-impaired subjects to understand speech in complex backgrounds.

II. METHOD

A. Subjects and materials

Seven normal-hearing subjects were tested. All had thresholds of 15 dB hearing level (HL) or better in their test ear at the standard audiometric frequencies from 250 to 8000 Hz, and were aged between 19 and 24 years. All subjects were native British English speakers.

Sentences from the coordinate response measure (CRM) corpus were used for testing (Moore, 1981; Kitterick and Summerfield, 2007). CRM sentences all have the same standard format: "Ready *callsign*, go to *color*, *number* now!" Subjects were required to identify the callsign, color, and number that they heard from a list of four (in the case of color) or eight (in the case of callsign and number) alternatives. Sentences were presented in a competing-talker background. A competing-talker background was used because, in a previous study, this background gave a large reduction in SRT when TFS information was added (Hopkins *et al.*, 2008). The background was randomly selected from a pas-

sage of continuous prose, spoken by a different talker. Silent intervals between sentences and pauses for breath were removed from the passage by hand editing. Natural-sounding pauses between words of less than 200 ms were left intact. Both target and competing talkers were male speakers of British English. The F0 of the target talker's voice was estimated to range from 130 to 200 Hz, while the competing talker had a larger F0 range of about 130 to 280 Hz.

B. Processing and equipment

Target and competing-speech signals were added together and subsequent processing was carried out on the combined signal. The signal was filtered into 30 channels, spanning a frequency range of 100 to 8000 Hz with an array of linear-phase, finite-impulse-response (FIR) filters. The filters had a variable order, chosen such that the transition bands of each filter had similar slopes when plotted on a logarithmic frequency scale. Each filter was designed to have a response of −6 dB (relative to the peak response) at the frequencies at which its response intersected with the responses of the two adjacent filters. Each channel was 1-ERB_N wide. Hence, the processing was not expected to have a large effect on the spectral information available to the central auditory system. Channels were divided into two groups by a cut-off channel, CO. For TFS-low conditions, channels up to and including CO were not processed further, and channels above CO were tone vocoded. For TFS-high conditions, channels above CO were not processed further, and channels up to and including CO were tone vocoded. For channels that were vocoded, the Hilbert transform was used to find the "analytic signal" for each channel (Hilbert, 1912; Bracewell, 1986), and the envelope was extracted by finding the absolute value of this analytic signal. Each channel envelope was used to modulate a sine wave with a frequency equal to the center frequency of the channel. Each modulated sine wave was then filtered using the original channel analysis filters to remove side bands that fell outside of the channel bandwidth. Finally, signals from all channels were aligned in time and combined.

All signals were generated with a high-quality 16-bit PC soundcard (Lynx One) at a sampling rate of 22 050 Hz, passed through a Mackie 1202-VLZ mixing desk, and presented to the subject monaurally via Sennheiser HD580 headphones. Subjects were seated in a double-walled sound-attenuating chamber.

C. Procedure

Six values of CO were used (0, 6, 12, 18, 24, and 30) for both the TFS-low conditions and the TFS-high conditions. For the TFS-low conditions, unprocessed information was included in channels up to and including CO (as in Hopkins *et al.*, 2008), and for the TFS-high conditions, unprocessed information was included in channels above CO. Note that the TFS-low condition with CO=0 was equivalent to the TFS-high condition with CO=30, and the TFS-high condition with CO=0 was equivalent to the TFS-low condition with CO=30. These were the conditions for which the whole signal was vocoded (the former) or unprocessed (the latter). All other values of CO were tested for both TFS-low and TFS-high conditions, giving ten conditions in total.

SRTs corresponding to the 70.7% correct point on the psychometric function were measured for each subject and condition. At the start of each run, the SBR was set to a value for which the subject was expected to identify all of the words in the target sentence correctly. A sentence was considered correct if the callsign, color, and number were correctly identified, and incorrect if any mistakes were made. A two-up, one-down adaptive procedure was used to set the SBR for each trial. If two sentences were correctly identified in succession, the SBR for the next sentence was set k dB lower; if a sentence was incorrectly identified, the next sentence was presented at a SBR that was k dB higher. For the first two turnpoints, k was equal to 4 dB, and for the remaining six turnpoints, k was equal to 2 dB. The SRT was taken to be the mean of the SBR values at the last six turnpoints. For SBRs of −16 dB or higher, the level of the target talker was fixed at 65 dB SPL, and the level of the competing talker was varied. For SBRs lower than −16 dB, the level of the competing talker was not increased further, to prevent the level of the combined signal from becoming uncomfortably loud; instead, the level of the competing talker was fixed, and the level of the target talker was reduced to give the desired SBR.

D. Analysis

A concern with the methods used here (and by Hopkins *et al.*, 2008) is the extent to which the tone-vocoder processing is successful in preserving the temporal envelope information available to the central auditory system while removing the TFS information. Here, the tone-vocoder processing was carried out using channels that were 1-ERB_N wide. This channel width was chosen to maximize the fidelity of envelope transmission to the central auditory system, while ensuring that TFS information was disrupted; the fidelity of envelope transmission is expected to increase as narrower channels are used, but this may also lead to a crude representation of the TFS in the tone-vocoded signal. To assess the effects of peripheral filtering on the information available to the central auditory system, both a tone-vocoded signal and the corresponding original signal were passed through an array of bandpass filters that were designed to have similar frequency selectivity to normal auditory filters (Glasberg and Moore, 1990). Fifty-nine overlapping fourth-order gammatone filters were used, spaced between 100 and 8000 Hz. Each had a bandwidth of 1-ERB_N. At the output of each filter, the envelope and TFS were decomposed using the Hilbert transform. The correlation, $r$env, between the envelope produced by the original signal and that produced by the tone-vocoded signal was found for each channel. Similar correlations were obtained for the TFS, giving rTFS. The original and tone-vocoded signals were time aligned, prior to measuring the correlations to compensate for the delays introduced by the tone-vocoder processing. Small misalignments in the original and processed signals could lead to a much-reduced value of rTFS, as the TFS within each channel fluctuates rapidly. To check that the time alignment had

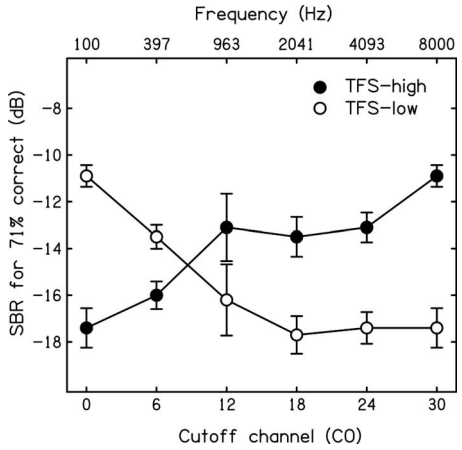

FIG. 1. SRTs plotted as a function of CO for TFS-high and TFS-low conditions. Error bars are plotted at ±1 standard error of the mean.

been successful, the correlations were measured with the processed signal advanced or delayed by time intervals up to 1 period of the channel center frequency. Correlations were measured for 20 time intervals in this range, and *r*TFS was taken to be the largest correlation measured. Averaged across the 59 filters, *r*env was equal to 0.936 and *r*TFS was equal to 0.014, indicating that the tone-vocoder processing was relatively successful at preserving the temporal envelope information and removing the TFS information from the original signal. There was a small difference between the value of *r*env for filters that had the same center frequency as the channel center frequencies used for the tone-vocoder processing, and the value of *r*env for the filters with center frequencies half way between those for the tone vocoder. The mean values of *r*env were 0.941 for the former and 0.932 for the latter. The same analysis was also carried out with an array of 59 filters with the same center frequencies, but with bandwidths of 2 ERB_N to simulate the loss of frequency selectivity that is typically found for subjects with moderate cochlear hearing loss (Glasberg and Moore, 1986). The mean value of *r*env at the output of these filters was 0.936, and the mean value of *r*TFS was 0.014. Thus, the vocoder processing was successful in preserving envelope cues and removing TFS cues when the simulated auditory filters were broader than normal.

III. RESULTS

SRTs as a function of CO are plotted in Fig. 1. For the TFS-low condition, where unprocessed information was present in channels up to and including CO, as in Hopkins *et al.* (2008), performance improved as CO increased, and more TFS information was presented, starting from the low-frequency channels. A one-way, repeated-measures, analysis of variance (ANOVA) showed that there was a significant effect of CO [$F(5,30)=12.3$; $p<0.001$]. A Fisher's least significant difference (LSD) procedure was used to test whether SRTs for different values of CO were different from each other. The results are shown in the top panel of Table I. SRTs improved for values of CO up to 12, but there was no significant improvement for higher values of CO.

TABLE I. Differences between mean SRTs measured with different pairs of values of CO for TFS-high and TFS-low conditions. Equivalent cut-off frequencies (Hz) are also shown. The LSDs calculated using Fisher's procedure were 2.3 (TFS-low condition) and 2.1 (TFS-high condition). Differences equal to or above this value are shown in bold.

		TFS-low					
CO		0	6	12	18	24	30
	Frequency	100	397	963	2041	4093	8000
0	100	0					
6	397	**2.7**	0				
12	963	**5.3**	**2.6**	0			
18	2041	**6.8**	**4.1**	1.5	0		
24	4093	**6.5**	**3.8**	1.2	0.3	0

30	8000	**6.5**	**5.2**	**2.3**	**2.7**	**2.3**	0

For the TFS-high condition, performance improved as CO was reduced, and more TFS information was presented, starting from the high-frequency channels. The effect of CO was significant [$F(5,30)=10.03$; $p<0.001$]. LSD test results are shown in the bottom panel of Table I. The pattern of the results broadly mirrored that for the TFS-low condition, with most change in performance when TFS was added to the low-frequency channels. However, performance significantly improved even when TFS information was added to the highest-frequency channels, a result that was not found for the TFS-low condition or by Hopkins *et al.* (2008).

IV. DISCUSSION

For both the TFS-low and TFS-high conditions, performance improved as more TFS information was added to the signal. For the TFS-low condition, performance improved as CO was increased. This is broadly consistent with the results of Hopkins *et al.* (2008), although Hopkins *et al.* (2008) found significant improvements for higher values of CO (up to CO=24 rather than up to CO=12), and the improvement in SRT from adding TFS across the whole spectrum was much larger (15.5 dB compared with 6.5 dB). A number of factors could account for these differences. First, Hopkins *et al.* (2008) used a noise vocoder, whereas a tone vocoder was used here. Whitmal *et al.* (2007) compared the intelligibility of noise and tone-vocoded stimuli, and found that the noise-vocoded stimuli were less intelligible, particularly when very narrow bands were used, as was the case for the bands used here and by Hopkins *et al.* (2008). Similarly, Stone *et al.* (2008) found that intelligibility was significantly higher for a tone vocoder than a noise vocoder when listening to speech in a competing-talker background. Whitmal *et al.* (2007) suggested that this difference in performance arose because

the narrow-band noise carriers used for the noise vocoder introduced random modulations, which could be confused with the envelope modulations in the speech signal. A tone carrier does not introduce these spurious modulations in the envelope of the vocoded signal. Distortions introduced by the noise vocoder could partly account for the poorer performance when CO was low, and a large proportion of the signal was vocoded. Souza and Rosen (2009) also pointed out that a tone vocoder may better preserve high-rate periodicity information, due to the presence of evenly spaced components corresponding to the side bands of a tone carrier.

For both the TFS-low and TFS-high conditions, the greatest changes in SRT occurred when TFS information was added to channels with center frequencies below 1000 Hz, which is consistent with the idea that TFS information is important for coding F0 information. However, performance was significantly better when CO=24 than when CO=30 for the TFS-high condition. For the TFS-low condition, there was no significant difference in performance when CO=24 and CO=30. This suggests that there is some redundancy in TFS information across spectral regions; adding TFS information to the highest-frequency region only improved performance when the rest of the channels were vocoded (in the TFS-high condition). When the other channels were unprocessed (as in the TFS-low condition), no improvement occurred, perhaps because the TFS information in that region was providing information that was redundant with the TFS information in lower-frequency channels; as a result, TFS information in the high-frequency channels did not add any information to that already present in the low-frequency channels.

The redundancy in the TFS information across frequency might be explained by the use of TFS information for "listening in the dips." TFS information in a narrow spectral region could be used to identify signal portions in the dips of a fluctuating masker. Envelope information in speech is highly correlated across frequency regions (Steeneken and Houtgast, 1999), so this information could be used to identify speech portions with a favorable SBR across a broad spectral region. The redundancy in TFS information could also be explained by a general redundancy in speech information across spectral regions. Turner *et al.* (1998) filtered nonsense syllables into four frequency bands, and measured weightings for the importance of each band for intelligibility. They found that the weightings differed depending on the combination of bands that was presented, suggesting some redundancy across bands. If TFS information is important for carrying phonetic information, then a general redundancy in speech information across frequency could explain the redundancy in TFS information that we observed.

Some aspects of the data from experiment 1 could be accounted for if it were assumed that the SRT had a "floor" value of about −18 dB. However, it is not clear why this should be the case; there was no limit imposed on the minimum SBR that could be presented, and information in the dips of a highly modulated masker (such as the competing talker used here) would be available at very negative SBRs. Indeed, two of the individual normal-hearing subjects had SRTs of less than −20 dB for the condition in which all of the channels were unprocessed. This floor in performance of −18 dB coincides with the SBR at which the signal was attenuated rather than the masker made louder to give the required SBR that was dictated by the adaptive procedure (see Sec. II C for details). This was done to prevent the signal from becoming uncomfortably loud. One possibility is that the target became less audible below this SBR, and so it contributed to a floor effect. However, this explanation is unlikely, as the target would have still been well above threshold for normal-hearing subjects down to much more negative SBRs than were used here.

V. EXPERIMENT TWO

A. Rationale

The results of experiment 1 suggest that there is some redundancy in TFS information across spectral regions. This means that it is difficult to infer the relative importance of TFS information in different spectral regions from data where TFS information has been added to a speech signal cumulatively (as was the case in experiment one and in Hopkins *et al.*, 2008), as the improvement in performance as TFS is added depends not only on the spectral region to which the information is added, but also on the TFS information that is already present in the signal. In experiment 2, to partially overcome this problem, the benefit of adding TFS to single isolated spectral regions was assessed. Both normal-hearing and hearing-impaired subjects were tested. Hopkins and Moore (2007) found that subjects with moderate cochlear hearing loss were often completely unable to use TFS information in complex sounds to discriminate harmonic and frequency-shifted tones. However, only tones with components above about 1 kHz were tested, and so it is possible that hearing-impaired subjects are generally more sensitive to TFS information at lower frequencies. Hearing-impaired subjects were tested in experiment 2 to investigate whether their reduced benefit from TFS information in speech, as measured by Hopkins *et al.* (2008) when TFS information was added starting from the low frequencies, was due to a general limitation in processing TFS information or due to a limitation specifically in processing TFS information at higher frequencies.

Another concern is that the improvement in performance when TFS information is added to a particular spectral region could be affected by the distribution of speech information across the frequency spectrum. For example, if TFS was added to a region that contributed little to speech intelligibility, a smaller improvement in performance might be expected than if TFS information was added to a spectral region that contributed a lot to speech intelligibility, even if TFS information was equally available in the two cases. This is a particular concern when testing hearing-impaired subjects, as access to TFS information in a particular spectral region could be limited by the audibility of the signal in that region, even when frequency-dependent gains are applied to try to ensure audibility, as was the case here (see below). To assess the contribution of each spectral region to speech intelligibility, the importance of envelope information within each spectral region was assessed by comparing performance

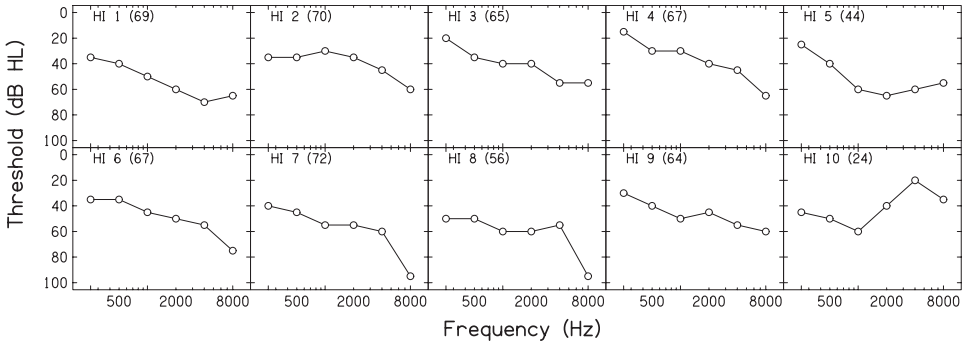

FIG. 2. Audiometric thresholds of the test ears of the hearing-impaired subjects. The age of each subject is shown in parentheses.

when a spectral notch was present in each frequency region (and all other regions were vocoded) to performance when all of the spectral regions were tone vocoded.

The frequencies at which TFS information is important would be expected to be different, depending on the type of information that is coded by TFS. If TFS information is primarily used for coding F0, TFS information should mainly be important for frequencies below about 1000 Hz, where resolved harmonics are present for the F0 values that typically occur in speech (although some information about the F0 would be present at higher frequencies, in the form of unresolved harmonics). If TFS information is used for coding information about the frequency spectrum of a sound, or for listening in the dips of a fluctuating masker, then TFS information could be important for frequencies above 1000 Hz, provided that the TFS information at these frequencies can be used by the central auditory system.

B. Methods

1. Subjects

The seven normal-hearing subjects who took part in experiment 1 also took part in experiment 2. Ten hearing-impaired subjects also took part. The audiometric thresholds of the test ears of the hearing-impaired subjects are shown in Fig. 2. The age of each subject is shown in parentheses. The better-hearing ear was used as the test ear for all subjects, apart from HI 10. The worse-hearing ear was used for HI 10 because this ear had previously been used for other psychoacoustic experiments in the laboratory. For the hearing-impaired subjects, the TEN(HL) test described by Moore *et al.* (2004) was used to assess whether cochlear dead regions were present. The results for the hearing-impaired subjects gave no evidence for cochlear dead regions between 500 and 4000 Hz in their test ears. None of the hearing-impaired subjects had air-bone gaps greater than 15 dB between 500 and 4000 Hz, indicating that their hearing losses were sensorineural in origin.

2. Stimuli, processing, and equipment

As for experiment 1, the target and background talker signals were summed, prior to further processing. The combined signal was filtered into 30 channels, as before, and the channels were divided into five spectral regions, each 6-ERB_N wide. The channel signals for four of the spectral regions were tone vocoded. For the remaining spectral region (1–5), two conditions were tested: one where the channel signals from that region were discarded (− conditions, 1−, 2−, 3−, 4−, and 5−), leading to a spectral notch in the processed signal, and one where there was unprocessed information in that spectral region (+ conditions, 1+, 2+, 3+, 4+, and 5+). For the hearing-impaired subjects, two comparison conditions were included: a condition where all channels were tone vocoded (allvoc), and a condition were all channels were unprocessed (allunproc). These conditions had already been included for the normal-hearing subjects, as part of experiment 1. For the normal-hearing subjects, as in experiment 1, the target speech was presented at a level of 65 dB SPL for SBRs of −16 dB or higher. The level of the competing talker was set to give the desired SBR. For SBRs lower than −16 dB, the level of the competing talker was not increased further, to prevent the combined signal from becoming uncomfortably loud. Instead, the level of the target talker was reduced to give the desired SBR. For the hearing-impaired subjects, gains were applied to the combined signal, according to the "Cambridge formula" hearing aid fitting prescription, individually according to the audiogram for each hearing-impaired subject (Moore and Glasberg, 1998). Gains were specified at audiometric frequencies between 250 and 6000 Hz. The Cambridge formula gains are designed to ensure speech audibility between these frequencies. The sentence material and test equipment were the same as for experiment 1.

3. Procedure

The procedure was the same as for experiment 1, except that the hearing-impaired subjects completed five runs per condition rather than three, so that the results for the different conditions could be compared more accurately for each subject, since previous studies have shown large individual differences among hearing-impaired subjects in their ability to use TFS (Lorenzi *et al.*, 2006; Hopkins *et al.*, 2008). For the normal-hearing subjects, experiments 1 and 2 were run simultaneously. Conditions from experiments 1 and 2 were interleaved during testing, and in cases where conditions for the two experiments were the same (for example the TFS-low CO=6 condition in experiment 1 and the 1+ condition in experiment 2), testing was not duplicated.

C. Results

Table II shows the mean scores [with corresponding standard deviations (SDs)] for the two comparison conditions and for each of the + and − conditions. The benefit

TABLE II. Mean and SDs of the SRTs for the normal-hearing and hearing-impaired subjects for experiment 2.

	Normal-hearing		Hearing-impaired	
	Mean	SD	Mean	SD
allunproc	−17.4	2.0	−5.8	6.3
allvoc	−10.9	1.1	−3.3	5.4
1+	−13.5	1.2	−3.8	6.2
2+	−14.0	1.6	−4.3	6.1
3+	−13.6	2.6	−3.7	5.2
4+	−12.7	1.5	−3.6	4.9
5+	−13.1	1.5	−3.2	4.9
1−	−8.6	2.2	0.9	4.4
2−	−7.5	2.8	1.3	5.0
3−	−6.4	2.5	−0.1	4.1
4−	−10.2	2.3	−1.9	4.8
5−	−10.0	3.5	−2.3	3.9

(improvement in SRT) from adding envelope information (open circles in Figs. 3 and 4) was calculated as the difference between the SRT for the allvoc condition and the SRT for the − condition for each spectral region. Similarly, the benefit from adding envelope and TFS information together (filled circles in Figs. 3 and 4) was calculated as the difference between SRTs for the − and the + conditions for each spectral region. The mean benefit scores for the normal-hearing subjects are shown in Fig. 3. A two-way within-subjects ANOVA on these scores showed significant effects of both spectral region (1–5) and information type (envelope and envelope+TFS) [$F(4,24)=4.65$; $p=0.006$ and $F(1,6)=6.46$; $p=0.04$, respectively], but no significant interaction between the factors [$F(4,24)=0.66$, $p=0.63$], suggesting that the relative benefit of TFS information was similar for each spectral region.

Mean benefit scores for the hearing-impaired subjects are shown in Fig. 4. A two-way within-subjects ANOVA on the mean benefit scores for the hearing-impaired subjects showed that there was a significant effect of spectral region [$F(4,36)=6.41$; $p<0.001$], but no significant effect of information type [$F(1,9)=0.03$; $p=0.87$], suggesting that, as a group, there was no significant benefit of TFS information over that provided by envelope information. There was no significant interaction between spectral region and the type of information that was added [$F(4.36)=1.11$; $p=0.37$]. However, there was a large amount of variability in the pattern of results across hearing-impaired subjects.

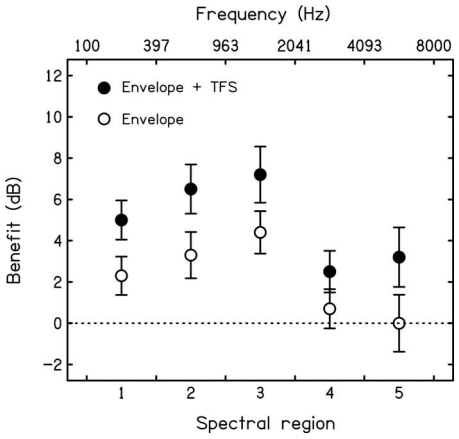

FIG. 3. Mean results of experiment 2 for the normal-hearing subjects. The benefit of adding envelope information (open circles) was calculated as the difference between the SRT for the allvoc condition and the SRT for the − condition for each spectral region. The benefit from adding envelope and TFS information together (filled circles) was calculated as the difference between SRTs for the corresponding − and + conditions. Error bars are plotted at ±1 standard error of the mean.

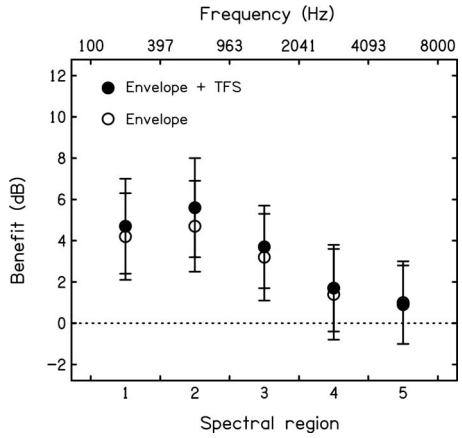

FIG. 4. As Fig. 3, but for the hearing-impaired subjects.

The individual results are shown in Fig. 5. Variability within individual subjects was also high, despite five SRT measurements per condition. Mean standard errors for the SRT measurements for individual subjects ranged from 0.6 to 1.5 dB. Some subjects showed a similar pattern of results to the normal-hearing subjects (e.g., HI 6 and HI 3, except for region 4), whereas other subjects showed no benefit from addition of TFS in most spectral regions (e.g., HI 1 and HI 4). A separate two-way ANOVA was performed on the benefit scores for each hearing-impaired subject with factors spectral region and information type. The benefit score for the addition of TFS information to a given spectral region was obtained as the difference between scores for the + and − conditions for that region. Even though there were five measures for each condition, the repetitions were not paired. Therefore, the difference between the mean scores for the five estimates in the + and − conditions was used in the ANOVA. This meant that there were no repeated measures. Hence, the interaction term was used to estimate the residual variance in the ANOVA. The effect of spectral region was significant ($p<0.05$) for subjects HI 1, HI 2, HI 4, HI 5, HI 6, HI 7, and HI 10, but the effect of information type was significant only for HI 6.

The mean benefit of adding TFS to the whole frequency spectrum (performance for the allunproc condition relative to performance for the allvoc condition) was 6.5 dB for the normal-hearing subjects, and 2.5 dB for the hearing-impaired subjects. A two-way, mixed design ANOVA with a between-subjects factor of subject type (normal-hearing and hearing impaired) and a within-subjects factor of condition (allvoc and allunproc) was performed on the SRTs for all subjects for the two conditions. The effects of subject type and condition were both significant [$F(1,15)=16.7$; $p<0.001$ and

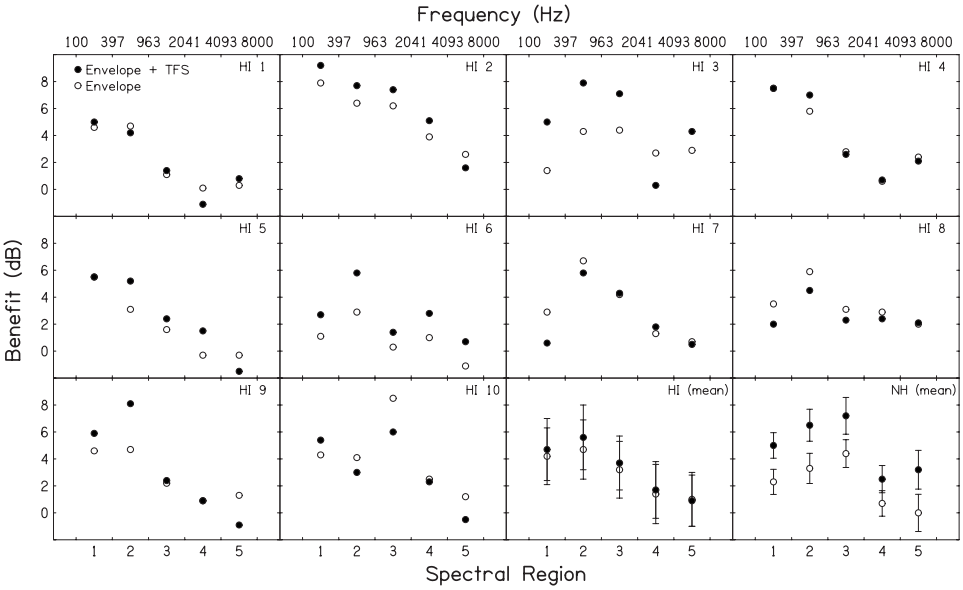

FIG. 5. Individual results of experiment two for the hearing-impaired subjects. Benefit scores were calculated in the same way as for Fig. 3. The bottom-right panels show the mean results for the hearing-impaired and normal-hearing subjects, for comparison. Error bars are plotted at ±1 standard error of the mean.

$F(1,15)=43.8$; $p<0.001$, respectively], and there was a significant interaction between the two factors [$F(1,15)=10.0$; $p=0.006$]. The individual scores for the hearing-impaired subjects are presented, together with the results of experiment 3, in Sec. VI B.

D. Discussion

For the normal-hearing subjects, the similar benefit of adding TFS information to the already-present envelope information for each of the spectral regions tested suggests that the importance of TFS information is not restricted to the coding of F0. If TFS information was only important for coding the F0s of the target and competing talkers, the most benefit would be expected for spectral regions 1 and 2, where resolved harmonics would have been present. The results are consistent with the idea that TFS information is important across the frequency spectrum. TFS could be important for coding the frequencies at which there are spectral peaks. For example, if at a particular time, there is a formant centered at frequency *fx* (and hence, one or more relatively intense stimulus components near *fx*), then, provided that these stimulus components are unresolved, channels centered close to *fx* will show TFS synchronized to *fx*, and this will be reflected in the patterns of phase-locking in those channels. Physiological evidence suggests that there may be insufficient information in the rate-place code to represent vowel formants at high levels (Young and Sachs, 1979). If information from the timing of spike discharges is included, then the representation of vowel formants is stable over a wide range of sound levels (Young and Sachs, 1979).

TFS information may also be important for conveying information about the quality of sounds. For example, a fricative such as *s* or *sh* has energy at high frequencies that is noisy. Replacing this noisy TFS information with a tone, as occurs with tone-vocoder processing, may impair the perception of fricatives, if information about the quality of the sound (its noisiness in this case) is carried by TFS information.

Another possible role for TFS information is related to listening in the dips. Hopkins and Moore (2009) showed that normal-hearing subjects benefited more from TFS information when listening in modulated noise than in steady noise. In the present study, TFS information could have been used for dip listening at any frequency region, provided the TFS information could be used by the central auditory system.

The benefit from TFS information at high frequencies (above 4000 Hz) is somewhat surprising, as it has traditionally been assumed that phase-locking information above 4000–5000 Hz is unusable. This assumption comes from physiological data in mammalian species other than humans, showing that phase locking to pure tones above this frequency is much degraded. Additionally, human psychophysical measurements that are assumed to reflect temporal mechanisms at low frequencies often worsen above 4000–5000 Hz (for example, pure-tone frequency discrimination), suggesting that temporal information is badly preserved at such frequencies. However, the limit of phase locking in humans is unknown. Heinz *et al.* (2001) used an auditory nerve model to investigate whether human pure-tone frequency and level discrimination could be accounted for by rate-place information alone at high frequencies. They used filters that had the same properties as human auditory filters (measured psychophysically) and phase-locking characteristics that were the same as those measured in the cat. They found that psychophysical performance was best predicted when both rate-place and temporal information were included in the model, for frequencies up to at least 10 000 Hz. This result suggests that, even if phase-locking characteristics in humans are similar to those in other mammalian species, some TFS information could be useful even at very high frequencies.

This hypothesis is supported by the data of Moore and Sek (2009b), who showed that normal-hearing subjects could discriminate complex tones on the basis of their TFS for frequencies up to at least 8000 Hz. They measured the discrimination of harmonic and "frequency-shifted" stimuli (where each component was shifted upwards by the same

amount in Hertz) that were filtered into the same frequency region to reduce excitation-pattern cues. They used the same method, as described in Sec. VI A (see later), but with high F0s (800 and 1000 Hz) and with the bandpass filter centered at 14F0 so that all of the components in the complexes fell above 8000 Hz. Moore and Sek (2009b) suggested that subjects may be able to use TFS derived from unresolved harmonics of complex tones at frequencies for which coding of pure tones using TFS is much reduced. They argued that, at high frequencies, the decoding of phase locking may be limited by refractoriness in the responses of auditory nerve fibers, because the refractory period of nerve fibers would be long relative to the time between peaks in the stimulus waveform. This means that the responses of many auditory nerve fibers would need to be compared to determine the frequency of a pure tone, because a single nerve fiber would be in a refractory state for many periods of the waveform. The situation is different for a periodic complex tone with the same center frequency that contains only harmonics that are unresolved. In this case, nerve fibers probably only fire in response to a few TFS peaks that are close to maxima in the envelope of the waveform. It is assumed that performance is based on time intervals between peaks in the TFS close to adjacent envelope maxima. These time intervals are much longer than the intervals between adjacent peaks in the TFS. Coding of these longer time intervals would be much less affected by refractoriness in auditory nerve fibers.

The reason that TFS information resulted in a reduction in SRT when added to the highest-frequency region alone could be related to the role of TFS information in conveying the noisy quality of the high-frequency energy in fricative sounds. The same result might not have been found if a noise vocoder had been used, rather than a tone vocoder, as in this case, the TFS information in the high-frequency channels would have retained a noisy quality when vocoded.

A possible concern with the methods used here is that the tone-vocoder processing introduces distortion in the envelope that could account for the poorer performance when the signals were entirely vocoded than when some unprocessed information was present. However, it seems unlikely that this could account for all of the differences in SRT that were observed. As described earlier, the correlations between the envelopes at the outputs of simulated auditory filters, in response to unprocessed and tone-vocoded stimuli, were high (over 0.93), and were similar when the simulated filters were 1-ERB_N or 2-ERB_N wide (simulating normal and impaired frequency selectivity, respectively). Given this, it is not clear why normal-hearing listeners would be affected differently than hearing-impaired listeners by the envelope distortions, and so it seems unlikely that this could account for the different pattern of results between the two groups. Also, for the highest spectral region (region 5), normal-hearing subjects showed almost no benefit from envelope information alone, but a large benefit when TFS and envelope information was added. It seems unlikely that this relatively large improvement could be accounted for by a slight improvement in envelope fidelity, given that envelope information alone had almost no effect on the SRT. However, disruption of envelope cues produced by the tone vocoder could account for some of the benefits that we have ascribed to the use of TFS information. Specifically, when TFS information was added in a particular spectral region (so that the signal was intact in that region), the envelope would have been coded somewhat more faithfully.

The results for the hearing-impaired subjects are consistent with those of Hopkins *et al.* (2008); the hearing-impaired subjects benefited less than the normal-hearing subjects from TFS information in speech, both when it was added to the whole spectrum, and when it was added to a narrow spectral region. The benefit to the hearing-impaired subjects from the addition of envelope information alone was similar to or larger than that found for normal-hearing subjects, which suggests that the gains that were applied to the signal, according to the audiogram of each subject, were successful in restoring audibility. The variability in the results across hearing-impaired subjects is also consistent with the findings of Hopkins *et al.* (2008), although the results for individual subjects were also rather variable, and so it was difficult to draw conclusions from the patterns of results for individual subjects. The lack of a significant benefit from the addition of TFS information for most of the hearing-impaired subjects could be due to the large standard errors associated with each benefit score. The differences across individual hearing-impaired subjects are discussed further in Sec. VI C.

VI. EXPERIMENT THREE: MEASURING SENSITIVITY TO TFS

The results of experiment 2 showed large individual variability in the ability of hearing-impaired subjects to benefit from TFS information in speech, when TFS information was added to the whole frequency spectrum. In experiment 3, sensitivity to TFS was measured for the same hearing-impaired subjects, using a psychophysical procedure. The results of the two experiments were compared to investigate the relationship between sensitivity to TFS in complex tones and the ability to use TFS information in speech in a competing-talker background.

A. Methods

The "TFS1" test described by Moore and Sek (2009a) was used, which is based on the method described by Hopkins and Moore (2007). The ten hearing-impaired subjects who took part in experiment 2 also took part in experiment 3. Four normal-hearing subjects (who did not take part in experiments 1 or 2) were also tested. The normal-hearing subjects were aged between 21 and 24 yrs and none were musically trained. The TFS1 test was designed as a quick method for measuring TFS sensitivity. The procedure took approximately 1 h, including task familiarization and practice runs. The same equipment was used as for experiments 1 and 2.

1. Stimuli

Subjects were required to discriminate harmonic tones (H) from frequency-shifted tones (S), in which each component was shifted upwards by the same amount in Hz(δ). Such complexes have the same envelope repetition rate, but differ-

ent TFS. Components were filtered using a fixed passband to minimize differences in the excitation patterns evoked by the H and S tones. The passband of the filter was 5F0 wide, and the skirts of the filter had a slope of 30 dB/octave. Two F0s were used (129 Hz and 264 Hz), and the bandpass filter was centered on the 11th harmonic in each case (corresponding to center frequencies of 1419 and 2904 Hz, respectively). These center frequencies were chosen to be the same as the center frequencies of spectral regions 3 and 4 in experiment 2. Center frequencies corresponding to spectral regions 1 and 2 in experiment 2 were not tested because Moore and Sek (2009a) showed that when the bandpass filter for the TFS1 test was centered at 11 times F0, normal-hearing subjects could only consistently perform the TFS1 test for center frequencies above 1100 Hz. The test was not used for a center frequency corresponding to that of region 5 because, at the time that the data were collected, the TFS1 test had not been validated for use with normal-hearing subjects at this frequency. More recently, Moore and Sek (2009b) showed that normal-hearing subjects could perform the task for frequencies up to at least 8000 Hz.

Complexes were presented at a level of 20 dB sensation level (SL), in threshold-equalizing noise (Moore *et al.*, 2000). The noise level, specified in a 1-ERB_N wide band centered at 1000 Hz, was 15 dB below the overall level of the complexes. The noise was designed to mask any combination tones and components on the skirts of the filter that were well away from the pass band. For the normal-hearing subjects, components as low as the seventh might have been audible in the background noise, and such components might have been partially resolved. However, the hearing-impaired subjects probably had broader auditory filters than normal, so it seems unlikely that they would have been able to resolve any components.

2. Procedure

A two-interval, two-alternative forced-choice task was used. Each interval contained four consecutive 200-ms complex tones. In one interval, all of the complex tones were harmonic (HHHH), and in the other, the tones alternated between harmonic and frequency shifted (HSHS). The subject was required to identify the interval that contained the frequency-shifted tones. The shift δ was varied adaptively in a two-up, one-down procedure. It was increased by a factor of k following an incorrect response, and reduced by a factor of k following two consecutive correct responses. For trials before the first turnpoint, k was equal to 1.953 (1.25^3). Then k was set to 1.5625 (1.25^2) until the second turnpoint had occurred; for trials after the second turnpoint, k was equal to 1.25. The threshold corresponding to 70.7% correct was estimated as the geometric mean of the values of δ at the last six turnpoints.

The largest difference between the H and S tones occurs for a frequency shift of 0.5F0. For some runs, a frequency shift larger than this was dictated by the adaptive procedure. If this happened three times in a run, then the test switched to a non-adaptive procedure. For these cases, the frequency shift was set at 0.5F0, 20 further trials were conducted, and the percentage of correct responses was measured.

3. Task familiarization and testing

The absolute detection thresholds for pure tones at each center frequency were determined at the beginning of the testing session using a two-down one-up adaptive procedure, so that the level of the H and S tones could be set accurately at 20 dB SL.

Hopkins and Moore (2007) reported that some hearing-impaired subjects performed no better than chance in a task similar to the one used here. To make sure that all subjects understood the task, a run was included that used the same procedure as the testing run, but different stimuli. Subjects were required to discriminate two harmonic tones with different F0s, rather than H and S tones. The same procedure and center frequencies were used as for testing. All of the subjects could perform the adaptive procedure for this task. Moore and Sek (2009a) reported only very small training effects for the stimuli and procedure described here. Consequently, just one training run was included with the test stimuli for each condition. Subjects then completed three test runs for each condition.

4. Analysis

In order to compare thresholds obtained from the adaptive procedure and percent correct scores from the non-adaptive procedure, both measures were converted to d' values (Green and Swets, 1974), using the method described by Hopkins and Moore (2007). Conversion was by means of a table of d' values for m-alternative forced-choice procedures (Hacker and Ratcliff, 1979). The adaptive procedure tracked the 70.7% correct point on the psychometric function, which corresponds to a d' of 0.78 for a two-alternative forced-choice task. When the adaptive procedure was used, the d' value that would have been measured for a difference of 0.5F0 Hz was calculated by dividing 0.78 by the threshold measured in the adaptive procedure, and by multiplying this value by 0.5F0. This is based on the assumption that d' is proportional to δ. The square root of the absolute value of the mean d' (with the sign of the values restored following transformation) was used in all of the statistical analyses, as this transformation results in roughly equal variance across conditions (Hopkins and Moore, 2007).

B. Results

A two-way, mixed model ANOVA was performed to assess the between-subject effect of subject type (normal-hearing or hearing impaired) and the within-subject effect of center frequency (1416 or 2904 Hz) on performance. The effect of subject type was highly significant [$F(1,12)=40.5$; $p<0.001$], but there was no significant effect of center frequency, or interaction between the factors [$F(1,12)=2.5$; $p=0.19$ and $F(1,12)=0.3$; $p=0.59$, respectively]. Consequently, further analysis was carried out on the mean d' scores for the two center frequencies for each subject. Figure 6 shows the benefit from adding TFS information to the whole frequency spectrum (bottom, quantified as the difference between SRTs for the unprocessed condition and those for the condition where all frequency channels were vocoded, as measured in experiment 2) and the d' values for

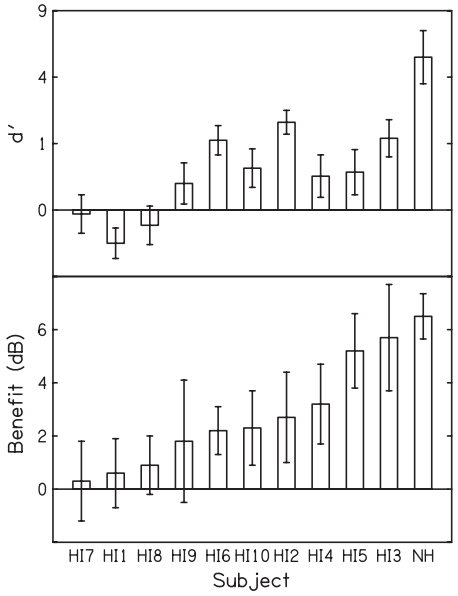

FIG. 6. Individual results for the hearing-impaired subjects and mean results for the normal-hearing subjects for experiments 2 and 3. The benefit from adding TFS information to the whole spectrum, as measured in experiment 2, is plotted in the bottom panel, ordered by performance. Scores from experiment 3 are plotted in the top panel, in the same order. Error bars show ±1 standard error of the mean.

TFS sensitivity (top), for each hearing-impaired subject. The mean results for the normal-hearing subjects are shown for comparison (note that different normal-hearing subjects took part in experiments 2 and 3, and so comparison of the individual data was not possible). The results are plotted with subjects in order of benefit from TFS as measured in experiment 2, and the results for the TFS1 test are plotted with subjects in the same order. For the hearing-impaired subjects, the benefit from adding TFS information in experiment 2 was significantly correlated with the mean TFS1 score from experiment 3 (Pearson's correlation coefficient, $r=0.66$, $p=0.04$). The same data are represented as a scatter plot in Fig. 7, with a regression line shown for the data from the hearing-impaired subjects. The line was calculated using a method described by Press *et al.* (1992), which minimizes the perpendicular distance between the points and the regression line, as is recommended for situations when there is variability in the data plotted on both axes. There was no

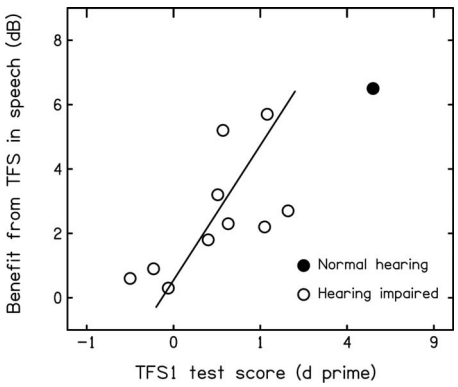

FIG. 7. As Fig. 6, but with the data plotted as a scatter plot, and a regression line fitted to the data for the individual hearing-impaired subjects.

significant correlation between the mean TFS1 scores and the mean absolute thresholds that were measured at the same center frequencies (1419 and 2904 Hz) for the hearing-impaired subjects ($r=-0.47$, $p=0.17$). However, the correlation between the means of the audiometric thresholds at 250, 500, 1000, and 2000 Hz, and the mean TFS1 scores, was significant ($r=-0.63$, $p=0.05$). The correlation between the mean audiometric threshold and the benefit from TFS information in speech was not significant ($r=-0.491$, $p=0.15$). When the effect of the mean audiometric threshold was partialled out, the correlation between the mean TFS1 test score and the benefit from adding TFS to the whole speech signal was not significant ($r=0.51$, $p=0.16$).

C. Discussion

The significantly better performance of the normal-hearing subjects than of the hearing-impaired subjects in discriminating complex tones on the basis of their TFS is consistent with the results of Hopkins and Moore (2007), who showed that hearing-impaired subjects with moderate cochlear hearing loss were very poor at discriminating similar stimuli. The results for the normal-hearing subjects are consistent with the results of Moore and Sek (2009a), who used the same method as was used here. They found that, for an F0 of 200 Hz and center frequency of 2200 Hz, normal-hearing subjects with little training had a mean threshold of 22 Hz, which is equivalent to a d' of 3.5, calculated using the method described in Sec. VI A 4.

Together, the results of experiments 2 and 3 support the idea that hearing-impaired subjects are less able to use TFS information than normal-hearing subjects, which is consistent with previous results (Buss *et al.*, 2004; Lacher-Fougère and Demany, 2005; Lorenzi *et al.*, 2006; Moore *et al.*, 2006a; Hopkins and Moore, 2007; Hopkins *et al.*, 2008). A deficit in TFS processing could occur by a number of mechanisms. A deficit in phase locking would reduce the fidelity of transmission of TFS to the central auditory system. Such a deficit was found in a physiological study of animals with induced hearing loss (Woolf *et al.*, 1981), although in a similar study such a deficit was not found (Harrison and Evans, 1979). It remains unclear whether such a deficit exists in human listeners with cochlear hearing loss. Another possibility is that the TFS processing deficits arise as a result of the broadened auditory filters that are typically found in subjects with cochlear hearing loss (Glasberg and Moore, 1986). The TFS at the output of a broader auditory filter would be more complex than for a narrower filter with the same center frequency, and this more complex information could be uninterpretable by the central auditory system.

The correlation between the benefit obtained from the addition of TFS to the whole speech signal and the sensitivity to TFS, measured using the TFS1 test, was modest, but significant. However, the correlation decreased and became non-significant when the effect of the mean audiometric threshold was partialled out. This could be taken as indicating that the correlation between the measures of sensitivity to TFS obtained in experiments 2 and 3 occurred partly because both were related to the absolute threshold. However, this

seems unlikely for the following reasons. First, scores for the TFS1 test were not significantly correlated with absolute thresholds at the center frequencies used for the TFS1 test. Second, the benefit from TFS information in speech, as measured in experiment 2, was not significantly correlated with the mean audiometric threshold.

The benefit scores for the addition of TFS information to the whole speech signal were associated with large standard errors for individual subjects. The correlation between the measures of sensitivity to TFS for experiments 2 and 3 might have been larger if the benefit scores had been measured more accurately. Also, the correlation might have been more significant if a larger number of subjects had been tested. It was hoped that the benefit of adding TFS information to speech in a given spectral region would be predicted by the sensitivity of a subject to TFS measured using the TFS1 test at the same center frequency. However, the present results were too variable to test this hypothesis: there was no significant benefit of adding TFS information to a narrow spectral region, either for the hearing-impaired subjects as a group, or for most of the individual subjects. It is not clear whether this lack of significant benefit reflected a complete inability to use TFS information in a narrow spectral region, or whether significant benefits would have been measured, had the SRTs for each condition been determined more accurately. Also, Moore and Sek (2009a) showed that when the bandpass filter was centered at 11 times F0, normal-hearing subjects could only consistently perform the TFS1 test for center frequencies above 1100 Hz. Consequently, sensitivity to TFS could only be assessed using the TFS1 test for center frequencies corresponding to two of the five spectral regions that were tested. The TFS1 test cannot be used to assess sensitivity to TFS information for frequencies below 1000 Hz, where TFS information is expected to be important in coding F0 information.

VII. CONCLUSIONS

For normal-hearing subjects, the largest benefit (reduction in SRT) of adding TFS information to a vocoded target and competing-talker signal was obtained when TFS information was added to channels with center frequencies below 1000 Hz. This was the case regardless of whether TFS information was added cumulatively, starting from the low-frequency or the high-frequency channels. This is consistent with the idea that TFS is important for coding F0 information. However, some benefit from adding TFS information was measured when TFS was added to the high-frequency channels only. A corresponding benefit was not measured when TFS was added to the same channels when TFS was already present in the low-frequency channels, suggesting that there is some redundancy in TFS information across frequencies.

In a second experiment, the improvement in SRT, when TFS information was added to each of five spectral regions (spanning 100–8000 Hz) was similar across regions for normal-hearing subjects, suggesting that TFS is important for coding information over and above that related to F0.

Hearing-impaired subjects as a group did not show a significantly greater benefit when TFS information was added to an isolated spectral region than when envelope information alone was added. The benefit from adding TFS information to the whole frequency spectrum was correlated with a psychophysical measure of TFS sensitivity across individual listeners, which adds support to the idea that sensitivity to TFS information is important for listening to speech in a complex background.

(Received 20 March 2009; revised 16 December 2009; accepted 22 December 2009)

Identification functions of 20 initial and 20 final consonants were characterized in 9600 randomly sampled consonant-vowel-consonant (CVC) tokens presented in speech-spectrum noise. Because of differences in the response criteria for different consonants, signal detection measures were used to quantify identifiability. Consonant-specific baseline signal-to-noise ratios (SNRs) were adjusted to produce a d' of 2.20 for each consonant. Consonant identification was measured at baseline SNRs (B), at B−6, and at B+6 dB. Baseline SNRs varied by more than 40 dB for different consonants. Confusion analysis revealed that single-feature place-of-articulation errors predominated at the highest SNR, while combined-feature errors predominated at the lowest SNR. Most consonants were identified at lower SNRs in initial than final syllable position. Vowel nuclei (/ɑ/, /i/, or /u/) significantly influenced the identifiability of 85% of consonants, with consistent vowel effects seen for consonant classes defined by manner, voicing, and place. Manner and voicing of initial and final consonants were processed independently, but place cues interacted: initial and final consonants differing in place of articulation were identified more accurately than those sharing the same place. Consonant identification in CVCs reveals contextual complexities in consonant processing.

I. INTRODUCTION

Although most spoken syllables contain multiple consonants, consonant identification of large consonants sets in multi-consonant syllables has received relatively little study. The current experiment investigated the identification of 20 initial and 20 final consonants in a pseudorandomly sampled set of 9600 consonant-vowel-consonant (CVC) tokens presented in speech-spectrum noise.

A. Quantifying consonant identification

In their classic study, Miller and Nicely (1955) found that the identifiability of different consonants presented in noise varies substantially: some consonants (e.g., nonsibilant fricatives) were difficult to identify even at high signal-to-noise ratios (SNRs), while others (e.g., sibilants) were accurately identified at much lower SNRs. For example, /ʃ/ hit rates at SNRs of −12 dB were similar to /ð/ hit rates at SNRs of +6 dB. Their results also suggested that comparisons of consonant identifiability using hit rate alone are potentially confounded by response biases associated with different consonants. For example, they found that hit rates for /v/ were much higher than hit rates for /ð/. However, at low and intermediate SNRs, the majority of /v/ responses were elicited by other consonants, particularly /ð/. Indeed, CVs containing /ð/ elicited more false /v/ responses than /ð/ hits. Similarly, Wang and Bilger (1973) found that CVs containing /ð/ elicited nearly twice as many false /v/ responses as /ð/ hits, while false /ð/ responses were rarely elicited by CVs containing /v/. Such asymmetric confusion patterns suggest that subjects have significant response biases: among confusable consonants, ambiguous phonological cues are much more likely to elicit the report of some consonants (e.g., /v/) rather than others (e.g., /ð/).

As a result, hit rate alone can misrepresent consonant identification accuracy. Metrics are needed that incorporate information from both hit and false response rates. Signal detection theory (Green and Swets, 1974) provides two such metrics: d', a measure of receiver sensitivity that quantifies the discriminability of sensory information, and beta, a criterion metric that quantifies the amount of sensory evidence needed to elicit a particular response. Therefore, the current experiments incorporated signal detection measures to quantify consonant identification performance following similar methods used in previous studies (Müsch and Buus, 2001b, 2001a).

B. Consonant identifiability in noise

Several previous studies have investigated the identification of small consonant sets in CVC syllables. Boothroyd and Nittrouer (1988) developed matched sets of 120 words and 120 nonsense syllables by combining ten initial consonants, ten vowels, and ten final consonants. Although they did not analyze the identification of individual consonants, their results suggested that initial consonants, final consonants, and vowels were processed independently in nonsense syllables. Benkí (2003) presented Boothroyd and Nittrouer's

[a)]Author to whom correspondence should be addressed. Electronic mail: dlwoods@ucdavis.edu

(1988) nonsense CVC tokens to 37 undergraduates and analyzed consonant-confusion patterns at four different SNRs spanning a range of 9 dB. Because of the small number of CVC tokens, separate subjects were tested at each SNR to avoid token repetition. Benkí (2003) found large differences in the identifiability of different consonants. For example, the sibilant /s/ was almost perfectly identified even at the most difficult SNR, whereas the non-sibilant fricative /f/ was frequently misidentified even at the highest SNR. These results imply that different consonants require markedly different SNRs for identification. However, because Benkí (2003) used only ten consonants, confusions between many potentially confusable consonant pairs (e.g., /s/ and /ʃ/) could not be examined. Moreover, because only 240 of 1000 possible CVC combinations were used, it was impossible to independently analyze the processing of initial consonants, final consonants, and vowels. Redford and Diehl (1999) used a completely randomized set of CVCs created by using the consonants /p/, /t/, /k/, /f/, /θ/, /s/, and /ʃ/) at initial and final positions combined with the three vowels /ɑ/, /i/, and /u/. The CVCs were presented at mid-sentence in different sentence contexts at SNRs of +15 dB. Significant differences were again found in consonant identification accuracy with non-sibilant fricatives proving particularly difficult to identify (e.g., /f/ and /θ/).

Previous studies of consonant identification in CVCs used small consonant sets and thus may have overestimated the identifiability of many consonants. For example, the unvoiced plosives (/p/, /t/, and /k/) are often confused with each other, but may also be confused with voiced plosives, affricates, /h/, and other unvoiced fricatives. The study of consonant identification in larger consonant sets has been largely restricted to single consonant (CV and VC) syllables. Miller and Nicely (1955) analyzed the identification of 16 common initial consonants in CVs with the vowel /ɑ/. There were five female participants, four of whom identified consonants in the CVs spoken by the fifth. Talkers rotated on successive blocks so that a total of approximately 7000 different tokens were presented at seven different SNRs ranging from −18 to +12 dB. Confusion matrices for 4000 CV token presentations (approximately 250 presentations of each consonant) were obtained at each SNR and revealed large differences in the identifiabilities of different consonants. For example, nasals were more accurately identified at −12 dB than non-sibilant fricatives (e.g., /θ/) at +6 dB. The percentage of consonants correctly identified improved with SNR, with mean hit rates increasing from 7.8% at −18 dB to 90.6% at +12 dB, producing an average performance/SNR (P/S) slope of 2.8%/dB. They found that the slopes of P/S functions were generally steepest around SNRs near mid-performance (e.g., 50% correct) levels. However, differences in the P/S slopes were evident for different consonants. For example, plosives had steeper P/S slopes (e.g., /t/ 5.9%/dB) than non-sibilant fricatives (e.g., /θ/ 2.3%/dB).

Wang and Bilger (1973) studied consonant identification in broadband noise using two different CV and VC lists, each with 16 consonants. They found large differences in consonant identification for both CVs and VCs, with non-sibilant fricatives again proving particularly difficult to identify. Phatak and Allen studied consonant identification in both speech-spectrum noise (Phatak and Allen, 2007) and white noise (Phatak *et al.*, 2008) using CVs containing 16 consonants paired with four vowels. Nasal consonants proved easy to identify in white noise but hard to identify in speech-spectrum noise. Again, non-sibilant fricatives proved particularly difficult to identify in both noise conditions. For example, /ð/ hit rates in speech-spectrum noise at 0 dB SNR were similar to /z/ hit rates at −22 dB SNR.

C. The identification of leading and trailing consonants

Several previous studies of CVCs have reported that initial consonants are more accurately identified than final consonants. For example, Benkí (2003) found lower error rates for initial than final consonants at all SNRs tested. Redford and Diehl (1999) also found that initial consonants were more accurately recognized than final consonants across most listening conditions. However, Redford and Diehl (1999) noted that the initial consonant advantage was absent for some consonants (e.g., /θ/) and was influenced by vowel context, being enhanced in syllables containing /ɑ/. Similar initial consonant advantages have been found in comparisons of CVs and VCs (Wang and Bilger, 1973; Dubno and Levitt, 1981). However, a recent study investigating consonant identification in CVs and VCs found the opposite result: final consonants were identified more accurately than initial consonants in six-talker speech babble (Cutler *et al.*, 2004). These unexpected results may have reflected differences in initial and final consonant masking levels. The babble-noise masker was created by manually selecting 1 s segments of continuous speech from each of six different talkers and then combining the six speech segments. This procedure may have resulted in a better alignment of the speech-babble amplitude envelopes at babble onset so that greater masking would have occurred for initial than final consonants.

D. Analyzing phonetic features

Consonant identification requires the accurate analysis of place, manner, and voicing features. Considerable evidence suggests that these features differ in their discriminability in noise. For example, Dubno and Levitt (1981) studied consonant confusions in speech-spectrum noise in 11 different CV and VC lists. In each list, seven, eight, or nine different consonants were presented with a single vowel (/ɑ/, /i/, or /u/) in speech-spectrum noise. They found higher rates for place than for manner errors, and higher rates for place errors than combined place+manner (P+M) errors. Because voiced and unvoiced consonants were presented in separate lists, voicing errors could not be evaluated. Other studies using larger consonant sets including both voiced and unvoiced consonants also found that place errors were more common than manner errors, and that both place and manner errors were more common than voicing errors (Miller and Nicely, 1955; Wang and Bilger, 1973; Levitt and Resnick, 1978; Helfer and Wilber, 1990; Gelfand *et al.*, 1992; Phatak and Allen, 2007; Phatak *et al.*, 2008).

E. Vowel influences on consonant identifiability

Previous studies also found that vowels influence consonant identifiability. For example, Wang and Bilger (1973) found that consonant identification varied with vowel: consonant report was most accurate for syllables containing /ɑ/, intermediate for syllables with /i/, and lowest for syllables containing /u/. Moreover, vowel context affected the identifiability of leading and trailing consonants differentially: leading consonants were more accurately identified in syllables containing /ɑ/ and trailing consonants were more accurately identified in syllables containing /i/. Dubno and Levitt (1981) also found an overall superiority of consonant processing in syllables containing /ɑ/. In particular, nasals were identified approximately twice as accurately in syllables containing /ɑ/ than in syllables containing /i/ or /u/. In contrast, affricates were most accurately reported in syllables containing /i/. In addition, they found an interaction between place of articulation and vowel: front and middle consonants were less accurately reported in syllables containing /i/ than /u/, whereas the reverse pattern was found for back consonants. Finally, in CVCs, Redford and Diehl (1999) found that vowel effects differed for initial and final consonants within a syllable: initial consonants were most accurately reported in syllables containing /ɑ/, whereas final consonants were most accurately reported in syllables containing /u/.

F. Interactions in identifying initial and final consonants

Interactions in the processing of initial and final consonants in CVCs have not been systematically examined. However, consonant-consonant interactions are known to alter the processing of place-of-articulation features over syllable-length silent gaps (Mann and Repp, 1981). This raises the possibility that interactions in the processing of initial and final consonant features might be observed in CVCs, for example, if stimulus-specific neuronal adaptation (Woods and Elmasian, 1983) reduced the salience of repeated consonant features.

G. The current experiment

The goal of the current experiment was to characterize the identification of consonants in CVCs that included 20 initial and final consonants combined with three vowels (/ɑ/, /i/, and /u/). In order to estimate average consonant confusions, performance measures were obtained from the pseudorandom sampling of 9600 different CVC syllable tokens. The large consonant set permitted the examination of an extensive set of potential consonant confusions. Signal detection theory was used to measure identification performance for each consonant over a consonant-specific range of SNRs adjusted to equate overall identification performance for different consonants. This permitted the characterization of both baseline identifiability and P/S functions for each consonant in initial and final syllable positions. This further allowed comparisons of the identifiabilities of consonant groups sharing similar place, manner, or voicing features as well as an analysis of the patterns of feature-processing errors (single-feature place, manner, voicing errors, and combined-feature errors) in initial and final syllable positions at different SNRs. Finally, the use of CVCs permitted an analysis of the effects of the vowel nucleus on the identifiability of initial and final consonants as well as the evaluation of possible interactions in the processing of initial and final consonants within a CVC.

II. METHODS

The present report describes consonant identification and consonant confusions observed in 34 560 trials, obtained from 16 young normal-hearing subjects who each participated in three separate 1 h testing sessions. Additional details about test-retest reliability, the relationship of consonant identification performance to audiometric thresholds, interactions in the processing of initial and final consonants in word and nonsense syllable tokens, and the relationship of consonant identification performance to sentence reception thresholds are provided elsewhere (Woods *et al.*, 2010).

A. Subjects

Sixteen young subjects (eight female and eight male, ages 18–30 yrs) with normal hearing (thresholds ≤20 dB hearing level at 250–4000 Hz)[1] each participated in three testing sessions within 11 days.

B. Syllable tokens

The CVC list included 1200 syllables constructed from the exhaustive combination of 20 initial consonants, 20 final consonants, and three vowels (/ɑ/, /i/, and /u/). Twenty-one consonants (/b/, /d/, /g/, /r/, /l/, /ŋ/, /n/, /m/, /v/, /ð/, /z/, /ʤ/, /ʧ/, /ʃ/, /s/, /θ/, /f/, /p/, /t/, /k/, and /h/) were used, 19 in both initial and final syllable positions, /h/ occurring in only the initial position, and /ŋ/ in only the final position. The token corpus was created by first recording 4800 syllable sets from each of four phonetically trained talkers (two male and two female) using an AKG C-410 head mounted microphone in an Industrial Acoustics Company (New York, NY) sound booth. The four talkers had been raised in different parts of the United States (two in the Midwest and two in California) and had slightly different American English speech patterns. Syllables were digitized at 16 bit resolution and 44.1 kHz sampling rate using MATLAB (The MathWorks, Inc., Natick, Ma). The complete syllable sets were reviewed by one of the authors (E.W.Y.) and the two best exemplars of each syllable (2400 tokens) were selected from each talker's corpus. Then, two listeners with normal hearing independently reviewed each of the 9600 syllables in the absence of masking noise to assure the intelligibility of all tokens. Whenever the intelligibility test failed, a new exemplar was substituted and further testing was performed among laboratory staff to assure the intelligibility of the substituted tokens. Within the entire 9600 token corpus syllable durations ranged from 350 to 890 ms (mean: 636 ms). For each token, 100 ms at the center of each vowel was identified by manual review to establish the time interval over which the noise masking levels would be linearly adjusted (on the dB scale) to provide appropriate masking levels for initial and final consonants differing in intrinsic identifiability (Fig. 1).

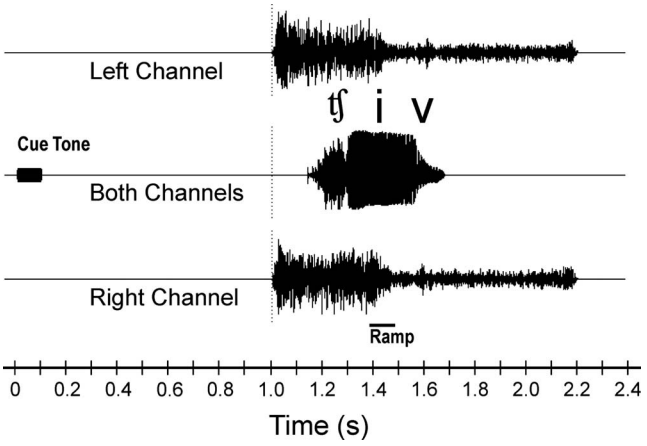

FIG. 1. Trial structure. Trials were cued by a 1.0 kHz tone. After 1.0 s two independent 1200 ms noise bursts were presented through the left and right loudspeakers. CVCs were presented simultaneously through both loudspeakers at random intervals after noise-burst onset. Noise amplitudes were modulated over a 100 ms interval during the mid-vowel segment of the CVC to provide appropriate masking levels for different initial and final consonants.

C. Speech-spectrum noise adjustment

Talker-specific speech-spectrum noise was used to mask each CVC token. The average spectrum for each talker was first obtained by averaging the spectra of all CVC tokens for that talker. This spectrum was then used to create a finite impulse response filter that was used to filter broadband white noise. Each filtered-noise file was trimmed of the first 0.5 s and cut into 100 different noise segments of 1200 ms duration each, which were then randomly sampled during the testing sessions.

D. Stimuli and procedure

Testing was performed in a 2.44×2.44 m single-walled, sound-attenuating testing room. The interior walls were covered by 2.5 cm thick acoustic foam resulting in ambient third-octave noise levels less than 20 dB sound pressure level (SPL) from 250 to 4000 Hz. In anticipation of future studies of hearing-impaired subjects with hearing aids, stimuli were presented through loudspeakers (M-Audio Studiophile AV 40). Immediately before the first CVC session, subjects were briefed with written and oral instructions and received ~5 min of training in identifying CVCs presented without masking noise.

During each session, each subject was presented with 720 different CVCs selected by constrained random sampling of the 9600 tokens. The CVCs were grouped by talker into 30-trial blocks with 24 talker-specific blocks presented during each experiment. Each trial (Fig. 1) began with a tone burst cue (100 ms, 1.0 kHz tone, 70 dB SPL). After a delay of 1.0 s, two randomly selected talker-specific noise bursts were presented independently through the left and right speakers, along with a single CVC presented synchronously from both loudspeakers. CVC onset times were randomized with respect to noise-burst onset with the constraint that each CVC began at least 100 ms after the onset of the noise bursts and ended at least 100 ms before their offset.

On each trial, the listener verbally reported the CVC token, referring, when necessary, to a list of acceptable initial and final consonants and vowels posted in the testing room. Responses were spoken into a microphone and phonetically transcribed using a modified QWERTY keyboard by an investigator (M.A.I.U.C.) listening through headphones in an adjacent room. Responses were spoken in quiet and subjects were queried via intercom when responses were invalid or poorly enunciated.[2] Subjects were given the option of repeating trials in cases of attentional lapse or noise interference (e.g., coughing, etc.). Each inter-trial interval of approximately 2 s included the time needed for syllable transcription plus a small delay (0.5 s) before the delivery of the warning tone signaling the next trial. Trials occurred at a rate of approximately 15/min so that each 720-syllable test required about 48 min in addition to rest breaks that occurred at each subject's discretion. Presentation software (NEUROBEHAVIORAL SYSTEMS, version 12.0) was used for stimulus delivery, masking noise and signal level adjustment, response monitoring, and d' calculations.

Syllable intensity was randomly roved from 70 to 75 dB SPL in 1 dB steps. Psychometric functions were measured for each initial and final consonant at three different SNRs: B−6, B, and B+6 dB relative to a baseline SNR (B) that was specific to each initial and final consonant. Consonant-specific SNR levels were established in preliminary experiments (see below). The SNR level (i.e., B−6 dB, B, or B +6 dB) varied randomly across trials.

During each test session, 720 tokens were randomly selected without repetition from the syllable corpus of 9600 tokens. Selection was constrained so that each initial and final consonant was presented exactly 12 times at each SNR. The 12 tokens included four syllables containing each of the three vowels /ɑ/, /i/, and /u/, with each syllable spoken by a different talker. CVC selection was selected based on the initial consonant, vowel, and final consonant so that each consonant was presented at initial and final syllable positions on 36 trials (i.e., 12 at each SNR) and each vowel was presented on 240 trials (80 at each SNR). Each token in the corpus had an equal probability of being presented. Following talker and CVC selection, one of the two CVC tokens spoken by that talker was randomly selected. This procedure resulted in the presentation of 240 tokens (60 from each talker) at each of the three baseline SNR levels (B−6, B, and B+6 dB). Because of the limited set of vowels and the low rate of vowel errors, only consonant identification was scored.

E. Baseline SNR adjustments to equate consonant identifiabilities

Two preliminary experiments were used to estimate the baseline SNRs needed to equate the identifiabilities of different consonants. In the first experiment, four members of the laboratory staff were tested repeatedly (22, 1 h sessions) while consonant-specific SNR levels were adjusted independently in initial and final syllable positions to equate the hit rates for different consonants. This approach revealed significant differences in the response criteria for different consonants. Therefore, signal detection theory was used to com-

TABLE I. SNRs used for the presentation of initial and final consonants in the main experiment.

	b	d	g	r	l	ŋ	n	m	v	ð	z	ʤ	ʧ	ʃ	s	θ	f	p	t	k	h
Initial	10.3	3.8	6.9	2.5	10.5	⋯	5.7	7.8	10.6	19.6	−2.6	−0.4	0.9	1.1	−7.4	19.7	9.1	12.7	−1.5	6.9	15.5
Final	13.0	11.6	13.8	−0.3	4.4	19.3	17.5	17.5	21.4	32.6	−1.8	4.5	0.4	0.3	−7.9	17.6	11.1	12.3	3.2	7.5	⋯

pute d' for each consonant using hit and false alarm (FA) rates. FAs were defined as consonant responses that occurred when a different consonant had been presented (e.g., a /v/ response when /ð/ was actually presented). An examination of the confusion matrices suggested that FAs did not occur randomly to all possible consonants, but rather occurred in response to a small group of potentially confusable consonants. For example, /p/ FAs occurred in response to /t/, /k/, /h/, /b/, and /g/ but were rarely observed in response to other consonants. On average, significant FAs (exceeding approximately 1% of total responses including hits) were produced by approximately 6.5 other consonants. Therefore, the FA rate was calculated by assuming a pool of 6.5 FA-producing stimuli. While assuming that a fixed pool size of FA-producing consonants was somewhat arbitrary, it eliminated the problem of estimating the FA-pool size for consonants identified using different criterion levels (see discussion below).

The results of the first preliminary study were used to adjust SNR levels to produce an estimated mean d' of 2.6 for each consonant that were used in the second preliminary experiment. Seven young naive volunteers with normal hearing participated after giving informed consent following local Institutional Review Board regulations. Each subject was tested on three occasions for a total of 21, 1 h sessions. Calculated d' values in the second preliminary experiment averaged 2.52 (72.9% correct) for initial consonants and 2.58 (74.8% correct) for final consonants.

The results of the second preliminary experiment were then used to make finer B-level adjustments in order to minimize variations in the identifiabilities of different consonants in the main experiment. In addition, the target d' was reduced to 2.20 (approximately 65% correct) to measure steeper portions of P/S functions. Additional baseline adjustments were also incorporated to equate performance for syllables spoken by different talkers (syllables spoken by female talkers were reduced by 1.8 dB on average) and for syllables containing different vowels (syllables with /i/ were reduced by 3.0 dB and those containing /ɑ/ were reduced by 1.2 dB relative to those containing /u/). The mean SNR values used for each consonant in the main experiment are shown in Table I. B values averaged 6.6 dB for initial consonants and 9.9 dB for independently adjusted final consonants. The range of B values needed to equate identifiabilities spanned 27.1 dB for initial consonants and 40.5 dB for final consonants.

F. Statistical analysis

The data were analyzed with analysis of variance (ANOVA) for repeated measures using the open-source CLEAVE program (T. J. Herron). The original degrees of freedom are reported for each test with the significance levels adjusted using the Box/Greenhouse–Geisser correction for inhomogeneity of variance when appropriate (Greenhouse and Geisser, 1959). In these cases, the original degrees of freedom are reported along with corrected significance (p) levels. Because of the large number of ANOVA comparisons, a relatively strict criterion ($p<0.01$) was used to evaluate statistical significance.

III. RESULTS

A. Quantifying consonant identification

On average, subjects correctly identified 64.1% of initial consonants and 65.2% of final consonants. However, although SNRs had been adjusted to equate d' values for all consonants, hit rates varied substantially for both initial consonants (range: 43.5%–82.5%) and final consonants (range: 43.2%–85.0%). Differences in hit rate were frequently accompanied by corresponding differences in FA rate. For example, the hit rate for /v/ was nearly twice as high as the hit rate for /s/ while the FA rate for /v/ was 8.8 times greater than the FA rate for /s/. Thus, these results revealed systematic differences in consonant response criteria similar to those observed in previous studies (Miller and Nicely, 1955; Wang and Bilger, 1973; Dubno and Levitt, 1981). The covariation in hit and FA rates was the primary reason that signal detection theory was used to analyze the results.

B. Consonant identifiability in noise

Analysis was first performed on initial and final consonants, averaged over vowels, speakers, and final or initial consonants, respectively. Thus, the d' value for each initial consonant reflected 1728 responses from the 16 subjects to 480 different randomly sampled CVC tokens beginning with

TABLE II. Observed d' and beta values for each consonant in initial and final positions.

that consonant and including 576 tokens presented at each SNR (B−6, B, and B+6). Table II shows d' and beta values for each consonant. The observed d' values averaged 2.18 for initial consonants (range 0.37d' units) and 2.19 for final consonants (range 0.48d' units). These values were similar to the targeted performance level ($d'=2.20$).

A repeated measures ANOVA was used to analyze the d' values for the 19 consonants that occurred in both the initial and final syllable positions. This analysis revealed that the mean SNRs of initial and final consonants had been effectively equated by the consonant- and position-specific SNR adjustments made on the basis of preliminary studies (position effect $[F(1,15)=0.45]$). However, the SNR adjustments had not fully corrected for small residual differences in the identifiabilities of different consonants, as reflected in a significant main effect of consonant $[F(18,270)=6.76,\ p<0.0001]$ reflecting differences in mean d' values for different consonants that ranged from 1.96 (/ð/) to 2.38 (/θ/).

The B levels needed to equate consonant identifiability at the $d'=2.20$ level based on the three-point psychometric functions of each consonant are shown in Table III. These values differed from the B values actually used (Table I) by an average of 0.09 dB (range −6.0 to +6.0 dB, excluding the final /ð/ and initial /θ/, the range was −1.9 to +2.3 dB). Standard errors of the SNR means across subjects averaged 0.62 dB. This suggests that the estimated B values needed to equate the identifiability of different consonants shown in Table III were generally precise to within less than 2.0 dB. Estimated B values spanned a range of 28.8 dB for initial consonants and 47.0 dB for final consonants.

B values varied with manner of articulation, with sibilants and affricates requiring the lowest SNRs, followed at increasing SNRs by liquids, plosives, nasals, and non-sibilant fricatives. In general, unvoiced consonants were identified at lower SNRs than voiced consonants. However, B values varied considerably even among consonant sharing similar manner and voicing. For example, among unvoiced plosives, /t/ was identified at SNRs about 10 dB lower than /p/, as was previously noted by Phatak and Allen (2007).

Beta values are also presented in Table II. There were no significant correlations between d' and beta for initial $[r(19)=0.04]$ or final $[r(19)=0.11]$ consonants. ANOVA for repeated measures was used to analyze beta values for the 19 consonants. There was a significant effect of consonant $[F(18,270)=20.79,\ p<0.0001]$ that reflected large differences in response criteria of different consonants. For example, subjects produced more than eight times more /v/ than /ʃ/ false alarms, reflected in respective beta values of 0.09 and 2.40.

Table IV shows the psychometric functions of d' and beta for the different consonants. Both beta and d' increased with increasing SNRs, but there was an insignificant correlation between their rates of increase ($r=0.26$). A repeated measures ANOVA was used to analyze the slopes of the d' P/S for the 19 consonants that occurred in both initial and final positions with consonant and position as factors. The position factor failed to reach significance. However, there was a highly significant main effect of consonant $[F(18,270)=23.68,\ p<0.0001]$. Non-sibilant fricatives (/v/, /ð/, /f/, and /θ/) had P/S functions with substantially shallower slopes (mean 0.08d'/dB) than did other consonant classes including plosives (0.15 d′/dB), sibilant fricatives (0.16d'/dB), nasals (0.16d'/dB), liquids (0.17d'/dB), and affricates (0.19d'/dB). Some of the differences in slope reflected the fact that certain consonants (e.g., the non-sibilant fricatives) remained hard to identify even at the highest SNRs. This was reflected in a highly significant correlation between the B values of each consonant and the slope of its P/S function $[r=-0.70,\ t(18)=5.82,\ p<0.001]$.

C. The identification of leading and trailing consonants

In agreement with previous reports (Wang and Bilger, 1973; Dubno and Levitt, 1981; Redford and Diehl, 1999), initial consonants were collectively detected at 3.3 dB lower SNRs than final consonants. However, this initial consonant advantage was not observed for all consonants: liquids were

detected at lower SNRs in final consonant position. There also remained small position × consonant interactions for d' [$F(18,270)=3.82$, $p<0.001$] after consonant- and position-specific B adjustments. For some consonants, d' values were higher in initial than final syllable position (e.g., /p/, /k/, and /ʃ/) but the opposite pattern was seen for other consonants (e.g., /ð/, /v/, and /s/). Beta values varied significantly with position [$F(1,15)=25.93$, $p<0.0001$] due to stricter criteria for initial than for final consonants (1.58 vs 1.46). Beta measures also showed a significant position × consonant interaction [$F(18,270)=15.89$, $p<0.0001$], reflecting the fact that some consonants showed different response criteria in initial and final syllable positions (e.g., /n/ and /l/).

Tables V and VI show the confusion matrices for the 34 560 initial and final consonants presented in the main experiment. The patterns of confusion resemble those reported in previous studies (Miller and Nicely, 1955; Wang and Bilger, 1973; Phatak and Allen, 2007). Across all consonants, FA rates in excess of 2% were produced by an average of 4.6 alternatives and FAs in excess of 1% were produced by an average of 7.2 alternatives. The remaining 11.8 response alternatives (particularly those differing in multiple phonetic

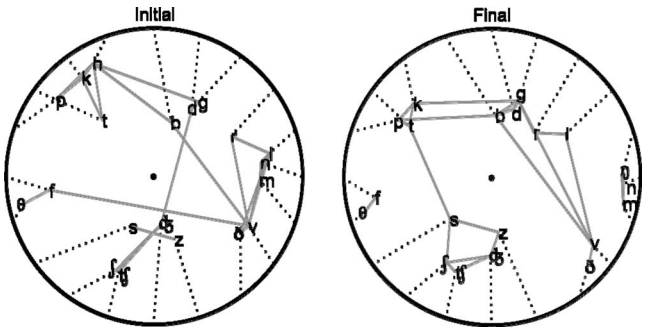

FIG. 2. Confusion clusters for initial and final consonants. Left: Consonant confusion clusters for initial consonants visualized using barycentric clustering. Initial consonants were first equally spaced around the confusion circle reflecting phonetic classification of voicing, manner, and place so that starting locations (clockwise from top center) were /b/, /d/, /g/, /r/, /l/, /n/, /m/, /v/, /ð/, /z/, /ʤ/, /ʧ/, /ʃ/, /s/, /θ/, /f/, /p/, /t/, /k/, and /h/, with /h/ adjacent to /b/. Then, each consonant was displaced from its initial position (dashed line) using iterated weighted averaging of its position with that of every other consonant based on the frequency of confusions between each consonant pair. Consonants that were frequently confused (e.g., /v/ and /ð/) cluster together at intermediate locations that also reflect confusions of one or both consonants in the pair with all other consonants. Gray lines connect the 12.5% of consonant pairs that showed greatest confusions. Right: Consonant confusion clusters for final consonants with starting position (top left-center) /b/, /d/, /g/, /r/, /l/, /ŋ/, /n/, /m/, /v/, /ð/, /z/, /ʤ/, /ʧ/, /ʃ/, /s/, /θ/, /f/, /p/, /t/, and /k/, with /k/ adjacent to /b/.

features from the target consonant) produced very low FA rates. Both FAs (in the columns) and misses (along the rows) were concentrated near the correct-response diagonal, indicating a preponderance of place errors. Other common confusions reflected manner errors conserving place and voice (e.g., /b/-/v/ and /b/-/m/ confusions) and voicing errors conserving place and manner (e.g., /b/-/p/ and /ʧ/-/ʤ/ confusions).

The confusion matrices presented in Tables V and VI reveal that consonants fell into confusable clusters of varying sizes. For some consonants, confusions were largely confined to consonants that shared manner (e.g., nasals in final consonant position). In contrast, other consonants showed confusions with larger consonant sets (e.g., initial /v/ with /b/, /ð/, /m/, /l/, /r/, and /f/). Figure 2 shows the clustering of consonant confusions, visualized using the barycentric algorithm developed by Cohen (2009) to characterize interrelated clusters of internet users. Consonants were initially placed in equidistant positions around a unit circle based on voicing, manner, and place features using the *a priori* consonant ordering shown in Tables V and VI. Unvoiced and voiced consonants were initially positioned on left and right sides of the circle, connected at the bottom across the voiced and unvoiced affricates and connected at the top across voiced and unvoiced plosives. Then, the location of each consonant was computed as an average of its current position, weighted by its hit rate, and the position of every other consonant weighted by number of false responses to that consonant. Two iterations were used to generate the cluster plots shown in Fig. 2. As a result of these iterations, each consonant was displaced from its initial position (dotted lines in Fig. 2) toward the locations of consonants with which it was confused.

Consonant pairs producing the most frequent confusions (top 12.5%, corresponding to total bi-directional confusion rates in excess of approximately 6% of hits) are shown connected by solid gray lines. For example, in final syllable position (Fig. 2, right) nasals were frequently confused with each other but rarely confused with any other consonants, so they moved to an intermediate position near /n/ on the circle edge. In contrast, in the initial syllable position (Fig. 2, left), the voiced sibilant /z/ was frequently confused with the unvoiced sibilant /s/ but also showed moderate rates of confusion with /t/, /ð/, /r/, and /d/, resulting in its displacement toward the center of the circle (Fig. 2, left).

The magnitude of the total displacement of consonants from their initial positions reflects both the initial consonant locations and the observed consonant confusions. For example, if two confusable consonants were initially placed in opposite positions on the confusion circle, both would move substantial distances toward the circle center. In contrast, if two confusable consonants were initially placed in adjacent positions, only small displacements would occur between their locations near the circle boundary. Thus, the overall magnitude of consonant displacement reflects in part the degree to which the initial consonant positions accurately predicted the confusions observed. In the current experiment, initial consonant placements were determined based on place, manner, and voicing features. Feature analysis (see below) revealed that place confusions occurred more frequently than manner confusions, and that manner confusions occurred more frequently than voicing confusions. Therefore, voiced and unvoiced consonants were placed on opposite sides of the circle. Within each voicing group, consonants were then segregated by manner. Finally, within each manner and voicing grouping, consonants were ordered by place of articulation. Consonants whose manner also defined that they are voiced (nasals and liquids) were centered within the voiced-consonant group. At the borders separating different manners, adjacent consonants were positioned to share place and voicing. Similarly, at the borders separating different voicings, adjacent consonants were positioned to share place and manner.

Permutation testing was used to evaluate how accurately the *a priori* consonant positions reflected the observed pattern of consonant confusions. This was accomplished by comparing the total consonant displacement distance with that produced by 10^7 unique random consonant positioning schemes. The *a priori* placement resulted in less displacement than 99.9998% of the random position schemes tested, with no significant differences observed between the magnitude of displacement obtained with the *a priori* positions and the magnitude of displacement obtained with the optimal random placement. This suggests that the initial consonant positions accurately captured the actual confusion clustering evident in the data.

Figure 2 shows the patterns of consonant confusions observed for initial and final consonants. Among initial consonants, the unvoiced plosives /p/, /t/, and /k/ were frequently confused with each other and also with /h/, and thus formed a relatively tight cluster in the upper right of the confusion circle. A relatively high frequency of /p/-/h/ confusions resulted in both /p/ and /h/ being attracted toward a location

intermediate between their initial positions. Because /t/ was occasionally confused with the sibilants and affricates located in the lower right quadrant of the circle, both /t/ and the sibilant-affricate cluster were displaced toward the circle center. These sibilant-affricate confusions were less common for /p/, /k/, and /h/, so these consonants remained closer to the circle circumference than /t/ in the unvoiced-plosive cluster.

Figure 2 shows clear confusion clustering of initial unvoiced plosives, voiced plosives, unvoiced non-sibilant fricatives, sibilants and affricates, voiced fricatives, and liquids and nasals. A few initial consonants (e.g., /v/, /b/, /h/, and /ʤ/) were frequently confused with consonants in more distant clusters. For example, voicing confusions were relatively frequent for /ʤ/-/ʧ/ pairs, and both of these consonants were confused with /ʃ/, /s/, and /z/. Similarly, voicing confusions occurred between /f/, /v/, /b/, and /h/, and manner confusions occurred between /b/ and /v/. In addition, /v/ was frequently confused with both nasals and liquids and was tightly clustered with /ð/, reflecting frequent confusions between this consonant pair. In general, confusion clusters were similar for initial and final consonants with a few exceptions. In the final consonant position, unvoiced plosives formed a tighter cluster in the absence of /h/, and nasals were particularly well discriminated from all other consonants including both voiced non-sibilant fricatives and liquids.

D. Analyzing phonetic features

Figure 3 shows the incidence of single-feature errors (place, manner, and voicing) and combined-feature errors for initial consonants (top) and final consonants (bottom) at the three different SNRs. Table VII shows the average number of consonants in each of the different feature-error categories.

ANOVA for repeated measures was first used to analyze error rates for different phonetic features with position, SNR, and feature (place-only [P], manner-only [M], voicing-only [V], P+M, P+V, M+V, and P+M+V) as factors. This analysis revealed no significant effect of position in the syllable, but revealed the expected main effect of SNR [$F(2,30)=1524.02$, $p<0.0001$]. There was also a large main effect of feature [$F(6,90)=467.28$, $p<0.0001$]: P errors were most frequent (10.2% of trials), followed by P+M (8.6%), M (6.6%), and V (3.3%) errors. The relatively high incidence of P+M errors has been reported previously (Dubno and Levitt, 1981) and reflected in part the fact that there were nearly twice as many consonants in the P+M category as the M category, and more than four times as many consonants in the P+M category as in the P category (Table VII). The remaining combined-feature errors generally occurred on less than 3% of trials except at the most difficult SNR. In addition, there were significant position × feature [$F(6,90)=85.85$, $p<0.0001$] and SNR × feature [$F(12,180)=138.01$, $p<0.0001$] interactions that were explored in additional ANOVAs.

The next ANOVA compared the incidence of different single-feature errors (P, M, and V). This analysis showed a main effect of feature [$F(2,30)=427.76$, $p<0.0001$], primarily reflecting the increased overall incidence of P errors

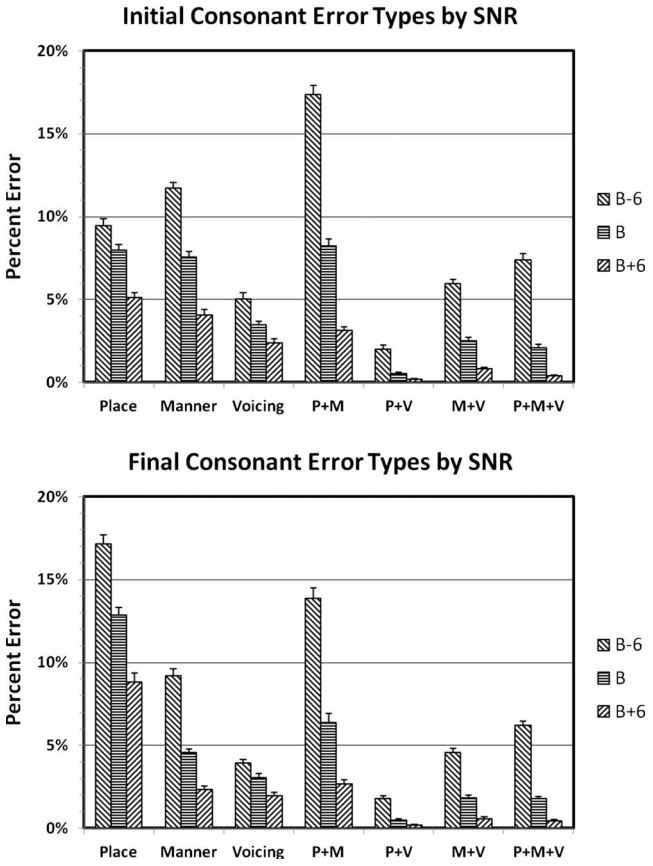

FIG. 3. Error rates for different phonetic features. Place, manner, voicing, P+M=place+manner, etc. Error bars show standard errors of the mean.

in comparison with M and V errors. There was also a main effect of position [$F(1,15)=22.18$, $p<0.0005$] due to fewer single-feature errors for initial than final consonants that was accompanied by a correspondingly greater incidence of combined-feature errors among initial consonants. Finally, there was a highly significant position × feature interaction [$F(2,30)=153.90$, $p<0.0001$], reflecting the fact that M and V errors were more common for initial than final consonants while P errors showed the opposite pattern.

In order to evaluate the changes in feature processing that accompanied increases in SNR, error rates for each feature and position were normalized relative to the total number of errors of each type. The SNR × feature interaction was significant [$F(12,180)=96.13$, $p<0.0001$], indicating that SNR differentially affected error rates for different features. An additional specific analysis examining only single-feature errors showed a significant effect of feature [$F(2,30)=53.02$, $p<0.000\,01$], reflecting the fact that M and V errors declined more rapidly than P errors with increases in SNR. Finally, additional *post-hoc* testing demonstrated that combined-feature errors declined more rapidly than P, M, or V errors ($p<0.001$ for all comparisons).

E. Vowel influences on consonant identifiability

The effects of vowel context on consonant processing were analyzed by comparing consonant identification performance as a function of the accompanying vowel for the 19 consonants that appeared in both initial and final syllable

TABLE VII. Average number of consonants sharing different features and combinations of features with each target consonant.

	Place	Manner	Voicing	P+M	P+V	M+V	PMV
Initial	1.30	2.50	0.70	5.30	1.10	2.60	5.50
Final	1.30	2.50	0.70	5.55	0.90	2.60	5.40

positions. The results were analyzed using repeated measures ANOVA with subjects, vowel, position, and consonant as factors. The SNRs of syllables containing different vowels had been adjusted in preliminary studies to reduce vowel-specific differences in overall mean syllable identifiability. As a result, the vowel main effect failed to reach significance [$F(2,30)=2.62$, $p<0.10$]. However, there was a highly significant vowel×position interaction [$F(2,30)=42.40$, $p<0.0001$]. This reflected the fact that initial consonants were identified more accurately than final consonants in syllables containing /ɑ/, whereas final consonants were identified more accurately than initial consonants in syllables containing /i/. Initial and final consonants were identified with comparable accuracy in syllables containing /u/.

There was also a highly significant vowel×consonant interaction [$F(36,540)=45.67$, $p<0.0001$], as shown in Table VIII. Separate ANOVAs analyzing vowel effects for each of the 19 consonants showed that d' measures for 16 of the 19 consonants (excepting /ʧ/, /d/, and /k/) were significantly influenced by the accompanying vowel. Vowel-related changes in d' ranged from 0.37 to 1.46 for different consonants and were generally highly significant [the average over all consonants was $F(2,30)=44.23$, $p<0.0001$]. For example, /m/ was identified much more accurately in syllables containing /ɑ/ than in syllables containing /i/ or /u/, producing vowel-related d' differences of 1.46. This would be equivalent to a 9.1 dB change in SNR estimated based on the P/S slope for /m/ ($0.16d'$/dB).

Figure 4 shows identification performance for initial and final consonants displayed on a vowel triangle with the distance of each consonant from each vowel apex inversely scaled by its d' value when presented with that vowel. Consonants with similar d' values for all vowels are located near the center of the triangle (e.g., /ʧ/). Figure 4 shows that initial nasals were preferentially identified with a /ɑ/, and better identified with /u/ than /i/, while final nasals were preferentially identified with a /ɑ/, but better identified with /i/ than /u/. Initial non-sibilant fricatives were poorly identified with /i/ and therefore clustered on the /ɑ/-/u/ boundary. In final syllable position, the fricatives /v/, /f/, and /θ/ showed less vowel specificity, while /ð/ was very poorly identified with both /a/ and /i/. Similarly, /t/ was poorly identified with /ɑ/ in both consonant positions, while /r/ was poorly identified with /u/ as an initial consonant and poorly identified with /ɑ/ as a final consonant.

Confusion matrices for initial and final consonants in syllables containing different vowels are included in Supplementary Tables 1–6 (see Supplementary material). Figure 5 shows the cluster confusion analyses as a function of vowel. An examination of the vowel effects on the confusion matrices clarifies the nature of the vowel-related changes in consonant confusions. For example, the confusion clusters of nasal consonants (/m/, /n/, and in final consonant position, /ŋ/) show that initial nasals are moderately confused with each other and also with the liquid /l/ when presented with /ɑ/. In contrast, when initial nasals were presented with /i/ or /u/ they were more often confused with each other (i.e., they are closer together in the confusion circle) and also confused with /l/, /r/, /v/, and /ð/. Similarly, final nasals presented with /ɑ/ are tightly clustered near the circle periphery, reflecting a low incidence of confusions with non-nasal consonants. They are also widely spaced from each other, reflecting enhanced within-nasal discrimination. Final nasals presented with /i/ remain distinct from other confusion clusters, but show increased within-nasal confusions. Final nasals presented with /u/ show a high frequency of within-nasal confusions as well as additional confusions with /l/ and /v/. Similarly, the poor discriminability of the final /ð/ when presented with /ɑ/ and /i/ can be seen to reflect its very poor discriminability from /v/. The discriminability of /v/ and /ð/ is improved when these consonants are presented with /u/.

Additional analyses were performed to examine the effects of vowel context on the processing of consonants with different manners, with vowel, position, and manner as factors. This analysis revealed a highly significant interaction between vowel and manner [$F(8,120)=125.44$, $p<0.0001$]. Sibilants, liquids, and plosives were identified most accurately in syllables containing /i/, non-sibilant fricatives were identified most accurately in syllables containing /u/, and nasals were identified most accurately in syllables containing /ɑ/.

The next analysis examined vowel context effects on

TABLE VIII. d' scores for initial and final consonants in syllables containing different vowels.

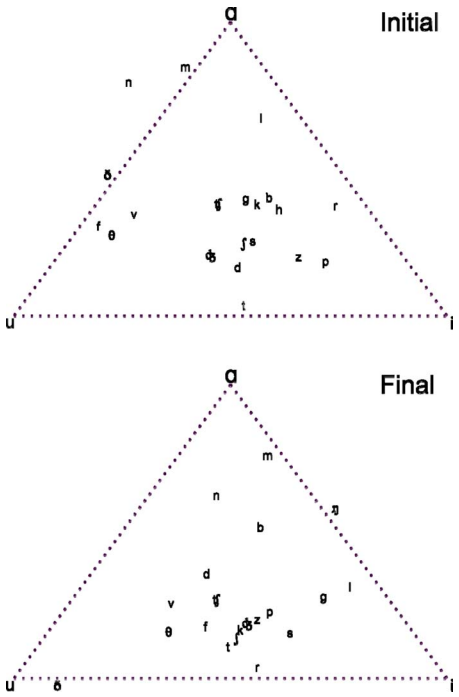

FIG. 4. (Color online) Consonant-vowel interactions shown on a triangular map of vowel space with the three vowels presented in the current experiment at the apices. The distance of each consonant from each vowel apex is inversely related to the d' measure for that vowel-consonant combination. Top=initial consonants; bottom=final consonants. The few consonants without significant vowel preferences (e.g., /ʧ/) are found near the center of the triangle. Consonants with strong vowel preferences lie closer to the preferred vowel (e.g., nasals are close to /ɑ/).

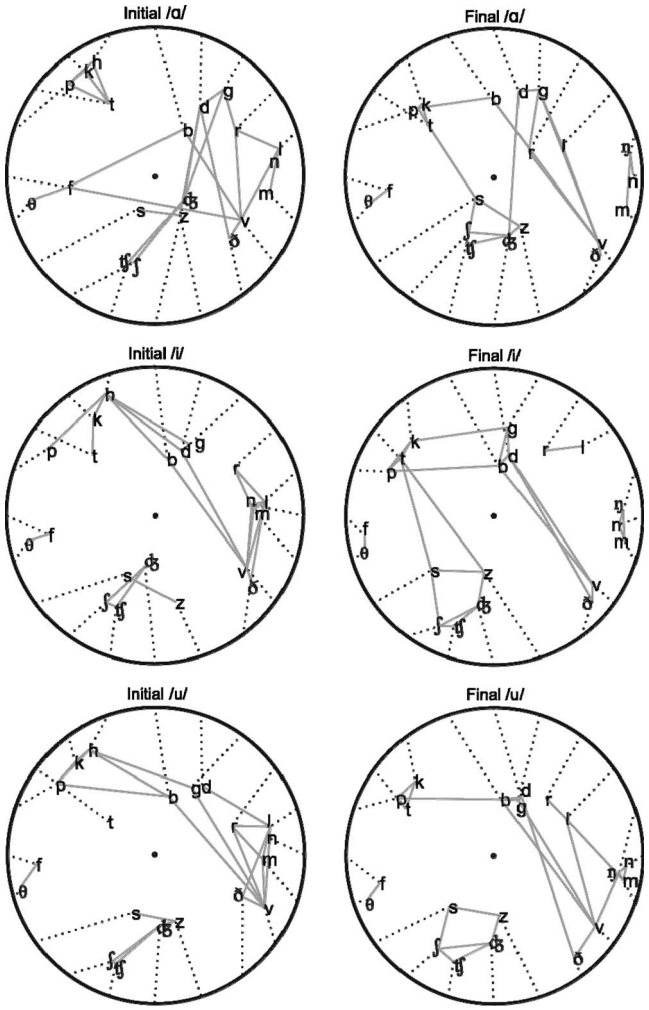

FIG. 5. Confusion clusters for initial (left) and final (right) consonants as a function of vowel. See Fig. 2 for further details.

place of articulation. There was a highly significant vowel $\times$place interaction $[F(4,60)=34.58,\ p<0.0001]$. Front consonants were perceived most accurately in syllables containing /ɑ/, middle consonants were perceived most accurately in syllables containing /u/, and back consonants were perceived most accurately in syllables containing /i/. There was also a significant interaction between vowel, syllable position, and place $[F(4,60)=6.02,\ p<0.002]$, indicating that vowel context effects on place differed at initial and final syllable positions.

Finally, there was also a significant vowel$\times$voicing interaction $[F(2,30)=57.97,\ p<0.0001]$. Unvoiced consonants were most accurately identified in syllables containing /u/, whereas voiced consonants were most accurately identified in syllables containing /ɑ/. There was no significant difference in vowel effects on the voicing of consonants at initial and final syllable positions $[F(2,30)=0.93, \text{NS}]$.

Vowel effects on feature processing were analyzed by evaluating the relative incidence of various types of feature errors in the vowel-specific confusion matrices presented in Supplementary Tables 1–6 (see supplementary material). An omnibus ANOVA indicated a highly significant interaction between vowel and error-type (P, M, V, P+M, P+V, M+V, and PMV) $[F(12,180)=33.70,\ p<0.0001]$ that was explored in additional ANOVAs. There were no significant main effects of vowel on the incidence of V errors $[F(2,30)=0.12]$ and only a trend toward a reduction in M errors with the vowel /i/ $[F(2,30)=3.36,\ p<0.06]$. However, there was a highly significant vowel main effect on the incidence of P errors $[F(2,30)=78.52,\ p<0.0001]$. P errors were increased in syllables containing /i/ relative to those containing /ɑ/ and /u/. P errors also showed a significant vowel$\times$position interaction $[F(2,30)=21.03,\ p<0.0001]$. Inter-vowel differences increased in the final syllable position due in large part to the overall increase in P errors in the final syllable position described above. An analysis of combined-feature errors also revealed a significant vowel main effect $[F(2,30)=53.81,\ p<0.0001]$ on the relative incidence of P+M errors. P+M errors were reduced in syllables containing /i/ relative to those containing /ɑ/ and /u/, without a significant vowel$\times$position interaction.

F. Interactions in identifying initial and final consonants

We evaluated the effects of consonant context using repeated measures ANOVAs with subject, vowel, consonant position, and matching of initial and final consonant features as factors. Separate analyses were performed for manner, place, and voicing features, each evaluated at the $p<0.01$ level of significance. There were no significant effects of matching on manner $[F(1,15)=1.58]$ or voicing $[F(1,15)=3.99,\ p<0.07]$. However, there was a highly significant

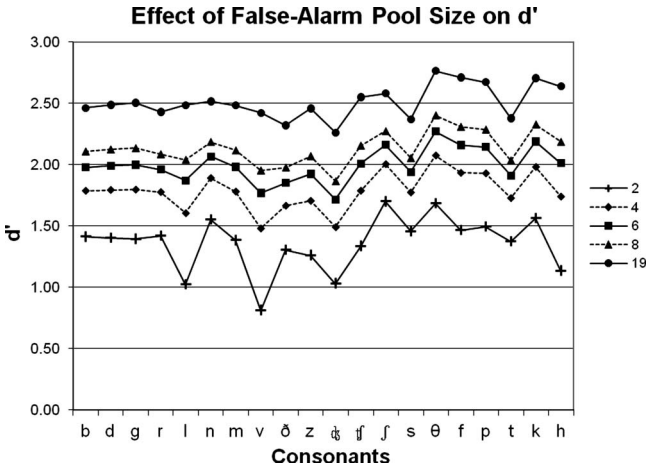

FIG. 6. d' values for initial consonants calculated with different false-alarm-pool sizes.

effect of matching on place $[F(1,15)=41.70,\ p<0.0001]$: subjects showed increased accuracy when initial and final consonants differed in place of articulation. This effect did not differ as a function of consonant position.

IV. DISCUSSION

A. Quantifying consonant identification

Both hit rate and d' were examined as metrics of consonant identification performance. Hit rates were confounded by large differences in response criteria associated with nearly ten-fold differences in the FA rates of different consonant responses. Miller and Nicely (1955) found similar results: up to ten-fold differences in the FA rates for different consonants at certain SNRs. Therefore, d' appeared to be a better metric for evaluating consonant identifiability because of its correction for differences in response criteria.

Unfortunately, there is no standard method of calculating d' under conditions where many potentially confusable signals are presented in noise. In the standard signal detection theory paradigm, the only trials presented are signal-plus-noise (associated with hits) or noise-alone (associated with FAs). However, in the current study, FAs assigned to a particular consonant response were usually generated by a number of different consonants with which it shared phonological and acoustic features. For example, /v/ FAs occurred on 29% of /ð/ trials, but on less than 0.2% of ʃ trials. These results suggest that some, but not all, consonants could be sensibly considered plausible FA-producing distractors. In our analysis we included only the plausible FA-producing consonants in the FA pool used to determine N, the divisor for the FA rate calculation. As noted in Sec. II, the size of the FA pool was estimated to be 6.5 consonants based on preliminary studies. This FA-pool size corresponded to consonants producing FA rates in excess of approximately 1.3% and was slightly greater than a FA-pool size (5.3) based on consonants that shared two phonetic features (e.g., manner and voicing) with each response.

Figure 6 shows d' values for initial consonants calculated using different FA-pool sizes ranging from 2 to 19 consonants. Increasing the FA-pool size decreases in FA rate and correspondingly increases the d'. The increase in d' values is greatest for consonants with high FA rates, e.g., /v/, /l/, and /h/ in Fig. 6. Although the d' curves differ somewhat at extreme FA-pool sizes, they have similar shapes over intermediate FA-pool sizes, indicating that the current results are largely insensitive to changes in the FA-pool size over realistic intermediate ranges.

B. Consonant identifiability in noise

The current experiment assessed listeners' abilities to identify 20 initial and 20 final consonants using spoken responses that included the majority of potential consonant confusions. To assure that confusion patterns were representative of average articulation patterns, syllables were randomly sampled from a set of 9600 tokens with equal sampling of each talker, vowel, and consonant at each SNR. Because the results of the current study are based on the random sampling of a very large CVC token set, they provide insights into the identification of American English consonants in typically articulated CVCs.

It is well known that some consonants are much easier to identify in noise than others (Wang and Bilger, 1973; Dubno and Levitt, 1981; Dubno *et al.*, 1982; Helfer and Huntley, 1991; Gelfand *et al.*, 1992; Benkí, 2003; Cutler *et al.*, 2004; Phatak and Allen, 2007; Phatak *et al.*, 2008). Previous studies suggest that SNR levels must be adjusted by 18 dB (Miller and Nicely, 1955) to 24 dB (Phatak and Allen, 2007) to equate hit rates across all consonants in 16-consonant sets. We found that even larger differences in SNR were needed to equate consonant identifiability in a 20-consonant set of initial (28.8 dB) and final (47.0 dB) consonants. The increased range of SNRs needed to equate consonant identifiability likely reflects in part the increased number of possible consonant confusions. The addition of the consonants /l/, /r/, /ʧ/, /h/, and /ŋ/ in the 20-consonant sets increased potential confusions for many consonants (particularly /ð/), reducing their discriminability and correspondingly increasing their required baseline SNR levels.

The pattern of results shown in Table III suggests that a subset of consonants (sibilants, affricates, liquids, and some plosives) provides the majority of consonant information in difficult listening situations (e.g., absolute SNRs less than 6 dB). Consonant information becomes available from less easily identified consonants only at higher SNRs. The results also revealed surprisingly large differences in identifiability of different consonants within the same phonetic class. For example, among initial plosives, baseline SNRs for /p/ and /t/ differed by 12.4 dB, while baseline SNRs for /b/ and /d/ differed by 7.1 dB. Phatak and Allen (2007) observed similar differences in the relative identifiability of these consonant pairs. These differences in plosive identifiability may reflect the greater high-frequency spectral energy in /t/ and /d/ plosive bursts with respect to /p/ and /b/ (Halle *et al.*, 1957), resulting in less effective masking by low-frequency speech-spectrum noise of the sort used in the current study.

Although the average psychometric functions obtained in this experiment had mean slopes that were similar to those reported in previous studies using nonsense CVCs (Boo-

throyd and Nittrouer, 1988), there were large differences in the P/S slopes of different consonants. Not surprisingly, harder-to-identify consonants (i.e., those that required higher baseline SNRs) had shallower slopes. This was due in part to the fact that harder-to-identify consonants (e.g., non-sibilant fricatives) remain difficult to identify even at high SNRs (Wiley *et al.*, 1979). In contrast, easier-to-identify consonants (e.g., sibilants) showed steeper psychometric functions. The correlation between baseline SNRs and P/S slopes suggests that consonant information from easy-to-identify consonants continues to provide the majority of consonant information in conversational speech at moderate noise levels.

C. The identification of leading and trailing consonants

Overall, we found that initial consonants were identified at consistently lower SNRs than final consonants, replicating the results of previous studies using smaller token sets (Wang and Bilger, 1973; Dubno and Levitt, 1981; Redford and Diehl, 1999; Benkí, 2003). These differences likely reflected slight increases in the amplitude and duration of initial consonants with respect to final consonants (Redford and Diehl, 1999). However, the magnitude of the initial consonant advantage differed for different consonant manners. Nasals showed particularly large initial consonant advantages as in previous reports (Dubno and Levitt, 1981; Repp and Svastikula, 1988). In contrast, liquids showed a final consonant advantage that has likewise been previously noted (Cutler *et al.*, 2008). Although d' had been equated for initial and final consonants, we found a significant position-related difference in response criteria: initial consonants were identified with stricter criteria than final consonants. In part, this may have reflected differences in the 20th consonant used in initial and final consonant sets: /h/ was a more potent FA-generator than /ŋ/.

Cluster analysis was used to visualize the confusions among consonants in initial and final syllable positions. This analysis revealed that the particular *a priori* categorization of consonants based on voice, manner, and place features provided a valid starting point for consonant-confusion analysis. Although consonants generally segregated into confusable clusters sharing manner and voicing, cluster analysis revealed considerable overlap between nasals and liquids and also between sibilants and affricates. Distant clusters were connected through "hub" consonants (e.g., /h/, /v/, /b/, and /ʤ/) that were frequently confused with consonants with distant clusters characterized by different manner and/or voicing features. Cluster analysis showed that confusion clusters were similar in initial and final consonant positions, with some clusters better segregated in initial syllable position and other clusters better segregated in final syllable position.

D. Analyzing phonetic features

Phonetic features differed in intelligibility. Among single-feature errors, P confusions were most common, followed by M and V confusions. Moreover, P confusions persisted to a greater degree at higher SNRs than M and particularly V confusions as in previous reports (Grant and Walden, 1996). We also found a high incidence of P+M errors, particularly at low SNRs, consistent with previous studies (Dubno and Levitt, 1981). P+M errors and other combined-feature errors declined more rapidly than did single-feature errors with increasing SNR.

The relative salience of different phonetic features also differed significantly as a function of syllable position. Combined feature errors were more common in initial than final consonant position (possibly because of the inclusion of /h/), while single-feature errors showed the opposite pattern. Moreover, among single-feature errors, V and M confusions were more common among initial consonants while P confusions were more common among final consonants. Differences in the articulation of initial and final consonants may have contributed to these results (Redford and Diehl, 1999). In addition, there are differences in the perceptual operations associated with the identification of initial and final consonants. Subjects begin extracting information about the initial consonant prior to receiving vowel information and must identify the consonant and vowel concurrently. The parallel analysis of the initial consonant and vowel may increase multi-feature as well as M and V errors that depend on the accurate analyses of the vowel nucleus. In contrast, the increase in place errors in final consonant position may have reflected the relative reduction in M and V errors in the final position subsequent to vowel identification. Alternatively, uncertainty in the onset time of the initial consonant and the resulting failure to accurately detect its onset might have given rise to increased multi-feature errors. The temporal uncertainty of final consonant delivery would have been reduced because of the additional timing cues provided by the vowel and the start of the vowel-consonant transition.

E. Vowel influences on consonant identifiability

Overall differences in consonant identifiability in syllables containing different vowels had been eliminated by small vowel-specific adjustments in syllable intensity. However, different vowel effects were observed in initial and final syllable positions. Initial consonants were more accurately identified in syllables containing /ɑ/ while final consonants were more accurately identified in syllables containing /i/, as observed in previous reports (Halle *et al.*, 1957; Wang and Bilger, 1973; Redford and Diehl, 1999).

Further analysis revealed that vowel space was not independent of consonant space: highly significant vowel × consonant interactions for 85% of consonants. These interactions were generally similar for consonants sharing similar manner. For example, nasals were more accurately identified with /ɑ/, as observed previously (Dubno and Levitt, 1981; Repp and Svastikula, 1988), while sibilants, plosives, and liquids were most accurately identified in syllables containing /i/, and non-sibilant fricatives were most accurately perceived in syllables containing /u/. These effects may have reflected more salient formant transitions in preferred consonant-vowel pairs. Vowels also interacted with place of articulation. Front consonants were perceived most accurately in syllables containing the back vowel /ɑ/, middle consonants were perceived most accurately in syllables contain-

ing /u/, and back consonants were perceived most accurately in syllables containing the front vowel /i/. These effects may have reflected the increased salience contrasts associated with greater tongue movements and presumably longer duration formant changes.

Confusion-cluster analysis was used to visualize vowel-consonant interactions. This analysis revealed variations in the clarity of different phonetic cues as a function of the vowel-nuclei of syllables. Vowel-related improvements in consonant identification were usually accompanied by a reduction in place confusions within clusters as well as reductions in confusions with distant clusters. We also found systematic differences in the overall frequency of P confusions as a function of vowel: P confusions increased with /i/ in comparison with /ɑ/ or /u/, whereas P+M errors showed a corresponding decrease. One possible explanation is that /i/ facilitated manner processing and thus converted potential P+M errors into P errors.

F. Interactions in identifying initial and final consonants

We found evidence of significant interactions between the processing of initial and final consonants in CVCs: both initial and final consonants were identified more accurately when they differed in place of articulation. No such interactions were found for voicing or manner. One possible explanation is because the analysis of place is more difficult than the analysis of manner or voicing, particularly at the final consonant position, it requires more time for analysis. This would increase the possibility of consonant-consonant interactions in place processing over the relatively long inter-consonant intervals of CVCs (Christiansen and Greenberg, 2008). The reduced accuracy found when initial and final consonants share place may thus reflect adaptation of the place feature at relatively short intervals.

V. CONCLUSIONS

Consonant identification in CVCs presented in noise is a highly complex process that is subject to many contextual influences. Different consonants are identifiable over widely different SNR ranges, suggesting that a subset of consonants contributes disproportionately to speech understanding during difficult listening situations. Cluster analysis of confusions revealed that consonants are segregated into perceptually distinct clusters, exhibiting high intracluster confusion rates and generally low rates of intercluster confusions. Perceptual clusters typically consist of consonants with the same manner and voicing, with the exception of nasal-liquid and sibilant-affricate clusters. Highly significant differences were observed in the identification of initial and final consonants, and consonant identification was strongly modulated by the accompanying vowel. In addition, consonant-consonant interactions were observed in the processing of initial and final consonant place features. These results suggest that consonant processing within CVCs is a complex, non-linear process that is subject to contextual modulation by consonant position, intervening vowels, and even other consonants.

[1]Pure tone thresholds (over 500, 1000, and 2000 Hz) averaged 6.71 dB HL (±1.93) in the left ear and 4.80 dB HL (±1.52) in the right, with average 8000 Hz thresholds of 10.94 dB HL (±2.95) and 6.88 dB HL (±2.58) in the left and right ears, respectively.

[2]Experimenter response transcription was used in preference to subject transcription to maintain the naturalness of the listening task, minimize procedural learning effects, and avoid scoring biases that might be introduced by listeners untrained in the use of the phonetic alphabet.

(Received 12 June 2009; revised 30 October 2009; accepted 31 December 2009)

The ability to recognize speech involves sensory, perceptual, and cognitive processes. For much of the history of speech perception research, investigators have focused on the first and third of these, asking how much and what kinds of sensory information are used by normal and impaired listeners, as well as how effective amounts of that information are altered by "top-down" cognitive processes. This experiment focused on perceptual processes, asking what accounts for how the sensory information in the speech signal gets organized. Two types of speech signals processed to remove properties that could be considered traditional acoustic cues (amplitude envelopes and sine wave replicas) were presented to 100 listeners in five groups: native English-speaking (L1) adults, 7-, 5-, and 3-year-olds, and native Mandarin-speaking adults who were excellent second-language (L2) users of English. The L2 adults performed more poorly than L1 adults with both kinds of signals. Children performed more poorly than L1 adults but showed disproportionately better performance for the sine waves than for the amplitude envelopes compared to both groups of adults. Sentence context had similar effects across groups, so variability in recognition was attributed to differences in perceptual organization of the sensory information, presumed to arise from native language experience. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3298435]

I. INTRODUCTION

The ability to recognize speech involves sensory, perceptual, and cognitive processes. Regarding the first of these, listeners must have some amount of access to the acoustic signal generated by the moving vocal tract of the speaker. Sensory impairments such as hearing loss can inhibit speech recognition if the impairment sufficiently precludes access to that sensory information. Research involving listeners with hearing loss has commonly focused on this aspect of perception, with questions explicitly addressing how much of the signal and what properties are needed for speech perception (e.g., Dorman *et al.*, 1985; Erber, 1971; Leek *et al.*, 1987; Revoile *et al.*, 1985; Stelmachowicz *et al.*, 1990). But while having access to sensory information in the speech signal is an obvious prerequisite to recognition, it is not sufficient to explain speech perception. This was demonstrated by Surprenant and Watson (2001), who tested the speech recognition of college students and also examined their discrimination for a number of related non-speech stimuli. Performance on the two kinds of tasks were not strongly correlated, leading the authors to conclude that "…factors higher in the sequence of processing than the auditory periphery account for significant variance in speech recognition—by both normal hearing and by hearing-impaired listeners." (p. 2094). The experiment reported here was designed to test the hypothesis that part of that variance is explained by how listeners perceptually organize the sensory information in the speech signal.

The idea that perceivers need to organize the sensory information reaching them is well accepted in the study of visual perception where displays such as the classic Ruben's vase illustrate the phenomenon: In that demonstration, viewers recognize either a vase or two symmetrical profiles depending on how they organize the sensory information that reaches their retinas. Scientists studying general auditory perception similarly examine the principles that underlie the recognition of the object responsible for generating the sensory information (Binder *et al.*, 2004; Bregman, 1990; Dau *et al.*, 2009; Griffiths and Warren, 2004). When it comes to speech perception, however, considerably less attention has been paid to how listeners perceptually organize the components of the signal in order to recover the sound-generating object, perhaps due to long-standing controversy over whether listeners actually ever do recover that object, which is the moving vocal tract (e.g., Liberman *et al.*, 1962; Lotto *et al.*, 2009). Be that as it may, the work that has been done on perceptual organization for speech demonstrates that listeners must integrate disparate spectral and temporal signal components appropriately in order to recover cohesive and linguistically relevant percepts (e.g., Best *et al.*, 1989; Remez *et al.*, 1994).

The work reported here follows years of investigation examining how the weighting of explicit acoustic cues to phonetic identity changes as children acquire experience with a native language. Acoustic cues are defined as spectrally discrete and temporally brief pieces of the speech sig-

TABLE I. Mean weighting coefficients for formant transitions and fricative-noise spectra for listeners in each age group. Group numbers are in italics, standard deviations are in parentheses (from Nittrouer and Lowenstein, 2009).

	3-year-olds (*23*)	5-year-olds (*22*)	7-year-olds (*20*)	Adults (*20*)
Formant transition	0.50 (0.15)	0.48 (0.19)	0.32 (0.15)	0.30 (0.17)
Fricative noise	0.66 (0.13)	0.71 (0.14)	0.81 (0.11)	0.82 (0.11)

nal that affect listeners' phonetic labeling when modified (Repp, 1982). Several cues can underlie a single phonetic distinction, and the way those cues are weighted varies depending on native language experience (e.g., Beddor and Strange, 1982; Crowther and Mann, 1994; Flege *et al.*, 1996; Gottfried and Beddor, 1988; Zampini *et al.*, 2000). Accordingly, children must discover the optimal weighting strategies in their native language, and their early weighting strategies differ from those of adults. In particular, children weight dynamic, spectral cues (i.e., formant transitions) more than adults, and weight stable spectral cues (e.g., noise spectra) less (Mayo *et al.*, 2003; Nittrouer, 1992; Nittrouer and Miller, 1997a, 1997b; Nittrouer and Studdert-Kennedy, 1987; Watson, 1997). Some evidence of this developmental shift comes from a study in which adults and children between 3 and 7 years of age were asked to label syllable-initial fricatives based on the spectral shape of fricative noises and on formant transitions at voicing onset (Nittrouer and Lowenstein, 2009). Computed weighting coefficients are shown in Table I. They indicate that the weighting of formant transitions diminished with increasing age, while the weighting of fricative-noise spectra increased.

Of course, formant transitions are just brief sections of more broadly modulating resonant frequencies created by vocal-tract cavities, which are continually changing in shape and size. Results across studies demonstrating children's reliance on formant transitions for phonetic labeling led to the broader hypothesis that children would show a perceptual advantage in organizing this kind of signal structure over other kinds of structure. To test that hypothesis, Nittrouer *et al.* (2009) presented two kinds of processed signals to three groups of listeners. Sine wave replicas of speech (Remez *et al.*, 1981) were used to provide a signal condition that preserved dynamic spectral structure, just the sort of structure for which children are expected to show an advantage. Vocoded stimuli (Shannon *et al.*, 1995) were also used as a comparison condition. These stimuli preserve amplitude structure across the utterance in a preselected number of frequency bands. The sentences in that study were all four words long with English syntax, but no semantic constraints. Two groups of adult listeners participated: native speakers of American English and native speakers of another language who were excellent second-language (L2) speakers of American English. Although native speakers of any language could presumably have been used, Mandarin Chinese speakers were selected because Fu *et al.* (1998) showed that they recognize vocoded Chinese sentences as well as native English speakers recognize vocoded English sentences. This group of adults was included both to test the idea that the perceptual organization of sensory information is language specific, and to serve as controls for the third group of listeners: 7-year-old native speakers of American English. If native English-speaking 7-year-olds had poorer recognition than L1 adults for either kind of processed stimuli, the inclusion of L2 adults would mitigate against the explanation that age-related differences in processing at the auditory periphery accounted for the outcome, assuming that L2 adults also performed more poorly than L1 adults.

Results showed that the L2 adults performed more poorly with both kinds of stimuli than the L1 adults, suggesting that how listeners perceptually organize acoustic structure in the speech signal is at least somewhat dependent on native language experience. That interpretation was motivated by outcomes of other studies. For example, Boysson-Bardies *et al.* (1986) showed that the long-term spectral shape of speech signals varies across languages, with some having more prominent spectral peaks and others having flatter spectra. The fact that listeners are sensitive to the spectral shape of their native language was demonstrated by Van Engen and Bradlow (2007), who reported that speech-shaped noise degraded speech recognition more when the shape of the noise was derived from speakers of the language in which testing was occurring, rather than from a different language. Apparently the way in which speech is produced creates structure in signals at global levels (i.e., longer than the phonetic segment and spectrally broad), and listeners are sensitive to how signals are structured at those levels in their native language.

The 7-year-old children in Nittrouer *et al.* (2009) were poor at recognizing sentences that preserved only amplitude structure, scoring similarly to the L2 adults. At the same time, 7-year-olds performed similarly to the L1 adults with the sine wave replicas. In fact, the 7-year-olds were the only group of listeners to show better performance for the sine wave stimuli than for the four-channel amplitude envelope (AE) stimuli (25.65% vs 13.68% correct, respectively); L1 and L2 adults had statistically identical recognition scores for the four-channel amplitude envelope and the sine wave stimuli: 28.17% correct for L1 adults across the two conditions and 9.99% correct for L2 adults. Of course, 7-year-olds' performance could have been rendered equivalent across conditions by increasing the number of channels in the amplitude envelope stimuli, but the critical outcome was precisely that they performed differently on two sets of data that evoked similar responses from adults. However, a caveat in those results was that different listeners participated in testing with the two kinds of signals, so within-group comparisons could not be made. That problem was corrected in the current study.

The perceptual advantage demonstrated by 7-year-olds in that experiment for sine wave stimuli was viewed as complimentary to earlier findings showing that children weight formant transitions more than adults in phonetic decisions. Speech processed to preserve only the amplitude envelopes of the original signal do not preserve that kind of dynamic spectral structure particularly well, whereas sine wave replicas do. Consequently, how well listeners of different ages can perceptually organize various kinds of signals seems partly related to the signal properties themselves. If the processed signal preserves properties to which listeners are especially sensitive, those listeners are better able to recover the auditory (or in the case of speech, the linguistic) object.

The current study was conducted to extend Nittrouer *et al.* (2009) by examining how children younger than 7 years of age, the youngest group in that study, perceptually organize processed speech signals. Because children younger than 7 years of age have consistently demonstrated even stronger weighting of dynamic spectral components in the speech signal, they should show even a stronger advantage in their recognition of the sine wave replicas over the amplitude envelope signals. However, the 7-year-olds in that study recognized fewer than 30% of the words correctly in two out of three conditions, and so we worried that younger children might not recognize any words at all if the same or similar stimuli were used. Therefore, we elected to use sentences that provided both syntactic and semantic constraints. Children as young as 3 years of age participated in this experiment. The goal was to examine listeners' abilities to perceptually organize the sensory information provided by dynamic spectral structure (as preserved by sine waves) and by amplitude envelopes. Four-channel amplitude envelope signals were used because adults had shown identical performance with those signals to that obtained with sine wave speech in Nittrouer *et al.* (2009). Native Mandarin-speaking adults participated again because their inclusion could help bolster arguments that age-related differences in speech recognition, if found, are likely not due to differences in auditory processing of the sensory information.

Our focus in this experiment was on the perceptual organization of linguistically relevant acoustic structure in the speech signal. Because we used sentence materials, however, we needed a way to ensure that any group differences observed were not due to linguistic context effects. Miller *et al.* (1951) are generally credited with being the first investigators to examine differences in speech recognition scores due to the context, in which the stimulus is presented. They showed that when isolated words presented in background noise were part of small sets made known to research participants, recognition was more accurate than when set size was larger. As their metric they used the difference in signal-to-noise ratio (SNR) needed to achieve a preselected target of 50% correct recognition. It was not long before other investigators extended the notion of set size to frequency of word usage: Commonly occurring words can be recognized at poorer SNRs than uncommonly occurring words (e.g., Broadbent, 1967; Howes, 1957; Rosenzweig and Postman, 1957). In the rhetoric of information theory, word frequency influences the number of effective channels of sensory information available to the perceiver.

Boothroyd (1968) developed several metrics that provide a way of quantifying the numbers of effective channels of information used by the perceiver. The metric of most relevance to the current work is known as the *j* factor and derives from the fact that the probability of recognizing a whole word is dependent on the probabilities of recognizing the separate parts (or phonemes) forming that word. If lexicality played no role in recognition, then the probability of recognizing a whole word correctly would be directly related to the probability of recognizing each of the parts, such that

$$p_w = p_p^n, \tag{1}$$

where p_w is the probability of recognizing the whole word, p_p is the probability of recognizing each part, or phoneme, and n is the number of parts in the whole. However, this relation holds only when it is necessary to recognize each part in order to recognize the whole, as happens with nonwords, for instance. When listening to real words, the lexical status of those words generally reduces the need to recognize each separate part in order to recover the whole. Therefore, we can change n to a dimensionless exponent, such as j, to quantify the effect of hearing these phonemes in a lexical context. This exponent varies between 1 and n, and the extent to which it is smaller than n indicates the magnitude of the context effect. Now Eq. (1) can be changed to

$$p_w = p_p^j, \tag{2}$$

where j is the number of independent channels of information, and we can solve for the effective number of channels of information in the word with

$$j = \log(p_w)/\log(p_p). \tag{3}$$

Boothroyd and Nittrouer (1988) demonstrated the validity of the j factor with the finding that j equaled 3.07 when listeners were asked to recognize nonsense CVCs. That value was not statistically different from the value of 3, which would be expected if listeners need to recognize each segment independently in order to recognize the whole syllable. By contrast, Boothroyd and Nittrouer (1988) reported a mean j of 2.46 when these same listeners were asked to recognize CVC real words. That value was statistically different from the 3.07 obtained for nonsense syllables. Together, these findings support the use of the j factor as a metric of the number of independent channels of information needed for recognition. This metric has been used by others for several clinical purposes such as assessing the abilities of deaf children to use lexical context (Boothroyd, 1985). Benkí (2003) used the j factor to index the lexical context effect of high-frequency words compared to low-frequency words. In addition to demonstrating a stronger context effect for high- over low-frequency words (j's of 2.25 and 2.46, respectively), Benkí (2003) replicated Boothroyd and Nittrouer's finding of a j equal to 3.07 for nonsense syllables.

Sentence context similarly improves listeners' abilities to recognize words under conditions of signal degradation (e.g., Boothroyd and Nittrouer, 1988; Duffy and Giolas,

1974; Giolas *et al.*, 1970; Kalikow *et al.*, 1977; Nittrouer and Boothroyd, 1990). When examining the effects of sentence context on word recognition, investigators are generally not interested in the effect of lexicality, but rather in the effects of syntactic and semantic constraints. Those effects can be quantified using Eq. (3) by making p_w the probability of recognizing the whole sentence and p_p the probability of recognizing each word in the sentence.

Nittrouer and Boothroyd (1990) computed the number of independent channels of information needed by adults and children (4–6 years of age) listening to sentences in their native language with signals degraded by the addition of noise at two SNRs: −3 dB and 0 dB. Two kinds of sentences were used: sentences that had appropriate syntactic structure, but no useful semantic information (syntax-only sentences), and sentences that provided clear syntactic structure, as well as strong semantic constraints (syntax+semantics sentences). All were comprised of four monosyllabic words. Across the two SNRs employed in that study, the mean *j* for adults listening to the syntax+semantics sentences was 2.32, and the mean *j* for children listening to those same sentences was 2.59. This age-related difference was not statistically significant, and so it may be concluded that children as young as 4 years are able to use syntactic structure and semantic context as well as adults, at least for simple sentences.

The *j* factor has not been used to assess the contributions of sentence context to recognition by adults listening to a second language, but several investigators have used the speech in noise (SPIN) test to evaluate this effect. In the SPIN test, listeners hear two kinds of sentences and must report the last word in each. In one kind of sentence, the words prior to the last word provide semantic information that strongly predicts that word (e.g., *My clock was wrong so I got to school late; After my bath I dried off with a towel.*). In the other kind of sentence, the preceding words provide no information that would especially predict the final word (e.g., *Mom talked about the pie. He read about the flood.*). Mayo *et al.* (1997) presented these sentences at several SNRs to L1 English listeners and L2 listeners who had learned English at ages varying from birth to early adulthood. Results showed that listeners who had learned English after the age of 14 years were less capable than native and early L2 learners at using the highly predictable sentence context to aid recognition of the final word. In another study, Bradlow and Alexander (2007) presented these same sentences to native and L2 English listeners, but used samples that could be described as plain or clear speech. Listeners in both groups showed more accurate recognition for words in the high-predictability contexts, but for L2 listeners this advantage was restricted to clear sentences.

The results above suggest that L2 adults are poorer at using sentence context for speech recognition than L1 adults. However, those results were obtained using the SPIN test, and there are important differences between that task and the way *j* factors are computed. In the SPIN test, recognition of only words in sentence-final position is being evaluated, and the comparison is between sentences that have strong semantic constraints (high predictability) and those that have neutral semantic constraints (low predictability). With *j* factors, recognition scores for all words within the sentences are involved in computation, and every word serves as context for every other word. The difference between these two methods is highlighted by the fact that young children show diminished semantic context effects on the SPIN test compared to older children (Elliott, 1979), but young children have *j* factors equivalent to those of adults, as long as syntax and semantics are within their language competencies (Nittrouer and Boothroyd, 1990). On the SPIN test, sentences with high and low predictabilities tend to differ in syntactic structure, with high-predictability sentences generally having more complex structures. That could constrain the abilities of children and L2 listeners to use the sentence context if the syntactic constructions are not within their competencies. This is not a concern when *j* factors are computed, both because the sentences that have been used involve simple syntactic constructions and because wholes and parts are scored from the same responses. Because of these differences, we did not necessarily expect L2 listeners to show the same deficits in using sentence context compared to L1 listeners that have been reported earlier.

In summary, the current experiment was designed to examine how listeners of different ages and native-language experience perceptually organize two kinds of signals derived from speech: sine wave replicas and amplitude envelopes. We hypothesized that L2 adults would be equally poor at recognition with both kinds of signals, but that children would show an advantage for the sine wave replicas over the amplitude envelope signals because they heavily weight global spectral structure in their speech perception. We selected sentence materials that we thought would produce similar context effects across listeners, but planned to compute *j* factors as a test of that assumption.

II. METHOD

A. Participants

100 listeners participated in this experiment: 80 native speakers of American English (20 adults, 20 7-year-olds, 20 5-year-olds, and 20 3-year-olds) and 20 adult, native speakers of Mandarin Chinese who were competent L2 speakers of English. None of the participants had listened to sine wave replicas or amplitude envelope speech before. All L2 speakers had started learning English between the ages of 12 and 14 years in language classes in China. They all came to the United States between the ages of 21 and 26 years to study, and were in the United States as graduate students, postdoctoral fellows, or junior faculty members. Mean age of the L1 adults was 24 years (range 19–35 years), and mean age of the L2 adults was 26 years (range 22–36 years). To participate, all listeners had to pass a hearing screening and demonstrate appropriate abilities to comprehend and produce spoken English. 3-year-olds were also given the Goldman–Fristoe 2 test of articulation (Goldman and Fristoe, 2000) to screen for speech problems. They were required to score at or better than the 30th percentile for their age. Each group was comprised of 10 males and 10 females, except for 7-year-olds (9 females, 11 males) and L2 listeners (11 females, 9 males).

B. Equipment

All speech samples were recorded in a sound booth, directly onto the computer hard drive, via an AKG C535 EB microphone, a Shure M268 amplifier, and a Creative Laboratories Soundblaster analog-to-digital converter. Perceptual testing took place in a sound booth, with the computer that controlled the experiment in an adjacent room. The hearing screening was done with a Welch Allen TM262 audiometer and TDH-39 earphones. Stimuli were stored on a computer and presented through a Samson headphone amplifier, and AKG-K141 headphones.

C. Stimuli

Seventy-two sentences were used as stimuli in this experiment: 12 for practice and 60 for testing. All were selected from the hearing in noise test for children (HINT-C) (Nilsson *et al.*, 1996; Nilsson *et al.*, 1994), and all were five words in length. The sentences selected for use are shown in the appendix. The HINT-C sentences were originally developed to test how well children can recognize speech in competing noise. They are five to eight words long, syntactically correct, and follow a subject-predicate structure. They are highly predictable semantically. Sentences from the HINT-C were used by Eisenberg *et al.* (2000) in an experiment looking at recognition of amplitude envelopes by adults and children. Those listeners, regardless of age, had close to 90% correct word recognition when listening to eight-channel envelope stimuli. With four-channel stimuli, adults had close to 70% correct word recognition and 5- to 7-year-olds had close to 35% correct word recognition. Thus, although our primary motivation for using four channels for the amplitude envelope stimuli was because Nittrouer *et al.* (2009) found that adults had equivalent word recognition for those stimuli and sine wave replicas, the Eisenberg *et al.* (2000) results supported the expectation that word recognition scores would be neither too close to 0 nor too close to 100%, at least for the amplitude envelope stimuli. Finally, we restricted our corpus to five-word sentences so that length would be consistent, and relatively brief, thereby minimizing concerns about memory.

The selected sentences were recorded at a 44.1-kHz sampling rate with 16-bit digitization by an adult male speaker of American English who is a trained phonetician. All sentences were equalized for mean rms amplitude across sentences before any processing was done, and all sentences were used to create sine wave (SW) and four-channel envelope signals. Because these latter stimuli preserve the amplitude envelopes in each of four channels, they are dubbed as AE stimuli in this report. For creating the SW stimuli, a PRAAT routine written by Darwin (http://www.lifesci.sussex.ac.uk/home/Chris_Darwin/Praatscripts/SWS) was used to extract the center frequencies of the first three formants. Stimuli were generated from these formant frequencies, and spectrograms were compared to spectrograms of the original sentences to ensure that the trajectories of the sine waves matched those of the formant frequencies.

To create the AE stimuli, a MATLAB routine was written. All signals were first low-pass filtered with an upper cut-off frequency of 8000 Hz. For the four-channel stimuli, cut-off frequencies between bands were 800, 1600, and 3200 Hz. Each channel was half-wave rectified, and results used to modulate white noise, limited by the same band-pass filters as those used to divide the speech signal into channels. Resulting bands of modulated noise were low-pass filtered using a 160-Hz high-frequency cut-off, and combined.

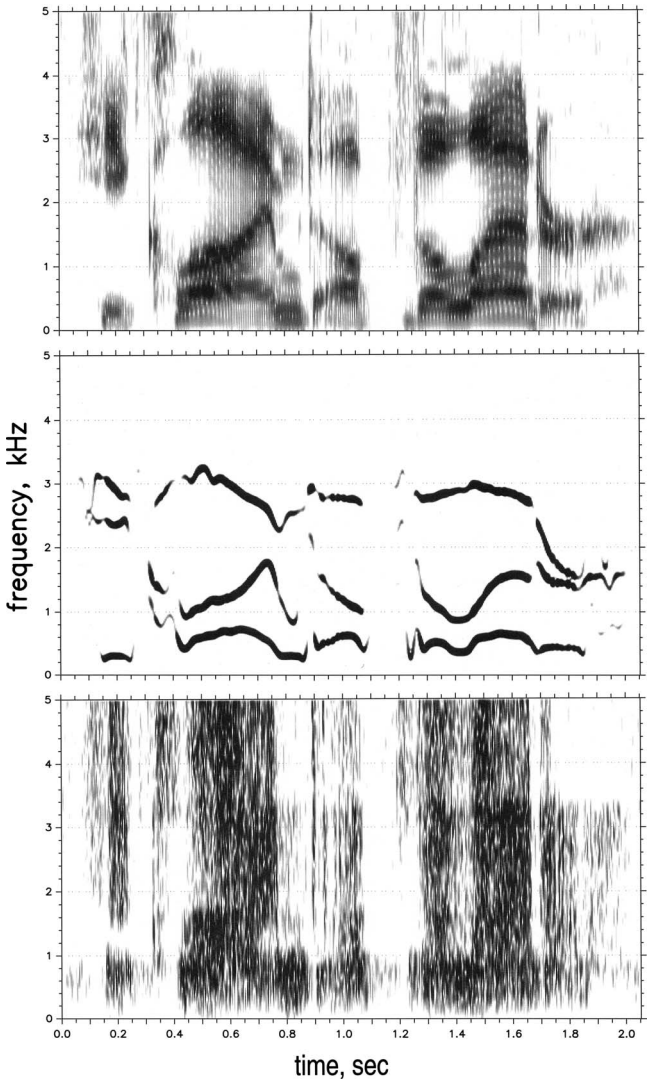

FIG. 1. Spectrograms of the sentence "He climbed up the ladder." (Top) Natural speech sample from which SW and AE stimuli were derived. (Middle) SW stimulus. (Bottom) Four-channel AE stimulus.

Figure 1 displays a natural speech sample of *He climbed up the ladder* (top panel), the SW replica (center panel), and the AE replica (bottom panel).

D. Procedures

All stimuli were presented under headphones at a peak intensity of 68 dB sound pressure level. For each participant, the software randomly selected 30 sentences to present as AE and 30 to present as SW prior to testing. Half of the participants heard all 30 AE sentences first, and then the SW sentences, and half of the participants heard all 30 SW sentences first, and then the AE sentences. Training was the same for each condition. For each of the six practice sentences, the

TABLE II. Mean percent correct words recognized by each group in each condition. Standard deviations are in parentheses. AE refers to amplitude envelope stimuli and SW refers to sine wave stimuli.

	L1 adults	7-year-olds	5-year-olds	3-year-olds	L2 adults
AE	79.53 (8.30)	43.85 (16.63)	30.73 (17.93)	16.23 (11.53)	33.47 (12.29)
SW	98.37 (1.38)	91.90 (3.03)	86.32 (6.11)	75.40 (15.22)	77.20 (8.78)

natural version was played first. The listener was instructed to listen and repeat it. Next, the listener was told "Now you will hear the sentence in a robot voice. Listen carefully so you can repeat it." The notion of a robot was invoked to personify the signal so that listeners would more readily hear the stimuli as speech. The children were specifically told that the SW sentences were spoken by a robot with a "squeaky voice," and the AE sentences were spoken by a robot with a "scratchy voice." For both the AE and SW conditions, listeners were asked at the end of the six-sentence practice if they were able to recognize the "robot's" productions as speech. It was made clear that the question was whether they could hear the stimuli as speech, rather than could they understand every word. If a listener either was unable to repeat any of the unprocessed sentences or failed to report hearing the processed signals as speech, he was dismissed. None of the listeners had difficulty hearing the AE sentences as speech. Two additional participants, one 3-year-old and one 5-year-old, were dismissed because they did not report hearing the SW sentences as speech.

During testing, the order of presentation of the sentences was randomized independently for each listener. Each sentence was played once, and the listener repeated it as best as possible. Participants could ask for a sentence to be replayed one time. Nittrouer *et al.* (2009) used three trials of each sentence, but listeners in all groups showed similar improvements across repetitions and means from the first to the third repetition never differed by more than 1 standard deviation. Consequently, the outcomes of that study would not have been different if only one repetition had been used, and so we had no motivation to use more repetitions in this study. The number of incorrect words for each sentence was entered into the program interface during testing. 5- and 7-year-olds moved a game piece along a game board every ten sentences, while 3-year-olds used a stamp to mark a paper grid after every five sentences, in order to maintain attention and give a sense of how much of the task remained.

After hearing the sentences in their processed forms, all sentences were played to listeners in their unprocessed forms. Listeners could get no more than 10% of the words wrong on this task. Data from two additional participants, one L2 adult and one 3-year-old, were excluded from analyses because they made too many errors repeating the unprocessed sentences. None of the other listeners had trouble comprehending the unprocessed sentences.

In addition to entering the number of words repeated incorrectly at the time of testing, participants were audiorecorded. A graduate student later listened to 15% of the recordings, and marked the number of words she heard as incorrect. Reliability coefficients were 1.00 for both AE and SW sentences for listeners of all ages.

III. RESULTS

A. Word recognition

The percentage of words correctly recognized across all sentences within any one condition served as the dependent measure. All statistics were performed using arcsine transforms because some listeners scored above 90% correct in the SW condition and others scored below 10% correct in the AE condition. As a preliminary test, analyses of variance (ANOVAs) were conducted on percent correct recognition scores for each group separately, based on whether they heard AE or SW sentences first. No significant order effect was observed for any group.

Next, the effect of English experience for the L2 adults was examined. Pearson product-moment correlation coefficients were computed between recognition scores for both the AE and SW sentences and the length of time the L2 adults had been speaking English based on when they began language classes. The correlation coefficient for AE sentences was -0.04, and for SW sentences it was -0.13. Neither was significant. In addition, correlation coefficients were computed between the numbers of years these participants had lived in the United States and their recognition scores. In this case, the correlation coefficient for AE sentences was -0.41, and for SW sentences, it was -0.27. Again, neither of these was significant; in fact, slightly negative correlations were found. The lack of an L2 experience effect matches findings by others: If learning starts after puberty, eventual proficiency is variable and unrelated to factors such as age of initial exposure or age of arrival in the new country (e.g., Johnson and Newport, 1989).

Table II shows mean correct word recognition for each group for each kind of stimulus. The greatest differences across groups occurred in the AE condition, with a difference of roughly 63% between the highest scoring group (L1 adults) and the lowest scoring group (3-year-olds). Groups performed more similarly in the SW condition, with a difference of only 23% between the highest and lowest scoring groups (again, L1 adults and 3-year-olds). This difference across conditions was due to 3-year-olds performing much better in the SW than in the AE condition, rather than to a decrement in performance for L1 adults in the AE condition. In fact, adults performed better in the SW than in the AE condition, just less so than children. When a two-way ANOVA was performed on these scores, with group as the between-subjects factor and signal type as the within-subjects factor, both main effects were significant: group, $F(4,95)=68.93$, $p<0.001$, and signal types, $F(1,95)=995.93$, $p<0.001$. Of particular interest, the group

TABLE III. Results of the statistical analyses of percent correct scores for group effects, using arc sine transforms. *F* ratios (shown in bold) are for one-way ANOVAs, with group as the between-subjects factor; t-tests are for *posthoc* comparisons. Degrees of freedom are 4, 95 for the ANOVAs, and 95 for the t-tests. Computed *p* values are shown. Bonferroni corrections for five multiple comparisons require a *p* of less than 0.005 for the comparison to be significant at the 0.05 level. Comparisons meeting this adjusted level are indicated by an asterisk.

	F ratio or *t*	*p*
AE sentences	**49.42**	<0.**001**
L1 adults vs 7-year-olds	7.22	<0.001*
L1 adults vs 5-year-olds	10.16	<0.001*
L1 adults vs 3-year-olds	13.31	<0.001*
L1 adults vs L2 adults	9.17	<0.001*
7- vs 5-year-olds	2.94	0.004*
7- vs 3-year-olds	6.09	<0.001*
7- vs L2 adults	1.95	0.054
5- vs 3-year-olds	3.16	0.002*
5- vs L2 adults	−0.99	NS
3- vs L2 adults	−4.14	<0.001*
SW sentences	**46.24**	<0.**001**
L1 adults vs 7-year-olds	5.03	<0.001*
L1 adults vs 5-year-olds	7.64	<0.001*
L1 adults vs 3-year-olds	11.60	<0.001*
L1 adults vs L2 adults	11.25	<0.001*
7- vs 5-year-olds	2.62	0.010
7- vs 3-year-olds	6.57	<0.001*
7- vs L2 adults	6.23	<0.001*

5- vs L2 adults	3.61	<0.001*
3- vs L2 adults	−0.34	NS

×signal type interaction was significant, $F(4,95)=12.64$, $p<0.001$, indicating that the variability in magnitude of the signal effect across groups was significant.

Table III shows the results of one-way ANOVAs and *posthoc* comparisons performed on word recognition scores for AE and SW stimuli separately. Significant main effects of group were found for both the AE and SW conditions, so *posthoc* comparisons among groups were examined. For the AE condition, L1 adults performed best, and mean correct recognition differed significantly from every other group. Differences were observed among all children's groups, with 7-year-olds performing the best, followed by 5-year-olds, and then 3-year-olds. Although 7-year-olds had better recognition scores than L2 adults, this difference was not significant once a Bonferroni correction was applied. However, this is the one statistical outcome that differed for untransformed and transformed data: When the ANOVA and *posthoc* comparisons were performed on untransformed scores, this comparison was unambiguously significant, $t(95)=2.38$, $p=0.019$, supporting the assertion that 7-year-olds performed more accurately than L2 adults. Five-year-olds performed similarly to L2 adults, but 3-year-olds performed significantly more poorly.

For the SW stimuli, L1 adults again performed the best, with a mean recognition score that differed significantly from every other group. 7- and 5-year-olds performed similarly, and the difference between their mean scores was not significant when a Bonferroni correction was applied. Both groups performed significantly better than 3-year-olds and L2 adults. 3-year-olds did not differ from L2 adults.

Prior to running this experiment, there was no reason to expect adults to be more accurate in their responses for one condition over the other: AE stimuli can be created with any number of channels, and we had selected four channels precisely because adults in Nittrouer *et al.* (2009) showed identical performance with four-channel AE and SW stimuli. 7-year-olds in that experiment were the only listener group to show better recognition for SW than for AE stimuli, and the difference between the two conditions was 12 percentage points. For this experiment, Table II indicates that, on the whole, listeners performed better with SW sentences than with AE sentences. That general result makes it important to investigate the magnitude of this condition-related difference across listener groups, and Table IV shows means of individual difference scores for each group. The L1 adults demonstrated the smallest difference across conditions, and the youngest children demonstrated the greatest difference. It may be that difference scores for L1 adults were constrained because many of these listeners showed near-perfect accuracy, especially with SW stimuli, but there can be no question that 3-year-olds showed an advantage for SW over AE stimuli. A one-way ANOVA done on these difference scores with group as the between-subjects factor revealed a significant effect, $F(4,95)=25.24$, $p<0.001$. *Posthoc* comparisons showed significant differences between L1 adults and all other groups. The comparison of 7- and 3-year-olds was significant. In addition, L2 adults showed significantly smaller difference scores than either 5- or 3-year-olds. Because the scores of these adults were not constrained by ceiling or floor effects, the finding suggests that the age-related difference for L1 listeners in condition effects is likely not entirely due to L1 adults scoring near the ceiling. Children were disproportionately more advantaged for the SW than the AE stimuli.

B. Top-down effects

Using the formula presented in the Introduction, *j* factors were computed for individual listeners using word and sentence recognition scores. Because this computation requires the use of sentence recognition scores, mean percentages of sentences recognized correctly for each group are shown in Table V, for AE and SW stimuli separately. Table VI shows mean *j* factors for each group. Scores for indi-

TABLE IV. Mean difference scores across the SW and AE conditions. Standard deviations are in parentheses.

	L1 adults	7-year-olds	5-year-olds	3-year-olds	L2 adults
Difference	18.83 (8.42)	48.05 (15.58)	55.58 (19.84)	59.17 (13.64)	43.73 (10.25)

TABLE V. Mean percent correct sentences recognized by each group in each condition. Standard deviations are in parentheses.

	L1 adults	7-year-olds	5-year-olds	3-year-olds	L2 adults
AE	61.00 (12.66)	19.00 (10.93)	8.50 (8.89)	0.67 (1.37)	7.50 (6.66)
SW	93.50 (4.90)	78.50 (7.45)	63.83 (10.88)	44.33 (18.26)	43.65 (13.91)

vidual listeners were not included if the number of words or sentences recognized correctly was greater than 95% or less than 5%. For the SW sentences, 19 out of 20 L1 adults had better than 95% correct word recognition. For the AE sentences, all 20 3-year-olds had poorer than 5% correct sentence recognition.

One-way ANOVAs were computed on individual *j* factors, for the AE and the SW stimuli separately. For the SW stimuli, scores for L1 adults were excluded. For the AE stimuli, scores for the 3-year-olds were excluded. Neither analysis revealed a significant *F* ratio, so it may be concluded that listeners in all groups had similar context effects.

Table VII shows mean *j* factors only for participants who had word and sentence recognition scores between 5% and 95% correct in both conditions. A two-way ANOVA was computed on these scores, with group as the between-subjects factor and stimulus type as the within-subjects factor. The effect of stimulus type was significant, $F(1,33)=43.27$, $p<0.001$, but not the group effect. The stimulus type × group interaction was not significant. Overall then, these *j* factors were smaller for the AE sentences than for the SW sentences, and that difference was consistent across listener groups.

C. Perceptual organization or top-down effects

The main findings emerging from these data are that the younger children showed an advantage in their perceptual organization of the SW stimuli over the AE stimuli, and the L2 adults were poor at perceptually organizing either type of signal. However, two constraints in the results could dampen enthusiasm for those conclusions: First, L1 adults showed ceiling effects for the SW stimuli. Consequently, the true difference in scores between the SW and AE conditions may not have been obtained for that group. The second constraint was that *j* factors could not be computed for all listeners. Possibly the listeners for whom *j* factors could not be computed accounted for the observed differences in signal effects across groups.

Those concerns can be ameliorated by looking at results for only those participants who provided *j* factors. Mean correct word recognition for these individuals are shown in Table VIII, and when these results are compared to those for all listeners shown on Table II, it is apparent that the same trends across groups are observed. Analyses of covariance performed on these values, using *j* factor as the covariate, resulted in significant group effects, for both the AE stimuli, $F(3,54)=75.88$, $p<0.001$, and the SW stimuli, $F(3,72)=18.89$, $p<0.001$.

Further support for the finding that young children did indeed show an advantage in their perceptual organization of SW stimuli, compared to adults, is obtained by looking across results for 5-year-olds and L2 adults. Table III indicates that listeners in these two groups scored the same with the AE stimuli. Tables VI and VII show that top-down effects were similar for listeners in the two groups. The only result that differs for listeners in the two groups concerns their performance with the SW stimuli: 5-year-olds scored significantly better than L2 adults, as indicated by a significant *posthoc* comparison (Table III). Even when scores are examined for only those 5-year-olds and L2 adults for whom *j* factors could be computed (Table VIII), it is apparent that listeners in both groups performed similarly for the AE stimuli, but 5-year-olds scored better with the SW stimuli.

Finally, it is important to the conclusions reached here that context effects were less for the signal condition in which listeners scored better: that is, the SW condition. That outcome indicates that it was not simply the case that something about the SW stimuli permitted stronger context effects. Instead, the enhanced recognition that young children showed for the SW stimuli seem to be due to their abilities to perceptually organize these signals more handily.

IV. DISCUSSION

The experiment reported here was conducted largely to examine whether the way in which listeners perceptually organize speech signals depends on their native language experience, and on the amount of that experience. An additional question concerned whether listeners are better able to recover relevant linguistic structure with some kinds of processed signals than with others: In particular, we asked whether listeners are better able to recover structure from signals that preserve sensory information to which they are especially sensitive.

TABLE VI. Mean *j* factors for the AE and SW conditions. N/A signifies that participants in that group either all scored above 95% correct (adults, SW words) or below 5% correct (3-year-olds, AE sentences). Standard deviations are in parentheses. The numbers of participants with *j* scores for each group are given in italics.

	L1 adults	7-year-olds	5-year-olds	3-year-olds	L2 adults
AE	2.26 (0.34), *20*	2.26 (0.55), *18*	2.43 (0.60), *10*	N/A	2.43 (0.48), *11*
SW	N/A	2.98 (0.94), *17*	3.36 (0.92), *20*	3.43 (0.82), *20*	3.42 (0.53), *20*

TABLE VII. Mean *j* factors for the AE and SW conditions for participants who had *j* scores for both conditions. The numbers of participants are given in italics under the group name. Standard deviations are in parentheses.

	7-year-olds (*15*)	5-year-olds (*10*)	L2 adults (*11*)
AE	2.23 (0.59)	2.43 (0.60)	2.43 (0.48)
SW	3.03 (0.99)	3.65 (0.81)	3.49 (0.67)

Looking first at results for adults, it was found that the non-native listeners had poorer speech recognition for both kinds of signals than did the native listeners. All participants were required to pass a hearing screening before testing, and so all had equal access to the sensory information available in these signals. Furthermore, *j* factors were similar for both groups of adults, so it may be concluded that top-down cognitive influences on speech recognition were similar in this experiment: Although others have shown effects for L2 adults, none were found for these sentences with simple syntax. Consequently, we are left to posit the locus of effect squarely on how the two groups perceptually organized the sensory information that they received. The suggestion made here is that every language has its own unique global structure. The long-term spectra computed by Boysson-Bardies *et al.* (1986) for samples from speakers of four different languages demonstrated this fact for spectral structure. Presumably languages also differ in terms of global temporal and amplitude structure, given that languages vary in rhythm and stress. Here, it is suggested that adults are familiar with the global structure of their native language, and organize speech signals accordingly. This idea is commensurate with what is known about the phonetic perception of listeners for non-native languages. Listeners organize sensory information in the speech signal according to the phonetic structure of their native language (Beddor and Strange, 1982; Abramson and Lisker, 1967; MacKain *et al.*, 1981), so much so, in fact, that the effect is often described as L1 interference (e.g., Flege and Port, 1981). However, ideas regarding how L1 interferes with the perception of L2 traditionally focus on sensory information at the level of the acoustic cue. The signals presented to listeners in this experiment lacked that level of signal detail; there were no properties constituting acoustic cues. Nonetheless, these L2 speakers had more difficulty than L1 listeners recognizing linguistically relevant structure. That can only mean that they were unable to perceptually organize the sensory information in the signals in such a way as to recover global structure in the L2.

The children in this study were obviously not affected by having a native language interfere with how they perceptually organized the signals they heard because they were listening to processed versions of their native language. Nonetheless, these children had poorer speech recognition for the processed signals than L1 adults. This age-related finding likely reflects the fact that children have not had ample time to become as familiar with the global structure of their native language as adult listeners. Of course, it could just be that children show deficits at recognizing any impoverished signal, but results of another study suggest otherwise. Nittrouer and Lowenstein (2009) presented fricative-vowel syllables to adults and children for fricative labeling. The fricative noises were synthetic and spanned a continuum from one appropriate for /s/ to one appropriate for /ʃ/. The vocalic portions were either from natural speech samples or were sine wave replicas of that natural speech. Children's labeling functions were indistinguishable across the two kinds of stimuli. Therefore, it may be concluded that children are capable of using the information in processed speech signals for recognition, at least at the level of phonetic labeling.

Alternatively, the age-related differences observed here could be attributable to children having poorer access to the sensory information available in the speech signal, perhaps because of immature auditory systems (e.g., Sussman, 1993). That seems unlikely, however, given that L2 adults also performed more poorly than L1 adults, and no one would attribute that difference to poorer access to sensory information.

Moreover, it was found that children had similar *j* factors to adults, and so age-related differences in word recognition cannot be attributed to differences in top-down effects. Again, it seems that the source of the variability in recognition scores for L1 listeners of different ages must be placed squarely on differences in abilities to perceptually organize the sensory information in order to recover linguistically relevant structure.

Finally, it is informative to examine relative performance for the two kinds of processed signals used in this experiment. Children showed disproportionately better performance for the SW stimuli than for the AE stimuli. For example, 5-year-olds performed similarly to L2 adults for AE stimuli but significantly better for SW stimuli. 3-year-olds, on the other hand, performed more poorly than L2 adults for AE stimuli, but similarly with SW stimuli. Thus, all listeners were better able to recognize speech with the SW stimuli than for the AE stimuli, but this advantage was disproportionately greater for the younger children. We speculate that the reason for this outcome is related to the fact that in recognizing speech, young children rely particularly strongly on the dynamic spectral components, which are preserved by sine wave replicas.

In conclusion, this experiment was designed as an extension of Nittrouer *et al.* (2009), which showed that native language experience affected listeners' abilities to perceptu-

TABLE VIII. Mean percent correct words recognized by listeners for whom *j* factors could be computed. Standard deviations are in parentheses.

	L1 adults	7-year-olds	5-year-olds	3-year-olds	L2 adults
AE	79.53 (8.30)	47.35 (13.37)	43.20 (10.08)	N/A	40.97 (9.78)
SW	N/A	91.14 (2.59)	86.32 (6.11)	75.40 (15.22)	77.20 (8.78)

ally organize processed speech signals, and that 7-year-olds showed greater benefits for SW over AE stimuli than adults. First, this experiment replicated the effect of native language experience: L2 adults performed more poorly than L1 listeners, in spite of having sufficient skills in their L2 to take graduate level course work. This difference in performance could not be attributed either to differences in sensory functioning or to differences in top-down cognitive effects. Second, this experiment extended the age-related findings of Nittrouer *et al.* (2009): Younger children than those who participated in that earlier study showed disproportionately enhanced performance for SW stimuli. 3-year-olds were able to recognize 75% of the words presented in SW sentences correctly. In sum, both native language experience and the extent of that experience have been found to influence listeners' abilities to organize sensory information in order to recover linguistically relevant structure.

These findings could have important implications for how we intervene with individuals, particularly children, who have hearing loss. At present, cochlear implants are not very good at preserving the kind of dynamic spectral information represented so well by the sine wave replicas used here. However, some individuals with severe-to-profound hearing loss have aidable hearing in the low frequencies. It may be worth exploiting that residual hearing in order to provide at least the first formant to these individuals through a hearing aid, and this practice could be especially beneficial for young children who rely heavily on dynamic spectral structure. Uchanski *et al.* (2009) found evidence to support this recommendation from one child with electric and acoustic hearing on the same side, and Nittrouer and Chapman (2009) found evidence from language outcomes of 58 children with hearing loss: Those who had some experience with combined electric and acoustic hearing fared better than children who had no such experience.

APPENDIX

Sentences from the HINT-C that were used are as follows. The words in parentheses indicate that either words are acceptable answers. The underlined word is the one that is said in creating the stimuli.

(a) Practice sentences

1. The yellow pears taste good.
2. (A/the) front yard (is/was) pretty.
3. The pond water (is/was) dirty.
4. The ground (is/was) very hard.
5. They painted (a/the) wall white.
6. (A/the) little girl (is/was) shouting.
7. (An/the) ice cream (is/was) melting.
8. (An/the) apple pie (is/was) baking.
9. (A/the) boy forgot his book.
10. The two farmers (are/were) talking.
11. The sky (is/was) very blue.
12. (A/the) black dog (is/was) hungry.

(b) Test sentences

1. Flowers grow in (a/the) garden.
2. She looked in her mirror.
3. They heard (a/the) funny noise.
4. (A/the) book tells (a/the) story.
5. (A/the) team (is/was) playing well.
6. (A/the) lady packed her bag.
7. They waited for an hour.
8. (A/the) silly boy (is/was) hiding.
9. (A/the) mailman shut (a/the) gate.
10. (A/the) dinner plate (is/was) hot.
11. They knocked on (a/the) window.
12. He (is/was) sucking his thumb.
13. He grew lots of vegetables.
14. He hung up his raincoat.
15. The police helped (a/the) driver.
16. He really scared his sister.
17. He found his brother hiding.
18. She lost her credit card.
19. He wore his yellow shirt.
20. The young people (are/were) dancing.
21. Her husband brought some flowers.
22. The children washed the plates.
23. (A/the) baby broke his cup.
24. They (are/were) coming for dinner.
25. They had a wonderful day.
26. The bananas (are/were) too ripe.
27. She argues with her sister.
28. (A/the) kitchen window (is/was) clean.
29. (A/the) mother heard (a/the) baby.
30. (An/the) apple pie (is/was) good.
31. New neighbors (are/were) moving in.
32. (A/the) woman cleaned her house.
33. The old gloves (are/were) dirty.
34. (A/the) painter uses (a/the) brush.
35. The bath water (is/was) warm.
36. Milk comes in (a/the) carton.
37. (A/the) ball bounced very high.
38. School got out early today.
39. The rain came pouring down.
40. (A/the) train (is/was) moving fast.
41. (A/the) baby slept all night.
42. Someone (is/was) crossing (a/the) road.
43. (A/the) big fish got away.
44. (A/the) man called the police.
45. (A/the) mailman brought (a/the) letter.
46. He climbed up (a/the) ladder.
47. He (is/was) washing his car.
48. The sun melted the snow.
49. The scissors (are/were) very sharp.
50. Swimmers can hold their breath.
51. (A/the) boy (is/was) running away.
52. (A/the) driver started (a/the) car.
53. The children helped their teacher.
54. (A/the) chicken laid some eggs.
55. (A/the) ball broke (a/the) window.
56. Snow falls in the winter.
57. (A/the) baby wants his bottle.
58. (An/the) orange (is/was) very sweet.

59. (An/the) oven door (is/was) open.
60. (A/the) family bought (a/the) house.

Perception of final fricative voicing: Native and nonnative listeners' use of vowel duration

Mirjam Broersma[a)]
Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, 6500 HE Nijmegen, The Netherlands

(Received 11 September 2008; revised 13 October 2009; accepted 22 December 2009)

Does experience with a perceptual cue for a phoneme contrast in the native language affect its use in a second language for a similar contrast in a different phonetic context? Two experiments investigated Dutch and English listeners' use of preceding vowel duration as a perceptual cue for nonword-final fricative voicing in English. Dutch listeners have native language experience with the use of vowel duration for vowel length and intervocalic obstruent voicing contrasts, but not for final voicing contrasts, as Dutch does not have voiced obstruents word-finally. Previous research [Broersma, M. (2005). J. Acoust. Soc. Am. **117**, 3890–3901; (2008) **124**, 712–715] showed that Dutch listeners used vowel duration less for final /v-f/ categorization than English listeners did when vowel duration varied only between subjects, discouraging its use as a perceptual cue. The present study assessed the use of vowel duration for final /v-f/ and /z-s/ contrasts when it varied within subjects. A goodness rating and a phonetic categorization experiment showed that Dutch listeners used vowel duration, but less than English listeners did. Thus, experience with a perceptual cue for a different contrast and for a similar contrast in a different position in the native language did not lead to native-like use of this cue in the second language.

I. INTRODUCTION

A lot is known about the perception of the sounds of a second language. A large body of research (see, e.g., the papers in Strange, 1995 and Bohn and Munro, 2007) has shown that mismatches between the phoneme repertoires of the first (L1) and second (L2) languages cause perceptual difficulties and that, therefore, distinguishing some L2 speech sounds is extremely difficult (Best and Strange, 1992), whereas distinguishing others is easy (Best *et al.*, 1988). Such research findings have inspired models of L2 or foreign language speech sound perception like the speech learning model (Flege, 1995) and the perceptual assimilation model (PAM) (Best *et al.*, 1988; Best and Tyler, 2007).

Not much is known, on the other hand, about the use of perceptual cues in L2 sound perception. It is not clear whether experience with the use of a perceptual cue in the L1 affects its use in the L2. In other words, can listeners "transfer" the use of an L1 perceptual cue to perception in the L2?

Experience with perceptual cues from the L1 might affect perception of similar L2 contrasts (e.g., French listeners' experience with preceding vowel duration as a cue for the final /z-s/ contrast may have affected their use of this cue for final /z-s/ decisions in English too; Flege and Hillenbrand, 1986) but it might also aid perception of completely different contrasts. Crowther and Mann (1992) found that native listeners of Japanese, which distinguishes between long and short vowels, were also sensitive to vowel duration when they categorized English final /d/ and /t/. Their experience with vowel duration as a perceptual cue for Japanese vowel contrasts might thus have aided their perception of English voiced and voiceless final stops.

Experience with perceptual cues from the L1 may, however, not always affect perception of L2 contrasts, even when the perceptual cue is used for similar L1 and L2 contrasts but in a different phonetic position. Broersma (2005, 2008) found that native listeners of Dutch, which has /v-f/ and /z-s/ contrasts similar to the English contrasts but does not distinguish between voiced and voiceless obstruents in word-final position, used the duration of the preceding vowel less consistently than English listeners did. Dutch listeners have native language experience with the use of vowel duration as a perceptual cue for vowel length contrasts and for intervocalic consonant voicing; yet, they did not seem to apply this experience when categorizing English final fricatives.

This paper further investigates the transfer of the use of perceptual cues from the L1 to the L2. It investigates to which extent Dutch listeners, who are familiar with the use of vowel duration as a perceptual cue, but not for final voicing contrasts (as their L1 does not have those), use vowel duration for this purpose when listening to English. To that end, the study of Broersma (2005, 2008) was extended with a different experimental design and a different paradigm.

In English, vowels are generally longer before a voiced final fricative than before a voiceless final fricative (Jones, 1950), and the duration of the preceding vowel affects listeners' perception of final fricatives as voiced or voiceless (Denes, 1955). Duration of the preceding vowel is a robust and very important perceptual cue for final fricative voicing for English listeners (Derr and Massaro, 1980; Hogan and Rozsypal, 1980; Raphael, 1972).

[a)]Electronic mail: mirjam@mirjambroersma.nl

Like English, Dutch has voiced and voiceless obstruents, namely, /b-p/, /d-t/, /v-f/, /z-s/, and /k/. All of the voiceless and none of the voiced obstruents can occur at the end of words in isolation (Booij, 1995). Dutch thus has a /z-s/ and a /v-f/ contrast, but does not have those contrasts in word-final position. Dutch listeners nevertheless do have some native language experience with the use of vowel duration for fricative voicing. For intervocalic two-obstruent sequences in Dutch (with the first, the second, or both being a fricative), duration of the preceding vowel plays a small but significant role for voicing perception (Van den Berg, 1987, 1988, 1989). For single intervocalic fricative voicing, no effect of vowel duration has been demonstrated on perception (e.g., Slis and Cohen, 1969b; Slis and Van Heugten, 1989), but vowels preceding a voiced intervocalic fricative are on average 40 ms longer than those preceding a voiceless intervocalic fricative in Dutch (Slis and Cohen, 1969a). Note that this difference for intervocalic fricatives in Dutch is much smaller than that before final fricatives in English; e.g., Peterson and Lehiste (1960) showed an average difference of 148 ms before voiced and voiceless final fricatives. Finally, results by Jongman *et al.* (1992) suggest that Dutch listeners can generalize their knowledge about the relation between vowel duration and intervocalic obstruent voicing to the case of word-final voicing, as the underlying voicing of voiceless word-final obstruents affects the way Dutch listeners categorize the duration of preceding vowels. Further, Dutch also has phonemically long and short vowels that are mainly distinguished by phonetic vowel duration (Booij, 1995). Thus, Dutch listeners have native language experience with the use of vowel duration as a perceptual cue both for obstruent voicing and vowel length contrasts.

The Dutch listeners studied by Broersma (2005, 2008) had a high level of proficiency in English as a second language and ample exposure to English. They had started receiving English instruction in primary school and were regularly exposed to English, i.e., through the media and in the educational system, as is common in The Netherlands. They therefore seem well equipped for a native-like use of preceding vowel duration as a perceptual cue for the English final /v-f/ and /z-s/ contrasts. Yet, the results of Broersma (2005, 2008) showed robust differences between the Dutch and the English listeners' use of vowel duration as a final fricative voicing cue in English.

In the experiment of Broersma (2005, 2008), vowel duration was made uninformative, and whereas the Dutch listeners initially used vowel duration to the same extent as the English listeners did, they soon stopped using it, whereas the English listeners kept using it persistently throughout the experiment. Thus, the Dutch but not the English listeners adapted their use of vowel duration to the nature of the experimental materials. Vowel duration was made uninformative to preclude the possibility that the Dutch listeners would use vowel duration only as a result of the stimulus materials, as in experiments with a limited number of variables, listeners may rely more on those variables than they would do with normal speech (Bohn, 1995; Bradlow, 1996). Thus, each participant heard either a phonetically long or a phonetically short vowel throughout the experiment, combined with a fricative from an 11-step voiced to voiceless continuum. Because for each participant vowel duration was kept constant, it was not an informative cue for final fricative voicing. Moreover, vowel duration mismatched the voicing information in the fricatives for some of the items (i.e., for /v/-like fricatives preceded by a short vowel and for /f/-like fricatives preceded by a long vowel).

Broersma (2005) showed that Dutch listeners used vowel duration less than English listeners did as a perceptual cue for the final /v-f/ contrast. Broersma (2008) further showed that the difference between the Dutch and English listeners' results was not immediately present, but arose during the first part of the experiment. In the 44 trials of the practice part of the experiment, the Dutch and the English listeners used vowel duration to a similar extent. After that, vowel duration did not affect Dutch listeners' responses anymore, whereas its effect remained unchanged for the English listeners' responses. For the English listeners, vowel duration strongly affected the responses, such that listeners in the long vowel condition gave more voiced responses than listeners in the short vowel condition did. Long vowels affected their categorization responses especially strongly; long vowels combined with fricatives at the voiceless end point of the continuum received 31% "V" responses. It was concluded that the Dutch listeners adapted to the nature of the stimulus materials more flexibly than the English listeners, who had extensive native language experience with vowel duration as a cue for final fricative voicing. The difference between the Dutch and the English listeners was thus at least partly related to the fact that vowel duration was kept constant for each participant due to the between-subjects design of the experiment.

Another indication that the experimental design induced a limited use of vowel duration as a perceptual cue for voicing are the categorization results for the final /z-s/ contrast (Broersma, 2005). For this contrast, neither the English nor the Dutch listeners' responses showed an effect of vowel duration, while previous research has shown that vowel duration is an important cue for final voicing distinctions for this contrast at least for English listeners (e.g., Derr and Massaro, 1980; Hogan and Rozsypal, 1980; Raphael, 1972). The question thus remains to which extent the results were due to the experimental design, and if there are also differences between Dutch and English listeners' use of vowel duration for the final /v-f/ contrast, and possibly for the final /z-s/ contrast, if vowel duration is not kept constant for each participant.

The present paper investigates Dutch and English listeners' use of vowel duration for final fricative voicing in English, with an experimental design that does not discourage the use of vowel duration as a perceptual cue. The same stimuli are used as in Broersma (2005, 2008), but now, instead of blocking vowel duration per participant, all participants are presented with both vowel durations (and with the 11 steps of the fricative voicing continuum, as in the earlier experiment). In Experiment 1, Dutch and English listeners' goodness ratings of the stimuli are collected. In Experiment 2, Dutch and English listeners' phonetic categorization of the

same stimuli is assessed. Experiment 2 is thus a replication of Broersma (2005, 2008), except that now, crucially, vowel duration is varied within subjects.

Both experiments address three questions. First, is there a difference between the Dutch and the English listeners' use of vowel duration for the /v-f/ contrast when it is an informative perceptual cue within the experiment? Second, is vowel duration used as a perceptual cue for the /z-s/ contrast as well, unlike in Broersma (2005, 2008) and, third, if so, do Dutch and English listeners use vowel duration differentially for the /z-s/ contrast?

II. EXPERIMENT 1

A. Method

1. Participants

Participants were 16 native speakers of Dutch and 16 native speakers of British English. None of them had participated in the experiments reported in Broersma (2005), but they were part of the same populations tested there. The Dutch participants were proficient in English as a second language. They had received on average 7 years of English instruction in primary and secondary schools and were regularly exposed to English through the media and at the university they attended. The English participants did not know any Dutch. The Dutch participants were recruited from the Max Planck Institute participant pool, and the English participants from the participant pool of the Laboratory of Experimental Psychology of the University of Sussex. None reported any speech or hearing disorders. All were volunteers and received a small fee for participation.

2. Materials

The same materials were used as in Broersma (2005). A male native speaker of British English recorded two tokens of the nonwords /ku:v/, /ku:f/, /fu:z/, and /fu:s/, in a clear citation style, in a soundproof booth. The materials were recorded with a Sennheiser microphone onto digital audiotape and downsampled to 16 kHz during transfer to a computer. Further editing was done with XWAVES software.

For each nonword, from one token, the final fricative was extracted. Thus, /v/, /f/, /z/, and /s/ were extracted from the end of each nonword, with the cut being made at the last positive zero crossing before the onset of frication noise. Two continua, one from /v/ to /f/ and one from /z/ to /s/, were created following the procedure of Stevenson (1979) and Repp (1981). The continua consisted of 11 steps, ranging from the natural voiced end point /v/ or /z/ (step 1) to the natural voiceless end point /f/ or /s/ (step 11), with 9 intermediate steps. To this end, first, the final /f/ and /s/ were shortened to match the durations of the final /v/ and /z/.[1] They were shortened by 56–127 ms (31%) for the /f/ and by 80–187 ms (30%) for the /s/ by removing a portion from the center of the fricative. Next, for the pairs of phonemes thus obtained, the amplitudes of the waveforms were added in varying proportions in 11 equally spaced steps (Stevenson, 1979; Repp, 1981).

For each nonword, a carrier containing all but the fricative was extracted from the other token. Thus, from the nonwords /ku:v/ and /ku:f/, /ku:/ was extracted, and from the nonwords /fu:z/ and /fu:s/, /fu:/ was extracted, removing the final fricative, truncating the signal at the last positive zero crossing before the start of the frication noise. For each continuum, there were thus two carriers. One carrier was originally pronounced with a voiced final fricative and contained a phonetically long vowel (of 257 ms for the /v-f/ and 233 ms for the /z-s/ contrast) and the other was originally pronounced with a voiceless final fricative and contained a phonetically short vowel (of 98 ms for the /v-f/ and 118 ms for the /z-s/ contrast).

For each continuum, the two end points and the nine intermediate steps were spliced onto the end of the appropriate carriers. Thus, for the /v-f/ continuum, all steps were spliced onto both /ku:/ carriers, and for the /z-s/ continuum, all steps were spliced onto both /fu:/ carriers. Auditory examination ensured that the manipulation had not resulted in audible discontinuities.

3. Design

Stimuli were blocked by contrast but not by vowel duration. There were four blocks, two for the /v-f/ contrast and two for the /z-s/ contrast. For the /v-f/ items, participants decided in one block to which extent each fricative sounded like a good "V," and in the other block to which extent the same items sounded like a good "F," and for the /z-s/ items, participants decided in one block to which extent each fricative sounded like a good "Z," and in the other block like a good "S." As the carrier for the /z-s/ contrast contained an /f/, the /v-f/ contrast was always tested before the /z-s/ contrast; otherwise the order of the blocks was counterbalanced. Each block contained all combinations of 11 fricatives and two carriers presented in random order.

4. Procedure

Participants were tested one at a time in a quiet room. They received written instructions in their native language that they would hear a series of English nonwords, and they were asked to pay attention to the final sound. Before each block, they were informed about the target sound in that block. Participants were instructed to decide whether the final sound of each stimulus was a very poor, fairly poor, fairly good, or very good instance of the target sound and to indicate their response by pressing one of four buttons, labeled from "1—poor" to "4—good."

The experiment started with a short practice during which the participants heard nonwords ending with a /b/ or a /p/, some of them unedited and others with the release burst removed (Broersma 2005, Experiment 1) and indicated to what degree this sound corresponded to a "B."

The experiment was controlled with Nijmegen Experiment Set-Up (NESU) software, and stimuli were presented binaurally, one at a time, over Sennheiser closed headphones at a comfortable listening level. Participants responded by pressing one of four response buttons. Stimuli were presented with 3000 ms intervals between onsets.

B. Results and discussion

Analyses of variance (ANOVAs) were done on averaged goodness ratings, with vowel duration and fricative voicing as within-subjects factors and native language as between-subjects factor. As a measure of effect size, *partial* η^2 is reported. A *partial* η^2 of 0.01 is considered to indicate a small effect size, a *partial* η^2 of 0.06 a medium, and of 0.14 a large effect size. Mean responses are presented in Table I.

First, for the "V" target, Fig. 1(a) shows that both for the Dutch and for the English listeners, as expected, goodness ratings are higher for items with a long vowel than for items with a short vowel [vowel duration: $F(1,30)=209.23, p<0.001$, *partial* $\eta^2=0.88$] and higher for items with more voiced fricatives than for items with less voiced fricatives [fricative voicing: $F(10,300)=8.86, p<0.001$, *partial* $\eta^2=0.23$]. Crucially, however, the use of vowel duration differs for the Dutch and English listeners in part of the voicing continuum, as reflected in a significant interaction among vowel duration, fricative voicing, and native language [$F(10,300)=2.79, p<0.01$, *partial* $\eta^2=0.09$]. For the English listeners, in the condition with the short preceding vowel, goodness ratings are higher for items with more voiced fricatives than for items with less voiced fricatives, as expected [$F(10,150)=9.36, p<0.001$, *partial* $\eta^2=0.38$], but in the condition with the long preceding vowel, there is no significant effect of fricative voicing [$F(10,150)=1.49, p>0.1$]. Thus, English listeners give stimuli with more voiced fricatives and stimuli with less voiced fricatives similar goodness ratings for "V" when they are preceded by a long vowel. For those listeners, indeed, there is an interaction between vowel duration and fricative voicing [$F(10,150)=4.97, p<0.001$, *partial* $\eta^2=0.25$]. Thus, long vowel durations affect the English listeners' goodness ratings more than short vowel durations do. For the Dutch listeners, on the other hand, there is no interaction between vowel duration and fricative voicing [$F(10,150)<1$]. For those listeners, goodness ratings are higher for items with more voiced fricatives than for items with less voiced fricatives [$F(10,150)=2.88, p<0.01$, *partial* $\eta^2=0.16$] for both vowel durations alike, and goodness ratings are higher for items with a long vowel than for items with a short vowel [$F(1,15)=91.70, p<0.001$, *partial* $\eta^2=0.86$]. This pattern is in line with the results reported in Broersma (2005, 2008) that for English listeners, when vowel duration and fricative voicing do not match, the long vowel but not the short vowel outweighs fricative voicing, but for Dutch listeners, long and short vowels affect /v-f/ categorization to the same extent.

Second, for the "F" target, Fig. 1(b) shows that for Dutch and English listeners, as expected, goodness ratings are higher for items with a short vowel than for items with a long vowel [$F(1,30)=27.13, p<0.001$, *partial* $\eta^2=0.48$] and higher for items with less voiced fricatives than for items with more voiced fricatives [$F(10,300)=14.69, p<0.001$, *partial* $\eta^2=0.33$]. Crucially, vowel duration affects Dutch listeners' goodness ratings for "F" less than the English listeners' ratings, as reflected in an interaction between vowel duration and native language [$F(1,30)=4.50, p<0.05$, *partial* $\eta^2=0.13$]. For the English listeners, the effect of vowel duration, in the expected direction, is significant [$F(1,15)=103.03, p<0.001$, *partial* $\eta^2=0.87$]; for the Dutch listeners, it is not [$F(1,15)=2.74, p>0.1$]. For the condition with the short preceding vowel, there is no difference between the Dutch and English' listeners' goodness ratings, [$F(1,30)<1$], but for the condition with the long preceding vowel, Dutch listeners give higher scores than English listeners do [$F(1,30)=11.01, p<0.01$, *partial* $\eta^2=0.27$]. Thus, not all vowel durations but specifically long vowel durations lead to different ratings for English listeners than for Dutch listeners. This is in line with the finding for the "V" target that long vowels affect the English listeners but not the Dutch listeners particularly strongly.

Comparing "V" and "F" targets, in the condition with the long vowel, Dutch listeners give high goodness ratings for the "V" target, but also relatively high goodness ratings for the "F" target. Thus, whereas the English listeners perceive stimuli with a long vowel as a good "V" and as a poor "F," the Dutch listeners perceive them as good exemplars of "V" but also as relatively good exemplars of "F", showing again that vowel duration is not as decisive for the Dutch listeners' perception of the goodness of the voicing of those fricatives as it is for the English listeners' perception.

For the "Z" target [Fig. 2(a)] and for the "S" target [Fig. 2(b)], crucially, vowel duration significantly affects goodness ratings too. For the "Z" target, items with a long vowel receive higher goodness ratings than items with a short vowel [$F(1,30)=68.43, p<0.001$, *partial* $\eta^2=0.70$], and for the "S" target, items with a short vowel receive higher goodness ratings than items with a long vowel [$F(1,30)=50.40, p<0.001$, *partial* $\eta^2=0.63$] for Dutch and English listeners alike. Further, the effect of fricative voicing is also as expected: for the "Z" target, goodness ratings are higher for items with more voiced fricatives than for items with less voiced fricatives [$F(10,300)=31.03, p<0.001$, *partial* $\eta^2=0.51$], and for the "S" target, goodness ratings are higher for items with less voiced fricatives than for items with more voiced fricatives [$F(10,300)=32.36, p<0.001$, *partial* $\eta^2=0.52$] for Dutch and English listeners alike.

Finally, comparing the /v-f/ and the /z-s/ contrast, there is an interaction between vowel duration and contrast [$F(1,30)=4.39, p<0.05$, *partial* $\eta^2=0.13$], confirming that the effect of vowel duration is larger for the /v-f/ contrast than for the /z-s/ contrast.

In summary, for the /v-f/ and the /z-s/ contrast, both vowel duration and fricative voicing affect the goodness ratings as expected: long vowels lead to higher goodness ratings than short vowels for voiced targets and vice versa for voiceless targets, and more voiced fricatives lead to higher goodness ratings than more voiceless fricatives for voiced targets and vice versa for voiceless targets. Effect sizes are large both for vowel duration and fricative voicing, but larger for the former than for the latter. Importantly, the effect of vowel duration is found not only for the /v-f/ contrast but also for the /z-s/ contrast.

For the /v-f/ contrast, vowel duration and, in particular, long vowels affect English listeners' goodness ratings more than Dutch listeners' ratings. These results are in line with the phonetic categorization results from Broersma (2005,

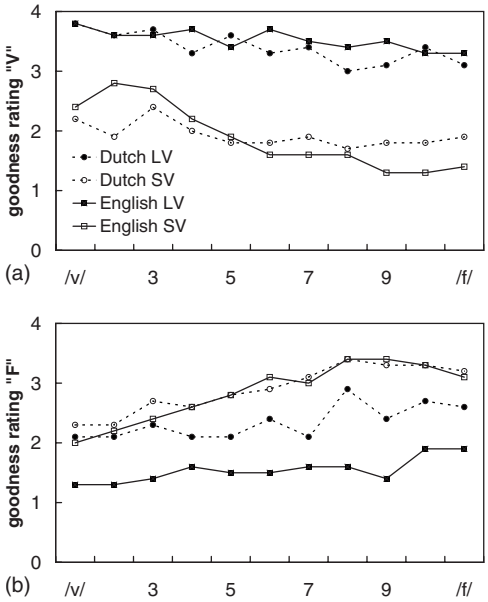

FIG. 1. Mean goodness rating as a function of the place on an 11-step /v/ to /f/ continuum, preceding vowel duration (LV: long vowel; SV: short vowel), and participants' native language: (a) target "V" and (b) target "F."

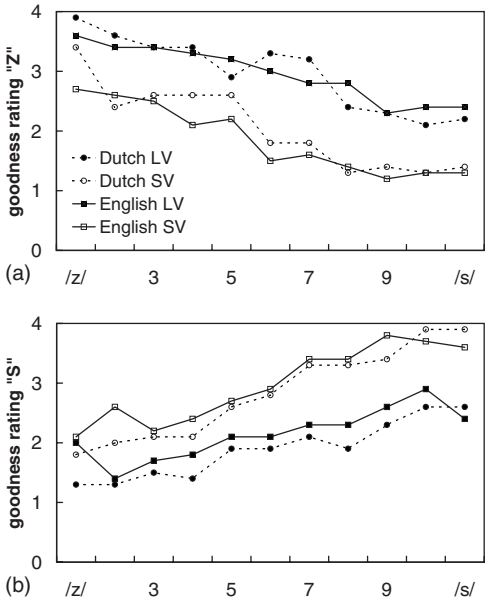

FIG. 2. Mean goodness rating as a function of the place on an 11-step /z/ to /s/ continuum, preceding vowel duration (LV: long vowel; SV: short vowel), and participants' native language: (a) target "Z" and (b) target "S."

2008) that showed a larger effect of vowel duration for English listeners than for Dutch listeners and an especially large effect of long vowel durations when combined with voiceless fricatives for English listeners. The present results show that those findings were not an artifact of the design of Broersma (2005, 2008), where vowel duration was kept constant for each participant, but is also found when vowel duration is varied for each participant.

Experiment 2 further investigates the use of vowel duration when it varies within subjects with a phonetic categorization task. The experiment is identical to that in Broersma (2005, 2008), except that all participants hear both the phonetically long vowel and the phonetically short vowel. Stimuli thus vary in vowel duration and in fricative voicing for each participant. Cue trading between temporal and spectral cues has often been found (Fitch *et al.*, 1980; Sinnott and Saporita, 2000), and a trading relation between vowel duration and fricative voicing is anticipated here too. Note that whereas fricative voicing varies in 11 steps, vowel duration varies in only two steps, which might make the latter variable relatively salient (Bohn, 1995). The experiment addresses the same three questions; first, whether there is still a difference between the Dutch and the English listeners' use of vowel duration for the /v-f/ contrast when it varies within subjects, second, whether vowel duration is used as a perceptual cue for the /z-s/ contrast, like in Experiment 1, but unlike in Broersma (2005, 2008), and third, whether Dutch and English listeners use vowel duration differentially for the /z-s/ contrast.

III. EXPERIMENT 2

A. Method

1. Participants

Participants were 16 native speakers of Dutch and 16 native speakers of British English, matching the description given for Experiment 1, none of whom had participated in Experiment 1.

2. Materials

The same materials were used as in Broersma (2005) and in Experiment 1.

3. Design

As in Experiment 1, stimuli were blocked by contrast but, unlike in Broersma (2005), not by vowel duration. Thus, each participant heard both the phonetically long and the phonetically short vowel within the same experiment and within the same block. As the carrier for the /z-s/ contrast contained an /f/, the /v-f/ contrast was always tested before the /z-s/ contrast. Each block contained 20 repetitions of all combinations of 11 fricatives and two carriers, yielding 440 trials per block. Items were semi-randomized, such that the same step of the fricative continuum could not occur twice in succession. There was no practice with the crucial contrasts, only with the /b-p/ contrast (as in Experiment 1).

4. Procedure

Participants were tested one at a time in a quiet room. They received written instructions in their native language that they would hear a series of English nonwords, which would be similar except for the final sound. They were instructed to decide whether this was a "V" or an "F," or a "Z" or an "S," respectively, and to indicate their response by pressing one of two buttons, labeled "V" and "F," or "Z" and "S." The experiment started with a short practice during which the participants categorized final stops as "B" or "P."

The experiment was controlled with NESU experimental software. Stimuli were presented binaurally, one at a time, over Sennheiser closed headphones at a comfortable listening level. Participants responded by pressing one of two response buttons. No time limit was imposed for the responses. After each button press, presentation of the next item started.

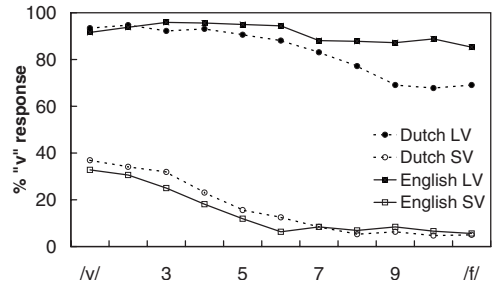

FIG. 3. Mean percentage of "V" responses as a function of the place on an 11-step /v/ to /f/ continuum, preceding vowel duration (LV: long vowel; SV: short vowel), and participants' native language.

B. Results and discussion

Two responses with reaction times longer than 10 000 ms were removed. As Figs. 3 and 4 show, for both contrasts, the effect of vowel duration is very large. The categorization curves are very shallow, and the mean percentages of "voiced" responses for the conditions with the long and short preceding vowels do not overlap, except for the Dutch listeners' responses for the /z-s/ contrast, where they just touch (with 57% "Z" responses for step 11 in the condition with the long preceding vowel and 58% for step 1 in the condition with the short preceding vowel). ANOVAs were done on arcsine transformed proportions of "voiced" responses, with vowel duration and fricative voicing as within-subjects factors and native language as between-subjects factor. Mean responses are presented in Table I.

Figure 3 shows that especially for the /v-f/ contrast, the effect of vowel duration is extremely large and the effect of fricative voicing is relatively small, both for the Dutch and for the English listeners. Indeed, stimuli with long vowels receive more "V" responses than stimuli with short vowels, both for the Dutch listeners [$F(1,15)=59.43, p<0.001$, *partial* $\eta^2=0.80$] and for the English listeners [$F(1,15)=160.95, p<0.001$, *partial* $\eta^2=0.92$]. Items with more voiced fricatives also receive significantly more "V" responses than items with less voiced fricatives for the Dutch listeners [$F(10,150)=12.83, p<0.001$, *partial* $\eta^2=0.46$] and for the English listeners [$F(10,150)=6.76, p<0.001$, *partial* $\eta^2=0.31$].

Crucially, however, there are differences between the Dutch and English listeners' categorization responses, reflected in a significant three-way interaction among vowel duration, fricative voicing, and native language [$F(10,300)=1.90, p<0.05$, *partial* $\eta^2=0.06$]. As Fig. 3 shows, in the condition with the long preceding vowel, the English listeners give more "V" responses than the Dutch listeners to items with less voiced fricatives. Indeed, in the condition with the long preceding vowel, the interaction between fricative voicing and native language is significant [$F(10,300)=2.60, p<0.005$, *partial* $\eta^2=0.08$]. For the condition with the short preceding vowel, there is no interaction between fricative voicing and native language [$F(10,300)<1$].

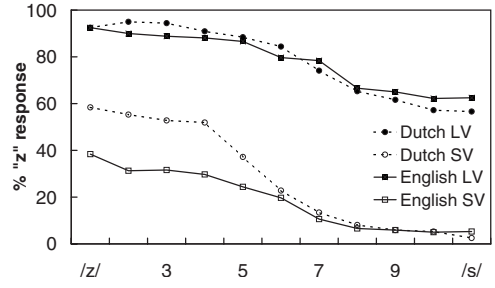

FIG. 4. Mean percentage of "Z" responses as a function of the place on an 11-step /z/ to /s/ continuum, preceding vowel duration (LV: long vowel; SV: short vowel), and participants' native language.

For the /z-s/ contrast, Fig. 4 again shows a large effect of vowel duration and a relatively small effect of fricative voicing, both for the Dutch and for the English listeners. Similar to the /v-f/ contrast, stimuli with long vowels receive more "Z" responses than stimuli with short vowels, both for the Dutch listeners [$F(1,15)=33.87, p<0.001$, *partial* $\eta^2=0.69$] and for the English listeners [$F(1,15)=61.49, p<0.001$, *partial* $\eta^2=0.80$]. Items with more voiced fricatives also receive significantly more "Z" responses than items with less voiced fricatives for the Dutch listeners [$F(10,150)=20.58, p<0.001$, *partial* $\eta^2=0.58$] and for the English listeners [$F(10,150)=14.21, p<0.001$, *partial* $\eta^2=0.49$].

Also similar to the /v-f/ contrast, there is a difference between the Dutch and English listeners' categorization responses, reflected in a significant three-way interaction among vowel duration, fricative voicing, and native language [$F(10,300)=2.09, p<0.05$, *partial* $\eta^2=0.07$]. Figure 4 shows that the difference between the Dutch and English listeners' responses is now located on the other side of the graph than for the /v-f/ contrast: in the condition with the short preceding vowel the English listeners give fewer "Z" responses than the Dutch listeners to items with more voiced fricatives. In that condition, the interaction between fricative voicing and native language is significant [$F(10,300)=2.98, p<0.001$, *partial* $\eta^2=0.09$]. For the condition with the long preceding vowel, there is no interaction between fricative voicing and native language [$F(10,300)<1$].

The results for the /v-f/ and /z-s/ contrasts are thus to a large extent similar: both Dutch and English listeners use vowel duration and fricative voicing as a perceptual cue, effect sizes are large both for vowel duration and fricative voicing but larger for the former than for the latter, and for both contrasts, differences between the Dutch and English listeners' responses appear where the stimuli contain mismatching cues. However, where these differences occur is different for both contrasts. For the /v-f/ contrast, English listeners give more "voiced" responses than the Dutch listeners do to items with less voiced fricatives preceded by a long vowel, and for the /z-s/ contrast, English listeners give more "voiceless" responses than the Dutch listeners do to items with more voiced fricatives preceded by a short vowel. Thus, in these places, the English listeners rely more on vowel duration than the Dutch listeners do.[2]

The results for the /v-f/ contrast are in line with those from Broersma (2005), where English listeners also gave more "voiced" responses than Dutch listeners did to long vowels combined with less voiced fricatives. For the /z-s/ contrast, on the other hand, there was no effect of vowel duration in that study. In the present study, the effect of

vowel duration is also smaller and the effect of fricative voicing is larger for the /z-s/ contrast than for the /v-f/ contrast (an ANOVA with contrast as an additional within-subjects factor shows significant interactions between vowel duration and contrast [$F(1,30)=11.37, p<0.01$, *partial* $\eta^2=0.28$)] and between fricative voicing and contrast [$F(10,300)=5.90, p<0.001$, *partial* $\eta^2=0.16$]). However, the effect size of vowel duration for the /z-s/ contrast is still very large, and crucially, vowel duration affects Dutch and English listeners differentially.

IV. GENERAL DISCUSSION

Three questions were raised in the Introduction. First, would Dutch and English listeners use vowel duration differently for the /v-f/ contrast when it was varied for each participant? Both experiments showed that this was indeed the case. Thus, the finding of Broersma (2005, 2008) that Dutch listeners used vowel duration less than English listeners did was not an artifact of the between-subjects manipulation of vowel duration in that study. In the present experiments, where the design did not discourage the use of vowel duration as a perceptual cue, Dutch listeners still used it less than English listeners did.

The second question was whether there would be an effect of vowel duration for the /z-s/ contrast when vowel duration varied within subjects. Indeed, in both experiments, a clear effect of vowel duration was found. Thus, the lack of such an effect in Broersma (2005) was most likely due to the design of that study. The finding that the English listeners used vowel duration for the final /z-s/ distinction is in line with earlier research (e.g., Derr and Massaro, 1980; Hogan and Rozsypal, 1980; Raphael, 1972). The effect of vowel duration was smaller for the /z-s/ contrast than for the /v-f/ contrast in both experiments.

The third question was whether Dutch and English listeners would use vowel duration differently for the /z-s/ contrast too. In Experiment 1, there were no differences between the Dutch and English listeners' use of vowel duration for the /z-s/ contrast. Experiment 2 (involving a more sensitive paradigm) showed, however, that English listeners used vowel duration more than Dutch listeners did. Thus, the differences between Dutch and English listeners' use of vowel duration as a perceptual cue are not limited to the /v-f/ contrast, but occur for the /z-s/ contrast too.

Experiment 2 was a replication of Broersma (2005, 2008), except for the within-subjects manipulation of vowel duration. The results show that this design choice affected the listeners' use of vowel duration as expected. In Experiment 2, a large effect size of vowel duration was found for both contrasts. (This was also the case in Experiment 1, where vowel duration was also varied for each participant.) In Broersma (2005, 2008), on the other hand, where vowel duration was varied only between subjects, the effect size of vowel duration for the /v-f/ contrast was medium (with a *partial* η^2 of 0.12), and there was no significant effect of vowel duration for the /z-s/ contrast.

What do these results mean in terms of perceptual accuracy? The differences between Dutch and English listeners, although very robust, were also especially prominent where perceptual cues mismatched. Further, Dutch listeners did use vowel duration as a final voicing cue, and the differences between the Dutch and the English listeners' use of vowel duration were relatively small compared to the overall size of the effect of vowel duration. This may explain why in a previous study (Broersma, 2005, Experiment 1) Dutch listeners were found to categorize unedited tokens of final voiced and voiceless fricatives as accurately as English listeners did and as accurately as word-initial fricatives. Their use of vowel duration might be sufficiently adequate to recognize final voiced and voiceless fricatives under normal circumstances (i.e., when perceptual cues do not mismatch). Further, they might successfully use other temporal, spectral, and power properties of the stimuli (e.g., Jongman *et al.*, 2000; Silbert and De Jong, 2008) to distinguish between voiced and voiceless final fricatives. Therefore, in normal language use, the differences in cue weighting demonstrated here might not hinder Dutch listeners' comprehension of English speech much, in line with the predictions of the PAM (Best *et al.*, 1988; Best and Tyler, 2007).

Finally, what do these results mean for the transfer of the use of perceptual cues from the L1 to the L2? It was argued in the Introduction that Dutch listeners were well equipped for the use of vowel duration as a perceptual cue for final fricative voicing. Dutch provides experience with the use of vowel duration as a perceptual cue for vowel length contrasts and even for intervocalic obstruent voicing contrasts. Despite their native language experience with the use of vowel duration as a perceptual cue, Dutch listeners used it less than English listeners did for the English final fricative voicing contrasts. Thus, the Dutch listeners (advanced L2 learners with ample exposure to English) did not seem to apply their L1 experience with vowel duration when listening to English contrasts. Whether their L1 experience affected the use of vowel duration for final fricative voicing at all, the present data cannot reveal, but the results showed that the Dutch listeners did not rely on this cue as strongly as native English listeners did. The findings extend those from Broersma (2005, 2008) and seem to reflect a robust difference between Dutch and English listeners' use of vowel duration that is not limited to a single phoneme contrast or to a particular experimental design or paradigm. Thus, experience with a perceptual cue for a contrast in the L1 may not suffice for the efficient use of this cue for a different contrast in the L2, or even for a similar contrast in a different phonetic position in the L2.

ACKNOWLEDGMENTS

This research was supported by a Veni grant from the Netherlands Organisation for Scientific Research (NWO). Many thanks to Alan Garnham of the Laboratory of Experimental Psychology, University of Sussex, and to Anne Cutler of the Max Planck Institute for Psycholinguistics, Nijmegen, for the opportunity to test participants in their laboratories. I am grateful to Marco van de Ven for testing Dutch participants and to an anonymous reviewer for helpful comments.

[1]Voiced and voiceless fricatives of equal duration were needed in order to create the continua. As frication noise is generally longer for voiceless final fricatives than for voiced final fricatives (Crystal and House, 1988; Silbert and De Jong, 2008) and listeners use frication duration as a perceptual cue for final fricative voicing (Watson, 1983), shortening the voiceless fricatives may have made them perceptually more voiced.

[2]In Broersma (2008), English listeners' use of vowel duration changed during the experiment. Here, this was not the case. The data for each contrast were split into seven parts. In an ANOVA with part as an additional within-subjects factor, there were no interactions with or main effect of part, showing that the use of vowel duration or fricative voicing did not change during the experiment.

Resistance to learning binaurally mismatched frequency-to-place maps: Implications for bilateral stimulation with cochlear implants[a)]

(Received 14 December 2007; revised 8 December 2009; accepted 22 December 2009)

Simulations of monaural cochlear implants in normal hearing listeners have shown that the deleterious effects of upward spectral shifting on speech perception can be overcome with training. This study simulates bilateral stimulation with a unilateral spectral shift to investigate whether listeners can adapt to upward-shifted speech information presented together with contralateral unshifted information. A six-channel, dichotic, interleaved sine-carrier vocoder simulated a binaurally mismatched frequency-to-place map. Odd channels were presented to one ear with an upward frequency shift equivalent to 6 mm on the basilar membrane, while even channels were presented to the contralateral ear unshifted. In Experiment 1, listeners were trained for 5.3 h with either the binaurally mismatched processor or with just the shifted monaural bands. In Experiment 2, the duration of training was 10 h, and the trained condition alternated between those of Experiment 1. While listeners showed learning in both experiments, intelligibility with the binaurally mismatched processor never exceeded, intelligibility with just the three unshifted bands, suggesting that listeners did not benefit from combining the mismatched maps, even though there was clear scope to do so. Frequency-place map alignment may thus be of importance when optimizing bilateral devices of the type studied here.

I. INTRODUCTION

For users of a cochlear implant (CI), the restoration of binaural hearing could provide a range of advantages including binaural squelch, the head-shadow effect, and increased stimulus redundancy, all of which may lead to better understanding of speech in noisy listening environments. Even though current CIs do not provide the fine structure information that contributes to binaural processing in normal hearing, a binaural advantage for speech perception has been reported in patients with bilateral cochlear implants (Dorman and Dahlstrom, 2004; Tyler *et al.*, 2005; Litovsky *et al.*, 2006; Wackym *et al.*, 2007; Tyler *et al.*, 2007) and for implants used in conjunction with acoustic hearing aids (HAs) (Iwaki *et al.*, 2004; Ching *et al.*, 2004; Hamzavi *et al.*, 2004; Ching *et al.*, 2005; Ching, 2005; Ching *et al.*, 2006).

While the potential benefits are manifold, the bilateral use of auditory devices raises new questions in CI frequency-place mapping. Cochlear implant electrode arrays are usually designed for an insertion depth of 25 mm into the typically 35 mm long cochlea. In many cases, however, the insertion achieved is shallower than this. Estimates based on *in vivo* computed tomography from 26 Nucleus-22 implant recipients showed insertion depths ranging from 11.9 to 25.9 mm, as well as considerable variation in cochlear length from 29.1 to 37.4 mm (Ketten *et al.*, 1998; Skinner *et al.*, 2002). The topography of the neural elements stimulated by the electrode contacts is not at present completely understood. The standard approach for estimating the effective characteristic frequency (CF) at each electrode contact has followed the frequency-to-place mapping of the organ of Corti established by Greenwood (1990). At the median insertion depth of 20 mm found by Ketten *et al.* (1998), the Greenwood map leads to an estimated CF of 1000 Hz. However, this map is not a realistic model for the CFs of CI electrodes placed near the modiolus, for which a spiral ganglion map seems more appropriate (Stakhovskaya *et al.*, 2007). A spiral ganglion frequency-to-place map assigns substantially lower CFs to a given electrode contact position than does Greenwood's organ of Corti map, especially for more apical electrode locations. It may therefore be important to consider proximity to the modiolar wall when estimating the effective CF of an electrode contact, which would require imaging of the cochlea and the electrode array for each subject.

Notwithstanding our incomplete knowledge of the effective CFs along an electrode array, the altered frequency-to-place mapping resulting from incomplete insertion of the implant electrode array and band-limited speech processing has demonstrable and sizable effects for monaural CIs (Skinner *et al.*, 2002). This has led to an ongoing debate about whether it is best to preserve tonotopic matching at the ex-

pense of a frequency-shifted map that is maximally informative for speech. Earlier acute studies using vocoder-based simulations of cochlear implant speech processing suggested that a basalward frequency shift larger than 3 mm, using an organ of Corti map, leads to large decreases in speech intelligibility (Dorman *et al.*, 1997a; Shannon *et al.*, 1998). Analogous downward shifts of CI processor analysis filter frequencies have been shown to have a similar effect on vowel recognition by CI patients (Fu and Shannon, 1999). Yet, more recent studies with both noise-vocoded simulations (Rosen *et al.*, 1999; Fu *et al.*, 2005b; Faulkner *et al.*, 2006; Smith and Faulkner, 2006) and cochlear implant patients (Fu *et al.*, 2002; Svirsky *et al.*, 2004; Fu *et al.*, 2005a) have allowed listeners time to adapt to altered frequency-place maps and have shown improved performance after a period of training. For example, Rosen *et al.* (1999) trained normal hearing listeners with noise-vocoded simulations of a 6.5 mm basalward shift and found that word recognition had improved from floor to 30% after 3 h of training.

However, with bilateral implants or a cochlear implant in combination with a contralateral HA, the frequency-place maps in the two ears may be very different. For bilateral implants, the two electrodes may be inserted to different depths, resulting in different degrees of basalward shift. This may also interact with varying patterns of nerve survival in the two ears. In the case of CI+HA, the HA ear will retain the natural frequency-place map (albeit with a limited frequency range), while the CI ear is likely to be subject to basalward place shifting. To what extent are listeners able to adapt when presented with frequency-place maps that differ between the two ears?

Dorman and Dahlstrom (2004) reported a binaural advantage for speech perception in two bilateral implant patients who had different cochlear implants in each ear, which may support the hypothesis that information from mismatched frequency-to-place maps can be combined. Patients showed improvements of 32%–34% on HINT sentences with the addition of the second implant over performance with the better ear alone. However, the study only included two subjects, and the method for determining mismatch between the ears—pitch-ranking of electrodes—was inexact. The authors conceded that the degree of mismatch between the ears was unknown, and thus the question of adaptation to such a mapping remains open.

Evidence from dichotic listening experiments suggests that speech information presented in complement across the two ears is easily integrated. Broadbent and Ladefoged (1957) showed that listeners presented with the F1 and F2 of a /da/ syllable separately to opposite ears perceived the syllable as /da/. This process, later termed *spectral fusion* by Cutting (1976), is robust to differences in level and fundamental frequency, but not relative onset time; the majority of listeners appear able to integrate (tonotopically matched) acoustic cues efficiently (Rubin *et al.*, 1992).

To the extent that the information delivered to each ear with bilateral CIs is in complement, a binaural advantage for speech perception should be expected. However, this might be achieved through various possible mechanisms. For example, the binaural combination of information is likely to be relatively easy if there are similar basalward shifts to each ear. Alternatively, if listeners were able to adapt to different degrees of basalward shift in each ear, then they might still be able to combine spectral cues from the two ears to show a binaural speech advantage: information that may have been perceived as conflicting initially may eventually be perceived as complementary after experience with the implants. However, many bilateral CI users do not show a binaural advantage for speech over the best ear alone for speech in quiet (Tyler *et al.*, 2007) or for speech in noise in the absence of directional differences (van Hoesel *et al.*, 2002; Wackym *et al.*, 2007). A recent study suggests that better-ear listening is especially apparent for bilateral CI users who show asymmetrical monaural speech scores in each ear (Mosnier *et al.*, 2009). It thus seems plausible that misaligned frequency-place maps between each ear may underpin a lack of binaural advantage for speech shown in some bilateral CI users.

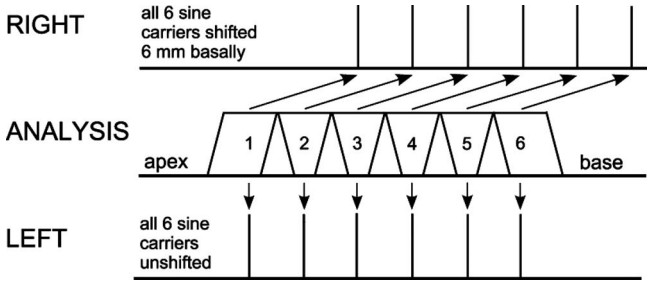

FIG. 1. Speech processing depicting sine-vocoded simulations of bilateral cochlear implants. Here, all analysis channels are presented to both ears, with the sine carriers at the right ear being upwardly shifted by an equivalent of 6 mm basilar membrane difference. In this configuration, the spectral information in each analysis band is delivered to different places in each ear. Further, the carrier frequencies for bands 1–4 in the right ear are the same as the carrier frequencies for bands 3–6 in the left ear so that there is an inter-aural conflict at each of these places.

A. Considerations for simulation methods sensitive to binaural advantage

Compared to monaural stimulation with cochlear implants, bilateral stimulation introduces complicating factors that may lead to decrements in speech perception. Consider the simplest case where contiguous frequency bands are vocoded and presented to each ear with an upward shift to one ear only, as in the bilateral six-channel sine vocoder illustrated in Fig. 1. Two distinct aspects of mapping conflict are evident. First, for each analysis band, the same spectral content is delivered to different tonotopic locations in each ear. Second, the carrier frequencies for bands 1–4 in the shifted ear are tonotopically aligned to the carriers for bands 3–6 in the unshifted ear so that the spectral information carried at each of these corresponding places is different in the two ears. The second of these conflicts may in addition lead to central masking (Mills *et al.*, 1996). A related but conceptually distinct global consequence of a mismatch of frequency mapping between the ears is that the central processing of spectral speech features cannot integrate information from the two ears without reference to an ear-specific transformation of the peripheral excitation pattern which needs to be learned.

A bilateral implant simulation of the type shown in Fig. 1, while representative of the information presented to an implant user, is not ideal for the study of adaptation to interaural mismatches of frequency mapping in normally hearing listeners. The primary difficulty with such a simulation is the redundancy of information between the shifted and unshifted ears. For tonotopically aligned speech in quiet, a binaural advantage can only be expected when there is some nonredundant information in each ear that can be exploited. The binaural advantage shown in some users of bilateral cochlear implants may arise from inter-aural variations in nerve survival or differences in spatial specificity at each ear that result in a sparcity of redundant information in each ear. However, for the normal hearing listener the signals will be completely redundant, which is especially problematic in a study where the intent is to encourage adaptation to a spectral shift to one ear only, because the information that can be gained by such adaptation is minimal. A second limitation of a bilateral implant simulation that employes the same contiguous analysis bands for both ears is that the local conflicts noted above are confounded with the global conflict that arises from the interpretation of two mismatched excitation patterns.

This redundancy can be eliminated through a configuration related to so-called *zipper processing*, which was initially proposed as an alternative processing strategy for bilateral CIs. Here only alternate electrodes at each ear were excited in an interleaved fashion with the aim of reducing interaction between electrodes (Lawson *et al.*, 2000). Data from pitch-ranking of electrodes across the ears were used to ensure, as far as possible, that the two ears were fitted without a significant mismatch of frequency-to-place mapping. The technique did not lead to improved speech scores compared to monaural fittings with the same total number of channels, but nor did it lead to decrements in speech intelligibility. While "zipper processing" has not been implemented clinically and is thus not representative of typical bilateral CI processing, the approach does provide a configuration that reduces redundancy and local conflicts of mapping between the two ears. It was thus ideal for the consideration of mismatched maps in normally hearing listeners in the absence of the confounding effects outlined above.

All speech processing was based on sine-excited vocoding (Loizou *et al.*, 2003). Sine carriers were chosen primarily to constrain the excitation patterns to avoid overlap of excitation in the two ears, which would be likely at the edges of noise-band carriers. The zipper-like (Lawson *et al.*, 2000) interleaved processing was chosen because it maximizes the potential advantage from the binaural combination of information between the two ears. In tests of dichotic speech perception in noise, Loizou *et al.* (2003) showed that for dichotically presented (unshifted) noise-vocoded speech, intelligibility was higher (and thus presumably binaural information more effectively combined) when channels were interleaved as here, rather than split according to low and high frequencies. Similar results were found for quiet speech in users of bilateral cochlear implants (Mani *et al.*, 2004).

The extent of mismatch between the ears was large at 6 mm to simulate the effect of a shallowly implanted electrode in one of two stimulated ears. Six channels were used, interleaved as three channels to each ear, to minimize the possibility of ceiling performance in unshifted conditions and at the same time to provide a shifted signal with sufficient information to be learnable. In relation to ceiling limits, it has been widely found that an unshifted three-channel vocoder leads to substantially poorer scores for most speech materials than an unshifted six-channel vocoder (Dorman *et al.*, 1997b; Fishman *et al.*, 1997; Loizou *et al.*, 1999). Thus, any improvements gained through adaptation to a mismatch between the two ears should be easily detectable. A pilot study showed that unshifted conditions were prone to ceiling effects with some easier speech materials, so the use of more than six channels in quiet was not explored (Faulkner, 2006). In relation to learnability, a 6.5 mm shifted four-band processor has been shown to allow fairly rapid adaptation given training (Rosen *et al.*, 1999).

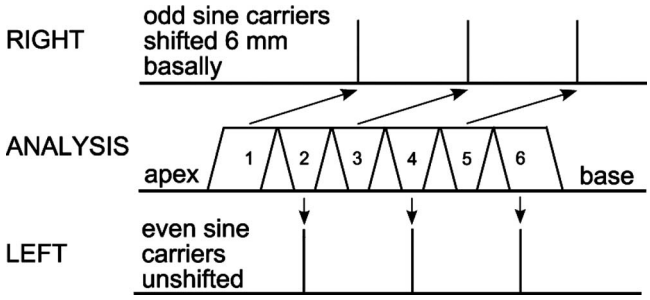

FIG. 2. Speech processing producing a binaurally mismatched frequency-to-place map. The middle panel represents the six spectral analysis bands covering the frequency range 200–5000 Hz. Temporal envelope information from channels 1, 3, and 5 is presented to the right ear (see top panel) imposed on sinusoidal carriers whose frequencies are shifted upward compared to the analysis channels to an extent equivalent to a 6 mm basalward shift on the basilar membrane. Temporal envelope information from channels 2, 4, and 6 is presented to the left ear (bottom panel) imposed on sinusoidal carriers that match the center frequencies of these three analysis bands.

Figure 2 shows a schematic representation of the binaurally mismatched processor that was employed. From low frequency (apical end) to high frequency (basal end), odd-numbered bands 1, 3, and 5 were presented to the right ear with the equivalent of a 6 mm basalward basilar membrane shift (assuming a 35 mm cochlea). Even-numbered bands 2, 4, and 6 were presented to the left ear without a shift.

B. Overview of research questions

In Experiment 1, we trained one group of listeners with a binaurally mismatched processor over eight 40 min training sessions, testing the extent of adaptation before, during, and after training. It was hypothesized that the presence of moderately intelligible unshifted frequency components may hinder adaptation to the shifted frequency map and thus to the binaurally mismatched processor. Consequently we also trained and tested a second group of listeners with just the shifted components to examine whether adaptation to the binaurally mismatched map could be facilitated by training with the shifted processor alone in the absence of the conflict between the two maps. In Experiment 2, we looked at how listeners adapt to the binaurally mismatched map over an

TABLE I. Conditions for Experiment 1.

Condition	Abbreviation	Component bands and shift	
		Right	Left
Six dichotic unshifted	6DU	1, 3, 5	2, 4, 6
Six dichotic odd shifted	6DOS	1, 3, 5 → 6 mm	2, 4, 6
Six odd shifted	6OS	1, 3, 5 → 6 mm 2, 4, 6	1, 3, 5 → 6 mm 2, 4, 6
Three even unshifted	3EU		2, 4, 6
Three odd shifted	3OS	1, 3, 5 → 6 mm	
Three odd unshifted	3OU	1, 3, 5	

extended course of training. We doubled the length of training and alternated training conditions from that of the two groups from Experiment 1 to see whether adaptation to binaurally mismatched frequency-place maps required a longer period and/or different type of training.

Perceptual adaptation to binaurally mismatched frequency-place maps has not been previously explored. If listeners do not learn to benefit from the binaurally mismatched maps, then this may reflect a constraint on plasticity for speech perception that could have implications for bilateral cochlear implant fittings. Alternative frequency-place mappings that avoid such binaural mismatches might be more optimal for speech recognition. If, however, a spectral mismatch can be learned, then the circumstances which facilitate this adaptation, such as specialized training techniques, need to be clarified.

II. EXPERIMENT 1

A. Method

1. Subjects

Twelve normally hearing speakers of British English took part, and each was paid for his or her participation. All had pure-tone audiometric thresholds better than 20 dB hearing level (HL) at octave frequencies from 250 to 8000 Hz. Ethical approval for this study was granted by the UCL/UCLH Joint Committee on the Ethics of Human Research.

2. Test conditions

Table I summarizes the six conditions tested in Experiment 1. These conditions were designed to assess what aspects of the signal were involved in any learning that took place. Test conditions were composed of monotic, dichotic, and diotic combinations of the spectral components outlined in Fig. 2 for the binaurally mismatched processor. Condition names were coded by number of channels, dichotic presentation, even- or odd-numbered channels, and shifted or unshifted presentation. When basalward shift was applied, it was always to the odd-numbered channels. Even-numbered channels were always unshifted.

The six dichotic unshifted (6DU) condition served as a control to assess maximal intelligibility. Here, unshifted odd- and even-numbered channels were interleaved between the ears. A pilot study indicated that this dichotic unshifted processor yielded intelligibility equivalent to a six-channel diotic processor. The main experimental condition (Fig. 2) was the six dichotic odd shifted (6DOS) condition. Here, odd-numbered bands were shifted an equivalent of 6 mm basally and presented to the right ear, while even-numbered bands were presented to the left ear without a shift. This binaurally mismatched processor was also used for training in one group of subjects. The six odd shifted (6OS) condition comprised the same six envelope-modulated carriers as the 6DOS condition, but was instead diotic: all bands were presented to both ears. In contrast to 6DOS, 6OS lacked any cue from ear of presentation to those carrier bands that were shifted. If performance here differed markedly from the 6DOS condition, this would suggest that listeners were learning to attune to information in an ear-specific manner. Conversely, if there was no difference, then we would infer that learning was occurring on the basis of the carrier frequencies. In the three even unshifted (3EU) condition, even-numbered channels alone were presented to the left ear unshifted. This was equivalent to the unshifted components of the 6DOS processor. In the three odd shifted (3OS) condition, odd-numbered channels were presented alone to the right ear with a 6 mm basalward shift. This comprised the shifted components of the 6DOS processor. This processor was also used for training in a second group of subjects. In the three odd unshifted (3OU) condition, odd-numbered channels were presented to the right ear unshifted. This condition was only tested for the group trained with the 3OS processor and allowed a comparison of the information provided by the odd- and even-numbered bands in the absence of shifting.

3. Signal processing

Center and crossover frequencies for the analysis and output filters were calculated using Greenwood's equation and its inverse, relating distance x (in mm) from the apex along the basilar membrane to characteristic frequency (in Hz). The assumed cochlear length was 35 mm (Greenwood, 1990).

$$\text{frequency} = 165.4(10^{0.06x} - 1),$$

$$x = \frac{1}{0.06}\log\left(\frac{\text{frequency}}{165.4} + 1\right).$$

The amplitude envelope of each band was extracted with an analysis filter, full-wave rectification, and a smoothing filter. The envelope was then multiplied by a sinusoid with frequency matching the center frequency of the band (or shifted equivalent). Finally, the requisite bands were summed and presented to the left and/or right ears as determined by pro-

TABLE II. Analysis band cutoff and carrier frequencies for each band in the unshifted (6DU, 3EU, and 3OU) and odd-band shifted (6DOS, OS, and 3OS) conditions.

Band	Analysis band cutoff (Hz)		Analysis band center frequency (Hz)	Carrier frequency (Hz)	
	Lower	Upper		Unshifted	Odd-shifted
1	200	403	290	290	878
2	403	718	543	543	543
3	718	1208	936	936	2359
4	1208	1971	1547	1547	1547
5	1971	3157	2498	2498	5937
6	3157	5000	3977	3977	3977

cessor condition. Table II shows input and output center frequencies as well as filter cutoffs. All processor conditions used the same six analysis filters and sine carriers at either the shifted or unshifted center frequencies of these analysis filters.

A real-time implementation of the vocoder processor was used for live training, while offline processing of the test material was implemented in MATLAB. This ensured identical repetition of test materials. Offline processing was executed at a 44.1 kHz sampling rate. Analysis bands were determined by a serial implementation of high-pass and low-pass third-order Butterworth IIR filters. Adjacent filter responses crossed at 3 dB down from the peak of the pass-band. Envelope smoothing used second-order low-pass Butterworth filters with a 32 Hz cutoff. Real time processing was implemented using the Aladdin Interactive DSP Workbench (Hitech Development AB, Sverige) and ran on a DSP card (Loughborough Sound Images TMSC31, Loughborough, UK). The computational power of the DSP was limited so the sampling rate was restricted to 16 kHz, and elliptical rather than Butterworth filter designs were used with the same 3 dB crossover frequencies as for the offline processing. Analysis filters consisted of fourth-order band-pass designs, while third-order low-pass filters were used for envelope smoothing.

In both testing and training, an equal loudness correction was applied to each of the shifted bands to preserve relative loudness across the spectra of unshifted and shifted speech. The correction was set to half the difference (in dB) between the minimal audible field threshold of the analysis filter and that at the center frequency of the shifted output filter. Minimal audible field values were taken from Robinson and Dadson (1956) and interpolated using a cubic spline fit to log frequency.

4. Training

Subjects were trained with connected discourse tracking (CDT) (De Filippo and Scott, 1978). In this method, the experimenter reads successive phrases from a text to the subject, who then repeats back what he or she heard. This allows the listener to acclimate to the spectrally distorted speech while engaging in a communication task that is similar to a conversation. The number of words repeated back correctly per minute provides a measure of progress throughout training. CDT has been shown to be an effective training method for spectrally shifted speech (Rosen *et al.*, 1999; Faulkner *et al.*, 2006).

The talker for the CDT portion of this experiment was the first author, C.S. Although she is a native speaker of a north-eastern dialect of American English, she had been living in the U.K. for 5 years at the time of testing and has been judged to have an accent similar to Standard Southern British English. CS's speech was not used for any of the testing. The talker read from the text in short phrases, and the listener repeated back what he or she heard. If the listener's response matched what the talker had said, the talker would move on to the next phrase. Otherwise the phrase was repeated. If after the third presentation, the listener could still not reproduce the phrase, the listener was presented the phrase as unprocessed speech (to the left ear only). Texts for CDT were chosen from the Heinemann Guided Readers series (elementary level). These texts are designed for learners of English as a second language and make use of controlled vocabulary and syntactic complexity. During training, the talker and subject were situated in adjacent sound-treated rooms. The room had a double-glazed window that enabled auditory-visual (AV) training. During auditory-only training, the window was blinded. A constant pink masking noise at 45 dBA was played in the listener's room to mask any speech from the talker that might be transmitted through the wall and window. The talker heard the listeners' responses over an intercom, and no attempt was made to prevent the listener hearing their own unprocessed voice when responding. Of the 12 subjects, 6 were trained with the 6DOS processor (6DOS-trained group), and the remaining 6 were trained with the 3OS processor (3OS-trained group).

5. Test materials

a. Sentence perception The IEEE/Harvard sentence lists (Rothauser *et al.*, 1969) were used, which have very little contextual information. Digital recordings of the sentences were from one male and one female talker of British English (16 bit, 48 kHz downsampled to 44.1 kHz). The 72 lists in the set each contained ten sentences with five keywords in each sentence. The first 36 lists were designated for the female talker, and the remaining 36 lists were designated for the male. A subset of 32 lists from each talker was used for the 6DOS-trained group, who were tested with fewer conditions. For each test session, two lists per condition were chosen from each talker set in a pseudo-random manner. No list appeared more than twice in the same condition across all of the subjects, and subjects never heard a list more than once. The subject was asked to repeat back to the experimenter as many words as he or she could, and no feedback was given. Words were counted correct when the word root was repeated correctly.

b. Vowel identification Vowel identification was included as a measure of the contribution of spectral cues in each condition and also as a source of both confusion and recognition accuracy data. If vowel confusions in the presence of spectral shift become more similar to those for unshifted processors after training, then this would reflect adaptation to the shifted speech. The task also allowed for the

TABLE III. Sequence of training and testing conditions for Experiment 1.

Session	Training	Processor	Testing
1	5 min audio visual (AV), 5 min auditory alone (AA)	6DU	*Familiarization:* Unprocessed vowels; *Pre-test*: IEEE sentences [2 lists × 5(6) conditions × 2 talkers], bVd identification [5 tokens × 5(6) conditions × 2 talkers]
2—5	5 min AV, 35 min AA	6DOS or 3OS	None
6	Familiarization if not immediately after session 5 (see text)		*Mid-test*: IEEE sentences [2 lists × 5(6) conditions × 2 talkers], bVd identification [5 tokens × 5(6) conditions × 2 talkers]
7—10	5 min AV, 35 min AA	6DOS or 3OS	None
11	Familiarization if not immediately after session 10 (see text)		*Post-test*: IEEE sentences [2 lists × 5(6) conditions × 2 talkers], bVd identification [5 tokens × 5(6) conditions × 2 talkers], IHR/BKB sentences (2 lists × 6 conditions × 2 talkers) (3OS-trained group only)

comparison of the intelligibility of the information contained in the unshifted odd and even subsets of channels, which was important for demonstrating that the information in these subsets of channels was not entirely redundant, and that there was room for improvement beyond the three channel unshifted speech. Further, since vowels can be described primarily by their first and second formants, vowel confusions can be easily mapped in terms of the relationship between the expected vowel and the output at the sine-carrier frequency of a given formant.

Nine b-vowel-d words in the carrier sentence "Say bVd again" were recorded by a male and female speaker of British English in anechoic conditions at a 48 kHz sampling rate and subsequently downsampled to 44.1 kHz. The male but not the female talker was the same as for the sentence test. Five tokens of each bVd word were recorded from each talker so that in an individual test of one talker in a given condition, there were 45 items. Vowels were restricted to monophthongs of similar duration so that listeners would need to rely on spectral cues for identification: /æ/ (bad), /ɑː/ (bard), /iː/ (bead), /e/ (bed), /ɜː/ (bird), /ɔː/ (board), /ɒ/ (bod), /uː/ (booed), and /ʌ/ (bud). A grid with all nine words appeared, and the subject clicked with the computer mouse on the button displaying the word they perceived. The vowels were represented on the buttons in the orthographic form given above. Before testing, the subject was given a practice session in which the vowel material was presented unprocessed, with a single token for each vowel and each talker. This enabled the subjects to familiarize themselves with the software and the task.

6. Procedure

Subjects were tested before training commenced, halfway through training, and at the end of training. All subjects completed the entire cycle of training and testing within a maximum of 2 weeks, with no more than a 2 day gap between successive sessions. Sentence and vowel test presentation was counterbalanced across the group. Within each test, stimuli were pseudo-randomized by block of condition and talker. Table III presents the sequence of training and testing for Experiment 1.

In the first session, subjects were acclimatized to unshifted sine-vocoding with a 10 min block of CDT with the DU processor prior to the pre-training test session. Previous experiments have demonstrated that listeners require a short period of acclimatization before they can reliably perceive speech through unshifted vocoders with a limited number of channels (Davis *et al.*, 2005). As in subsequent CDT training sessions, the first 5 min of the familiarization block were AV, while the remaining 5 min were auditory alone (AA). Following the pretest, subjects were trained with CDT in four 40 min training sessions with either the dichotic odd shifted speech (6DOS-trained group) or the monaural three shifted channel speech (3OS-trained group). Subjects were tested after the fourth training session. If the testing session did not take place immediately following a training session, then the experimenter administered a 10 min (five AV, five AA) CDT block with the 6DOS or 3OS processor, which was not counted toward the total hours of training. Following this mid-training test session, subjects underwent four more 40 min training sessions with the same processor as in the first four sessions, and then completed the post-training testing.

Testing took place in a sound-treated room with presentation of the processed speech over Sennheiser HD280 headphones. The level was set by the experimenter to a comfortable listening level, and this level was used by all participants.

B. Results

Test data were analyzed using repeated measures analysis of variance (ANOVA), with within subject factors of test session, condition, and talker, and where relevant, a between subjects factor of processor used in training. Hyunh–Feldt epsilon corrections were applied to all F tests for factors with more than one degree of freedom. Hyunh–Feldt adjusted degrees of freedom have been rounded to the nearest integral value, and the significance criterion was $p=0.05$. *A priori* hypotheses were tested using planned contrasts, and *post-hoc* testing was carried out using Bonferroni-adjusted paired comparisons. Data were typically pooled by talker, unless there was a significant interaction between talker and processor that could not be attributed to floor effects with the shifted (3OS) condition.

1. IEEE sentence perception

a. 6DOS-trained group Keywords correct for the IEEE sentence test across training sessions for the two talkers combined are shown in the left-hand panel of Fig. 3. For the

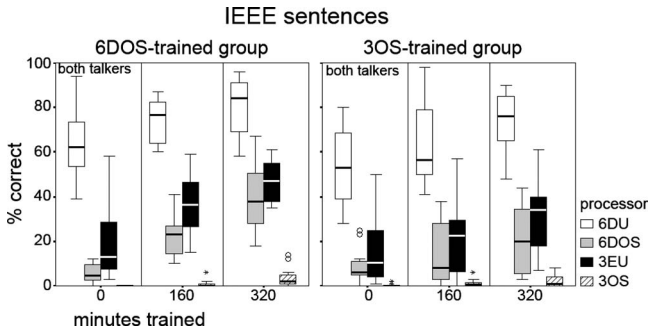

FIG. 3. Experiment 1 box-and-whisker plots of IEEE sentence scores as a function of training time. The box shows interquartile range over six subjects, the bar shows the median, and the whiskers show the complete range excluding any outlying values (shown as open circles or asterisks). Plots are shown for the two talkers combined. A vertical reference line separates each training time period. Scores for the 6DOS-trained group are in the left-hand panel, while scores for the 3OS-trained group are in the right panel. The plots show the four main conditions: 6DU, 6DOS, 3EU, and 3OS.

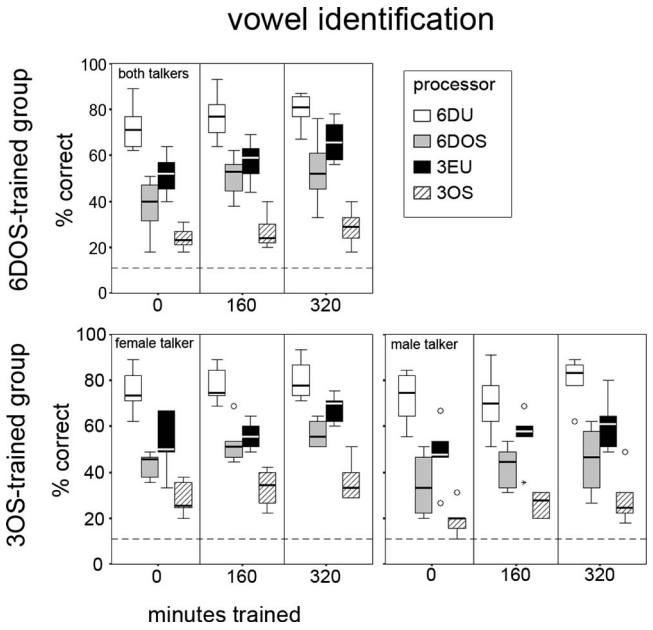

FIG. 4. Experiment 1 vowel identification scores as a function of training time. Scores for the 6DOS-trained group are in the top panel, while scores for the 3OS-trained group are in the bottom two panels. The 3OS-trained group showed a significant talker by processor interaction, so plots for each of the two talkers are given separately. The vertical reference line separates the training time periods, and the horizontal reference line indicates chance performance, which was 11.1%.

6DOS-trained group, performance with the 3OS processor remained close to floor throughout training, while intelligibility with all other processors tended to increase. This was indicated by a significant training session with processor interaction [$F(8,40)=445$, $p<0.001$]. Scores have been pooled by talker, although they were slightly better with the male talker in all but the 3OS condition, which is reflected by the significant interaction of talker with processor [$F(3,17)=6.57$, $p=0.003$]. When the data were reanalyzed excluding the 3OS condition, these interactions were no longer significant, and significant main effects were evident for number of training sessions [$F(2,10)=71.5$, $p<0.001$] and processor [$F(2,9)=146$, $p<0.001$].

Post-hoc testing on the post-training sentence scores revealed three key findings. First, performance with the three unshifted channels (3EU) was significantly worse than with the dichotic unshifted (6DU) condition ($p=0.001$), which is a clear indication that there was room for improvement with the additional channels in the shifted ear. Second, there was no significant difference between the 6DOS condition and the 3EU condition, which indicates that subjects did not show a binaural advantage. If they had, we would expect to see performance with this processor exceeding that in the 3EU condition, as was found for the 6DU condition.

b. 3OS-trained group Scores for IEEE sentence recognition for the 3OS-trained group are shown in the right-hand panel of Fig. 3. A repeated measures ANOVA showed significant main effects of number of training sessions [$F(2,10)=36.0$, $p<0.001$] and processor [$F(3,16)=85.9$, $p<0.001$], but there was no significant training session with processor interaction, indicating significant improvement with training that was relatively similar in all conditions, including 3OS.

Post-hoc comparisons of post-training sentence scores for the 3OS-trained group were similar to the 6DOS-trained group across conditions. Performance with 6DU was significantly better than 3EU ($p<0.001$), while there was no significant difference in intelligibility between 6DOS and 6EU. Thus while the intelligibility scores for this group were generally lower and improvements with training smaller than for the 6DOS-trained group, the pattern between conditions is similar. Subjects adapted to the vocoder processing, but there is no evidence of a binaural advantage with the mismatched frequency-place maps.

2. Vowel identification

a. 6DOS-trained group Vowel identification scores for the two talkers combined are summarized in the top panel of Fig. 4. The overall pattern of results is similar to that seen for sentences. There were significant main effects of number of training sessions [$F(2,10)=37.4$, $p<0.001$] and processor [$F(4,20)=102$, $p<0.001$] and a significant training sessions with processor interaction [$F(8,40)=89.6$, $p=0.005$]. The lower bound of the 95% confidence interval was above chance level performance (11%) at all test points and for all conditions, confirming that vowel recognition scores were significantly greater than chance.

Importantly, *post-hoc* testing showed significant improvements in all conditions between the pre-test and post-test sessions ($p<0.05$), including 3OS, and a planned contrast of training sessions within the 3OS condition also showed significant improvement after training in this condition ($p=0.01$). While the significant interaction of training session with processor may indicate that improvement with the 3OS condition was smaller than the improvement in the other conditions, this is nonetheless evidence of learning in this condition. Despite the improvement in the 3OS condition, again there was no significant difference between 3EU and 6DOS after training, even though performance with 3EU was significantly worse than with 6DU ($p=0.02$). Thus, while there was room for improvement by the addition of the odd channels (3EU<6DU), and there was evidence of learning

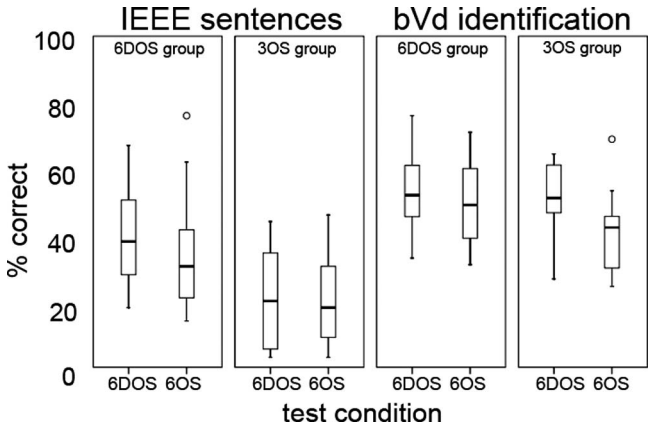

FIG. 5. Comparison of dichotic (6DOS) versus diotic (6OS) presentation of mismatched frequency-place maps within each stimulus type and training group from Experiment 1. The IEEE scores are in the left two panels (6DOS and 3OS groups, respectively), while the bVd identification scores are in the two panels on the right (6DOS and 3OS groups, respectively).

when these channels were shifted, subjects did not show a binaural advantage with the mismatched frequency-place maps.

b. 3OS-trained group The bottom panels of Fig. 4 show vowel identification scores for the 3OS-trained group. A repeated measures ANOVA showed a significant talker with processor interaction [$F(5,25)=3.58$, ($p=0.014$)], so the boxplots and subsequent analyses are given for each talker individually. In Bonferroni-corrected comparisons of talker within each condition, intelligibility with the female talker was significantly better than with the male only for conditions where spectral shifting was present, i.e., 6DOS, 6OS, and 3OS. In unshifted conditions, there was no significant difference in intelligibility between the talkers. This may indicate a gender-specific adaptation to the shifted speech since all experience with shifted speech outside of testing was also with a female talker. More evidence for this comes from a planned contrast of test sessions within the 3OS condition, which showed significant improvement with training only for the female talker ($p=0.009$).

For both talkers, the lower 95% confidence limit was above chance for all test conditions and at all test points. The ANOVAs also showed significant main effects of session [female: $F(2,10)=21.2$, ($p<0.001$); male: $F(2,10)=10.1$, ($p=0.004$)] and processor [female: $F(5,25)=45.7$, ($p<0.001$); male: $F(4,19)=33.7$, ($p<0.001$)], but no significant session by processor interaction for either talker. Like the IEEE sentences for this group, then, this analysis suggests that there were significant and similar levels of learning for this group in all conditions, including 3OS.

3. Comparison of dichotic versus diotic presentation

Mismatched maps were compared under dichotic and diotic conditions to test the hypothesis that subjects had learned to ignore information from the shifted ear. Boxplots comparing post-training intelligibility with the dichotic and diotic presentations of the mismatched maps are presented in Fig. 5. The left two panels give scores for IEEE sentences, and the right two panels for bVd identification. The results are presented for the two talkers combined. The scores were entered into a repeated measures ANOVA. For the 6DOS-trained group, there was no significant difference between dichotic (6DOS) versus diotic (6OS) presentation for sentences or vowels. This suggests that if this group had adapted by suppressing or ignoring information, this could only have been on the basis of carrier frequency rather than ear of input. By contrast in the 3OS-trained group, Bonferroni-corrected comparisons showed that post-training vowel identification was significantly worse for the diotic condition than the dichotic condition ($p=0.04$). This suggests that subjects in the 3OS-trained group were still relying on cues to ear presentation when listening to the mismatched maps since intelligibility was decreased when this cue was removed.

4. Comparison of unshifted odd and even channels

Intelligibility with unshifted even and odd channels (3EU and 3OU) was compared for the 3OS-trained group to confirm that the speech information in each subset of channels was not redundant. This is important for demonstrating that there was speech information that could be gained through the binaural combination of odd and even channels. The post-training results are summarized in the left (IEEE sentences) and right (vowel identification) panels of Fig. 6.

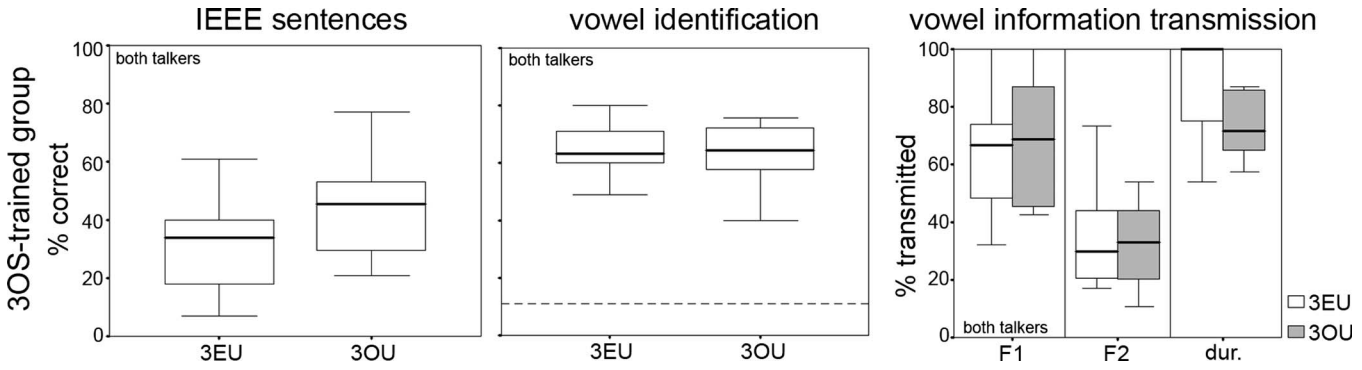

FIG. 6. Comparison of post-training scores for the unshifted even (3EU) and odd (3OU) channels for the 3OS-trained group of Experiment 1. The left panel shows IEEE sentence scores, the middle panel shows bVd identification, and the right panel shows percent of vowel feature information (F1, F2, and duration) transmitted. The results are shown for the two talkers combined.

TABLE IV. Feature definitions for the F1, F2, and duration features for each of the nine vowels. F1 was binary (open, close); F2 was tertiary (front, back, central); and duration was binary (long, short).

Feature	æ	ɑː	iː	e	ɜː	ɔː	ɒ	uː	ʌ
F1	o	o	c	o	c	o	o	c	o
F2	f	b	f	f	c	b	b	b	b
Duration	l	l	l	s	l	l	s	l	s

Surprisingly, intelligibility with the IEEE sentences was significantly better with the 3OU channels than the 3EU channels after training ($p=0.007$).

For vowel recognition, the ANOVA revealed no significant difference between these conditions for overall vowel recognition accuracy. The post-training vowel confusions for 3EU and 3OU were also analyzed in terms of information transfer (Miller and Nicely, 1955). Features of F1, F2, and duration were analyzed according to the feature definitions set out in Table IV. The results for the two talkers combined are summarized in the right-hand panel of Fig. 6. A repeated measures ANOVA revealed no significant difference between 3EU and 3OU in terms of information transfer for any of the three features. However, an χ^2 analysis showed that vowel confusions differed significantly between the two processors ($p<0.0001$). Hence there are clearly differences of detail between the vowel features conveyed by odd compared to the even bands, but no evidence of a difference across the set of vowels in the level of feature information provided by these two sets of bands.

These detailed differences in vowel confusions probably reflect the complementary representation of spectral information in each of the subsets of channels and also the sparse spectral coding which presents vowel formant energy only at the discrete carrier frequencies of the sine vocoder. For example, the /i:/ vowel was almost always incorrectly recognized as /u:/ in the odd unshifted condition (3OU) (87% of the time), but was recognized fairly accurately in the even unshifted condition (3EU) (77% correct). The F2 of this vowel for the female talker was around 2850 Hz, but the sine carrier for the analysis filter encompassing F2 was 2498 Hz, so F2 energy was lowered in frequency which could account for /i:/ being recognized as /u:/. For the /u:/ vowel, both F1 (319 Hz) and F2 (1980 Hz) frequencies fell within the analysis filters of odd-numbered bands. As would be expected, this vowel was recognized accurately in the odd channel condition (3OU) (85% correct), but in the even channel condition (3EU), accuracy was low (28%), and there was no consistent pattern in confusions since energy from formant frequencies was largely absent in this condition for this vowel. Taken together with the finding that 6DU was always better than 3EU in this experiment, there is thus clear evidence that the lack of binaural advantage shown with the binaurally mismatched processor (6DOS) compared to the even unshifted channels (3EU) is not attributable to a redundancy of speech information in the even and odd bands.

5. Vowel information transmission analysis

A further information transmission analysis of the post-training vowel confusions was performed to examine in more detail the information provided in the different processor conditions. The results for Experiment 1 are summarized in the left and middle panels of Fig. 7. Repeated measures ANOVAs for each training group were computed on the percentage of information transferred, with within-subjects factors of processor (6DOS, 3EU, and 3OS only), feature (F1, F2, and duration), and talker. For each group, there was a significant interaction of processor with feature [6DOS-trained group: $F(4,20)=3.17$, $p=0.036$; 3OS-trained group: $F(4,20)=12$, $p<0.001$]. Despite the equivalent post-training intelligibility scores for vowel identification, Bonferroni-corrected comparisons of processors within each feature revealed that the information transmitted with the 6DOS processor was significantly less than that with the unshifted 3EU processor, though this depended on feature and training group. For the F1 feature, this reduction in information was only marginally significant for the 6DOS-trained group ($p=0.048$), but was more significant for the 3OS-trained group ($p=0.008$). In fact, for the 3OS-trained group, there was no significant difference in F1 information for the 6DOS and 3OS conditions. Less F2 information was transmitted for 6DOS than 3EU for the 6DOS-trained group only ($p=0.03$), while less duration information was transmitted for the 3OS-trained group only ($p=0.025$). Not surprisingly, the information transmitted with the 3OS processor was always significantly worse than that with 3EU. This pattern of results suggests that subjects were not simply ignoring the shifted information in the 6DOS condition, and that training condition impacted the binaural combination of information.

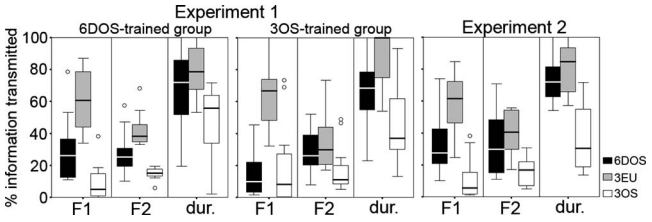

FIG. 7. Percent of vowel feature information (F1, F2, and duration) transmitted for the 6DOS, 3EU, and 3OS conditions. The results are shown for the two talkers combined. Scores are broken down by experimental group: the left panel shows Experiment 1 6DOS-trained group, the middle panel Experiment 1 3OS-trained group, and the right panel scores from Experiment 2.

C. Discussion

For both groups of subjects, performance with 6DU exceeded performance with 3EU in all but one subtest. Moreover, for the 3OS-trained group, the 3OU channels showed higher IEEE scores than the 3EU channels after training, and vowel confusions differed significantly with these processors. This is clear evidence that the information conveyed by the odd channels was not redundant in the presence of the even channels, which suggests that there was room for improvement if listeners could learn to use unshifted and shifted channels together for binaural advantage. However, neither group of subjects showed a binaural advantage for the binaurally mismatched processor since post-training intelligibility with the 6DOS processor never exceeded that with the 3EU processor for any of the speech materials.

Post-training intelligibility was similar in the 6DOS and 3EU conditions, which is consistent with the view that subjects had adapted to 6DOS by attending to the "better ear"—i.e., the unshifted frequencies. However, the information transfer analysis revealed that for both groups of subjects, vowel information transferred with the binaural 6DOS condition was significantly worse for some features than that for the monaural 3EU condition, which suggests a more complicated listening strategy. The binaural combination of shifted and unshifted channels may have led to a fused but "incorrect" percept—a process referred to as "psychoacoustic fusion" by Cutting (1976). It is also possible that the combination of shifted and unshifted channels was somehow distracting and thus led to more errors. The different pattern of results in the two groups suggests that the training condition affected the binaural combination of information. For the F1 feature, explicit training with the 6DOS condition seems to have mitigated the deficit with 6DOS compared to 3EU since for this group the difference was only marginally significant. By contrast, explicit training with 3OS seems to have been more beneficial for F2 information since only the 6DOS-trained group showed significantly worse F2 information transmission with 6DOS than 3EU.

Notwithstanding these apparent training condition effects, it seems clear that neither group of subjects learned to combine the shifted and unshifted channels in a way that led to a binaural advantage for speech over the time course in Experiment 1. It is possible that the period of learning required to show a binaural advantage for mismatched frequency-place maps may be longer than that needed for simple monaural basalward shifts. The improvements shown here were small and did not reach an asymptotic level after 5 h, 20 min of training, which may indicate that subjects were still learning at the point of final testing. This was especially true for the 3OS condition, which proved particularly difficult for the listeners in this study. While the difficulty in learning 3OS appears to contrast with previous studies with monaural basally shifted speech (Rosen *et al.*, 1999), the sparse spectral representation in the processing is a novel feature that has not been previously studied and may have been a source of difficulty. Tyler and Summerfield (1996) showed that cochlear implant patients are still adjusting to their speech processors 6 months and longer after implantation, and the training times considered here were very short by comparison.

It is also possible that adaptation to mismatched frequency-place maps requires experience with both the shifted alone (3OS) and binaurally mismatched (6DOS) maps. For the 6DOS-trained group, training led to larger improvements overall, and there was some evidence of adaptation specific to the shifted bands (3OS). While training with 3OS led to smaller overall improvements, for this group there was evidence of shift-specific learning and better transmission of F2 information in the 6DOS condition. While training with just the shifted components (3OS) alone may be insufficient to allow for a binaural advantage from the mismatched maps, a period of training with just the shifted map may facilitate adaptation to the shifted components, which may only then lead to a binaural advantage with sufficient further training.

Experiment 2 was designed to further explore the effects of type and time course of training on accommodation of mismatched frequency maps. The training period was doubled, and listeners were trained with both the shifted bands alone (3OS) and with these bands in combination with unshifted bands (6DOS) to provide listeners with extensive experience in both conditions.

III. EXPERIMENT 2

A. Method

1. Subjects

Six normally hearing speakers of British English took part and were paid to participate. They all had normal (<20 dB HL) pure-tone thresholds at 0.5, 1, 2, and 4 kHz. None had participated in Experiment 1.

2. Signal processing

Signal processing was the same as for Experiment 1.

3. Training

Training for Experiment 2 was similar to Experiment 1, with the exception that subjects were trained in 30 sessions each of 20 min. Each training session was divided into 10 min blocks which alternated between the 6DOS and 3OS processors. Author K.M., a speaker of Standard Southern British English, was the training talker for Experiment 2.

4. Test materials

Test materials for Experiment 2 included the same IEEE sentence and vowel identification tests from Experiment 1. Because of floor effects with the 3OS condition in Experiment 1, we also used easier high-context BKB (Bench*et al.*, 1979) and IHR (Institute of Hearing Research, MacLeod and Summerfield, 1990) sentences in order to more clearly demonstrate learning with 3OS. These two sentence sets have similar syntactic constructions and are essentially equivalent in intelligibility. The female talker was the same as that for the IEEE sentences, but the male talker was different. The BKB sentences consist of 16 sentences per list with either 3 or 4 keywords per sentence, making 50 keywords per list. The IHR sentences consist of 15 sentences of 3 keywords each, hence 45 keywords per list. BKB sentences were used for familiarization testing, with IHR sentences used for all subsequent testing.

5. Procedure

Table V sets out the testing and training regime used for Experiment 2, which is similar to that of the previous experiment, with the following modifications. A familiarization test session was included at session 1 in which subjects were tested with the IEEE sentences, the Bamford–Kowal–Bench (BKB) sentences, and vowels. This was primarily for familiarization so that any rapid adaptation to the unshifted vocoder processing would occur before training commenced

TABLE V. Sequence of training and testing conditions for Experiment 2.

Session	Training	Processor	Testing
1	5 min AV, 5 min AA	6DU	Familiarization: Unprocessed vowels; *Pre-test*: IEEE sentences (2 lists × 4 conditions × 2 talkers), BKB sentences (2 lists × 3 conditions × 2 talkers), bVd identification (5 tokens × 4 conditions × 2 talkers)
2	…	…	*Second Pre-test*: IEEE sentences (2 lists × 4 conditions × 2 talkers), IHR sentences (2 lists × 3 conditions × 2 talkers), bVd identification (5 tokens × 4 conditions × 2 talkers)
3	5 min AV × 2, 5 min AA × 2	6DOS+3OS	None
4–17	10 min AA × 2	6DOS+3OS	None
18	…	…	*Mid-test*: IEEE sentences (2 lists × 4 conditions × 2 talkers), IHR sentences (2 lists × 3 conditions × 2 talkers), bVd identification (5 tokens × 5 conditions × 2 talkers)
19–33	10 min AA × 2	6DOS+3OS	None
33	…	…	*Post-test*: IEEE sentences (2 lists × 4 conditions × 2 talkers), IHR sentences (2 lists × 3 conditions × 2 talkers), bVd identification (5 tokens × 5 conditions × 2 talkers)

(Davis *et al.*, 2005). BKB sentences were used for easy material in only the very first pre-training session. After session 1, only IHR sentences were used for easy sentence material. Also, in the first training session only (session 3 in Table V) the first 5 min with each processor was auditory-visual. All subsequent training for this experiment was auditory only. All other procedural considerations were the same as for Experiment 1.

6. Conditions

Four test conditions were used in Experiment 2: 6DU, 6DOS, 3EU, and 3OS. Because we anticipated ceiling effects with the easy sentence material and the dichotic unshifted (6DU) processor, this condition was not tested with the IHR sentences.

B. Results

1. Test exposure learning

A repeated measures ANOVA was used to compare results between the first two pre-training test sessions. No significant differences between these two test sessions were found for either the IEEE sentence test or the vowel test, which implies that any further improvements beyond the second test session were likely the result of training rather than incidental learning. All subsequent analyses are therefore based on the final three test sessions.

2. IEEE sentences

Scores for the IEEE sentences across training sessions are shown for the two talkers combined in the top left panel of Fig. 8. Performance tended to improve with training in all conditions. An ANOVA on data from the final three test sessions showed significant main effects of number of training sessions [$F(2,10)=29.0$, $p<0.001$] and processor [$F(1,5)=72.2$, $p<0.001$]. While there was a significant session with talker interaction [$F(2,10)=6.85$, $p=0.013$], there was no training session with processor interaction, which indicates that learning through training was similar in all conditions, including 3OS. This is a similar finding to the 3OS-trained group in Experiment 1, who had an equivalent amount of training with the 3OS condition as the subjects in this experiment.

Here there was also direct evidence of learning of the shifted bands (3OS) since a planned contrast of training sessions in this condition showed intelligibility after training was significantly better than before training ($p=0.038$). Yet despite this learning, and the extended period of training in Experiment 2, there was still no evidence of an advantage for the mismatched maps. In *post-hoc* tests, performance with 6DOS and 3EU did not differ, even though there was room for improvement after 10 h of training since 3EU was worse than 6DU ($p=0.02$).

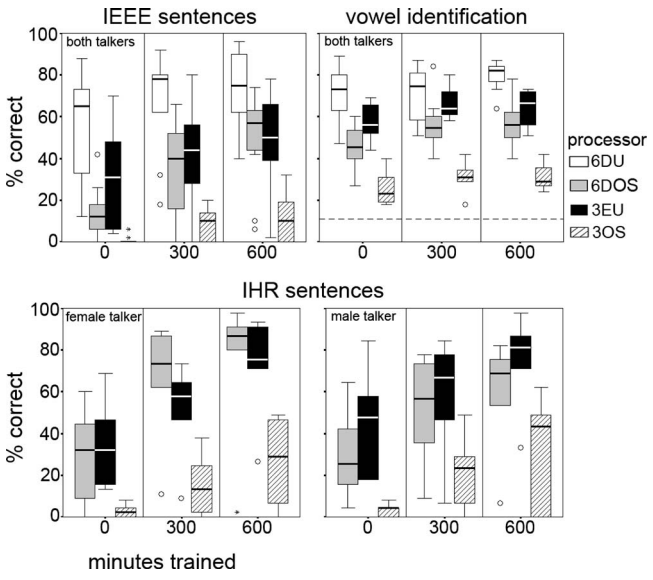

FIG. 8. Performance as a function of amount of training for the final three test sessions of Experiment 2. The top left panel shows IEEE sentence scores, and the top right panel vowel identification. In the bottom two panels are scores for the IHR sentences, which have been split by talker because of a significant talker effect. Training time periods are separated by vertical lines, and for the vowel identification, the horizontal reference line indicates chance performance (11.1%).

3. High-context (IHR) sentences

The bottom panels of Fig. 8 show scores for the IHR sentences for the female and male talkers individually. ANOVA showed a significant interaction between talker and processor [$F(2,8)=6.58$, $p=0.022$], so scores for each talker were analyzed separately. These showed significant effects of training session and condition. The bottom panels of Fig. 8 show that median intelligibility of the 3OS condition improved from close to floor before training to near 40% for both talkers after training, which is a much higher level of intelligibility for this processor than that seen in Experiment 1. A planned contrast showed that improvement with training in this condition was significant ($p=0.02$).

Surprisingly, *post-hoc* tests on the data from all six subjects showed that, for the male talker, post-training intelligibility with 3OS did not differ significantly from that with the 6DOS processor. This may have been the result of increased learning with the 3OS processor. However, performance for the 6DOS condition was significantly worse than the 3EU condition for this talker, which may also indicate interference or distraction from the addition of the shifted channels. Despite clear evidence of adaptation to 3OS, however, subjects did not show an advantage for the mismatched maps since performance with 3EU and 6DOS did not differ significantly after training.

4. Vowel identification

Boxplots of vowel identification for the two talkers combined appear in the top right panel of Fig. 8. ANOVA on the final three test sessions showed significant main effects of session [$F(2,8)=20.4$, $p=0.001$] and processor [$F(3,15)=77.8$, $p<0.001$], but no significant interactions. The lower bound of the 95% confidence interval of the estimated marginal mean was always greater than 11%, indicating that intelligibility was statistically greater than chance for all conditions and at all test points. While a planned contrast showed significant learning of the shifted channels (3OS) with training ($p=0.046$), *post-hoc* testing on the post-training vowel scores revealed no significant difference in intelligibility between the 6DOS and 3EU processors, so subjects did not show a binaural advantage for the mismatched maps, despite having room for improvement to do so (6DU $>$3EU, $p=0.014$). Moreover, a planned contrast showed that post-training vowel intelligibility was marginally worse with the binaurally mismatched processor (6DOS) than with the monaural unshifted bands (3EU). Although this test just missed significance ($p=0.051$), the finding is suggestive of distraction with the addition of the shifted channels, rather than binaural benefit.

As for Experiment 1, the post-training vowel confusion matrices were entered into an information transfer analysis to explore the differences in information transmission with the 6DOS, 3EU, and 3OS processors. The findings are shown in the right panel of Fig. 7. The percent information transmitted was then entered into a repeated measures ANOVA, with within-subjects factors of talker, processor (6DOS, 3EU, and 3OS only), and feature (F1, F2, and duration). The ANOVA revealed no significant effect of talker, but there was a significant interaction of processor with feature [$F(4,20)=4.16$, $p=0.013$]. The F1 information transmitted was significantly lower for 6DOS than for 3EU ($p=0.036$), but there was no difference between these conditions for F2 and duration information. Information transmission with 3OS was always significantly worse than 6DOS and 3EU.

C. Discussion

Subjects in Experiment 2 showed greater signs of adaptation to the shifted portion of the binaurally mismatched processor (3OS) than those in the previous experiment. First, interactions of session with processor were not found for the IEEE sentences and vowel recognition, which indicates that learning through training was similar in all conditions. There was a significant session with processor interaction for the IHR sentences, but this was the result of ceiling effects with 3EU. More significantly, there was direct evidence of learning of 3OS since planned contrasts of sessions within the 3OS condition showed significantly better intelligibility after training with all test materials. Median intelligibility of easy sentences with just the three shifted bands (3OS) after 10 h training improved from near floor to around 40%. In Experiment 1, by contrast, post-training intelligibility with 3OS was near floor with easy sentences for the 3OS-trained group.

Intelligibility with 3OS was only clearly above floor levels with interspersed and/or concurrent training with unshifted vocoded speech: although the 3OS-trained group in Experiment 1 received the same amount of training with that condition as the subjects in Experiment 2, only the latter group of subjects showed such improvements. The greater improvement may have arisen from either more exposure time to the shifted speech (through exposure to both 6DOS and 3OS), from the concurrent and/or interspersed exposure to easier unshifted speech, or a combination of the two. Recently Li *et al.* (2009) showed that unsupervised adaptation to a large basalward shift (8 mm) only occurred with interspersed exposure to a more moderate basalward shift (4 mm). It thus seems plausible that exposure to an easier condition may facilitate the learning of more difficult speech conditions. However, the increased learning of 3OS in Experiment 2 may also have been the result of a change in training talker.

Despite this increased evidence of adaptation to the basally shifted speech and the extended training period allowed for adaptation, again no binaural advantage was found for the binaurally mismatched frequency-place maps. Performance with the 6DOS processor never exceeded that with the three unshifted channels alone (3EU), even though there was clear room for improvement from the addition of the odd channels, since 3EU was typically worse than 6DU. Moreover, there was some evidence of interference from the shifted bands when they were presented together with the unshifted bands since post-training performance with 6DOS was worse than 3EU for the vowels, the male talker IHR sentences, and F1 information transmission. This latter finding is similar to the 3OS-trained group in Experiment 1 and

suggests that explicitly training with the 3OS condition may make the shifted F1 information difficult to ignore when presented with unshifted information in 6DOS.

IV. GENERAL DISCUSSION

A. Resistance to learning

Listeners in both experiments demonstrated evidence of adaptation following a period of training, yet intelligibility with the 6DOS processor never exceeded that with just the three unshifted channels (3EU). The findings thus indicate that listeners are resistant to learning cochlear frequency-to-place maps that differ greatly between the ears. The mechanism involved in adaptation to binaurally mismatched frequency-place maps is likely to be different from that for adaptation to monaural basalward spectral shifts, where significant if partial adaptation is evident after as little as 3 h training (Rosen *et al.*, 1999).

In particular, learning of the 3OS condition proved more difficult than expected on the basis of previous studies. In Experiment 1, improvements in this condition were small. Experiment 2 showed significant improvements, but these only appeared over the longer time course of training and with concurrent and interspersed training with unshifted channels (6DOS), which was somewhat surprising. The smaller number and non-contiguous output of the shifted channels, or differences in the parameters of the vocoding, such as carrier type and smoothing filter, may have influenced the outcome of training. Most simulation studies showing adaptation to upward spectral shifts have employed noise-vocoding (Rosen *et al.*, 1999; Faulkner *et al.*, 2001, 2003; Fu and Galvin III, 2003; Faulkner *et al.*, 2006; Smith and Faulkner, 2006; Stacey and Summerfield, 2007), although there is also evidence of adaptation with sine-vocoding (Li and Fu, 2007; Li *et al.*, 2009). While an earlier study indicated that these should be equivalent in intelligibility (Dorman *et al.*, 1997b), emerging evidence suggests that for small numbers of channels, there are significant differences in the intelligibility of unshifted noise and sine vocoders (Souza and Rosen, 2009), with noise vocoders being more intelligible when envelope smoothing frequency is low (30 Hz, similar to that used here). What may be a comparable resistance to learning of shifted spectral cues has been observed for frequency-lowered amplitude envelope signals when these were, as here, limited to fairly low-rate (50 Hz) modulations and imposed on sinusoidal carriers (Grant *et al.*, 1994). However, that was a study of auditory-visual speech perception so listeners may have had less to gain from learning to reinterpret the frequency-shifted spectral information than would be the case here.

Even if this resistance to learning were in part due to the use of a low smoothing cut-off frequency with sine-vocoding, it can be argued that low-frequency envelope smoothing should be preferred when simulating CI processors because users of current cochlear implant systems are not sensitive to higher-rate modulations. Moreover, the use of noise vocoders here would not have been suitable since overlap of noise carriers between the ears may have led to confounding effects. Notwithstanding these considerations, there was clear evidence of adaptation to the 3OS processor, especially in Experiment 2, yet still no evidence of a binaural advantage, so it seems unlikely that the more difficult 3OS condition is the sole explanation for the lack of binaural advantage.

It is possible that aspects of the training procedure, such as the listener hearing their own voice unprocessed during training, or the listener returning to everyday speech conditions outside of the experiment, may have hindered adaptation. However, the training procedure was identical to that used in previous studies. Rosen *et al.* (1999) showed adaptation to four-channel noise-vocoded speech with a 6.5 mm basalward shift in just 1 h and 20 min, and further studies have shown adaptation in comparably short time periods (Faulkner *et al.*, 2006; Smith and Faulkner, 2006). Though the processing in the present experiments was markedly different from that typically considered in previous adaptation studies (e.g., sparsely sampled output at each ear and binaurally mismatched, sine-excited vocoding), the training times were comparably longer to compensate for the anticipated increased difficulty. Yet despite the extended course of training in these experiments (5–10 h), subjects showed no evidence of a binaural advantage for the binaurally mismatched processing, even though there was evidence of adaptation to the monaural shifted speech, especially in Experiment 2. It thus seems unlikely that the lack of binaural advantage shown in these experiments is entirely attributable to a deficiency in the training procedure.

A novel aspect of the frequency-place mapping examined here, and a possible source of this resistance to learning, is the altered relative frequency order of the output bands in the binaurally mismatched processor. When combinations of shifted and unshifted bands were presented together, as in the 6DOS and 6OS processors, the output consisted of frequency information that had been shifted in both frequency and relative order. Ranking the output with reference to the relative frequency order of the input analysis bands yields, from low to high frequency, (2–1–4–3–6–5). Informative cross-frequency patterns, such as relative frequencies of the first and second formants, may as a result be destroyed. Evidence from the experiments here suggests that, despite the enriched frequency content, listeners do not learn to combine this altered output in the same way as for matched frequency-place maps. If the shifted channels contributed to intelligibility with 6DOS at all, they appeared to serve as a distraction, with the transmission of first formant information being particularly vulnerable.

The lack of binaural advantage for combinations of shifted and unshifted bands shown here may be indicative of a constraint on plasticity for speech perception to cases where relative frequency order has been preserved. This would be consistent with the finding that a frequency-warped but order-preserving frequency-to-place map is relatively easy to learn (Smith and Faulkner, 2006). There is, however, some evidence to the contrary: in his seminal study on adaptation to spectrally altered speech, Blesser (1972) trained listeners with speech that had been spectrally rotated around 1600 Hz so that low frequencies became high and vice versa. Even under such drastic conditions, some listeners did even-

tually learn to converse, although this did not appear until much later in the study, which consisted of 20 45 min sessions. Azadpour (2008) also found that listeners could adapt to aspects of spectrally rotated speech over a similar time course to that in Experiment 1.

With spectrally rotated speech, however, the relative ordering of frequency information is intact, even if it has been inverted. By contrast, the processing used here may selectively invert speech cues such as vowel formant patterns which may result in a novel percept, in addition to cues being presented to the wrong frequency region. In the present investigations, this appeared to hinder adaptation. Specifically, in Experiment 1, there was evidence of shift-specific adaptation to the 3OS condition for both groups for the vowel test, yet listeners still did not show a binaural advantage when listening in the 6DOS condition. This was despite the fact that in the absence of shifting, the three even (3EU) and three odd (3OU) processors resulted in significantly different vowel confusions, which would imply that there was room for improvement by combining the information if the listener had been able to do so.

B. Implications for bilateral stimulation with cochlear implants

Since performance did not reach asymptote in either of the present experiments, it remains to be determined whether continued learning beyond that demonstrated here would be shown, or whether this is too difficult a mapping to learn fully. In this respect, it is difficult to interpret the implications of this resistance for cochlear implant patients because the extent of their experience with any clinically fitted processor will be far greater than the 5–10 h examined in the laboratory here. For example, the group of patients investigated by Tyler and Summerfield (1997) reached asymptotic performance an average of 30–40 month post implantation.

Several studies have shown that some patients experience a synergistic improvement when using both implants over either implant on its own, even for speech in a quiet laboratory (Dorman and Dahlstrom, 2004; Litovsky *et al.*, 2006). The drastic spectral mismatch examined here may arguably be more representative of the mismatch with acoustic hearing and may be uncommon between two bilateral electrode arrays of the same design. Smaller mismatches than that studied here may be tolerated by CI users. Yet, not all bilateral CI users show an advantage over their best ear alone (Wackym *et al.*, 2007; Tyler *et al.*, 2007) and substantially mismatched frequency-place maps underpin this lack of advantage.[1] In a recent study of patients with bilateral cochlear implants, Mosnier *et al.* (2009) found that bilateral CI patients with asymmetrical monaural CI speech scores did not show a binaural advantage for speech in quiet, which suggests a difficulty with mismatched frequency-place maps.

Since the processor design considered here did not directly simulate typical bilateral implant systems currently in use, there may be limitations to generalizing the findings to CI patients. The speech processors were designed to minimize redundancy between the two ears in order to investigate global aspects of binaural place mismatch in the absence of local conflicts due to (1) the presentation of the same information to two different places or to (2) the presentation of different information to the same tonotopic location in each ear. However, typical bilateral cochlear implant systems do deliver roughly the same signal to each ear. Interleaving channels between the ears may have left insufficient cues to bind unshifted and shifted channels into a single auditory object. An increase in signal redundancy provided with "typical" bilateral processing may facilitate auditory grouping and thus the binaural combination of mismatched maps. However, the more spectrally rich signal provided by the better ear (i.e., the ear with the smallest degree of shift) with non-interleaved processing could also lead listeners to learn to attend to the better ear alone. Further research could explore whether amplitude comodulation of the shifted and unshifted channels would facilitate grouping of the mismatched signals as a single auditory object and thus allow for a binaural advantage (Carrell and Opie, 1992).

Current bilateral cochlear implants are fitted by mapping the full spectrum of speech information to each ear, but this is not a requirement for robust speech perception, as is clearly demonstrated by the speech intelligibility advantage with electro-acoustic stimulation (Ching, 2005). Alternative frequency-place mapping strategies could seek to align the frequency range delivered to each ear through assigning processor filter frequencies that were matched according to interaural location. For cases of asymmetrical insertion depths, this would likely entail that the highest and lowest channels were presented to only one ear. Such an alternative processing strategy would avoid drastic mismatches of frequency-place maps between the ears while maximizing signal redundancy and may ultimately lead to a stronger binaural advantage. To this end, robust methods for matching frequency-place maps between the ears for humans would need to be developed. New research into more objective techniques, such as the binaural interaction component of the evoked auditory brainstem response (EABR), as described by Smith and Delgutte (2007), could prove promising.

Many of the benefits of binaural hearing are realized for speech in noise, where differences in the sound signal at each ear can be used to obtain a better representation of what has been said. Indeed, of the two subjects tested by Dorman and Dahlstrom (2004), one showed binaural benefit over the better ear only in the noise condition. Better-ear effects may dominate in the absence of noise and thus limit any potential binaural advantage from the mismatched signals at each ear. If the signal here were presented in noise, listeners may have stronger motivation to rely on the shifted channels. When testing in noise, it may also be possible to use more spectral bands without achieving ceiling effects with the unshifted speech, and this increased spectral resolution may, in turn, facilitate learning.[2]

Current cochlear implant systems do not contribute the fine structure information thought to underpin many binaural hearing phenomena in normal hearing listeners. However, Long and colleagues showed at least one bilateral cochlear implantee to be sensitive to the interaural time difference (ITD) and interaural level difference (ILD) cues provided solely through envelope information. Crucially, this was limited to cases where interaural electrode pairs were matched

in frequency (Long *et al.*, 2003). Normal hearing listeners also demonstrate best ITD (Nuetzel and Hafter, 1981) and ILD (Francart and Wouters, 2007) detection for similar interaural cochlear place regions. Though perhaps through a different underlying mechanism than has been considered here, evidence from psychophysics is thus consistent with the present research and suggests that maintaining similar frequency-place maps between the ears may be important for optimizing bilateral CI fittings.

V. CONCLUSION

This research examined whether listeners could learn to demonstrate a binaural advantage for speech information with a unilateral spectral shift. Despite undergoing significantly longer training periods than in previous studies with monaural spectral shifts, subjects in the present investigations never showed a binaural advantage for the binaurally mismatched frequency-place map. Post-training performance with the binaurally mismatched processor never exceeded that with the three unshifted channels, even after 10 h of training. This resistance to learning is suggestive of a constraint on speech perceptual plasticity to instances where relative frequency order is preserved. It may thus be important to keep frequency-place maps similar in the two ears when optimizing bilateral CIs for speech perception. The results are consistent with psychophysical studies in bilateral cochlear implant patients, which have also called for matching interaural electrode pairs in order to restore ITD and ILD sensitivities.

[1]Evidence from studies with a self-selecting tool for frequency-place mappings supports this conclusion. Fitzgerald *et al.* (2007) found that normal hearing subjects, when listening to simulations of CI processing, preferred frequency-place maps that minimized the mismatch between the ears, regardless of spectral shift.

[2]In a related study, Long *et al.* (2004) used 12 channel binaurally interleaved vocoders similar to those described here, with one ear processed in noise. Listeners in their experiment demonstrated a binaural advantage for consonant perception over either ear on its own. This could not be attributed to binaural redundancy since the interleaved channels ensured that each ear was getting different information. However, the processor in their study was tonotopically matched in both ears. It merits exploration whether this advantage remains if a spectral shift is introduced to one ear.

Two-microphone separation of speech mixtures based on interclass variance maximization

Maximo Cobos[a] and Jose J. Lopez
Institute of Telecommunications and Multimedia Applications, Universidad Politécnica de Valencia, Valencia 46022, Spain

(Received 28 May 2009; revised 11 November 2009; accepted 24 December 2009)

Sparse methods for speech separation have become a discussed issue in acoustic signal processing. These sparse methods provide a powerful approach to the separation of several signals in the underdetermined case, i.e., when there are more sources than sensors. In this paper, a two-microphone separation method is presented. The proposed algorithm is based on grouping time-frequency points with similar direction-of-arrival (DOA) using a multi-level thresholding approach. The thresholds are calculated via the maximization of the interclass variance between DOA estimates and allow to identify angular sections, wherein the speakers are located with a strong likelihood. These sections define a set of time-frequency masks that are able to separate several sound sources in realistic scenarios and with little computational cost. Several experiments carried out under different mixing situations are discussed, showing the validity of the proposed approach. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3294713]

I. INTRODUCTION

Humans are surrounded by sound. If we try to concentrate and listen carefully to the things that happen in our environment, probably we will be able to identify more than one source of sound. This fact reveals an important property of human hearing: the ability to distinguish individual sound sources from complex mixtures of sound. When talking about the perception of speech in complex acoustic environments, this human ability is usually related to the well known *cocktail party problem*, first described by Cherry in 1953.[1] The cocktail party effect describes the ability to focus one's listening attention on a single talker among a mixture of conversations and background noises, ignoring other conversations and enabling us to talk in a noisy place.[2] The complex understanding of sound scenes is so familiar to humans that we usually take it for granted and we perform this task without being aware of it. However, computational methods aimed at imitating our hearing sense and brain for understanding complex sound material are far from performing with such an accuracy and are still an active research line that involves mathematical, physical, and psychological issues. In this context, a common approach to achieve understanding of complex sound scenes is usually sound source separation. The solution to the problem of sound separation in real environments is essential for many applications, including automatic speech recognition, music information retrieval, and hearing-aid systems.[3]

The task of estimating and recovering independent source signals from a set of mixtures obtained by one or several observation channels is known as *blind source separation*. Most of the existing separation algorithms are based on statistical assumptions, mainly, sources statistically independent and non-Gaussian. These assumptions often lead to the *independent component analysis* approach.[4] These algorithms have shown to be successful in the linear complete case, when as many observations as sources are available. When the mixing process is convolutive, each sensor observes the original source signals convolved with the impulse response between each source and sensor, making the estimation of the sources even more difficult.[5] This is the case of real mixtures recorded in a room by a set of microphones. Methods based on independent component analysis for convolutive mixtures often apply the separation algorithm separately in each frequency bin using a time-frequency transformation of the observed mixtures. This approach introduces the well-known permutation problem: the different frequency components of the signals are "swapped" and require an alignment process.[6] Moreover, when there are more sources than observation channels, the problem is *underdetermined* (or degenerate), and other properties of the sources such as *sparsity* are exploited. In a strict sense, sparsity means that most signal components are zero. In a practical sense, sparsity means that most signal components are relatively small.[7] Sparsity and overcomplete dictionaries have been discussed in the literature with the aim of giving a solution to the underdetermined problem.[8] Lewicki and Sejnowski[9] proposed an algorithm for learning overcomplete representations of the sources via *maximum a posteriori* estimation. Sparse recovery of the sources was also addressed via l_1-norm minimization by Donoho.[10] When dealing with speech mixtures, it has been shown that they are sparser in the time-frequency domain than in the time domain.[11] Yilmaz *et al.*[12] assumed that the sources are disjoint in the time-frequency domain, i.e., there exists only one source in a given time-frequency point. This assumption leads to the *time-frequency masking* approach. Algorithms based on time-frequency masking have shown to provide significant results in the separation of realistic mixtures of speech; however,

[a]Author to whom correspondence should be addressed. Electronic mail: mcobos@iteam.upv.es

most approaches suffer from the dependency on initial cluster centroids[13] or the accuracy of a peak detection step.[12]

In this paper, we present a source separation algorithm based on time-frequency masking. Inspired by image segmentation techniques, the separation is achieved by using a *maximum interclass variance*[14] criterion between the angular distribution of the sources. Maximization of interclass variance was recently shown to provide successful results in the separation of instantaneous music mixtures.[15] We demonstrate how under the same criterion, it is possible to achieve fast separation of simultaneous speakers in reverberant scenarios by identifying different angular areas wherein the speakers are located with a strong likelihood. These areas are defined by a set of thresholds that, applied to the distribution of DOA estimates in the time-frequency domain, provide the binary masks that separate the sources. We present a complete set of examples using real speech mixtures, considering different degrees of reverberation, different number of sources, and a range of angular separations of speakers. The results show the capability of our approach to separate different speech sources in real situations with minimal computational cost. In addition, the method does not need to perform a previous estimation of the mixing matrix nor to search for peaks or specify initial values, which results in a more robust reverberation and unsupervised algorithm.

This paper is structured as follows: in Sec. II, the description of the source separation problem is presented. In Sec. III, the proposed approach is described in detail. In Sec. IV, some experiments with speech mixtures are presented, and a performance evaluation is carried out considering different mixing situations. Finally, in Sec. V, the conclusions of this work are summarized.

II. THE SOURCE SEPARATION PROBLEM

In the last years, increasingly attention has been given to the source separation problem.[16] The term *blind* is usually employed when very little information about the sources and the mixing process is known. In some situations, recovering the sources from the recorded mixtures or segregating a particular source is very desirable. This can also reveal information about the mixing system that may be useful for other applications. The simplest mixing model is the instantaneous model, where the different mixture channels are formed by linear combinations of the sources. However, in real applications, the mixing process is more complex: each mixture is the sum of all the original source signals filtered by their corresponding source-to-sensor acoustic channel. The impulse response of this channel carries the information of the acoustic environment where the signals have been mixed.

In this section, we review the usual mixing model used for the separation of realistic mixtures of speech and describe the time-frequency masking approach that is effective for separating sparse sources.

A. Mixing model

In this work we consider a two-microphone array setup. The signals recorded by a pair of microphones, $i=1,2$, in a room where N sound sources are present can be modeled as a finite impulse response convolutive mixture, written as

$$x_i(t) = \sum_{j=1}^{N} \sum_{\ell=0}^{L_m-1} h_{ij}(\ell) s_j(t-\ell), \quad i=1,2, \tag{1}$$

where $x_i(t)$ is the signal recorded at the ith microphone at time sample t, $s_j(t)$ is the jth source signal, $h_{ij}(t)$ is the impulse response of the acoustic path from source j to sensor i, and L_m is the maximum length of all impulse responses. More generally, the mixing process can be written as

$$x_i(t) = \sum_{j=1}^{N} s_{ij}(t), \quad i=1,2, \tag{2}$$

where s_{ij} is called the image of the jth source in the ith microphone

$$s_{ij}(t) = \sum_{\ell=0}^{L_m-1} h_{ij}(\ell) s_j(t-\ell). \tag{3}$$

A simplification of the convolutive model can be found in the particular case when only the direct path from each source to each sensor is considered. In this case, only an arrival delay τ_{ij} between each source-sensor pair is sufficient to explain the generation of the mixtures. Thus, the mixing filters of the model become $h_{ij}(t)=a_{ij}\delta(t-\tau_{ij})$, resulting in the anechoic mixing model

$$x_i(t) = \sum_{j=1}^{N} a_{ij} s_j(t-\tau_{ij}), \quad i=1,2,\ldots, \tag{4}$$

where τ_{ij} and a_{ij} are the arrival delay and attenuation factor between source s_j and sensor i, respectively.

It is here useful for Secs. III and IV to rewrite the above model in the time-frequency domain, considering the short-time Fourier transform (STFT). This transform divides a time-domain signal into a series of small overlapping pieces; each of these pieces is windowed and then individually Fourier transformed.[17] Due to the linearity of the STFT, the above model can be expressed as

$$X_i(k,m) = \sum_{j=1}^{N} a_{ij} S_j(k,m) e^{-j2\pi f_k \tau_{ij}}, \quad i=1,2, \tag{5}$$

where k and m are the frequency and time frame indices, respectively, $S_j(k,m)$ denotes the STFT of the source signal $s_j(t)$, f_k is the frequency corresponding to frequency index k, and τ_{ij} is the time delay corresponding to the path from source s_j to sensor i. Throughout this paper, the above simplified model will be considered.

B. Time-frequency masking

Signal decompositions or additive expansions have been shown to provide a sparse representation of audio signals, which is a desirable feature for many speech processing systems. A signal is said to be sparse if most of its components are zero or close to zero. In the source separation context, the advantage of a sparse signal representation is clear: the sparser a signal is, the less probability it will overlap with

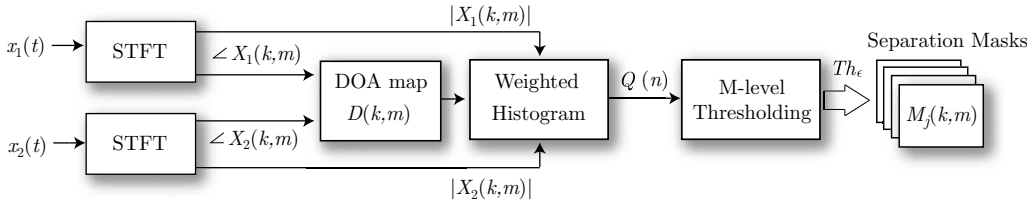

FIG. 1. Block diagram of the separation method.

other signals in a mixture.[18] Time-frequency representations have been widely used with the aim of working with sparse sources, being the STFT the most common transform used for the separation of underdetermined speech mixtures.

The problem of separating more sources than mixtures is not only related to the difficulty of estimating more mixing parameters from a reduced set of data, but in providing a meaningful solution to the system of Eq. (4). In fact, the sparsity provided by time-frequency representations is sufficient to estimate the complete set of mixing parameters with relatively good accuracy,[12] but some criterion is still required to recover the sources from the infinite possible solutions to the problem.

In this context, one of the most simple and powerful approaches for recovering multiple source signals from a mixture is time-frequency masking. It should be noted that the term "masking" here means weighting (filtering) the mixture, which is different from the same term used in psychoacoustics, where it means blocking the target sound by using acoustic interference. If the sources are assumed to be W-disjoint orthogonal (WDO), it is likely that every time-frequency point in the mixture with significant energy is dominated by the contribution of only one source. The "W" in WDO refers to the analysis window used in the time-frequency transform.[19] This can be mathematically expressed as

$$S_j(k,m)S_{j'}(k,m) = 0, \quad \forall\, j \neq j', \quad \forall\, k,m. \tag{6}$$

The above equation means that two different sources never share energy in the same time-frequency point. Therefore, time-frequency masking approaches attempt to identify the dominating source in each time-frequency bin (k,m), obtaining a binary mask (filter) $M_j(k,m)$ that separates the jth source from the mixture. The estimates of the spatial images of the sources can be directly obtained by applying the masks to the input mixtures

$$\hat{S}_{ij}(k,m) = M_j(k,m)X_i(k,m), \quad \forall\, k,m. \tag{7}$$

The estimates in the time domain $\hat{s}_{ij}(t)$ are obtained applying the inverse STFT operator. Further processing methods can be used for improving the isolation of the sources by means of refined time-frequency masks.[20]

1. The ideal binary mask

Consider the sum of all the signals that interfere with source s_j in the STFT domain

$$U_j(k,m) = \sum_{j'=1, j' \neq j}^{N} S_{j'}(k,m), \quad \forall\, k,m. \tag{8}$$

The *ideal binary mask* for a source $S_j(k,m)$ is defined as the binary time-frequency mask that is 1 for bins where its energy is higher than all the interfering sources:

$$M^{\text{ideal}}(k,m) = \begin{cases} 1 & \text{if } 20\log\left(\dfrac{|S_j(k,m)|}{|U_j(k,m)|}\right) \geq 0 \\ 0 & \text{elsewhere} \end{cases} \quad \forall\, k,m. \tag{9}$$

This mask has been shown to be optimal when applied to a sound mixture,[12] and that is why the ideal binary mask has been suggested as a major computational goal of sound source separation algorithms. This is specially true in *computational auditory scene analysis*,[21] since it has proven to be highly effective for robust automatic speech recognition systems and improved human speech intelligibility in noise.[22]

III. SEPARATION FRAMEWORK

An overview of the different stages of the separation algorithm is depicted in Fig. 1. The approach presented in this paper can be summarized in the following steps:

1. *DOA map calculation.* The input channels are transformed into the STFT domain. The phase information in each time-frequency point is used for estimating the DOA of a given frequency in the current analysis window. A DOA map matrix is formed with the estimations obtained from the analyzed signal.
2. *Coherence test and weighted histogram.* A coherence test is performed with the aim of identifying reliable DOA estimates and increasing the robustness against reverberation. In addition, robustness is further improved by using the STFT magnitude of both input channels to construct an amplitude-weighted histogram. This histogram is the input for the multi-level thresholding algorithm.
3. *Multi-level thresholding.* The histogram obtained in the previous step is processed for calculating a set of thresholds that maximizes the interclass variance of the time-frequency points according to their estimated DOA. These thresholds are used for segmenting the DOA map into the final separation masks.

In Secs. IIIA–IIIC the above steps are described in detail.

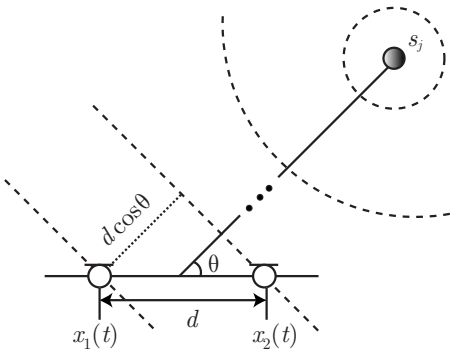

FIG. 2. Two microphones capturing a signal from a source s_j with direction-of-arrival θ. The path difference between both sensors is $d\cos\theta$.

A. DOA map

The DOA map $D(k,m)$ is calculated from the phase difference in the two microphone signals. Figure 2 shows a pair of microphones, capturing the signal arriving from a source s_j with angle θ. The inter-microphone distance is d. Assuming that the source is sufficiently distant to consider plane wavefront incidence, the path difference between the two microphones is $d\cos\theta$.

Given the model of Eq. (5), the relation between the phase difference of the two sensors and the incidence angle of the source for frequency f_k and time frame m is given by the next equation:

$$\angle X_2(k,m) - \angle X_1(k,m) = 2\pi f_k(\tau_{2j} - \tau_{1j}) = 2\pi f_k\left(\frac{d\cos\theta}{c}\right), \tag{10}$$

where $\angle(\,)$ denotes the phase of a complex number and c is the speed of sound ($\approx$340 m/s).

The DOA map represents the cosine of the DOA ($\cos\theta$) for each frequency f_k at each time window m, and it is calculated from the STFT of the mixture channels as

$$D(k,m) = \frac{c}{2\pi f_k d}\angle\left(\frac{X_1(k,m)}{X_2(k,m)}\right), \quad \forall\, k,m. \tag{11}$$

Note that frequencies above $f_k > c/2d$ will suffer from spatial aliasing.[12] Nevertheless, speech sources concentrate most of their energy below 5 kHz and small distances ($d \sim 3$ cm) easily satisfy this condition for the effective bandwidth of speech.

In Figs. 3(a) and 3(b) the left and right channel spectrograms of a mixture of three speakers in an anechoic environment are represented. In this mixture, the speakers are uniformly distributed in the azimuth plane. The amplitude relationship (in dB) between the two channels is represented in Fig. 3(c). Note that very little information is provided by amplitude differences when the microphones are very close to each other. In fact, when the inter-microphone distance verifies $d \ll D$, being D the distance between the source and the array, then $a_{1j} \approx a_{2j}$, and so the modulus $|X_1(k,m)|/$

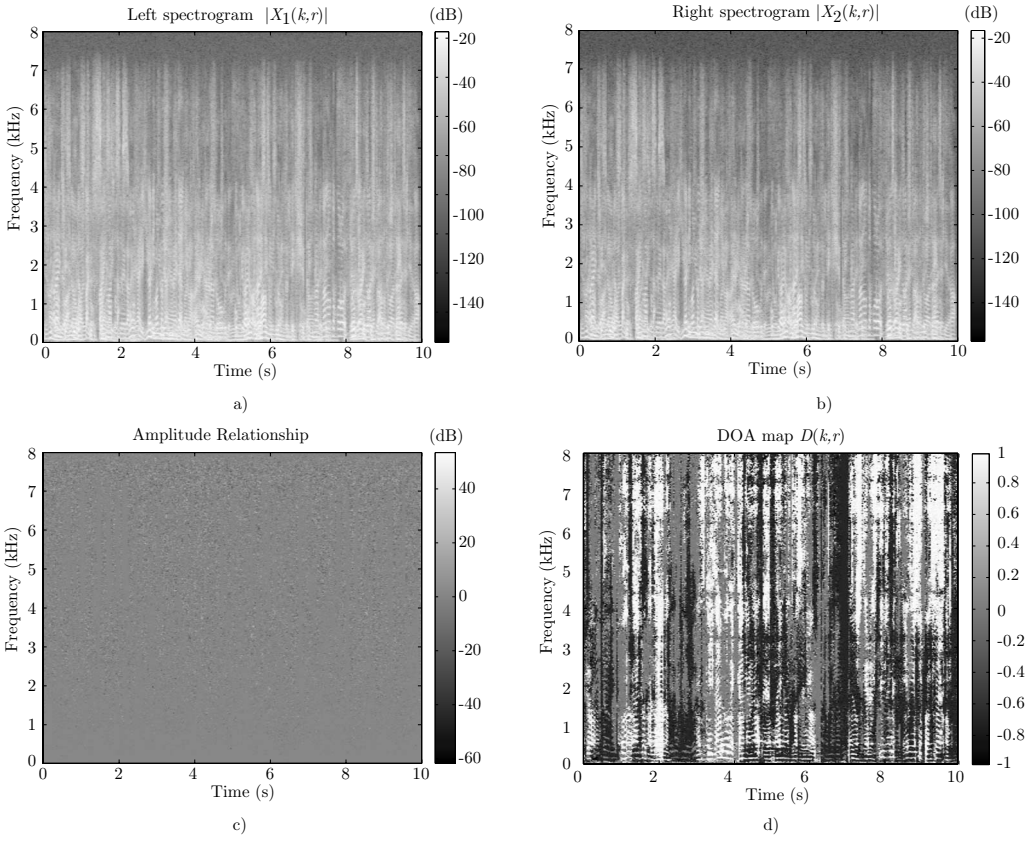

FIG. 3. (a) Left observation channel spectrogram; (b) right observation channel spectrogram; (c) amplitude relationship between the two channels, calculated as $20\log_{10}(|X_1(k,m)|/|X_2(k,m)|)$; and (d) DOA map of the mixture.

$|X_2(k,m)| \approx 1$. However, the DOA map extracted from the phase information of the mixtures [Fig. 3(d)] shows clear zones related to the activity of the three speakers in the time-frequency domain. It is also important to notice that the use of the phase difference as localization cue has another advantage over the amplitude ratio, since it avoids the division by zero when $|X_2(k,m)|=0$.

Under anechoic conditions, the different zones corresponding to each speaker are highly visible as different gray-level zones, which support the presence of predominant speech signals. However, when the mixing is convolutive, multiple reflections of the source signal arrive at both microphones. These reflections cause deviations in the DOA estimation and the zones corresponding to each speaker are harder to identify. In Sec. IV, the performance of the algorithm will be evaluated considering different degrees of reverberation with the aim of showing the degradation introduced by room reflections.

B. Coherence test and weighted histogram

1. Interaural coherence and coherence tests

If a single source in free-field is considered, sound from only one direction arrives at the microphones with a deterministic *interaural time difference*, and thus, the DOA of the source can be easily determined by the observed phase difference, as explained in Sec. III A. However, in complex listening situations, i.e., in the presence of other sound sources or room reflections, it often occurs that sound from different directions concurrently reaches the sensor array, resulting in erroneous DOA estimations.

The robustness of the method against these complex environments can be improved by discarding time-frequency bins where other sources and reverberation are dominant. This is done by means of a coherence test. In fact, from an auditory perspective, *interaural coherence* plays an important role on the localization of sound events in complex listening situations. Thus, the degree of "similarity" between the left and right ear entrance signals has been shown to provide a very important cue for dealing with the localization of sources in difficult environments. A measure for interaural coherence usually has a range between 0 and 1, where 0 means that two signals are coherent (signals are equal with possibly a different scaling and delay) and 1 means that the signals are independent.[23] For example, Faller proposed a successful localization system based on interaural time differences and coherence estimated from the normalized cross-correlation function.[24] From an algebraic perspective, Mohan *et al.*[25] proposed recently a coherence test in the time-frequency domain based on the identification of low-rank bins, where the time-frequency covariance matrix of the input mixtures has effective low-rank (ideally 1 when a time-frequency point is dominated by only one source). Alternatively, Avendano proposed the use of the following *short-time coherence function*[26]

$$\Phi(k,m) = \frac{|\Phi_{12}(k,m)|}{\sqrt{\Phi_{11}(k,m)\Phi_{22}(k,m)}}, \tag{12}$$

where the statistics $\Phi_{ii'}(k,m)$ are a practical way of computing the inter-channel correlation $E\{X_i(k,m)X^*_{i'},(k,m)\}$, given by

$$\Phi_{ii'}(k,m) = (1-\lambda)\Phi_{ii'}(k,m-1) + \lambda X_i(k,m)X^*_{i'}(k,m), \tag{13}$$

where * denotes complex conjugation. The classical coherence function is defined for wide-sense stationary random processes.[27] However, due to the non-stationarity of speech, this function introduces a forgetting factor $\lambda \in [0,1]$ to compute for the cross-correlation between the observation channels on a block of time frames, which can be adjusted to balance between current and previous estimations. The coherence function $\Phi(k,m)$ has values close to 1 in time-frequency regions where a source is present, and it is usually smaller when sounds from different directions overlap. Therefore, high-coherence bins above a certain threshold Φ_T are selected as having reliable DOA estimates (for example, $\Phi_T > 0.9$). This pre-selection is used to identify time-frequency points that are more likely to give a better estimation of the DOA, which results in a sharper histogram, as it will be seen in Sec. III B 2.

2. Amplitude-weighted histogram

The use of histograms for studying phasic behaviors of microphone arrays has already been discussed in the literature, for example, in the use of *delayograms*.[28] Histograms provide a simple way for roughly estimating an underlying probability density function based on observed data. In our approach, the histogram obtained from the DOA estimates in the time-frequency domain reveals important information about the angular distribution of the sources and makes it able to carry out the separation, considering this distribution as a mixture of classes that are angularly spaced.

As commented in Sec. III B 1, the effect of a non-ideal scenario affects negatively the estimation of the DOA at each time-frequency bin. This is due to the phase distortion caused in the observation channels as a result of other source contributions and reverberation. If the phase is not very much altered in a given time-frequency bin, the estimated DOA calculated from the phase difference at that bin will be similar to the real one. In contrast, if the phase has been distorted by other sources or room reflections, the quality of the estimation will be poorer. This effect is depicted in Fig. 4. In this figure, it can be seen the addition of two phasors. One phasor represents the source of interest s_d and the other, s_i, represents the total contribution of the interference (other sources and reflections). It can be observed that the phase deviation $\Delta\phi$ caused by the interference is highly related to the magnitude of the observation channel. In Fig. 4(a), the deviation produced by the total interference is significantly smaller than in Fig. 4(b).

Considering the above relationship between magnitude and phase stability in a given time-frequency bin, a more accurate segmentation of the DOA map will be achieved if

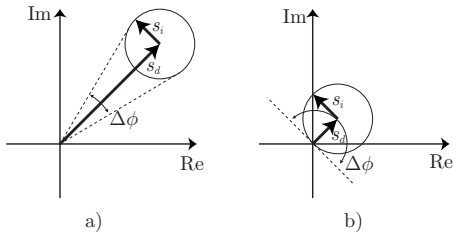

FIG. 4. (a) Possible phase deviation $\Delta\phi$ when the source of interest s_d has big amplitude in comparison to the total interference s_i; (b) possible phase deviation $\Delta\phi$ when the source of interest s_d has low amplitude in comparison to the total interference s_i.

points with high magnitude are given a greater weight in the formation of the histogram. Assuming L_c uniform containers in the range of $[-D_{\max}, D_{\max}]$ (usually $D_{\max} \approx 1$), the center of each container in the histogram is given by

$$z_n = D_{\max}\left(\frac{2n+1}{L_c} - 1\right), \quad n = 0, \ldots, L_c - 1. \tag{14}$$

The histogram $Q(n)$ is calculated by summing all the weighting factors of the time-frequency points with DOA values lying in each of the L_c containers previously defined.

$$Q(n) = \sum_{(k,m)\in\mathcal{S}_n} g(k,m), \quad n = 0, \ldots, L_c - 1, \tag{15}$$

where $g(k,m)$ is the weighting factor for the (k,m) point and $\mathcal{S}_n = \{(k,m) | L_c | D(k,m) - z_n | \langle 1, \Phi(k,m) \rangle \Phi_T\}$, i.e., the set of coherence-selected points with $D(k,m)$ in the value range defined by container n. The weighting factor is simply the mean amplitude value of that point in the two observation channels

$$g(k,m) = \frac{|X_1(k,m)| + |X_2(k,m)|}{2}. \tag{16}$$

Figure 5 shows different normalized histograms for the example mixture of three sources and different amounts of reverberation simulated with different wall reflection factors ρ.[29] It can be clearly observed how the peaks corresponding to the presence of the three speakers are clearly distinguishable in the anechoic case, but they broaden and overlap with one another as soon as reverberation increases (dotted lines). However, note how the peaky structure is highly enhanced when the histogram is computed from high-coherence time-frequency bins selected by means of a coherence test (solid line).

C. Multi-level thresholding

Thresholding is an important technique for image segmentation, which is used for the identification and extraction of targets from their background on the basis of the distribution of pixel intensities in image objects. In this work, we propose to consider the DOA map as an image where different objects are present (sources with different DOA). One of the most referenced thresholding methods in image processing is the Otsu method.[14] Several works have shown that, despite it was published a long time ago (1979), the Otsu method is one of the better threshold selection algorithms for general real world images.[30,31] The key concept underlying this segmentation method is the maximization of the *interclass variance* (or minimization of the *intraclass variance).* This clustering technique has been selected in the proposed audio separation framework for some remarkable advantages. On the one hand, it is very general; no specific histogram shape is assumed. This is a desirable feature because the shape of the histogram may change a lot depending on the mixing configuration, the spectral overlap, or the room reverberation. On the other hand, the Otsu method has been shown to work well and reliably under many different situations: different types of images, additive noise, etc. In addition, the extension of this algorithm to multi-level thresholding is straightforward, which enables to carry out the separation of more sources than mixtures. There also exists an efficient implementation of this algorithm, which opens the possibility to implement a real-time separation system. Moreover, as opposed to other clustering methods, there is no need for detecting peaks nor for specifying initial centroid values, which leads to a more unsupervised approach.

In our separation context, the aim of the proposed approach is to find the thresholds that maximize the interclass variance of the distribution of DOA estimates, given the histogram generated in the previous step. The ideas underlying the Otsu threshold selection method are described next.

1. The Otsu algorithm

In this section, the Otsu algorithm[14] is briefly described. The probability of a value in the middle of container n of the histogram is given by

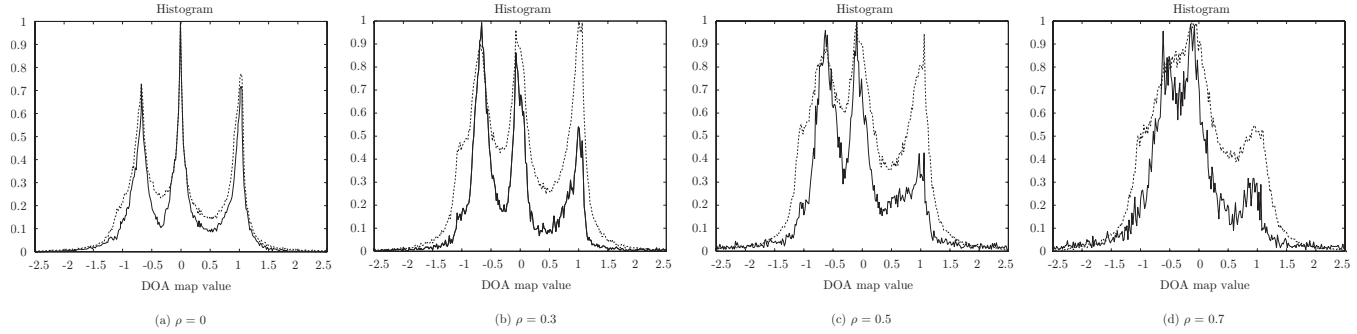

FIG. 5. Weighted histograms (normalized) for a mixture of three sources without pre-selection (dotted line) and with pre-selection (solid line) for different wall reflection factor ρ.

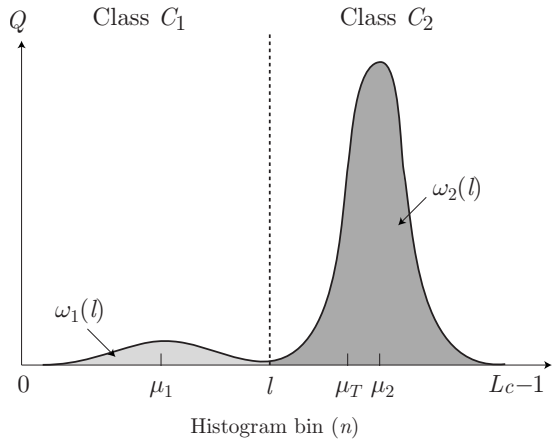

FIG. 6. Histogram divided into two classes.

$$p_n = \frac{Q(n)}{\kappa} \quad \text{with} \quad \kappa = \sum_{n=1}^{L_c} Q(n). \tag{17}$$

In the case of bi-level thresholding, the time-frequency points are divided into two classes: C_1, with DOA values in the range given by the histogram bins $n \in [1, \ldots, l]$, and C_2, with values within the bins $n \in [l+1, \ldots, L_c]$. The different variables involved in the segmentation are depicted in Fig. 6. The probability distributions for the two classes are as follows:

$$C_1: p_1/\omega_1(l), \ldots, p_l/\omega_1(l), \tag{18}$$

$$C_2: p_{l+1}/\omega_2(l), p_{l+2}/\omega_2(l), \ldots, p_{L_c}/\omega_2(l), \tag{19}$$

where $\omega_1(l) = \Sigma_{n=1}^{l} p_n$ and $\omega_2(l) = \Sigma_{n=l+1}^{L_c} p_n$.

The means for classes C_1 and C_2 are

$$\mu_1 = \sum_{n=1}^{l} n \frac{p_n}{\omega_1(l)}, \quad \mu_2 = \sum_{n=l+1}^{L} n \frac{p_n}{\omega_2(l)}. \tag{20}$$

Let μ_T be the mean value for all the selected DOA estimates. Then

$$\omega_1 \mu_1 + \omega_2 \mu_2 = \mu_T, \tag{21}$$

$$\omega_1 + \omega_2 = 1. \tag{22}$$

The between-class variance is defined as

$$\sigma_B^2 = \omega_1(\mu_1 - \mu_T)^2 + \omega_2(\mu_2 - \mu_T)^2. \tag{23}$$

For bi-level thresholding, it has been verified that the optimal threshold l^* is chosen so that the between-class variance σ_B^2 is maximized, that is

$$l^* = \arg \max_l \{\sigma_B^2(l)\}, \quad 1 \le l \le L_c. \tag{24}$$

The previous formula can be extended to multi-level thresholding as follows: assuming that there are $M-1$ thresholds, $\{l_1, l_2, \ldots, l_{M-1}\}$, which divide the DOA map into M classes: C_1 for $[1, \ldots, l_1]$, C_2 for $[l_1+1, \ldots, l_2]$, C_ϵ for $[l_{\epsilon-1}+1, \ldots, l_\epsilon]$, and C_M for $[l_{M-1}+1, \ldots, L_c]$. The optimal thresholds $l_1^*, l_2^*, \ldots, l_{M-1}^*$ are chosen by maximizing σ_B^2 as follows:

TABLE I. Computational complexity of Liao's fast algorithm.

$\sigma_B'^2$	Total computation
Addition	$(M-1)(L_c-M+1)^{M-1}2L_c$
Subtraction	$L_c(L_c-1)$
Multiplication	L_c
Division	$L_c(L_c+1)$
Direct index	$M(L_c-M+1)^{M-1}$

$$\{l_1^*, l_2^*, \ldots, l_{M-1}^*\} = \arg \max_{l_1, l_2, \ldots, l_{M-1}} \{\sigma_B^2(l_1, l_2, \ldots, l_{M-1})\}, \tag{25}$$

for $1 \le l_1 \le l_2 \cdots l_{M-1} < L_c$ and

$$\sigma_B^2(l_1, l_2, \ldots, l_{M-1}) = \sum_{\epsilon=1}^{M} \omega_\epsilon (\mu_\epsilon - \mu_T)^2, \tag{26}$$

with $\omega_\epsilon = \Sigma_{n \in C_\epsilon} p_n$, and $\mu_\epsilon = \Sigma_{n \in C_\epsilon} n(p_n/\omega_\epsilon)$.

The ω_ϵ in Eq. (26) is regarded as the zeroth-order cumulative moment of the ϵth class C_ϵ, and the numerator in the definition of μ_ϵ is regarded as the first-order cumulative moment of C_ϵ, that is

$$\mu(\epsilon) = \sum_{n \in C_\epsilon} n p_n. \tag{27}$$

Regardless of the number of classes being considered during the thresholding process, the sum of the cumulative probability functions of M classes equals one ($\Sigma_{\epsilon=1}^{M} \omega_\epsilon = 1$), and the mean of the DOA values considered is equal to the sum of the means of M classes weighted by their cumulative probabilities ($\mu_T = \Sigma_{\epsilon=1}^{M} \omega_\epsilon \mu_\epsilon$). Thus, the interclass variance in Eq. (26) can be rewritten as

$$\sigma_B^2(l_1, l_2, \ldots, l_{M-1}) = \sum_{\epsilon=1}^{M} \omega_\epsilon \mu_\epsilon^2 - \mu_T^2. \tag{28}$$

Because the second term in Eq. (28) is independent from the choice of the thresholds, the optimal thresholds can be chosen by maximizing $\sigma_B'^2$, which is defined as the summation term on the right-hand side of Eq. (28)

$$\{l_1^*, l_2^*, \ldots, l_{M-1}^*\} = \arg \max_{l_1, l_2, \ldots, l_{M-1}} \left\{ \sigma_B'^2 = \sum_{\epsilon=1}^{M} \omega_\epsilon \mu_\epsilon^2 \right\}, \tag{29}$$

The final thresholding values will be those in the middle of containers $n = l_\epsilon^*$:

$$\mathrm{Th}_\epsilon = z_n|_{n=l_\epsilon^*}. \tag{30}$$

2. Efficient implementation

Liao *et al.*[32] proposed a complexity-reduced algorithm based on the recursive calculation of $\sigma_B'^2$. By using a set of look-up tables, the complexity of the algorithm is reduced to the number of operations shown in Table I. It can be observed that the number of operations depends on the number of histogram bins L_c and the number of classes considered M, which is assumed to be equal to the number of sources N. If the number of sources is not known beforehand, several

methods can be used for estimating the number of sources or deciding the optimum number of thresholds.[33,34]

D. Binary masks

The calculated thresholds define the binary masks corresponding to each class in the DOA map. The separation binary masks are given by

$$M_j(k,m) = \begin{cases} 1 & \text{if } \mathrm{Th}_{j-1} < D(k,m) \le \mathrm{Th}_j \\ & \forall\, k,m \\ 0 & \text{elsewhere} \end{cases}, \tag{31}$$

with $j=1,\ldots,N$, N being the number of sources, $\mathrm{Th}_0=-1$, and $\mathrm{Th}_N=1$. The estimates of the images of the sources in each of the observation channels can be directly obtained by applying the separation masks to the STFT of the mixtures, as in Eq. (7).

1. Dynamic separation

Note that a dynamic approach of the described processing is straightforward. In Secs. III A–III C, a DOA map has been introduced and several thresholds have been calculated, considering a histogram that covered estimates over a set of time frames. However, the time length of the DOA map can be modified in real-time applications, allowing to recalculate the separating thresholds in a dynamic way. This approach opens the possibility of separating moving sources. In Sec. IV, several experiments will be carried out to evaluate the performance of the algorithm under different mixing situations and recording setups, including the case of moving speakers.

IV. EXPERIMENTS

In this section, we evaluate the performance of the proposed method under different mixing situations. The validity of the approach is shown by means of a set of experiments designed with the aim of discussing the performance of the algorithm in cases of special interest, involving different angular separation and number of speakers, different degrees of reverberation, moving sources, and speech sources recorded in a real room.

The input signals and processing parameters used in the experiments are as follows: the audio sources (male and female speeches) were extracted from the public data provided in *The 2008 Signal Separation Evaluation Campaign*.[35] They are sampled at 16 kHz, 16 bits, and have a duration of 10 s. The STFT was computed using Hann windows[36] of 1024 samples of length, with a hop size of 512 samples (50% overlap). The parameters of the Otsu algorithm were $L_c=200$, $\Phi_T=0.95$, $\lambda=0.6$, and $d=0.02$.

A. Objective performance criteria

Some performance measures in source separation processing have already been described in the literature. Vincent *et al.*[37] proposed some objective performance measures that are broadly used by the separation community. These measures are the source to distortion ratio (SDR), source to interferences ratio (SIR), and source to artifact ratio (SAR). In the *First Stereo Audio Source Separation Evaluation Campaign*,[38] the image to spatial distortion ratio (ISR) was introduced for taking into account the comparison with the true source images in multi-channel separation algorithms. These criteria can be computed for all types of separation algorithms, avoiding the need for knowing the separating filters or masks. The criteria derive from the decomposition of an estimated source image as

$$\hat{s}_{ij}(t) = s_{ij}(t) + e_{ij}^{\mathrm{spat}}(t) + e_{ij}^{\mathrm{interf}}(t) + e_{ij}^{\mathrm{artif}}(t), \tag{32}$$

where $s_{ij}^{\mathrm{img}}(t)$ is the true source image, and $e_{ij}^{\mathrm{spat}}(t)$, $e_{ij}^{\mathrm{interf}}(t)$, and $e_{ij}^{\mathrm{artif}}(t)$ are distinct error components representing spatial (or filtering) distortion, interference, and artifacts. The signal $s_{ij}(t)+e_{ij}^{\mathrm{spat}}(t)$ is obtained by least-squares projection of the estimated source image onto the signal subspace spanned by filtered versions of the true source image. Similarly, the signal $s_{ij}(t)+e_{ij}^{\mathrm{spat}}(t)+e_{ij}^{\mathrm{interf}}(t)$ is obtained by least-squares projection of the estimated source image onto the signal subspace spanned by filtered versions of all the source images.

From this decomposition, the mentioned performance measures are defined as follows: the image to spatial distortion ratio is given by

$$\mathrm{ISR} = 10\log_{10}\frac{\sum_{i=1}^{2}\sum_{t} s_{ij}(t)^2}{\sum_{i=1}^{2}\sum_{t} e_{ij}^{\mathrm{spat}}(t)^2}. \tag{33}$$

Similarly, we define the source to interferences ratio as

$$\mathrm{SIR} = 10\log_{10}\frac{\sum_{i=1}^{2}\sum_{t} (s_{ij}(t) + e_{ij}^{\mathrm{spat}}(t))^2}{\sum_{i=1}^{2}\sum_{t} e_{ij}^{\mathrm{interf}}(t)^2}, \tag{34}$$

the source to artifact ratio as

$$\mathrm{SAR} = 10\log_{10}\frac{\sum_{i=1}^{2}\sum_{t} (s_{ij}(t) + e_{ij}^{\mathrm{spat}}(t) + e_{ij}^{\mathrm{interf}}(t))^2}{\sum_{i=1}^{2}\sum_{t} e_{ij}^{\mathrm{artif}}(t)^2}, \tag{35}$$

and finally, the signal to distortion ratio as

$$\mathrm{SDR} = 10\log_{10}\frac{\sum_{i=1}^{2}\sum_{t} s_{ij}(t)^2}{\sum_{i=1}^{2}\sum_{t} (e_{ij}^{\mathrm{artif}}(t) + e_{ij}^{\mathrm{spat}}(t) + e_{ij}^{\mathrm{interf}}(t))^2}. \tag{36}$$

Recall again that the above definitions were proposed by Vincent[38] with the aim of extending his original work[37] to multi-channel signals.

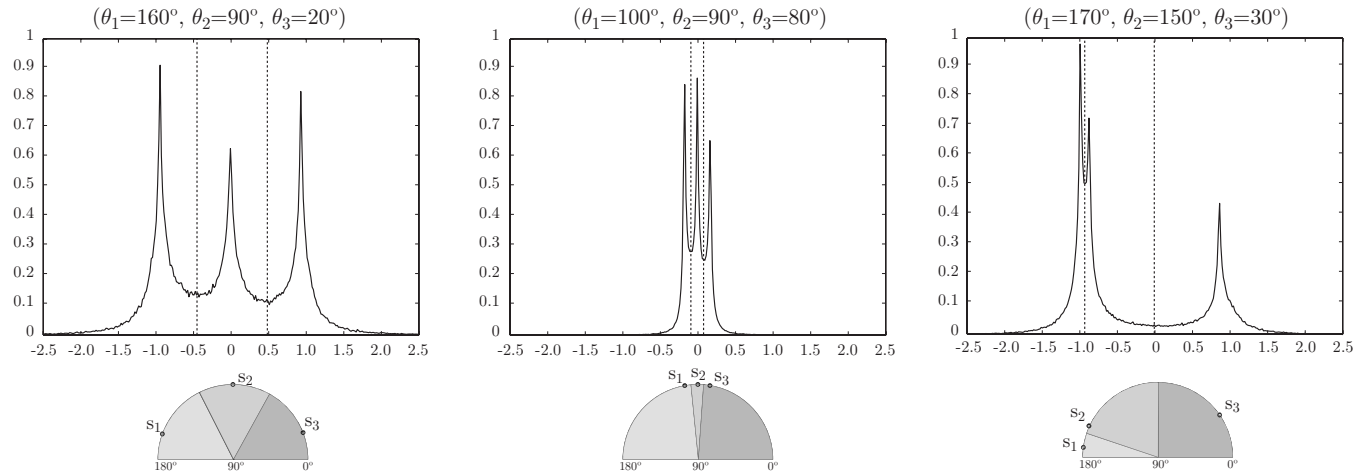

FIG. 7. Histograms and separation thresholds for different source arrangements with ρ=0 (anechoic). The angular segmentation of the azimuth plane for each case is depicted at the bottom of each graph, showing how the sources are effectively clustered in different angular sections even when they are close to each other.

B. Angular separation of speakers

The capability of the algorithm to decide the angular areas wherein the speakers are located is shown in Fig. 7, where an anechoic scenario and three speech sources have been considered in order to better visualize how the method works (later experiments will consider room reflections and more speakers). The separation thresholds (marked as dotted vertical lines) are accurately positioned between the source peaks, segmenting the azimuth plane into angular areas that denote the presence of each speaker. Notice how the segmentation is successfully performed even in the case when the angular separation between the sources is very small (10°).

C. Robustness against reverberation

The degradation introduced by reverberation with respect to the anechoic case is shown in Fig. 8. The peaks that appear in the histogram are more distorted when the wall reflection factor ρ is increased, making the detection of the speakers more difficult in the presence of room reflections. Note that despite the observed degradation, only slight differences between the angular source areas are produced. It is important to remark that the histograms have been constructed considering only high-coherence bins, so the effect that pre-selection has in improving the robustness against reverberation is here clearly observed.

D. Number of speakers

The number of speakers in the mixture affects the performance of the algorithm. Nevertheless, Fig. 9 shows how the thresholds correctly separate the source distributions even when four sources are present and room reflections are considered. When N=5 two sources are clustered into the same region, but the other sources have been correctly detected. Therefore, even in the case when many sources are present, the algorithm is still able to provide correct results for most of the sources.

E. Moving sources

The dynamic approach of Sec. III D 1 has been considered in an example, where there are two static sources and

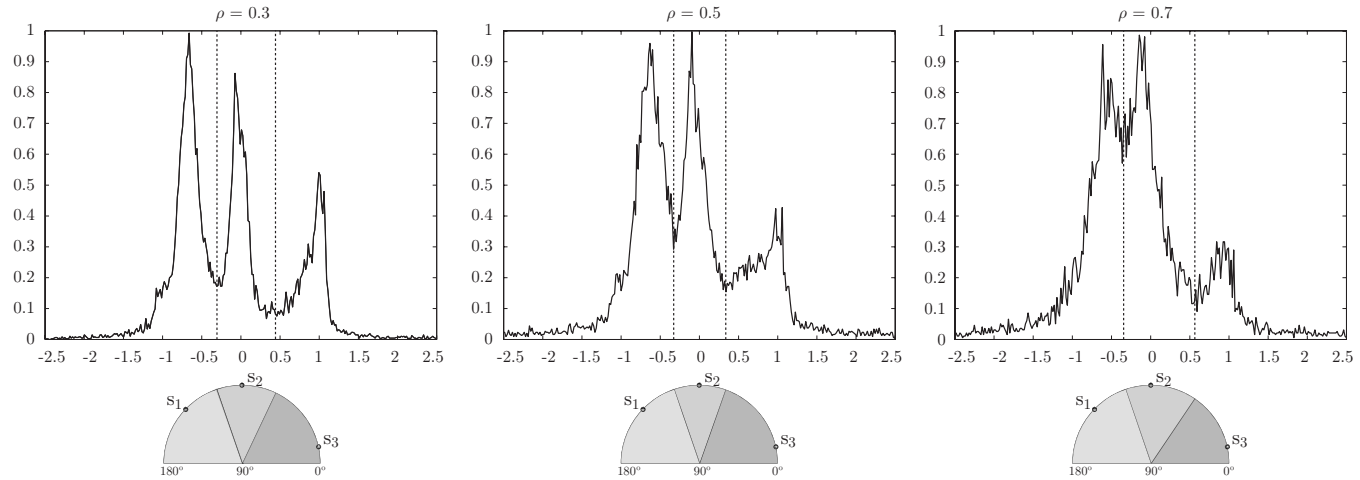

FIG. 8. Histograms and separation thresholds for different degrees of reverberation as a function of the wall reflection factor ρ. The speakers are at locations ((θ_1=135°, θ_2=90°, and θ_3=20°)). Note that despite the degradation of the histograms with reverberation, only slight differences between the angular source areas are produced.

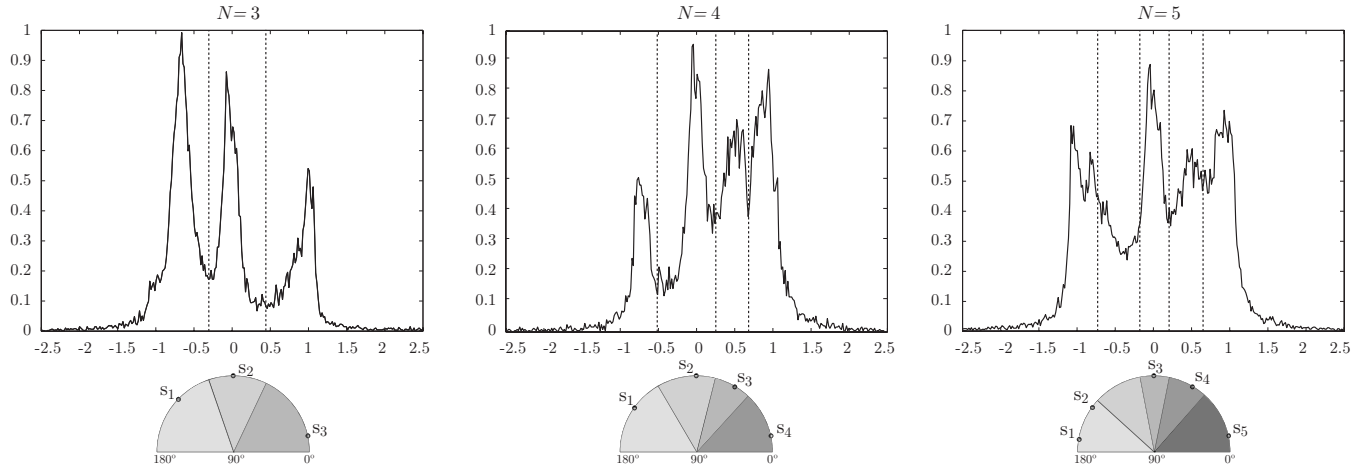

FIG. 9. Histograms and separation thresholds for different number of speakers in a room with moderate reverberation $\rho=0.3$: (a) $\theta_1=135°$, $\theta_2=90°$, and $\theta_3=20°$; (b) $\theta_1=135°$, $\theta_2=90°$, $\theta_3=60°$, and $\theta_4=20°$; (c) $\theta_1=170°$, $\theta_2=135°$, $\theta_3=90°$, $\theta_4=60°$, and $\theta_5=20°$.

one moving source going from $\theta=0°$ to $\theta=150°$ in a time period of 4 s. The thresholds are calculated every 0.8 s and the separation masks are consequently updated, taking into account the new histograms. Figure 10 shows the histograms obtained in each update step with the thresholds obtained as output of the segmentation process. Note how the thresholds are correctly updated in each step. At $t=2.4$ s the moving source is at the same location as one of the static sources. Although the angular distributions are correctly identified, the overlapping sources cannot be separated if they are at the same angular location. Obviously, when there are crossings between angular source positions, the separation masks are interchanged; thus, a tracking stage must be included in order to preserve the identity between each source and its corresponding mask. The solutions to these problems are out of the scope of this paper, but will be addressed in the future.

F. Source separation performance

The objective performance measures for different separation examples with $N=3$ and $N=4$ sources are shown in Tables II and III, respectively. The values given correspond to the average results over all the sources for each separation experiment. The angular positions of the sources were ($\theta_1=135°$, $\theta_2=90°$, and $\theta_3=20°$) in the three source example, and ($\theta_1=135°$, $\theta_2=90°$, $\theta_3=60°$, and $\theta_3=20°$) in the four source case. For comparison purposes, the performance measures achieved by the ideal binary mask in each experiment are also included. Consider that the results provided by the ideal binary mask are always the optimal and can be understood as the maximum quality achievable by binary time-frequency masking. However, the original sources are needed to compute for the ideal binary mask, and state-of-

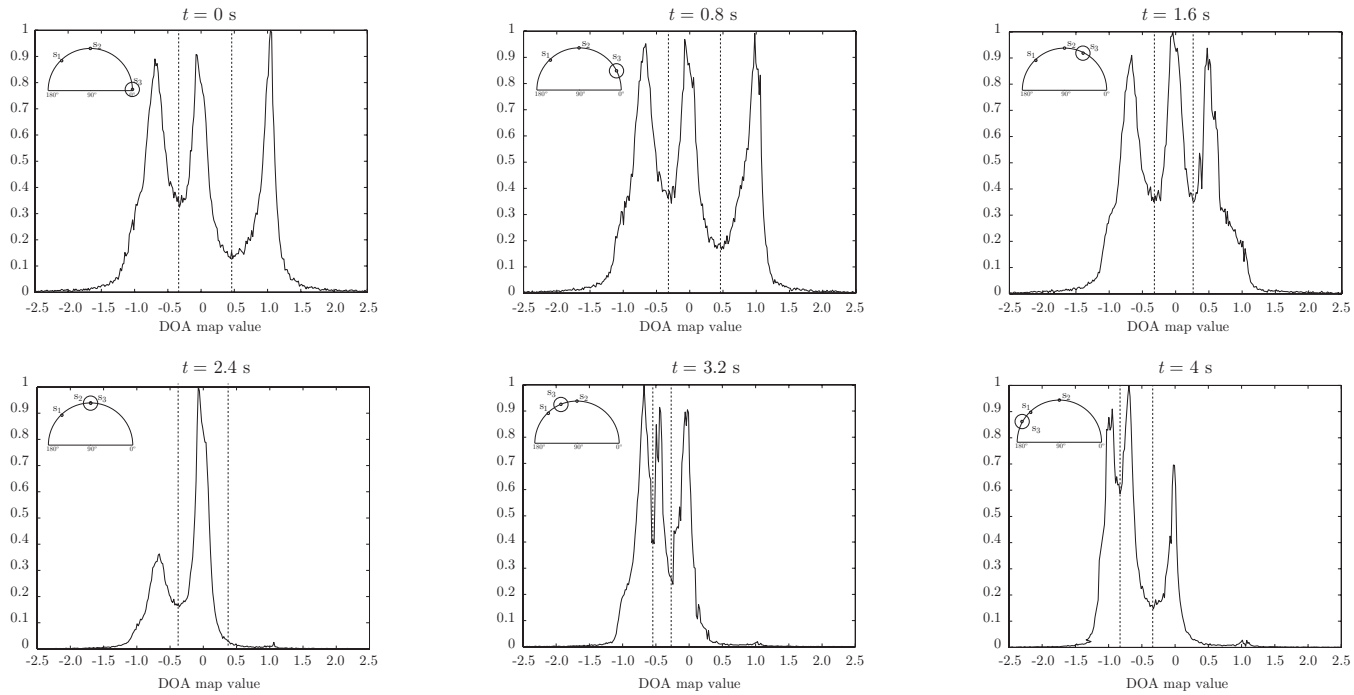

FIG. 10. Histograms and separation thresholds for the moving source example at different time instants.

TABLE II. Average objective performance measures for $N=3$ sources.

	$N=3$							
	$\rho=0$		$\rho=0.3$		$\rho=0.5$		$\rho=0.7$	
	Proposed	Ideal	Proposed	Ideal	Proposed	Ideal	Proposed	Ideal
SDR	6.4	9.5	2.6	9.2	1.9	8.9	0.9	8.2
ISR	15.1	20.0	10.1	18.9	7.8	18.2	5.6	17.4
SIR	15.3	22.0	10.7	20.6	8.3	19.7	2.8	18.3
SAR	6.9	9.7	5.6	9.6	4.6	9.3	4.4	8.5

the-art algorithms are still far from achieving similar performance for reverberant scenarios and a high number of sources. As expected, the performance of the algorithm is decreased when there are more sources in the mixture or the degree of reverberation is higher. This is not only true for the proposed algorithm but also for the case of the ideal binary mask, which also shows a degradation in the demixing performance due to these two factors. Of all the performance measures, SAR and SDR are more affected by an increment in the number of sources, while reverberation has a greater influence on the SIR and ISR measures.

G. Separation performance in real office rooms

Experiments using mixture signals recorded in a real office room have also been conducted in the context of the 2008 Signal Separation Evaluation Campaign. These were acquired in a chamber with cushion walls, using the loudspeaker and microphone arrangement depicted in Fig. 11. The room had a reverberation time of $RT_{60}=130$ ms, and the experiments were carried out by considering mixtures of male and female speech sources. These mixtures were sampled at 16 kHz and had a duration of 10 s. The intermicrophone distance was set to 5 cm. Table IV shows the average results for these experiments together with the results of the ideal binary mask. Note how the results in a real case are even better than those obtained in previous simulations with reverberation. Audio files can be downloaded at ⟨www.irisa.fr/metiss/SiSEC08/SiSEC_underdetermined/test_eval.html⟩. The measures shown in the table confirm how the method is able to separate real mixtures of speech with little computation time. This is further discussed in Sec. IV H.

H. Computation time

The times required by the proposed algorithm for deciding the angular separation areas as a function of the number of sources N and the number of histogram bins L_c are shown in Table V. The processor used for measuring these times was an Intel Core2 2.0 GHz. Note how the number of sources considered has the greatest influence on the computation time. Nevertheless, a very high number of histogram bins is not necessary, since the angular resolution of the method is mainly imposed by reverberation. Moreover, L_c can be modified, depending on the computational power of the processor, which is another advantage for real-time implementations.

TABLE III. Average objective performance measures for $N=4$ sources.

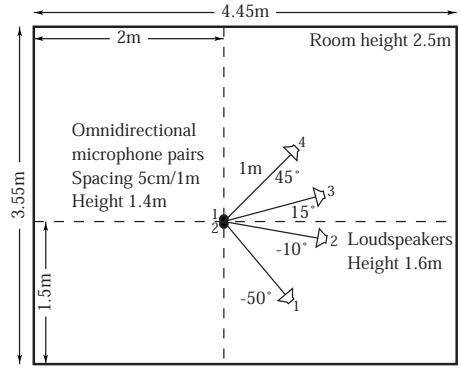

FIG. 11. Arrangement for the recording of real speech mixtures (extracted from Ref. 38).

V. CONCLUSION

In this paper, a method for separating real mixtures of speech using two microphones has been presented. The proposed algorithm is based on grouping time-frequency points with similar DOA using a multi-level thresholding approach. The thresholds are calculated via the maximization of the interclass variance between DOA estimates, and they allow to identify angular sections, wherein the speakers are located with a strong likelihood.

Separation is efficiently achieved without the need for estimating the mixing matrix nor detecting peaks or specifying initial centroid values as with other clustering approaches. Moreover, although the method is based on the anechoic mixing model, two features have been proposed to improve the robustness against reverberation: a coherence test and a weighted histogram. These features allow to perform separation in realistic acoustic scenarios.

The validity of the method has been studied over a complete set of experiments, including both simulations and real speech mixtures of up to four sources. The results show that

Do ferrets perceive relative pitch?

Pingbo Yin, Jonathan B. Fritz, and Shihab A. Shamma
Neural Systems Laboratory, Institute for Systems Research, University of Maryland, College Park, Maryland 20742

(Received 18 March 2009; revised 13 November 2009; accepted 13 December 2009)

The existence of relative pitch perception in animals is difficult to demonstrate, since unlike humans, animals often attend to absolute rather than relative properties of sound elements. However, the results of the present study show that ferrets can be trained using relative pitch to discriminate two-tone sequences (rising vs. falling). Three ferrets were trained using a positive-reinforcement paradigm in which sequences of reference (one to five repeats) and target stimuli were presented, and animals were rewarded only when responding correctly to the target. The training procedure consisted of three training phases that successively shaped the ferrets to attend to relative pitch. In Phase-1 training, animals learned the basic task with sequences of invariant tone-pairs and could use absolute pitch information. During Phase-2 training, in order to emphasize relative cues, absolute pitch was varied each trial within a two-octave frequency range. In Phase-3 training, absolute pitch cues were removed, and only relative cue information was available to solve the task. Two ferrets successfully completed training on all three phases and achieved significant discriminative performance over the trained four-octave frequency range. These results suggest that ferrets can be trained to discern the relative pitch relationship of a sequence of tone-pairs independent of frequency. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3290988]

I. INTRODUCTION

A significant amount of information is encoded in the contour patterns (rises and falls) of the pitch of acoustic signals, such as in speech and music. For example, human subjects can easily recognize sentence type on the basis of pitch contour alone in the absence of other information (Ladefoged, 1982). The frequency transpositions of a melody are readily recognized by most adult, and even infant, human listeners as the "same" and are perceived as structural equivalents of the original melody (Dowling and Fujitani, 1971; Demany and Armand, 1984; Trehub *et al.*, 1984; Trehub and Hannon, 2006). Although human listeners can remember the exact musical intervals of familiar melodies, they appear to remember only the frequency contour of less familiar or novel stimuli (Dowling and Fujitani, 1971; Dowling, 1978; Bartlett and Dowling, 1980). Unlike humans, who attend chiefly to the relationships *between* sound elements, animals more heavily weight the *absolute* frequency of sound elements in their perceptual decisions and appear to be less attentive to *relative* pitch changes. Consequently, it has been difficult to train animals to attend to the relative pitch between sound elements, as D'Amato (1988) concluded after extensive behavioral research on monkeys and rats.

Most studies conducted with nonhuman species, including several species of birds (Hulse and Cynx, 1985, 1986; Ratcliffe and Weisman, 1986; Dooling *et al.*, 1987; Page *et al.*, 1989; Cynx, 1993; Weisman *et al.*, 2004) and monkeys (D'Amato and Salmon, 1984; D'Amato, 1988; Izumi, 2001, 2003; Brosch *et al.*, 2004, 2006), suggest that animals generally encode absolute pitch and have rather limited abilities to recognize the relative pitch contours of tonal stimuli. Songbirds have been shown to learn a relative pitch strategy, recognizing an ordinal rule for tone sequences that rise or fall in frequency regardless of the absolute frequency components. However, when the sequences were shifted out of the trained frequency range, they lost the discrimination. It then required as many trials to acquire a new discrimination as they needed to learn in the original discrimination (Hulse and Cynx, 1985; Cynx, 1993). Furthermore, songbirds failed to learn relative pitch discrimination when the absolute pitch cues were removed from the training (Page *et al.*, 1989), indicating the primacy of absolute pitch perception in these species. Although a frequency range constraint was also noted in nonhuman mammals (Izumi, 2001, 2003), there are now two studies indicating that some nonhuman mammalian species are capable of relative pitch as measured by octave generalizations—rhesus monkeys (Wright *et al.*, 2000) and dolphins (Ralston and Herman, 1995).

In a recent behavioral study, Walker *et al.* (2009) successfully trained ferrets on a two-alternative forced choice task to discriminate sounds that were higher or lower in pitch than a reference sound. Since the reference sound remained constant throughout a given session, the animal could use absolute strategies to solve the task. However, the result might also suggest that ferrets can be trained to utilize relative pitch cues in sequential sounds. The goal of the present study was to develop a new animal model to study the neural mechanisms underlying auditory pattern categorization based on direction of pitch changes (pitch contours) of tone sequences, and more generally to understand the neural basis and correlates of recognition and discrimination of spectrotemporally complex sounds. A training procedure which gradually directed animals to attend to the relative pitch change of two-tone sequences (rising vs falling) has been successfully developed, and the present report provides evi-

dence of ferrets' capability to categorize tonal patterns solely on the basis of these two-tone step changes over the trained frequency range.

II. METHODS

A. Subjects

Three naïve female adult ferrets, weighing 600–900 g, were used in this behavioral study. The animals were trained on a positive-reinforcement operant paradigm with water as reward. The ferrets were placed on a water-control protocol on which they were typically trained 5 days per week and obtained *ad libitum* water over the weekend. On training days, animals received one or two training sessions (~100 trials in each session to satiation). All procedures conformed to the NIH policy on experimental animal care and use and were approved by the IACUC of the University of Maryland.

B. Experimental apparatus

Ferrets were tested in a customized-design wire mesh training cage (8 in. width × 15 in. depth × 9 in. height) which was placed within a single-walled, sound attenuated chamber (IAC). A lick sensitive waterspout (1 in. × 1.5 in.) stood 5 in. above the floor of the training cage. The waterspout was connected to a computer controlled water dispenser (Crist Instrument Co., Inc., Maryland, USA). A loudspeaker (Manger MSW, Germany) was positioned 10 cm in front of the cage, and the animal's behavior was monitored by video camera.

C. Basic behavioral paradigm

The positive-reinforcement operant paradigm used in these experiments differed substantially from previous behavioral studies in the laboratory that used a conditioning avoidance paradigm (Fritz *et al.*, 2003). In the current study, ferrets were trained to lick a waterspout as the behavioral response to a target sound (unlike the conditioned avoidance paradigm, in which ferrets learned to refrain from ongoing licking when the target sound was presented). Each training session started with delivery of a drop of water (~0.5 ml) to initiate licking of the waterspout. The first trial, and subsequent trials, began after the animal had consumed the water and then refrained from licking the spout for a minimum of 0.5 s, as illustrated in Fig. 1. A trial consisted of a sequence of one to five similar reference (non-target) sounds, followed by a different (target) sound. The inter-stimulus-interval between all references and target sound was 1.25 s. The animal was rewarded with a small drop of water when it licked the spout within a given time window *after* the target sound (*last* shaded area in Fig. 1). It received a 3–6 s timeout penalty if it did not lick during the target sound. The target reward drop volume (0.1–0.3 ml) was adjusted for each trial according to the licking pattern during the preceding reference stimuli. Specifically, the reward drop volume was inversely proportional to false-alarm rate of the trial in order to discourage licking during the reference stimuli. An additional click sound was played as a secondary "reinforcer" following water delivery during the early stages of training. The total

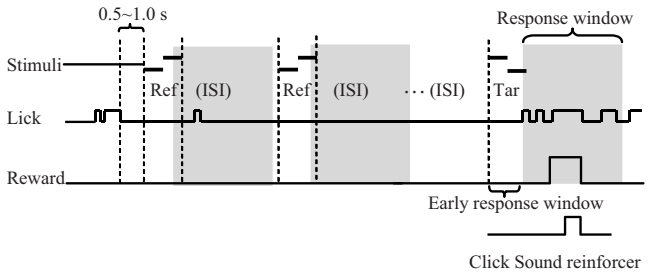

FIG. 1. *Positive-reinforcement operant paradigm.* A trial was initiated when the animal refrained from licking the waterspout for 0.5–1.0 s. A reference sound (non-target) was presented and repeated randomly one to five times after trial initiation. A target sound followed the reference sounds. When the ferret licked the waterspout within a 1.2 s response time window after target onset (*the shaded target period*), its response was counted as a *hit*, which was followed by water reward. If the ferret licked the waterspout within a corresponding time window after reference sound onset (*the shaded reference period*), its response was counted as a *false alarm*, which caused reduction in reward volume. A miss of the target lead to a 3–6 s timeout penalty after completion of the trial. A click sound was played as a secondary reward reinforcer after water reward delivery.

number of reference stimuli presented in given trial varied from trial to trial and was selected from a pseudo-random sequence, in which there was an equiprobable likelihood that the target sound would be presented at each position in the sequence (from second to fifth position). A training session ended when the animal did not lick the spout in two consecutive trials.

D. Training procedure and stimuli

Training began with a 1–2 day habituation period during which animals were allowed to explore the training cage and learned to obtain water by licking the waterspout. Training was continued by a pre-training phase of approximately 2 weeks in which water delivery was associated with sounds.

All acoustic stimuli were two-tone sequences, 300 ms in duration, and ~70 dB SPL. Each tone component in the two-tone sequence was 150 ms duration and was ramped with 5 ms rise-fall time. There was no silent gap between the tones. The frequency separation between the two tones was 1/3 (Phase 1) or 1/2 octaves (Phases 2 and 3).

Two ferrets (H and J) were trained to discriminate the downward sequences (*the target sequence*) from the upward sequences (*the reference sequence*), and one ferret (M) was trained to discriminate upward sequences (*the target sequence*) from the downward sequences (*the reference sequence*). Animals underwent a three-phase training schedule [Figs. 2(A)–2(C)] to be gradually directed to the final task requirements.

Initially, ferrets were trained with an easy version of the task (*Phase-1 training*), in which both the reference and target sequences were comprised of a fixed frequency tone-pair [the left panel in Fig. 2(D)]. The same tone-pair (with the same two tones arranged either upward or downward) was used during this entire training phase [Fig. 2(A)]. To perform the task, animals could either utilize the absolute frequencies of the tones (e.g., the initial and/or terminal pitch of the sequence) and/or relative properties of the tone sequence, specifically the direction of pitch change (rising vs falling).

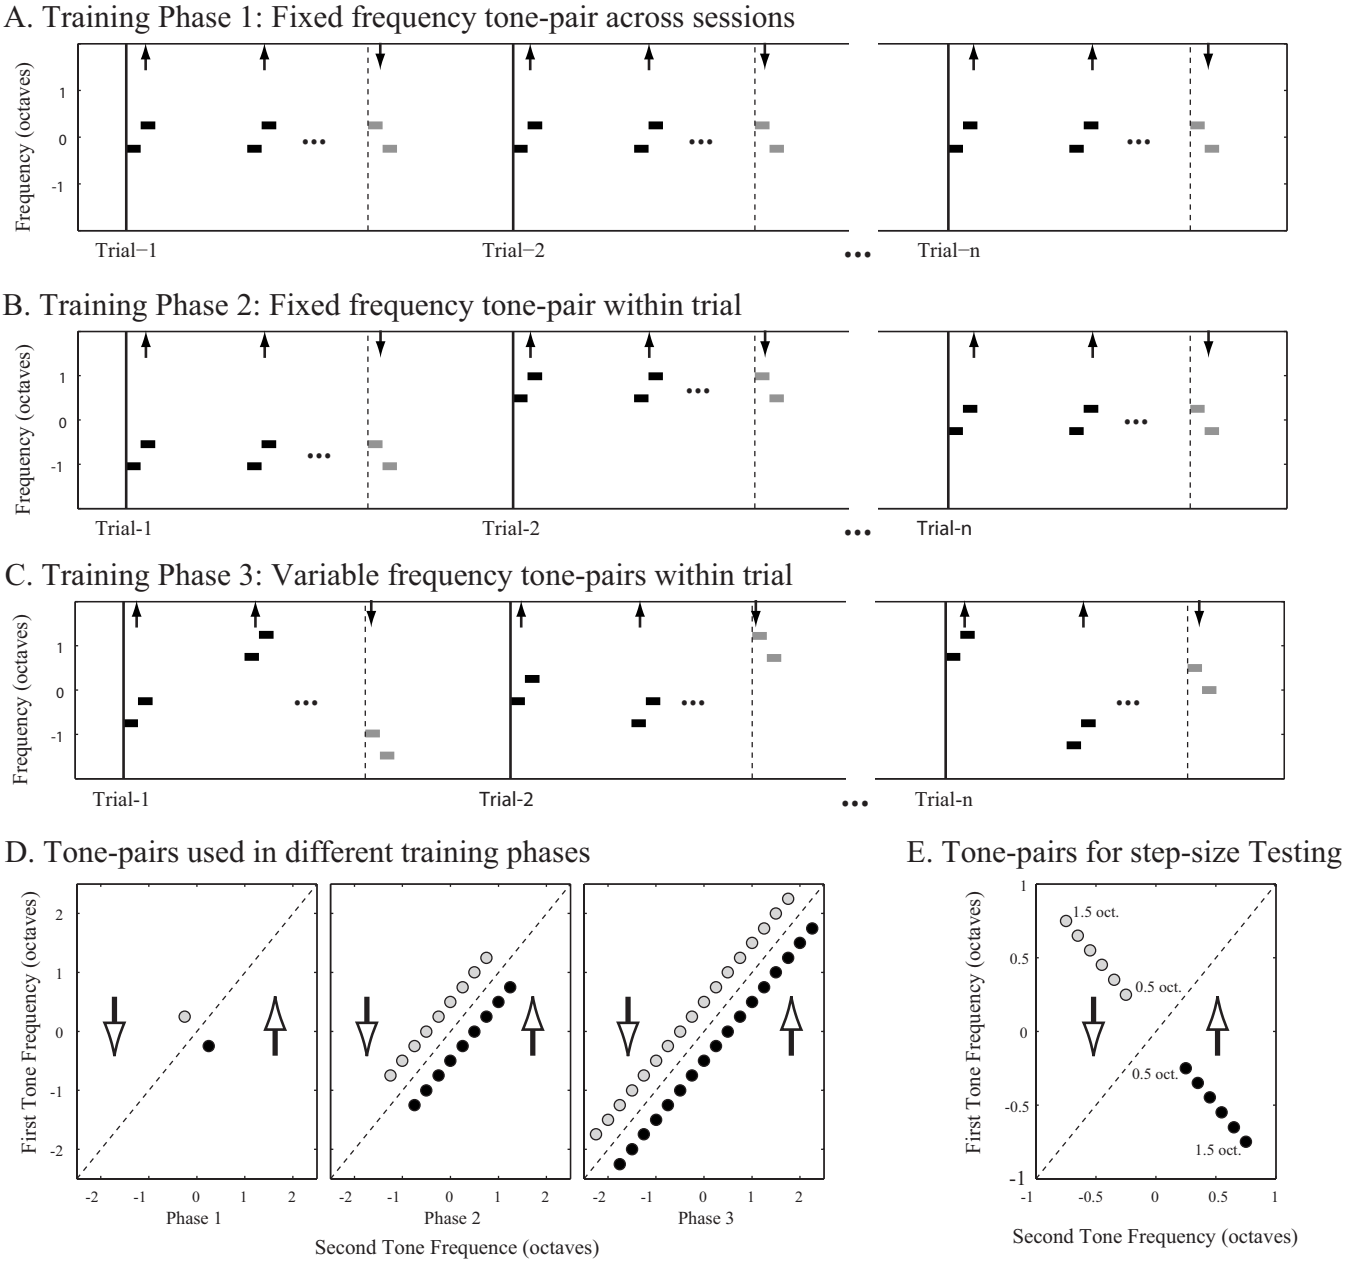

FIG. 2. *Two-tone sequence discrimination task: Training procedures and stimuli sets*. (A) Phase-1 training: The reference and target sequences were comprised of one tone-pair with fixed frequency across all training sessions. (B) Phase-2 training: The reference and target sequences for each trial were comprised of one tone-pair with fixed frequency, while the frequency of the tone-pair was changed randomly between successive trials. (C) Phase-3 training: Each of the reference or target sequences in a given trial was comprised of different tone-pairs for which the frequency of the tone-pair was chosen randomly from a set of 17 possible pairs. (D) Tone-pairs in different training phases: The rising and falling two-tone sequences were made from 1 tone-pair in Phase 1 (*the left panel*), 9 tone-pairs in Phase 2 (*the middle panel*), and up to 17 tone-pairs in Phase 3 (*the right panel*). The tone components of the two-tone sequence were $\frac{1}{2}$ octave apart in frequency, and the frequency contours of the sequences were roved up or down with $\frac{1}{4}$ octave increments. (E) Tone-pairs for step-size testing: The stimulus set varied the frequency separation between component tones, ranging from 0.5 up to 1.5 octaves. The solid vertical lines in (A)–(C) indicate the beginning of the trials. The vertical dashed lines indicate the target onset of each trial. The diagonal lines in (D) and (E) denote the iso-frequency line. The up and down arrows indicate directions of the reference and target sequence in (A)–(C) and of the quadrants in (D) and (E).

Once the behavioral criterion was achieved (see Sec. II E), two animals received one or more additional tone-pairs in Phase-1 training. All animals then began Phase-2 training, in which the two-tone sequence for each trial consisted of a randomly picked tone-pair within a limited frequency range [Fig. 2(B)]. The frequency of the tone-pair was varied between trials over a frequency range that was gradually expanded up to two octaves around the initial frequency with $\frac{1}{4}$ octave increments, forming nine different rising or falling sequences at the end of this phase [the middle panel in Fig. 2(D)]. In the final stage, training Phase 3, all reference and target sequences within each trial were randomly chosen [Fig. 2(C)] so that the absolute frequency of the sequences varied, and the only fixed parameter was the direction of pitch change (rising or falling). The frequency range of the tone-pairs at this training stage was expanded to four octaves for a total of 17 rising or falling sequences [the right panel in Fig. 2(D)].

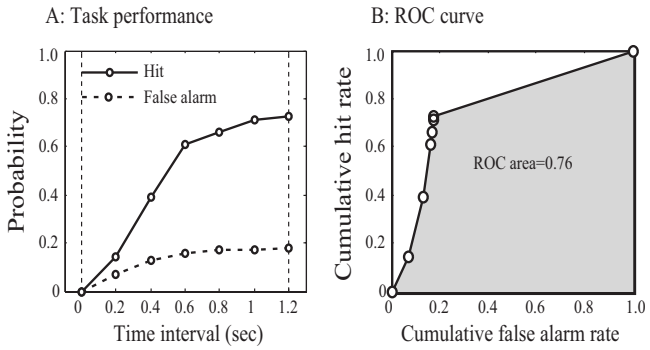

FIG. 3. *Construction of ROC curve.* (A) The probabilities for hit (*solid line*) and false alarm (*dashed line*) were independently computed at each of the time intervals from 0.0 to 1.2 s with 0.2 s increments following the onset of the response window after the target and reference. The vertical dashed lines indicate the start and the end of the response window. (B) The false-alarm probability function was plotted against hit probability function to construct the ROC curve (*solid line*). The area under the ROC curve (*shaded area*) was a measure of discriminative performance of the task.

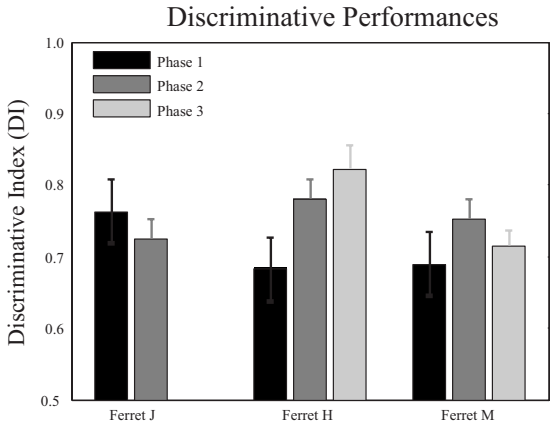

FIG. 4. *Discriminative performances for all training phases.* The bar plots show the average DI values, each of which was computed from ten consecutive sessions of Phase 1 (*black*), Phase 2 (*dark gray*), and Phase 3 (*light gray*) performances after reaching training criterion. The error bar indicates standard deviation.

A different stimulus set was used to test the effect of the step-size of tone-pairs on the discriminative performance after completion of Phase-3 training. This stimulus set included six upward and six downward sequences, which were compromised of six tone-pairs whose frequencies were [1200 1697], [1120 1819], [1045 1949], [975 2089], [909 2239], and [849 2400] Hz, respectively. Therefore, the frequency separation (or interval) between component tones in those sequences varied from 0.5 to 1.5 octaves [see Fig. 2(E)].

E. Data analysis

The timing of the first-lick after each of the references and target stimuli was recorded as the behavioral response to the stimulus on each trial. The task performance level was assessed by an analysis based on signal detection theory, in which both behavioral response accuracy and the behavioral response latency were exploited. The use of latency information in the analysis was useful in case of a difficult discrimination (Carterette *et al.*, 1965; Emmerich *et al.*, 1972) and also in obtaining a sufficient number of probability values for accurate determination of a receiver operating characteristic (ROC). A "first-lick" was defined as a hit or a false alarm depending on whether it was fallen in the response window following a target or non-target (the reference) sound (the shading zones after each sequence in Fig. 1). The probabilities of the hit (response after a target sound) and the false alarm (response after a non-target sound) were independently computed as function of the time intervals (from 0.0 to 1.2 s with an increment of 0.2 s) following the onset of the response window [Fig. 3(A)]. The ROC was then formed by the obtained probability functions (i.e., hit rate vs false-alarm rate function) [Fig. 3(B)]. The area under the ROC was taken as a measure of the task performance and was defined as the discriminative index (DI). This index yields a value of 0.5 for random performance, greater than 0.5 but less than 1.0 for nonrandom performance, and 1.0 for perfect performance. In each training session, the DI value was calculated from the original data and also from bootstrapped trials. In bootstrapped trials, the relationship between the behavioral responses (the First-lick time) and the stimulus tags (reference and target) was shuffled, and a shuffled-DI value was calculated. This process was repeated 50 times, and the mean value and the standard deviation of these shuffled-DI values were determined. A training session was considered to show significant discriminative performance if the obtained DI value was more than two standard deviations above the shuffled-DI mean. The behavioral criterion for achieving successful performance was defined as significant discriminative performance for a minimum of five consecutive training sessions. Animals could receive additional training on a given training phase after reaching criterion. Sessions with less than 40 trials were excluded from further analysis.

III. RESULTS AND DISCUSSIONS

Three ferrets were trained on the two-tone discrimination task. Two of them completed all three phases of training. The third ferret was suspended from further training after completion of two phases (it was withdrawn from the study because it was suffering weight loss due to a severe and debilitating gastrointestinal infection). Figure 4 shows the mean performance of the ferrets across ten consecutive sessions after reaching behavioral criterion at each of the three training phases. All three animals reached behavioral criterion in the first two training phases and yielded mean DI values between 0.68–0.76 ($M=0.71$, s.d.$=0.05$) for Phase 1 and 0.72–0.77 ($M=0.75$, s.d.$=0.03$) for Phase 2. The performance of the two animals completing the final training phase (Phase 3) yielded DI values of 0.71 and 0.82, respectively ($M=0.76$, s.d.$=0.08$).

A. Phase-1 training and frequency transposition

Training in Phase 1 took about 30–60 sessions before animals reached behavioral criterion. Since animals in Phase 1 could use either absolute or relative pitch to discriminate the target from reference sequences, if relative was being employed, then animals would easily generalize their training on the first tone-pair to a new tone-pair with different

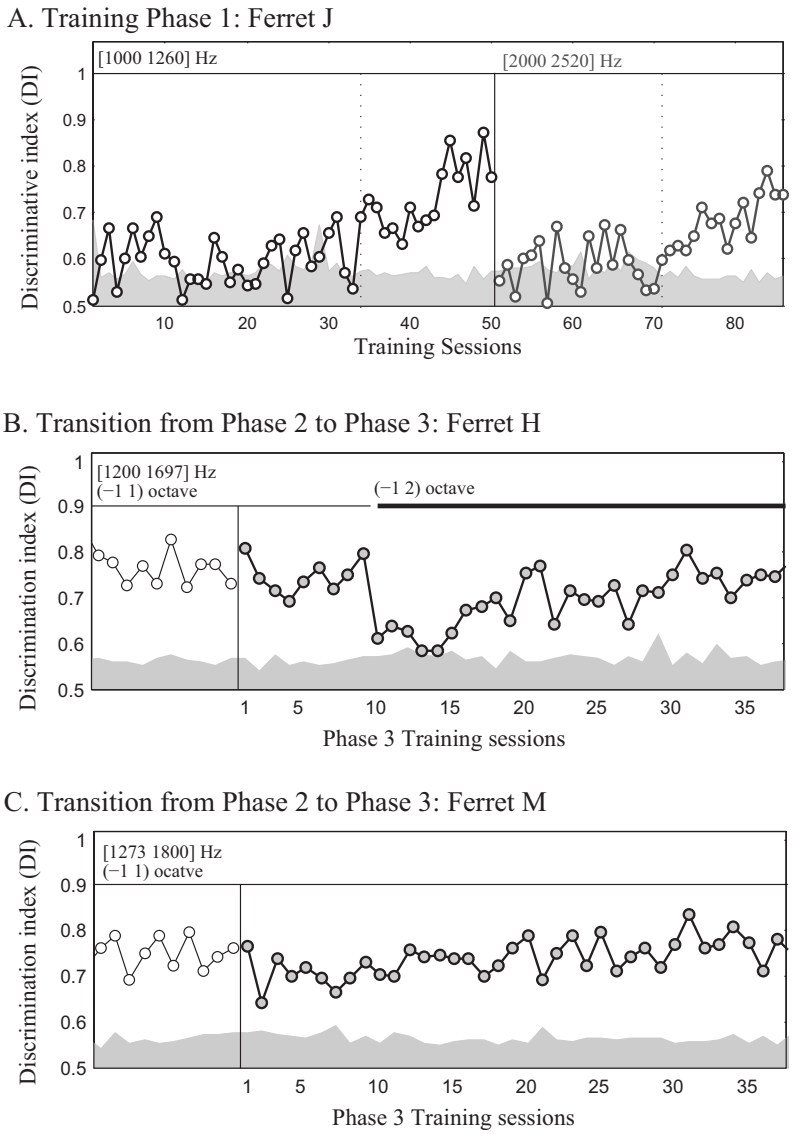

FIG. 5. *The frequency transposition in Phase-1 training and the transition from Phase 2 to Phase 3.* (A) The figure shows Phase-1 training data for ferret J. Phase-1 training was started (Training session=0) with a tone-pair at frequencies [1000 1260] Hz, and after learning the first pair, training was continued (Training session=50) with the second tone-pair at frequencies [2000 2520] Hz (*the vertical solid line*). [(B) and (C)] The animals maintained a high performance level when moved from Phase 2 (*open circles*) into Phase 3 (*filled circles*) when training within the same frequency range (indicated by the *thin horizontal line on the top of each figure*). In (B) the starting frequency range varied one octave above and below the initial frequency of the tone-pair [1200, 1697] Hz. Performance deteriorated when the frequency range of possible tone-pairs was extended an additional octave to two octaves above the initial tone-pair [indicated by the *thick horizontal line* in (B)] and regained after additional Phase-3 training. In (C) there was no change in frequency range during the transition from Phase 2 to Phase 3. The shaded area in (A)–(C) indicate the baseline performance (mean plus two standard deviation of the shuffled-DIs). A DI value above those dashed lines indicates a significant discriminative performance.

absolute frequencies. In order to test this conjecture, two ferrets were tested with a second tone-pair after learning the first tone-pair in Phase 1. The ferrets' behavioral discrimination initially plummeted with the new tone-pair, and the animals performed at chance level. The example shown in Fig. 5(A) is from ferret J. In Phase 1, ferret J was trained on its first tone-pair (1000 and 1260 Hz) for 34 sessions until it reached behavioral criterion (the first vertical dashed line). Performance initially declined to a random level [the shaded area in Fig. 5(A)] when a new tone-pair (2000 and 2520 Hz) was introduced in Training Session 50. It took another 21 training sessions (the second vertical dashed line) to reach behavioral criterion for consistent performance for the second tone-pair, though ferret J learned this discrimination faster than for the first tone-pair. This behavioral pattern was tested and replicated in ferret M. These behavioral results, showing that the animals did not generalize to new tone-pair in Phase 1, indicate that the animals' performance probably relied upon absolute pitch rather than relative pitch cues during Phase-1 training.

B. Transitioning from Phase 1 to Phase 2 and Phase 3: Learning relative pitch

Training in Phase 2 started after animals reached behavioral criterion on one (ferret H) or more tone-pairs (ferrets M and J) during Phase 1. In Phase-2 sessions, the reference and target stimuli in each trial consisted of upward and down-

ward versions of the same tone-pair (randomly chosen for each trial from a small set of tone-pairs) that remained constant throughout a given trial [see Fig. 2(B)]. The training began with a set of three tone-pairs near the frequencies of the last tone-pair in Phase-1 training. The number of tone-pairs used in Phase-2 training sessions was gradually expanded up to nine tone-pairs, spanning a two-octave frequency range [see the middle panel in Fig. 2(D)]. All three ferrets reached significant discriminative performance within the two-octave frequency range after 24 (ferret H), 68 (ferret M), or 77 (ferret J) training sessions. Since the absolute frequencies of tone-pairs in the reference and target sequence of a given trial changed on a trial-by-trial basis, using absolute cues (as in Phase 1) was no longer an efficient strategy for task performance. It is more likely that animals used relative pitch to solve the task than the alternative that the animals memorized the absolute cues and responses for each of the nine possible tone-pairs.

Two ferrets (H and M) progressed to Phase-3 training, in which each reference and target sequence in a trial was randomly chosen from a set of up to 17 tone-pairs which spanned four octaves [see Fig. 2(C) and the right panel in Fig. 2(D)]. Both animals maintained a significant discriminative performance when transitioning from Phase-2 to Phase-3 training, as shown in Figs. 5(B) and 5(C). These results indicate that the ferrets probably used the relative frequency contours of the sequence to solve the task in training Phase 2. However, even at this stage of training, animals did not generalize across all frequencies, and behavioral performance deteriorated when the frequency range of the tone-pairs expanded to a new frequency region, as indicated in Fig. 5(B). Apparently, the animals had generalized their performance only in a two-octave frequency range which had been achieved during Phase-2 training, and hence additional training was necessary to extend the discriminative performance to a larger frequency range.

Both ferrets (H and M) achieved significant discriminative performance with a four-octave frequency range after additional Phase-3 training, as illustrated in Fig. 4 (the light gray bars show Phase-3 performance for each ferret) and Fig. 6(A) (the two curves show performance over the frequency range for each ferret). Figure 6(A) shows the ferrets' discriminative performance for each of the tone-pairs after the animals reached performance criterion in Phase 3. In order to have sufficient behavioral data to compute the DI for each of the tone-pairs, the data in Fig. 6(A) were pooled from all ten sessions (the same data set as in Fig. 4). The significant discriminative performances were confirmed for all of the tone-pairs within the trained frequency range. The DIs from all tone-pairs within the four-octave frequency range [the lines with filled circle in Fig. 6(A)] were more than two standard deviations above the mean for shuffled-DIs [the dashed line in Fig. 6(A)]. The best performance was found at the tone-pairs in the middle frequency range for both ferrets. This result indicates that even though the ferrets could "partially" generalize the frequency contour categories within a wide frequency range after additional Phase-3 training, they were still subject to a frequency range constraint as in other nonhuman species (Hulse and Cynx, 1985; Izumi, 2001).

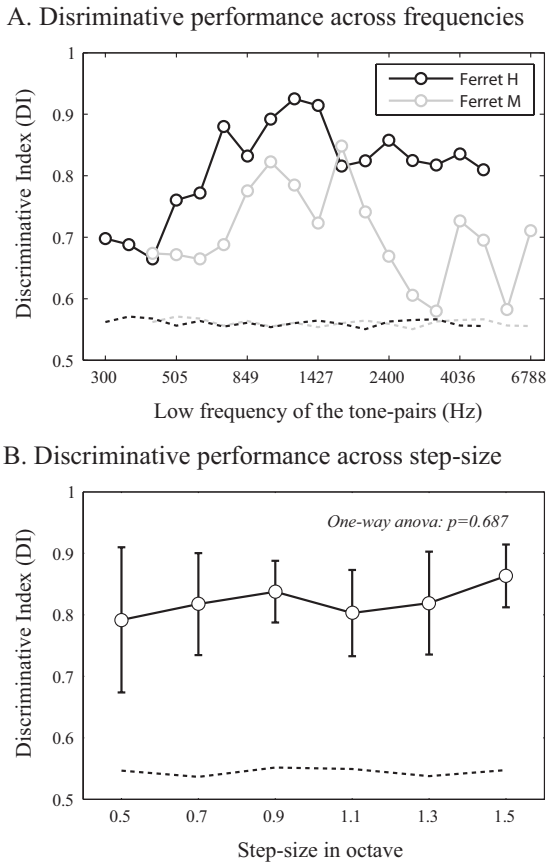

FIG. 6. *Discriminative performance across frequencies and step-sizes of the tone-pairs.* (A) Phase-3 data sets were the same as used in Fig. 4 for both ferrets M and H. The trials from all of those ten sessions were pooled together to compute the discriminative index for each of the tone-pairs. The significant discriminative performances were confirmed at all the tone-pairs within four-octave training frequency range. (B) Discriminative index at each frequency separation is represented as mean ± standard deviation (N =6). There is no significant difference in discriminative performance across the frequency separations between the component tones of the sequence. The horizontal dashed lines in (A) and (B) indicate the baseline performance (mean plus two standard deviation of the shuffled-DIs). A DI value above those dashed lines indicates a significant discriminative performance.

Those profiles of behavioral performance across the frequency range might be explained by the training history of the animals, which showed a similar profile of experienced frequencies.

C. The effect of frequency separation on task performance

In a separate set of experiments, the effects on task performance of the size of the frequency separation between the two component tones in the sequence were probed by a completely new set of two-tone sequences. As illustrated in Fig. 2(E), this stimulus set had novel two-tone sequences with variable frequency separation (0.5–1.5 octaves). Each reference and target was randomly picked from the stimulus list. One ferret was tested with this stimulus set alternately with the fixed standard frequency separation of 1/2 octave. There was no significant difference in behavioral performance across the different frequency separations [*one-way* ANOVA, p=0.687, Fig. 6(B)]. This result suggests that the animals did not attend to the interval size between the component tones

in the sequence, but simply to the direction of pitch change of the two-tone sequence. This result was also seen in human subjects in melody recognitions. The recognition of randomly generated melodies (novel melodies) was dominated by contours, while for familiar melodies both the contours and intervals were critical for recognition (Dowling and Fujitani, 1971; Dowling, 1978).

IV. GENERAL DISCUSSION

This study successfully demonstrated that ferrets are capable of relative pitch perception within a trained frequency range. With a three-phase training strategy, ferrets could learn to extract the relative pitch cue (the frequency contour) to discriminate between rising and falling two-tone sequences, independent of the absolute frequency of the tone sequence, over a four-octave range of frequencies.

During Phase-1 training, ferrets apparently used absolute pitch cues and discriminated target sequences from the reference sequences based on the initial or terminal pitch of the tone sequence. Transposition of the learned tone-pair to a different frequency caused a significant deterioration of performance, and animals needed to be retrained in order to master the new tone-pair. This result suggests that ferrets, like other nonhuman species, do not use relative pitch to solve contour discrimination tasks as a primary strategy, but are likely to use the absolute pitch of the tones in the sequence (particularly when the tone-pair frequencies are fixed).

However, ferrets were able to discriminate contour for multiple tone-pairs during Phase-2 training and appear to have learned to extract and utilize relative pitch cues in order to solve the task. Although the tone-pair frequencies remained constant within a given trial, and hence changes of the initial or ending pitch of the sequences could be used, ferrets appear to attend to the frequency contour within the sequence (relative cue) to solve the task. The behavioral evidence shown in Figs. 5(B) and 5(C) clearly indicates that performance on Phase 2 was very easily transferred to Phase 3, where the relative frequency contours were the only available cue. However, additional training was needed in Phase 3 in order to *expand* the frequency range over which the task was performed [indicated in Fig. 5(B)].

Sinnott *et al.* (1987) observed asymmetrical frequency discrimination in human subjects and some nonhuman primates and suggested that this asymmetrical sensitivity might relate to aspects of the species' vocal communication signal. However, in D'Amato's behavioral studies (reviewed in D'Amato, 1988), cebus monkeys and rats failed octave-generalization tests and also failed to demonstrate extraction of pitch contours. D'Amato concluded that perception of pitch contours requires specialized mechanisms that most animals lack and that "monkeys can't hum a tune … because they don't hear them" (D'Amato, 1988). This result was somewhat puzzling since birds and nonhuman primates are known to be capable of utilizing pitch cues and contours in vocal communication and recognition (Morton, 1977; Ratcliffe and Weisman, 1986; Weisman and Ratcliffe, 2004). In subsequent behavioral studies, rhesus monkeys were shown to generalize tonal melodies to whole one- and two-octave transpositions, but could not generalize over fractional transpositions, e.g., 0.5 octave or 1.5 octaves (Wright *et al.*, 2000). These observations are very intriguing, but also raise additional questions since adult human subjects can generalize for both tonal and atonal melodies over both octave and non-octave transpositions (McDermott and Hauser, 2005), suggesting that there may be limitations in relative pitch in nonhuman primates. There is also some behavioral evidence for perception and generalization of frequency contours to octave transpositions in one bottlenose dolphin (Ralston and Herman, 1995), but these claims need replication and further study.

The failure of ferrets to fully generalize to untrained frequency ranges in the present study suggests that ferrets were also subject to a frequency range constraint as described in other nonhuman species, including songbirds, rats, and monkeys (D'Amato and Salmon, 1984; Hulse and Cynx, 1985, 1986; Dooling *et al.*, 1987; Cynx, 1993; Wright *et al.*, 2000; Izumi, 2001). These nonhuman species have been found to have difficulty generalizing contour categories to novel frequency ranges and contours. Ferrets, however, did acquire good discriminative performance in the new frequency range in just a few training sessions [Fig. 5(B)]. This acquisition was much faster than the case with songbirds that required as many trials as they had in learning the original discrimination (Hulse and Cynx, 1985; Cynx, 1993). The frequency range constraint revealed the extent of absolute pitch perception in relative pitch perception. Although the relationship between the relative and absolute pitch perception remains unclear, the failure to acquire relative discrimination when eliminating the absolute cues suggests that relative pitch in songbirds may depend on first identifying the patterns on the basis of their absolute pitches (Page *et al.*, 1989). By contrast, in the present study, absolute pitch cues were available during only Phase-1 training, but not during the generalization training phases (Phases 2 and 3). Thus, animals learned the task with relative cues over a four-octave frequency range. These results indicate that ferrets, while not as good as humans, are somewhat better than songbirds in learning to utilize relative pitch cues.

Studies by Weisman *et al.* (1998) demonstrated that songbirds (even individuals reared in isolation) and parrots have highly accurate absolute pitch perception. In comparison, nonhuman mammals (such as rats) and humans exhibited only weak absolute pitch perception when classifying frequencies into ranges (Njegovan *et al.*, 1995; Weisman *et al.*, 1998, 2004). These findings lead Weisman to propose that there is a general difference in auditory processing in absolute and relative pitch perception between mammals (including humans) and songbirds (Weisman *et al.*, 2004). The results in ferrets are consistent with this hypothesis. Along with other recent behavioral studies on birds and monkeys (Page *et al.*, 1989; Wright *et al.*, 2000; Izumi, 2001; Brosch *et al.*, 2004), the present results provide evidence that animals can be trained to extract relative pitch when needed to perform a tonal pattern discrimination task.

V. CONCLUSIONS

The present study provides the evidence that ferrets can extract the tonal contour, independent of frequencies [Fig. 6(A)] and frequency separations [Fig. 6(B)] of the two-tone sequences. Appropriate task design and behavioral training procedures, such as the generalization training in Phase 2 in current study, are necessary to direct animal's attention to the relational features of the sequences and to develop a relational solution of the task. Similarly, an early study on birds (Page *et al.*, 1989) found that starlings extracted relative pitch from the pitch patterns only after acquiring a discrimination that permitted both absolute and relative pitch solutions. Although the natural tendency for animals may be to attend to the absolute properties of sound, the results of the present study suggest that they can still be trained to attend to relative pitch information.

(Received 1 April 2009; revised 18 December 2009; accepted 18 December 2009)

Many animal species acoustically communicate at the same place and time generating complex acoustic environments. However, the acoustic parameter space is usually structured, with each species emitting identifiable signals. While signal partitioning has been reported, very few analyses include the mechanical spectral response of auditory organs. The loud chorus generated by three cicadas (*Cicada orni*, *Cicadatra atra*, and *Lyristes plebejus*) was studied. The vibration pattern of *L. plebejus* shows traveling waves as previously observed in *Ctra. atra*. The spectral properties of both calling songs and tympanal auditory systems primarily indicate that each species uses its own frequency band. Male tympanal membranes (TMs) are tuned to their own song's dominant frequency, except for *C. orni*, which is sensitive to the lowest frequency band of its song. In contrast, female TMs are broadly tuned to the male songs. *Ctra. atra* females differ by tuning to frequencies slightly higher than the male song. Hence, acoustic space partitioning occurs for both emitter and receiver, but does not seem to fully preclude interference risk as some spectral overlap exists. In addition to the local physical ecology of each species, selective attention to conspecific signals is likely to be enhanced by further mechanical and neuronal processing.

I. INTRODUCTION

Animals communicating with sound are often simultaneously active in the same habitat. They generate multispecies choruses with intense acoustic interference, each calling species being a source of noise to the others (Römer, 1993). Several strategies to increase the information transfer have been hypothesized (Brumm and Slabbekoorn, 2005). One strategy is the production of species-specific signals, leading to a partitioning of the acoustic parameter space through temporal and/or frequency exclusion in accordance with the signal space concept and the matched-filter hypothesis (Capranica and Moffat, 1983; Nelson and Marler, 1990). Partitioning has been particularly illustrated in frogs, crickets, and cicadas (Hödl, 1977; Riede, 1993; Lüddecke *et al.*, 2000; Sueur, 2002; Diwakar and Balakrishnan, 2007a). The validity of a signal partitioning strategy is linked, however, to the sensory capacity of the receivers, in this case the spectral sensitivity of the auditory system.

In this study, the particular role of peripheral auditory processing in the detection and selection of species-specific signals through frequency selection was investigated for three cicada species, *Cicada orni*, *Cicadatra atra*, and *Lyristes plebejus*. The male songs of these three cicada species are broadcasted within the same habitat and at the same time (Boulard and Mondon, 1995). Hundreds of specimens can be found on a single tree generating a continuous and loud chorus (Fig. 1, electronic supplementary material sound S1). Using scanning laser Doppler vibrometry on field-collected animals, the vibrations of *L. plebejus* tympanal membrane (TM) are first described and then compared with those of *C. orni* and *Ctra. atra*, which have previously revealed traveling and standing waves, respectively (Sueur *et al.*, 2006, 2008a, 2008b). The frequency characteristics of both the calling song (CS), together with the mechanical response of the tympanal membrane, are then quantified and compared across the three species. The study reveals that *L. plebejus* TM moves following a traveling wave pattern. Furthermore, these three closely related cicadas share acoustic space through frequency exclusion. Finally, it is shown that some frequency selectivity takes place at the peripheral level of the TM, although this tuning is quite broad and does not completely match the CS dominant frequency.

II. METHOD

A. Calling song recording and analysis

The CS of 15 males per species (*C. orni*, *Ctra. atra*, and *L. plebejus*) were recorded in France from 1995 to 2008 and

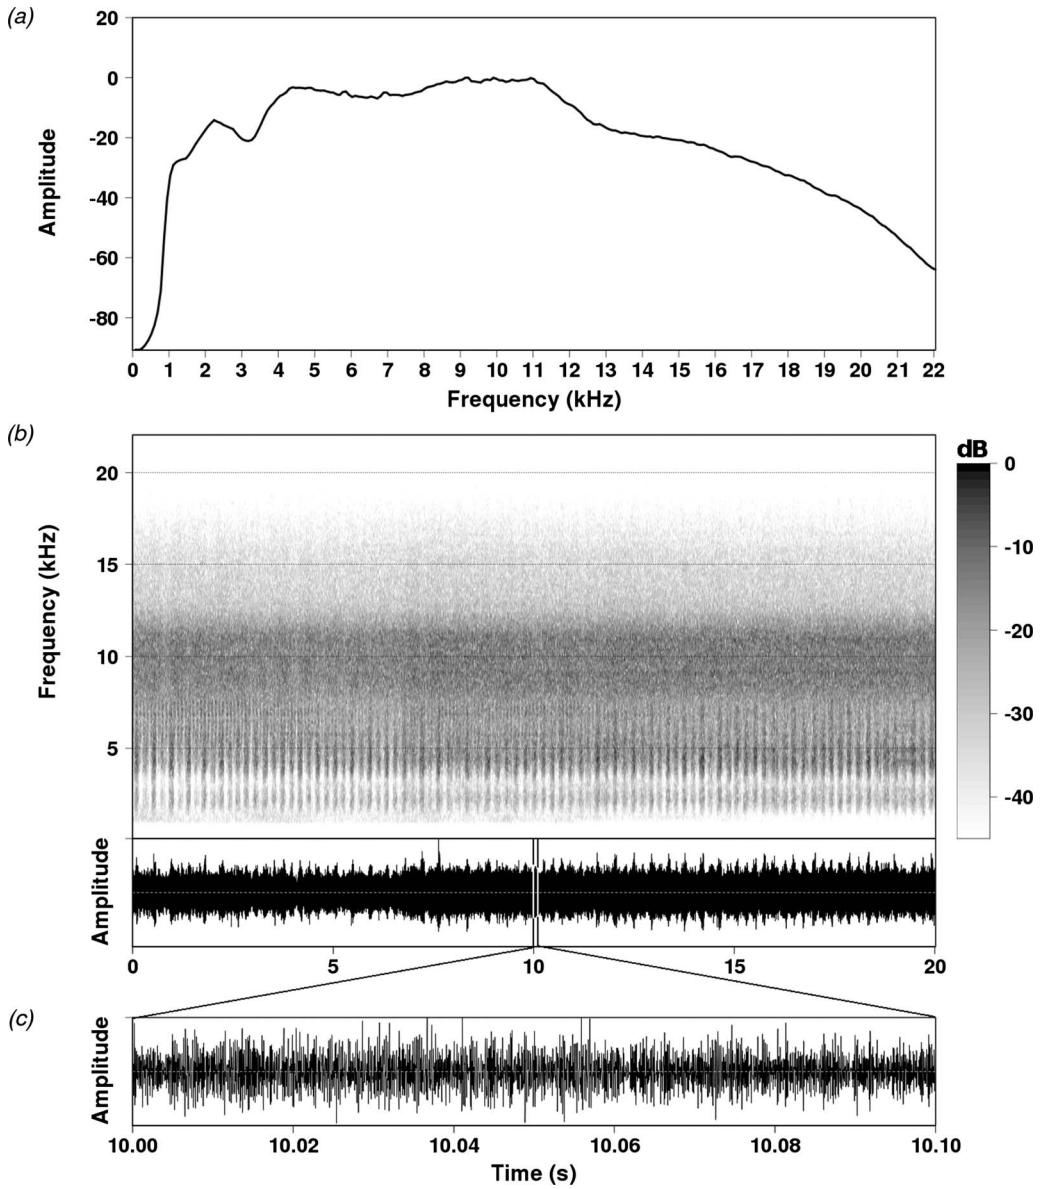

FIG. 1. Chorus of *C. orni*, *Ctra. Atra*, and *L. plejus* recorded in Cuges-les-Pins, France. (a) Mean spectrum, (b) spectrogram and oscillogram, and (c) detailed oscillogram corresponding to the zone delimited by the vertical lines on the oscillogram depicted in (b). A 1-kHz high-pass filter was applied to the sound to remove background noise due to wind. Short-term Fourier analysis parameters: Hamming window, frequency resolution=12.5 Hz, and dynamic range =45 dB.

analyzed in the frequency domain. Ten recordings of *C. orni* made in 2001 were already used in Sueur *et al.*, 2006, and four recordings of *Ctra. atra* made in 2006 in Sales-le-Château were already used in Sueur *et al.*, 2006. Sampling details for each species can be found in Table I. Isolated males were recorded from a distance of 0.5–1 m using a Telinga Pro4PiP microphone connected to a Sony TCD-D8 digital recorder or with a Sennheiser ME64 microphone connected to a Marantz PMD 670 digital recorder. The sampling frequency was 44.1 kHz. 1 min of each CS was analyzed in the frequency domain using the package SEEWAVE (Sueur *et al.*, 2008a), which is implemented in the R environment (R Development Core Team, 2009). A mean frequency spectrum was computed using a sliding Fourier transform (12.5 Hz resolution, nonoverlapping Hamming window).

B. Tympanal membrane mechanics

Specimens were caught and studied in 2005, 2007, and 2008. Specimens of *Ctra. atra* collected in 2005 (15 specimens) were used in Sueur *et al.*, 2008a, 2008b but mean spectra data were not reported. Data for *C. orni* collected in 2007 (19 specimens) were extracted from Sueur *et al.*, 2008a, 2008b and completed by new data obtained in 2008. Sampling details for each species can be found in Table I. Animals were cooled to 8–10 °C, transferred to Bristol (UK) in an icebox, and then placed at 24–26 °C and 40%–62% relative humidity for >2 h before measurements. The sound-induced vibrations of the TM were measured with a Polytec PSV-300-F microscanning laser Doppler vibrometer, with an OFV-056 scanning head. One ear was examined per animal. The wings and the legs were cut back before me-

TABLE I. Location of recordings and specimens collected for TM mechanics. Recordings of *C. orni* made in 2001 in Peyriac-de-Mer and Molitg-les-Bains were already used in Sueur *et al.* (2008b). Recordings of *Ctra. atra* made in 2005 in Sales-le-Château in 2005 were already used in Sueur *et al.* (2006). Specimens of *C. orni* and *Ctra. atra* and collected for TM mechanics in 2005 and 2007 were previously used in Sueur *et al.* (2006, 2008b), respectively.

chanical measurements. The operculum and the meracanthus that ventrally cover the tympanal organs, but are not mechanically linked to them, were also removed. Animals were not anaesthetized during measurements but were firmly attached to a horizontal brass bar (6 mm wide, 1 mm thick, and 16 mm long) using BLU-TACK (Bostik-Findley, Stafford, UK). The overall spectral properties of the TM were assessed by orienting the animals such that the vibrometer could scan the TM as completely as possible, perpendicular to its surface. The tympanal ridge (TR) area closest to the apodeme could not always be examined, as in *C. orni* and *L. plebejus* females where it was hidden by a cuticular sternal expansion that could not be removed without compromising the auditory system's mechanical integrity. The mechanical deflections of *L. plebejus* tympanum were characterized in detail to ensure a comparison with those of *C. orni* and *Ctra. atra* that were previously described (Sueur *et al.*, 2006, 2008b).

Experiments were carried out on a TMC 784-443-12R vibration isolation table located in a 20 m^3 acoustic isolation booth (Industrial Acoustics IAC series 1204A). TM vibrations were examined in response to frequency modulated (FM) signals (80-ms duration) sweeping at similar intensity all frequencies from 1 to 22.05 kHz (±1 dB). Acoustic stimuli were amplified with a TAFE570 Sony Amplifier, and broadcasted 0.25 m from the cicada with an ESS AMT-1 loudspeaker. Stimulation intensity was 66 dB sound pressure level (SPL) at the cicada. Reference SPL was measured using a Bruel & Kjaer 4138 microphone and Bruel & Kjaer 2633 preamplifier, with a linear response in the measured frequency range. Microphone sensitivity was calibrated using a Bruel & Kjaer 4231 sound level calibrator. The microphone was positioned 10 mm from the tympanum, with its diaphragm parallel to the direction of sound propagation. Signals were simultaneously sampled at 102.4 kHz. Sets of 15 data windows were acquired and averaged for each measurement point. Using a fast Fourier transform (rectangular window), a frequency spectrum was produced for the microphone and laser signals with a resolution of 12.5 Hz. Vibrometry frequency spectra were normalized to those of the reference microphone by the computation of the following transfer function:

$$H(f) = \frac{G_{ab}(f)}{G_{aa}(f)}, \tag{1}$$

where $G_{ab}(f)$ is the cross-spectrum of the reference and velocity signals and $G_{aa}(f)$ is the autospectrum of the reference signal. The data reliability was estimated by means of magnitude-squared coherence (C) functions between the laser and microphone signals, as follows:

$$C(f) = \frac{G_{ab}(f)G_{ba}(f)}{G_{aa}(f)G_{bb}(f)}, \tag{2}$$

where $G_{ab}(f)$ is the cross-spectrum of the velocity signal and reference signal (Fourier transform of the cross correlation function between the two time series), $G_{ba}(f)$ is the cross-spectrum of the reference signal and velocity signal, $G_{aa}(f)$ and $G_{bb}(f)$ are, respectively, the autospectra of the reference signal and of the velocity signal. Only highly coherent measurements (>85%) with minimal contamination by unrelated noise were used.

C. Simulated chorus spectrum and tympanal spectral filters

To test the filtering effect of the TM on the sound produced by a chorus, the CS mean spectrum of each species was normalized and summed. This spectrum was multiplied by the normalized TM mean spectrum of each species and of each sex. A sound file was built adding at equal amplitude level from each of the three species (electronic supplementary material sound S2). Simulated chorus finite impulse response (FIR) filters were applied to this summed sound file (Stoddard, 1998). To apply this filter, an inverse Fourier transform of TM spectral properties of each species and sex

was computed. This transform resulted in a series of impulse responses. Each of them was convolved with the summed sound file, as follows:

$$y(t) = (h * x)(t), \tag{3}$$

with $y(t)$ the filtered signal, $x(t)$ the original signal, and $h(t)$ the impulse response.

D. Spectral description and comparison

For each spectrum, the dominant frequency (frequency peak of highest energy) and the spectral flatness measure (SFM) were estimated. SFM was calculated as follows:

$$\mathrm{SFM} = n \times \frac{\sqrt[n]{\prod f_i}}{\sum f_i}, \tag{4}$$

where n is the number of f_i frequency bands constituting the spectrum. Values of SFM lie between 0 and 1, which, respectively, indicate a highly tuned resonating system and a nonresonating system.

Overlap between the spectra was assessed with the index (I) as follows:

$$I = 1 - \frac{\sum (S_1(f_i) - S_2(f_i))}{2}, \tag{5}$$

where $S_1(f)$ and $S_2(f)$ are the probability mass functions of the spectra to be compared.

Values of I range from 0 to 1, respectively, indicating nonoverlapping and similar spectra. Originally expressed as amplitude data (mV for recorded songs) or gain data (nm Pa^{-1} for TM vibrations), spectra were normalized to a maximum of 1 before computing mean spectra and estimating interval confidence. All statistics were computed using R (R Development Core Team, 2009).

III. RESULTS

A. Vibration pattern of *L. plebejus* tympanum

The tympanum of *L. plebejus* showed the same general structure as found in *C. orni* and *Ctra. atra* with a thin transparent membrane crossed by a spearlike TR (Sueur *et al.*, 2006, 2008a, 2008b). As in the two other species, there was a clear sexual dimorphism in *L. plebejus* affecting both size and shape (Fig. 2). The male tympanum was large and rectangular, the TR being small compared to the whole surface of the membrane. The female tympanum was smaller, had a triangular shape, and showed a dark and large TR whose length was almost three-quarters that of the largest membrane width. When scanning the whole surface of the male TM, it appeared that the central zone moved much less than the lateral ones. In particular, the lateral area where the TR was located showed a typical traveling wave going along the TR from its apex to its base.

The envelope of the wave in motion along the TR was particularly apparent when the response was displayed every 40° of phase angle in the full oscillation cycle (Fig. 3). This motion was confirmed by analyzing the phase lag as a function of stimulus frequency. Phase lag was substantial, exceeding the phase lag expected for the displacement response of a simple oscillator (maximum of −90° at frequencies above resonance). Lag increased as a function of frequency. At higher frequencies, such as 15 kHz, the phase lag reached −600° (Fig. 4). When stimulated, the whole female tympanum moved and the TR was similarly crossed by a traveling wave going from the apex to the base. The displacement amplitude of the traveling wave was ten times smaller than the one observed in males (Fig. 3). The phase lag reached −150° at 15 kHz (Fig. 4).

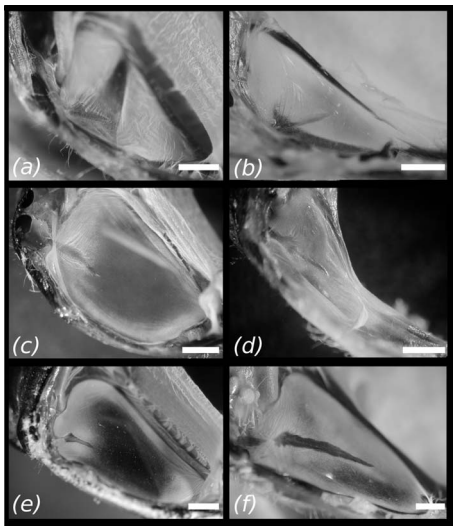

FIG. 2. Posterior view of female (left column) and male (right column) tympanum of [(a) and (b)] *C. orni*, [(c) and (d)] *Ctra. Atra*, and [(e) and (f)] *L. plebejus*. Note the different scales. Scale bars=0.5 mm.

B. Calling songs of the three species

Each species' CS occupied a specific frequency channel minimizing acoustic competition. CS spectra of the three

FIG. 3. Envelopes of mechanical deflections along *L. plebejus* TR from its apex (x) to its base (y). Deflections are shown for phase increments of 40° in the full oscillation cycle. Top: male TR driven at 5.475 kHz. Bottom: female TR driven at 6.925 kHz. In each case, the driving frequency is the frequency of sound played back that deflected the TR the most, i.e., that induced the mean greatest deflection. Note the change of y left scale.

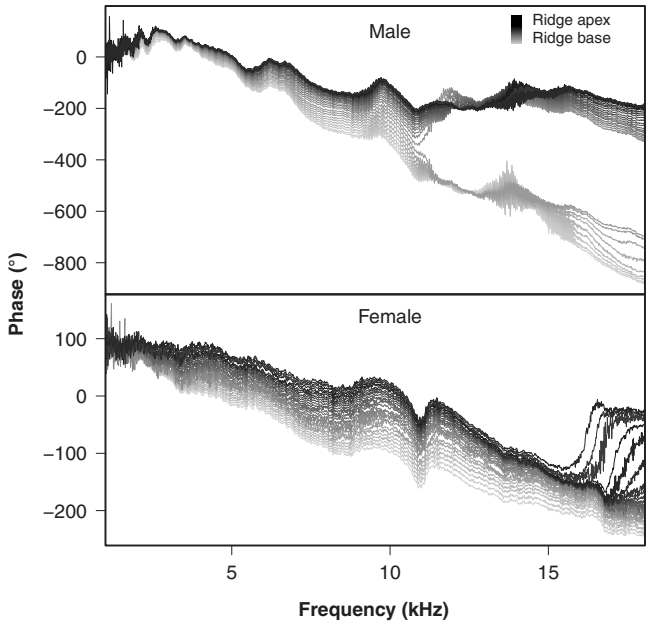

FIG. 4. Phase response along *L. plebejus* TR as a function of the driving frequency. The phase response shows an increasing lag with both frequency and distance along the TR. The phase lag increases to −245° for females and to −880° for males.

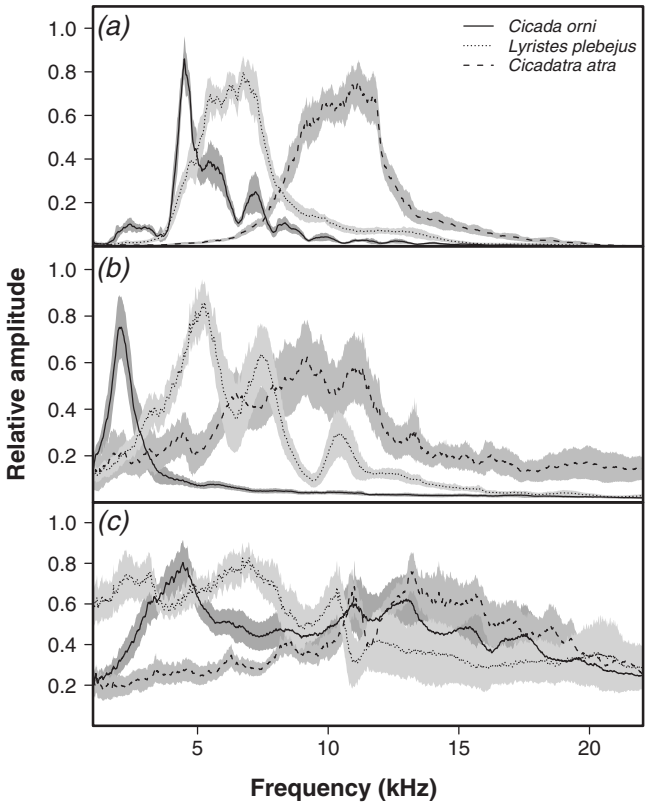

FIG. 5. Frequency spectra of the CS, and of both sex's TM vibrations. (a) Calling song, (b) male TM, and (c) female TM. Bold lines (*C. orni*: solid, *Ctra. atra*: dotted, and *L. plebejus*: dashed) refer to the mean of the individual spectra and surface to the 95% confidence interval. Spectra were normalized to a maximum of 1 before mean and interval confidence estimations. Sample sizes: 15 *C. orni*, 15 *Ctra. atra*, and 15. *L. plebejus* for CS; 13 *C. orni*, 13 *Ctra. atra*, and 10 *L. plebejus* for male TM; 11 *C. orni*, 13 *Ctra. atra*, and 9 *L. plebejus* for female TM.

species showed similar low flatness values but different dominant frequencies [see Fig. 5(a) and Table II]. CS spectra did not overlap except for *C. orni* and *L. plebejus* between 4 and 6 kHz, leading to a higher similarity index than between *Ctra. atra* and *C. orni*, and *Ctra. atra* and *L. plebejus*, respectively (Table III).

C. Tympanal spectral characteristics of the three species

Male TMs of *C. orni* and *L. plebejus* were sharply tuned, and the male TM of *C. orni* was not tuned to its own CS. Male TM spectra showed different flatness and dominant frequency values [Fig. 5(b), Table II]. The TM dominant frequency corresponded to the CS dominant frequency, except for *C. orni* where an important mismatch appeared (Welch *t*-test for the dominant frequency, $df=1$, $p<0.001$). The similarity index indicated the highest values occurring between male TM and CS spectra of the same species (Table III).

Female TMs of *C. orni* and *L. plebejus* were broadly tuned, and female TMs of *Ctra. atra* were not sharply tuned to their conspecific CS. Female TM showed similar high flatness values, but different dominant frequencies [Fig. 5(c), Table II]. The dominant frequency of the female TM of *C. orni* and *L. plebejus* matched the dominant frequency of their CS, whereas the *Ctra. atra* female TM dominant frequency was significantly higher (Welch *t*-test, $df=1$, $p<.001$). The similarity index showed the highest values between the female TM and CS spectra of the same species except in the case of *C. orni*, for which an additional sensitivity was present at higher frequencies (Table III).

The TMs of *C. orni* males and females acted as sharp and broad low-pass filters, respectively [Fig. 6(a); electronic supplementary material sounds S3 and S4]. The TMs of *Ctra. atra* acted as broad high-pass filters [Fig. 6(b); electronic supplementary material sounds S5 and S6]. The TMs of *L. plebejus* acted as broad low-pass filters [Fig. 6(c); electronic supplementary material sounds S7 and S8].

IV. DISCUSSION

The chorus of *C. orni*, *Ctra. atra*, and *L. plebejus* generates a complex acoustic environment. However, each species shows a specific calling spectrum in the frequency domain, leading to a partitioning in accordance with the signal space concept and the matched-filter hypothesis (Capranica and Moffat, 1983; Nelson and Marler, 1990). In this context, this work shows that the TM not only operates as an acousticomechanical transducer, but also as a frequency filter that contributes to signal detection and recognition. The TMs of the three species, except for the males of *C. orni*, show resonance peaks that match the highest energy peak of the conspecific CS. The TM detuning of male *C. orni* does not produce a total filtering of the surrounding noise as the filter frequency response is not totally flat above 3 kHz. However, it significantly increases the lower frequency band of the chorus, thus selectively enhancing the component produced by *C. orni* and reducing signal competition with *L. plebejus* in the 4–6 kHz range. This also prevents the male from being deafened by its own song (Sueur *et al.*, 2008b).

TABLE II. Spectral properties of the CS and the TM. Values of spectral flatness could range from 0 to 1, which, respectively, are indicative of a highly tuned resonating system and a nonresonating system. Mean values are compared with an analysis of variance.

Spectral parameters	*C. orni*	*Ctra. atra*	*L. plebejus*	$F_{d.f}$	*p*
		CS			
Dominant frequency (kHz)	4.51 ± 0.15 (*n*=15)	10.78 ± 0.86 (*n*=15)	6.57 ± 0.67 (*n*=15)	$376.4_{2,42}$	<0.001
Spectral flatness	0.21 ± 0.04 (*n*=15)	0.27 ± 0.08 (*n*=15)	0.22 ± 0.09 (*n*=15)	$2.1_{2,42}$	0.135

The mechanical aspect of peripheral signal processing found in the cicada is similar to that already documented for several grasshopper and moth species (Windmill *et al.*, 2006, 2008). In particular, the TM deflection pattern of *L. plebejus* measured in this work shows a convergence with the TM vibrations previously described for *Ctra. atra* (Sueur *et al.*, 2006) with a traveling wave that goes along the TR. *C. orni* appears then as unique since the TM moves following a standing wavelike behavior with a simple up-and-down oscillation (Sueur *et al.*, 2008b). The origin of this notable difference in modes of vibrations has still to be discovered but is probably linked to differences in membrane shape, thickness, and stiffness.

Each different cicada TM does not filter out all of the background noise due to other cicada species. This is particularly true for females, which show tympanal mechanical responses with broad spectra. To respond appropriately to the conspecific male CS and no other, a female must decode the species-specific information embedded within the signal alone or in a chorus. Several mechanisms very likely contribute to this process, starting with the reception of sound by the TM (Robert and Hoy, 2007) and interneuronal selective responses (Fonseca *et al.*, 2000), altogether supporting the recognition of conspecific CS. In the present experiments, the TR apex was not always optically accessible. Hence the resonant frequency peak measured may be underestimated, in particular, for *L. plebejus* and *C. orni* females. The apex resonance may be lower and sharper. Connected to the auditory neurons by an apodeme, the TR is a key structure that, through its vibration, transmits frequency information to the nervous system. The exact mechanisms of information transfer between TR and sensory neurons are unknown but the apodeme of *C. atra* has been recently proved to work as an additional frequency filter that sharpens frequency tuning around the CS dominant frequency (Windmill *et al.*, 2009). There is also some neurophysiological evidence for another filter enhancing frequency selection, as fine frequency analysis can be achieved by auditory interneurons (Fonseca *et al.*, 2000).

Evidently, in addition to spectral composition, the temporal structure of the CS is also important for species-specific recognition (Gerhardt and Huber, 2002). Within the chorus, to the human ear, species-specific patterns seem to be lost. Yet, previous research has shown that temporal domain selective audition is possible through the action of neuronal temporal filters, as illustrated in cicadas (Huber *et al.*, 1990) and katydids (Schul, 1998). Another way to reduce interference is the use of substrate-borne signals that could be trans-

TABLE III. Similarity (*I*) between the CS and TM spectra. Values of *I* could range from 0 to 1, which, respectively, are indicative of nonoverlapping and similar spectra. Bold style indicates for each species the correspondence between CS spectrum and TM spectrum (table diagonal).

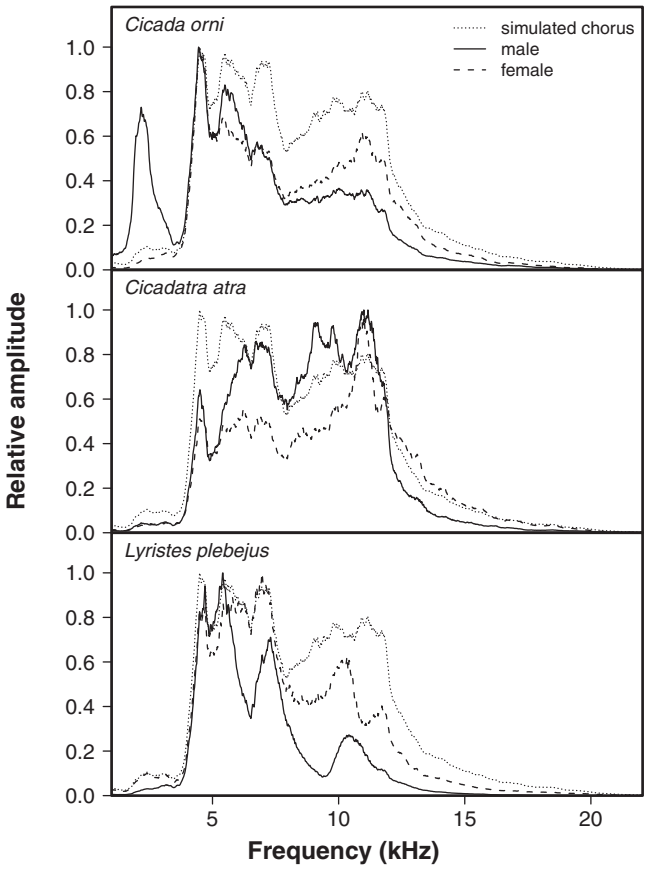

FIG. 6. Frequency-filter effect of the TM on a simulated chorus spectrum. Dotted gray lines refer to the summed spectrum of the CS mean spectra of the three species, and black lines refer to the summed spectrum when filtered by the TM (male: solid; female: dashed). All spectra were normalized to a maximum of 1.

mitted at close range when partners stay on the same plant part (Cocroft and Rodríguez, 2005) and the selection by each species of a particular microhabitat (Hödl, 1977; Sueur, 2002; Diwakar and Balakrishnan, 2007b). Here each species seems to occupy a different position in the tree: *L. plebejus* at the tip of canopy thin branches, *C. orni* on trunk and large branches as already reported (Claridge *et al.*, 1979), and *Ctra. atra* on small branches.

V. CONCLUSIONS

This study reveals that three closely related cicadas share acoustic space through frequency exclusion. It is also shown that some frequency selectivity takes place at the peripheral level of the TM. However, this peripheral tuning is quite broad, not perfectly matching the CS dominant frequency. Comparing the three species considered here, it is apparent that the peripheral processing achieved by the TM has evolved to carry out at least two tasks: the transduction of acoustic energy and the early processing of sound-induced vibrations. It should be noted that the actual frequency selectivity of the different TMs may be higher than reported here, as it was not always possible to measure the entire TM area with the laser vibrometry technique. It is also unclear how the peripheral (mechanical) frequency selectivity of the TM relates to the further stages of auditory processing, with the transfer of information to the sensory neurons, the interneurons, up to the brain. Finally, this work describes the TM response of only three, closely related, cicadas, yet has shown startling differences in the mechanics of those responses between one species and the others. There are approximately 2500 species of cicada worldwide, suggesting that there may be many further different peripheral auditory mechanisms still to be discovered.

ACKNOWLEDGMENTS

ACOUSTICAL NEWS

Elaine Moran
Acoustical Society of America, Suite 1NO1, 2 Huntington Quadrangle, Melville, NY 11747-4502

Editor's Note: *Readers of this journal are encouraged to submit news items on awards, appointments, and other activities about themselves or their colleagues. Deadline dates for news items and notices are 2 months prior to publication.*

President's report on the 158th meeting of the Acoustical Society of America held in San Antonio, Texas

The 158th meeting of the Acoustical Society of America was held 26-30 October 2009 at the Hyatt Regency San Antonio Hotel in San Antonio, Texas. This was the first time that the Society has met in this city.

The meeting drew a total of 880 registrants, including 148 nonmembers, 234 students and 91 registrants from outside North America. There were 16 registrants from Japan; 13 from France; 8 from Korea; 7 from the UK; 6 from Russia; 5 each from Germany and Taiwan; 4 each from Chile and China; 3 each from Brazil, Norway, Singapore, and Sweden; 2 each from Italy and Portugal; and 1 each from Australia, Austria, Denmark, Finland, India, the Netherlands, and Thailand. North American countries, Canada, Mexico, and the United States, accounted for 22, 3, and 764 respectively.

A total of 660 papers, organized into 82 sessions, covered the areas of interest of all 13 Technical Committees. The meeting also included 10 meetings dealing with standards. The evening tutorial lecture series was continued by Kathleen P. King of Fordham University who presented "Podcasting Demystified: From Concept to Production for Every Budget."

A short course titled "Acoustic Imaging Applications: Seismic, Underwater, Biomedical, and Speech" was held with a group of 26 students. The instructors were Max Deffenbaugh, research geophysicist with ExxonMobil Research & Engineering Company, Jules Jaffe, Research Oceanographer at the Scripps Institution of Oceanography, Christy Holland, Associate Professor in the Department of Biomedical Engineering at the University of Cincinnati, and Maureen Stone, Professor at the University of Maryland Dental School.

A technical tour was organized to visit ETS-Lindgren Acoustic Research Laboratory and Factory. The tour included a technical discussion on acoustic test facilities followed by a factory tour. Participants toured several state-of-the-art chambers for acoustic test services, including a hemianechoic chamber and two reverberation chambers, impedance tubes and supporting acoustic test equipment and software.

The Society's thirteen Technical Committees held open meetings during the San Antonio meeting where they made plans for special sessions at upcoming ASA meetings, discussed topics of interest to the attendees and held informal socials after the end of the official business. These are working, collegial meetings and all people attending Society meetings are encouraged to attend and to participate in the discussions. More information about Technical Committees, including minutes of meetings, can be found on the ASA Website http://asa.aip.org/committees.html, and in the Acoustical News section of JASA in the September and November issues.

The ASA Student Council hosted a Student Reception with over 100 people in attendance. This reception, which was sponsored by ASA and supported by the National Council of Acoustical Consultants, enabled students to meet with established members of the Acoustical Society of America. Several of the Technical Committees awarded Best Student Paper Awards or Young Presenter Awards to students and young professionals who presented papers at the meeting. The list of award recipients, as well as other information for students, can be found online at the ASA Student Zone website http://www.acosoc.org/student/.

Social events included the two social hours held on Tuesday and Thursday, an "icebreaker" and a reception for students, a Jam Session, the Fellows Luncheon and the morning coffee breaks. A special program for students to meet one-on-one with members of the ASA over lunch, which is held at each meeting, was organized by the Committee on Education in Acoustics. These social events provided the settings for participants to meet in relaxed settings to encourage social exchange and informal discussions. The Women in Acoustics Luncheon was held on Wednesday afternoon with attendance of about 75. The Fellows Luncheon was attended by 100 people who heard a talk by Professor Todd Ditmire of the University of Texas at Austin Physics Department about very high energy lasers and some potential applications.

The plenary session included announcements, acknowledgment of the members and other volunteers who organized the meeting and the presentation of awards and certificates to newly-elected Fellows.

ASA President Whitlow Au presided over the Plenary Session and Awards Ceremony (see Fig. 1).

In September 2009, Whitlow Au and Charles Schmid traveled to Beijing to attend the 10th Western Pacific Acoustics Conference (WESPAC) and to meet with a delegation of Chinese acousticians to continue discussions to organize a future joint meeting of the ASA with the Acoustical Society of China. The Chinese delegation included Jing Tian (president of the Acoustical Society of China), Tom Ho (president of the Hong Kong Institute of Acoustics), Fengha Li (Institute of Acoustics China Academy of Sciences), and Renhe Zhang (Chinese representative to WESPAC). At that meeting, it was suggested that since WESPAC is scheduled to meet in Hong Kong in 2012, that ASA should consider making that meeting a joint ASA-WESPAC (which would include the Acoustical Society of China). Tom Ho and Maurice Kwok-leung attended the San Antonio meeting and made a presentation to the Executive and Technical Councils proposing a joint meeting. The Technical Council referred the proposal for discussion at each of the open technical committee meetings and favorable responses were received. Based on the Technical Council report, the Executive Council voted to move ahead with the joint meeting in Hong Kong, tentatively set for May of 2012.

Mardi Hastings, Chair of the Spring 2010 meeting, addressed the audience and invited and encouraged them to attend that meeting to be held in Baltimore, Maryland, in April (see Fig. 2).

Two ASA Science Writing Awards were presented. The 2008 Science Writing Award in Acoustics for Journalists was presented to Rachel Ehrenberg for her article "Stranded: A Whale of a Mystery" in *Science News*, July 2008 (see Fig. 3). The 2008 Science Writing Award for Professionals in Acoustics was presented to Ingo Titze for his article "The Human Instrument" in *Scientific American*, January 2008 (see Fig. 4).

 0001-4966/2010/127(3)/1692/7/$25.00

FIG. 2. (Color online) Mardi Hastings, Chair of the Spring 2010 meeting.

The ASA President introduced Kenneth Suslick, recipient of the 2009 Student Council Mentoring Award (see Fig. 5). He then introduced James F. Lynch, recipient of the Munk Award. The Munk Award and Medal are granted jointly by The Oceanography Society, the Office of Naval Research, and the Office of the Oceanographer of the Navy. There have been eight recipients since the award was established in 1993. This was the first time that the Munk Award was presented at an ASA meeting. James Lynch presented the Munk Award Lecture titled "Acoustical oceanography and shallow water acoustics" earlier in the meeting (see Fig. 6).

FIG. 4. (Color online) ASA President Whitlow Au (l) presents Science Writing Award for Professionals in Acoustics to Ingo R. Titze (r).

The 2009 Rossing Prize in Acoustics Education was presented to James F. Sanders, who is retired from the Naval Postgraduate School. The award includes a silver medal and a prize of $4,000. Dr. Sanders presented the Acoustics Education Prize Lecture titled "Fundamental acoustics education and applications" earlier in the meeting (see Fig. 7).

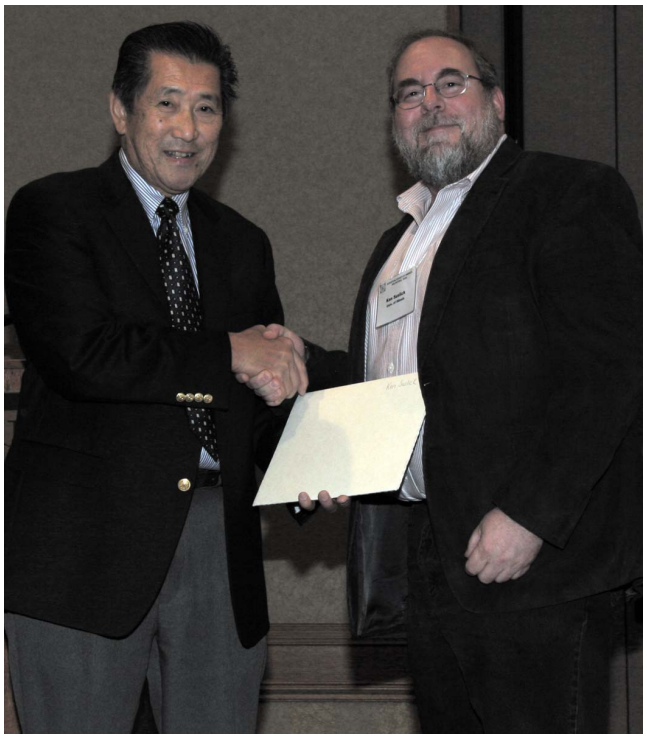

FIG. 5. (Color online) ASA President Whitlow Au (l) presents Student Council Mentoring Award to Kenneth Suslick (r).

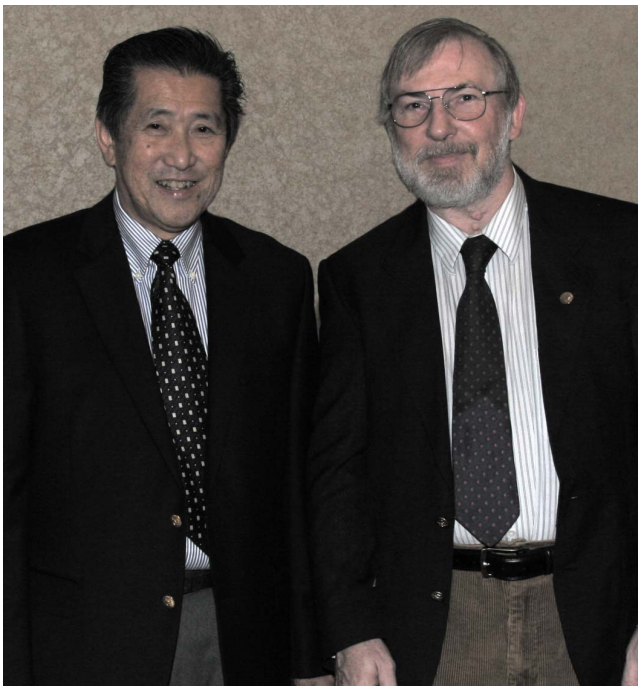

FIG. 6. (Color online) ASA President Whitlow Au (l) congratulates James F. Lynch, recipient of the 2009 Munk Award (r).

FIG. 8. (Color online) ASA President Whitlow Au (l) presents Silver Medal in Acoustical Oceanography to Robert C. Spindel (r).

The Silver Medal in Acoustical Oceanography was presented to Robert C. Spindel of the University of Washington "for implementation of ocean acoustic tomography and basin scale acoustic thermometry" (see Fig. 8). The Silver Medal in Noise was presented to Michael R. Stinson, National Research Council of Canada, "for contributions to outdoor sound propagation, acoustical materials, and ear canal acoustics" (see Fig. 9).

Election of twenty members to Fellow grade was announced and fellowship certificates were presented. New fellows are: David L. Adams, Michael A. Averkiou, Constantin C. Coussios, Diane Dalecki, Mostafa Fatemi, Kullervo H. Hynynen, Michael F. Insana, Boris G. Katsnelson, Robert G. Leisure, Plilipos C. Loizou, Patrick J. Loughlin, David A. Mann, David K. Mellinger, Ralph T. Muehleisen, Susan N. Nittrouer, Dennis A. Paoletti, Kevin B. Smith, Andrew J. Szeri, Shin-ichiro Umemura, and Oleg A. Sapozhnikov (see Fig. 10).

ASA President Whitlow Au introduced Clark Penrod, Chair of the San Antonio meeting (see Fig. 11) who expressed the Society's thanks to mem-

Photo by C. Schmid.

We hope that you will consider attending a future meeting of the Society to participate in the many interesting technical events and to meet with colleagues in both technical and social settings. Information about future meetings can be found in the *Journal* and on the ASA Home Page at ⟨http://asa.aip.org⟩.

WHITLOW W.L. AU
President 2009–2010

Regional Chapter News

Madras Regional Chapter

The Madras Regional Chapter of the Acoustical Society of America (MIRC-ASA) held three meetings in 2009, on 27 June, 8 August, and 26–27 November. The meeting in November was held jointly with the Acoustical Society of India (ASI). Silver and Gold Medal awards were presented by the International Research Institute for the Deaf (IRID), a unit of the Acoustical Foundation (AFECT).

At the 27 June meeting, Dr. P. Iyamperumal, Executive Director of Tamil Nadu Science and Technology Center (TNSTC), State Govt. of Tamil Nadu, Chennai, delivered an invited lecture titled "Architect of Burlap Planetarium" which reviewed the basics of acoustics. A large number of students and teachers participated in the meeting and 33 student projects were received.

The MIRC-ASA/IRID Acoustics Fair ceremony was held at TNSTC on 8 August. The following students in the junior group received awards from MIRC-ASA: Ms. B. Divya, Ms. S. Dixitha, Sri T. M. Krishnakumar (First place), Sri G.R. Ratheesh, Sri V. Srinivas, Sri K.E. Srivatsav, Ms. N. Venkatalakshmi., Sri V. Vaasanthosh, and Sri V.L. Venkatavaradhan (see

FIG. A1. (Color online) Student award presentation ceremony: (l to r) H. S. Paul (Chapter President), S. Dixita, N. Venkatalakshmi. V. Srinivas, G. R. Ratheesh, T. M. Krishnakumar, V. L. Venkatavadhan, K. E. Srivatsav, B. Divya, V. Vaasanthosh, R. Dhilsha (Chapter Treasurer).

FIG. A2. (Color online) First place student award presentation ceremony: (l to r) P. Iyamperumal (E.D., TNSTC), T. M. Krishnakumar, H. S. Paul (Chapter President).

FIG. A3. (Color online) H. S. Paul (l) presents Gold Medal to Dr. V. Bhujanga Rao (r).

FIG. A4. (Color online) Student award presentation ceremony: (l to r) V. Bhujanga Rao (ASI President), A. Ramachandraiah (ASI Vice President), S. Fatima (award recipient), H. S. Paul (Chapter President), S. K. Ray (Symposium Chair), and N.S. Naidu (ASI General Secretary).

FIG. A5. (Color online) (l to r) V. Bhujanga Rao (ASI President), A. Ramachandraiah (ASI Vice President), G. Rajkumar (award winner), H. S. Paul (Chapter President), S. K. Ray (Symposium Chair), and N.S. Naidu (ASI General Secretary).

FIG. A6. (Color online) (l to r) V. Bhujanga Rao (ASI President), A. Ramachandraiah (ASI Vice President), G. S. H. Gautham (award winner), H. S. Paul (Chapter President), S. K. Ray (Symposium Chair), and N.S. Naidu (ASI General Secretary).

Figs. A1 and A2). Awards were presented by H.S. Paul (President and Chapter Representative of MIRC-ASA and President of AFECT & IRID) and R. Dhilsha (Treasurer of MIRC-ASA). The MIRC-ASA Chapter expresses its gratitude to Dr. P. Iyamperumal, E.D. of the Tamil Nadu Science and Technology Center who paid for all expenses of the fair and provided all facilities for the first meeting.

The joint meeting between Acoustical Society of India (ASI) and MIRC-ASA was held 26-28 November 2009 at the Research Center Imarat (RCI), DRDO, Hyderabad, A.P. Sri K. Jagadisan (Convener of the Symposium) and Sri S. K. Ray (Chairman of the Symposium), Director of RCI, DRDO, Hyderabad, A.P. made arrangements for the MIRC-ASA chapter meeting to be incorporated into the main ASI meeting to strengthen the mutual bond between ASI and MIRC-ASA and to encourage the spread of acoustical science throughout India.

The MIRC-ASA and IRID (AFECT) award ceremony was conducted during the ASI opening session. Prof. A. Ramachandraiah (Vice President of MIRC-ASA and Trustee of AFECT) read the citation for Gold Medal recipient Dr. V. Bhujanga Rao, Director and Outstanding Scientist of Naval Science and Technological Laboratory (NSTL), Visakhapatnam, A.P. and President of ASI (see Fig. A3). The Gold Medal award is a joint venture of MIRC-ASA & IRID. After the opening session, Dr. Rao delivered the Mira Paul Memorial Distinguished Lecture on "Design of Indigenous Affordable Cochlear Implant System."

The following students were awarded MIRC-ASA best paper awards at the November meeting: Ms. S. Fatima, Sri G. Rajkumar, Sri G.S.H. Gowtha (see Figs. A4–A6). The following students also received awards in absentia Sri M. M. Armstrong Arasu, Ms. Lakshimi Venkatesh, and Sri E. Rajasekar.

Calendar of Meetings and Congresses

Compiled by the Information Service of the International Commission for Acoustics

2010

8–10 March	Chofu, Japan. Spring Meeting of the Acoustical Society of Japan.
15–18 March	Berlin, Germany. Meeting of the German Association for Acoustics DAGA 2010. http://www.daga-tagung.de/2010
15–19 March	Dallas, TX, USA. International Conference on Acoustics, Speech, and SignalProcessing. http://icassp2010.org
7–9 April	Cambridge, UK. David Weston Sonar Performance Assessment Symposium
19–23 April	Baltimore, MD, USA. Joint meeting: 159th Meeting of the Acoustical Society ofAmerica and Noise-Con 2010. http://asa.aip.org/meetings.html
27–30 April	Ghent, Belgium. Institute of Acoustics/Belgian Acoustical Association JointMeeting. http://www.ioa.org.uk/viewupcoming.asp
6–7 May	Paris, France. 2nd International Symposium on Ambisonics and SphericalAcoustics. http://ambisonics10.ircam.fr
10–12 May	Bergen, Norway. Baltic-Nordic Acoustics Meeting 2010. E-mail: sanordby@norsonic.com
9–11 June	Aalborg, Denmark. 14th Conference on Low Frequency Noise and Vibration. http://lowfrequency2010.org
13–16 June	Lisbon, Portugal. INTERNOISE2010. http://www.internoise2010.org
5–9 July	Istanbul, Turkey. 10th European Conference on Underwater Acoustics. http://ecua-2010-istanbul.org
18–22 July	Cairo, Egypt. 17thh International Congress on Sound and Vibration (ICSV17). http://www.icsv17.org
23–27 August	Sydney, Australia. International Congress on Acoustics 2010.http://www.ica2010sydney.org
23–27 August	Seattle, USA. 11tth International Conference on Music Perception and Cognition.
29–31 August	Melbourne, Australia. International Symposium on Room Acoustics (ISRA2010). http://www.isra2010.org
14–18 September	Kyoto, Japan. 5th Animal Sonar Symposium. http://cse.fra.affrc.go.jp/akamatsu/AnimalSonar.html
15–18 September	Ljubljania, Slovenia. Alps-Adria-Acoustics Association Meeting jointwith EAA. E-mail: mirko.cudina@fs.uni-lj.si
20–22 September	Leuven, Belgium, International Conference on Noise and VibrationEngineering (ISMA2010). http://www.isma-isaac.be
26–30 September	Makuhari, Japan. Interspeech 2010—ICSLP. http://www.interspeech2010.org
11–14 October	San Diego, Cal. USA. IEEE 2010 Ultrasonics Symposium. E-mail: b.potter@vectron.com
14–16 October	Niagara-on-the Lake, Ont., Canada. Acoustics Week in Canada. http://caa-aca.ca/E/index.html
11–14 October	San Diego, California, USA. IEEE 2010 Ultrasonics Symposium. E-mail: bpotter@vectron.com
13–15 October	Leon, Spain. 41st Spanish Congress of Acoustics and 6th Iberian Acoustics Congress. http:// www.sea-acustica.es
18–22 October	Nagahama, Japan. 10th International Workshop on Railway Noise (IWRN10). http://www.rtri.or.jp/IWRN10/first.announcement.html
15–19 November	Cancún, Mexico. 2nd Pan-American Meeting on Acoustics. http://asa.aip.org/meetings.html

2011

22–27 May	Prague, Czech Republic. International Conference on Acoustics, Speech, and Signal Processing (IEEE ICASSP 2011). http://www.icassp2011.com
23–27 May	Seattle, WA, USA. 160th meeting of the Acoustical Society of America. http://asa.aip.org/meetings.html
27 June–1 July	Aalborg, Denmark. Forum Acusticum 2011. http://www.fa2011.org
24–28 July	Tokyo, Japan. 19th International Symposium on Nonlinear Acoustics (ISNA 19). http://www.isna19.com
27–31 August	Florence, Italy. Interspeech 2011. http://www.interspeech2011.org
4–7 September	Osaka, Japan. Internoise 2011. http://www.internoise2011.com
5–8 September	Gdansk, Poland. International Congress on Ultrasonics. http://icu2011.ug.edu.pl/index.html

2012

20–25 March	Kyoto, Japan. IEEE International Conference on Acoustics, Speech, and Signal Processing. http://www.icssp2012.com

2013

26–31 March	Vancouver, Canada. 2013 IEEE International Conference on Acoustics, Speech, and Signal Processing (ICASSP). http://www.icassp2013.com
2–7 June	Montréal, Canada. 21st International Congress on Acoustics (ICA 2013). http://www.ica2013montreal.org

ACOUSTICAL STANDARDS NEWS

Susan B. Blaeser, Standards Manager
ASA Standards Secretariat, Acoustical Society of America, 35 Pinelawn Rd., Suite 114E, Melville, NY 11747 [Tel.: (631) 390-0215; Fax: (631) 390-0217; e-mail: asastds@aip.org]

Paul D. Schomer, Standards Director
Schomer and Associates, 2117 Robert Drive, Champaign, IL 61821 [Tel.: (217) 359-6602; Fax: (217) 359-3303; e-mail: Schomer@SchomerAndAssociates.com]

American National Standards (ANSI Standards) developed by Accredited Standards Committees S1, S2, S3, and S12 in the areas of acoustics, mechanical vibration and shock, bioacoustics, and noise, respectively, are published by the Acoustical Society of America (ASA). In addition to these standards, ASA publishes catalogs of Acoustical Standards, both National and International. To receive copies of the latest Standards catalogs, please contact Susan B. Blaeser.

Comments are welcomed on all material in Acoustical Standards News.

This Acoustical Standards News section in JASA, as well as the National and International Catalogs of Acoustical Standards, and other information on the Standards Program of the Acoustical Society of America, are available via the ASA home page: http://asa.aip.org.

Standards Meetings Calendar—National

Accredited Standards Committees S1, Acoustics; S2, Mechanical Vibration and Shock; S3, Bioacoustics; S3/SC 1, Animal Bioacoustics; and S12, Noise, along with the U.S. Technical Advisory Groups to ISO/TC 43, ISO/TC 43/SC 1, ISO/TC 108 and its five Subcommittees, and IEC/TC 29, ASACOS and the Standards Plenary Group will meet in conjunction with the Joint 159th ASA Meeting and Noise-Con 2010 to be held in Baltimore, Maryland, 19-23 April 2010. Specific meeting dates and times follow:

• Tuesday, 20 April 2010

– **7:15 a.m.—8:45 a.m.**—ASA Committee on Standards **(ASACOS)**. Meeting of the Committee that directs the Standards Program of the Acoustical Society.

• Thursday, 22 April 2010

– **8:00 a.m.—9:00 a.m.**—Standards Committee **Plenary** Group Meeting (PL)—To discuss national and international items relevant to Accredited Standards Committees S1, S2, S3, S3/SC1, and S12. **This meeting will include the meetings of the U.S. TAGs to ISO/TC 43, ISO/TC 43/SC 1, ISO/TC 108 and its subcommittees, and IEC/TC 29**.

– **9:15 a.m.—10:30 a.m.**—Meeting of Accredited Standards Committee **S12** on Noise

– **11:00 a.m.—12:00 p.m.**—Meeting of Accredited Standards Committee **S2** on Mechanical Vibration and Shock

– **1:45 p.m.—2:45 p.m.**—Meeting of Accredited Standards Committee **S1** on Acoustics

– **3:00 p.m.—4:15 p.m.**—Meeting of Accredited Standards Committee **S3** on Bioacoustics

– **4:30 p.m.—5:30 p.m.**—Meeting of Accredited Standards Committee **S3/SC 1** on Animal Bioacoustics

Standards Meetings Calendar—International

• 20–24 September 2010

– **ISO/TC 108/SC 4 and ISO/TC 108/SC 5**—London, UK

• 27 September–1 October 2010

– **ISO/TC 108** and its subcommittees **ISO/TC 108/SC 2, SC 3**, and **SC 6**, London, UK

For additional information on these meetings, please contact the Standards Secretariat.

Thanks to our Volunteers!

The ASA Standards Secretariat would like the thank the following people for volunteering their time and expertise to coordinate comments and formulate recommendations for the U.S. vote on numerous ISO and IEC documents throughout the second half of the past year. Their efforts are greatly appreciated and extremely valuable. The following is a list of volunteers from July 2009 through the end of the year.

K. Bever

P.D. Schomer
D.J. Vendittis

STANDARDS NEWS FROM THE UNITED STATES

American National Standards Call for Comment on Proposals Listed

This section solicits comments on proposed new American National Standards and on proposals to revise, reaffirm, or withdraw approval of existing standards. The dates listed in parentheses are for information only.

ASA (ASC S12) (Acoustical Society of America)

Revisions

BSR/ASA S12.42-201x, Methods for the Measurement of Insertion Loss of Hearing Protection Devices in Continuous or Impulsive Noise Using

Microphone-in-Real-Ear or Acoustic Test Fixture Procedures (revision and redesignation of ANSI S12.42-1995 (R2004))

Provides two methods for measuring the insertion loss of any hearing protection device (HPD) that encloses the ears, caps the ears, or occludes the earcanals. This standard contains information on instrumentation, calibration, electroacoustic requirements, subject selection and training, procedures for locating ear-mounted microphones and HPDs to measure sound pressure levels at the ear, specifications describing suitable ATFs, and methods for reporting the calculated insertion-loss values. (December 28, 2009)

ASME (American Society of Mechanical Engineers)

Revisions

BSR/ASME BPVC Section V-201x, Nondestructive Examination (11/05/09 Meeting) (revision of ANSI/ASME BPVC 2007 Edition)

Contains requirements and methods for nondestructive examination (NDE), which are referenced and required by other Sections of the Code. These NDE methods are intended to detect surface and internal imperfections in materials, welds, fabricated parts and components. The following NDE methods are addressed: radiography; ultrasonics; liquid penetrant; magnetic particle; eddy current; visual; leak testing; and acoustic emission. (February 1, 2010)

ATIS (Alliance for Telecommunications Industry Solutions)

Reaffirmations

BSR ATIS 0300221-1995 (R201x), OAM&P—In-Service, Nonintrusive Measurement Device (NMD) Voice Service Measurements (reaffirmation of ANSI ATIS 0300221-1995 (R2004))

Provides specifications for in-service nonintrusive measurement devices (INMD) used to measure various parameters of importance to voice service transmission maintenance of telecommunications networks. These measurement devices are used primarily for the measurement of voicegrade analog parameters such as speech level, noise level, echo path loss and echo path delay. This standard specifies interface, measurement range and accuracy requirements for measuring voicegrade transmission parameters as well as descriptions of optional functions associated with these parameters. (January 18, 2010)

TIA (Telecommunications Industry Association)

Revisions

BSR/TIA 470.120-C-201x, Telecommunications—Telephone Terminal Equipment—Transmission Requirements for Analog Speakerphones (revision and redesignation of ANSI/TIA 470-B-1997)

Provides speakerphone acoustic performance requirements for Customer Premises Equipment (CPE) intended for analog connection to the Public Switched Telephone Network (PSTN). These requirements should ensure compatibility and satisfactory performance to the user in a high percentage of installations. Test measurement methods reference procedures in IEEE Std 1329, where applicable. (January 11, 2010)

Final Actions on American National Standards

The standards actions listed below have been approved by the ANSI Board of Standards Review (BSR) or by an ANSI-Audited Designator, as applicable.

AHRI (Air-Conditioning, Heating, and Refrigeration Institute)

New Standards

ANSI/AHRI Standard 270-2009, Sound Performance Rating of Outdoor Unitary Equipment (new standard)

ANSI/AHRI Standard 300-2009, Sound Rating and Sound Transmission Loss of Packaged Terminal Equipment (new standard)

ANSI/AHRI Standard 350-2009, Sound Performance Rating of Non-Ducted Indoor Air-Conditioning Equipment (new standard)

ASA (ASC S2) (Acoustical Society of America)

Reaffirmations

ANSI/ASA S2.31-1979 (R2009), Methods for the Experimental Determination of Mechanical Mobility—Part 1: Basic Definitions and Transducers (reaffirmation and redesignation of ANSI S2.31-1979 (R2004))

ANSI/ASA S2.32-1982 (R2009), Methods for the Experimental Determination of Mechanical Mobility—Part 2: Measurements Using Single-Point Translational Excitation (reaffirmation and redesignation of ANSI S2.32-1982 (R2004))

ASA (ASC S12) (Acoustical Society of America)

Reaffirmations

ANSI/ASA S12.53/Part 2-1999 (R2009)/ISO 3743-2-1994 (R2009), Acoustics—Determination of sound power levels of noise sources using sound pressure—Engineering methods for small, movable sources in reverberant fields—Part 2: Methods for special reverberation test rooms (reaffirmation and redesignation of ANSI S12.53/Part 2-1999/ISO 3743-2-1994 (R2004))

Project Initiation Notification System (PINS)

ANSI Procedures require notification of ANSI by ANSI-accredited standards developers of the initiation and scope of activities expected to result in new or revised American National Standards. This information is a key element in planning and coordinating American National Standards.

The following is a list of proposed new American National Standards or revisions to existing American National Standards that have been received from ANSI-accredited standards developers that utilize the periodic maintenance option in connection with their standards. Directly and materially affected interests wishing to receive more information should contact the standards developer directly.

ASA (ASC S3) (Acoustical Society of America)

BSR/ASA S3.41-201x, Audible Emergency Notification and Evacuation Signal (revision and redesignation of ANSI ASA S3.41-1990 (R2008))

Applies to an audible emergency notification and evacuation signal. This standard specifies three parameters of the signals, i.e., temporal pattern, sound pressure level, and intelligibility (in voice systems as required) at all places within the intended signal reception. The spectral content of the signal is not specified and should be selected to satisfy specific site requirements and/or regulations. It applies to the audible signal and not to the individual signaling system components. Project Need: To broaden this standard owing to recent consideration for addressing the unique needs of handicapped individuals and the increased concern and need for heightened personal safety. Stakeholders: DOD, telecomunications industry, educators, administrators, manufacturing facilities management.

STANDARDS NEWS FROM ABROAD

(Partially derived from *ANSI Standards Action*, with appreciation.)

Newly Published ISO and IEC Standards

Listed here are new and revised standards recently approved and promulgated by ISO—the International Organization for Standardization.

ISO Standards

Acoustics (TC 43)

ISO 3822-3/Amd1:2009, Acoustics—Laboratory tests on noise emission from appliances and equipment used in water supply installations—Part 3: Mounting and operating conditions for in-line valves and appliances—Amendment 1

ISO 8253-2:2009, Acoustics—Audiometric test methods—Part 2: Sound field audiometry with pure-tone and narrow-band test signals

COMPRESSORS, PNEUMATIC TOOLS AND PNEUMATIC MACHINES (TC 118)

ISO 28927-1:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 1: Angle and vertical grinders

ISO 28927-2:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 2: Wrenches, nutrunners and screwdrivers

ISO 28927-3:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 3: Polishers and rotary, orbital and random orbital sanders

ISO 28927-5:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 5: Drills and impact drills

ISO 28927-6:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 6: Rammers

ISO 28927-7:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 7: Nibblers and shears

ISO 28927-8:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 8: Saws, polishing and filing machines with reciprocating action and small saws with oscillating or rotating action

ISO 28927-9:2009, Hand-held portable power tools—Test methods for evaluation of vibration emission—Part 9: Scaling hammers and needle scalers

ISO and IEC Draft International Standards

ISO

Acoustics (TC 43)

ISO/DIS 3382-3, Acoustics—Measurement of room acoustic parameters—Part 3: Open plan spaces (2/25/2010)

MECHANICAL VIBRATION AND SHOCK (TC 108)

ISO/DIS 7626-1, Vibration and shock—Experimental determination of mechanical mobility—Part 1: Basic definitions and transducers (2/1/2010)

ISO/DIS 13379-1, Condition monitoring and diagnostics of machines—Data interpretation and diagnostics techniques—Part 1: General guidelines (1/21/2010)

IEC Draft Standards

59/546/FDIS, IEC 60704-1 Ed 3.0: Household and similar electrical appliances—Test code for the determination of airborne noise—Part 1: General requirements, (01/29/2010)

REVIEWS OF ACOUSTICAL PATENTS

Sean A. Fulop
Dept. of Linguistics, PB92
California State University Fresno
5245 N. Backer Ave., Fresno, California 93740

Lloyd Rice
11222 Flatiron Drive, Lafayette, Colorado 80026

The purpose of these acoustical patent reviews is to provide enough information for a Journal reader to decide whether to seek more information from the patent itself. Any opinions expressed here are those of reviewers as individuals and are not legal opinions. Printed copies of United States Patents may be ordered at $3.00 each from the Commissioner of Patents and Trademarks, Washington, DC 20231. Patents are available via the internet at http://www.uspto.gov.

7,587,826

43.10.Pr HAND HELD VIBRATING KNIFE

John David Stutz, Suffolk, Virginia
15 September 2009 (Class 30/142); filed 17 January 2006

A knife as described in this patent is made to vibrate by a motor-driven imbalanced rotor attached near the handle. The patent makes no mention of user-adjusted controls or of counter-rotating elements for changing the direction and/or magnitude of the vibrations. It does mention that the rotating elements generate a gyroscopic effect that may be used to stabilize the blade during the cutting process, but provides no hint of how this unlikely benefit may be achieved in practice.—EEU

7,598,640

43.10.Pr VIBRATION EXCITER

Christian Heichel *et al.*, assignors to ABI Anlagentechnik-Baumaschinen-Industriebedarf Maschinenfabrik und Vertriebsgesellschaft mbH
6 October 2009 (Class 310/81); filed in Germany 7 March 2007

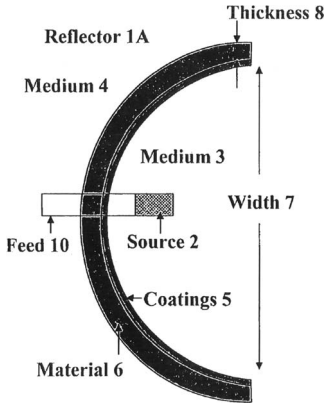
This vibration generator, intended for use in vibratory pile driving and the like, is based on the time-honored configuration consisting of imbalance masses on counter-rotating shafts. A rotary hydraulic oscillating motor, built into one of the shafts, is provided for changing the relative position of these masses. A disk brake can lock the arrangement to the housing in a desired orientation.—EEU

7,593,289

43.35.Zc REFLECTORS AND REFLECTOR LIGHT AND SOUND SOURCE SYSTEMS

Raymond B. Schaefer *et al.*, assignors to Phoenix Science & Technology, Incorporated
22 September 2009 (Class 367/138); filed 17 April 2006

According to this patent, a variety of industrial and military applications make use of concentrated light and/or sound—paint stripping, for example. Sound can be generated by a spark or other source that delivers substantial energy in the ultrasonic range. Several embodiments are described, but they all make use of a multi-layer reflector. The material and



thickness of the base layer 6 are chosen for efficient sound reflection, and coatings 5 are chosen for efficient light reflection.—GLA

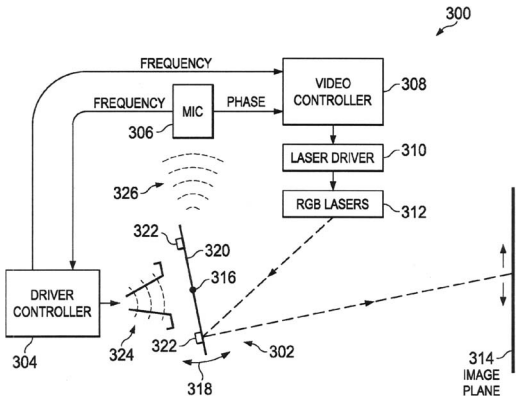
7,586,659

43.38.Ar AUDIO MEMS MIRROR FEEDBACK

Arthur Monroe Turner and Varkey George, assignors to Texas Instruments Incorporated
8 September 2009 (Class 359/199.1); filed 16 January 2009

This curious patent discloses the use of a microelectronic mechanical (MEMS) microphone to detect the motions of a MEMS mirror device of the type that is used in projection televisions. The only complete representation of the mechanism being patented is shown in the figure included here. The patent disclosure is not very detailed in its description, but it appears that the microphone is used to detect the velocity of air pulses coming from the edge of the moving mirror. The patent appears to be for a concept rather than a working device, as the authors make no mention of the fact that the majority of the signal from the microphone in this position would be at the second harmonic of the motion frequency, and they mention electromagnetic actuation of the mirrors as a possibility when there are no MEMS-scale solenoids available at this time, at least to this reviewer's knowledge. One would also

 0001-4966/2010/127(3)/1702/10/$25.00



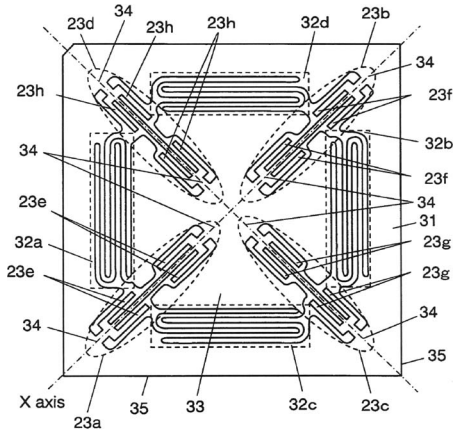
question the wisdom of using air as a coupling medium within a feedback loop, with the possibility of external interference and atmospheric effects affecting the response of the system.—JAH

7,587,941

43.38.Ar VIBRATION PIEZOELECTRIC ACCELERATION SENSOR

Jiro Terada *et al.*, assignors to Panasonic Corporation
15 September 2009 (Class 73/514.29); filed in Japan 2 March 2004

This patent discloses the use of a suspended plate as a mass for acceleration sensing. The plate is instrumented with piezoelectric strain gauges of a peculiar design situated at all four corners of the plate, as shown in the figure. These strain gauges have two active elements, one on either end of a silicon bar. They are used in transmitter/receiver pairs, each coupled to an



accompanying closed loop electromechanical resonator circuit. Apparently the inventors intend to use the transverse vibrations of the suspending bars as the sensing principle for they disclose the use of frequency to voltage converters in the detection electronics associated with the patented device. This implies that they rely on the tension in the bars as the frequency-determining factor, as opposed to the flexural stiffness of the bars. They apparently have the capability to fabricate very slender bars for this to work as illustrated.—JAH

7,598,655

43.38.Ar PIEZOELECTRIC TRANSFORMER DRIVING APPARATUS AND PIEZOELECTRIC TRANSFORMER DRIVING METHOD

Yasuhide Matsuo and Akira Mizutani, assignors to Tamura Corporation
6 October 2009 (Class 310/318); filed in Japan 6 October 2003

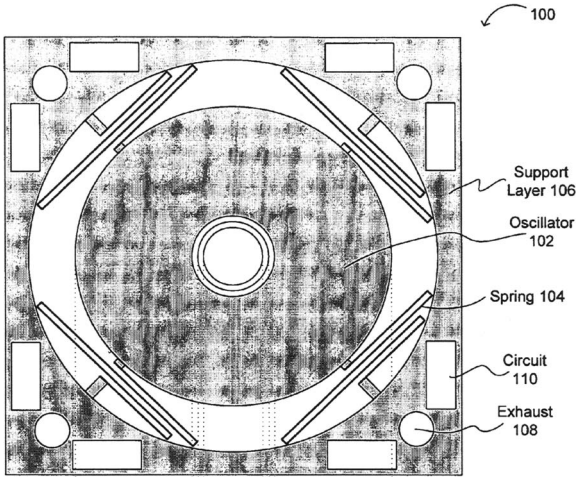
This patent discloses the use of Rosen-type piezoelectric transformers to drive high-voltage electronic devices differentially from low-voltage ac. The principle is fairly well established, but this patent provides a useful introduction to anyone interested in the details of the implementation.—JAH

7,570,775

43.38.Dv MICROELECTROMECHANICAL SPEAKER

Shinichi Araki, assignor to Sony Corporation
4 August 2009 (Class 381/191); filed 3 March 2005

What appears to be a very small electrodynamic loudspeaker of the moving magnet type is disclosed. Oscillator 102 (commonly called a diaphragm) is supported by springs 104. Exhaust ports 108 relieve back pressure or tune the back chamber. The coil and magnetic material are located in



the center of the diaphragm and are supported by a rigid layer below 102. How the coil and magnetic material are fabricated are briefly described. No device dimensions are noted, nor are the sensitivity or frequency response, for the device.—NAS

7,586,241

43.38.Fx ELECTROACOUSTIC TRANSDUCER

Hideaki Kuroda and Yoshihiro Sonoda, assignors to Murata Manufacturing Company, Limited
8 September 2009 (Class 310/348); filed in Japan 24 November 2005

The authors disclose the use of a flexible film substrate for mounting piezoelectric bimorph elements on in order to increase its radiating efficiency into air. The elements are disposed bilaterally in pairs or quadrilaterally around the film, which is supported by a rigid frame. The elements are rather large compared to the dimensions of the frame that supports the flexible film, which leads one to believe that the authors have not tried to optimize the size of and/or placement of the transducers. There is no discussion of the actual efficiency improvement over the bare transducers when radiating into air, but in reality one must trade off the improvement against the cost and complexity of fabricating and using such a hybrid structure.—JAH

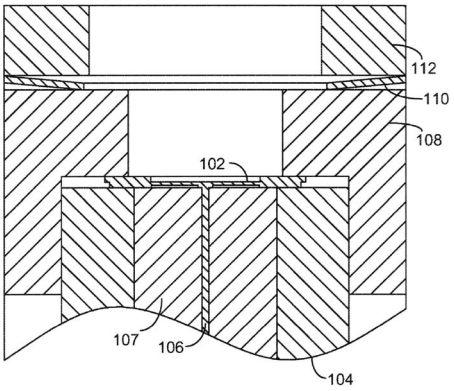
7,561,277

43.38.Gy MEMS FIBER OPTIC MICROPHONE

Ken K. Chin *et al.*, assignors to New Jersey Institute of Technology
14 July 2009 (Class 356/480); filed 18 May 2007

Micro-electric mechanical systems Fabry–Pérot diaphragm 102 is clamped to stainless steel ferrule 104 of single mode fiber 106, which is enclosed by zirconia ferrule 107, by washer 108, disk spring 110, and win-

dow cap 112. The patent states that the optic power output versus applied pressure of the device is an Airy function (how this is detected and decoded



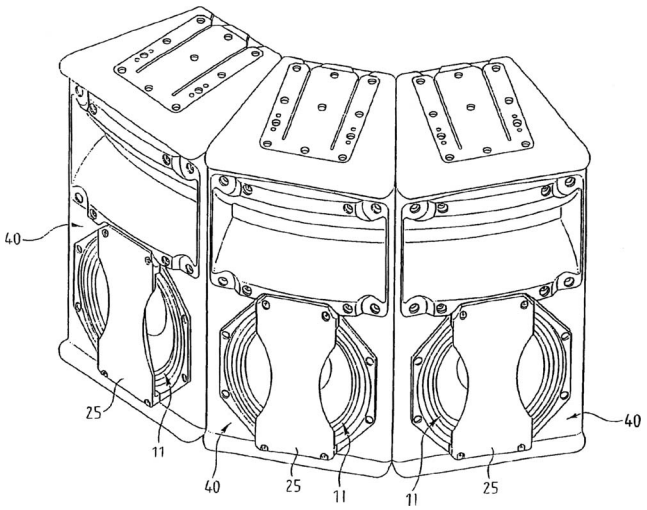
at the other end of the fiber is not described), and that multiple light sources are compatible with the device, including distributed feedback single mode lasers as well as (lower cost) LEDs. The description in the patent is concise and informative.—NAS

7,596,236

43.38.Hz LOUDSPEAKER WITH DIRECT EMISSION AND OPTIMISED RADIATION

Eric Vincenot, assignor to Nexo
29 September 2009 (Class 381/160); filed in France 23 July 2001

The illustration shows a typical curved line array, with cone loudspeakers 11 reproducing low and mid frequencies. If the speakers are, say, 30 cm apart then pattern control "explodes" above 550 Hz, whereas the high frequency horns operate efficiently only above 1 kHz or so. To get around



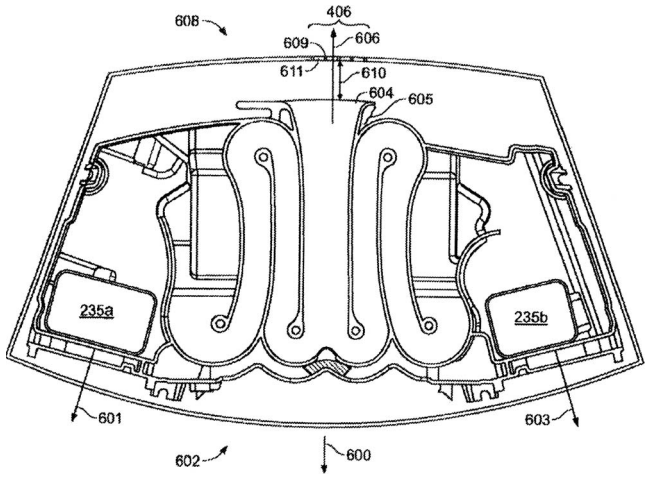
this problem some manufacturers use a pair of smaller woofers in each cabinet rather than a single larger speaker. The penalty is a reduction in cone area of about 50%. For many years, Nexo has employed a clever alternative: sound from each woofer exits through two horizontal slots, one above the other. In this improved version, a single "blocking member" 25 is attached to a conventional front-mount woofer.—GLA

7,584,820

43.38.Ja ACOUSTIC RADIATING

Robert Preston Parker and Dewey Potter, assignors to Bose Corporation
8 September 2009 (Class 181/155); filed 9 August 2004

The patent text includes some interesting ideas about loudspeakers mounted on tuned pipes, but few of these are actually included in the patent claims. The preferred embodiment consists of a pair of forward-facing loudspeakers 601 and 603 whose rear radiation passes through folded



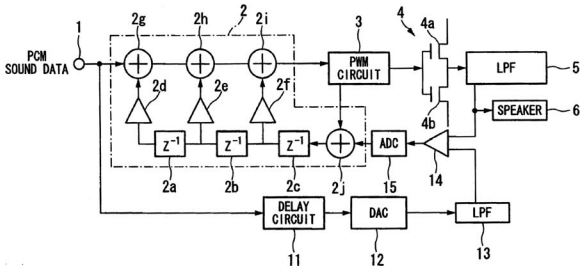
waveguides joined to a common exit 604. For this geometry to work reliably in a stereo system, channel separation should be progressively reduced below 200 Hz or so to provide monophonic bass drive, but this is not mentioned in the patent.—GLA

7,586,370

43.38.Lc CLASS D AMPLIFIER

Morito Morishima, assignor to Yamaha Corporation
8 September 2009 (Class 330/251); filed in Japan 18 March 2005

This is an interesting class D amplifier circuit. Also, the patent itself is interesting in that ten embodiments are described at some length yet the patent claims are few and short, with only a single independent claim. All



embodiments include two pulse width modulation circuits, complete with output lowpass filters 13 and 41. The two lowpassed analog signals are compared in summing amplifier 46, and the resulting error signal is used to provide corrective feedback.—GLA

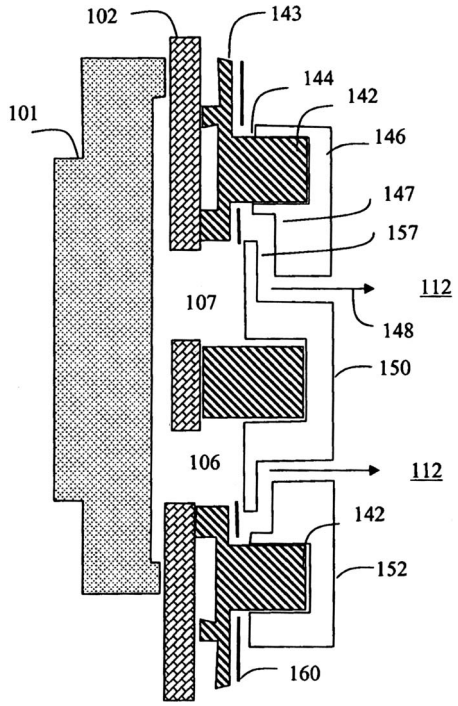
7,590,234

43.38.Si KEYPAD WITH FLANGED KEYS FOR HIGH AUDIO FRONT PORTING COMMUNICATION PRODUCTS

Donald W. Burnette *et al.*, assignors to Motorola, Incorporated
15 September 2009 (Class 379/433.07); filed 18 November 2005

Unlike Yamaha's U.S. Patent No. 7,586,370 which condenses ten distinct embodiments into four short claims, this patent manages to expand a one-sentence concept into 18 patent claims. In the effort to provide more and more functions in less and less space, some cellular phones use the keypad as a loudspeaker grill. However, current "zero-gap" keypads have no rigid separators between keys. As a result, any holes in the back membrane

can be seen by the user. Horrors! The remedy disclosed here is to use



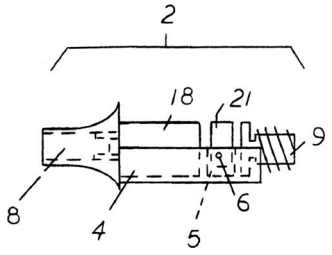
flanged keys, providing a concealed air path from speaker 101 to the outside world, as indicated by arrows 148.—GLA

7,590,258

43.38.Si IN-EAR EARPHONE

Mark Andrew Krywko, Bradenton, Florida
15 September 2009 (Class 381/380); filed 5 July 2007

Every component of this earphone is adjustable, removable, or replaceable. Ear tip 8, for example, can be selected for preferred treble response. The patent claims include two odd requirements: the receiver must



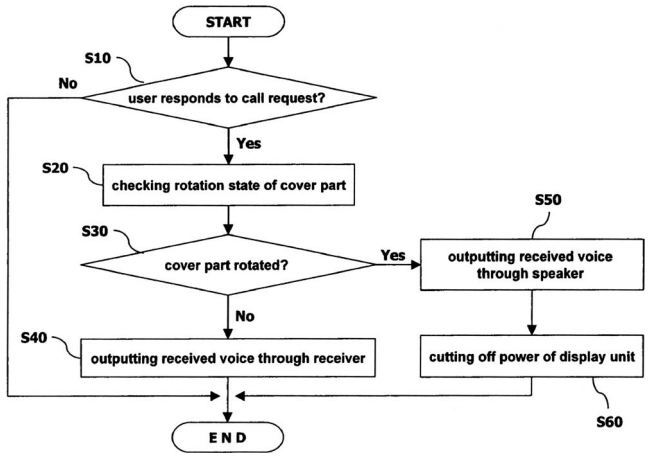
be a "single armature speaker" and the connecting cable must be coaxial.—GLA

7,590,431

43.38.Si SYSTEM AND METHOD FOR OUTPUTTING DUAL VOICE OF MOBILE TERMINAL

Hun-Soo Lee, assignor to LG Electronics Incorporated
15 September 2009 (Class 455/569.1); filed in Republic of Korea 27 November 2003

Cellular phones must be heard whether the case is open or closed, and this seemingly simple requirement is the basis for more than a half-dozen patents. In some cases, adjustable waveguides are used to control the output of a single loudspeaker; in others, the electrical signal is switched between two speakers. This patent belongs to the second category. As might be expected, it has become increasingly difficult to tiptoe around prior art, and a note of desperation has crept into the patent claims. Among other things, it is necessary that "…the swivel hinge rotates in a direction perpendicular to a front surface of the folder part," and "…at least one of the different output



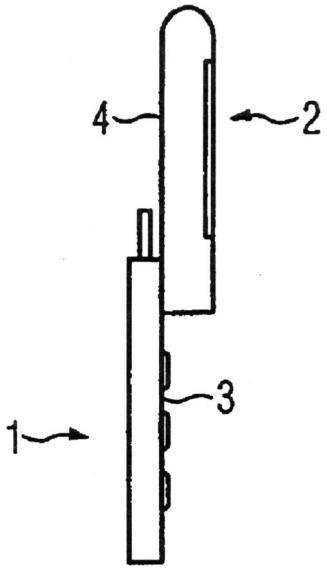
devices is controlled with reference to a sound pressure conversion table stored in memory."—GLA

7,590,436

43.38.Si SLIDER MOBILE TELEPHONE COMPRISING A BENDING WAVE LOUDSPEAKER

Michael Hülskemper, assignor to Palm, Incorporated
15 September 2009 (Class 455/575.4); filed in Germany 12 December 2002

When this sliding-case phone is open as shown, the rear surface 4 of display section 2 functions as a bending wave loudspeaker. That is it, folks.



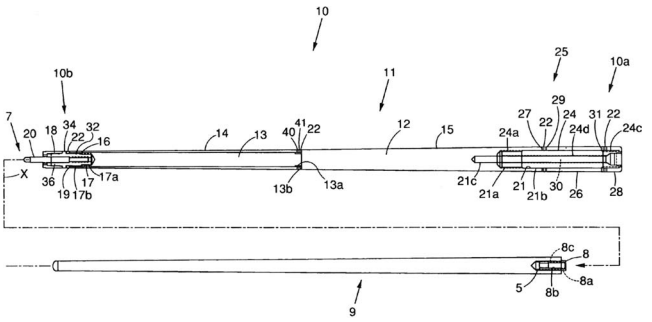
Watch this space for the next big audio advancement from Palm Inc.—GLA

7,559,847

43.40.Kd CUE STICK

Paul D. Costain and Karim Belhaj, assignors to Clawson Custom Cues, Incorporated
14 July 2009 (Class 473/44); filed 17 July 2007

Vibration damping inserts 16 and 24 are placed in the proximal and distal ends, respectively, of butt portion 11 of cue stick 10, which can be, but are not limited to, linen reinforced phenolic material, such as NEMA L Type



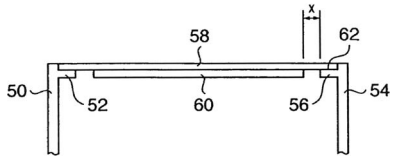
FBI or NEMA LE Type FEI, and are said to damp the vibrations in the stick when the distal end of shaft portion 9 strikes a billiard ball.—NAS

7,568,984

43.40.Tm HOLLOW GOLF CLUB HEAD

Hideo Matsunaga, assignor to Bridgestone Sports Company, Limited
4 August 2009 (Class 473/332); filed in Japan 23 August 2005

The patent states that to increase the launch angle of a golf ball when struck by a hollow golf club head, which are known as drivers, the ratio of rigidity of the sole portion of the club head to the side portion should be



1:0.2–0.6, the ratio of the average thickness of the sole portion to the crown portion should be 1:0.5–0.7, and the ratio of Young's modulus of the materials used in the sole portion and the crown portion should be 1:0.5–0.8. Two graphs showing several values for the specified ratios versus launch angle and initial ball speed are presented. However, when the crown portion rigidity is reduced, the elastic deformation is increased relative to "ordinary" club heads, so the crown portion "rings" and "excellent ball feel cannot sometimes be obtained." To cure this deficiency, while retaining the benefits of the preferred ratios, vibration absorbing layer 60 is bonded or otherwise affixed to crown portion 58.—NAS

7,591,209

43.40.Tm VIBRATION SUPPRESSING CUTTING TOOL

Daisuke Murakami *et al.*, assignors to Sumitomo Electric Hardmetal Corporation
22 September 2009 (Class 82/158); filed in Japan 26 November 2003

Vibration suppression is accomplished by means of a mass that is located in a cavity in the tool and that essentially rattles as the tool vibrates. The mass is made of a material whose density is greater than that of the tool's material. Clearances of 0.01–0.5 mm are suggested between the surfaces of the mass and the sides of the cavity enclosing it.—EEU

7,592,901

43.40.Tm INPUT DEVICE

Hidetaka Furusho, assignor to Alps Electric Company, Limited
22 September 2009 (Class 340/407.1); filed in Japan 25 August 2004

In order to provide tactile feedback to a touch-screen device's user when he touches a point on the screen, the back of the screen is provided with a planar electrode array. The electrodes are arranged in stripes of alternating polarity so that localized areas can be made to vibrate by application of a voltage via an external driving circuit.—EEU

7,592,801

43.40.Yq METHODS AND APPARATUS FOR VIBRATION DETECTION

James M. Bailey *et al.*, assignors to Allegro Microsystems, Incorporated
22 September 2009 (Class 324/207.25); filed 21 March 2008

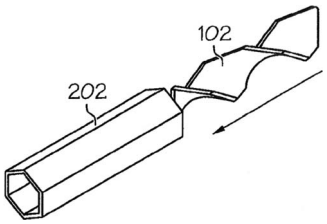
This patent pertains to means for differentiating between rotational and lateral vibration motions of rotating ferrous objects, such as gears. It takes note of the fact that a magnetic proximity sensor can only detect the change in the magnetic field as an object, such as a gear tooth, and moves relative to the sensor; the sensor cannot differentiate between the gear vibrating in rotation relative to the sensor and oscillatory changes in the air gap between the sensor and gear. The method of this patent overcomes this problem by using a plurality of magnetic proximity sensors, rotation detectors, and rotation-agreement processors.—EEU

7,562,742

43.50.Gf AIR EXHAUST/INLET SOUND ATTENUATION MECHANISM

Don A. Gilliland *et al.*, assignors to International Business Machines Corporation
21 July 2009 (Class 181/280); filed 13 June 2008

Inner member 102 has a 360 deg twist and is shaped so that it fits, snugly, in outer member 202. As such the axial twist provides a labyrinth path for both air flow and electromagnetic waves. By suitable choice of



materials, which should have suitable sound damping and electromagnetic attenuating characteristics, for the inner and outer members, combined with the hex-packing design of the other sleeve, a method and system are disclosed that allow forced air cooling of an electronic device as well as electromagnetic interference shielding through the air vent.—NAS

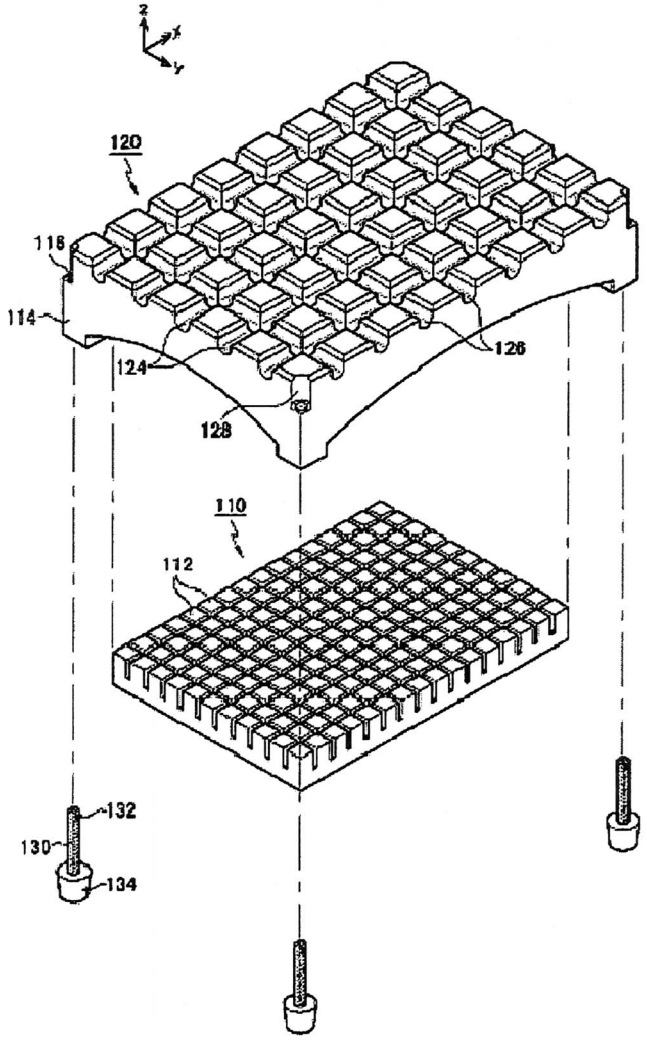
7,594,365

43.55.Ti HEATING FLOOR SYSTEM

Se-Chang Kang *et al.*, assignors to LG Chem, Limited
29 September 2009 (Class 52/220.2); filed in Republic of Korea 15 September 2005

The patent describes a polypropylene panel that sits on four corner legs and supports radiant heating pipes in the grooves on the upper side of the panel. The legs reduce point of contact with the floor structure below and thus reduce sound transfer. The protrusions under the panel (defined by the

grooves on the upper side) interlock with a thermal insulating panel.



The system will save time and money because of the ease of installation.—CJR

7,586,239

43.58.Kr MEMS VIBRATING STRUCTURE USING A SINGLE-CRYSTAL PIEZOELECTRIC THIN FILM LAYER

Sheng-Shian Li *et al.*, assignors to RF Micro Devices, Incorporated
8 September 2009 (Class 310/328.02); filed 6 June 2008

The authors describe a micro-electronic mechanical structure that incorporates a thin film of single-crystal piezoelectric material such as lithium niobate or lithium tantalate into a lateral or thickness mode resonator structure in silicon. The silicon is micromachined so as to be suspended by supporting arms only, confining the resonances to an area whose lateral dimensions can be accurately defined and controlled by lithographic techniques. The resulting layered structure has high mechanical Q, it is claimed, because the vibrations are segregated into the suspended volume. This device is useful for the rf electronics industry, where the filters used have frequencies high enough to benefit from the small dimensions of these devices. The construction principles are similar to many other film bulk acoustic resonators, however.—JAH

7,587,052

43.66.Ts HEARING AID AND METHOD FOR ADJUSTING A HEARING AID

Thomas Kasztelan, assignor to Siemens Audiologische Technik GmbH
8 September 2009 (Class 381/60); filed in Germany 21 May 2004

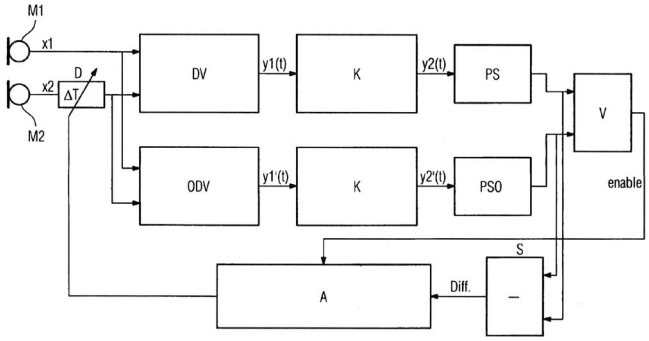
Measured frequency response data obtained while the hearing aid is worn in the user's ear are stored in the hearing aid and utilized to provide faster and more accurate fitting adjustments than would be achieved using average frequency response data stored in the fitting software.—DAP

7,587,058

43.66.Ts METHOD AND DEVICE FOR MATCHING THE PHASES OF MICROPHONE SIGNALS OF A DIRECTIONAL MICROPHONE OF A HEARING AID

Eghart Fischer and Henning Puder, assignors to Siemens Audiologische Technik GmbH
8 September 2009 (Class 381/313); filed in Germany 5 March 2004

To match the phase of two microphone outputs in a directional system, the omnidirectional and directional signal level outputs are matched without



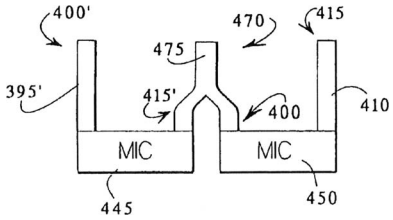
knowing the position of the acoustic source generating the test signals by adjusting a delay applied to one of the microphone outputs. The delay is adjusted only if the directional signal level is higher than the omnidirectional signal level.—DAP

7,590,253

43.66.Ts HEARING AID HAVING SWITCHABLE FIRST AND SECOND ORDER DIRECTIONAL RESPONSES

Mead C. Killion, assignors to Etymotic Research, Incorporated
15 September 2009 (Class 381/313); filed 25 October 2006

A custom hearing aid comprises at least two microphone housings and a faceplate having at least two sound passages acoustically coupling sound



from one or more of the sound openings to the microphone housings. Diffraction scoops with wind screens are placed over the sound openings. The hearing aid switches between an omnidirectional response and a directional response equalized to the omnidirectional response. The switching can be

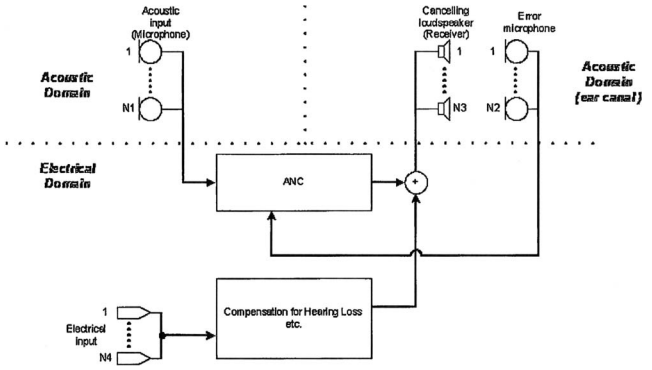
either done manually via a switch or automatically depending on the ambient noise level.—DAP

7,590,254

43.66.Ts HEARING AID WITH ACTIVE NOISE CANCELING

Jes Olsen, assignor to Oticon A/S
15 September 2009 (Class 381/328); filed in Denmark 26 November 2003

One commonly employed method of reducing the sensation of occlusion in hearing aid fittings is to leave the ear canal partially open, which also allows ambient sounds into the ear canal by bypassing the hearing aid signal processing. To reduce such unwanted ambient sounds when a wireless signal



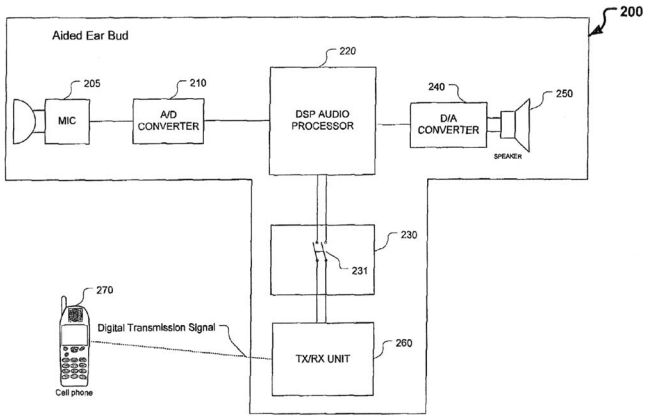
or direct audio input signal is received, the output of an internal microphone picking up sound in the ear canal is used as an error signal, in conjunction with the ambient microphone pickup(s), to generate a compensation signal that partially cancels the ambient sound in the ear canal.—DAP

7,593,537

43.66.Ts AIDED EAR BUD

Mark Enzmann, assignor to AT&T Mobility II LLC
22 September 2009 (Class 381/315); filed 7 June 2007

A hearing aid switches between two operating modes via commands received from a mobile device when answering an incoming call or initiating an outgoing call. One operating mode is normal hearing aid functionality. In the other mode, the hearing aid microphone picks up the user's voice and transmits it to the mobile device and receives an audio signal from the mobile device representing call content. This received signal is mixed with



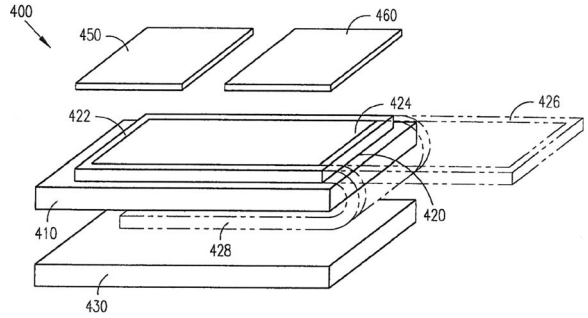
the hearing aid microphone signal, depending on the ambient noise level, and modified by a frequency-amplification map stored in the hearing aid according to the listening needs of the user. Transmissions between the mobile device and hearing aid may be wireless.—DAP

7,593,538

43.66.Ts ANTENNAS FOR HEARING AIDS

Beau Jay Polinske, assignor to Starkey Laboratories, Incorporated
22 September 2009 (Class 381/322); filed 17 February 2006

A flexible antenna, comprising at least one flexible metal trace connected to communication electronics in a hearing aid, is adapted for assembly with a hybrid circuit. The antenna may have several planar coils that



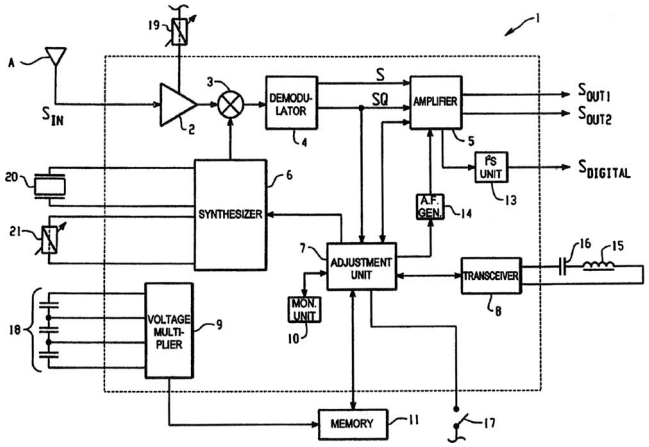
may be connected to form a helical coil.—DAP

7,596,237

43.66.Ts METHOD FOR CONTROLLING A TRANSMISSION SYSTEM, APPLICATION OF THE METHOD, A TRANSMISSION SYSTEM, A RECEIVER AND A HEARING AID

Jean-Claude Constantin, assignor to Phonak AG
29 September 2009 (Class 381/314); filed 18 September 2000

Audio signals are transmitted wirelessly on independent transmission channels to a number of hearing aids, which have been configured from parameters transmitted wirelessly on independent transmission channels. Each audio signal is transmitted at a predefined carrier frequency.—DAP



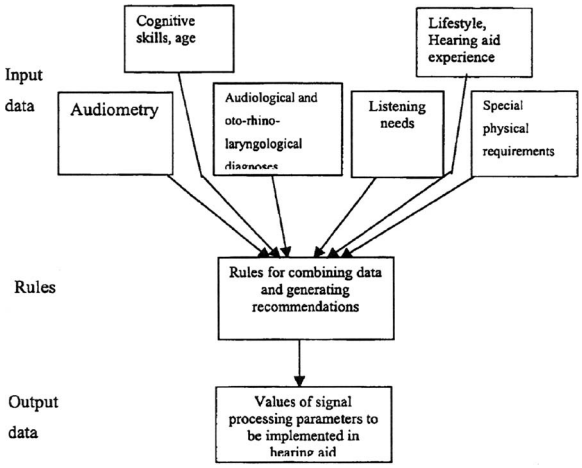
7,599,499

43.66.Ts METHOD FOR FITTING A HEARING AID TO THE NEEDS OF A HEARING AID USER AND ASSISTIVE TOOL FOR USE WHEN FITTING A HEARING AID TO A HEARING AID USER

Graham Naylor, assignor to Oticon A/S
6 October 2009 (Class 381/60); filed in Denmark 28 September 2001

Initial hearing aid signal processing parameters are derived from the

wearer's audiological data and level of cognitive functionality. Cognitive functionality is determined by the wearer's age, medical records, present or previous occupation, or a cognitive performance test or conversation with



the wearer or persons associated with the wearer. Optionally, the wearer's lifestyle, sound environments, and previous hearing aid experience may also be taken into consideration.—DAP

7,599,507

43.66.Ts HEARING AID AND A METHOD FOR ENHANCING SPEECH INTELLIGIBILITY

Martin Hansen, assignor to Widex A/S
6 October 2009 (Class 381/317); filed 12 January 2005

After the hearing aid or an external processor analyzes the sound environment surrounding the hearing aid wearer, an estimate of speech intelligibility is made by the hearing aid or external processor from the initial hearing aid gain vector values, ambient speech levels, and noise levels in a set of frequency bands. The gain vector values in a number of frequency bands are modified automatically to maximize speech intelligibility. The gain vector values may also be adjusted to maintain a calculated loudness below a loudness upper limit.—DAP

7,239,999

43.72.−p SPEED CONTROL PLAYBACK OF PARAMETRIC SPEECH ENCODED DIGITAL AUDIO

Changwon D. Rhee, assignor to Intel Corporation
3 July 2007 (Class 704/211); filed 23 July 2002

This patent presents a simple means for solving a simple problem with pitch-corrected speed control applied to coded speech playback. Various schemes are described for properly equalizing the number of audio samples contained in speech frames received from a decoder (such as linear predictive), with the number of audio samples that are to be used by a prior-art type of playback speed controller.—SAF

7,246,058

43.72.Ar DETECTING VOICED AND UNVOICED SPEECH USING BOTH ACOUSTIC AND NONACOUSTIC SENSORS

Gregory C. Burnett, assignor to Aliph, Incorporated
17 July 2007 (Class 704/226); filed 30 May 2002

This patent presents methods for detecting voiced speech segments with the aid of a general electromagnetic movement sensor that has been patented separately. This latter sends out weak radio waves that reflect off the target. The reflected waves are combined with the transmitted waves, and the combination is checked for phase shifts, which are presumably caused by movement of the target, such as a speaker's neck or throat tissue.—SAF

7,236,922

43.72.Fx SPEECH RECOGNITION WITH FEEDBACK FROM NATURAL LANGUAGE PROCESSING FOR ADAPTATION OF ACOUSTIC MODEL

Hitoshi Honda *et al.*, assignors to Sony Corporation
26 June 2007 (Class 704/2); filed in Japan 30 September 1999

This patent presents a dialog system with speech recognition and synthesis that all seems to be prior art, with the exception of one innovation. A scheme is included for performing speaker adaptation on-line, which is again according to prior art, except for the idea to use information from the dialog system to assign "zones" in the dialog that are likely to provide good-quality adaptation results. The dialog structure is used to detect erroneous recognition, and these zones of the dialog are then omitted from the speech that will be used to perform adaptation.—SAF

7,236,931

43.72.Fx SYSTEMS AND METHODS FOR AUTOMATIC ACOUSTIC SPEAKER ADAPTATION IN COMPUTER-ASSISTED TRANSCRIPTION SYSTEMS

Chuang He and Jianxiong Wu, assignors to USB AG, Stamford Branch
26 June 2007 (Class 704/235); filed 28 April 2003

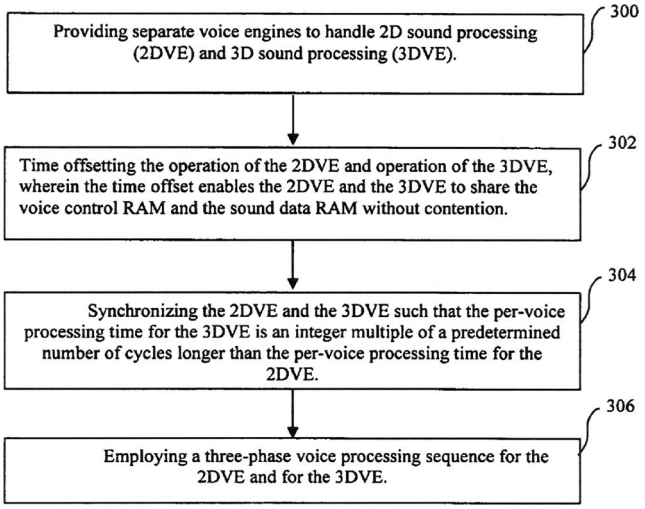
A transcription system is described which performs speaker adaptation by making use of "semi-literal" transcripts that were created at an initial stage by speech recognition using the speaker-independent acoustic models. Various means are put forth for creating maximally correct semi-literal transcripts prior to adaptation.—SAF

7,587,310

43.72.Gy SOUND PROCESSOR ARCHITECTURE USING SINGLE PORT MEMORY UNIT

David H. Lin, assignor to LSI Corporation
8 September 2009 (Class 704/200); filed 30 August 2004

For power and cost savings during at least one of three processing



phases, the two-dimensional (2D) and three-dimensional (3D) voice engines

in a sound processor are synchronized and share at least one single port memory by time-multiplexing without contention. The mixer in the sound processor has separate buffers for the 2D voices, 3D voices, and reverberation.—DAP

7,240,005

43.72.Ja METHOD OF CONTROLLING HIGH-SPEED READING IN A TEXT-TO-SPEECH CONVERSION SYSTEM

Keiichi Chihara, assignor to Oki Electric Industry Company, Limited
3 July 2007 (Class 704/267); filed in Japan 26 June 2001

Speech synthesis systems are sometimes used to perform text read-out at a high speech rate. The patent notes that standard speech synthesis prosody is totally inappropriate for extremely high speech rates, and a scheme is proposed for altering the prosody in various ways to render speech more intelligible at high speed.—SAF

7,249,020

43.72.Ja VOICE SYNTHESIZING METHOD USING INDEPENDENT SAMPLING FREQUENCIES AND APPARATUS THEREFOR

Reishi Kondo, assignor to NEC Corporation
24 July 2007 (Class 704/258); filed in Japan 18 April 2001

This incredibly mundane and obvious patent describes a means of selecting a lower sampling rate for voiced speech segments and a higher sampling rate for unvoiced speech segments stored in a speech synthesis sound database. The objective is to reduce storage requirements.—SAF

7,588,538

43.80.Vj ULTRASONIC DIAGNOSTIC EQUIPMENT AND IMAGE PROCESSING APPARATUS

Yoichi Ogasawara *et al.*, assignors to Kabushiki Kaisha Toshiba
15 September 2009 (Class 600/454); filed in Japan 11 September 2003

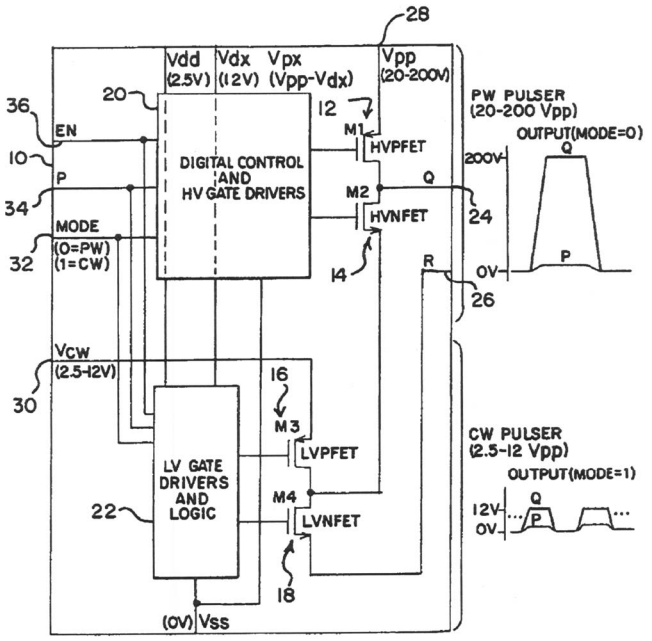
After a contrast agent comprised of gas bubbles is injected into a subject, b-scan imaging is performed using a high acoustic intensity to acquire the maximum echo intensities and to break the bubbles. Subsequent b-scan imaging is performed at different times by using low or moderate acoustic intensities that do not break contrast medium bubbles. Data obtained from the scans are analyzed and displayed.—RCW

7,588,539

43.80.Vj INTEGRATED LOW-POWER PW/CW TRANSMITTER

David A. Petersen, assignor to Siemens Medical Solutions USA, Incorporated
15 September 2009 (Class 600/459); filed 19 January 2005

High-voltage and low-voltage switches are integrated on a semiconductor chip. The high-voltage switches are used for pulse-wave operation and the low-voltage switches are used for continuous-wave operation. Both



the pulse and continuous waveforms come from a common output.—RCW

7,588,540

43.80.Vj ULTRASONIC PROBE FOR SCANNING A VOLUME

An Nguyen-Dinh *et al.*, assignors to Vermon
15 September 2009 (Class 600/459); filed 8 April 2005

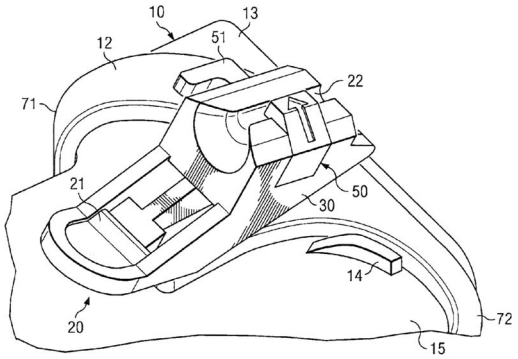
This probe includes a flexible membrane seal. The membrane permits immersion in a coupling fluid through which the probe moves to scan planes in succession. Portions of the membrane also reduce parasitic drag forces produced during movement of the probe.—RCW

7,588,541

43.80.Vj METHOD AND SYSTEM FOR POSITIONING A MEDICAL DEVICE AT ONE OR MORE ANGLES RELATIVE TO AN IMAGING PROBE

Jared Floyd and Steven Bunce, assignors to SonoSite, Incorporated
15 September 2009 (Class 600/461); filed 28 January 2004

A needle guide is attached to the end of an ultrasound imaging probe. The user positions the needle by looking at an ultrasound image produced



with the probe containing the needle. Both the needle and the guide can be released from the probe.—RCW

7,591,786

43.80.Vj DOCK FOR CONNECTING PERIPHERAL DEVICES TO A MODULAR DIAGNOSTIC ULTRASOUND APPARATUS

Randy T. Holmberg *et al.*, assignors to SonoSite, Incorporated
22 September 2009 (Class 600/437); filed 31 January 2003

This apparatus contains a system electronics module, input-output ports, and docking stations that can be released from the system module.—RCW

7,591,787

43.80.Vj METHOD FOR REMOVING DOPPLER ANGLE AMBIGUITY

Piero Tortoli, Firenze, Italy
22 September 2009 (Class 600/454); filed 15 September 2005

An ultrasound beam is initially oriented in a direction essentially perpendicular to the direction of blood flow, and a Doppler spectrum of blood echoes is obtained. The beam is then re-oriented so the Doppler spectrum of blood echoes is essentially symmetric around the zero frequency, and the Doppler spectrum is again determined. The rate of blood flow is calculated using the angle between the ultrasound beams and the Doppler frequency of the echoes obtained from the second ultrasound beam.—RCW

7,591,788

43.80.Vj ADAPTIVE CONTRAST AGENT MEDICAL IMAGING

Patrick J. Phillips and Ismayil Guracar, assignors to Siemens Medical Solutions USA, Incorporated
22 September 2009 (Class 600/458); filed 19 August 2003

A contrast agent imaging mode is dynamically determined and optimized by using a selected transmit level or real-time measurement of the contrast agent signal. An interface allows this imaging mode to be used without a need to switch between multiple modes or contrast agent detection techniques and associated contrast agent imaging parameters. This permits an imaging session without a user switching the mode of system operation.—RCW

7,593,554

43.80.Vj SYSTEM AND METHOD FOR COMPARING ULTRASOUND IMAGES CORRESPONDING TO TWO USER-SELECTED DATA POINTS

Edward A. Miller *et al.*, assignors to Koninklijke Philips Electronics N.V.
22 September 2009 (Class 382/128); filed 3 October 2002

A graphical user interface displays curves that provide data about a sequence of ultrasound images. By selecting a point on a curve, a corresponding ultrasound image is displayed. By selecting another point on the same or another curve, another corresponding ultrasound image is displayed. The two ultrasound frames can then be compared.—RCW

7,597,663

43.80.Vj ADJUNCTIVE ULTRASOUND PROCESSING AND DISPLAY FOR BREAST CANCER SCREENING

Shih-Ping Wang *et al.*, assignors to U-Systems, Incorporated
6 October 2009 (Class 600/437); filed 27 November 2002

Ultrasound scans spanning a volume are displayed. A user can navigate among images showing a thick cross section, a selected enlarged thick cross section, and a planar image. The contrast in the thick cross-sectional images can be inverted prior to display so that bright structures in an x-ray mammogram are also bright in the ultrasound image.—RCW

7,597,664

43.80.Vj MEASURING TRANSDUCER MOVEMENT METHODS AND SYSTEMS FOR MULTI-DIMENSIONAL ULTRASOUND IMAGING

Paul H. Jones *et al.*, assignors to Siemens Medical Solutions USA, Incorporated
6 October 2009 (Class 600/437); filed 30 October 2006

An optical sensor in an ultrasound transducer measures motion along the skin in a way similar to the way that a mouse in a personal computer measures movement. The transducer can be tilted at an angle toward or away from the direction in which the transducer is translated. The distance of travel is determined by angle-correcting the movement that is measured.—RCW

Architectural Acoustics Noise, and INCE: Acoustics of Green Buildings

Brandon D. Tinianov, Cochair
Serious Materials, 1250 Elko Dr., Sunnyvale, CA 94089-2213

David M. Sykes, Cochair
Remington Partners, Inc., 23 Buckingham St., Cambridge, MA 02138

Ralph T. Muehleisen, Cochair
Illinois Inst. of Technology, Civil and Architectural Engineering, 3201 S. Dearborn, Chicago, IL 60616

Chair's Introduction—8:00

Invited Papers

8:05

1aAAa1. US Green Building Council's role as a change agent in the North American construction market. Brandon D. Tinianov (Serious Mater., 1250 Elko Dr., Sunnyvale, CA 94089, btinianov@seriousmaterials.com)

After observing market reaction to the U.S. Green Building Councils (USGBC) Leadership in Energy and Environmental Design (LEED), one could conclude that it may be the most powerful voluntary market transformation tool encountered in the modern building industry. The LEED voluntary system is not only entering a very diverse array of markets but stimulating changes in product design, professional practices, and educational curricula. It is also prompting debate in various circles another healthy sign of market transformation. This presentation will provide an overview of who USGBC represents, how they view green buildings, and the specifics of how this market transformation takes place.

8:20

1aAAa2. A review of the new Leadership in Energy and Environmental Design v3 green building rating system. Ralph T. Muehleisen (Civil, Arch. and Env. Eng., Ill. Inst. of Tech., Chicago, IL 60616, muehleisen@iit.edu)

Leadership in Energy and Environmental Design (LEED) has become the *de facto* standard green building rating system in the US. On April 27, 2009 the US Green Building Council launched LEED v3 which is a major change to the previous version, becoming more flexible and prioritizing energy efficiency and greenhouse gas emissions. In particular, the prerequisites and credits amongst the various "flavors" of LEED have been harmonized for increased consistency, credit weights have been adjusted to better reflect impact on human and environmental health concerns, and credit weightings now reflect regional environmental issues. Acoustical consultants and engineers need to be aware of and understand these changes because they need to work with architects and other engineers who are designing buildings to meet the new LEED requirements. In this presentation, LEED v3 and the current implementation, LEED 2009, are reviewed.

8:35

1aAAa3. Architectural acoustics: Emerging opportunities require new materials and solutions. David M. Sykes (Remington Partners LLC, 23 Buckingham St., Cambridge, MA 02138, dsykes@healthcareacoustics.org), William Cavanaugh (Cavanaugh Tocci Assoc., Sudbury, MA 01776), Mandy Kachur (Acoust. by Design, Ann Arbor, MI), Erica Ryherd (Georgia Inst. of Technol., Atlanta, GA), and Alexis Kurtz (Arup Acoust., New York, NY)

The landscape is changing. New 2010 code-level acoustical guidelines for healthcare facilities and new 2009 LEED environmental quality criteria for acoustics in green buildings (LEED) create demand for acoustical solutions that stretch the boundaries of current practice. In many cases, these needs cannot be met by traditional methods, materials, technologies, or best practices in design & construction. Unfortunately, technical development has been constrained for 3 decades by absence of government support for R&D and by litigation against many manufacturers of acoustical materials. As a result, serious re-thinking is needed by materials manufacturers, technology developers, solutions providers, research scientists, and consultants. This paper gives an overview of these emerging needs and outlines new ways of thinking about architectural acoustics. Topics include (1) new requirements (renewable sources, VOCs, recyclability, lightweight construction, infection control/cleanability, and daylight transmission); (2) materials (re-purposed, adapted, and new); (3) construction method & procedures (pre-fabricated solutions, & new sources thereof, and the changing role of value engineering); (4) measurement & monitoring method & equipment (MEMS, wireless sensors, smart-phone applications, and cloud computing); and (5) code & rating systems (including post-construction performance inspection & certification procedures and the need for periodic monitoring & re-certification).

8:50

1aAAa4. Unintended consequences: Acoustical outcomes in LEED (Leadership in Energy and Environmental Design) certified offices. Kevin Powell (Office of Appl. Sci., GSA Public Bldgs. Service, 555 Battery St., Rm. 518, San Francisco, CA 94111, kevin.powell@gsa.gov)

Recent research conducted by the US General Services Administration and the Center for the Built Environment at UC Berkeley disclosed an anomaly about "green building" interiors that is an unintended consequence of the current LEED rating system. The anomaly is this: occupants of offices that have been upgraded to achieve LEED certification express high levels of satisfaction with the "indoor environmental quality" of almost all attributes of these spaces; but there is one exception where occupant scores are lower than before. Their increased dissatisfaction has to do with acoustics and privacy. What is it about LEED-rated offices that cause increased dissatisfaction? Why are occupants uncomfortable with the "acoustical comfort" of the new LEED-certified offices? Is it because there are more reflective, hard surfaces—such as exposed ceilings—causing noise to reverberate? Or because HVAC systems have become quieter? Or because partition heights have been lowered to allow better airflow and more natural light, resulting in less privacy? Since increased occupant dissatisfaction may result in reduced productivity or increased absenteeism, the GSA's Office of Research has been examining this issue and report on its findings and conclusions.

9:05

1aAAa5. Understanding and specifying green noise control materials. Brandon D. Tinianov (Serious Mater., 1250 Elko Dr., Sunnyvale, CA 94089, BTinianov@seriousmaterials.com)

Specification of green acoustical materials is difficult to implement from the acoustical expert's perspective. A contributing factor is the accepted definition of "green" that is poorly understood by the acoustical community. The widely accepted interpretation of the term does not refer exclusively to building materials that have a high recycled material content or are made without the use of toxic chemicals but extends to the entire project. Overall building design implications extend beyond material content to water consumption, energy use, and to the health and wellness of the occupants. These larger considerations are reflected in the most prevalent green rating system, the LEED rating system as established by the United States Green Building Council (USGBC). Within the framework of a larger, holistic building system, acoustical material can be considered green on three levels: (a) its contribution to the health and comfort of the building occupants, (b) environmentally preferable nature of its components or manufacturing process, and (c) its secondary performance features that have a positive impact on other building systems. Acoustical experts must therefore review the "green-ness" of sound control materials in this same framework. A review of such an approach and a review of existing green acoustical products will be presented.

9:20

1aAAa6. Acoustics and the leadership in energy and environmental design rating systems. Benjamin Markham (Acentech Inc., 33 Moulton St., Cambridge, MA 02138)

The leadership in energy and environmental design (LEED) rating systems address acoustics explicitly in but a few of their many credits. More profound are the implications of LEED-driven design on a building acoustics, typically in pursuit of LEED credits where no explicit reference to acoustics, noise, or acoustical design exists. Using project case studies as a guide, this presentation will outline some of the conflicts as well as synergies between "best practice" acoustical design and design decisions made on the basis of achieving certain LEED credits. A range of example credits will be presented along with the ramifications of such credits on building acoustics, including the effects of sustainable site credits on environmental noise isolation, energy and atmosphere credits on background noise levels, materials and resources credits on acoustical material specification, and indoor environmental quality credits on sound isolation and other acoustical design elements.

9:35

1aAAa7. Acoustics and the Leadership in Energy and Environmental Design (LEED) certification—Why education and healthcare came first. Kurt Rockstroh (Steffian Bradley Architects, 100 Summer St., Boston, MA 02110-2106, kurtr@steffian.com), David Sykes (Remington Partners, Cambridge, MA 02138), William Cavanaugh, and Gregory Tocci (Cavanaugh Tocci Assoc., Sudbury, MA)

Three decades of Washington neglecting the noise problem in America resulted in general ignorance of and data about human health impacts. This is true with politicians, agency heads, foundations, doctors, educators, architects and builders—whether they "advocate green policies" or not. So when LEED redefined the term "environmental quality" to include acoustics, they focused on "populations at risk"—children (schools), and sick people (healthcare facilities where scientific research on human subjects is routine). Meanwhile, healthcare professionals became attuned to noise and privacy from HIPAA and the patient-centered-care movement. In 2005, the Facility Guidelines Institute, which each re-issues the 60-year-old Guidelines for Design and Construction of Healthcare Facilities every 4 years resolved to address this problem. We commissioned TC-AA.NS.SC to develop comprehensive acoustical guidelines which were completed in 2006 and launched this January. Once drafted, the acoustical guidelines were quickly piloted for LEED by Green Guide for Healthcare, and then the LEED Environmental Quality Technical Advisory Group adopted them as the Reference Standard for LEED HC. From HC it will find broader acceptance in other LEED programs. This process ensures that acoustics re-enters public policy supported by independent, transdisciplinary research on human health impacts and by multiple rounds of peer review in healthcare.

9:50

1aAAa8. Acoustical materials for a green world: The sustainable design transformation of the architectural acoustics industry. Mandy Kachur (Acoust. by Design, Inc., 303 Detroit St., Ste. 304, Ann Arbor, MI 48104, mandy@acousticsbydesign.com), Daniel Bruck, and Jeanette Hesedahl (BRC Acoust. & Technol. Consulting, Seattle, WA 98134)

The focus on sustainable and healthy building materials has intensified over the last few years. This is true particularly in healthcare, educational, and environmentally friendly or "green," facilities, where an increasing awareness of acoustics has resulted in a higher demand for innovative products. As the healthcare industry pushes for greater patient comfort, increased speech privacy, and green design, new acoustical products must satisfy multiple requirements. In educational facilities, the U.S. Green Building Council's Leadership in Energy and Environmental Design (LEED) for Schools rating system promotes the use of green products, which extends to acoustical materials. Additionally, some educational facility owners are hesitant to allow traditional types of sound absorbers such as fiberglass duct liner for fear of health issues. Consequently, acoustical materials manufacturers have responded with new and repurposed materials to suit these needs. Because many of these materials have been recently introduced, a significant amount of project time can be expended on research to select an appropriate material to suit the new requirements. In an attempt to streamline the selection process, this overview will identify a number of these new and repurposed materials and provide feedback on their use from architects, engineers, and owners.

1aAAa9. Aerogels: A "Green" thermo-acoustic insulation material with nanoscale properties. James Satterwhite (Cabot Corp., 157 Concord Rd., Billerica, MA 01821, james_satterwhite@cabot-corp.com)

Aerogels are a well-known class of thermal insulation derived from nanoscience that has "green" benefits including translucence, thinness, hydrophobicity, light weight, and flexibility. Recently, the acoustical properties of aerogels have been characterized. Aerogels are currently available in building materials like skylights and exterior glazing, fabrics-based roofing membranes, and flexible blankets for insulating underwater pipelines and building walls. In 2008–2009, laboratory testing and field research began on the acoustical properties of thin profile (2–8-mm) architectural "tensile membrane" fabrics incorporating silica aerogel granules. Data from a tension structure in Canada—where aerogel-enhanced fabric was used to block aircraft noise—exhibited excellent acoustic absorption and acoustic impedance matching properties compared to insulators of comparable thickness. The material increased transmission loss of exterior to interior noise and also reduced indoor reverberation. In the same period, US field tests demonstrated an aerogel blanket material as a surface treatment in open offices to reduce broadband reverberation, resulting in increased speech intelligibility and privacy and enhanced acoustical comfort. These acoustical attributes combined with aerogels' thermal value, thin form factor, translucence, hydrophobicity, light weight, and absence of VOCs had led to growing interest in green building applications ranging from aircraft interiors to hospitals.

10:30

1aAAa10. Materials science: A "Green" acoustical wall treatment for controlling room reverberation in healthcare. Francis Babineau (Johns Manville, 10100 West Ute Ave., Littleton, CO 80127, francis.babineau@jm.com)

In healthcare, green criteria must be coupled with a higher standard of stringent infection control requirements. This study was conducted to explore an alternate method for reducing room reverberation in a healthcare setting. Reverberation time (RT) plays an important role in noise levels and speech privacy which are key factors in healthcare. However, RT is difficult to control in healthcare facilities due to strict durability and infection control requirements. In this study of a private patient room in a hospital, instead of improving the ceiling to reduce reverberation, the walls were treated with a new, thin, acoustically absorptive, but paintable, wall material. The wall treatment was a new-to-market acoustical finish with absorption coefficients ranging from 0.05–0.6. To achieve reverberation control, several walls of the room were covered with the treatment. Reverberation times were measured before and after installation, and results were consistent with predicted values. Despite being a small study, results suggest that a thin, paintable, acoustical wall treatment that meets criteria for infection control and durability can be an effective method for controlling reverberation in healthcare facilities, thereby creating a more comfortable environment for patients and staff while giving architects increased design flexibility.

10:45

1aAAa11. Going green may require new professional relationships and different solution providers. Bennett Brooks (27 Hartford Turnpike, Vernon, CT 06066, bbrooks@brooks-acoustics.com) and Jason Perrone (BKM Technol. Group, East Hartford, CT 06108)

Change is always welcome but often confusing. One way climate change impacts the acoustics profession is through the sudden, government-driven rush to make buildings green by conforming to Energy Star and the U.S. Green Building Council's LEED rating system (acoustics have only recently become part of the "environmental quality" vocabulary of these systems). Two more ways change impacts acousticians are first the emergence of technologically advanced materials and devices (often from companies you do not know), and second, the emergence of new "solution-providers" with prior contractual relationships with your clients. The presenters represent three entities that have been cooperating to address green-related acoustical issues for large corporate clients in the Northeast USA. The projects described in this presentation have been instructive for all three parties: new materials have been put to use in unexpected ways, independent testing validated the efficacy of novel solutions, and client relationships were managed by a corporation previously unrecognized by most acoustical engineers but that has spent a decade establishing a level of skill in acoustics appreciated by government agencies and leading corporations that have streamlined supply chains and therefore seek to use a limited number of existing supplier relationships to implement change.

11:00

1aAAa12. Electro-acoustic architecture: Is it Green? Roger W. Schwenke (Meyer Sound Labs., 2832 San Pablo Ave, Berkeley, CA 94702, rogers@meyersound.com) and Jason R. Duty (Charles M. Salter Assoc., Inc., San Francisco, CA 94104)

Electro-acoustic architecture systems offer a means of changing the acoustic properties of a room electronically. They are an alternative to physically variable acoustics, where acoustic properties are changed by retractable curtains and doors opening to reverberant chambers, etc. This paper will address the question of whether electro-acoustic systems are a Green alternative to physically variable acoustics. In order to have a reverberation time appropriate for symphonic music, a room must have a large cubic volume and hard heavy surfaces. In contrast, in a room with an electro-acoustic system, the physical reverberation time is desired to be low even at low frequencies. Therefore, the cubic volume can be low and surfaces can be made of a lightweight material over an airspace. This affects the amount of energy needed to deliver materials, construct the building, and operate HVAC and lighting systems. A lower volume building means less pollution and waste during construction, and allows for more open space around the building, and/or higher development density. Electro-acoustic systems can easily be designed as a renovation, thus recycling existing buildings. Case studies will be reviewed demonstrating these issues.

11:15

1aAAa13. Green classroom acoustics: Sound or noise? Glenn E. Sweitzer (Sweitzer LLP, 4504 N. Hereford Dr., Muncie, IN 47304, glenn.sweitzer@gmail.com)

Architectural acoustics is underrepresented in current green building rating systems. While acoustics factors are embodied in green building issues, their scoring potentials remain untapped. An alternative, individual user-oriented basis is tested for scoring architectural acoustics factors. Key architectural acoustics factors embodied in the currently prevailing LEED Green Building Rating System are identified. Selected acoustics factors, and relevant criteria, are studied in the context of four similar school classrooms in one K-5 school. To assess the relative values of these factors, four K-5 teachers are surveyed and then interviewed regarding sound and noise control strategies used in their respective classrooms by academic subject, visual and aural media, and teacher-student and student-student configurations . Reported outcomes are compared with measured sound transmission index (STI) values for selected activity configurations in each classroom. Results suggest that passive sound and noise control in individual classrooms can be used to improve STI by academic subject, presentation media, and teacher and student configurations. Accordingly, scoring for an individual classroom will vary by the passive as well as active noise control means used. Examples are discussed.

1aAAb1. Communication behavior of pupils and teachers in highly absorbent classrooms: A pleading for room acoustic comfort in schools. Markus Oberdoerster (Saint-Gobain Ecophon GmbH, Taschenmacher Str. 8, 23566 Lbeck, Germany, markus.oberdoerster@ecophon.de) and Gerhart Tiesler (Univ. of Bremen, 28334 Bremen, Germany)

This lecture refers to an interdisciplinary research project conducted 2001–2005 by acousticians, pedagogues, and occupational scientists at the Bremen University. It investigates the kind of work and communication behavior in elementary school classrooms and the influence that is given by the acoustic environment. Using a database of 175 examined lessons an analysis is made of how different kinds of work (frontal lessons vs differentiated lessons) have an effect on the sound level in the classroom. Parameters are discussed, which can describe classroom acoustics appropriately. Also discussed are how altered room characteristics (e.g., increased absorption, shortened reverberation time, and improved speech intelligibility) affect the sound level in the context of each kind of work. A methodical examination of the database allows an assessment of mean values but also of the detailed teaching phases, as characterized by certain pedagogical factors. The results provide the basis for discussion of stress and work demands of teachers.

1aAB1. An acoustic modeling graphical-user-interface tool for the marine conservationist. Laurel Henderson, Michael Porter, and Christian de Moustier (Heat, Light, and Sound Res., 3366 N. Torrey Pines Court, La Jolla, CA 92037, laurel@hlsresearch.com)

We develop an interactive tool to estimate the total level of anthropogenic and natural noise received by marine animals. This tool will help the marine conservationist assess potential noise-exposure risks. It uses physics-based underwater-acoustic models from the Acoustics Toolbox (http://oalib.hlsresearch.com/). Input choices include ocean area, seasonal sound speed profiles, and wind speed from NOAA and OAML databases. Sound sources can be chosen individually from a panel or by the dozens from a table with built-in representative values of various noise sources, including ships of various sizes, marine construction, navy sonars, and explosives. The user can either study the effects of the built-in noise sources or alter the table with actual noise-sources at known locations. Databases of marine mammal densities can be overlain, or the received acoustic level at chosen points on the map can be saved. We will review the background of the acoustic models used in the GUI and give a short demonstration of the capabilities of this tool.

8:35

1aAB2. Modeling marine mammal sound exposure levels due to ship traffic noise. Christian de Moustier, Michael B. Porter, and Laurel Henderson (HLS Res., Inc., 3366 North Torrey Pines Court, Ste. 310, La Jolla, CA 92037)

Noise due to ship traffic is a pervasive component of the global and local ocean noise from 10 to 500 Hz, but little is known of its effects on marine mammals because such effects depend on the sound exposure levels at a given location. The approach presented here consists of modeling the sound field due to various spatial distributions of noise sources located 5–10 m below the sea surface. We approximate a three-dimensional sound field by computing the sound propagation from each source along a prescribed number of two-dimensional vertical radial slices of a range-dependent environment, which includes bathymetry, seafloor geoacoustic properties, water column sound speed profiles, and sea surface roughness. Propagation results from all sources are incoherently summed to form the overall sound exposure map. By varying the density of ships in a given area we can simulate the effects of shipping lanes and assess how the characteristics of the underlying seafloor alter the results.

8:50

1aAB3. Investigations of marine mammal exposure to sound scattered from the sea surface. Ahmad Abawi, Michael Porter (Heat, Light, and Sound Res., Inc., La Jolla, CA 92037), and Martin Siderius (Portland State Univ., Portland, OR 97201)

Scattering of sound from the rough sea surface results in variations in sound intensity. If the surface height variations are smooth, as they are during a swell, the surface can act as a concave mirror and amplify the sound intensity at its focal region. We have shown both analytically and using numerical modeling that the intensity at the focal region is a function of frequency: for a singly curved surface, the intensity at the focus varies linearly with frequency and for a doubly curved surface, this dependence is quadratic. Scattering of sound waves from a rough surface can also result in a reduction in intensity through dispersion. In this paper, we investigate the possible effects of exposure to sound scattered from the sea surface on marine mammals by computing the scintillation index as a function of range and depth for a variety of ocean environments, including those with surface ducts. We compute the scintillation index using a Monte Carlo technique, where for each surface height realization, we compute the scattered field in the waveguide exactly using the virtual source technique. We compute the Green's functions needed in the virtual source technique using the Scooter propagation model.

1aAB4. Odontocete hearing: Effects of noise and measurement during echolocation. Paul E. Nachtigall (Marine Mammal Res. Program, Hawaii Inst. of Marine Biology, P.O. Box 1106, Kailua, HI) and Alexander Ya. Supin (Inst. of Ecology and Evolution, Russian Acad. of Sci., Leninsky Prospekt, Moscow, Russia)

Noise that interferes with active echolocation can come from either outside sources or be self-generated. Our work on temporary threshold shifts has shown that either lower levels of anthropogenic noise presented for long time periods or intense sonar pings for short time periods can produce temporary reduction in sensitivity and temporary threshold shifts. Intense anthropogenic sounds intended to disrupt echolocation can also reduce echolocation performance. Our measurements of hearing during echolocation have shown that self-generated intense outgoing signals are managed by the whale's auditory system by (1) the use of forward masking as an automatic gain control system, (2) anatomical (or neurological) damping of outgoing signals, and (3) active manipulation of sensitivity levels of over all hearing. These processes of hearing allow the whale to adjust its hearing during echolocation to maximize the hearing of echoes. Measurements of hearing while a false killer whale actively echolocated, by measuring auditory evoked potentials, showed that the whale heard returns from a small cylinder better than it heard its own outgoing 180-dB clicks that produced the echo returns from the cylinder. Interactions between outside anthropogenic noise and the hearing of self-generated intense sounds during echolocation remain largely unexplored.

9:25

1aAB5. Observing the behavioral response of herring exposed to mid-frequency sonar signals. Nils Olav Handegard, Lise Doksaeter, Olav Rune Godoe (Inst. of Marine Res., NO-5817 Bergen, Norway, nilsolav@imr.no), and Petter H. Kvadsheim (Maritime Systems Div., Norwegian Defence Res. Establishment, NO-3191 Horten, Norway)

There is general concern on how mid-frequency military sonars might affect aquatic animals. Approaches used to investigate possible effects on Norwegian spring spawning herring (*Clupea harengus*) are presented. Experiments were performed in a sheltered fjord area, in the open ocean, and in a net pen. In the fjord area, the behavior of the exposed herring was monitored using an upward-looking bottom-moored echo sounder. For the open ocean experiment, schools of exposed herring were tracked using omnidirectional sonar. In the controlled net-pen experiments, the herring were towed into a fjord basin. The net-pen was equipped with a horizontal pointing and an upward-looking split-beam echo sounder to monitor the behavior, a hydrophone to measure the exposure levels, and a video camera to verify the observed behavior. In all experiments the herring was exposed to relevant naval sonar signals using operational sources mounted on a research vessel or operated from a frigate. For the net-pen experiments, the herring were also exposed to other audible sound sources to investigate the robustness of the methodology to detect reaction patterns. The pros and cons of the different observational approaches are discussed. [Work supported by the Research Council of Norway Grant No. 184705.]

1aAB6. Loggerhead turtles dive in response to airgun sound exposure. Stacy L. DeRuiter (Acoust. and Seismic Service, Ifremer, BP 70, 29280 Plouzané, France) and Kamel Larbi Doukara (Univ. of Oran Es-Senia, BP 1524, El M'Naouer 31000, Oran, Algeria)

Visual observations of the behavior of over 150 loggerhead turtles (*Caretta caretta*) were collected over a period of 2 weeks during a seismic survey in the Mediterranean Sea off Algeria in September and October 2009. All turtles were observed during active operation of an airgun array that had a peak source level of 252 dB *re* 1 μPa. Recordings from three hull-mounted hydrophones allowed concurrent estimation of near-surface airgun array source signatures and sound exposure levels. Of the 53% of turtles that were successfully visually tracked until they had passed more than 100 m behind the seismic vessel, 51% dived at or before their closest point of approach to the airgun array. Among animals that dived, approximately 20% did so immediately following an airgun shot, often showing a startle response that was clearly distinguishable from the predominant basking behavior. Turtle dive probability as a function of distance from the airgun array and sound exposure level will be considered in detail. The observed diving behavior may be interpreted as an avoidance response and may have negative consequences for turtles if it interferes with thermoregulation (basking) or results in inhabitual energy expenditures.

Invited Paper

10:25

1aAB7. Changes in vocal behavior of individual North Atlantic right whales in increased noise. Susan E. Parks (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804, sep20@psu.edu), Mark Johnson (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), Douglas Nowacek (Duke Univ., Beaufort, NC 28516), and Peter Tyack (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

This study investigates the impacts of anthropogenic noise exposure on the vocal behavior of individual North Atlantic right whales, a baleen whale species found in the urban coastal waters off the east coast of the United States and Canada. A non-invasive acoustic recording tag, the Dtag, was used to record the noise levels received by individual whales and the vocalizations they produced in the Bay of Fundy, Canada. These data were used to assess the variability in the received levels (and therefore source level), duration, and frequency content of calls produced by the tagged whale in varying ambient noise conditions. A single stereotyped call type, the 'upcall,' was selected for these measurements. Individual whales producing multiple calls showed increases in received call amplitude and minimum frequency in increasing low-frequency noise conditions. This is one of the first studies to document call intensity changes in baleen whales in response to short-term changes in anthropogenic noise in their environment. This evidence for individual call modification in response to changes in background noise has implications for both descriptive studies of vocal behavior and design for passive acoustic monitoring systems for marine species.

10:45

1aAB8. Acoustic compensation to shipping and airgun noise by Mediterranean fin whales (*Balaenoptera physalus*). Manuel Castellote (Natl. Marine Mammal Lab., Alaska Fisheries Sci. Ctr./NOAA, 7600 Sand Point Way, N.E. F/AKC3, Seattle, WA 98115, mcastellote@hotmail.com), Cristopher W. Clark (Cornell Univ., Ithaca, NY 14850), and Marc O. Lammers (The Hawaii Inst. of Marine Biology, Kaneohe, Hawaii 96744)

Seafloor recorders were deployed in the western Mediterranean Sea and adjacent Atlantic waters during 2006–2009 to monitor noise levels and fin whale presence. Acoustic parameters of 20-Hz pulses (pulse duration, bandwidth and intervals, and center and peak frequencies) were compared for areas with different shipping noise levels, different shipping intensities in the Strait of Gibraltar and during seismic airgun events. Statistically significant differences were detected between noise contexts. In general, acoustic parameter values decreased with increased noise levels. In high-noise conditions, 20-Hz pulse duration shortened, bandwidth decreased, and center and peak frequencies decreased. Similar results were obtained in the presence of airgun events, and bearings to singing whales indicated that whales moved away from the airgun source and out of our detection area for a time period that extended well beyond the duration of the airgun activity. This study provides evidence that fin whales modify their acoustic behavior to compensate for increased ambient noise and shows that under some conditions they will leave an area for an extended period. Sensitization and habituation processes may play a role in these behaviors and are discussed in the context of these results.

11:00

1aAB9. Anthropogenic noise and sound production by beluga whales (*Delphinapterus leucas*) in Cook Inlet, Alaska during early August 2007. Cara F. Hotchkin (Ecology IGDP 165 Appl. Res. Lab, The Pennsylvania State Univ., University Park, PA 16802, cfh121@psu.edu.), Susan E. Parks (The Penn State Univ., State College, PA 16804), and Barbara A. Mahoney (Natl. Marine Fisheries Service, Anchorage, AK 99513)

The beluga whale population in Cook Inlet, Ak, has a limited range centered near the Port of Anchorage and was declared endangered in 2008. One potential threat to the belugas recovery is anthropogenic noise, which may disrupt communication and normal behaviors. This project used a boat-based single hydrophone system to evaluate noise levels at several locations in Cook Inlet on 6 days from 2–14 August, 2007. Belugas were encountered twice, at the Port of Anchorage and near the Little Susitna River. Recorded vocalizations were analyzed to develop a provisional description of the whales' repertoire. Call frequencies ranged from 381 Hz to 24 kHz (the limit of the recording system), with most energy at frequencies above 2 kHz. Most vocalizations were similar to call types of other beluga populations. Broadband and 1/3-octave band levels were evaluated for noise from tidal flow and ships at the Port of Anchorage. Vessel noise levels were highest below 0.5 kHz, but frequencies ranged to greater than 8 kHz (distance to source $<$ 200 m). Based on the overlap in frequency between beluga vocalizations and ship noise, anthropogenic sound may mask beluga communication near vessels in Cook Inlet.

11:15

1aAB10. Cook Inlet beluga whale echolocations at the Port of Anchorage expansion. Ana Širović and Lindsey S. Kendall (Alaska Pacific Univ., 4101 Univ. Dr., Anchorage, AK 99508)

Ocean noise levels increase as a result of human activities. As a result, the effects of anthropogenic noise on marine mammals are a growing concern. A genetically distinct population of beluga whales in Cook Inlet was listed as endangered under the Endangered Species Act in 2008. NOAA has identified many potential threats to the Cook Inlet beluga whale population, including coastal development and anthropogenic noise. The Port of Anchorage Marine Terminal Redevelopment Project, currently underway in Upper Cook Inlet, involves several types of water construction activities, including pile driving. However, the effect of pile driving noise on beluga whales is unknown. A passive acoustic array of sonobuoys was deployed during 20 days in August and September 2009 to acoustically detect the presence of beluga whales in the vicinity of in-water pile driving at the Port project site. Beluga whale echolocation clicks were detected on days when the whales were also visually sighted by the on-site visual observers. Whistles and burst pulses were not commonly detected from beluga whales in this area.

11:30

1aAB11. Hearing ability of the lined seahorse (*Hippocampus erectus*). Susan M. Hastings, Meghan R. Kelly, Lisa L. Wu (Thomas Jefferson High School for Sci. and Technol., 6560 Braddock Rd., Alexandria, VA 22312), and Mardi C. Hastings (6422 Crosswoods Dr., Falls Church, VA 22044, mchastings@verizon.net)

The lined seahorse (*Hippocampus erectus*), a member of the family Syngnathidae (pipefishes and seahorses), occurs in coastal waters of the western Atlantic, Gulf of Mexico, and Caribbean Sea. This harmless species is listed as "vulnerable" on the International Union for the Conservation of Nature (IUCN) List of Threatened Species, meaning that it has a high risk of extinction in the medium-term future primarily due to declines in population from targeted catch, bycatch, and degradation of habitat. However, because little is known about hearing in Syngnathids, it is difficult to assess potential effects of anthropogenic sound on these animals. In this study auditory evoked potentials (AEPs) were measured in four *H. erectus* specimens to determine hearing thresholds and bandwidth. Thresholds were determined using the staircase method with exposures to tone bursts between 50 Hz and 21.6 kHz. At low frequencies *H. erectus* had AEP thresholds similar to other bony fishes; however, at frequencies above 2 kHz its auditory sensitivity was similar to that of clupeiform species which detect ultrasound [Mann *et al.*, J. Acoust. Soc. Am. (2001)]. The results of this study provide hearing data that can be used to understand potential effects of human-generated noise on *Hippocampus erectus* and other seahorse species.

1aAO1. The accessible Arctic Ocean. John W. Farrell, III (US Arctic Res. Commission, 4350 N. Fairfax Dr., Ste. 510, Arlington, VA 22203, jfarrell@arctic.gov)

Scientific evidence indicates that global climate changes, and the most rapid changes are in the Arctic. Northern temperatures have increased twice as fast as elsewhere, the areal extent and thickness of Arctic sea ice have decreased dramatically, sea level rises as oceans warm and as glaciers and icesheets melt, and the ocean becomes more acidic as it absorbs atmospheric carbon dioxide. Changes in climate, as well as advances in technology, and the demand for resources have resulted in a newly accessible Arctic Ocean that invites to commercial fishing, shipping, tourism, mineral, and energy extraction interests and catches the attention of the US Coast Guard and the US Navy, among others. Many activities associated with these interests have implications for sound in the sea, and this presentation will present some of these at an overarching level. The United States has barely begun the baseline oceanographic research necessary to support national and international goals for ecosystem-based management and marine spatial planning in the Arctic Ocean. The US Arctic Research Commission, an independent federal agency, that advises Congress and the Executive Branch calls for Arctic Ocean research that would help policy makers address these issues.

9:25

1aAO2. The Arctic underwater acoustic environment. Christine Erbe (JASCO Appl. Sci., Brisbane Technol. Park, 1 Clunies Ross Ct, Eight Mile Plains, Queensland 4113, Australia, christine@jasco.com)

This talk gives an overview of the underwater acoustic environment in the Arctic. Sources of sound will be reviewed, including natural ambient noise (physical + biological) and man-made noise. Sound propagation characteristics will be discussed and examples from field studies will be presented. Features unique to the Arctic will be highlighted. Potential impacts of underwater noise on marine mammals will be summarized. Wild guesses will be made in an attempt to estimate how things might change in the future, particularly relating to climate change.

9:45

1aAO3. Soundscapes under sea ice: Can we listen for open water? Jeffrey Nystuen (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105 and HCMR, Attica, Greece, nystuen@apl.washington.edu) and Jennifer Miksis-Olds (Penn State Univ., State College, PA 16804)

Different geophysical conditions at the ocean surface generate distinctive sound spectra underwater, thereby allowing the physical environment to be monitored using passive acoustics. In the central Bering Sea, a passive aquatic listener (PAL) was deployed on the NOAA M5 mooring through the 2008 and 2009 winter seasons, allowing the ambient sound under sea ice to be recorded. Distinctive features of sea ice soundscapes include loud sound levels during periods of ice formation and very quiet high-frequency levels during periods of solid ice coverage. These soundscapes do have distinctive spectra features that distinguish them from other geophysical conditions, including wind-generated spectra, drizzle, and rainfall onto open water. This indicates that it is possible to listen for ice-free surface conditions. In turn, this will allow sub-surface ocean instrumentation on drifters, profilers, or moorings to detect open water and surface during relatively safe ice-free surface conditions (by listening), thus minimizing damage risk and allowing data transfer by satellite data links, an important advance for engineering oceanographic studies in ice covered seas. [Work sponsored by ONR Marine Mammals.]

10:05—10:30 Break

10:30

1aAO4. Acoustic monitoring of a melting Arctic Ocean. Peter N. Mikhalevsky (Acoust. and Marine Systems Operation, SAIC, 4001 N. Fairfax St., Arlington, VA 22203, mikhalevskyp@saic.com)

The waters of the Arctic Ocean have been warming since the early 1990s. Average maximum temperatures have risen by more than 1 °C. In the last 20 years submarine measurements of sea ice draft have shown a 40% reduction in average sea ice thickness while satellite remote sensing has shown a 14% reduction in sea-ice extent over the same period decreasing at a rate of 3%–5% per decade with thicker multi-year ice at 7%–10% per decade. Forecasts indicate that if these trends continue the Arctic Ocean could be ice-free in the summer before the end of this century. Significant effort is needed to expand our observational capabilities in the Arctic Ocean to support better modeling, forecasting, and improve our understanding of this critical ocean and the linkages to global climate. One technique acoustic thermometry has been shown to be a very effective for monitoring average heat content and average temperature in the Arctic Ocean and, in particular, in the Arctic Intermediate Water layer. Two experiments conducted in 1994 and 1999 measured the warming and demonstrated the feasibility of long term observations. Plans are in process to incorporate acoustic thermometry and tomography in *in-situ* Arctic Ocean observatories.

10:50

1aAO5. Improved assessment of Arctic and Antarctic zooplankton: From acoustic scattering models to a better understanding of polar ecosystems. Joseph D. Warren, Joy N. Smith (School of Marine and Atmospheric Sci., Stony Brook Univ., 239 Montauk Hwy., Southampton, NY 11968, joe.warren@stonybrook.edu), Patrick H. Ressler (Alaska Fisheries Sci. Ctr., NOAA, Seattle, WA 98115), and David A. Demer (Southwest Fisheries Sci. Ctr., NOAA, La Jolla, CA 92037)

Polar regions contain some of the most productive (and in some cases unspoiled) ecosystems on the planet. Zooplankton, particularly krill, are the preferred prey for numerous fish, bird, and mammal species including animals that are endangered, commercially fished, or ecologically important. Acoustic echosounders provide an excellent method for assessing the abundance and distribution of zooplankton over large areas (> 100 s km^2) through ship-based surveys and with high-temporal and spatial resolution. However, in order to accurately convert acoustic backscatter into a biologically meaningful measure (e.g., animal abundance, biomass, and calories), validated scattering models with well-understood input parameters are needed. This talk will present data from both Antarctic and Arctic (Bering Sea) zooplankton with regard to improvement of scattering models and the range and variability of model inputs for krill and other zooplankton, implications of these changes on acoustic estimates of zooplankton biomass or other metrics, and how these data may be used in ecosystem studies, particularly the relationships between zooplankton and their higher-trophic level predators.

1aAO6. Quantifying fish behavior with high-frequency scientific echo sounder and parametric sonar. Olav Rune Godø, Rolf J. Korneliussen (Inst. of Marine Res., P.O. Box 1870 Nordnes, N-5817 Bergen, Norway), and Kenneth G. Foote (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Schools of Norwegian spring-spawning herring (*Clupea harengus*) were observed in their wintering area off the northwest coast of Norway in November 2009 with the Simrad EK60 scientific echo sounder operating at 18, 38, 70, 120, and 200 kHz and Kongsberg TOPAS parametric sub-bottom profiling sonar, with nominal difference-frequency bandwidth 0.5–6 kHz. The beamwidths are 7 deg except at 18 kHz, where it is 11 deg. The TOPAS difference-frequency beamwidth decreases with both range and frequency, but lies within the range 3–5 deg at the depths of the detected schools, typically 50–300 m. The registered depths of the upper surfaces of the detected schools have been compared, indicating that the apparent depth often, but not always, is inversely related to beamwidth. The phenomenon seems to be related to the pattern of backscattering with respect to frequency within the same school, which appears to have two distinct modes. The results are analyzed and discussed relative to the phenomenon of gas release and avoidance reaction. 1aAO7. Target strength spectrum of Atlantic herring over a low-kilohertz frequency band. Kenneth G. Foote (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), Olav Rune Godø, Rolf J. Korneliussen, and Eirik Tenningen (Inst. of Marine Res., Nordnes, N-5817 Bergen, Norway)

Atlantic herring (*Clupea harengus*) in the stock of Norwegian spring-spawning herring were observed in their wintering area off the northwest coast of Norway in November 2009. The volume backscattering coefficient s_V was measured with the Simrad EK60/38-kHz scientific echo sounder, yielding numerical values of fish density ρ through the fundamental equation of echo integration $s_V = \rho\sigma$, where ρ is the mean backscattering cross section of the ensonified fish. Derived values of ρ were used to convert measurements of s_V made with the Kongsberg TOPAS PS18 parametric sub-bottom profiling sonar to infer σ, thence its logarithmic measure target strength, over the approximate difference-frequency band 1.5–6 kHz. [Work supported by ONR Award No. N000140910482 and Norwegian Research Council Grant No. 184705.]

1aBB1. Visualization of atherosclerotic plaque mechanical properties using model based intravascular ultrasound elastography. Michael S. Richards, Shayin Jing, and Marvin M. Doyley (Dept. Elect. and Comp. Eng., Univ. of Rochester, Rochester, NY 14627)

Cardiovascular disease related deaths occur primarily from fatty plaques inside an artery that rupture and cause clots that disrupt blood flow. The study of arterial plaque mechanics is essential to the monitoring of atherosclerosis and the detection of vulnerable plaques or the likelihood of their rupture. The aim of this work is to measure and image the mechanical behavior of plaques using a clinically available intravascular ultrasound system (IVUS). To test the methods, radial displacements were measured from simulated images and phantom data within two dimensional IVUS rf images using standard elastography techniques. Simulations and phantom experiments were designed to mimic arterial geometries and deformations, which include plaque regions of varying stiffnesses. In addition, an optimization inversion algorithm was used to infer the elastic modulus of the underlying material. This algorithm utilizes a finite element based model and assumes that the deformation is quasi-static, plane strain and that the material is incompressible and linear elastic. The full spatially reconstructed modulus images, with no geometric constraints, are presented and compared to radial strain images. The phantom results are compared to the known modulus contrasts, and the simulated images are compared to contrasts and distributions.

1aBB2. *In-vivo* time reversal blastography: A passive correlation tomography of complex shear wave field within in soft tissues. Stefan Catheline, Thomas Gallot, Philippe Roux, Javier Brum, and Carlos Negreira (Laboratoire de Gophysique Interne et Tectonophysique (LGIT), CNRS & Universit de Grenoble, France, stefan.catheline@obs.ujf-grenoble.fr)

Heartbeats, breathing, and muscle activity: the human body presents natural sources of vibration creating a complex shear wave field. Such a noise is demonstrated in this work to be useful for quantitative elasticity imaging. Indeed, the shear wave noise inside soft tissues is measured by ultrasonic techniques developed in elastography. The particle motions estimated along lines or planes inside the medium can be used as artificial stars for time reversal experiments. In another language, Green's functions can be recovered from noise correlations which results in a totally passive imaging technique. The use of shear wavelength or phase speed to reconstruct an elasticity mapping will be discussed.

8:30

1aBB3. Time reversal elastography: A correlation tomography of complex shear wave field in soft solids. Thomas Gallot, Stefan Catheline, Philippe Roux, Javier Brum, and Carlos Negreira (Laboratoire de Gophysique Interne et Tectonophysique (LGIT), CNRS & Universit de Grenoble, France, thomas.gallot@obs.ujf-grenoble.fr)

Shear waves in a soft solid can be focalized using time-reversal (TR) methods. The shear velocity, directly related to the elasticity of the medium, can be evaluated from the TR field. This study proposes to perform quantitative imaging of the mechanical properties inside a soft solid. Shear waves are created by finger impacts all over the surface of the solid. One component of the vectorial field inside the solid is measured by ultrasonic techniques developed in elastography. Inspired from Green's function retrieval methods, the TR field is computed from cross-correlation of this random-like displacement signal. One point is chosen as a virtual source where the spatio-temporal refocusing is observed. Thus the method allows focalization of shear wave everywhere inside the solid without any source embedded in the solid. The local shear velocity is then deduced from the TR field. Finally, a two dimensional velocity map of a bi-layer medium is performed.

1aBB4. Clutter and sources of image degradation in fundamental and harmonic ultrasound imaging. Gianmarco Pinton (Institut Langevin, Laboratoire Ondes et Acoustique, ESPCI, 10 rue Vauquelin, Paris 75005, France, gianmarco.pinton@gmail.com) and Jeremy Dahl (Duke Univ., Durham, NC)

Although harmonic imaging is used extensively, the mechanisms for image quality improvement are still poorly understood. Complex simulations or experiments that incorporate the effects of tissue heterogeneities and multiple scattering are required to describe image quality metrics such as clutter noise and less sensitivity to phase aberration. A finite difference simulation of ultrasonic propagation in a medium with heterogeneities in nonlinearity, attenuation, density, and speed of sound is presented. We investigate scattering from sub-wavelength targets and from macroscopic tissue structure. The simulated acoustic response from a single sub-wavelength scatterer is compared to analytical results for different scatterer sizes. This numerical implementation is then used to model tissue in the human body based on the visible human project and insonication from a from a 2.1-MHz diagnostic transducer. There is a close agreement between the analytical Rayleigh distribution, where the scattered intensity is proportional to f^4, and simulation. The primary source of image degradation in the fundamental PSF comes from reverberation in the near-field abdominal structures. Phase aberration is the largest source of clutter in the harmonic PSF. Clutter in the PSFs occurs primarily from low-level contributions distributed over a large area.

1aBB5. Feasibility study of superharmonic imaging using chirps. Paul L. M. J. van Neer, Mike G. Danilouchkine, Guillaume M. Matte (Dept. of Biomedical Eng., Erasmus Medical Ctr., Rm. Ee 23.32, Dr. Molewaterplein 50, 3015 GR Rotterdam, The Netherlands, p.vanneer@erasmusmc.nl), Martin D. Verweij (Delft Univ. of Technol., Mekelweg 4, 2628 CD Delft, The Netherlands), and Nico de Jong (Erasmus Medical Ctr., 3015 GR Rotterdam, The Netherlands)

Superharmonic imaging (SHI) targets a combination of the third to fifth harmonics. It was proven to have certain advantages in comparison with the established imaging standards in medical ultrasound. SHI enhances the spa-

tial resolution and improves the quality of echographic images, mainly by eliminating reverberation artifacts at the chest wall. However, SHI suffers from ripple artifacts, originating from the spectral gaps in between harmonics, and degrading the temporal resolution. To solve this a chirp-based SHI protocol was employed and its characteristics investigated, i.e., point spread function (PSF). The protocol was implemented for an interleaved phased array probe (44+44 elements tuned at 1.0+3.7 MHz), connected to a fully programmable ultrasound system. A linear chirp (center frequency 1 MHz; bandwidth 40%) was used for excitation. To obtain the PSF, the rf traces were recorded at focus along the lateral axis and convolved with the decoding signal. This was computed using KZK simulations. A PSF comparison between a superharmonic chirp and the third harmonic of a 2.5-cycle Gaussian apodized sinus burst at 1 MHz showed a decrease in axial pulse length of 46% at −6 dB and 32% at the −20 dB level in favor of SHI. Chirp based SHI is virtually free of ripple artifacts and therefore feasible.

1aBB6. Kramers–Kronig relationships applied to shear wave propagation in soft tissues. Matthew W. Urban, Shigao Chen, Carolina Amador, and James F. Greenleaf (Dept. of Physio. and Biomedical Eng., Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55905, urban.matthew@mayo.edu)

Multiple methods have been proposed to characterize the viscoelastic material properties of soft tissues to differentiate normal from pathological tissue. Shearwave dispersion ultrasound vibrometry is a method that uses the dispersion of the shear wave velocity to characterize tissue shear elasticity and viscosity. It has recently been shown [M. W. Urban and J. F. Greenleaf, Phys. Med. Biol. **54**, 5919–5933 (2009)] that the Kramers–Kronig relationships can be applied to shear wave measurements in *ex vivo* skeletal muscle over a frequency bandwidth of 100–600 Hz. We will describe this process where shear wave attenuation is modeled using a power law, and the shear wave velocity dispersion is predicted by applying the Kramers–Kronig relationships. In this study, we apply this method to shear wave propagation measurements made in different soft tissues such as *ex vivo* porcine skeletal muscle and kidney and *in vivo* porcine liver. The shear wave velocity predictions using the Kramers–Kronig relationships agree with the velocity measurements. The mean square error for these tissues ranged from 0.0024–0.0625 m^2/s^2. The Kramers–Kronig relationships can be used in shear wave propagation measurements in different types of soft tissues. [This work was supported in part by NIH Grants Nos. EB002167 and DK082408.]

1aBB7. Visualizing the functional properties of life-threatening atherosclerotic plaques using targeted ultrasound contrast agent and intravascular ultrasound. M. M. Doyley, H. Shekhar (Dept. of Elec. and Comput. Eng., Hopeman Eng. Bldg., Univ. of Rochester, Rochester, NY, doyley@ece.rochester.ed), J. S. Allen (Univ. of Hawaii-Manoa, Honolulu, HJ), and J. Rychak (Targeson, Inc., La Jolla, CA 92037)

Acute coronary syndromes may occur when life-threatening atherosclerotic plaques rupture in the later stages of advance cardiovascular disease. Coronary angiography is currently the gold standard for assessing the severity of coronary disease; however, its efficacy is questionable. We have developed a prototype intravascular ultrasound (IVUS) system to assess the functional properties (i.e., inflammation or angiogenesis or both) of atherosclerotic plaques and the arterial wall. In this paper, we report on the results of flow studies that were conducted to assess the nonlinear acoustic behavior of a novel perflourocarbon ultrasound contrast agent, Targestar, at high-transmit frequencies (30 and 40 MHz). Pulsatile flow studies were conducted with vessel phantoms. The subharmonic response of the targeted and non-targeted agents by applying an eight-order band-pass filter to the digitized radio-frequency echo frames. We compared the fundamental and subharmonic signals in absolute and relative terms using paired t-tests. SHI IVUS improves the visualization of the plaque relative to the main vessel, and the subharmonic behavior of the bubbles compared favorable to our theoretical expectations.

9:45

1aBB8. Estimating ultrasound attenuation along the propagation path using a reference phantom. Yassin Labyed and Timothy Bigelow (Dept. of ECpE, Iowa State Univ., 2215 Coover Hall, Ames, IO 50011)

The objective of this study is to develop an algorithm that uses backscattered data to estimate the total attenuation of ultrasound along the propagation path. The sample and a reference phantom are scanned using the same transducer and same power settings. The power spectrum of the gated window in the ROI of the sample is divided by the power spectrum of the reference phantom. The resulting ratio is then multiplied by four Gaussian filters at four different center frequencies to obtain four new spectra. The center frequency of each new spectrum is equal to the center frequency of the Gaussian filter shifted by a term that is proportional to the total attenuation. The total attenuation is calculated by monitoring the shift in the center frequencies of the new spectra with respect to the center frequencies of the Gaussian filters. The algorithm is tested using rf data generated by computer simulations. The sample and the reference had attenuation coefficients 0.7 and 0.5 dB/cm MHz, respectively. The error in the attenuation estimate is less than 5% for an ROI that is five pulse lengths long and contains 50 independent beam lines. [Work supported by NIH Grant CA111289.]

1aBB9. Effective scatterer size estimation based on mathematical form factors in a rat fibroadenoma model. Lauren A. Wirtzfeld (Bioacoustics Res. Lab., Elec. and Comput. Eng., Univ. of Illinois, 405 N. Mathews, Urbana, IL, 61801, lwirtz@uiuc.edu), Zachary T. Hafez, Ellora Sen-Gupta, Andrew P. Battles, Rita J. Miller, Sandhya Sawarte, Michael L. Oelze (Univ. of Illinois, Urbana, IL, 61801), Timothy J. Hall (Univ. of Wisconsin, Madison, WI, 53705), and William D. O'Brien, Jr. (Univ. of Illinois, Urbana, IL, 61801)

Quantitative ultrasound imaging is a model-based approach aimed at lesion detection and classification. In this study, the backscattered rf from rat fibroadenomas was fitted to two mathematical models to yield effective scatterer diameter (ESD). The goal was to aid in understanding potential sources of scattering in live rat tumors. Data were acquired using three single-element transducers with center frequencies of 3.5, 7.5, and 13 MHz. Reference scans were acquired from a Plexiglas plate. Two different theoretical models of scattering were fitted to the data; a fluid filled sphere model, which does not support shear waves, and the spherical Gaussian model for the scatterer. Twenty histologically confirmed fibroadenomas were analyzed. The ESD values obtained spanned the range of typical acini sizes observed in the histology of the fibroadenomas, from approximately 50 μm with the 13-MHz transducer up to 200–300 μm with the 3.5-MHz transducer. The estimates from the Gaussian model were consistently higher than for the fluid filled sphere. The estimates of ESD decreased with increasing frequency, and microstructures corresponding to these different scales were observed in histology. [Work supported by NIH Grant R01CA111289.]

10:45

1aBB10. Inter-comparison of ultrasonic backscatter coefficient measurements of live rat fibroadenomas across multiple imaging platforms. Lauren A. Wirtzfeld (Bioacoustics Res. Lab., Elec. and Comput. Eng., Univ. of Illinois, 405 N. Mathews, Urbana, IL 61801, lwirtz@uiuc.edu), Goutam Ghoshal, Zachary T. Hafez (Univ. of Illinois, Urbana, IL 61801), Kibo Nam (Univ. of Wisconsin, Madison, WI 53705), Yassin Labyed (Iowa State Univ., Ames, IA 50011), Janelle A. Anderson, M-Teresa Herd (Univ. of Wisconsin, Madison, WI 53705), Rita J. Miller, Sandhya Sawarte (Univ. of Illinois, Urbana, IL 61801), James A. Zagzebski (Univ. of Wisconsin, Madison, WI 53705), Timothy A. Bigelow (Iowa State Univ., Ames, IA 50011), Timothy J. Hall (Univ. of Wisconsin, Madison, WI 53705), Michael L. Oelze, and William D. O'Brien, Jr. (Univ. of Illinois, Urbana, IL 61801)

The backscatter coefficient (BSC) as a function of frequency is a system and operator independent parameter. It is the basis for some quantitative ultrasound (QUS) based on spectral analysis being translated into clinical use. This study aims to extend previous work in well-characterized physical phantoms to live animals where tissue properties are unknown. Six Sprague Dawley rats with spontaneous mammary tumors (five fibroadenomas and one carcinoma) were imaged with three clinical systems (Zonare Z.one, Ul-

trasonix RP, and Siemens S2000) and one single element laboratory system. Data were acquired from approximately the same region of the tumor with each scanner using independent setups. Scans of a reference phantom and Plexiglas plate were acquired for the clinical and laboratory systems, respectively. The data were analyzed using methods developed by the respective research group. BSC versus frequency plots show agreement in magnitude and trend among the different systems. The BSC estimates overlap each other, showing no more variability between systems than between consecutive imaging planes demonstrating agreement across multiple platforms and varied processing techniques between laboratories. Results support the potential to base diagnoses on QUS parameters. [Work was supported by NIH Grant R01CA111289.]

11:00

1aBB11. Array measurement and imaging of sound transmission through the lungs. Zoujun Dai, Ying Peng, and Thomas J. Royston (Univ. of Illinois at Chicago, Chicago, IL 60607, daizoujun@gmail.com)

Non-contacting scanning laser Doppler vibrometry (SLDV) was used to measure torso surface motion at an array of points caused by sound introduced into the lungs in human subjects. The SLDV serves as a gold standard as it does not have the complexity of surface contact dynamics. Additionally, a sensor array integrated into a compliant mesh fabric chair was constructed and tested as a less expensive and faster means of acquiring similar acoustic array data. Silicone gel-coupled, piezoelectric contact sensors for the detection of subsurface acoustic sources at the skin surface were used in the array. Array measurements were processed to determine the response at each measurement point as a function of frequency up to 1.6 kHz. Acoustic images were generated indicating the amplitude level at each point relative to the amplitude measured at the suprasternal notch, which served as the reference input. The acoustic measurements illustrated the complexity of sound transmission in the human lung and chest. Expected attenuation over the scapulae and below the diaphragm was observed. There were other significant variations as a function of location and frequency; measurement results are discussed. [Work supported by NIH Grant # EB008373.]

11:15

1aBB12. Simulations for investigating contrast mechanism of biological cells with high-frequency scanning acoustic microscopy. Yada Juntarapaso (Graduate Program in Acoust., The Penn State Univ., Univ. Park, PA 16802) and Richard L. Tutwiler (The Penn State Univ., State College, PA 16804-0030)

Scanning acoustic microscopy (SAM) is one of the most powerful techniques for nondestructive evaluation and it is a promising tool to characterize the elastic properties of biological tissues/cells. Exploring a single cell is important since there is a connection between single cell biomechanics and human cancer. SAM provides advantages for investigating cells in the fact that it is non-invasive, provides elastic properties information in sub-cellular details, and no chemical stain on the cells. The first goal of this research is to develop a program for simulating the images and contrast mechanism obtained by high-frequency SAM. We focus on the mechanical and acoustical properties of HeLa cells, which can be analyzed from the $V(z)$ response. Two new algorithms for simulating $V(z)$ responses involve calculation of reflectance function for coupling medium/cell/substrate system, and are constructed based on ray theory and wave theory (angular spectrum). The second goal is to design/optimize transducer arrays for SAM. One-dimensional and two-dimensional (2-D) linear array and phased arrays are simulated using FIELD II program to analyze image resolution and volumetric imaging capabilities. The new 2-D array design will enhance the performance of SAM by electronically scanning and by providing a four-dimensional image of the cells development phase.

Session 1aMU

Musical Acoustics: String Instruments

Paul A. Wheeler, Chair
Utah State Univ., Electrical and Computer Engineering, 1595 N. 1600 E., Logan, UT 84341

Invited Papers

9:30

1aMU1. Traditional string instruments of the world. Paul A. Wheeler (ECE Dept., Utah State Univ., 4120 Old Main Hill, Logan, UT 84322-4120, paul.wheeler@usu.edu)

The string instruments best known to musicians, educated in western music, are the orchestral strings (violin, viola, cello, and double bass) with the addition of the guitar and harp. This represents a very small sample of string instruments used throughout the world. This paper is intended to introduce the variety of string instruments used in traditional music of world cultures. The instruments include the following: (1) musical bows—the berimbau of Brazil; (2) African and European lyres—the krar of Ethiopia and crwth of Wales; (3) harps—the ennanga of Uganda, saung gauk of Burma, and the Paraguyan harp; (4) plucked lutes—the charango of the Andes of Arabia, the balalaika of Russia, sitar of India, and the pipa of China; (5) fiddles (bowed lutes)—the hurdy-gurdy and nyckelharpa of Europe, the imzad of North Africa, the sarangi of India, and the morin khuur of Mongolia; (6) plucked zithers - the valiha of Madagascar, kantele of Finland, dan bau of Vietnam, and the zheng of China; and (7) dulcimers (hammered zithers)—the cimbalom of Hungary, santoor of Iran, and the yangqin of China.

10:00

1aMU2. Contemporary approaches to modeling violin tone, dynamics, and response. F. J. Denaro (Dept. of Biology, Morgan State Univ., 1700 East Cold Spring Ln, Baltimore, MD 21251)

Long-time-average spectral graphs of violin tone reveal some important characteristics of excellent instruments. Included are good dynamic range and frequency response. Significantly there is a marked response in the 194–649 Hz range (high sonority), a lower response for 649–1296 Hz (nasal), good response for 1830–4342 Hz (brilliance), and low response in the 4340–6300 Hz (harsh) [H.

Dunnwald, Catgut. Acoust. Soc. J. **1**, 1–5 (1991)]. In this talk a working protocol on how to modify the frequency response in each of these areas is explained. Important insights obtained from the burnish/hydrate (B/H) method will be used to illustrate how this can be done in a systematic fashion. The B/H method produces reversible stiffness changes in the plate area of choice. As a result it is possible to evaluate the change in tone and response by listening or by acoustical measurements. If the change is a desired one, it can be made permanent by removing the wood. While the frequency ranges noted above display a degree of interdependence, addressing them independently has led to a general pattern on where the needed plate and corpus modifications should be placed for an excellent violin.

10:30—10:45 Break

Contributed Papers

10:45

1aMU3. High-speed imaging techniques for harpsichord plucking action. Marshall J. Brown (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, mjbrown3@uno.edu), C.-Y. Jack Perng (Stanford Univ., Stanford, CA), Thomas D. Rossing (Stanford Univ., Stanford, CA), and Juliette W. Ioup (Univ. of New Orleans, New Orleans, LA)

Harpsichords contain vibrating strings whose motion has been studied extensively. The harpsichord sound is produced by a plectrum plucking the string, a behavior not well modeled at present. A high-speed video camera is used to image sequentially the plucking action of a harpsichord plectrum of modern plastic. This action is quite complicated and highly impulsive, too fast for the human eye to register. The tongue holding the plectrum moves backward in the escapement as well as when the plectrum slips by the string as the jack returns to its rest position. The plectrum may contact the string more than once during these events. The high-speed camera is a Casio Exilim Pro EX-F1, capable of 1200 frames/s. To study the plectrum action, monochords and harpsichords were used. One of the major difficulties with high-speed camera images provides sufficient light while maintaining CMOS saturation and keeping image coherence maximized for the fast shutter action. Various solutions to this problem were tested, including using direct sunlight. Further problems encountered (such as CMOS color response) will be described and their solutions discussed. Images show the plucking, the escapement, the plectrum motion, and the string excitation in detail during the plucking action.

11:00

1aMU4. Toward the modeling of harpsichord plucking. Chao-Yu J. Perng (Dept. of Phys., Stanford Univ., 382 Via Pueblo Mall, Stanford, CA 94305, perng@stanford.edu), Thomas D. Rossing (Stanford Univ., CA 94305), Marshall J. Brown, and Juliette W. Ioup (Univ. of New Orleans, New Orleans, LA 70148)

The harpsichord's plucking action is much less studied than the piano's hammer striking action. A theoretical model was first proposed [D. H. Griffel, J. Sound Vib. **175**, 289–297 (1994)] treating the plectrum as a rigid body or two rigid bodies connected with a torsional spring. This was later investigated experimentally [N. Giordano and J. P. Winans II, J. Sound Vib. **224**, 455–473 (1999)] using a capacitive sensor, resulting in a more refined model based on simple one-dimensional beam dynamics. In our work, we employ various string position sensors, and a more detailed plucked string trajectory is captured and analyzed. Also aided by high-speed camera images, studies on the detailed plectrum's shape of deflection are done. By a more rigorous treatment of elastic beam theory and looking into interactions of the plectrum and string after the initial release, we present a revised model on the plucking mechanism of the harpsichord string that contributes to its characteristic tone quality.

11:15

1aMU5. Haptic interaction for music with unrestricted freedom of the musician's motion: Promoting augmented interaction with physical tools. Edgar Berdahl, Gunter Niemeyer, and Julius O. Smith, III (Dept. of Music, CCRMA, Stanford Univ., Stanford, CA 94305, eberdahl@ccrma.stanford.edu)

A haptic musical instrument is an electromechanical musical instrument that provides a musician not only with audio feedback but also with force feedback. Many commercial force feedback devices consist of a tool, such as a thimble or pen, attached to the end of a robotic arm. The musician can grab onto the tool and use it to manipulate a virtual musical instrument. While this configuration provides multiple degrees of freedom, it is suboptimal for many musical interactions. For instance, typically the workspace of the arm is restricted, which can detract from the musician's enjoyment of the experience. The workspace restriction can be resolved by freeing the tool from the end of the haptic device and having the musician hold the tool, which may be a plectrum, bow, or drumstick, in his or her hand. Further benefits can be reaped if multiple points of haptic interaction are available, enabling the musician to manipulate the points and move freely in between them. A dual voice coil woofer provides a convenient collocated sensor /motor for constructing a single degree-of-freedom point of haptic interaction. We present an example instrument in which a musician employs a conventional plectrum to interact with a virtual digital waveguide string.

11:30

1aMU6. Acoustic changes produced by hydration and burnishing of violin plates. F. J. Denaro (Dept. of Biology, Morgan State Univ., 1700 East Cold Spring Ln, Baltimore, MD 21251) and M. R. Serbyn (Morgan State Univ., Baltimore, MD 21251)

To achieve the proper balance of tone and loudness throughout the frequency range of a fine violin, various methods of plate tuning have been proposed. Unfortunately, their effectiveness can be judged only *a posteriori*, for even if a violin plate response is well characterized, where to work the wood is poorly known. What is needed is a process that does not remove wood until the desired acoustical characteristics are produced regardless of the method used. The technique proposed by us consists of systematic hydrations and/or compressional burnishing of focal areas of the violin plates or corpus. Hydration is acoustically equivalent to a decrease in stiffness, while burnishing increases stiffness. Both are reversible without marked changes to the wood. In order to establish how these treatments affect the material constants of the plates, strips of maple and pine were tested in both treated and untreated states and the changes noted. Results suggest temporary changes to plate stiffness. The magnitude of these changes is sufficient to affect acoustic signatures and holographic patterns and hence can be detected. The accumulative effects of such changes to violin tone are noted in our companion paper.

11:45

1aMU7. Systematic optimization of violin tone by an acoustically reversible approach: The burnish/hydration technique. F. J. Denaro (Dept. of Biology, Morgan State Univ., 1700 East Cold Spring Ln, Baltimore, MD 21251) and M. R. Serbyn (Morgan State Univ., Baltimore, MD 21251)

The companion paper supports the hypothesis that focal alterations to the stiffness of the wood can be produced by compressional burnishing or hydration of discreet areas of the plates or corpus. The effects of both burnishing and hydration are reversible. Therefore, one has real-time-feedback for modeling optimal violin tone. As a result only those acoustic changes which are desired are made permanent by removal of wood. To develop proof of concept we applied this approach to both top and back plates and to violins in the white. The experiments consisted of evaluation of tap tone frequencies and evaluating violins played in the white. Standard recording- and signal-analysis equipment was used. The conclusions drawn from measurements correlated well with those from listening, that is, incremental changes in the tone produced by this technique can guide the carving of the plates. An important strength of the technique is that it can be applied with other

methods of plate tuning, namely, tap-tone methods, holographic techniques, computer analysis, etc. The approach should provide a valuable adjunct in making instruments of the violin family.

12:00

1aMU8. Estimation of loop filter coefficient for the silk stringed instruments. Sangjin Cho and Uipil Chong (School of Elec. Eng., Univ. of Ulsan, Ulsan, Republic of Korea, sjcho75@ulsan.ac.kr)

It is very important to represent an exact attenuation of a sound in a physical modeling of the plucked string instruments. Vlimki *et al.* proposed a simple one-pole low-pass filter called loop filter to depict the attenuation of the sound in the extended KS algorithm. In order to estimate the filter coefficient, attenuations and gains of each harmonic are measured and calculated, respectively. The coefficient can be obtained by using the mean squared error between magnitude response of the filter and the gains of each harmonic. In this case, unlike steel stringed instruments, the accuracy of filter coefficient estimation for the silk stringed instruments depends entirely upon choosing the specific region of the recorded sound. In this paper, 84 different notes of the silk stringed instrument called Gayageum, Korean traditional plucked-string instrument, were recorded, and estimation of filter coefficient was performed for the following regions: entire, decay, sustain, and RT1 (reverberation time) region. The estimation results were good in order of decay, RT1, sustain, and entire region. Especially, the performance for the decay region was very good. [This work was supported by the Korea Science and Engineering Foundation (KOSEF) grant funded by the Korea government (MEST) (No. R01-2008-000-20493-0).]

Chair's Introduction—8:00

Invited Paper

8:05

1aNCa1. Sonic boom: From bang to puff. Kenneth J. Plotkin (Wyle Labs., 241 18th St. S., Ste. 701, Arlington, VA 22202, kenneth.plotkin@wyle.com)

For almost 40 years commercial supersonic flight over land has been prohibited because of the negative impact of sonic booms. During that time, technology advances have raised the possibility of a muted sonic boom—a sonic "puff"—that could be acceptable over populated areas. This paper reviews the physics of sonic boom generation and propagation, and why booms from conventional aircraft are usually *N*-waves with unacceptably large shock waves. The low-boom shaping technology that can minimize shocks, thus reducing sonic boom loudness to acceptable levels, is presented. The success of the DARPA/NASA Shaped Sonic Boom Demonstrator in validating shaping theory is discussed. Concepts for attaining practical aircraft configurations, versus ideal optimal shapes, are described.

8:45—8:50 Questions

8:50—9:00 Announcements

Session 1aNCb

NOISE-CON: Materials for Noise Control—Manufacturer Presentations

Stephen I. Roth, Chair
Roth Acoustical Associates, 2352 Norton Rd., Pittsburgh, PA 15241

Contributed Papers

9:15

1aNCb1. Effect of intrinsic parameters on sound absorption and transmission loss: A parametric study. Paresh Shravage, Sachin Jain, and Nagesh Karanth (Automotive Res. Assoc. of India, Noise Vib. and Harshness Lab, Automotive Res. Assoc. of India (ARAI), S. No 102, Vetal Tekadi, Off Paud Rd., Kothrud, Pune 411038, India pareshshravage@gmail.com)

Sound absorbing materials are indispensable nowadays for noise control treatments in transport industry. The acoustical behavior of these acoustic materials is governed by five physical (e.g., porosity, flow resistivity, tortuosity, viscous characteristic length, and thermal characteristic length) as well as three mechanical parameters (e.g., Young's modulus, Poisson ratio, and loss factor). The characterization of these porous materials is very crucial as it plays an important role in design and development stage itself for predicting acoustic behavior of multilayer porous materials for higher sound absorption and transmission loss. This prediction depends on measurement accuracy of macroscopic physical parameters which are very difficult to measure except porosity and flow resistivity, which is the only standardized test until today; also availability of such rigs is also a problem for manufactures as they are available only at specialized test laboratories. This paper presents effect of all of these parameters on sound absorption coefficient and transmission loss of the porous materials using Johnson—Champoux—Allard and Biot model for poroelastic materials. It also discusses results of simulation with effect of each parameter on acoustic behavior of the sound absorbing materials.

9:30

1aNCb2. A comparison of analytical and optimization inverse techniques for characterizing intrinsic parameters of porous materials. Paresh Shravage, Sachin Jain, and Nagesh Karanth (Noise Vib. and Harshness Lab, The Automotive Res. Assoc. of India (ARAI), Survey No. 102, Vetal Hill, Off Paud Rd., Kothrud, Pune 411 038, India, pareshshravage @gmail.com)

In recent years, sound absorbing materials are finding many applications in transport industry. In automobiles, they are used as noise control treatments in engine compartment as well as in passenger cabin. To understand and simulate acoustic behavior of these noise control treatments, intrinsic physical parameters are required. The acoustical behavior of poroelastic material is governed by five macroscopic intrinsic parameters, e.g., porosity, flow resistivity, tortuosity, and characteristics lengths as well as three mechanical parameters. Out of these five physical parameters, porosity and flow resistivity can be measured directly by available standardized methods. But measurement of physical parameters such as tortuosity, viscous, and thermal characteristic lengths is very difficult and no accepted procedure is available for their measurement. As an alternative, analytical inverse approach (mid-frequency) and optimization technique Genetic algorithm are well known in the literature. This paper compares the results from both techniques for intrinsic parameters. It also presents the effect of inverted parameters on sound absorption and transmission loss of the porous materials using Johnson–Champoux–Allard model.

9:45

1aNCb3. Hand troweled and spray applied sound absorbing acoustical plasters. Howard Podolsky and Andrew Sarcinella (Pyrok Inc., 121 Sunset Rd., Mamaroneck, New York 10543, howard@pyrok.com)

This paper will discuss the types of hand applied and spray applied sound absorbing acoustical plasters manufactured by Pyrok Inc. Pyrok Acoustement products are spray applied acoustical plasters which are formulated with gypsum plaster or Portland cement. The Portland cement Acoustement 40 can be used for exterior as well as interior applications. Acoustment Plaster 20 and Acoustment Plaster 40 are gypsum based and are for interior applications only. The Pyrok StarSilent System has a smooth hand trowel applied finish that looks like monolithic drywall as well as a superfine sprayed finish. This paper will also discuss ASTM C423 testing and how it relates to spray and hand applied acoustical plasters. Although all spray applied and hand applied sound absorbing products are tested to ASTM C423, there are differences and inconsistancies when evaluating and comparing their sound absorption data.

10:00

1aNCb4. Numerical study of noise transmission through functionally graded panels. Changzheng Huang and Steve Nutt (Dept. of Chemical Eng. and Mater. Sci., Univ. of Southern California, 3651 Watt Way, VHE 602 Los Angeles, CA 90089-0241, changzh@usc.edu)

Functionally graded panels are panels made of either functionally graded materials (FGMs) or functionally graded structures. FGM panels are traditionally used as thermal insulation barriers and they find applications in space and launch vehicles. Functionally graded structures include foams with continuous variations in pore size from one side to the other side. Such foams are incorporated as the core layer in sandwich panels. The latter is often used as partition walls in the building and transportation industries. In this study, we are concerned with the noise transmission characteristics of functionally graded panels. We developed an analytical model to derive the transfer matrix for the functionally graded medium. Using this model, we were able to make numerical predictions for sound transmission through functionally graded panels. The gradation parameter provides an additional degree of freedom in controlling the noise transmission characteristics. This is helpful in maximizing the noise reduction in panel design. Furthermore, our transfer matrix model applies to conventional discretely layered panels as well. In fact, the latter is just a special case in our modeling formulation. Numerical examples and results are presented and discussed.

10:15—10:30 Break

10:30

1aNCb5. Achieving minimum impact insulation class 50 rating using resilient clip technology in lightweight construction. Wilson Byrick (Pliteq Inc., 1370 Don Mills Rd., Unit 300 Toronto, ON M3B 3N7, Canada, wbyrick@pliteq.com)

Resilient clip technology is an alternative to resilient channel for supporting gypsum wallboard in fire rated wall and floor-ceiling assemblies. Lightweight wood frame construction presents challenges in meeting building code requirements for impact insulation class (IIC) and sound transmission class (STC) ratings in floor-ceiling assemblies. Through laboratory testing we were able to compare different floor-ceiling assemblies commonly used in multi-family construction. Two different structures were tested, an 18 in. open web truss, 24 in. o.c., and a 12 in. engineered joist (TJI) 24 in. o.c. Various finish floor coverings were used including ceramic tile, vinyl, and engineered wood. Structures achieved minimum IIC and STC 50 with

and without 3/4 in. Gypsum concrete. Resilient rubber underlayment of varying thickness can further improve the IIC and STC ratings of the assembly as can adding a second layer of gypsum wallboard.

10:45

1aNCb6. Quieting small centrifugal fans: A material manufacturer's view. Steven M. Brown and Dan LaForgia (The Soundcoat Co. Inc., 1 Burt Dr., Deer Park, NY 11729, sbrown@soundcoat.com)

Noise control treatments have been developed for small centrifugal fans in fan trays. The fan trays are employed in cooling mobile electronics equipment. Similar treatments can be employed in stationary equipment racks used in the information technology and telecom industries. The noise control treatments incorporate especially sculpted sound absorbing material. This paper discusses the considerations used in developing the treatments, the resulting sculpted design of the treatments, and the acoustical material used in producing the treatments. The achieved noise reductions are presented. Comments are made on the resultant improvements in airflow and accompanying cooling capacity.

11:00

1aNCb7. Heating, ventilation, and air conditioning flexible duct acoustical solutions. Neil Silverman (Flexmaster USA, Inc., 4545 Pine Timbers # 324, Houston, TX 77041, neil@flexmasterusa.com)

Flexmaster USA has been manufacturing the highest quality flexible duct available for commercial applications for over 30 years and has a wide array of selections. There are three very distinct choices, type 6, type 8, and our Medical Grade Triple Lock Acoustical that have been tested by Energistics Laboratory, which is a research and test facility dedicated to the HVAC industry. The testing for Flexmaster USA's type 6, SPUN BOND Nylon, type 8, chlorinated polyethylene (CPE) fabric, and model MGA TLM (aluminum corrugated flexible duct) has shown significant reduction in sound. In other words, they absorb unwanted sound, including the most important mid-range frequencies. Our products listed here will significantly reduce unwanted noise in all of your rooms. These products allows sound—not air flow—to permeate through the liner and become absorbed inside the insulation. Each 6 in. test specimen was tested both straight and with a 90 deg bend for velocities of 0 FPM, 500 FPM, and 1000 FPM and compared to hard metal duct at the same velocities. Diameters of 6 in. thru 16 in. were provided by Flexmaster USA directly to Energistics Laboratory for the testing that was concluded in July of 2006. Unique to others in the industry, Flexmaster USA manufactures flexible duct without the use of glues or adhesives. The mechanical-locked inner core maintains its shape

11:15

1aNCb8. Low-mass–high-transmission loss portable speech isolation room for very important person protection. Mark Rubino (Industrial Noise Control, Inc., 401 Airport Rd. North Aurora, IL 60542, MRubino @industrialnoisecontrol.com)

This case study examines the design, construction, and testing of a lightweight, easily transportable speech isolation room capable of providing substantial anti-eavesdropping countermeasures for use by high-level government and intelligence agencies as a secure meeting and communications center that can be readily deployed worldwide. The performance criteria requiring a minimum field STC-35 utilizing a modular, scalable mechanical design capable of repeated assembly without the use of tools, a maximum component weight of 2.65 lb/ft^2 a 2 in. maximum wall thickness, and the incorporation of active and passive ventilation required the development of a robust, multi-layered composite panel and joining system as well as ancillary components. Using a combination of non-metallic limp mass and rigid metallic barriers separated by decouplers of varying properties in an aluminum shell brake-formed to distort natural resonance, we were able to achieve significant transmission loss (up to 45 dB) in the speech range of frequencies equaling the performance of commercially available products of nearly twice the weight and bulk. Interior room acoustical characteristics were optimized by using modular demountable sound absorptive units.

11:30

1aNCb9. Modular room design. Craig D'Anna (Industrial Acoust. Co., 1160 Commerce Ave., Bronx, NY 10462, cdanna@industrialacoustics.com)

Modular acoustical panels have been used to construct noise control enclosures at least since the early 1950s. This paper presents examples of the early days of modular acoustical enclosures and illustrates the current state of the art where pre-engineered acoustical panels are used to construct acoustical environments for Music Practice, Broadcast Facilities, Recording Rooms, and Sensitive Compartmented Information Facilities in a shorter period of time and at a lower cost than traditional drywall construction. Numerous examples are presented illustrating how, through the use of pre-engineered acoustical panel systems, manufacturers are able to guarantee the acoustical characteristics of a space while maintaining the ability to expand, demount, and relocate the rooms at a later point in time. The benefits of a no-hassle installation and acoustic guarantee, as well as multiple options for fit and finish that will equal the best craftsman's fine handiwork, are presented.

11:45

1aNCb10. Pearl Palms concert theater. Steven Udolph (Tectum Inc., P.O. Box 3002, Newark, OH 43058, sudolph@tectum.com) and Tera Aurther (Badertscher Communls)

The Pearl Theater was designed and built to meet the demands of both the sophisticated local market and the demanding high-end tourist market in Las Vegas, NV. These markets will quickly dismiss any venue that does not deliver a superior performance, as will the performers that a venue like this must attract in the highly competitive environment, that is, Las Vegas. The Pearl delivers for the audience, the performers, and the owners. Studio X at the Palms is the largest and best-equipped recording facility ever built in Las Vegas. The Pearl Concert Theater is hard wired to the studio to allow artists to conveniently and cost effectively create albums of their live performances in the theater. For the owners to realize a return on their investment in these facilities, the acoustics in the 3294 sq.ft theater had to be impeccable. But the need for a sophisticated sound environment was just the beginning. The aesthetics of the 2400-seat theater were also a major priority. To address both concerns, Dean Roofing & Insulation installed 25000 sq. ft of Tectum 1 in. panels in all of the traffic ways and throughout the theater. The Tectum panels and the seats are the only sound absorbing materials used in this project.

Session 1aNCc

NOISE-CON, Noise, and Signal Processing in Acoustics: Active Noise Control

Marty Johnson, Chair
Virginia Tech, 143 Durham Hall, Blacksburg, VA 24061

Contributed Papers

9:15

1aNCc1. A novel delayless frequency-domain filtered-x least mean squares algorithm for active noise control. Jie Duan and Teik Lim (Univ. of Cincinnati, 730 Riddle Rd., Apt. 205N, Cincinnati, OH 45220, duanjieee02@gmail.com)

The delayless frequency-domain implementation of least mean squares (LMS) algorithm is attractive because it can eliminate undesired block delay in the signal path while still remain the advantages of the frequency-domain LMS algorithm. However, the conventional delayless frequency-domain LMS experiences difficulties in slow convergence when it is applied to harmonic signal control at some frequencies. In this study, an overlap-save implementation of the delayless frequency-domain LMS algorithm is proposed to overcome the convergence problem mentioned above. Simulations show that the proposed implementation has better performance than the original one either in the pure tone application or in the vehicle powertrain noise application.

9:30

1aNCc2. Active noise control of magnetic resonance imaging scanner using inverse modeling technique. Mingfeng Li, Brent Rudd, and Jing-Huei Lee (Mech. Eng., Univ. of Cincinnati, 584-D Rhodes Hall, P.O. Box 210072, Cincinnati, OH 45221-0072, limf@ucmail.uc.edu)

In active noise control applications, internal model control (IMC) is a strategy to convert from feedback to feedforward control. In this configuration, the optimal solution of the controller will be the inverse model of the secondary path. However, the inverse model of the secondary path may not always exist. In fact, for the non-minimal phase system, the inverse model is unstable. In this case, the non-causal or delayed version of the inverse model will be employed. In general, this approach is not suitable for active noise control if the objective is to treat broadband noise. However, for harmonic signal control, this is not an issue. Magnetic resonance imaging (MRI), a procedure for medical diagnosis and biomedical research, generates undesirable levels of acoustic noise emission. The noise is normally dominated by clusters of harmonics throughout the audio spectrum. Due to its tonal nature, MRI noise control is a candidate for IMC. In this paper, an active noise control scheme using the inverse modeling technique is proposed and studied for pre-recorded MRI noises obtained during operation of a 4T whole-body MRI scanner. The recorded MRI noise is played back through a stereo system in a sound quality room and controlled using a headset equipped with the proposed active controller. The results demonstrate almost 20 dB reduction can be achieved.

9:45

1aNCc3. Active noise control of multiple cooling fans. Ryan Rust, Jonathan Blotter, Scott Sommerfeldt, and Kent Gee (Brigham Young Univ., 435 Crabtree Bldg., Provo, UT 84602, ryrust@gmail.com)

Fans are used to dissipate heat from electronic devices to keep the components working properly but create noise as a byproduct. Multiple fans are often needed in computer servers and other types of electronic equipment to adequately cool them. The fan array increases the cooling rate but also increases the noise produced. In addition to the added noise, differences between fans due to manufacturing cause the fans to rotate at different speeds, creating an annoying beat frequency. Feed forward active noise control was studied for an exhaust mounted two fan array using near field error sensors and control speakers. The tonal noise content of the blade passage frequency and the first harmonic was controlled at the error sensors for each fan. The tonal noise content was also reduced in the far field and the beat frequency reduced.

10:00

1aNCc4. A physically motivated room reverberation enhancement system that is stable in any (passive) room. Edgar Berdahl, Gunter Niemeyer, and Julius O. Smith III (Dept. of Music, CCRMA, Stanford Univ., Stanford, CA 94305, eberdahl@ccrma.stanford.edu)

Prior active room reverberation enhancement systems have typically employed microphones, artificial reverberator filters, and loudspeakers to change the reverberant properties of a room. However, acoustic feedback from the loudspeakers to the microphones has had the potential to drive such systems unstable. In contrast, techniques from feedback control can be used to design a stable room reverberation enhancement system from the ground up. A feedback controller implements a passive connection between virtual acoustic spaces, which are realized using digital waveguide networks, and special transducers, which operate concurrently as microphones and loudspeakers. Because the feedback controller models a passive system, it is theoretically stable for arbitrarily large loop gains in any (passive) acoustic environment. As a consequence, the system does not suffer from "ringing tones" at high-loop gains in the same way as prior systems have suffered. Furthermore, the system does not need to be re-calibrated if the properties of the room change or even if moved to a whole new room. Finally, this method for designing room reverberation enhancement systems may generally result in more realistic reverberant sound because it implements the acoustical features of a system that could exist naturally in the physical world.

10:15

1aNCc5. An electroacoustic sound transmission system that is stable in any (passive) acoustic environment. Edgar Berdahl (Berdahl Innovations, 103 Cortland Ave., San Francisco, CA 94110), Dan Harris (Sennheiser Res. Lab., 3239 El Camino Real, Palo Alto, CA 94306), Gunter Niemeyer, and Julius Smith, III (Dept. of Music, CCRMA, Stanford Univ., Stanford, CA 94305)

Active electroacoustic systems are commonly employed to transmit sound from one location to another. For example, consider the following configuration: a person talks into a microphone, which produces an electrically amplified signal for driving a loudspeaker, and the loudspeaker induces an output acoustic signal allowing someone else at a more distant location to hear the person talking. Unfortunately, such system designs typically do not consider acoustic feedback, which can destabilize the system and result in "howling." In contrast, a feedback control system can transmit sound from one location to another using collocated microphone/loudspeaker transducers without the risk of howling. We design feedback controllers that model positive real (i.e., passive) systems, such as a spring and a gyrator. The spring controller essentially binds the diaphragms of the two transducers together. We relate the spring controller to the string connecting two tin cans together in the classical tin can telephone. Measurements are performed on a real feedback control system with two transducers. Because the feedback controller models a passive system, it is stable in any (passive) acoustic environment. [Sennheiser Electronic Corporation helped support this work.]

10:30

1aNCc6. Three-dimensional audio interface: A user's survey. Kim Abouchacra, Solara Sinno (Dept. of Otolaryngol.-Head and Neck Surgery, AUBMC, American Univ. of Beirut, 11-0236 Beirut, Lebanon, ks05@aub.edu.lb), and Tomasz Letowski (U.S. Army Res. Lab., Aberdeen Proving Ground, MD)

Increasing complexity of military vehicles, high noise levels, and the command and control demands of modern warfare put high physical and mental load on crews operating the vehicles. The need for indirect driving and simultaneous control of various robotic systems demands multisensory interfaces between the crew and the operated systems. One of the promising types of new interfaces is a three-dimensional (3-D) audio interface that presents warning signals and tactical messages at spatial locations associated with the content of the emitted signals or messages. However, not all the information can be displayed through a 3-D interface with needed resolution and sound quality and either too little or too much information can be equally detrimental to the user. This paper is the summary of data obtained through a user's survey administered to 105 tankers regarding expected functionality of 3-D interfaces in armored vehicles. The results of the survey strongly support the value of the 3-D audio interface for most of the vehicle's systems and for most operational conditions. The general results and the specific details of the survey will be discussed.

NOISE-CON, Noise, and Architectural Acoustics: Building Design and Construction for Effective Acoustic Performance

Kenric Van Wyk, Chair
Acoustics By Design, 123 East Fulton, Grand Rapids, MI 49503

Contributed Papers

9:15

1aNCd1. Acoustical considerations in future building design processes. Tyrone Hunter (Balance Acoust., 7710 Hazard Ctr., Dr. E-102, San Diego, CA 92108, huntert3@asme.org)

"Sustainability" is the major buzzword in the building design and construction arena today. The context often talks about products that will result in a smaller initial and ongoing carbon footprint. This paper will look at the idea of sustainability as a process, covering the end-to-end design and construction process as well as the process of generating and managing building data during its life cycle. The advent of lean construction and building information modeling is an opportunity to make acoustics more inherent to the conceptual design and prevent it from being a casualty of the "value engineering". Significant questions do arise, however, with regard to the acoustical information needed for such processes. These questions include, but are not limited to, what information is needed, who will need it, and how will it be exchanged. The answers to these questions differ when considering the above-mentioned processes and efforts to be holistically efficient and sustainable. The answers to these questions will be integrated into how building design is taught with regard to acoustics other specialties.

9:30

1aNCd2. Classroom noise at the Applied Research Laboratory, Penn State. Marshall Long (Marshall Long Acoust., 13636 Riverside Dr., Sherman Oaks, CA 91423, mlacoustics@sbcglobal.net)

Session 3.8: Building Design and Construction for Effective Acoustic Performance Classroom Noise at ARL Penn State by Marshall Long The Applied Research Laboratory at Penn State is a well known center of acoustics education in the United States. When Marshall Long Acoustics was selected to be the acoustical engineer on the new ARL building, we were particularly careful to check every noise source. When we went out on the final inspection, the question arose, "Why is the background noise level NC 42 in a classroom when it should be under 30?" The answer was not so elementary my dear Watson.

9:45

1aNCd3. Acoustics of technology enabled collaborative learning environments. Gregory A. Coudriet and Jeffery E. Babich (The Sextant Group, Inc., 730 River Ave., Ste. 600, Pittsburgh, PA 15212, gcoudriet @thesextantgroup.com)

Collaborative classrooms and workstations are increasingly common in higher education buildings. These spaces present unique acoustical challenges that force designers to rethink traditional concepts and solutions. In student-centered classrooms, the lecturer is removed as the visual and acoustical center of attention. Instead, students are seated in groups around technology enabled workstations, often facing away from the lecturer and other students. Acoustical conditions must support small-group interaction, classroom discussion, and learning via multimedia content. Outside the classroom, collaborative workstations vary greatly, but typically facilitate small-group interaction around a multimedia display and/or work surface. To promote impromptu use by students, these spaces are often open to highly public areas of learning commons, classroom buildings, and digital libraries. Traditional noise control solutions fail to isolate these spaces without compromising their spontaneous feel and function. Despite obvious acoustical challenges, both space types will continue to proliferate and new acoustical solutions must be developed.

10:00

1aNCd4. Small deviations and big failures in vibration and noise isolation. Byron Davis and Ahmad Bayat (Vibro-Acoust. Consultants, 490 Post St., Ste 1427, San Francisco, CA 94102, byron@va-consult.com)

The difference between design intent and actual implementation is frequently a problem in real constructions. For vibration and noise isolation hardware, seemingly innocuous deviations can result in major deficiencies in performance. From hardware selection to installation and adjustment, vibration isolation systems present significant challenges. In this paper, we offer insight into a broad spectrum of problematic rotating mechanical systems. Numerous categories of vibration-isolation failure are identified, and detailed photographs highlight subtle errors in isolator selection, installation, and adjustment that can lead to poor vibration and noise performance. Before-and-after vibration data are presented to illustrate the effect of poorly isolated rotating machinery. A spectacular example of comprehensive facility-wide failures is given, with ground vibration data from a brownfield site adjacent to an outdated textile plant.

10:15

1aNCd5. Retrofit structural insulated panels increase sound transmission loss of existing single family houses impacted by highway noise. Scott Harvey, PE (Phoenix Noise & Vib., LLC, 5216 Chairmans Ct., Ste. 107, Frederick, MD 21703-2881, sharvey@phoenixnv.com)

Owners of newly constructed houses complained of interior noise from a nearby interstate highway. The houses were constructed using structural insulated panels (SIPs) as opposed to conventional 2x4 wood studs. The SIPs are composed of 3.5 in. of expanded polystyrene insulation sandwiched between two layers of oriented strand board (OSB) and exhibit higher thermal efficiency than conventional construction. Sound transmission loss testing of the standard SIPs, however, reveals relatively low acoustical performance especially in the 630 Hz range. This characteristic acted as a band pass filter allowing only a portion of the broadband traffic noise to enter the house. The observed traffic noise inside the house had a clear tonal quality adding to the annoyance of the traffic noise impact. After consideration of several remedial options the builder decided to retrofit the exterior of the impacted houses using a combination of standard resilient channel, insulation, and additional OSB. Some window replacements were also required. These treatments resulted in reduced interior noise levels especially in the 630 Hz range.

10:30—10:45 Break

10:45

1aNCd6. The influence of openings in a partition on its of tonal sound transmission loss and some applications. Giora Rosenhouse (Technion-Israel Inst. of Technol., Prof. Giora Rosenhouse 89 Hagalil Str., Haifa 32684 Israel, fwamtech@bezeqint.net)

Kirchhoff's integral developed for optics [Born and Wolf 1970] and its approximations by Fraunhofer and Fresnel constitute a useful tool in acoustics, in general, as well as in building acoustics. They help in estimation of the changes in the sound level at the control point due to arbitrarily shaped solid barriers and openings in such barriers or partitions. While noise analysis justifies energetic approach, tonal sound is sensitive to frequency, phase, and interference effects. This dependence yields the mapping of positive and negative Fresnel zones over the barrier or the aperture. Those zones depend also on the location of the source and the control point. Since sound waves under regular conditions are linear and we assume locally reacting surfaces, then a small barrier or an aperture, which is located over a single Fresnel zone, causes a stronger acoustic effect at the control point than exactly the same elements if they cover parts of Fresnel zones of different signs. This situation allows, according to the need, acoustic design for minimization or maximization of the effect of apertures and barriers on the sound level at the control point. Applications involve arbitrarily shaped sound barriers, arbitrarily shaped openings in partitions and barriers, acoustic tiles, and transmission loss of non-uniform partition.

11:00

1aNCd7. Sound isolation provided by shading screens applied in facades. Jorge Matos and Antonio Carvalho (Lab. of Acoust., College of Eng., Univ. of Porto, 4200-465 Porto, Portugal, carvalho@fe.up.pt)

In most European countries, legislation exists about airborne sound insulation in dwellings, including facades. Mainly in southern European countries, the glazed windows of building facades normally have shading systems to minimize the excessive heating of interior rooms due to the solar rays' incidence and to provide for darkening of the room. The effect regarding sound isolation of those shading systems is usually not analyzed in the buildings' acoustic project. This study presents laboratory measured values of weighted sound isolation index (Rw) provided by several shading system types (outside and interior screens of different materials) and presents a simple model to predict their sound isolation index.

11:15

1aNCd8. Case study: Computer modeling of exterior mechanical noise from an existing building to develop mitigation for code compliance. Roman Wowk and Chris Papadimos (818 Fifth Ave., Ste. 207, San Rafael, CA 94901, roman@papadimosgroup.com)

This paper presents a case study of how computer modeling was used to develop exterior noise treatments for an existing building. Sound pressure measurements were used to first establish existing ambient noise levels and characterize building noise sources. Following that, a computer model of the building and surrounding area was constructed using commercially available environmental noise modeling software. Noise sources were modeled using sound power spectra from equipment manufacturers or approximated from measured sound pressure levels. The predicted ambient noise levels compared favorably to the measured data, thus validating the accuracy of the model. Once this baseline condition was established, a new building proposed between the existing building and the residences was added in the model to predict how it would function as a barrier to reduced noise at the residences. To develop additional noise treatments necessary for code compliance, the model was then used to determine the contribution of each piece of equipment at key receiver locations. Specific equipment could be targeted when considering noise treatments and noise exposure maps could quickly be produced for a combination of scenarios to aid in finding the most cost-effective solution.

11:30

1aNCd9. A simple estimation of z vibration for a Hopsca above depot by analog measurement and analysis in a metro station. Jiping Zhang (Environ. Impact Assessment Ctr., Zhejiang Res. and Design Inst. of Environ. Protection, 109 Tian Mu Shan Rd., Hangzhou 310007, China, jpzhang@mail.hz.zj.cn), Jianxiong Weng, Lei Wang, and Yexiang Jiang (Hangzhou Metro Group Ltd., Hangzhou 310000, China)

The word Hopsca means Hotel + Office + Park + Shopping mall + Convention + Apartment and was originated from La Defense in Paris of France in 1986. Metro depot is generally a parking and maintenance base and covers a large area and available land resources. It is a feasible approach to achieve comprehensive land utilization to develop top head estates above the depot by building residential, business, commercial, and recreational and sports urban functions. Such cases are well done, for example, in Hong Kong but generally few. The Metro in Hangzhou City of China is developing such a Hopsca. Because the trains will run and receive maintenance in the depot, the vibration and noise must be designed not transmitted to the top head estates. It will be very valuable to study the transmission and control of the vibration. This paper managed to estimate the complex vibration by simple analog measurement and analysis on a typical aboveground metro station with top head urban functions in Shanghai City of China.

1aNCd10. Acoustics of energy efficient elevator systems. Darshit Joshi (Polysonics Corp., 405 Belle Air Ln., Warrenton, VA 20186, darshitj@polysonics.com)

Traditional systems for vertical transportation require both machinery and space to operate. New, high performance, elevators eliminate these requirements, and in doing so significantly decrease the noise and vibration impacts associated with the traditional system architecture. Furthermore, machine roomless elevator systems offer superior electrical efficiency, a reduction in shaft wall requirements, centralized structural loading, and eliminate the need for pits, sumps, and the possibility for water contamination from spilled hydraulic oil. Also, interior environmental considerations are impacted by a number of innovations that result in a reduction in hydraulic pump, pump room and plumbing noise, motor and cab vibrations, and other significant improvements. Finally, the cost associated with ongoing maintenance and support such as lubrication of steel ropes is greatly reduced through the use of systems and technologies specifically engineered to reduce the need for many routine services that conventional systems require.

9:15

1aNCe1. An examination of the combined effects of loudness, tonalness, and roughness on annoyance ratings of aircraft noise. Shashikant More and Patricia Davies (School of Mech. Eng., Purdue Univ., West Lafayette, IN 47907, shashi@purdue.edu)

This study is part of a broader investigation into how noise characteristics other than loudness affect people's responses to aircraft noise. In previous studies, some evidence of increase in annoyance ratings with increased tonalness and roughness was found when loudness was kept constant and only tonalness or roughness was increased. The objective of this study was to investigate the combined effects of loudness, tonalness, and roughness on annoyance ratings of aircraft noise. A simulation program was used to generate two sets of stimuli based on flyover after take-off events of an Airbus-310, a Boeing-757, and an MD-80 aircraft. For nine stimuli in Set A based on an Airbus-310 recording, both tonalness and roughness varied while loudness kept constant. The 12 stimuli in Set B are based on recordings of all three aircrafts. In this test loudness, tonalness, and roughness were all varied. Subjects rated these sounds on an annoyance scale. Most of the subjects found to be very sensitive to tonalness when both tonalness and roughness varied and loudness was kept constant. Loudness was found to be the major contributor to annoyance when loudness, tonalness, and roughness varied simultaneously but tonalness and roughness also influenced the annoyance ratings.

9:30

1aNCe2. Determining sound quality judgments for metric development. André Fiebig and Klaus Genuit (HEAD Acoust. GmbH, Ebertstr. 30a, 52134 Herzogenrath, Germany, andre.fiebig@head-acoustics.de)

The sound quality of various technical products has become important for manufacturers. It is interpreted as among the most relevant factors regarding perceived product quality and is important in gaining market advantage. Usually, the purpose of sound quality studies is to derive a relationship between the subjective attributes and physical properties of sound. But how can valuable and meaningful subjective data be obtained? Identifying the most important psycho-physical quantities reflecting human responses to specific evaluation criteria depends on the applied method and the test design. Weighting factors for individual parameters in a combined metric depend strongly on the sounds used, the test environment, and the evaluation task. This paper will contrast the strengths and weaknesses of different methods, and discuss their level of inaccuracy in the intended application. The possibility of combining methods could be a step forward to achieve more grounded results and to enhance the explanatory power of developed metrics. Results of a few case studies will be presented, and options for combining different methods will be discussed.

9:45

1aNCe3. The need for a "green" sound of e-cars—The challenge of passung. Brigitte Schulte-Fortkamp (Inst. of Fluid Mech. and Eng. Acoust., Technische Universität Berlin, Einsteinufer 25, D-10587, Berlin, Germany, brigitte.schulte-fortkamp@tu-berlin.de)

The climate change is forcing to develop E-cars and also rethink how an E-car should sound. There is little agreement over what the sound should be. Some car manufactures seem to think about to make the cars more loud. But the question is how should a sound "sound" to provide the message about this ecological car? For sure there is a lack of collaboration to be filled amongst engineering and further future orientated science. Moreover, there is a clear need to get to know how the future client will accept such the new cars and how an appropriate sound will support this acceptation. Whenever the acoustical design of vehicles is under scrutiny, the crucial question about the appropriate method of evaluation arises. Many studies show that not only acoustic but also non-acoustic parameters have a major influence. Methods that give the opportunity to test the quality of the given ambience and to register the effects and evaluations in their functional interdependence as well as the influence of personal and contextual factors are needed to solve the upcoming problems to design the sounds of E-cars ecologically appropriate. This concept will be introduced.

10:00

1aNCe4. Prediction of subjective annoyance for transient sounds using a loudness-based impulsiveness measure. Andrew Willemsen, Mohan Rao (Dept. of Mech. Eng.-Eng. Mech., Michigan Technolog. Univ., 1400 Townsend Dr., Houghton, MI 49931, amwillem@mtu.edu), and Jasper Wong (Xerox Corp.)

This paper presents a study on the characterization of the sound quality of transient sounds via fundamental psychoacoustic measures. Specifically, the overall subjective perception of annoyance for transient sounds was studied. Through magnitude estimation and paired comparison jury evaluation experiments, the subjective annoyance magnitudes of 15 transient sounds were determined. For each sound, several objective psychoacoustic measures were calculated, and using simple linear regression models, the relationships between these objective measures and the subjective annoyance magnitudes were investigated. Examined psychoacoustic measures included loudness, sharpness, roughness, fluctuation strength, tonality, and a new loudness-based measure of impulsiveness. The new impulsiveness measure is based on the summation of the magnitudes of impulse-induced peaks in the loudness time history for a sound (calculated according to DIN 45631 /A1). The models were analyzed using several statistical measures of model significance and fit. It was found that for the transient sounds studied, significant relationships existed between subjective annoyance and each of the following psychoacoustic measures: loudness, sharpness, roughness, and loudness-based impulsiveness. These four measures were then combined into a single model for predicting subjective annoyance using multiple linear regression analysis. It was found that this model was highly correlated to the subjective annoyance of transient sounds.

1aNCf1. Effect of damping on noise and vibration response of tubes. Avinash Patil (Material Sci. Corp., 6855 Commerce Blvd., Canton, MI 48187, avinash.patil@matsci.com)

Noise and vibration response of cylindrical tubes is critical in many applications such as automotive intake and exhaust manifolds, appliance tubes, and fluid flow pipes. One of the approaches of controlling noise and vibration response is to introduce damping in the tube. An investigation of tubes with dimensions similar to that of intake manifold tube of a large truck is presented in this paper. Two tubes were investigated, viz., monolithic steel tube and laminated steel tube. Dispersion relation for the tube was analyzed. Effects of structural waves propagating in axial and circumferential directions were studied for their coupling with acoustic space. Effects of ring frequency of the cylinder and critical frequency of the material were analyzed. An experimental investigation was conducted for the tubes. Experimental results are explained with the help of theoretical analysis of the tube.

10:45

1aNCf2. A comparison of displacement and velocity proportional dampers for use in aircraft. Mike Hudik and Mark Downing (Lord Corp., 2000 W Grandview Blvd., Erie, PA 16509, mike.hudik@lord.com)

Surface effect dampers have been used in aircraft to aid in the attenuation of shimmy conditions on the nose landing gear. Shimmy conditions can lead to increased cockpit noise, increased component wear on the nose landing gear, and a decrease in aircraft control during operation. Hydraulic fluid filled dampers have traditionally been used to attenuate shimmy. They are, however, susceptible to leaking. This in turn relates to a decrease in performance and ultimately an increase in maintenance cost. Surface effect dampers use metal sliding over a rubber piston to create a combination of viscoelastic and Coulomb damping. This construction is immune to leaking and offers unique performance in comparison to hydraulic. This paper provides an overview of the difference between surface effect and hydraulic dampers for shimmy attenuation. Points to be touched on will include damper principles, equations of motion, the theoretical hysteresis curve, volumetric efficiency, and observations related to product life. Part test data will be compared to theory. Furthermore, this paper will discuss the process of completing the STC for a particular aircraft, discussing both the laboratory and the on-wing testing required to show the functional characteristics are satisfied.

11:00

1aNCf3. Rail and wheel vibration absorber performance testing. James Tuman Nelson (Wilson, Ihrig & Assoc., 5776 Broadway, Oakland, CA 94618, jnelson@wiai.com)

Rail and wheel dynamic vibration absorbers have been proposed as noise reduction measures for rail transit systems in Europe and the United States. These absorbers are essentially tuned spring-mass systems that add damping to the rail or wheel, and can effectively control wheel squeal. Their noise reduction effectiveness for rolling noise and rail corrugation noise is less clear. The extensive test results of under-car and wayside noise reductions are presented and discussed for wheel vibration absorbers at the San Francisco Bay Area Rapid Transit (BART) system for operations on resilient direct fixation fasteners. These results are compared with test results obtained under TCRP Project C3 at the Portland Tri-Met light rail system for both rail and wheel vibration absorbers. The reduction in pinned-pinned mode rail vibration by application of rail vibration absorbers on ballast-and-tie track at Tri-Met is discussed.

11:15

1aNCf4. The effects of structural damping on the radiated noise of circular saw blades during operation. Alan Hufnagel (Material Sci. Corp., 6855 Commerce Blvd., Canton, MI 48187, alan.hufnagel@matsci.com)

Noise from circular saw blades is a common industrial noise problem. A circular saw blade using constrained layer damping technology can significantly reduce the noise emitted during the cutting process. The noise reduction benefit of a constrained layer blade will be demonstrated. The influence of constrained layer damper design parameters on the blade noise reduction will be presented.

11:30

1aNCf5. Design and characterization of a tuned vibration absorber for exhaust components. Keith Ptak (Lord Corp., 2000 W Grandview Blvd., Erie, PA 16509, keith_ptak@lord.com)

Truck exhaust components must withstand vibration inputs from the diesel engine as well as from road inputs. Cumulative damage from the significant mileage these vehicles are exposed to can be severe; however, customers have an expectation that the components will last the life of the vehicle. Tuned vibration absorbers (TVAs) are an effective way to mitigate vibrations resulting from excitation of resonances due to random vibration exposure. A pipe section was tested to verify its expected mode shapes to aid in proper TVA placement. Subsequent tests were performed not only with TVAs but also with an equivalent mass in order to determine the true improvement due to the TVA effect. This paper covers a case study demonstrating the use of a TVA to achieve a 60% reduction in vibration.

11:45

1aNCf6. Predictability of field airborne noise isolation from laboratory testing. John LoVerde and Wayland Dong (1711 16th St., Santa Monica, CA 90404, jloverde@veneklasen.com)

The relationship between laboratory and field noise isolation tests of nominally identical assemblies is a longstanding question in acoustics [LoVerde and Dong, J. Acoust. Soc Am. **122**, 2955 (2007)]. Many building codes allow field airborne noise isolation ratings (ASTC, NIC, or NNIC) to be five points lower than the corresponding laboratory rating (STC), but the origin of this relationship is not documented thoroughly in the literature. Different wood framed floor/ceiling systems were tested multiple times in the laboratory to determine performance prior to implementation in the field. Field testing was performed in a variety of completed buildings to determine the actual acoustical performance of the assemblies that were installed. The results of this testing for airborne sound isolation is presented. The authors will present analysis of the predictability of field test results based on laboratory test and the apparent translation from laboratory to field testing.

8:00

1aNSa1. Perspective on launch noise: Measurement, prediction, and characterization. Sally Anne McInerny (Dept of Mech. Eng., Univ. of Alabama at Birmingham, BEC 356D, 1530 3rd Ave S., Birmingham, AL 35294)

The noise generated by launch vehicles is examined in terms of the key source, radiation, instrumentation, and estimation issues. Basic source and acoustic radiation characteristics of un-deflected rocket exhausts are compared and contrasted with those of supersonic jets. Next, the instrumentation demands of, and unique characterization methods applied to, rocket noise sound pressure measurements are discussed. Finally, on vehicle sound pressure measurements during the launch from a covered pad are presented. Contradictions between these loads and those predicted using traditional lift-off loads methods are highlighted. This paper concludes with a brief outline of research and instrumentation needed to improve agreement between the physics of the prediction model and the actual measured lift-off loads.

8:40

1aNSa2. Liftoff acoustic environment of the sounding rocket ATK Launch Vehicle (ALV-X1): Prediction versus measurement. J. Houston (Jacobs/ESTS Group, 1525 Perimeter Parkway, Ste. 330, Huntsville, AL 35806), Douglas Counter, R. Jeremy Kenny (NASA Marshall Space Flight Ctr., Huntsville, AL), and John Murphy (ATK Space Systems, Elkton, MD)

Launched from the Mid-Atlantic Regional Spaceport (MARS) Pad 01B on August 22, 2008, the ATK Launch Vehicle (ALV-X1) provided an opportunity to measure liftoff acoustic noise data. Predicted liftoff acoustic environments were developed by both NASA MSFC and ATK engineers. ATK engineers developed predictions for use in determining vibro-acoustic loads using the method described in the monograph NASA SP-8072. The MSFC ALV-X1 liftoff acoustic prediction was made with the Vehicle Acoustic Environment Prediction Program (VAEPP). The VAEPP and SP-8072 methods predict acoustic pressures of rocket systems generally scaled to existing rocket motor data based upon designed motor or engine characteristics. The predicted acoustic pressures are sound-pressure spectra at specific positions on the vehicle. This paper presents the measured liftoff acoustics on the vehicle and tower. Additionally, the ALV-X1 liftoff data can be scaled to define liftoff environments for the NASA Constellation program Ares vehicles.

9:00

1aNSa3. Acoustic design of launch pad for advanced solid rocket. Seiji Tsutsumi, Kota Fukuda, Ryoji Takaki, Tatsuya Ishii, and Kyoichi Ui (JAXA, 3-1-1 Yoshinodai Sagamihara, Kanagawa 229-8510, Japan)

In the mission of the Advanced Solid Rocket studied in JAXA, the launch-pad is required to improve the operation performance as well as to reduce the cost. While, exhaust plume from the solid booster generates severe acoutic wave so that decrease in the acoustic level at lift-off is also an important design issue. Preliminary trade-off analysis is peformend by using computational fluid dynamics. Major noise sources such as the Mach wave and the impingement noise and their correlation with the vehicle's altitude are revealed. The knowledge of the acoustic characteristics gives us idea how to decrease the acoustic level within the mission requirements. Based on the configuration found in the numerical study, subscale test using 1/43 scale mock-up is planned to ensure the acoustic level around the vehicle.

9:20

1aNSa4. Prediction of the acoustic environment on the launch pad for the Ares I rocket, including the effects of drift and water suppression. Kenneth J. Plotkin (Wyle Labs., 241 18th St. S., Ste. 701, Arlington, VA 22202, kenneth.plotkin@wyle.com)

A model, PAD, has been developed for prediction of noise in the vicinity of launch vehicles, with specific application to the mobile launcher and tower for the Ares I launch vehicle. It follows the basic principles of a traditional NASA model [NASA Report No. SP-8072 (1971)] but uses an updated rocket sound power source model developed by Sutherland [AIAA Paper No. 93-4383 (1993)] together with updates for the distribution and directivity of sources along the rocket plume. The effect of the deflector on plume geometry and shielding by the launcher deck are included in the model. Overall and spectral (octave band or psd) levels are predicted at specific points or on a regular grid of lateral and vertical positions on and around the launcher. A basic version of PAD was used for nominal acoustic predictions for vertical lift with all exhaust flow going through the flame hole in the deck and no water suppression (AIAA Paper No. 2009-3163). The model has since been extended to account for lateral drift of the vehicle, with consequent impingement of the plume on the deck and for the effect of water suppression systems. [Work supported by the National Aeronautics and Space Administration.]

9:40

1aNSa5. A post-flight ignition overpressure review for the Arex I-X test rocket. David A. Alvord (1525 Perimeter Parkway, Ste. 330, Huntsville, AL 35806)

Ares I-X post flight ignition overpressure review ignition overpressure (IOP) is an unsteady fluid flow and acoustic phenomena caused by the rapid expansion of gas from the rocket nozzle within a ducted launching space resulting in an initially higher overpressure wave. This wave is potentially dangerous to the structural integrity of the vehicle. An in-depth look at the IOP environments resulting from the Ares I-X solid rocket booster configuration showed good correlation between the pre-flight predictions and post-flight analysis results. Correlation between the chamber pressure and IOP transients showed successful acoustic mitigation, containing the strongest IOP waves below the mobile launch pad deck. The flight data allowed subsequent verification and validation of Ares I-X unsteady fluid ducted launcher predictions, computational fluid dynamic models, and strong correlation to historical shuttle data.

10:00—10:20 Break

10:20

1aNSa6. High-speed jet noise: A two source model. Christopher K. W. Tam (Dept. of Mathematics, Florida State Univ., Tallahassee, FL 32306-4510, tam@math.fsu.edu)

Recent experiments on high-speed jets indicate that jet noise is made up of two components. One component dominates in a conical sector surrounding the jet axis in the downstream direction. Experimental evidence suggests that this noise component is generated by the large turbulence structures of the jet flow. The other component is dominant in the sideline and upstream directions. There is ample experimental evidence showing that this noise component is generated by the fine scale turbulence of the jet. Optical observations confirm that there is a separation of turbulence scales in jets. Jet turbulence consists of large structures with length scale of the order of the jet diameter and fine scale turbulence with a much smaller length scale. These two types of turbulent fluid motions, with large disparate length scales, co-exist in the first one and half core length of the jet. In this presentation, extensive far field noise and direct correlation data are provided to support the two-noise source model. The validity of the two-noise source model is also strongly supported by near acoustic field measurements.

10:40

1aNSa7. Near-field energy-based measurements of small solid rocket motors. Kent L. Gee, Jarom H. Giraud (Dept. of Phys. and Astronomy, Brigham Young Univ., N283 Eyring Sci. Ctr., Provo, UT 84602, kentgee@byu.edu), and Jonathan D. Blotter (Brigham Young Univ., Provo, UT 84602)

Results of detailed near-field energy-based measurements of small solid rocket motors are described. The 5-in. center perforated motors are tested to ensure thrust equivalence of Shuttle reusable solid rocket motor propellant samples. An array of four three-dimensional acoustic probes, located as close as two nozzle diameters to the plume shear layer, was located at nine positions for a total of 36 measurement points. The data collected were used to create maps of near-field energy-based quantities in the vicinity of the plume. In particular, the time-averaged vector intensity reveals the direction of the net acoustic energy flow away from the rocket plume, permitting direct characterization of the source region from these motors as a function of frequency. Further, these measurements establish the utility of energy-based acoustic quantities in aeroacoustic source measurement and modeling. [Work supported by an STTR from NASA Stennis Space Center. The cooperation of ATK Space Systems Test Services is gratefully acknowledged.]

11:00

1aNSa8. Acoustic measurements for small solid rocket motors. Magda B. Vargas (All Points Logistics/ESTS Group, NASA Marshall Space Flight Ctr., Huntsville, AL 35812, magda.b.vargas@nasa.gov) and R. Jeremy Kenny (NASA Marshall Space Flight Ctr., Huntsville, AL 35812)

Rocket acoustic noise can induce loads and vibration on the vehicle as well as the surrounding structures. Models have been developed to predict these acoustic loads based on scaling existing solid rocket motor data. The NASA Marshall Space Flight Center acoustics team has measured several small solid rocket motors (thrust below 150 000 lbf) to anchor prediction models. These data will provide NASA the capability to predict the acoustic environments and consequent vibro-acoustic response of larger rockets (thrust above 1 000 000 lbf) such as those planned for the NASA Constellation program. This paper presents the methods used to measure acoustic data during the static firing of small solid rocket motors and the trends found in the data.

11:20

1aNSa9. An acoustical comparison of sub-scale and full-scale. Jared M. Haynes and Robert J. Kenny (Marshall Space Flight Ctr., MS ER42, Huntsville, AL 35812)

Recently, members of the Marshall Space Flight Center (MSFC) Fluid Dynamics Branch and Wyle Labs measured far-field acoustic data during a series of three reusable solid rocket motor (RSRM) horizontal static tests conducted in Promontory, UT. The test motors included the Technical Evaluation Motor 13 (TEM-13), Flight Verification Motor 2 (FVM-2), and the Flight Simulation Motor 15 (FSM-15). Similar far-field data were collected during horizontal static tests of sub-scale solid rocket motors at MSFC. Far-field acoustical measurements were taken at multiple angles within a circular array centered about the nozzle exit plane, each positioned at a radial distance of 80 nozzle-exit-diameters from the nozzle. This type of measurement configuration is useful for calculating rocket noise characteristics such as those outlined in the NASA SP-8072 "Acoustic Loads Generated by the Propulsion System." Acoustical scaling comparisons are made between the test motors, with particular interest in the overall sound power, acoustic efficiency, non-dimensional relative sound power spectrum, and directivity. Since most empirical data in the NASA SP-8072 methodology are derived from small rockets, this investigation provides an opportunity to check the data collapse between a sub-scale and full-scale rocket motor.

Technical Univ. Berlin, Einsteinufer 25, Secr TA 7, Berlin, 10587, Germany

Invited Papers

9:30

1aNSb1. Multichannel soundscape recording techniques. Alex U. Case (Sound Recording Tech., UMass Lowell, 35 Wilder St., Lowell, MA 01854, alex_case@uml.edu)

Several goals motivate the recording a soundscape: measurement, archiving, mitigation, preservation, design, modeling, education, marketing, and entertainment. Salient properties of a soundscape are similarly broad: levels versus frequency and time, their averages and associated statistics, discrete sound source identities, distance, localization, size, spaciousness, envelopment, and additional subjective sound qualities, sometimes subtle. While traditional noise metrics are based on single microphone measurements, a soundscape is better captured, quantified, and studied using multi-microphone techniques. Multichannel recording techniques for large-scale soundscapes, borrowed from the multitrack recording practices of concert halls and recording studios, are defined and compared. The resulting data and audio files are evaluated for their ability to satisfy the needs of owners, designers, and end-users of a soundscape.

10:10—10:30 Break

10:30

1aNSb2. Listen to the change of a soundscape. Klaus Genuit and Andre Fiebig (HEAD acoustics GmbH, Ebertstr. 30a, 52134 Herzogenrath, Germany, klaus.genuit@head-acoustics.de)

The general understanding of soundscapes as musical compositions requires the analysis of the sonic environment as a whole as well as in its different facets comparable to the study of music. However, soundscape studies often differ in the way the investigated soundscapes are recorded. In addition, a lot of soundscape articles lack an exhaustive description of the measurement conditions and protocol. This impedes the comparison of soundscape studies and their results. Therefore, it seems there is a need for measurement guidelines to provide a common basis allowing for subsequent comparative studies. The authors have proposed in previous papers measurement guidelines which could help to establish a common ground with respect to soundscape measurements. To check the adequacy and applicability of the recommended procedures for the (physical) measurement of soundscapes, several recordings of historic places in Aachen are realized and analyzed. Here, binaural recordings are performed, which allows for an aurally-accurate reproduction of the environmental sound. In supplemental laboratory tests, the conflict between the experience of the sound in the real urban space and the listening in artificial test situations is examined. Furthermore, the paper presents the change of the soundscape and its composition over time.

11:10

1aNSb3. Cultural soundscape of the Grant-Kohrs Ranch national historic site. Robert C. Maher (Elec. and Comput. Eng., Montana State Univ., 610 Cobleigh Hall, Bozeman, MT 59717-3780, rob.maher@montana.edu)

It is often noted that although many parks and historic sites *look* as they did a century ago, very few *sound* as they once did. Management principles of U.S. National Parks and Historic Sites include the need to "preserve soundscape resources and values of the parks to the greatest extent possible to protect opportunities for appropriate transmission of cultural and historic sounds that are fundamental components of the purposes and values for which the parks were established." Therefore, a critical part of soundscape management is to determine the existing ambient soundscape to detect trends and changes. An ongoing project at Grant-Kohrs Ranch National Historic Site, located just north of Deer Lodge, Montana, involves a year-long continuous audio recording and soundscape characterization. The recording status and example soundscape excerpts are presented and discussed.

Psychological and Physiological Acoustics and Noise: Noise-Induced Hearing Loss: From Physiology to Prevention

Sharon G. Kujawa, Cochair
Massachusetts Eye and Ear Infirmary, 243 Charles St., Boston, MA 02114

Kim S. Schairer, Cochair
Univ. of Wisconsin, Dept. of Communicative Disorders, 1975 Willow Dr., Madison, WI 53706

Chair's Introduction—8:00

Invited Papers

8:05

1aPP1. Epidemiology of noise-induced hearing loss. Yuri Agrawal (Dept. of Otolaryngol.-Head and Neck Surgery, Johns Hopkins Univ., 601 N. Caroline St., Baltimore, MD 21287)

Noise exposure is a significant risk factor for hearing loss; recent analyses from a national sample of US adults have shown that occupational and firearm noise exposure increase the risk of hearing loss by 60% and 90%, respectively. Noise trauma typically produces a high-frequency pattern of hearing loss due to hair cell injury in the cochlear base, in contrast to cardiovascular risk factors which appear to cause cochlear damage across the frequency range. Significant interactions between noise exposure and cardiovascular risks have been demonstrated, such that these exposures exert a multiplicative detrimental effect on hearing thresholds. Although exposure to industrial occupational noise may be decreasing in the US population, the rising use of personal listening devices—particularly among children and young adults—is raising concern for a surge in hearing loss prevalence in the younger population. Indeed, recent data from the US population suggest that during the 1999–2004 time interval, significant increases in the prevalence of hearing loss were observed only among young adults. Further longitudinal analyses of children and young adults will be required to better characterize the hearing risks associated with these new forms of noise exposure.

8:40

1aPP2. Biology of noise-induced hearing loss. M. Charles Liberman (Eaton-Peabody Labs., Massachusetts Eye and Ear Infirmary, 243 Charles St., Boston, MA 02114)

This talk will review recent research on the cellular and molecular changes underlying noise-induced hearing loss (NIHL) and potential therapeutic approaches to its prevention and/or mitigation. Topics will include (1) the functionally important structural changes underlying reversible versus irreversible NIHL, (2) the factors affecting vulnerability to NIHL, (3) the inadequacy of threshold testing as a measure of noise-induced cochlear damage, and (4) the possible utility of antioxidant and other chemical therapies.

9:15

1aPP3. Spectrotemporal integration in listeners with normal hearing and those with noise induced hearing loss: An application of the Meddis Matlab Auditory Periphery (MAP) model. Lawrence L. Feth, Evelyn M. Hoglund, Yonghee Oh (Dept. of Speech and Hearing Sci., The Ohio State Univ., 110 Pressey Hall, 1070 Carmack Rd., Columbus, OH 43210), and Ray Meddis (Univ. of Essex, Colchester CO4 3SQ, United Kingdom)

Our recent study of spectrotemporal integration by human listeners with normal hearing has shown that the detection thresholds for signals made up of multiple bursts of brief tones improve as the number of bursts is increased. Elementary signals consisted of 10-ms tone bursts centered on 1 of 12 frequencies spaced 1 ERB apart. Complexes were constructed by adding individual tone bursts along the temporal or spectral dimension, or both. Quiet thresholds were measured using a one interval adaptive procedure. There was no significant difference in performance for a variety of time by frequency patterns used to construct the signals. Even random selection of tone frequencies for each signal presentation did not degrade integration performance. The current study measured spectral integration, temporal integration, and spectrotemporal integration in listeners with noise induced hearing loss as well as in normal-hearing listeners. The Meddis MAP model was adjusted to fit integration performance for the normal-hearing listeners and then used to predict the performance by NIHL listeners by modifying the outer hair cell parameters. [Research supported by a grant from the Office of Naval Research # N000140911017.]

9:30

1aPP4. Effect of noise-induced hearing loss on a multi-channel listening task. Kim Abouchacra (Dept. of Otolaryngol.-Head and Neck Surgery, Medical Ctr., AUBMC, American Univ. of Beirut, P.O. Box 11-0236, Beirut, Lebanon, ks05@aub.edu.lb), Janet Koehnke, Joan Besing (Montclair State Univ., Montclair, NJ 07043), and Tomasz Letowski (U.S. Army Res. Lab., Aberdeen Proving Ground, MD 21005-5425)

Monitoring multi-channel radio communication is a common activity for many military and civilian professionals, such as those who work in tactical operation centers, command-control towers, and voice interception facilities. In such environments, communication is critical and errors in speech understanding could cost time, equipment, and even loss of life. When an individual has a hearing loss, these costs have the potential to increase substantially. The purpose of this study was to compare speech recognition scores (SRSs) of listeners with normal hearing and noise-induced hearing loss, when target messages were presented with two, three, or four interfering messages through various spatial and non-spatial auditory displays. For both groups, SRSs decreased for all display types as the number of competing messages increased. However, listeners with hearing impairment had significantly poorer SRSs than listeners with normal hearing, with decreases in scores ranging from 10%–25% in all conditions. While both groups benefited from spatial auditory displays, listeners with hearing impairment demonstrated significantly greater improvement in SRS than those with normal hearing. These findings support the use of spatial displays for multi-channel monitoring tasks and highlight potential costs associated with hearing loss especially in the absence of spatial displays.

1aPP5. Behavioral consequences of weakened medial olivocochlear efferent noise-control mechanisms in mice. Amanda M. Lauer and Bradford J. May (Dept. of Otolaryngol.-HNS, Johns Hopkins Univ., 521 Traylor Bldg., 720 Rutland Ave., Baltimore, MD 21205)

The mammalian medial olivocochlear (MOC) efferent feedback system protects the ear from intense noise exposure, aids in cochlear gain control, and improves responses to signals in noise. Unequivocal behavioral effects of eliminating MOC feedback have been difficult to demonstrate. We used an acoustic startle reflex (ASR) modification paradigm to reveal behavioral effects of eliminating MOC feedback in mice. Mice lacking the alpha9 nicotinic acetylcholine receptor subunit showed increased facilitation of the ASR reflex in the presence of background noise, abnormal responses to brief fluctuations in background noise, and abnormal inhibition of the ASR by changes in the location of noise in azimuth and elevation. Abnormal behavioral responses occurred in the absence of cochlear hearing loss. The behavioral effects of weakened MOC feedback may reflect both direct and indirect effects of abnormal cochlear gain control in the presence of noise. The results provide further evidence for a role of MOC efferent feedback in hearing in noise and demonstrate that noise-related hearing deficits can occur when hearing thresholds are normal.

10:10

1aPP6. Susceptibility to intense impulse noise: Evidence from the Albuquerque dataset. G. Richard Price (Auditory Hazard Anal., P.O. Box 368, Charlestown, MD 21914, Ahanal.@comcast.net)

For theoretical and applied reasons, there has long been an interest in the problem of susceptibility to hearing loss from intense sounds; yet no useful predictive indices have been found. Some evidence suggests that susceptibility cannot be considered as a constant for individual ears; however, thinking and experimental designs often assume that it is. A critical data set in this regard are the US Army's Albuquerque studies [Johnson, D. L. (1994) USAARL Contract Report No. 94-2, U.S. Army Aeromedical Research Laboratory, Rucker, AL] in which human Ss were exposed repeatedly to explosive sources. An analysis of individual threshold shift data finds that of 28 instances in which ears showed a threshold shift 15 dB or higher, 25 Ss subsequently passed higher levels of exposure, sometimes much higher levels. This outcome was clearly contrary to the expectation that they were susceptible ears. Issues such as HPD fit and random elements in exposures are demonstrably a part of the problem. Susceptibility, at present, should probably be considered a statistical concept, appropriate to groups of Ss.

1aPP7. Noise-induced hearing loss in the U.S. Military: A review. Larry Humes (Dept. of Speech & Hearing Sci., Indiana Univ., Bloomington, IN 47405, humes@indiana.edu)

This presentation will review some of the key findings of an Institute of Medicine committee report [Humes *et al.* Noise and Military Service: Implications for Hearing Loss and Tinnitus (The National Academies, Washington, DC, 2005.] on noise-induced hearing loss in U.S. military personnel since World War II. With regard to hearing loss, the majority of the data available at the time of the report were average group hearing thresholds from cross-sectional studies. Patterns of hearing loss consistent with noise exposure could be seen in several cross-sectional studies of military personnel. These average data indicated that hearing thresholds were worse in those groups with more years of military service. However, these cross-sectional data were not a sufficient basis for attributing greater hearing loss solely to a longer exposure to military noise while in the military. With the information available, it was not possible to establish the precise proportion of a given military population that developed noise-induced hearing loss during military service, the amount of hearing loss incurred, or the relative risk of noise-induced hearing loss for a given individual, based on his or her branch of military service, occupational specialty, or service era.

1aPP8. National occupational research agenda for hearing loss in the manufacturing sector. William J. Murphy (CDC/NIOSH Hearing Loss Prevention Team, 4676 Columbia Parkway, MS C-27, Cincinnati, OH 45226-1998)

The National Institute for Occupational Safety and Health (NIOSH) has developed the National Occupational Research Agenda (NORA) as a means of organizing and prioritizing its research efforts in occupational safety and health. Research has been categorized across 8 industrial sectors and 22 cross-sectors. Among these, the manufacturing sector is the largest sector in which hearing loss occurs due to occupational exposures. The NIOSH Manufacturing Sector Council has developed strategic research goals to be completed by government, academic, and industry stakeholders. Foremost among these goals were the identification and inventory of sources of noise exposure resulting in hearing loss, and the determination of behavioral and exposure factors that contribute to the risk of hearing loss. This paper will outline the efforts of the Manufacturing Sector Council to identify research needs, outline research partnership opportunities, and seek effective means of implementing the research agenda to reduce the incidence of hearing loss among American workers.

Invited Paper

11:15

1aPP9. Development of therapeutics to protect the inner ear: Support from animal models. Colleen Le Prell (Dept. of Communicative Disord., Univ. of Florida, Gainesville, FL colleeng@phhp.ufl.edu), Kevin Ohlemiller (Central Inst. for the Deaf, Washington Univ., St. Louis, MO), David Dolan, and Josef Miller (Univ. of Michigan, Ann Arbor, MI)

Noise-induced hearing loss (NIHL) is a significant clinical, social, and economic issue. Although we once thought virtually all NIHL was a consequence of mechanical damage to cells in the inner ear, we now know that intense metabolic activity drives the formation of free radicals (short-lived, unstable, highly reactive clusters of atoms) in the inner ear. Studies in animals have clearly shown that free radicals formed during and after noise importantly contribute to NIHL, and many laboratories have demonstrated that free radical scavengers ("antioxidants") reduce NIHL in animal subjects. Our group, including investigators at multiple institutions, has specifically shown that the combination of beta-carotene, vitamins C and E, and magnesium is highly effective in preventing NIHL and sensory cell death in guinea pigs and mice. Use of free radical scavengers, or antioxidants, to prevent noise-induced deficits has thus become a clinical research goal. Given the multitude of intracellular events that occur during and after noise, it is not surprising that other agents are also potentially useful therapeutic agents. Translational investigations are essential to confirm potential utility of these agents in the human inner ear.

1aUW1. Laboratory experimental results for synthetic aperture sensing applied to mine detection. S. C. Walker, W. A. Kuperman (Marine Physical Lab., Scripps Inst. of Oceanogr., La Jolla, CA 92093), Stephane Aumary, and Ghislain Marais (French Naval Acad. Res. Inst. (IRENAV))

Recent interest in mine detection has focused on the use of synthetic aperture sonar (SAS) array processing techniques to improve the along track sensor resolution of mobile side looking sonar platforms. We present the results of a series of laboratory experiments designed to study the effectiveness of various SAS array processing techniques for detection, localization, and classification of proud and buried objects. The experiments are carried out on a small spatial scale at ultrasonic frequencies. Notably, we find it possible to detect, localize, and classify buried objects (on the order of a wavelength in scale) from a great distance (hundreds of wavelengths).

8:15

1aUW2. Characterization and modeling of synthetic aperture sonar imagery. Anthony P. Lyons (Appl. Res. Lab., Penn State Univ., State College, PA 16804, apl2@psu.edu), Douglas A. Abraham (CausaSci LLC, Arlington, VA 22205), and Shawn F. Johnson (Johns Hopkins Univ., Laurel, MD 20723)

The characterization and modeling of synthetic aperture sonar (SAS) image statistics are of importance for developing target-on-background detection and classification algorithms and for developing specialized filters for speckle noise reduction. A simple model is presented to predict the impact of amplitude scaling caused by seafloor ripples on SAS image speckle statistics. The continuous variation in scattering strength produced by ripples (i.e., ripple-induced changes in seafloor slope) is treated as a deterministic amplitude scaling on image speckle produced by the SAS imaging process. Changes in image statistics caused by ripples are quantified in terms of an effective K-distribution shape parameter. Agreement between shape parameter estimated from the scaling model and from SAS data collected in experiments off of Panama City, FL and off of the Ligurian coast of near La Spezia, Italy illustrates the efficacy of the model. [Work supported by ONR Grant Nos. N00014-04-1-0013 and N00014-06-1-0245.]

8:30

1aUW3. Time-domain numerical simulation of scattering by objects in the seafloor. David C. Calvo (Acoust. Div., Naval Res. Lab., Washington, DC 20375), Mario Zampolli (TNO Defense, Security and Safety, The Hague, Netherlands), Jill P. Bingham, Saikat Dey, and Harry J. Simpson (Naval Res. Lab., Washington, DC 20375)

Numerical simulation of scattering in the time domain offers potential implementation advantages in comparison with frequency-domain methods. By using explicit numerical time integration schemes, elastic stresses and velocities can typically be advanced using only spatially local information which makes parallelization by domain decomposition straightforward to implement in comparison with the solution of a large linear system of equations. On the other hand, incorporation of frequency-dependent sound speed and attenuation appears more challenging in the time domain with the general need to compute convolutions under non-FFT friendly conditions. This talk presents efficiency gains for the elastodynamic finite integration technique (EFIT) which is similar to the finite-difference time-domain method (FDTD). We present results on using explicit decomposition of scattered and incident wave fields and far-field projection in the time domain with the discrete Helmholtz–Kirchhoff integral. We also present incorporation of frequency-dependent material parameters by efficient recursive convolution techniques that have been used successfully to create time-domain perfectly matched layers [J. A. Roden and S. D. Gedney, Microwave Opt. Technol. Lett. **27**, 334–338, (2000)]. As an application example, we present results on computing bistatic target strength variance for a two-dimensional object located near a statistically rough seafloor. [Work sponsored by the Office of Naval Research.]

8:45

1aUW4. Testing and modeling of a spiral wave front beacon for use in navigation. Benjamin R. Dzikowicz (Naval Res. Lab., Code 7130, 4555 Overlook Ave., Washington, DC 20375-5320) and Brian T. Hefner (Univ. of Washington, Seattle, WA 98105-6698)

A beacon with two cylindrical elements of 3-1 composite material has been developed, tested, and modeled for use in navigation. The displacement of each element is radial and the phase of the outgoing wave front is determined by the cross-section of the cylinder. One element, the reference, has a circular cross-section which produces circular wave fronts. The second element has a radius that varies linearly with angle such that there is a displacement of one wavelength over 360 deg; the resulting wave front is spiral. This beacon improves on a prototype presented at a prior meeting [Dzikowicz and Hefner, J. Acoust. Soc. Am. **125**, 2540 (2009)]. Results from experiments conducted at the Naval Surface Warfare Center, Panama City Division are compared with finite element models. Surface displacement of the elements is determined by the use of laser Doppler vibrometry. Variation in the field due to geometry and surface displacement variation are discussed. A simple navigational test shows the efficacy of the beacon. [Work supported by the Office of Naval Research.]

9:00

1aUW5. Small scale test bed for studying multiaspect and multistatic sonar systems. Patrick C. Malvoso, John S. Stroud, Raymond Lim, Joseph L. Lopes (Naval Surface Warfare Ctr., Panama City Div. Code T11, Panama City, FL 32407, john.stroud@navy.mil), and Benjamin R. Dzikowicz (Naval Res. Lab., Washington, DC 20375-5320)

A nominally 1:50 scale acoustic test bed is operational at the Naval Surface Warfare Center-Panama City Division (NSWC-PCD) to image free-field, bottom, and buried targets using multiaspect, bistatic, backscatter, forward scatter, and synthetic aperture sonar (SAS) techniques. The test bed is designed to test and study novel geometries and techniques faster and cheaper than can be done in the field. Using precise translational positioning systems mitigates any issues associated with positioning of multiple sonar platforms in the field. The use of two transmit and receive transducer platforms is superior to a single platform, which is restricted to purely backscattered imaging, for producing SAS images. With two platforms, one can generate four images, two using backscattered return data and two using data sent from one platform to the other. Thus, the system is inherently both dual aspect and bistatic. The setup, including the scaled sediment, acoustic sources and receivers, and computer controlled translational stages, is described. Preliminary beamformed data are presented showing the relationships between each of the images described above. In addition, techniques to

mitigate the interference of direct path returns in forward-scattering geometries are discussed. [Work sponsored by the Office of Naval Research.]

9:15

1aUW6. Forward scatter target strength extraction in a littoral environment. Larry A. Kraus, Alain R. Berdoz, Danial L. Amon, Philip A. Frank, Steve W. Liskey (Global Strategies Group (North America), 2200 Defense Hwy., Crofton, MD 21114), Joseph A. Bucaro (Excet, Inc., Springfield, VA), Harry J. Simpson, Brian H. Houston, and David C. Calvo (Naval Res. Lab., Washington, DC)

A rail-based system was used to collect forward and near-forward scattered echoes from a spherical shell in 14-m waters near Shell Island, Panama City, FL. The source was positioned 25 m from the scattering target and the 48-m horizontal rail on the opposite side, also 25 m from the target. The major obstacle to obtaining high-quality forward scatter target strength versus frequency and angle is the extraction of the much stronger time and position overlapping incident source signal. In previous laboratory measurements, this is accomplished with high precision by direct measurement of the incident field before the scattering target is positioned, a method not possible in a target search scenario or in a less stable environment. Here an attempt is made to obtain the forward scattered target strength by post-processing the received signals obtained in the littoral environment which contain both the echo and the overlapping source signal. The methodology involves using a wavenumber domain filter to remove the incident wave followed by standard synthetic aperture procedures to extract the desired target scattered signal. The resulting forward scattered target strength will be compared to what we expect analytically and experimentally from this simple target. [Work supported by ONR].

9:30

1aUW7. Forward scatter and backscatter low-frequency synthetic array measurements of the structural acoustic response from proud targets using a 48-m-long rail in a littoral environment. Harry J. Simpson, Zachary J. Waters, David C. Calvo, Brian H. Houston (Physical Acoust., Branch Code 7130, Naval Res. Lab., Washington, DC 20375), Alain R. Berdoz, Danial L. Amon, Philip A. Frank, Steve W. Liskey, Larry A. Kraus (Global Strategies Group (North America), Crofton, MD), and Joseph A. Bucaro (Excet, Inc., Springfield, VA)

A series of short range (25-m) forward scatter and backscatter measurements in a littoral environment was conducted to quantify the structural acoustic response from proud targets in the 2–23 kHz frequency band. The water channel was 14 m deep in the Gulf of Mexico near Shell Island, Panama City FL. The bottom was a medium grained sand. The acoustic forward scatter response of the proud targets was measured in a bistatic configuration with the source 25 m from the target and a receiver mounted on a 48-m-long rail. The rail is used to position the receiver and synthetically quantify the structural acoustic forward scatter response. A second source was co-located with the receiver on the rail, and monostatic backscatter measurements were also taken for each target. The structural acoustic response was analyzed and will be reported. The synthetic array experimental results are compared and contrasted with laboratory measurements. The laboratory measurements are convolved with water channel propagation predictions using a parabolic equation model of the littoral environment. The convolved laboratory target strengths compare well with the synthetic array measurements, and a detailed discussion of the comparison will be presented. [Work supported by ONR.]

9:45

1aUW8. Detection of a resonant target in shallow water using iterative, single-channel time reversal at low frequencies (2–23 kHz). Zachary J. Waters, Harry J. Simpson, Benjamin R. Dzikowicz, Brian H. Houston (Physical Acoust. Branch Code 7130, Naval Res. Lab., Washington, DC 20375-5320), Alain R. Berdoz, and Larry A. Kraus (Global Strategies Group (North America), Crofton, MD 21114)

Iterative time reversal with a single-channel transducer has been shown to enhance echoes from resonant targets both in scaled high-frequency (0.5–2-MHz) laboratory experiments [Waters *et al.*, IEEE UFFC **56**, 1429 (2009)] and in mid-frequency (20–200-kHz) pond experiments [Dzikowicz *et al.*, J. Acoust. Soc. Am. 123, 3755 (2008)]. These techniques are applied to study scattered returns from a proud, spherical target at low frequencies, 2–23 kHz, in a littoral environment. Monostatic scattering experiments are conducted in the Gulf of Mexico near Panama City, FL in 14-m-deep water. The target, a 60-cm-diameter stainless steel spherical shell (1.5 cm thick), rests on a sandy bottom at a range of 35 m from a rail-mounted source-receiver pair positioned at a height of 2.3 m from the bottom. Through iterative retransmission of windowed and time reversed scattering returns, enhancement of target echoes with respect to background noise and reverberation is explored. Frequencies to which the time reversal process converges are compared with analytical predictions and pristine laboratory measurements of the free-field scattering response. [Work supported by ONR.]

10:30

1aUW9. Wave separation and signal isolation via line-scan supersonic acoustic holography. Timothy M. Marston, Philip L. Marston (Dept. of. Phys. and Astronomy, Washington State Univ., Pullman, WA 99164 2814, marston@wsu.edu), and Kevin L. Williams (Univ. of Washington, Seattle, WA 98105)

Pressure signals scattered from a target and received by a line array can be buried in noise having similar frequency content, such as reflections from nearby interfaces or objects adjacent to the target. In such circumstances, it may be difficult to isolate the desired signal through the use of standard linear time-invariant filtering techniques, because the frequency content of the signal and noise are identical. Supersonic line-scan holography, however, can be used in many such circumstances to achieve signal isolation by back-propagating the acoustic signal to a focal region, spatially and temporally filtering the signal around the focal region, and forward-propagating the isolated signal to the original array location. This technique was used to measure the bistatic angular scattering pattern of a small target driven at resonance. This was done in a water tank using a hydrophone scanned along a line. A demonstration of how this method was used to isolate the signal from larger, overlapping reflections will be given. The method was also applied to backscattering measured with a scanned transducer and fixed proud cylinder resting on sediment. [Work supported by ONR.]

10:45

1aUW10. Scattering of linear frequency modulated chirps by resonators: Effect on pulse compression. Jon La Follett and Philip L. Marston (Dept. Phys. and Astronomy, Washington State Univ., Pullman, WA 99164-2814, jon.lafollett@email.wsu.edu)

Pulse compression is a common technique used to improve the signal to noise ratio and time resolution of a sonar system. A linear frequency modulated (LFM) chirp is one type of excitation used in conjunction with matched filtering to produce pulse compressed time domain data. This approach uses a correlation between the transmitted and received signals. Scattering by a target having a narrow resonance within the bandwidth of the LFM chirp may contain a superposition of specular scattering and scattering features associated with the transient response of the resonator. If the frequency sweep rate is not sufficiently slow relative to the ring-down time of the resonator, the transient response may result in artificial features and decreased time resolution in the pulse compressed signal due to decreased correlation with the transmitted signal. To explore this effect, water tank experiments were carried using a water filled cylindrical shell as the resonant target. Experiments demonstrate that for sufficiently rapid chirp rates, the target response envelope has an oscillatory modulation that affects the pulse compressed signal. [Research supported by ONR.]

11:00

1aUW11. Scattering experiments for exploring pressure gradient coupling to modes of solid cylinders. Timothy M. Marston and Philip L. Marston (Dept. Phys. and Astronomy, Washington State Univ., Pullman, WA 99164 2814, marston@wsu.edu)

Grazing illumination of a target close to a flat interface as well as evanescent wave illumination of a buried target can produce significant vertical acoustic pressure gradients at a target. A prior experiment [Espana *et al.*, J. Acoust. Soc. Am. 126, 2187 (2009)] demonstrated the selective coupling to a mode of a flat-ended solid horizontal circular cylinder. The cylinder's axis was positioned so that the vertical pressure gradient was large at the end of the cylinder. The present investigation explores this coupling for wider variety cylinders in which the end of the cylinder was modified to include a flat paddle. Such a paddle resembles a fin-like appendage. When a flat vertical paddle is subjected to a vertical pressure gradient, the associated torque on the paddle facilitates the excitation of torsional modes of the solid cylinder. The radiation damping is found to increase for larger paddles. Targets modified in this way facilitate the investigation of specific scattering mechanisms. Coupling to this type of mode is suppressed when the cylinder's axis is at a pressure anti-node where the pressure gradient vanishes. [Work supported by ONR.]

11:15

1aUW12. Boundary enhanced helical ray coupling to high-frequency modes of solid aluminum cylinders. Jon La Follett and Philip L. Marston (Dept. Phys. and Astronomy, Washington State Univ., Pullman, WA 99164-2814, jon.lafollett@email.wsu.edu)

Surface guided leaky Rayleigh waves have been shown to provide a significant contribution to the backscattering by a solid metallic cylinder [K. Gipson and P. L. Marston, J. Acoust. Soc. Am. 106, 1673 (1999)]. Free field observations of the backscattering by solid aluminum cylinders confirm that both meridional and helical rays contribute to the backscattering for different angles of cylinder tilt [K. Baik, Ph.D. thesis, WSU (2008)]. Those studies show that a previously developed criteria, based on the length of the cylinder, limits the range of tilt angles for which helical rays can contribute [F. J. Blonigen and P. L. Marston, J. Acoust. Soc. Am. 112, 528 (2002)]. Experiments with solid aluminum cylinders placed near a flat reflecting boundary suggest that the presence of a boundary can increase the number of helical ray paths that contribute to the backscattering; this increase can lead to increased backscattering amplitudes and an increased range of angles for which coupling to helical rays can occur. To investigate this effect, solid aluminum cylinders were suspended below the free surface of a water tank. Targets were illuminated from below at grazing incidence, and the backscattering was measured as a function of target rotation. [Work supported by ONR.]

Session 1pAA

Architectural Acoustics: Required Accuracy of Absorption, Scattering, and Diffusion Coefficients

Peter D'Antonio, Chair
RPG Diffusor Systems Inc., 651C Commerce Dr., Upper Marlboro, MD 20774

Chair's Introduction—1:00

Invited Papers

1:05

1pAA1. Absorption, scattering, and diffusion coefficients: Overview. Peter D'Antonio (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774, pdantonio@rpginc.com)

Acoustical design and computer modeling rely on the availability, accuracy, and use of coefficients which characterize how boundary surfaces affect incident sound. At this time three coefficients have been developed to characterize how incident sound is modified by absorptive and scattering surfaces. The random incidence absorption coefficient, which is a measure of the proportion of incident sound that is absorbed, is measured according to ISO 354/ASTM C423. It is well known that coefficients measured according to this standard suffer from several systematic errors which will be reviewed. Measurement of the random incidence scattering coefficient, which is the proportion of incident energy scattered in non-specular directions and used in computer modeling programs, is experimentally determined by ISO 17497-1. The limitations of this standard and applications will be discussed. Measurement of the diffusion coefficient, which is a measure of the uniformity of scattered sound and used to evaluate potential surfaces and in optimization programs, is described in AES-4id-2001 and ISO 17497-2 (pending). As with all standards it too has limitations which will be discussed. Detailed information on all three coefficients is given in Cox, T. J., and DAntonio, P. (2009). *Acoustic Absorbers and Diffusers* (Taylor & Francis, London).

1:25

1pAA2. Absorption coefficient error propagation into room acoustics parameters. Michael Vorländer (Inst. of Tech. Acoust., RWTH Aachen Univ. D-52056 Aachen, Germany)

It is well known that random-incidence absorption coefficients suffer from measurement uncertainties. Whether or not these uncertainties affect the quality of results from room acoustic prediction models depends on the specific case. One might argue that the absorption of the most relevant material must be known accurately. This, however, could be the material with highest absorption or the material with the largest surface area. In this presentation, the true random-incidence absorption coefficient and measurement uncertainties related to the current ISO 354 are briefly discussed. Then, in order to get a better view on the consequences of those uncertainties, quantitative uncertainties of some predicted parameters such as reverberation time, strength, and clarity are calculated by using an error propagation. Effects of uncertainties of absorption coefficients distributed in various room configurations are presented and discussed.

1:45

1pAA3. The true absorption—Measurements and coefficients. Christian Nocke (Akustikbuero Oldenburg, Katharinenstr. 10, 26121 Oldenburg, Germany, nocke@akustikbuero-oldenburg.de)

Many measurement procedures for sound absorption rely on approximations or necessitate special restrictions. The measurements in the tube usually only cover small samples and rely on a plane wave at normal incidence of sound. Reverberation chamber measurements assume diffuse sound fields and other constraints. Furthermore sound absorbers might show local or non-local reaction, e.g., angle dependence of the acoustic surface impedance or not. The performance of sound absorbers, either in a room or outdoors, often involves neither plane sound waves nor diffuse sound fields. This is one motivation for the development of measurement procedures applicable where the sound absorber is actually used, namely, *in-situ* methods. The paper will present a short historical review on the development of measurement techniques of sound absorption or the acoustic surface impedance. Measurement examples will be shown for some of the methods presented and compared to each other.

2:05

1pAA4. Investigation of the just noticeable difference of scattering coefficient in auralized concert halls. Renzo Vitale and Michael Vorländer (Inst. of Tech. Acoust., RWTH Aachen Univ., Neustrasse 50, 52066 Aachen, Germany, rvi@akustik.rwth-aachen.de)

The use of scattering coefficient in room acoustics simulations has proved to be an essential factor for improving the validity of results, as it quantifies the amount of the diffuse sound field in enclosed spaces. Measurement methods have been described in the norm ISO 17497. Available data, whose lack is still one of the weak points, are fairly growing. Moreover, the relationship between the physical quantity and perceptual aspects still remains unclear. Aim of this study is a first investigation toward the comprehension of the influence of scattering coefficient on the sound as perceived from the audience. The target is to quantify the just noticeable differences for variable scattering coefficients associated with lateral wall diffusers of a simulated concert hall. Several musical stimuli convolved with binaural room impulse responses are used as source signals for listening tests. Results focusing on perceptual aspects will be presented and discussed.

2:25

1pAA5. Characterizing scattering coefficients numerically via the fast multipole accelerated boundary element method. Nail A. Gumerov and Ramani Duraiswami (Perceptual Interfaces and Reality Lab., UMIACS, Univ. of Maryland, College Park, MD 20742, gumerov@umiacs.umd.edu)

Various panels are used in acoustical installations to provide desired characteristics to spaces to be used for listening. These panels have complex shapes with geometrical features that have sizes corresponding to wavelengths of sounds of interest. The complex interaction of acoustical waves with these shapes is what gives these surfaces their desirable properties. Experimental characterization of the acoustical properties of these surfaces under random and specular incidence is relatively time consuming. An alternate procedure is to numerically simulate the scattering behavior, and then computing the coefficients of interest from the simulation. A significant obstacle to such computations is the time taken for simulation. Fast multipole acceleration of boundary element methods [Gumerov & Duraiswami, J. Acoust. Soc. Am. **125** (2009)] is a promising approach to speeding up computations. We report on the application of this method to the computation of various scattering coefficients.

2:45

1pAA6. Evolution and uses of the diffusion coefficient: 1994–2010. Peter D'Antonio (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774, pdantonio@rpginc.com)

A measurement method to determine the diffusion coefficient was first proposed at the Sabine Centennial Symposium in 1994. The method involved a boundary measurement technique which was carried out in a reflection free zone to determine the scattered impulse responses at 5 deg resolution from which the uniformity of third octave polar responses could be determined. In 2001, an information document (AES-4id-2001) was published describing this technique and the determination of the diffusion coefficient from the autocorrelation of the third-octave polar responses. This technique is being enshrined as ISO 17497-2, which will complement the scattering coefficient standard ISO 17497-1. This presentation will review the evolution of the diffusion coefficient, describe the current measurement and characterization technique, and detail its limitations and accuracy. Two examples of its use will be given. The first example will illustrate how the directional and random incidence diffusion coefficients can be used to evaluate the bandwidth and scattering uniformity of several potential one-dimensional and two-dimensional diffusing surfaces. The second example will demonstrate how the coefficient can be used as a metric to create new surfaces, using a shape optimization computer program, which combines boundary element and multi-dimensional minimization techniques.

3:05—3:20 Break

3:20

1pAA7. Comparison of measurement and simulation of the scattered pressure distribution from partly absorbing surfaces. Konstantinos Dadiotis, Jamie A. S. Angus, and Trevor J. Cox (Acoust. Res. Ctr., Univ. of Salford, Greater Manchester M37JT, United Kingdom)

When diffusion or scattering from a surface if discussed usually it refers to the distribution of pressure reflected from a rigid surface while the amount of reflected energy is not discussed. In this paper the scattered pressure distribution from surfaces that consist of absorbing and reflecting elements has been measured following the ISO 17497-2. The requirements of the standard were not perfectly

met as the signal to noise ratio was lower than required due to the absorbing nature of the surface and high-low-frequency noise in the measuring system. The measured results were then compared with simulations using boundary element modeling. The comparison showed good agreement. Finally the issue of the reflected energy was discussed.

3:40

1pAA8. Design of sound diffusion in concert halls using scale models. Jin Yong Jeon and Yong Hee Kim (Dept. of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea, jyjeon@hanyang.ac.kr)

Effects of surface diffusion from lateral walls on concert hall acoustics were investigated to determine diffuser profiles. The design factors of diffusers in concert halls are geometrical shape, structural height, and surface coverage. Diffusion and scattering coefficients of the diffusers were measured in a 1:10 scale model reverberation chamber. Then, it was applied to scale model concert halls by design factors of diffusers. Acoustical parameters such as RT, EDT, C80, and sound pressure level (SPL) were calculated from the impulse responses. In addition, the numbers and amplitudes of the reflection peaks within −20 dB after the direct sound were calculated to evaluate the diffuseness in the halls. As a result, diffusers commonly yielded decrease in RT and SPL but contributed to increase in uniformity of RT and SPL. It was also found that the diffusive lateral surfaces close to the stage area are more effective in increasing both Np and ES. Appropriate design directions of diffuser are discussed from the measured results.

1pAA9. Characterizing rooms regarding reverberation time prediction and the sensitivity to absorption and scattering coefficient accuracy. B.-I. Dalenback (CATT, Mariagatan 16A, SE-41471 Gothenburg, Sweden, bid@catt.se) and Sarah Brown (RPG Diffusor Systems, Inc., Upper Marlboro, MD 20774)

Prediction of reverberation time (T30) using ray-tracing and similar algorithms naturally requires realistic input data, but the degree of data accuracy required varies with the room properties. In some types of rooms, accurate coefficients are crucial while in other types it is less crucial and the prediction results are less sensitive. This paper will attempt to classify rooms, according to their sensitivity to the input data due to their geometrical mixing (or diffusing) properties and the absorption, distribution. At the one end are found non-mixing geometries with uneven absorption, making a good estimate of the scattering coefficients crucial, at the other end are found mixing geometries with a mildly varying absorption distribution where prediction is safer and where estimated, or readily available, absorption coefficients can be used and where the choice of scattering coefficients has little impact. Due to the natural frequency dependence of both absorption and scattering coefficients the classification may also differ between octave-band predictions in the same room. Predictions are also difficult in rooms where the decay is not exponential. However, measures, e.g., STI and C80, may still be well predicted since they do not rely on fitting a straight line to a non-straight logarithmic decay.

4:15

1pAA10. Improving the accuracy of sound absorption measurements. Charles Moritz, Jennifer Shaw, and Armando Carrera (Blachford Inc., 1445 Powis Rd., West Chicago, IL 60185, cmoritz@blachfordinc.com)

Sound absorption test methods, such as ASTM C423, provide criteria for test chamber qualification. Measurements required during the ASTM C423 qualification process examine the variation in decay rates with microphone and test specimen locations. In addition, it is recommended to measure the change in sound absorption coefficients of a reference specimen with various amounts of diffusion in the room. However, there is little published information regarding systematic methods for determining diffuser, microphone, or specimen locations; therefore, qualification or improvement to the reverberation room depends on the acoustician's best judgment. As part of a continual improvement process to reduce testing variation, a mapping technique was utilized to visualize the three dimensional sound field in the room and determine changes necessary to improve the diffusion and repeatability of sound absorption measurements.

4:30

1pAA11. Quantifying the diffuseness of a sound field using a combined pressure and particle velocity sensor. Jonathan M. Botts, Philip W. Robinson (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., Troy, NY), Hans-Elias de Bree (Microflown Technologies and HAN Univ., Arnhem, The Netherlands), and Ning Xiang (Rensselaer Polytechnic Inst., Troy, NY 12180)

In many areas of acoustics, the degree to which a sound field is mixed, diffuse, or spatially uniform is important in understanding the system. In the case of performance spaces, it influences the audience's perception of the performance. More generally, it may have implications on the assessment of measurements taken in a space since often the evaluation of room-acoustic measurements relies on diffuse field assumptions. Several techniques have been proposed to quantify the diffuseness in a space, and one of the more recent methods will be investigated in this paper. Signals measured with a combined pressure and particle velocity sensor are used to calculate energy density and average intensity. The degree of diffuseness is then associated with the relationship between these two quantities. This paper discusses aspects of the relevant theory and practical implementation.

4:45

1pAA12. Simulating diffuseness with geometry variations of room surfaces. Sentagi S. Utami and Mojtaba Navvab (Dept. of Architecture, Univ. of Michigan, 2000 Bonisteel Boulevard, Ann Arbor, MI 48109, sentagi@umich.edu)

Several methods have been proposed to quantify the sound-field diffuseness utilizing measurements, room-acoustic modeling, and subjective assessment. Methods for measurements require sophisticated equipment with special consideration limited on quantifying uniformity of diffuseness in reverberant chambers. This study provides a systematic technique in simulating the sound-field diffuseness. The room simulated is typical rooms requiring need to control problems of echoes where the sound energy is often need to be conserved as well. Theoretical consideration on the sound source characteristics, source to receiver distances, geometrical size of the room surfaces, and material characteristics is taken into account and being altered in the simulation. Detail of the geometry variations in room surfaces is the major concern. Typical parameters in room acoustics are utilized to quantify the sound-field diffuseness. The results have shown that the geometry variations are correlated with the following energy properties: (1) reverberation times, (2) energies of the direct sound and reflections, (3) ratio of early-to-reverberant energies, and (4) the ratio of intensities of sound waves impinging on surfaces and reflecting back with its directional distributions.

5:00

1pAA13. On the accuracy of the subtraction method for *in-situ* reflection and diffusion coefficient measurements. Philip Robinson and Ning Xiang (Graduate Program in Architectural Acoust., Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180)

The subtraction method is a technique critical to measuring *in-situ* reflection/absorption coefficients as well as diffusion coefficients. In order to isolate a reflection, a reference measurement including only direct sound is subtracted from one with direct sound and the reflection of interest. However, taking two measurements with exactly the same direct sound component is complicated by environmental conditions, such as changes in temperature, air movement, and exact microphone positioning. These variations

can cause small time differences between the reference and the measurement which prevent complete subtraction of the direct sound; the residual direct sound then pollutes analysis of the isolated reflection. This work evaluates several methods to compensate for the differences to achieve minimal interference from the residual direct sound. A metric for gauging the success of the subtraction is proposed and the influence of the subtraction effectiveness on variations in the measured diffusion coefficient will also be discussed.

5:15

1pAA14. Inverse boundary and finite element formulations for the determination of high-frequency specific impedance. Alexander Bockman and Ning Xiang (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, xiangn@rpi.edu)

Material databases for consulting acousticians require accurate determination of specific impedance. Such data are typically gathered from the composition of data sets obtained from impedance tubes. In such tubes, the restriction of frequencies under test to those that satisfy a plane wave assumption for the tube geometry in question allows for the application of a one-dimensional transfer function analysis. Such tubes rarely achieve accuracy at the upper and lower ends of their operating spectra. Thus, the compositing of detailed data sets may produce significant error. For researchers of wave based methods of acoustic wave propagation, this represents a severe limitation. However, these data sets may be re-purposed for an extension of frequencies under test by the application of an inverse problem formulation of the boundary element method. The method accurately predicts data obtained within a larger impedance tube and further well extrapolates to data observed in a smaller impedance tube. Moreover, the method provides confidence in the consistency of specific impedance determination in composite data sets.

5:30

1pAA15. Higher-order impedance boundary conditions for finite difference solutions to the wave equation. Alexander Bockman, Jonathan Botts, and Ning Xiang (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., Troy, NY 12180)

Higher-order finite difference methods for the solution of the wave equation are well established. The interchangeability of temporal and spatial derivatives allows for exact representations of the differential equation in difference forms to the order of accuracy desired. Realistic impedance conditions, however, germane to problems of an architectural acoustics origin, are typically given as ratios of pressure and velocity in the frequency domain. This work develops fourth order-accurate time domain boundary conditions for the types of materials typically encountered in the architectural acoustics field. Accuracy and agreement of numerical simulations to scale model measurements are compared and discussed, as is computational cost relative to lower-order methods.

1pAB1. Preliminary analysis of effects of pile driving sounds on fish. Arthur N. Popper, Brandon M. Casper, Jiakun Song, David Sanderson-Kilchenstein (Dept. of Biology, Univ. of Maryland, College Park, MD 20742), Thomas Carlson (Pacific Northwest Natl. Labs., Battelle, Portland, OR 97204), and Michele B. Halvorsen (Univ. of Maryland, College Park, MD 20742)

There is continuing concern about the potential effects on fishes of the sounds produced during pile driving activities. Data in the literature are unclear as to physiological and behavioral effects. The earlier studies also generally did not include either experimental controls or control of signal parameters. We have developed a unique laboratory device that permits accurate simulation of impulsive pile driving signals in controlled experiments. Juvenile Chinook salmon were exposed to different combinations of sound levels and number of strikes to achieve various cumulative sound exposure levels. Controls received identical treatment as experimental animals, but without sound. The fish were evaluated by necropsy for assessment of barotrauma. Necropsies were conducted on exposed and control fish with experimenter not knowing the stimulus parameters. Preliminary analysis of results show that the extent of barotrauma rises with increased cumulative sound exposure level (SEL). Future experiments will examine effects of lower SELs as well as long-term effects that may arise at various time periods post-exposure. Ultimately, other species will be examined in order to develop broader criteria for exposure to pile driving sounds. (Work supported by NCHRP, CALTRANS, and MMS.)

1:20

1pAB2. Anthropogenic noise: Is this an issue for elasmobranch fishes? Brandon M. Casper and Arthur N. Popper (Dept. of Biology, Univ. of Maryland, College Park, MD 20742, bcasper@umd.edu)

Underwater anthropogenic noise has developed into a major national and international issue since it is becoming more apparent that human activities can have an adverse effect on the survival of fish stocks. It is unclear, however, whether human-generated noise in the aquatic environment could have an effect on the health and behavior of elasmobranch fishes (sharks, skates, and rays), a group already being threatened worldwide due to overfishing. Many sources of anthropogenic noise produce sounds in the frequency range detectable

by these fishes; however, elasmobranchs are not considered to have sensitive hearing and therefore we do not know if they could be affected by these sounds. A review will be presented of what is known and unknown in regard to elasmobranch hearing abilities as well as behavioral studies in which sharks were exposed to or attracted by auditory stimuli. With these in mind, the goal will be to address whether anthropogenic environmental noise could be having deleterious effects on elasmobranch fishes.

1pAB3. Natural modes of vibration in the auditory system of a teleost. Carl R. Schilt (Bigleaf Sci. Services, P.O. Box 225, North Bonneville, WA 98639, schilt@saw.net), Ted W. Cranford (QMC Consulting, Inc., San Diego, CA), Petr Krysl (UCSD, San Diego, CA), Robert E. Shadwick (UBC, Vancouver, BC, CA), and Anthony D. Hawkins (Loughine, Ltd., Aberdeen, Scotland)

Fishes are diverse in hearing systems and anatomy. Doing actual bioacoustic experiments with even one species, candidate sound, and acoustic environment is difficult to conduct and to generalize. Our modeling approach, if properly carried out and validated, will enable us to do virtual bioacoustic experiments that will enhance knowledge of biophysical phenomena with economy of time and resources. We present preliminary results of a project that extends to fishes our finite-element modeling methods, which have been used to investigate marine mammal bioacoustics. These methods involve obtaining appropriate specimens, scanning them with x-ray CT, measuring elasticity of tissues, and constructing a finite-element model. Then we simulate the interactions between selected anthropogenic sounds and the model of the fish. Here we introduce vibrational analysis with fishes, simulating the resonant frequencies of the otoliths and surrounding structures in a large sciaenid fish (the white seabass, *Atractoscion nobilis*). Our preliminary analysis indicates the potential for complex relative motions among otoliths and, by implication, their sensory maculae.

1pAB4. Metric for biological assessment of injury by percussive and decompressive exposure to impulsive sound. Thomas J. Carlson (Pacific Northwest Natl. Lab., 620 SW 5th Ave., Ste. 810, Portland, OR 97204-1423, thomas.carlson@pnl.gov)

Field and laboratory assessment of barotrauma to fish caused by percussion and/or decompression is complicated by the occurrence of injuries that do not result in immediate mortality. Accurate estimation of the consequence of exposure to impulsive sound must consider injuries that result in mortality delayed beyond typical post-exposure holding periods of exposed animals or that debilitate and lead to indirect mortality. Research of the response of fish to impulsive decompression over the past several years has resulted in development of a metric, mortal injury, that appears to more completely describe the biological cost to juvenile fish of exposure to rapid decompression. This measurement method has been extended to assessment of the response of juvenile fish to exposure to impulsive sound caused by blasting. The implications for assessment of take of listed species by blasting is evaluated by comparing mortality assessed over a 48-h holding period following exposure with that by necropsy for determination of mortal injury immediately following exposure.

2:15

1pAB5. Auditory hair cell regeneration in teleost fishes: A review. Michael E. Smith (Dept. of Biology, Western Kentucky Univ., 1906 College Heights Blvd., Bowling Green, KY 42101, michael.smith1@wku.edu)

Exposure to high levels of sound can cause damage to the auditory hair cells of many organisms, including fishes, resulting in hearing deficits. While such exposure can lead to permanent hearing loss in mammals, other phylogenetically older nonmammalian vertebrates, such as birds, reptiles, amphibians, and fishes, can spontaneously regenerate hair cells in both the vestibular and auditory portions of the inner ear following trauma. The general mechanism of hair cell regeneration is currently being examined in a number of different taxa, but data are limited on hair cell regeneration in the inner ear of fishes. This presentation will summarize the few studies that have examined auditory hair cell regeneration in teleost fishes and compare the results reported for fishes to those reported for other species. While understanding the process of hair cell regeneration in fishes has biomedical relevance, this knowledge could also benefit marine managers attempting to mitigate the effects of anthropogenic noise on fishes. [Work supported by NIH P20 RR16481.]

2:35

1pAB6. Noise-induced hearing loss: From animals to humans. Colleen Le Prell (Dept. of Communicative Disord., Univ. of Florida, Box 100174, Gainesville, FL 32610, colleeng@phhp.ufl.edu)

Exposure to noise can result in neural swelling, mechanical damage, and/or a toxic accumulation of free radicals. The type and extent of the pathology, the amount of hearing loss, and the permanence of the hearing loss all vary with the level and duration of the noise insult. In addition, noise exposures in which sound level rapidly changes over time are more harmful than relatively constant level exposures. These relationships have been carefully worked out in animal models, and key findings will be reviewed. Evaluating the effects of noise on the human inner ear is more challenging. Exposures in the work place and other real-world environments can be challenging to control, and in those studies evaluating long-term effects of noise, the subjects are exposed to variable non-study noise sources. Exposures in the laboratory that induce temporary changes in human hearing carry their own challenges. In this lecture, we will discuss various human models for studies on the effects of noise, and we will present new data on temporary hearing changes in human subjects that listen to music with digital audio players. Several metrics used to measure the effects of noise will be discussed.

2:55—3:15 Break

3:15

1pAB7. Effects of mid-frequency sonar on fish. Michele B. Halvorsen (Dept. of Biology, Univ. of Maryland, College Park, MD 20742, mb_halvorsen@yahoo.com), David A. Zeddies (Marine Acoust. Inc., Arlington, VA 22203), William Ellison (Marine Acoust. Inc., Middletown, RI 02482), Jiakun Song (Univ. of Maryland, College Park, MD 20742), David R. Chicoine (New York Chiropractic College, Seneca Falls, NY 13148), and Arthur N. Popper (Univ. of Maryland, College Park, MD 20742)

There is significant concern that high-intensity sounds can impact fish physiology and behavior. Important sources of such sounds are commercial and military sonars. A recent publication reports that exposure to low-frequency active (LFA) sonar might result in hearing loss in some fish species, but did not damage any tissues [Popper *et al.* (**2007**). J. Acoust. Soc. Am. **122**, 623–635]. We have extended our studies to include U.S. Navy mid-frequency sonar. Fish were exposed to a 3-s-long signal that consisted of a 2-s 2.8–3 .8-kHz frequency sweep, immediately followed by a 1-s 3.3-kHz tone). The stimulus was repeated five times with a 25-s interval. Fish were subsequently tested for hearing sensitivity and examined both grossly and microscopically for tissue damage. Some temporary hearing loss was found in catfish, species known to hear sounds above 1000 Hz, whereas there was no effect in fish which do not hear above about 1 kHz. There was no gross damage to any tissue, and microscopic examination showed no effect on any tissues. [Work supported by Office of the U.S. Chief of Naval Operations.]

1pAB8. Noise dose for aquatic animals: Preliminary estimates for two seismic surveys. Nils Olav Handegard (Inst. of Marine Res., NO-5817 Bergen, Norway, nilsolav@imr.no)

In humans, a daily noise dose is defined and used to regulate noise exposure in the working environment. This is an integrated measure of sound intensity over the working day, typically 8 h in duration. When investigating behavioral effects on aquatic animals exposed to anthropogenic noise, a comparable measure would be valuable, especially when transient but powerful underwater noise sources such as seismic air-guns and mid- and low-frequency sonars are being used or are being considered for use. Here, an integrated noise dose measure is defined. Preliminary estimates of this noise-dose measure are given for two different seismic surveys.

3:50

1pAB9. Assessing and regulating the impact of sound and vibration upon fish. Anthony Hawkins (Loughine Ltd., Kincraig, Blairs, Aberdeen AB12 5YT, United Kingdom, a.hawkins@btconnect.com)

The generation of very high-sound levels in water has the potential to change the behavior of fish and in extreme cases cause injury. Such sounds may be generated by pile driving, seismic exploration, low-frequency sonar equipment, ships, and underwater dredging and drilling activities. Some land-based activities like drilling, excavation work, and vibroseis may also generate sound and vibration which subsequently enters adjacent water bodies like lakes and rivers. It has become commonplace for regulatory agencies to require the impact of these sound-making activities to be formally assessed for their impact upon aquatic animals, including fish. The procedures for carrying out these assessments vary and, in many instances, are poorly performed or subject to uncertainty. The uncertainties which come into play when impacts upon fish are assessed include lack of knowledge on the sensitivity and response of fish to sounds, the physical conditions surrounding sound generation and propagation, and the metrics to be applied to the stimulus received by the fish. This paper will consider those sound exposure criteria applied to fish for regulatory purposes and how they might be refined.

4:05

1pAB10. A model for predicting effects of sound on auditory sensory cells in fishes. Mardi C. Hastings (Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332, mardi.hastings@gatech.edu)

Relationships among peripheral auditory mechanics, characteristics of sound exposure, and effects on auditory tissues in fishes are not understood. Several studies in the literature have reported varying degrees of damage to auditory hair cells in different species exposed to different types of sounds; however, there appears to be no correlation between sound exposure level and observed damage. In effort to understand mechanisms underlying hearing loss and hair cell damage and to predict their occurrence, a mathematical model of the peripheral auditory system in fishes was developed to study the dynamic response of the ear to incident sound in five different species. This model determines relative motion between the sensory epithelium and otolith in the inner ear, which causes bending of the apical ciliary bundles of auditory hair cells. Excessive relative motion predicted by the model was correlated with hair cell damage and found to be in good agreement with results of studies reported in the literature. Swim bladder geometry, otolith size, anatomical connections between swim bladder and inner ear, and spectral characteristics and amplitude of the received sound were found to affect the degree of hair cell damage. [Work supported by the International Association of Oil and Gas Producers.]

4:20

1pAB11. Assessment of the acoustic effects on marine animals by an offshore wind farm. James H. Miller, Gopu R. Potty, Kathleen Vigness Raposa, David Casagrande, Lisa A. Miller (Dept. of Ocean Eng., Univ. of Rhode Island, Narragansett, RI 02882, miller@uri.edu), Jeffrey A. Nystuen (Univ. of Washington, Seattle, WA 98105), and Peter M. Scheifele (Univ. of Cincinnati, Cincinnati, OH 45267)

As part of the planning for an offshore wind farm in Rhode Island coastal waters, an assessment of the potential acoustic effects on the ecosystem is being conducted. The developer has proposed to initially deploy eight 3.6-MW wind turbines within 3 nm of Block Island. Two passive aquatic listener (PAL) systems were deployed south of Block Island from October 6 to November 11, 2008. Using data from the PALs, ambient noise histograms were computed for this pre-construction phase. The largest sources of noise in the area at low frequencies were found to be from shipping, wind, rain, and biological sources. In addition, transmission loss measurements were also made in the region to calibrate a geoacoustic model. Measurements of airborne noise from a 1.5-MW land-based wind turbine already in operation in Rhode Island were made in 1/3-octave bands and near the proposed wind-farm site. A preliminary assessment of the effects of the offshore wind farm on marine animals at these sites will be presented. A plan for monitoring the noise field and potential biological effects during construction and operation of the windfarm is presented. [Funding provided by the RI Office of Energy Resources.]

1pAO1. Marine bioacoustics in a changing Arctic. Robert C. Gisiner (Marine Mammal Commission, Rm. 700, 4340 East-West Hwy., Bethesda, MD 20814, bgisiner@mmc.gov)

The retreat of summer ice in the Arctic during the past 5 years has been accompanied by a surge of alarm about iconic ice-associated marine mammal species: polar bears, walrus, ringed seals, and others. Changes for subarctic species of mammals, fishes, and planktonic organisms have not received as much attention, but will also need to be monitored. The paucity of data about Arctic marine mammals is now more than ever a serious impediment to good decision making. One of the greatest sources of hope is the tremendous advance in marine bioacoustic sensing technology that has occurred within the past decade. Passive and active acoustic technologies offer new means of obtaining biological data in a summer Arctic Ocean where ice is less available as a platform for animals and scientists, and in a winter Arctic Ocean that will continue to be one of the most difficult research environments in the world.

1:20

1pAO2. Including passive acoustic capability in Arctic ocean observing systems. Sue E. Moore (NOAA/Fisheries S&T, 7600 Sand Point Way NE, Seattle, WA 98115, sue.moore@noaa.gov), Kathleen M. Stafford (Univ. of Washington, Seattle, WA 98105), Catherine L. Berchok (NOAA, Seattle, WA 98115), Humfrey Melling (Inst. of Ocean Sci. DFO, Sidney, BC V8L 4B2, Canada), and Oystein Wiig (Univ. Oslo, Blindern, N-0318 Oslo, Norway)

Over the past decade, long-term deployments of passive acoustic recorders have provided a new baseline on the seasonal occurrence of large whale species in remote regions of the world ocean. In the Arctic, passive acoustic sampling has identified both whale calls and sounds from anthropogenic sources (ships and seismic profiling), activities that are expected to increase with diminished sea ice cover. In 2008, NOAA capitalized on an opportunity to join on-going IPY projects by inclusion of recorders at three High Arctic mooring sites: one on the Chukchi Plateau and two on either side of Fram Strait. The recorders (AURAL-M2) provided a year of sub-sampled (9 min on/11 min off) recordings at 0.1 Hz to 4 kHz (8192 sampling rate), which encompasses the bandwidth of whale and ice seal calls. Data from the recorders were complemented by a suite of standard oceanographic measures from other instruments on the mooring line. Provisional results show novel occurrence of both marine mammal and anthropogenic signals in the High Arctic. To realize the vision of a Global Ocean Acoustic Observing Network [Dushaw *et al.* (2009)], passive acoustic technology must become a standard sampling component, especially in the Arctic during this time of rapid climate change.

1:40

1pAO3. Effects of seismic exploration activities on bowhead whale call distribution in the Alaskan Beaufort Sea. Susanna B. Blackwell (Greeneridge Sci., Inc., 1411 Firestone Rd., Goleta, CA 93117, susanna@greeneridge.com), Christopher S. Nations, Trent L. McDonald (WEST, Inc., Cheyenne, WY 82001), Aaron Thode (Scripps Inst. of Oceanogr., La Jolla, CA 92093), Katherine H. Kim, Charles R. Greene, Jr. (Greeneridge Sci., Inc., Goleta, CA 93117), and A. Michael Macrander (Shell Exploration & Production Co., Anchorage, AK 99503)

Airgun use during seismic exploration activities is known to cause a decrease in call detection rates (used here as a proxy for calling rates) in migrating bowhead whales. However, the received airgun sound levels at the whales, at which behavioral changes occur, are not known. To address this question 40 directional autonomous seafloor acoustic recorders (DASARs) were deployed in autumn 2008 at five sites along the migration corridor of bowhead whales during ongoing marine seismic exploration activities. Over 440 000 whale calls were detected and localized by triangulation. Concurrently, over 100 000 airgun pulses were detected and analyzed. The study area was divided into a hexagonal grid (hexagon width 1.75 km). The received level (SPL and cumulative SEL) of airgun sounds was modeled for each hexagon in the study area and each 15-min period over the entire season, using information on the timing and location of airgun activities, the size of the airgun array being used, the depth of the DASARs recording the airgun sounds, and other covariates. Logistic regression was then used to model occurrence of whale calls as a function of received level, distance offshore, and other covariates. [Work supported by Shell Exploration and Production Company.]

2:00

1pAO4. Are they really not there? Using passive acoustics to overcome false absences in the study of vocal species that are rare, secretive, or distributed at low densities. Tracey L. Rogers, Carolyn J. Hogg, Michaela B. Ciaglia (Evol. and Ecol. Res. Ctr., School of BEES, Univ. of NSW, Sydney 2052, Australia tracey.rogers@unsw.edu.au), and Douglas H. Cato (Defence Sci. and Technol. Organisation, New South Wales, Australia)

Estimating abundance and spatial use behavior can be challenging for marine species that are rarely sighted. This situation is exacerbated in the polar regions due to the peculiar logistical difficulties of working in the pack ice, which makes survey effort enormously expensive. Presented is a simple approach for modeling sounds per animal over a unit time as a relative index for species where there is information on the production of vocalizations (acoustic behavior including seasonal calling patterns, diurnal calling patterns, inter-individual stereotypy, inter-sexual stereotypy, audience effect, and predictable calling rate over a unit of time) and the detection range of those vocalizations (survey distance—theoretical estimates calculated with call intensities). We focus on an Antarctic pack ice seal, the leopard seal, and Hydrurga leptonyx, as estimating abundance from survey effort faces challenges. Our case study shows that with the advent of more sophisticated marine engineering coupled with effort focused on the pertinent parameters of acoustic behavioral ecology we can open up the scope to study the behavior of rare, secretive, or low-density species across a range of site occupancy studies, density, and habitat use at a time when we need to develop cost efficient tools to glean an understanding of what is happening in these most vulnerable locations.

2:20

1pAO5. From psychophysics to management of noise-disturbance in a large, Arctic carnivore, the polar bear. Ann E. Bowles (Hubbs-SeaWorld Res. Inst., 2595 Ingraham St., San Diego, CA 92109, abowles@hswri.com) and Megan A. Owen (San Diego Zoo Inst. for Conservation Res., San Diego, CA 92112-0551)

About 50% of maternal dens excavated by pregnant female polar bears on Alaska's North Slope occur on land or land-fast ice. Management agencies and the public have raised concerns that noise from human activities could adversely affect denning female polar bears, causing den abandonment, interference with communication, altered habitat use, or behavioral and physiological stress. Although US Fish and Wildlife Service uses approach limits to prevent disturbance of denning females that are assumed to be conservative, no science-based standards have been developed and uncontrolled human activities are still possible. The potential for effects will be reviewed in light of published evidence and measurements of polar bear auditory thresholds [Bowles *et al.* (2008). J. Acoust. Soc. Am. **123**, 3509] to show how an understanding of species-specific psychophysical characteristics is needed to assess the impact of noise disturbance from industrial activities. Scientific challenges to quantifying effects include identifying efficient noise metrics and practical methods for measuring adverse responses. The negative ramifications of disturbance may be intensified due to anticipated reductions in polar bear physical condition as their sea ice habitat declines.

2:40

1pAO6. Air-borne noise in the Arctic and implications for polar bears. Alexander O MacGillivray (JASCO Appl. Sci., 2101-4464 Markham St., Victoria BC, V8Z 7X8 Canada) and Christine Erbe (JASCO Appl. Sci., Bellbowrie, Queensland 4070, Australia)

An increasing number of Arctic animal populations are listed as threatened. The list includes ungulates, terrestrial carnivores, marine mammals, and birds. Potential threats are habitat degradation and loss, pollution, prey depletion, harvesting pressure (as a result of human population growth), climate change, and noise. Growing exploration and industrialization of the Arctic come with an increase in underwater and air-borne noise. Sources of noise relate to oil, gas and mineral exploration and production, hydroelectric schemes, construction (of ports, buildings, roads), tourism, and traffic (marine, land-based and air). Noise and vibration measurements of land-based industrial activities will be presented, including excavation equipment, various types of ground vehicles, and blasting. Sound propagation characteristics will be explained. Results of a study measuring the transmission of industrial noise into polar bear dens will be shown and the potential effects of noise on Arctic animals will be discussed.

Kim (Greeneridge Sci., Inc., 1411 Firestone Rd., Santa Barbara, CA 93117, khkim@greeneridge.com), Aaron Thode (Scripps Inst. of Oceanogr., La Jolla, CA 92093-0238), and Charles R. Greene, Jr. (Greeneridge Sci., Inc., Santa Barbara, CA 93117)

In 2008, vocalizing bowhead whales (*Balaena mysticetus*) conducted their fall migration in the Beaufort Sea amidst short- and long-range seismic exploration activities. Whale calls and airgun pulses were recorded on five arrays of Directional Autonomous Seafloor Acoustic Recorders (DASARs) deployed along 280 km of Alaska's North Slope. One particular sequence of pulses was recorded from the *Louis S. St. Laurent*, a Canadian geophysical vessel conducting surveys in deep offshore waters in collaboration with the United States Geological Survey (USGS), thus providing a fix on the location of some distant airgun activity. The distant airgun signals display an interesting selection of long-range propagation effects, which will be discussed and analyzed in the context of range-dependent propagation modeling in a combined deep-water upward-refracting and shallow-water bottom-interacting environment. [Work supported by the U.S. Geological Survey.]

1pAO8. Ambient noise in the Chukchi Sea, July 07 Oct 2009. Bruce Martin, Julien Delarue, and David Hannay (JASCO Res., 1496 Lower Water St., Halifax, NS B3B 1R9, Canada, bruce@jasco.com)

Shell Exploration and Production Company and ConocoPhillips Alaska have commissioned a multi-year acoustic study of marine mammal vocalization activity and ambient sound levels in the Alaskan Chukchi Sea. A large acoustic dataset, collected between July 2007 and October 2009, has been analyzed and has provided a wealth of information about the seasonal soundscape of the Chukchi Sea. This paper presents the ambient noise results throughout the acquisition time period. The analysis investigates the contributions made to ambient levels by shipping, marine mammals, seismic activity, and ice. We will show how short term weather conditions can

strongly affect the noise levels measured on bottom-moored recorders. Certain mammal vocalizations such as bearded seal trills and bowhead moans can dominate ambient noise levels over large time periods.

1pAO9. Where do the Chukchi Sea fin whales come from? Looking for answers in the structure of songs recorded in the Bering Sea and Western North Pacific. Julien Delarue (JASCO Appl. Sci., 432-1496 Lower Water St., Halifax, NS B3J 1R9, Canada), Dave K. Mellinger (Oregon State Univ., Newport, OR 97365), Kathleen M. Stafford (Univ. of Washington, Seattle, WA 98105), and Catherine L. Berchok (NOAA/AFSC, Seattle, WA 98115)

Fin whales are common throughout the North Pacific and have recently been detected acoustically as far north as the northeastern Chukchi Sea. Non-acoustic evidence suggests that North Pacific fin whales are segregated into two populations wintering along the Asian and North American coast with at least some animals intermingling in the summer in the Bering Sea-Aleutian Islands area. Male fin whales produce regionally distinctive songs which are likely indicative of population structure. In this study we evaluated the relationship of fin whales recorded in the northeastern Chukchi (2007 and 2009) and southeastern Bering (2007–2008) seas by comparing the structure of their song. Additionally, we investigated whether fin whales detected in these areas could be part of an Asian population by comparing their songs to those recorded near the Emperor Seamounts in the western North Pacific (2007). The results will be discussed in light of the current knowledge on North Pacific fin whale population structure.

1pAO10. Factors influencing biodiversity and marine animal habitat use in the Bering Sea. Jennifer L. Miksis-Olds (Appl. Res. Lab., Penn State, P.O. Box 30, State College, PA 16804, jlm91@psu.edu) and Jeffrey A. Nystuen (Univ. of Washington, Seattle, WA 98105)

A combination of active and passive acoustic technology was integrated into NOAA oceanographic moorings at two locations on the eastern Bering Sea shelf. Physical, biological, and acoustical oceanographic instruments made synoptic measurements of marine mammal presence, zooplankton/fish concentrations, physical oceanographic processes, primary production, and sound levels from 2008–2009. Synergistic factors influencing biodiversity and marine animal habitat use were investigated. Observed patterns in the central Bering Sea indicate that ecosystem dynamics and the acoustic environment are strongly driven by sea ice. Marine mammal presence and diversity were tightly coupled to sea ice presence. Bowhead whales and ice seals dominated the acoustic soundscape during the winter and spring, whereas geophysical signals dominated during the fall and summer months. Zooplankton abundance was also tightly linked to ice coverage. Time series of acoustic backscattering strength during the winter months indicated that the zooplankton community rapidly responds to short period of open water at a level that equals or exceeds maximum volume backscatter values at other times of the year. Integrated data such as these will be vital in understanding the relationship between marine mammals, zooplankton, and the physical environment. [Work supported by ONR.]

4:30

1pAO11. Analysis of marine mammal detections from the Bering Sea relative to a 10 day retreat of sea ice in March 2009. Samuel L. Denes (Grad. Prog. in Acoust. and Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804-0030, sld980@psu.edu) and Jennifer L. Miksis-Olds (The Penn State Univ., State College, PA 16804-0030)

Patterns of marine mammal detections from an adaptive sub-sampling acoustic recorder deployed in the Bering Sea are related to a temporary retreat of sea ice. Ice coverage data from the NOAA Ice Desk showed a 10 day period in March 2009 during which no ice was detected over an NOAA oceanographic mooring equipped with the acoustic recorder. During periods of ice coverage, bearded seal and bowhead whale vocalizations dominated the soundscape and were the primary sources triggering a high-duty cycle sampling mode. Bearded seal vocalizations decreased immediately following the transition from ice cover to open water. The sub-sampling protocol limits the number of short duration sound clips recorded each day in order to conserve power and storage space during year deployments. Periods with ice coverage preceding and following the ice retreat exceeded the maximum daily limit within the first 2 h of the day. During the first day of open water, there were only two detections. Temporal variation in the number of bearded seal detections is highly coupled to sea ice characteristics, illustrating the importance of this environmental feature to the bearded seal mating system. [Work supported by ONR.]

1pAO12. Right whale distribution in the Bering Sea revisited: A fresh look. Jessica Crance, Catherine Berchok, Phillip Clapham (NOAA Natl. Marine Mammal Lab., 7600 Sand Point Way, Seattle, WA 98115, jessica.crance@noaa.gov), Marc Lammers, Whitlow W. L. Au (Hawaii Inst. of Marine Biology, Kaneohe, HI 96744), David K. Mellinger, and Sharon Nieukirk (Oregon State Univ., Newport, OR 97365)

The North Pacific right whale (*Eubalaena japonica*) is one of the most endangered baleen whales in the world, with current abundance estimates of fewer than 40 individuals. As such, it has been the focus of intensive population monitoring studies. Long-term passive acoustic monitoring is a useful tool for assessing distribution, habitat use, and population status of marine mammals. For Bering Sea right whales, past analyses of distribution were based on their stereotyped upsweep call. Results from sonobuoy recordings made during the 2008 and 2009 southeastern Bering Sea right whale cruises, however, found gunshot calls to be much more common. To assess whether inclusion of gunshot call detections will change our understanding of the spatial and temporal distribution of North Pacific right whales, we examined four years (2006–2009) of long-term recordings made by the National Marine Mammal Laboratory and the Pacific Marine Environmental Laboratory at six different locations on the Bering Sea shelf. A comparison of the results using upsweeps, gunshots, and a combination of both will be presented. [Work supported by an Inter-Agency Agreement from the Minerals Management Service.]

5:00

1pAO13. Results and insights from operational acoustic monitoring networks in the Chukchi Sea, Summer-Fall 2006 and 2008. Russell A. Charif, Ann Warde, Dimitri Ponirakis, Anita Murray, Charles Muirhead, Michael Pitzrick, Christopher W. Clark (Bioacoustics Res. Program, Cornell Univ., 159 Sapsucker Woods Rd., Ithaca, NY 148504), Sheyna Wisdom (URS Corp., Anchorage, AK 99503), and Caryn Rea (Conoco Phillips Alaska, Inc., Anchorage, AK 99501-3439)

Recordings for marine mammals were collected in the Chukchi Sea in the 2006 and 2008 summer-fall seasons in proximity to seismic exploration activities. 2006 data were from MARUs off Cape Lisburne, Pt. Lay, Wainwright, and Pt. Barrow, AK. 2008 data were from MARUs in the Burger and Klondike areas. In 2006, belugas, but no bowheads, were rarely detected off Cape Lisburne in July–September. Bowheads, but no belugas, were detected off Wainwright, Lay, and Barrow in September–October, with bowheads very common off Barrow. Seismic airgun sounds were common on distant MARUs off Cape Lisburne, Lay, and Wainwright. There were very few seismic events detected off Barrow and those few were all close to 0-dB SNR. In 2008, bowheads were more common at Burger than Klondike and occurred mostly during the latter part of the September–October period; belugas were not detected at Burger and only on 6 days early in the period at Klondike; walrus were more common at Burger than at Klondike. In both areas bowhead densities were low-moderate. Seismic sparker sounds were detected on 7 and 28 days at Burger and Klondike, respectively, with higher received levels at Klondike.

1pBB1. A two-scale model to describe cavitation dynamics in viscoelastic media. Stéphane Labouret, Jamie R. T. Collin, and Constantin C. Coussios (Biomedical Ultrason. & Biotherapy Lab. (BUBL), Inst. of Biomedical Eng., Dept. of Eng. Sci., Univ. of Oxford, Headington, Oxford OX3 7DQ, United Kingdom, stephane.labouret@eng.ox.ac.uk)

In spite of several decades of research on cavitation inception and onset in biological media, the exact environment experienced by a cavitating bubble at the micro-scale and in the MHz frequency range remains poorly understood. Comparison of model-based predictions of bubble behavior with optical observations in transparent media suggests that the mechanical property values of the medium could be up to two magnitudes different than the corresponding static values. Several viscoelastic media, such as tissue or tissue-mimicking materials, have been recently shown to exhibit a submicron structure which can be assumed equivalent to a pure liquid up to a characteristic length scale and essentially viscoelastic thereafter. The present work proposes an extension to the model recently proposed by Yang and Church [J. Acoust. Soc. Am. (2005)] that takes this dual scale into account. Model predictions are validated against experimental results obtained by inducing single-bubble inertial collapses in an agar-based tissue mimicking material using short pulses produced by a 1.1-MHz HIFU transducer; the resulting acoustic emissions are acquired using a calibrated passive cavitation detector, thus enabling direct comparison with the inertial cavitation threshold and radiated sound amplitude predicted by the single-scale and novel dual-scale models.

1pBB2. High-intensity focused ultrasound as a potential treatment modality for heterotopic ossification. Sandra L. Poliachik (Orthopaedics and Sports Medicine, Univ. of Washington, 325 Ninth Ave., Seattle, WA 98104, poliachi@u.washington.edu), Tatiana D. Khokhlova, and Michael R. Bailey (Univ. of Washington, Seattle, WA 98105)

Heterotopic ossification (HO) is the growth of bone in abnormal locations such as soft tissue. HO is a frequent secondary complication of common trauma, e.g., amputation or spinal cord injury. HO causes pain, motion restriction, and poor prosthetic fitting. Current HO treatments include nonsteroidal anti-inflammatory drugs, radiation, surgery, and shock-waves, but HO often returns. In this work, feasibility of HO treatment using high-intensity focused ultrasound (HIFU) is studied. HIFU may induce destruction of HO nodules by a combination of thermal ablation and mechanical erosion through bubble activity. In preliminary experiments bone sections from rodent proximal tibiae embedded in polyacrylamide gel were used as tissue phantoms; subsequent experiments were performed on HO induced in a mouse calf muscle. A 2-MHz focused transducer was used to generate pulses of shock waves with peak positive pressure of 67 MPa, duration of 10–100 ms, and 1%–10% duty cycle. High-resolution microCT imaging of the samples was performed prior to and following HIFU exposure. Both mechanical damage of the porous bone structure and thermal denaturation of the bone were observed. The data obtained suggest that HIFU may be an option for non-invasive treatment of HO. 1pBB3. Nonlinear distortion associated with high-intensity focused ultrasound creates apparent displacements in acoustic radiation force imaging. Andrew B. Draudt and Robin O. Cleveland (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02474)

An acoustic radiation force imaging (ARFI) system has been developed which employs a 1.1-MHz high-intensity focused ultrasound (HIFU) source to create the pushing beam (0.5–7-MPa peak pressure) and a focused 7.5-MHz transducer (mounted concentrically in a hole of the HIFU transducer) to create the imaging pulse. The motion of tissue is determined by recording multiple A-lines from the imaging transducer and using speckle tracking to estimate displacement. The HIFU was amplitude modulated to result in a time-varying radiation force and imaging pulses transmitted simultaneously in order to monitor tissue motion during the push phase. Measurements of the pressure waveforms in water indicated that nonlinear distortion of the HIFU could advance the arrival time of the imaging pulse if it was on a pressure peak and retard it if it was on a pressure trough, resulting in apparent displacements on the order of 5 μm. The apparent displacement varied with the phase at which the ARFI was transmitted and increased with the HIFU pressure amplitude. Experiments with ARFI in chicken breast indicated that the apparent displacement varied with depth which appeared to be related to differences in the diffraction patterns of the two sources. 1pBB4. Rytov modeling for backscatter monitoring of high-intensity focused ultrasound therapy. Gavriel Speyer, Peter Kaczkowski, Andrew Brayman, and Lawrence Crum (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

Accurate monitoring of high-intensity focused ultrasound (HIFU) therapy is critical for ensuring proper treatment. Changes in time of flight for diagnostic ultrasound (DU) backscatter have been recognized as a means to identify temperature changes between two DU frames, captured before and after HIFU therapy. Estimates of heating from precisely controlled HIFU experiments strongly indicate that DU measurements are formed by an interaction between the heated material and a diffuse DU beam, as opposed to the commonly assumed ray model for the DU beam. The existence of a diffuse beam can be explained using the Rytov method, where temperature induced changes in material properties affect the phase and amplitude of the probing signal, with cumulative effects produced over characteristic volumes, and not simply depths. In particular, the temperature effect for on-axis backscatter is shown to be a generalization of the models proposed by Simon (1998) and Moreno (1996), with the phase determined by a complex weighted average of temperature in cross sections perpendicular to the DU

beam axis. Results are illustrated using data obtained from gel phantoms, where the beam interaction is shown to provide therapy estimates consistent with the true therapy. [Work supported by NIH grant 5R01CA109557].

1pBB5. Tissue erosion using millisecond boiling in high-intensity focused ultrasound fields. Michael S. Canney (INSERM U556, 151 Cours Albert Thomas, Lyon Cedex 03, France), Tatiana D. Khokhlova, Yak-Nam Wang, Vera A. Khokhlova, Michael R. Bailey, and Lawrence A. Crum (Univ. of Washington, Seattle, WA 98105)

High-intensity focused ultrasound (HIFU) transducers can be operated at high-pressure amplitudes of greater than 60 MPa and low-duty cycles of 1% or less to induce controlled bubble activity that fractionates tissue. The goal of this work was to investigate fractionation not from mechanically induced cavitation but from thermally induced boiling created by HIFU shock waves. Experiments were performed using a 2-MHz HIFU source. The focus was placed in *ex vivo* bovine heart and liver samples. Cavitation and boiling were monitored during exposures using a high-voltage probe in parallel with the HIFU source and with an ultrasound imaging system. Various exposure protocols were performed in which the time-averaged intensity and total energy delivered were maintained constant. The types of lesions induced in tissue ranged from purely thermal to purely mechanical depending on the pulsing protocol used. A pulsing protocol in which the pulse length was on the order of the time to boil (of only several milliseconds) and duty cycle was low ($<1\%$) was found to be a highly repeatable method for inducing mechanical effects with little evidence of thermal damage, as confirmed by histology. [Work supported by NIH EB007643, NSBRI SMST01601, and RFBR 09-02-01530.]

1pBB6. Enhanced high inensity focused ultrasound-induced heating in a phantom. Cecille Pemberton Labuda (Dept. of Phys. Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677, cpembert@olemiss.edu)

High intensity focused ultrasound (HIFU) has the capability to induce hemostasis through rapid delivery of energy in the HIFU focal region. HIFU effectively induces hemostasis in small blood vessels; however, as vessel size increases, loss of heat to the flow increases until HIFU treatment is only minimally effective. A new method to enhance the HIFU-induced heating effect was investigated. Single polymer fibers embedded in a heat-sensitive phantom are shown to increase the size of HIFU-induced lesions as compared to controls. Polymer meshes were then embedded in the phantom and the size of the HIFU-induced lesions produced were compared with control lesions.

2:30

1pBB7. Transcranial microbubble destruction by using re-focusing ultrasound. Po-Wen Cheng (Graduate Inst. of Biomedical Electrons and Bioinformatics, Natl. Taiwan Univ., Rm. 731, MD Bldg., No. 1, Sec. 4, Roosevelt Rd., Taipei, Taiwan 106, f95921110@ntu.edu.tw) and Pai-Chi Li (Natl. Taiwan Univ., Taipei, Taiwan 106)

Administration of microbubbles (MBs) during transcranial Doppler monitoring further accelerates ultrasound-enhanced thrombolysis. However, low efficiency of transcranial ultrasound transmission resulting from phase aberrations through skull is still an obstacle. To alleviate this, re-focusing by phase aberration correction using echoes from microbubbles can be performed. Two re-focusing methods were designed for transcranial MB destruction. One is adjusting the emission phases derived from the channel-to-channel correlation of received signals. The other is simply adjusting the transmit focal depth. This is possible because the phase aberrations typically result in approximately parabolic delay errors. Focusing quality was compared using finite difference time domain simulations, and the mechanical index (MI) distributions were calculated as indices for likelihood of microbubble destruction. Using the correlation based methods, the beamwidth becomes 45.5% narrower than that by using the time reversal method. The MI can also be increased by 15.9% while keeping it under safety range. Adjusting the transducer position, on the other hand, can also enhance the focusing efficiency and improve efficiency of ultrasound-enhanced thrombolysis. It is also easy to implement using current clinical systems.

2:45

1pBB8. Noninvasive *in vivo* cavitation threshold detection during blood-brain barrier opening using focused ultrasound and the contrast agent and definity. Yao-Sheng Tung, Fotis Vlachos, Thomas Deffieux, and James Choi (Dept. of Biomedical Eng., Columbia Univ., Vanderbilt Clinic 12-232, 622 W. 168th, New York, NY 10032 ek2191@columbia.edu)

The *in vivo* cavitation response associated with blood-brain barrier (BBB) opening as induced by transcranial focused ultrasound (FUS) and microbubbles was studied in order to better identify the underlying mechanism. A cylindrically focused hydrophone, confocal with the FUS transducer, was used as a passive cavitation detector (PCD) to identify the threshold of inertial cavitation (IC) in the presence of definity microbubbles. After definity was injected intravenously, pulsed FUS, with parameters previously shown to generate opening, was applied (frequency: 1.525 MHz, peak-rarefactional pressure: 0.30–0.60 MPa, duty cycle: 20%, PRF: 10 Hz, duration: 1 min) on the right hippocampus of five mice *in vivo* through their intact skin and skull. T1-weighted MRI was used to verify BBB opening. A spectrogram was generated at each pressure in order to detect the IC onset and duration. The IC threshold detected was 0.60 MPa and mainly occurred during the first 50 cycles. Harmonics were also detected during BBB opening starting at 0.30 MPa indicating stable cavitation occurrence. In conclusion, stable and inertial cavitation could be detected *in vivo* without craniotomy and IC is not required for BBB opening. [This work was supported by NIH R21EY018505, NIH R01EB009014 and NSF CAREER 0644713.

1pBB9. Cooperative radiation and losses in bubble clusters. Derek C. Thomas, Yurii A. Ilinskii, and Mark F. Hamilton (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713-8029)

In existing models for single bubble dynamics it is necessary to account for radiation damping, a consequence of fluid compressibility. A similar correction is necessary when modeling systems of coupled bubbles. The coupling alters the collective dynamics and therefore the acoustic power radiated. In the linear approximation and for compact clusters in which the bubbles pulsate in phase, the radiation damping per bubble increases in proportion to the number N of bubbles in the cluster, and the acoustic power is N times greater than is radiated by the cluster in the absence of bubble interaction. The latter effect is relevant to passive detection of cavitation noise as an indicator of the onset and degree of cavitation in therapeutic applications such as shock wave lithotripsy and high-intensity focused ultrasound. The effect that collective radiation damping has on the dynamics of several simple systems is considered for both small and large pulsations, and the relative magnitude of the effect is compared with damping due to viscosity and thermal conductivity. [Work supported by the ARL:UT McKinney Fellowship in Acoustics and NIH DK070618.]

1pBB10. Effects of quadrupole and octupole modes on coupled nonlinear bubble interactions. Eru Kurihara, Todd A. Hay, Jason P. Kurtz, Yurii A. Ilinskii, and Mark F. Hamilton (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713-8029)

Photographs of bubble cluster dynamics have shown that under sufficiently intense acoustic excitation, neighboring bubbles may undergo shape deformation and even form opposing liquid jets. Jetting is one of the chief mechanisms thought responsible for cavitation-induced erosion. Therefore, a better understanding of the phenomenon would be beneficial in improving the efficacy of and reducing collateral damage during medical procedures such as shock wave lithotripsy. Previous efforts to model aspherical collapse of a bubble near an interface have utilized purely numerical methods. In this presentation we derive dynamical equations for the coupled motion of two translating, aspherical gas bubbles. Deformation of the initially spherical

bubble surfaces is taken into account by including quadrupole and octupole spherical harmonics in the boundary conditions on each bubble. For an axisymmetric geometry, this results in a set of eight coupled second-order ordinary differential equations that may be integrated numerically in time. The effect of surface tension and shear viscosity on quadrupole and octupole contributions is included in a consistent manner. Simulation results agree qualitatively with measurements and predict the formation of opposing liquid jets for bubbles which are sufficiently close to one another. [Work supported by NIH DK070618.]

1pBB11. A new acoustic lens design for electromagnetic shock wave lithotripters. Nathan Smith, W. Neal Simmons, Georgy Sankin, and Pei Zhong (Dept. of Mech. Eng. and Mat. Sci., Duke Univ., Durham, NC 27708)

The third-generation electromagnetic (EM) shock wave lithotripters often have narrow focal width and high-peak pressure compared to the original HM-3. In addition, the pressure waveform produced by a typical EM lithotripter has a secondary compressive wave that suppresses lithotripter pulse induced cavitation, which is an important mechanism for stone comminution. These features have been contributed to the reduced effectiveness of the modern EM lithotripters. To overcome these drawbacks, we have designed a new acoustic lens for the Siemens Modularis EM lithotripter that produces an idealized pressure waveform similar to the HM-3 with broad focal width and low-peak pressure. At acoustic pulse energy of 53 mJ, the new lens design enlarges the -6 dB focal width of the Modularis by 47% while significantly reducing the second compressive wave throughout its focal plane. After 2000 shocks, *in vitro* comminution produced by the original and new lens designs are 100% and 99% at the lithotripter focus, and (49 .7$\pm$15.0)% and (75.3$\pm$8.74)% ($p < 0.001$) at 10 mm off axis, respectively. Corresponding values *in vivo* are (63.4$\pm$17.4)% and (83.3$\pm$8.5)% ($p < 0.01$), demonstrating the significant performance improvement provided by the new lens design. [Work supported by NIH Grant Nos. R01DK052985 and S10RR016802.]

1pBB12. Gas content of the medium surrounding a stone has a significant effect on the efficiency of stone breakage in shock wave lithotripsy. Yuri A. Pishchalnikov (Dynaflow, Inc., 10621-J Iron Bridge Rd., Jessup, MD 20794, yurapish@gmail.com), Anthony J. Zancanaro, James C. Williams, Jr., and James A. McAteer (Indiana Univ., Indianapolis, IN, 46202-5120)

In shock wave lithotripsy inertial collapse of cavitation bubbles produces daughter microbubbles [Y. A. Pishchalnikov *et al.*, BJU Int. **102**, 1681–1686 (2008)]. This will cause proliferation of bubbles only if daughter microbubbles survive until the arrival of the next shock wave (SW). While the time interval between SWs is determined by the firing rate of the lithotripter, the dissolution time of microbubbles depends on concentration of dissolved gas in the water. Thus, the same firing rate may produce different cavitation fields depending on the gas concentration. We assessed how the concentration of dissolved gas in the water tank affected SWs and the efficiency of stone comminution. More numerous bubbles generated in nondegassed water caused a dramatic reduction in the trailing negative-pressure component of the SWs, while the leading positive-pressure phase remained almost unchanged. It required 3.5 times more SWs to break stones in nondegassed water than in water degassed to 30% ($P<0.001$). This suggests that changes in temporal profiles of the SWs associated with cavitation are responsible for reduced efficiency of stone comminution observed in dense cavitation fields, regardless of whether these denser cavitation clouds were generated by using a faster rate or higher gas content. [Work supported by NIH-DK43881.]

4:30

1pBB13. Hydrophone array for instantaneous measurement of lithotripter fields. Jonathan M. Kracht (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215), Jeffrey A. Ketterling (Riverside Res. Inst., New York, NY 10038), and Robin O. Cleveland (Boston Univ., Boston, MA 02215)

Electrohydraulic lithotripters employ a spark placed within a hemiellipsoidal reflector to generate shock waves (SWs). The shot-to-shot jitter in the spark location results in variability in acoustic measurements, e.g., 50% variation in peak positive pressure. Field measurements with a single-element hydrophone therefore only provide average field properties over many SWs. The ability to obtain an instantaneous "snapshot" of the sound field would have broad implications for advancing the understanding of how lithotripters fragment stones and damage kidney tissue. Here linear hydrophone arrays consisting of 20 elements were created by bonding a piezopolymer film to copper-clad polyimide. An array pattern was etched on the copper to provide individual connections to the 20 elements. Failure testing of the hydrophone array was conducted in a piezoelectric lithotripter that generated 60 MPa peak pressure. The sensitivity of the hydrophone remained relatively constant through the first 500 SWs and then gradually decreasing over a 500–1000 SW period. This reduction was attributed to damage from cavitation activity and was confirmed by visual inspection after testing. A new hydrophone was developed and results from measurements of an electrohydraulic lithotripter will be reported. [Work supported by the National Institutes of Health (DK081119 and DK43881).]

1pBB14. Pocket-sized ultrasonic surgical and rehabilitation solutions: From the lab bench to clinical trials. George K. Lewis, Jr., William L. Olbricht, and Peter Henderson (Dept. of Biomedical Eng., Cornell Univ., 108 Olin Hall, Ithaca, NY 14853, george@cornellbme.com)

The use of ultrasound in medicine has quickly evolved in the last decade as a therapeutic modality and means to treat disease independently or in combination with other therapeutic regimes such as chemotherapy. The interaction of ultrasonic waves with soft mammalian tissues has the innate impact of enhancing tissue permeability to therapeutics, increasing local blood flow at low-acoustic powers, and causing tissue necrosis and cell death at higher-energy levels. We have developed multiple pocket-sized (4$\times$2$\times$1 in.) lithium battery powered therapeutic ultrasound units based off of our novel ultra-efficient electrical amplifier design that produces acoustic energies for low- and high-power applications (1–130 W). The portable ultrasound technology has been used in our laboratory to enhance ten-fold the delivery and efficacy of convection enhanced drug delivery to treat brain gliomas *in vitro* and *in vivo*. Our clinical collaborates at Weill Cornell Medical Hospital use our devices at high powers to non-invasively cauterize veins as a novel method of varicose vein treatment. Our clinical collaborators provide new avenues of ultrasound research and critical user feedback on the technology to aid refinements in its implementation in hand-held acoustic applications.

1pMU1. Learning by playing: Musical acoustics of found objects. Laurie McNeil (Dept. of Phys. and Astronomy, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC 27599-3255, mcneil@physics.unc.edu)

"Teaching by telling" has been shown to be ineffective in many physics contexts, and acoustics is no exception. In my 10 years of teaching, a freshman seminar "The Interplay of Music and Physics," about the physics of musical instruments, I have learned that there are some concepts that students learn only by making their own instruments and discovering how the success of the instruments depends on them. My colleague Professor Brent Wissick of our Department of Music and I have team-taught this class to college students of a broad range of backgrounds and majors. The students design and build stringed and wind instruments out of whatever they can find lying around their dorm rooms. At the end of the semester, they give a concert of music of their own composition, played on the instruments they have created. In this presentation, I will discuss what we have learned about how such activities teach the students acoustical principles in ways that more conventional means do not accomplish.

1:30

1pMU2. Homemade "woodwind" and "brass" instruments. Stephen Luzader (59 Centennial St., Frostburg, MD 21532, sluzader @frostburg.edu)

PVC pipe is an ideal material for the construction of wind instruments, both "woodwind" (using a reed) or "brass" (using the lips). Instruments can be made using a combination of PVC construction along with parts of actual musical instruments, such as a clarinet mouthpiece and reed or a trumpet mouthpiece, or they can be manufactured entirely from PVC and other materials. For panpipes, the lengths of the tubes are easily determined by choosing a standard pitch frequency and the basic interval between tones (e.g., 440 Hz and equal temperament) and then using basic physics to calculate the required tube lengths. For instruments using side holes, the locations of the holes can be determined by choosing a standard pitch frequency and interval and then calculating the required distances of the holes from the driven end of the pipe. The basic theory will be reviewed, and several different instruments will be demonstrated.

1:55

1pMU3. Homemade musical instruments for the classroom. Thomas J. Senior (355 Dell Ln., Highland Park, IL 60035-5310)

Pan pipes produced using drinking straws provide a very inexpensive way for students to study the nature of resonant columns and musical scales. A slide whistle is also easily made using the straws. Most students easily learn to produce tones from the pan pipes/slide whistle. For situations where too many loud sounds would be undesirable, the "Palm Pipe" offers a similar learning experience. The palm pipe is a single length of PVC pipe that can be played by striking the palm on the end of the tube to produce a tuned percussive sound. Methods for the production of slide whistles, pan pipes, and palm pipes will be described and demonstrated in this presentation. A few other "musical" devices will be shown as time permits, including a stadium horn and a thunder drum.

2:20

1pMU4. Homemade musical instruments. Ann Sayre Wiseman (284 Huron Ave., Cambridge, MA 02138, ansayre@aol.com)

When the creative arts were dropped from the school curriculum for lack of money in 1972, as Program Director at the Boston Children's Museum Visitor Center (Jamaica Plain), we created low-cost learning by doing workshops for teachers using available materials. Out of this an orchestra of good sounds was born. Good sounds found in the kitchen and junk yard by tapping everything to hear its note. We made excellent conduit-pipe xylophones, drums, horns, strings, and percussion instruments hung from a frame. A low cost musical program any teacher could include in the curriculum, involving math, history, and research, the kind of learning you never forget when making useful things by hand with your own initiative. These recipes became Making Things Handbook of Creative Dis-

coveries, winning awards, and freely photocopied by teachers who wrote this book is my classroom bible. The handmade orchestra became another book: Making Musical Things and in 2002 Storybook Press republished it as Making Music, including John Langstaff's Inovative Clock Orchestra and the Art of Conducting. As an Expressive Therapist in 2005 with International exchange groups, we took these workshops abroad to show students and medical professionals the healing powers of the creative process.

2:35

1pMU5. The homemade didgeridoo: An ancient acoustic resonator. Chad A. Greene (Dept. Mech. Eng. and Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78712-0292)

The didgeridoo is an ancient Aboriginal instrument traditionally crafted from Eucalyptus trees which have been hollowed out by termites. The instrument is an excellent example of a simple one-dimensional acoustic resonator with a fundamental resonance corresponding to one-half wavelength. Today, the ubiquity and low cost of PVC pipes make didgeridoos inexpensive, easy to find, and trivial to construct from materials found at any hardware store. Students will have fun learning to make sounds with the instrument—perhaps they will even learn the technique of circular breathing—all while exploring fundamental principles of acoustics. As further investigation students can hum as they play, resulting in "beats, the speed of which can be adjusted by changing the pitch of the hum.

2:50

1pMU6. Homemade digital musical instruments. Edgar Berdahl, Wendy Ju, and Julius O. Smith, III (Dept. of Music, CCRMA, Stanford Univ., Stanford, CA 94305, eberdahl@ccrma.stanford.edu)

Homemade musical instruments are wonderful tools for getting students interested in learning about acoustics. Homemade *digital* musical instruments can similarly engage students, provoking them to learn more about the modern world surrounding them. In addition, the tools for developing homemade digital musical instruments are now becoming so easy to access that students can benefit from them too. The Arduino tool chain is introduced for interfacing sensing circuits with the computer over a USB port. Modern sensors are so simple that only a basic understanding of the voltage divider is required for building many useful sensing circuits. Synthesizing sound according to incoming data from the sensors is equally straightforward due to graphical environments commonly employed for sound synthesis programming. While many sound synthesis models are available, physical models of acoustic musical instruments are especially intriguing because students can relate to interacting with physical objects. Step-by-step instructions are provided for ordering parts and creating a simple but easily extensible homemade digital musical instrument that triggers sounds from a physical model of a vibrating string.

3:15

1pMU7. Pedagogical possibilities: Some ideas for instrument making in the classroom. Bart Hopkin (P.O. Box 421, Point Reyes Station, CA 94956, emi@windworld.com)

As a brief introduction, historical etchings of a few intriguing 19th century contraptions for classroom demonstrations of acoustic principles will be shown. Following that, several classroom-buildable musical instruments will be described. The emphasis will be on instruments that effectively illustrate acoustic or mathematical principles. They will also be fun to make and play, and practical in a classroom context, requiring a minimum of special tools, skills, or materials. Topics to be illustrated through hands-on instrument making may include relationships between frequency, wavelength and pitch, harmonic and inharmonic overtones, relationships between drivers, radiating surfaces and atmosphere, linear and inverse-squared functions, and more.

1pMU8. Building a musical instrument as a laboratory project in a short-term course. Andrew C. Morrison (Dept. of Phys., DePaul Univ., 2219 N. Kenmore, Chicago, IL 60614-3504)

In a month-long short course titled "Sound, Music, and Hearing" students were required to design and build their own instruments as a final laboratory project. The assignment requires that the instrument be able to play a scale of a minimum of five notes recognizable to the ear of the instructor. Students were allowed to work in pairs, or alone on the instrument laboratory. A review of strategies for overcoming the challenges of including an instrument building laboratory in a short-term course designed for general education credit is presented.

3:45

1pMU9. America's next top physics rockers: A project based learning unit in which students build, perform, and explain homemade instruments. Charles H. Sabatier (Mount Vernon High School, 8515 Old Mount Vernon Rd., Alexandria, VA 22309, charles.sabatier@fcps.edu)

Project based learning requires that students engage with content in order to be successful in completing a project. This teaching method creates a need-to-know which motivates students to learn more so than the traditional physics unit. Knowledge and skills outside of the physics content such as preparing presentations, using tools and technology, and utilizing different writing styles are required to be successful in the project. Making the project authentic is necessary to truly motivate students to exceed expectations. In this particular project based learning unit, students have built their own musical instruments, performed a musical piece in a small group, and taught others about how their instruments work individually and as an ensemble. In completing this project, students learn about vibrations, resonance, amplitude, frequency, wavelength, and how the characteristics of their instruments affect these physics principles. In order to make this project truly authentic, the top students will be selected to perform and explain their instruments as part of this talk. All students participating in this project (pending funding) will attend the session and support their classmates in this presentation. If funding is not available, video clips of student performances and explanations will be substituted.

1pMU10. Homemade musical instruments from Westtown school. Barry, H. Feierman (Dept. of Phys., Westtown School, West Chester, PA 19382)

Westtown School has implemented a team-taught collaborative class in high school featuring the Music and Science Departments. A new course, The Physics of Sound/Music, aims to teach students about the physics of sound waves and music theory. The course is open to 11th/12th graders and is team-taught by a science teacher and a music teacher. Objective: Each student will demonstrate his/her knowledge through the design and construction of a new, unique musical instrument,write a musical composition to feature the instrument, and play that piece in a student recital. This course is an elective open to students who have already completed chemistry and physics, and appeals to students who would like a creative challenge in terms of both design and construction of a musical instrument. This paper will be to describe the nature of the course, the experience of its two teachers, and to allow some of the students in the class to demonstrate their home-made instruments and talk about their experience. [Westtown School is a K-12 Quaker co-ed boarding school near Philadelphia.]

1pNCa1. Modeling with the use of the commercial software package CADNAA (Computer-Aided Noise Abatement) to estimate the probability of awakening associated with train horns. Stephen Szulecki (The Noise Consultancy, LLC, 309 Van Neste Rd. Flemington, NJ 08822, steve-noiseconsultancy@comcast.net), Eric Zwerling, Craig Anderson, and Barbara Turpin (Rutgers Univ. Noise Tech. Assistance Ctr.)

The Rutgers University Noise Technical Assistance Center conducted a long-term acoustical study to assess the noise exposure of residents in Teaneck, NJ to noise associated with idling freight trains. One of the noise sources evaluated was idle-related horn usage, at locations other than grade crossings. Trains on an adjacent track overtaking an idling locomotive regularly blow their horn as they approach and pass an idling train. The primary impact on the community due to this type of horn use is sleep disturbance. In order to evaluate this impact, an analysis was performed using CADNAA acoustical modeling software, in an innovative manner, to evaluate the probability of awakening (POA) as a result of idle-related horn usage based on ANSI/ASAS-12.9-2008/Part 6, a standard for estimating awakenings. The standard presents a series of formulas that calculate the POA as a function of a sound exposure level of a single or series of noise events. Other factors influencing the POA are time since retiring and whether the sound is new or existing. The model output is a graphic of equal-probability contours showing the POA at least once throughout the night.

1:15

1pNCa2. Transit noise and community choices. Ahmed El-Aassar (5801 Grayson Rd., Harrisburg, PA 17111, aelaassar@envact.com) and David Dubbink (Noise Management Inst.)

Transit innovations and expansions are a central part of initiatives to construct more livable communities. As part of the National Environmental Policy Act process, public involvement is required and public feedback and support are essential for projects to move forward. Generally, accessibility improvements are welcomed by the public, but the potential for increased noise is often met with opposition—and concerns about transit noise can stifle initiatives. One way to build community acceptance is to accurately compare transit options. The authors explain how community groups and decision makers in Florida responded to a presentation system providing direct acoustic experience of over a dozen transit modes, from light rail guideway transit to commuter railways. The goal of the acoustic presentation was to compare existing freight train sound levels to those of an array of transit technologies. The audio-visual presentation included interactive videos and computer animations, allowing proposed transit modes to be heard at different distances and in outdoor or indoor settings.

1:30

1pNCa3. Contemporary consulting practice in California's central coast. David Lord (45dB.com, 299 Albert Dr., San Luis Obispo, CA 93405, dl@45db.com)

The resolution of technical, theoretical, and practical issues for a small consultancy in a remote location brings better results and greater satisfaction to all involved. This paper will describe the range of consulting projects encountered in a typical year and will briefly cover the technical tools used and their application to modest-scale residential and commercial development in the Central Coast of California. The acoustics consultant's responsibility and influence on project development require technical expertise, negotiation, and tailored explanations-on-demand of principles and details to clients, design professionals, builders, and planners as well as interested and sometimes skeptical community groups.

1:45

1pNCa4. A case study in cooperation: A gravel pit and its community. Edward Duncan and Kenneth Kaliski (Resource Systems Group, 55 Railroad Row, White River Junction, VT 05001, eduncan@rsginc.com)

It is often the case in the permitting and operation of gravel extraction and crushed stone quarries that aggregate companies and the local community are pitted against one another. This paper presents a case study of an existing gravel pit that came together with the community to work through concerns about the existing operations and a proposed expansion. The topics

of discussion include the interesting dynamics involved in the consulting process, resulting mitigation to meet local standards and community concerns, conflicts of interests, and the local permitting process. The cooperative process used is presented in contrast to traditional systems using case studies of projects that have undergone permitting using more adversarial process models.

2:00

1pNCa5. Evaluation of crowd noise in Beaver Stadium during Penn State football games. Andrew Barnard, Stephen Hambric (ARL/Penn State, P.O. Box 30, State College, PA 16804, arb279@psu.edu), and Steve Porter (Head Acoust.)

Sound pressure level measurements were made at Penn State (PSU) football games at Beaver Stadium, on the PSU campus, in Fall 2009. Twelve sound level meters were positioned around the field, on the press box, on the luxury suites, and outside the stadium to capture the characteristics of the crowd noise. The loudest portion of the sideline area was determined along with the maximum equivalent *A*-weighted sound pressure level. Additionally a HEAD VISOR acoustic array was utilized in conjunction with a portable white noise generator in order to determine which portions of the student section were generating the majority of the sound pressure on the field level. The results indicate which sections of students are able to most effectively project their voices onto the field.

2:15

1pNCa6. A three-stage approach to understanding listener perception of weapon signature for small arms. Jeremy Gaston and Tomasz Letowski (Dept. of the Army US Army Res. Lab., US Army Res. Lab., Aberdeen Proving Ground, MD 21005-5066)

The ability to identify and interpret impulse sounds from small arms weapon fire is a very important element of soldier's situational awareness that is critically needed to avoid potential danger. For example, differentiation of hostile from friendly weapon fire can indicate the need for increased vigilance and can reveal the approximate location of an enemy element. In addition, estimation of weapon size can be used to infer the resources of an enemy element. Despite the potential operational importance of these sounds, little is known about listener perception of impulse weapon sounds. The present work investigates listener ability to differentiate signatures of various small arms based on high-quality recordings of single-shot impulse sounds. Following the three-stage approach developed by Pastore *et al.* (2008) for studying natural sound perception, the interrelationships between weapon source properties, the physical attributes of the sounds produced and listener perception are evaluated for a number of small arms weapons. The mappings of these relationships provide the basis for developing training techniques for improving listener weapon signature identification ability.

2:30

1pNCa7. Design and test of a manufacturing building to meet a 40 dB from above 300 Hz up property line night noise limit. Angelo Campanella (Campanella Assoc., 3201 Ridgewood Dr., Hilliard, OH 43026, a.campanella@att.net)

A new one-story manufacturing plant was designed to operate around the clock 7 days a week. Its south property line adjoined existing residential lots. The existing noise ordinance required that the property line noise from the plant shall not exceed 40 dB at all frequencies above 300 Hz at night. The city had already erected an eight barrier mound near that line. Positions of plant air handling HVAC systems were revised to minimize sound emission to the south. Barriers were designed for the outdoor HVAC condensers. The building wall near noisy plant equipment was provided extra attenuation. On commissioning, it was found that a fan needed on the south facade was running above design speed and was readjusted. Sound at the property line was then so quiet compared to the environment that additional monitoring was conducted halfway between the plant wall and the property line. Measurement at the property line was made in 1/3 octave bands, and then parsed to approximate the old octave band limits format to demonstrate compliance.

2:45

1pNCa8. Limiting technology for modeling community noise from petrochemical facilities. Frank Brittain (Bechtel, Corp., 2255 Peavine Valley Rd., Reno, NV 89523, fhbritta@bechtel.com)

Modeling community noise is a vital part of designing any petrochemical, power, or industrial facility to meet community noise limits. Increasingly ray tracing, which is state-of-the-art software, is being used. Limitations of ray tracing can be categorized as those arising from the commercially available software (including ISO 9613 usually used for calculating outdoor propagation) and those related to input to the software. The former was covered by Brittain and Hale, Noise-Con 2008. The latter is covered in this paper. There are many technologies, which are needed to model community noise that are weak or for which data are not readily available. If the modeler understands where the technology is weak, then more effective models can be developed, and inaccuracies in the result can be better interpreted. Weak technologies or lack of data includes the following: modeling air coolers and cooling towers, modeling ducts and pipe racks, IL of pipeline and duct lagging, TL of building walls, noise radiated by building walls, source directivity, and—last but not least—getting accurate noise source data. Most of these become more critical at low frequencies. Each of these and their impact on design will be discussed.

3:00

1pNCa9. Creation of combined noise maps for noise prediction in petrochemical plants. Arindam Ghosh (KT-2425C, 601 Jefferson, Houston, TX 77002, arindam.ghosh@kbr.com)

Design of petrochemical plants involves producing detailed noise models with predicted noise contours at fine grids such as 1 m. However, background noise data collected during pre-construction environmental impact assessments (EIAs) are typically gathered at a few selected points. Since it is impractical for all the measurements to match the prediction grid, the measured data must be interpolated. This paper discusses how the survey grid is selected and interpolation optimized to meet the overall project noise control design basis and the post-start-up noise survey needs. The strategy varies based on the existing operational situation (brown-field or green-field), the type of land-use (rural or urban), the nature of terrain (flat or hilly), and the planned plant use (process area, loading and storage area, or administrative buildings). Finally, the unique needs for petrochemical process plants (as opposed to general city planning) for long term and area-wide background noise measurements are outlined.

3:30

1pNCb1. Petrol-chemical plant noise models: Noise surveys, model development and validation. Hans Forschner, Sr. and Jim Steedman (Navcon Eng. Network, 701 W. Las Palmas Dr., Fullerton, CA 92835 Forschner@navcon.com)

Developments in computer modeling & presentation software has changed how acoustical engineers approach noise planning, mitigation, trending projects. The ability to quickly and accurately develop a three dimensional (3-D) noise model of a project area and/or to create noise contours from measured data allow for a more rigorous analysis in a shorter period of time while maintaining a level of consistency with current acoustical engineering standards and practices. This paper describes the procedures and methods for generating 3-D computer noise models, validating noise models, and graphically comparing measured and predicted noise levels.

3:45

1pNCb2. Noise prediction for industrial facilities. Wolfgang Probst (DataKustik GmbH, Gewerbering 5, 86926 Greifenberg, Germany, info @datakustik.com)

The methodologies used to predict the noise caused by industrial facilities are presented and ranked. There are a lot more scientifically based methods that use certain approximations to solve or apply the wave equation in a layered atmosphere. These methods are usable to predict even meteorological influences with long distance propagation but can hardly be used with complex source and surface geometries for receivers nearby. This latter case is the preferred application of engineering models using simple geometric ray approximations. The techniques to use it with complex and extended sources are presented. This includes the use of parametrized source description for technical sources such as motors, gears, pipes, and cooling towers and numerical aspects such as projection or angle scanning. It is shown how an intelligent software technique like the "object tree" supports the generation of variants of a plant including different steps of noise reduction measures.

4:00

1pNCb3. Ray-tracing and spreadsheet modeling of power plant noise. Marlund E. Hale (Adv. Eng. Acoust., Adv. Eng. Acoust., 663 Bristol Ave., Simi Valley, CA 93065, noisedoc@aol.com)

Community noise limits are often imposed on power plant designs. Many power plant sites are planned for rural locations where the residences are relatively close by or at some distance away. During the preliminary design of power plants, design options, along with any predicted environmental impacts and needed mitigation measures, are often discussed with appropriate regulatory agencies and local residents. A design phase noise model can be used to demonstrate the compliance status with local noise regulations. Several proprietary noise modeling methods have been developed by engineering and design-build companies. Spreadsheet noise models are often used to obtain a preliminary look at potential plant noise impacts. More sophisticated, commercially available, ray-tracing software is also available, but at a large initial cost in both time and money. Such modeling software allows one to model a large array of conditions and factors affecting noise propagation that are not possible using simple spreadsheet modeling. This paper compares the modeling results by both methods for two very different power plant sites, one surrounded by flat open terrain and the other located in a small valley surrounded by hilly forested terrain. Measured property line and community noise data are presented along with the modeling results.

4:15

1pNCb4. Anatomy of a quiet power plant: A case study. Jeff Szymanski (Black & Veatch, 11401 Lamar Ave., Overland Park, KS 66211, szymanskijd@bv.com)

Details of noise control design are presented for a recent power plant expansion project that involved the addition of heat recovery steam generation to a gas-fired power plant in the US. The project, including its expansion, was subject to a 45 dBA nighttime property boundary sound level limit. The development and coordination of noise control design for large and small equipment packages, some of which would be located within several meters of the property boundary, are discussed in detail. Sound level measurements are presented and discussed, particularly with regard to the challenges involved with conducting sound level measurements in the presence of ambient sound levels that often approached the allowable noise limit.

4:30

1pNCb5. Pipe noise prediction and sound insulation design by using modelling and field measurements. Giuseppe Squadrone (Tecnimont S.p .A., viale Monte Grappa, 3 20124 Milano Italy, g.squadrone@tecnimont.it)

Since engineering companies usually develop industrial complex by combining and connecting among them many static and rotating equipment with piping, the noise calculation and model of the latter are necessary when carrying out acoustic design to comply with occupational and environmental noise limits. According to the set of available input data, different design procedures can be followed both to model pipe noise and to design sound reduction systems, if needed. Examples of methods for piping noise modeling and insulation design, starting from inside or outside pipe noise levels given by equipment supplier or from in field measured noise or vibration levels, are here shown, analyzed, and discussed. Specifically, the paper describes case studies of steel piping system relevant to installation usually present in a generic industrial plant: a steam pressure reduction station, constituted by control valves and desuperheating devices; a large cooling water pump; and a feeding cooling water station where, accidentally, a regulation valve was excessively noisy. In-plant noise measurements after start up, for methodology reliability evaluation, are reported and discussed too.

1pNCc1. Suggested modifications to the American Society for Testing and Materials E-477. Jerry Lilly (JGL Acoust., Inc., 5266 NW Village Park Dr., Issaquah, WA 98027, jerry@jglacoustics.com)

ASTM E-477 is the current standard test method used in North America for evaluating the acoustic and aerodynamic performance of duct silencers. The test method uses, at a minimum, a source chamber, a test duct (that includes a test specimen), and a reverberation chamber. If testing under flow is desired, the system also requires a fan chamber that can provided quiet airflow through the test duct. The results of the test method yield silencer insertion loss, self-generated noise, both as a function of acoustic frequency and flow velocity, and pressure drop. There are several problems with the current test method, some that are being addressed by the ASTM working group that is responsible for the development and maintenance of this standard. This paper will highlight the most significant problems associated with the current standard and propose modifications to the standard that should, if adopted, improve the intra-laboratory reproducibility of the test results.

1:15

1pNCc2. Model for the design of a hydraulic silencer with dispersive liner. Ken Marek, Nick Earnhart, and Ken Cunefare (George W. Woodruff School of Mech. Eng., Georgia Inst. of Technol., 771 Ferst Dr., J. Erskine Love Bldg., Grad Box 334, Atlanta, GA 30332, ken.marek@gatech.edu)

An in-line hydraulic silencer with a dispersive lining material shows promise for effective fluid noise suppression. For this design, a rigid outer shell encases an annular dispersive medium, where fluid flow is straight through the annulus. A model is developed to predict input port impedance and acoustic transmission loss of the hydraulic silencer. These predictions are used to develop a set of design parameters for the liner, including material properties and geometric dimensions. Design parameters can then be optimized for a given set of working conditions and frequency ranges of interest. Model development is discussed along with comparisons to experimental data.

1:30

1pNCc3. Evaluation of hydraulic silencers. Nick Earnhart, Ken Marek, and Ken Cunefare (Georgia Inst. of Technol., 771 Ferst Dr., Grad Box 261, Atlanta, GA 30332, nick.earnhart@gatech.edu)

Hydraulic silencers are devices used to mitigate fluid-borne noise in fluid power systems. Fluid-borne noise may be produced by positive-displacement pumps and interacts with system components to generate vibration and air-borne noise. It is of interest to quantify the performance of silencers with regard to the input reflection coefficient and transmission loss. A test rig has been constructed that uses a six-sensor method to determine these quantities. Construction and methodology will be presented along with results for apparent transmission loss comparing a commercially available silencer to a novel prototype.

1:45

1pNCc4. Optimal silencer baffle positioning within an air handling unit. Mark Storm (URS Corp., 1615 Murray Canyon Rd., Ste. 1000, San Diego, CA 92108, mark_storm@urscorp.com)

A stationary bank of rectangular modular sound traps or free-standing sound attenuating parallel baffle "columns" installed within a central station air handling unit (AHU) is a common technique for controlling fan noise in a ducted heating, ventilating, or air-conditioning system. Recent design developments by a leading custom AHU manufacturer offer the ability to move these columns within the AHU, so that they can be positioned close to a noise source (e.g., a plenum fan) during operation and pushed away in order to allow AHU component inspection and maintenance. While the columns have a fixed shape and set of features (perforated facing, sound absorbing fill, etc.), this study examines their sound attenuating performance relative to position variance from the source (i.e., fan noise) and the AHU inlet or outlet port at which desired sound levels are often specified. The objective, should such column position variance has meaningful influence on net transmission loss or noise reduction for the AHU, is to estimate optimal geometry(ies) than can be tested and subsequently established as guidance for superior AHU noise control design.

2:00

1pNCc5. Mine ventillation silencer. Jonathan Weinstein (Industrial Acoust. Co., 1160 Commerce Ave., Bronx, NY 10462, jweinstein @industrialacoustics.com)

Mine exhaust ventilation fans provide essential fresh air. The extracted air from the mine is often moist and laden with dust, so that conventional silencers would very quickly clog as the wet dust forms on silencer baffles and blocks the perforations in the baffle skins. This paper presents a case history of the solution to this problem where tuned cavity silencer baffles were installed in an existing exhaust evase of a mine ventilation fan. Sound attenuation is achieved using tuned cavities which are resistant to blockage caused by the wet dust. This performance was successfully demonstrated with a half scale model tested in a laboratory wind tunnel.

2:15

1pNCc6. A true to life application for flow driven resonators: Industrial chiller cooling fan noise reduction. Lee J. Gorny and Gary H. Koopmann (The Pennsylvania State Universtiy, 157 Hammond Bldg., Univ. Park, PA 16802, ljg138@psu.edu)

A project has been conducted to verify the efficacy of tunable resonators in reducing the tonal noise output from an industrial chiller's cooling fan. The primary goals of this work were to demonstrate resonator source robustness for attenuating blade tone noise generated by fixed speed fans, radiating primarily in a single direction, that have non-ideal, un-ducted flow conditions. BPF tones radiated by the fan are reduced by as much as 14 dB in the flow stream and 10 dB outside, demonstrating the effectiveness of resonators for realistic applications. A manually tunable fixed mouth location resonator configuration was designed and developed as a first step in testing resonator effectiveness for quieting production chillers operating at a fixed speed and steady loading. The test enclosure was developed to simulate the fan's environment for a production device, mimicking the convoluted inlet flow, exit through a radiator. Changes in loading were accomplished through adjustment of a flow control door. Additional flow obstructions inside of the enclosure added and removed to demonstrate their effect on overall tonal noise radiation and to test resonator effectiveness in reducing various interaction noise sources.

2:30

1pNCc7. Dissipative diesel engine exhaust muffler featuring sintered metal fiber as acoustical fill liner. Mark Storm (X Sound Technologies LLC, 4251 E. Thomas Rd., Phoenix, AZ 85018, mstorm@xsoundtech.com)

Conventional exhaust muffler design for diesel truck applications often involves a combination of dissipative and reactive elements in order to provide generally broadband sound attenuation for the purpose of suppressing engine exhaust noise during normal operation or engine braking (i.e., venting compressed air through the exhaust system). The reactive portions of the muffler are usually present to provide low-frequency spectrum transmission loss that cannot readily be achieved with classical perforated-n'-packing dissipative design. However, unlike standard perforated metal liners that are used to separate the exhaust gas stream from the muffler's surrounding volume of acoustically absorbent fill, liner materials such as micro-perforate and sintered metal fiber (SMF) metals offer high porosity and high-flow resistance that should improve low-frequency dissipative sound absorption. This study contrasts the modeled insertion loss, transmission loss, and noise reduction performance of a dissipative-only muffler design featuring an SMF liner with that of a popular conventional dissipative-reactive combination muffler design. Discovered performance advantages and disadvantages should reveal pathways for subsequent muffler design development that utilizes advanced liner materials such as micro-perforates and SMF.

2:45

1pNCc8. Noise reduction under the hood of a portable air-purifying respirator system by means of a muffler insert. Robert Marsh (Polymer Technologies, 420 Corporate Blvd., Newark, DE 19702, bobm@polytechinc.com)

Speech intelligibility is probably never more important than in emergency situations. Recently a manufacturer of a portable air-purifying respirator system requested assistance in lowering the noise level that users were encountering under the hood. In operation, the noise level and sound quality in the hood were reported to be objectionable and concern about the ability of personnel to communicate effectively was expressed. Typically, choosing quieter components would be the first step in evaluating various acoustical treatment packages. However, since the components of the blower exposed to the air path were already NIOSH approved, choosing an alternate blower was not a viable option. Polymer Technologies embarked on a study that evaluated the blower and the paths to the receiver, successfully providing attenuation options that could be easily implemented. Prototype testing proved that substantial acoustical attenuation could be achieved by utilizing an in-line muffler lined with acoustical absorption material. The maximum benefit achieved was in excess of a 14 dBA reduction in the overall sound pressure level under the hood at ear level and resulted in what was considered to be a more "acceptable" sound.

1pNCd1. Rapid deterioration of sound level benefits for quieter pavements in Washington state based on the on-board sound intensity method. Tim Sexton (Washington State Dept. of Transportation (WSDOT), 15700 Dayton Ave. N, NB82-138 Seattle, WA 98133, sextont@wsdot.wa.gov)

This paper provides detailed descriptions of the three test sections of "quieter" pavement evaluated by the Washington State Department of Transportation (WSDOT) using the on-board sound intensity (OBSI) method and the unique deterioration of those pavements. Within 6 months of installation, OBSI for the test sections were not audibly lower than the control sections. OBSI is the predominant metric used to evaluate the success of quieter pavements in Washington State. Monthly OBSI measurements describe the seasonal variability in measured sound levels and highlight more rapid general sound level increases in the test pavements relative to the control. Asphalt mix compositions and installation procedures used in Washington were similar, or identical, to those used in southern states where the same pavements have been successful. Challenges to the success of all pavements in Washington State include studded tires, frequent freeze-thaw cycles, and cool summers that encourage lower surface temperatures during installation than in southern states. These challenges are particularly significant for open-graded friction course OGFC pavements as evidenced by spikes in OBSI measurements following seasonal weather events. Parallels between OBSI measurements and structural durability measurements are described in detail.

3:30

1pNCd2. The acoustic longevity of various pavements for noise reduction performance based on on-board sound intensity measurements. Paul Donavan (Illingworth & Rodkin, Inc., 505 Petaluma Blvd., South Petaluma, CA 94952, pdonavan@illingworthrodkin.com)

When quieter pavements are used for purposes of reducing traffic noise levels, one issue of concern is how long will the noise reduction performance be maintained or what is its "acoustic longevity." To address this issue, both the states of California and Arizona have established on-going research projects on a number of different pavement types including the broad groups of asphalt and portland cement concrete (AC and PCC, respectively). These pavements have been monitored routinely with on-board sound intensity measurements since the time of initial construction yielding data over periods of 4–7 years. The pavements consist of 11 PCC pavements of different texture and 13 AC sections of varying constructions. The results of these measurements are presented and discussed. In another approach of evaluating acoustic longevity, pavements of the same construction, but different years of build have also been evaluated to examine longer periods of time. The results of this approach are also presented along with a discussion of the issues involved with the two methods.

3:45

1pNCd3. Quiet concrete pavement surfaces. Robert Rasmussen, Robert Whirledge (The Transtec Group, Inc., 6111 Balcones Dr., Austin, TX 78731, robotto@thetranstecgroup.com), and Paul Wiegand (Natl. Concrete Pavement Technol. Ctr.)

For the last 5 years, a comprehensive evaluation has been conducted on hundreds of concrete pavement surfaces throughout the US, Canada, and

Europe. These data have been synthesized in a manner that allows the highway industry to make important decisions about how best to design and construct concrete pavements to reduce tire-pavement noise levels without compromising other important aspects such as durability, safety, and cost. While a significant amount of variability is present in the data, clear trends have been identified. Some surfaces, such as diamond grinding, appear to be among the best alternatives available today for reducing tire-pavement noise. Meanwhile, recent trials of more unconventional surfaces have yielded mixed results. In the end, the techniques for concrete pavement surfacing today include a vast array of choices. The selection of the best surface for the particular job can now be made more confidently given this improved understanding of the potential impacts due to tire-pavement noise.

4:00

1pNCd4. Noise generation in contraction joints in Portland cement concrete. Tyler Dare (Purdue Univ., 140 S. Martin Jischke Dr., West Lafayette, IN 47907-2031, tdare@purdue.edu) and Robert Bernhard (Notre Dame Univ.)

Contraction joints between slabs of Portland cement concrete have a major impact on measured tire-pavement noise levels. It has been proposed that during the interval when the contact patch of the tire is over the joint, the system acts as a Helmholtz resonator, and that this mechanism is responsible for the majority of the increased noise due to contraction joints. In this paper, this mechanism is investigated through theoretical calculations and experimentation. Intensity probes were used to measure noise near joints of varying widths using Purdue University's Tire-Pavement Test Apparatus (TPTA). The TPTA was used to discover relationships between vehicle speed, joint width, and measured sound pressure and sound intensity spectra near the joint and the tire.

4:15

1pNCd5. On-board sound intensity measurements and results in Florida. Roger Wayson, John MacDonald (US DOT, Volpe Natl. Transportation System Ctr., 3925 Lakeview Dr., Cottonwood Shores, TX 78657, roger.wayson@dot.gov), and Mariano Berrios (Florida Dept. of Transportation)

This paper describes an investigation of on-board sound intensity (OBSI) and concurrent wayside sound levels along multiple roadway surfaces in the state of Florida. By conducting concurrent sampling of the OBSI and wayside noise not only were insights into the pavement texture noise generation at the tire/pavement interface possible but direct comparisons allowed findings on the propagation characteristics as well. Measurement values, pavement rankings, multiple findings, and preliminary statistical modeling will be shown.

1pNCe1. Comparison of sea modeling approaches for vibration transmission through beam structures. Ignatius Vaz, Bryce Gardner (ESI North America, 32605 W 12 Mile Rd., Ste. 350 Farmington Hills, MI 48334-3379, ignatius.vaz@esi-group.com), Vincent Cotoni (ESI Group R&D), and Shuo Wang (NASA Johnson Space Ctr.)

Transmission through beams can become a significant path in many structure-borne problems, especially in aircraft or launch vehicles. Statistical energy analysis (SEA) is widely used for the vibro-acoustic modeling of high-frequency problems. However, in a system-level SEA model, even at higher frequencies, some beams can exhibit low-modal behavior and might not be a good SEA representation. Vibration transmission through beams involves both resonant and non-resonant transmission paths. Typically the non-resonant path is dominant at low frequencies and the resonant path at high frequencies. This paper describes various modeling approaches for describing the transmission through beams over a broad frequency range. SEA modeling techniques will be compared to the hybrid FE-SEA method, energy flow method, and the finite element method for various beam configurations. Modeling beams under pre-stressed conditions is also investigated.

1:15

1pNCe2. Coupling loss factor estimation for plates joined at a point: Analysis and experiment. Mark Ewing, Kranthi Vatti (Aerosp. Eng., Univ. of Kansas, 1530 West 15th St., Lawrence, KS 66045, mewing@ku.edu), and Ignatius Vaz (ESI)

Coupling loss factors for two lightly damped plates joined at a point, but otherwise free to respond in lateral vibration, have been studied both analytically and experimentally. This study forms the basis for on-going estimations of the transient coupling loss factors of the same system. Statistical energy analysis (using VA ONE) and the finite element method (using NASTRAN) have been used to predict the coupling loss factors. The finite element predictions are based on the averaged responses for a range of boundary conditions on the plates, essentially a "pseudo-statistical" approach. Experimentally, two techniques have been used. First, following the approach by Lai and Soom, a force transducer has been used to measure the force between the plates as it is used to attach them. Simultaneously, the kinetic energies in the two plates are measured by three accelerometers attached to each plate during both transient and persistent excitations of the plates, one at a time. The coupling loss factors are estimated by balancing the transmitted energies with the kinetic energies in the two plates. Then, the coupling loss factors were assessed by a more "traditional" approach, namely, balancing the power input to a plate with the energies of the plates. The estimations from these four approaches compare as well as may be expected for these lightly damped plates.

1:30

1pNCe3. Coupling loss factor estimation for plates joined along a line: Analysis and experiment. Mark Ewing, Kranthi Vatti (Univ. of Kansas, 1530 West 15th St., Lawrence, KS 66045, mewing@ku.edu), and Ignatius Vaz (ESI)

Coupling loss factors for two plates joined at a line (a 90-deg bend), but otherwise free to respond in lateral vibration, have been studied both analytically and experimentally. Two cases have been studied: one with no

added damping and one in which one of the plates has a small amount of damping provided by a constrained layer treatment. Statistical energy analysis (using VA ONE) and the finite element method (using NASTRAN) have been used to predict the coupling loss factors. The finite element predictions are based on the averaged responses for a range of boundary conditions on the plates, essentially a "pseudo-statistical" approach. Experimentally, one of the plates was excited while the kinetic energy of the two plates was assessed with a scanning laser vibrometer (scanning a dozen or more points) and four accelerometers on each plate. Both impulse and persistent excitations were used. The coupling loss factors were assessed by balancing the power input with the energies of the plates, also using the estimated modal densities. The estimations from the analytical and experimental approaches compare as well as may be expected for the lightly damped plates case, but very well for the case of one plate having a damping treatment.

1:45

1pNCe4. Development of hybrid one-dimensional finite element/analytical method for analysis of lamb wave propagation characteristics in composit panels. Yong-Joe Kim and Je-Heon Han (Dept. of Mech. Eng., Texas A&M Univ., 315 Eng./Phys. Bldg. Office Wing, College Station, TX 77843-3123, joekim@tamu.edu)

The objective of this study is to develop a hybrid one-dimensional finite element (1-D FE)/analytical method to analyze the Lamb wave propagation characteristics of composite panels. Here, it is proposed to model a composite panel using a finite element approximation in the thickness direction while analytical solutions are assumed in the plane directions. Thus, it makes possible to use small number of finite elements even for high-frequency analysis in computationally efficient manner. By solving the eigenvalue problem of the resulting 1-D FE/analytical matrix equation, the dispersion relations of the Lamb waves propagating in the composite panel can be calculated in wave number/frequency domain. Note that the dispersion relations can be used to determine the frequency, wavelength, and wave speed of a specific Lamb wave mode that can be used to monitor the specific structural defects of the composite panel. For the purpose of validating the proposed method, the dynamic responses of a composite panel are measured. The measured data are transformed into wave number/frequency domain by applying spatial Fourier transform, which result in measured dispersion relations. It is shown that the dispersion relations obtained by using the proposed hybrid method agree well with the measured dispersion relations.

2:00

1pNCe5. Experimental validation of finite element–boundary element model dynamic strain model under diffuse acoustic field loading. Ben Tsoi (Jet Propulsion Lab., 4800 Oak Grove Dr., Pasadena, CA 91109, wan.b.tsoi@jpl.nasa.gov), Bryce Gardner, and Vincent Cotoni (ESI Group NA)

Structural finite element (FE) models naturally output displacement or acceleration response data. However, they can also be used to compute stress, internal forces, and strain response. When coupled with a boundary element model (BEM) of the fluid surrounding the structure, a fully coupled analysis can be performed. Modeling a diffuse acoustic field in the BEM fluid provides an excitation like that found when the structure is placed in a reverberation chamber. Fully coupling the structural FE model to the acoustic BEM model provides a means to predict not only the acceleration response of the panel to diffuse field loading but also the ability to predict the dynamic stress and strain response. This type of model has been available with current predictive tools, but experimental validation of the prediction of dynamic stress or strain is difficult to find. An aluminum panel was instrumented with accelerometers and strain gauges and hung in a reverberation room and subjected to a diffuse acoustic field. This paper presents the comparison of the experimental and predicted results.

2:15

1pNCe6. Modeling the low-, mid-, and high-frequency response of poro-elastic materials in vibro-acoustics applications. Vincent Cotoni (ESI Group, 12555 High Bluff Dr., San Diego, CA 92130, vincent.cotoni@esi-group.com)

A method is presented for representing layered poro-elastic materials and acoustic fluids in a finite element (FE) model of a structure. The method is based on the hybrid FE-statistical energy analysis (SEA) formulation that allows the coupling of FE and SEA descriptions of various subsystems in a model. By making use of the dynamic properties of poro-elastic materials and acoustic fluids (in terms of wavelength and uncertainty), the method is made particularly fast and appropriate for the prediction of the vibro-acoustic response at midfrequencies. The method allows to quickly incorporate acoustics and/or noise control treatment in an existing finite element model of a structure. Given the frequency range of applicability, it complements the existing low-frequency methods (structure and poro-elastic material described with FE, acoustic fluid described with FE, infinite elements, or boundary elements) and high-frequency methods (structure, poro-elastic material, and acoustic fluid described with SEA). The formulation is derived and a number of validation examples are presented.

2:30

1pNCe7. A comparison of visco-thermal models for the vibro-acoustic analysis of hearing aids. Júlio A. Cordioli, Gustavo Martins, and Roberto Jordan (Federal Univ. of Santa Catarina, Campus Univ.-Trindade, Federal Univ. of Santa Catarina Campus Universitrio-Trindade Florianópolis, SC 88090-400 Brazil, cordioli@emc.ufsc.br)

The performance of a hearing aid is directly related to its vibro-acoustics characteristics, which must be taken in account during the design process. Different vibro-acoustic aspects of a hearing aid may be analyzed, including the structural transmission from the loudspeaker to the microphone, which may lead to an unwanted feedback, or the frequency response of the system composed by loudspeaker, tube, earmold and ear channel (considering a behind-the-ear hearing aid). In view of the reduced dimensions of the system it is argued that the vibro-acoustic analysis of such system must take in account visco-thermal effects in the description of the propagation of acoustical waves. In this paper, a simplified system is considered including the loudspeaker membrane, tube, and coupler (element commonly used for testing hearing aids). Results for three different approaches for the vibro-acoustic analysis of the system are compared with experimental data: (i) standard acoustical wave model, (ii) the low reduced frequency model, and (iii) the full linearized Navier–Stokes model. Results show that for the case considered the visco-thermal effects must be taken in account, while the choice between models (ii) and (iii) must be made in view of the system geometry.

2:45

1pNCe8. Systematic approach to passenger vehicle air induction tuning. Antoni Szatkowski, Sean Li, and Jaspal Sandhu (NVH Development & Eng., Chrysler LLC, P.O. Box 21-8004, Auburn Hills, MI 48321-8004, as32@chrysler.com)

Air induction sound level and quality is a key contributor to in-vehicle powertrain NVH performance. This paper describes the process of tuning the air induction systems (AISs) at Chrysler LLC. Simple sound quality metrics are developed to quantify the AIS sound quality. Data acquisition and processing is standardized. A new methodology is presented, how to tune the AIS to meet the desired sound quality, and to optimize the cost, weight, and packaging space. Practical examples are presented to demonstrate how the specific targets are being achieved.

1pNCf1. Influence of various uncertainty factors on the result of beamforming measurements. Markus Mller-Trapet and Pascal Dietrich (Inst. of Tech. Acoust., RWTH Aachen Univ., Neustraße 50, 52066, Aachen Germany, mmt@akustik.rwth-aachen.de)

In a previous publication [Mller-Trapet and Dietrich (2009)], a virtual measurement environment for sound-source localization on vibrating structures was presented. Based on surface velocity data obtained from laser-scanning-vibrometry measurements, the boundary-element-method is used to simulate the sound radiation from a vibrating plate toward a microphone array under ideal conditions. The advantage of this approach is that the measurement conditions can be perfectly controlled and real sources can be considered, without restrictions on the type of source. The virtual measurement environment will now be used to investigate the effect of some of the uncertainties that can be encountered during beamforming measurements. For the most common planar array geometries, the beamforming source maps will be calculated for varying signal-to-noise ratios and different array imperfections (uncertainties in the location of the microphones and deviation from the omni-directional directivity pattern of the microphones). As a measure of comparison, the two-dimensional normalized cross-correlation between the ideal source map and the source map with added uncertainties will be evaluated and discussed.

3:45

1pNCf2. An analysis of the Doppler shifted aircraft noise signature as measured by a hydrophone located within an evanescent field and implication for localization. David R. Dall'Osto and Peter H. Dahl (Dept. of Mech. Eng. and Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

Simultaneous measurements of the acoustic pressure field across the air-water interface, at site in Puget Sound, WA, are analyzed in terms of the Doppler signature of propeller driven aircraft. Measurements in the 50–300-Hz range are considered for various aircraft over flights. The Doppler shift recorded in air by a microphone placed 3 m above the air-water interface is modeled using standard Doppler theory. The hydrophone, placed at a depth 2.5 m below the air-water interface, reveals two Doppler shifts; one associated with the propagating transmitted acoustic field and the other associated with an evanescent field. A parametrized model for these two observed Doppler shifts is presented, utilizing ray theory and Snell's law applied to a plane wave decomposition of the source wave fronts with, $kH \gg 1$, where H is the source height and k is the wave number. It will be shown that analysis of the underwater acoustic field can be used to determine the altitude and closest point of approach (CPA) of a passing tonal source, with support from experimental data recorded by the hydrophone lying within the detection limits of the evanescent field. [Work supported by Washington Sea Grant and ONR.]

4:00

1pNCf3. Interior Fourier near-field acoustical holography using energy density. Zachary A. Collins (Dept. of Mech. Eng., Brigham Young Univ., Provo, UT 84602, zcollins26@gmail.com), Kent L. Gee, Scott D. Sommerfeldt, and Jonathan D. Blotter (Brigham Young Univ., Provo, UT 84602)

Near-field acoustical holography (NAH) is used to reconstruct three-dimensional acoustic fields from a two-dimensional planar measurement. During previous work at BYU, a method has been developed called energy-based near-field acoustical holography which reduced the number of needed measurements by 75%. Other recent advances have expanded the theory to interior spaces where multiple sources and/or reflections are present. This paper presents a new method for reconstructing interior acoustic parameters using Fourier NAH and a single plane of energy density measurements. Energy density is measured using a six-microphone array. First, the probe measurements are used to create a Hermite surface pressure interpolation on two separate planes. These two planes are used to approximate the normal particle velocity as well as to separate the incoming and outgoing waves using the spatial Fourier-transform method. Once separated, traditional Fourier NAH is used to reconstruct the pressure and normal particle velocity at any point in space. Analytical and experimental results are shown and compared to exterior Fourier NAH approximations. Other drawbacks and benefits are discussed.

4:15

1pNCf4. Conformal mapping based on spherical array measurements: Noise source identification in a car cabin. Karim Haddad (Bruel & Kjaer SVM A/S, Skodsborgvej 307, 2850 Naerum, Denmark, khaddad@bksv.com)

Spherical beamforming based on spherical array is a technique well suited for in-cabin noise source identification, especially from mid- to high frequencies. One aspect of these imaging techniques based on acoustic measurements is how to link detected acoustic sources with the environment. Two main alternatives are currently used. The first possibility is based on pictures of the environment: pictures are superimposed on the acoustic map for an easy identification of sources. The main advantages are its quickness for setup and also it is a good solution to efficiently keep track of any change in the environment. The second possibility is the use of a model describing the objects around the microphone array. It is an interesting solution to describe precisely the medium. But also in terms of accuracy, it provides the correct distances from objects to the acoustic sensor: the level of sources could be more accurately determined. This last option can therefore generate an acoustic map conformal to the surrounding environment. In this paper, we use the conformal mapping technique in a case study concerning tests done in a car cabin using a spherical array.

4:30

1pNCf5. A user friendly, cost-effective and portable tool for locating multiple arbitrary sound sources in three-dimensional space in real time. Na Zhu and Sean F. Wu (Dept. of Mech. Eng., Wayne State Univ., Detroit, MI 48202, linda_zhuna@hotmail.com)

In many engineering applications, it is highly desirable to quickly and easily locate sound sources even if the accuracy and spatial resolution are not very high. Most systems and tools available in the market are based on beamforming technology, which are portable, easy to use, and easy to understand. However, beamforming requires a prior knowledge of the general location of a target source and a large number of microphones, which increases the overall costs. Also, its frequency range is limited by the size of the microphone array. In this paper, a user friendly, cost-effective and portable system for locating multiple arbitrary sound sources in three-dimensional space in real time is presented. In particular, this system requires four microphones only, covers the entire audible frequency range, and does not require any prior knowledge of whereabouts of the target sources. The underlying principle of this methodology is a hybrid approach consisting of modeling of sound radiation from point sources in a free field, triangulation, and signal processing techniques. Both numerical and experimental validations are demonstrated and an error analysis in locating arbitrary sources is performed. The main cause of errors is found to be due to the fact that the basic formulations are for a free field, whereas in practice the measurement environment is a non-free field.

4:45

1pNCf6. Panel contribution analysis for a large complex structure. Sandeep Mylavarapu and Sean F. Wu (Dept. of Mech. Eng., Wayne State Univ., Petroit, MI dz2727@wayne.edu)

This paper presents a newly developed panel contribution analysis using the Helmholtz equation least squares method for a large complex structure. The approach requires only one set of the acoustic pressures measured in the near field of a vibrating structure. Using these input data, the normal surface velocity and acoustic pressure are reconstructed, from which the normal acoustic intensity distribution is calculated. Next, the normal acoustic intensity is correlated to the acoustic pressure at any field point of interest. In this way, the relative contributions from individual panels toward acoustic radiation at any field point can be ranked, and the critical panel(s) of a vibrating structure can be identified. Numerical simulations using this approach for identifying critical panels inside a passenger compartment are presented.

1pNSa1. Directivity indices for rocket noise modeling: Measurement considerations. Jarom H. Giraud and Kent L. Gee (Dept. of Phys. and Astronomy, Eyring Sci. Ctr., Brigham Young Univ., 84602 Provo, UT, jaromgiraud@gmail.com)

Long-standing rocket noise models use far-field directivity indices to predict acoustic radiation loading on and near a launch vehicle. This approach raises a number of critical questions including where does the geometric far field begin for the frequencies of interest? and how does probable nonlinear propagation of noise away from the source affect these indices? Data collected on a static, horizontally fired GEM-60 solid rocket motor provide some insight into these questions. In the near field, microphones were located along a line approximately eight nozzle diameters from the shear layer. In addition, microphones were placed along two radials near the peak directivity angle at 63, 125, and 250 nozzle diameters. Analysis of these data indicates that nonlinear propagation dramatically affects the high-frequency directivity patterns along the peak radiation angles. In addition, the extended length of the source likely pushes the onset of the geometric far field to beyond 100 nozzle diameters for low frequencies.

1:40

1pNSa2. Acoustic measurement in the static firing tests of solid rocket motors. Tatsuya Ishii, Hideshi Oinuma, Junichi Kazawa (Aviation Program Group, JAXA, 7-44-1 Jindaiji-Higashi-Machi, Chofu, Tokyo 182-8522, Japan), Kota Fukuda, Seiji Tsutsumi (JEDI Ctr., JAXA, 3-1-1 Yoshinodai, Sagamihara, Kanagawa 229-8510, Japan), Kyoichi Ui (Space Transportation Mission Directorate, JAXA, Tsukuba-shi, Ibaraki 305-8505, Japan), and Kenji Minesugi (Inst. of Space and Astronautical Sci., JAXA, Sagamihara, Kanagawa 229-8510, Japan)

Acoustic management is essential for establishing a reliable and cost-competitive rocket system. A solid propellant motor during its lift-off imposes high levels of pressure and vibration on the fairing of the rocket, sometimes leading to crucial damage of the payload. One approach to resolve this problem is to decrease the sound sources caused by high-speed plume of the rocket booster. Japan Aerospace Exploration Agency (JAXA), aiming at the advanced solid rocket, started computational prediction that helps design a launch-pad

with less acoustic impact. For validating the computation codes and modeling the acoustic characteristics, the experimental acoustic data of solid rocket motors have long been desired. Fortunately, we had opportunities of the ground firing tests with several motors. In this presentation, the acoustic measurement including the sensors, the set-up, and the data reduction carried out in these tests will be discussed.

2:00

1pNSa3. A model for the prediction of community noise from launch vehicles. Kenneth J. Plotkin (Wyle Labs., 241 18th St. S., Ste. 701, Arlington, VA 22202, kenneth.plotkin@wyle.com)

A model, RNOISE, has been developed for prediction of far-field community noise from the launch and boost phase of launch vehicles. It follows the moving source principles of an early NASA model [Wilhold *et al.*, NASA Report No. TN D-1832 (1963)] but uses a noise source and directivity model developed by Sutherland [AIAA Paper No. 93-4383 (1993)] together with modern propagation algorithms as employed in the time simulation aircraft models NMSIM (NoiseMap Simulation) and AAM (Advanced Acoustic Model). RNOISE, first used for environmental analysis in the mid-1990s, is a spectral time simulation model, generating predictions of one-third octave band spectra on the ground as a function of time. Predictions may be made at a single point or on a grid. Recent improvements to RNOISE are the ability to read flight path data from a PCBoom format trajectory file, and output of time history grids in the TIG format used by NMSIM, AAM, and RNM (Rotorcraft Noise Model). This permits presentation of results as animations as well as traditional static contours.

2:20

1pNSa4. Rocket motor microphone investigation. Eric Herrera, Debbie Pilkey (ATK Launch Systems, P.O. Box 707, Brigham City, UT 84302), Kent L. Gee, Jarom H. Giraud, and Devin J. Young (Brigham Young Univ., Provo, UT 84602)

Identification of optimal microphone configurations and instrumentation is underway as a continuous process improvement effort at ATK Space Systems, where large solid rocket motors (SRMs) have been tested for decades. Rocket motor tests provide a unique environment which cannot be fully duplicated in a laboratory. This is especially true for the largest SRM ever to be tested, Demonstration Motor I (DM-I), which is the five-segment first stage of the NASA Constellation program's Ares I launch vehicle. During the DM-I firing, two separate arrays of pressure transducers with various vent tube configurations, microphones, accelerometers, and temperature sensors were placed at locations near the motor. The objectives were to better determine the vibration levels and temperature to which acoustic gages are subjected and to examine their comparative performance for different vent tube configurations, particularly at low frequencies (10–30 Hz). Results from the DM-I and corroborating laboratory tests reveal very different low-frequency responses for the pressure transducers that depend critically on vent tube configuration. This and other issues are discussed.

2:40

1pNSa5. Condenser microphone protective grid correction for high-frequency measurements. Erik N. Lee and Reginald M. Bennett (Marshall Space Flight Ctr., MS ER42, Huntsville, AL 35812)

Use of a protective grid on small diameter microphones can prolong the lifetime of the unit, but the high-frequency effects can complicate data interpretation. Analytical methods have been developed to correct for the grid effect at high frequencies. Specifically, the analysis pertains to quantifying the microphone protective grid response characteristics in the acoustic near field of a rocket plume noise source. A frequency response function computation using two microphones will be explained. Experimental and instrumentation setup details will be provided. The resulting frequency response function for a B&K 4944 condenser microphone protective grid will be presented, along with associated uncertainties.

1pNSb1. Assessing the acoustical attributes of preserved historic structures. Eric L. Reuter (Reuter Assoc., LLC, P.O. Box 4623, Portsmouth, NH 03802, ereuter@reuterassociates.com)

Acoustical attributes of several preserved historic structures have been measured using contemporary techniques and metrics. These include outdoor-to-indoor and indoor-to-indoor impulse response and noise reduction measurements. Combined, these measurements allow for simulation, both quantitative and qualitative, of the indoor soundscapes of the past. These data will be presented, along with audio examples of historical noise sources, as experienced from indoors.

1:40

1pNSb2. Listening to soundscape as the music of life. Caroline Cance (INCAS3, Dr. Nassaulaan 9, P.O. Box 797, Assen 9400 AT, The Netherlands, ccance@gmail.com), Danièle Dubois and Hugues Genevois (CNRS-Univ. Paris 6-MCC, Paris 75015, France)

The musician M. Shafer introduced, in 1970, the word and the concept of soundscapes as "the tuning of the world," driving our attention to the quality of the sounding environment, therefore comparable to music. The concept of soundscape has been developed within acousticians' communities, and the research slowly evolved from "noise effect," "noise control," or "noise annoyance" to "sound quality" or "soundscape" and "soundscaping." Also, around 70 electroacoustics music has promoted every day noises as musical sounds, and nowadays computer music blurs the boundaries between musical instruments and new technological devices and tools. We would like to present here our research conducted in perception and evaluation both in music (and more precisely on digital music) and in everyday noise and soundscapes to discuss some of the following questions: What makes a noise a musical sound? Its acoustic properties? That it is produced by a specific (musical) instrument? The time, places (streets? concert halls?) or ways one hears/listens to it (personal involvement, purpose)? Are the boundaries between music and noise the same in different communities (acousticians, musicians, instrument makers, every one in the street)? How do the concepts of music/noise evolve in time and space, and people?

2:20

1pNSb3. The daily rhythm of the soundscape "Nauener Platz" in Berlin. Brigitte Schulte-Fortkamp (Inst. of Fluid Mech. and Eng. Acoust., Technische Universitt Berlin, 10587 Berlin, Germany)

Rhythm in soundscape characterizes the time structure of the soundscape with its distinctive sound events embedded in comprehensive acoustical scenery. The "Nauener Platz" evaluation was balancing between acoustic measurements, architectural planning, and the expertise from people living in the area to contribute to the reconstruction of the place. Information of a new understanding and concept of a public place was underlying the development of the new Soundscape based on noise reduction and audio islands playing the sound people like to live with in that area. This Soundscape will be provided here in musical performance also explaining the cultural and social issues behind. The Soundscape Project is a module of the Project "Nauener Platz-Remodelling for Young and Old" in the framework of the research program "Experimental Housing and Urban Development (ExWoSt)" of the "Federal Ministry of Transport, Building, and Urban Affairs (BMVBS)" by the "Federal Office for Building and Regional Planning (BBR)." It is related to the fields of research (ExWoSt) concerned with "Innovation of Urban Neighbourhoods for Families and the Elderly."

1pNSb4. Measurement of whole hike soundscapes in a national park setting. G. (Randy) Stanley (Natural Sounds Program, U.S. Natl. Park Service, 1201 Oakridge Dr., Ste. 100, Fort Collins, CO 80525)

Measurements of whole hike soundscapes were made in Mount Rushmore National Park. The goal was to capture the time and space varying aural stimulus that a hiker experiences while walking through an environment. Two elements were employed: A portable binaural headset recording system and an array of audio recorders arranged at intervals along the trail. Various elements of the recorded soundscapes will be summarized and reproduced in part for the audience. In addition, expected analyses and anticipated challenges will be discussed.

4:00

1pNSb5. Exploring the soundscape of nature. Gary W. Siebein, Keely M. Siebein, Lucky Tsaih, Sang Bum Park (Univ. of Florida School of Architecture, P.O. Box 115702, Gainesville, FL 32611), Chris P. Jones, Reece Skelton, and Joshua Fisher (Siebein Assoc., Inc., Gainesville, FL 32607)

A study of a state park situated along a spring fed river was conducted to try to understand the nature of the soundscape of a park intended to be used by people for recreational purposes as well as to preserve the qualities of the natural ecosystems in the area. The study explores the qualitative and quantitative aspects of the ambient sound as composed of a series of specific acoustic events related to natural sounds of wildlife, water flows and weather, human use of the park, maintenance operations by park staff, and off-site noise intrusions from adjoining land uses. The acoustic "rooms" of the site are identified by the characteristics of their impulse responses. The rooms are linked by acoustic itineraries related to each of the user groups. Modeling of animal, weather, and human sounds is used to construct the acoustic rhythms of the site from limited, practical data acquisition of existing sounds. Recordings of real and simulated sound fields from the park were evaluated by listeners to determine qualitative and quantitative relationships of real and modeled sounds.

1pNSc1. Urban acoustic and seismic noise measurements in Baltimore. Donald G. Albert and Stephen N. Decato (ERDC Cold Regions Res. and Eng. Lab., 72 Lyme Rd., Hanover, NH 03755)

Acoustic and seismic sensors have good potential for passive, non-line-of-sight, detection, localization, and monitoring of natural and human activities. However, to fulfill this potential, sensor algorithms must be designed to not only robustly identify signals of interest but also to cope with environmental effects including high levels of background noise often found in urban areas. This paper presents experimental measurements conducted in Baltimore and at other locations to investigate noise levels in rural, urban, and industrial environments for audio frequencies between 6 Hz and 20 kHz and seismic frequencies from 6 to 1000 Hz. Because of the interest in large-scale Earth studies, there are hardly any previous seismic measurements in this high-frequency band and also most were done in remote areas specifically to avoid cultural noise. The measured urban seismic spectra tend to have more structure and variation in shape from one location to another compared to the acoustic spectra, and a more rapid decay with increasing frequency, usually about 30 dB from 30 to 600 Hz. The urban acoustic peak frequency is usually around 60 Hz, while the peak seismic frequencies are usually less than 25 Hz. [Work funded by U.S. Army.]

1:50

1pNSc2. Investigation of noise barriers with resonators by the indirect boundary element method. Markus Auerbach (Federal Hwy. Res. Inst. (BASt), Bruederstr. 53, D-51427 Bergisch Gladbach, Germany, m.auerbach@bast.de), Andreas Bockstedte, Olgierd Zaleski, Marian Markiewicz (Novicos GmbH, D-21073 Hamburg, Germany), Otto von Estorff (Hamburg Univ. of Technol. (TUHH), 21073 Hamburg, Germany), and Wolfram Bartolomaeus (Federal Hwy. Res. Inst. (BASt), D-51427 Bergisch Gladbach, Germany)

Noise barriers are the most common solutions to protect against noise pollution. They are very effective in the mitigation of road noise, but their high effectiveness often involves undesirably huge constructions. Following the demand for improving the efficiency without increasing the heights, a new procedure has been developed, which allows for extending a typical noise barrier by a line of resonators in a quite efficient way. It is based on numerical investigations including the indirect boundary element method. Several

representative calculations are shown which demonstrate how the new approach can be used. The procedure turns out to be computationally very powerful and it seems to be a very promising step toward a more efficient design of sound barriers featuring high effectiveness at moderate overall heights. Measurements at a 20 m wide and 4 m high noise barrier with and without the device will be presented.

2:10

1pNSc3. Modeling of sound fields in urban streets using a one-dimensional transport equation model. Yun Jing and Ning Xiang (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., Troy, NY 12180)

This paper presents a one-dimensional transport equation model for acoustic field predictions in urban streets. Considering urban streets as elongated enclosures, acoustic properties of the surfaces are typically quite different. For example, the top and two ends are often open and the streets are usually reflective. A recently developed one-dimensional transport equation [Jing *et al.*, J. Acoust. Soc. Am. **125**, 2735 (2009)] is extended to model non-uniform absorption and scattering coefficients and is applied to urban streets acoustic predictions. This paper discusses preliminary experimental results obtained from a tenth scale-model to validate the model.

2:30

1pNSc4. Numerical and experimental studies for reducing the transmission of low frequency sound through windows. Andrew M. Jessop, Kai Ming Li, and J. Stuart Bolton (Ray W. Herrick Labs., 140 S. Martin Jischke Dr., West Lafayette, IN 47907-2031)

Windows are a common path for low-frequency sound transmission from outside to inside due to their light weight and low damping. The use of non-periodic stiffening elements to increase window transmission loss without reducing visibility is considered here. The effect of elastic mounting of the window to the surrounding structure as a possible contributor to low-frequency noise transmission was also examined. A finite element model allowing for panel stiffening, either by clamping or by adding variable-stiffness beams within the panel, was constructed; the model allowed for variable positioning of such elements. Several double-panel configurations, representing double-pane windows typically used in energy-efficient constructions, were also modeled with various clamped-stiffening elements. Scale-model measurements of transmission loss of aluminum panels were performed to verify the character of the predictions with variable edge stiffness as used in the numerical models. The computational results show that low-frequency sound below 150 Hz can be reduced by several dB through careful use of stiffening elements and that resilient mounting can reduce the transmission loss of low-frequency sound through windows.

2:50

1pNSc5. Parametric study of the sound insulation performance of a ventilation window. S. K. Tang (Dept. of Bldg. Services Eng., The Hong Kong Polytechnic Univ.), D Suen, and S. K. Chan (Campus Development Office, The Hong Kong Polytechnic Univ.)

The sound insulation performance of a specifically designed facade device, which allows natural ventilation but can provide relatively high-sound insulation, is studied experimentally in the present study. The experiment was carried out in two coupled rooms with one of them very reverberant and the other made semi-anechoic. The former acted as the receiver room and the latter contained a linear loudspeaker array (25 loudspeakers) as the noise source. The full scale facade device was installed on the concrete brick wall between the coupled rooms. Nine microphones were used to measure the average sound intensity inside the reverberant room. The effect of the size of the device opening (for ventilation) on the sound insertion loss was then determined by the difference between the average intensities with and without the device (an opened window). The present results show that the present facade device can offer additional acoustical protection of ~12–13 dB(A) compared to that resulted from the conventional openable window design when exposed to traffic noise. The introduction of sound absorption materials at the top internal surface of the window cavity in general can result in a maximum of 2 dB extra benefit.

3:10—3:30 Break

Contributed Papers

3:30

1pNSc6. Three-dimensional pseudospectral time-domain calculations of sound propagation to closed urban courtyards. Maarten Hornikx (Dept. of Mech. Eng., K.U. Leuven, Celestijnenlaan 300b-bus 2420, B-3001 Heverlee, Belgium, maarten.hornikx@mech.kuleuven.be) and Jens Forssén (Chalmers Univ. Tech., Gothenburg S-41296, Sweden)

Because contemporary urban environments suffer from excessive levels of road traffic noise, access to courtyards with low-noise levels is essential in order to offer urban sound environments of high quality with regard to health and perceived sound. Due to limitations in computational resources, accurate prediction of road traffic noise to urban courtyards has mainly been restricted to modeling the courtyards in two dimensions. To calculate sound propagation from road traffic to three-dimensional courtyards, the extended Fourier pseudospectral time-domain method is used here. This numerical domain discretization method solves the linearized Euler equations, where spatial derivatives are evaluated based on an eigenfunction expansion and thereby requires only two spatial points per wavelength. The time iteration is done using a low-storage optimized six-stage Runge–Kutta method. Calculation results, in time and frequency domains, display the difference of treating courtyards in two and three dimensions. As one of the results, it is concluded that the effect of noise abatement in the form of facade absorption treatments is larger for a setting in three dimensions than in two dimensions.

3:45

1pNSc7. Influence of impedance distribution and optimal impedance design in the context of noise barriers. Alexandre Jolibois, Victor W. Sparrow (Grad. Program in Acoust., Penn State, 201 Appl. Sci. Bldg., University Park, PA 16802, auj145@psu.edu), Denis Duhamel (Ecole des Ponts ParisTech, 77455 Marne La Vallée, France), and Jérôme Defrance (Ctr. Scientifique et Technique du Bâtiment, 38400 Saint-Martin-d'Hères, France)

Noise barriers are commonly used to protect people from railways or roads traffic noise. However, the optimal design of those barriers is still an open problem since lots of different results have been obtained, depending on the method utilized. In this paper, instead of focusing on the shape of the barrier itself, a new method involving optimization of the impedance distribution on a control surface of simple geometry and containing the barrier has been used. First, numerical simulations have been carried out with the

two dimensional boundary element method in order to predict the sound pressure level around any impedance scatterer. Analytical solution for the scattering of a line source by an infinite constant impedance circular cylinder has been derived and used for validation. Second the influence of the impedance distribution in the case of a circular cylindrical control surface has also been studied to determine an optimal impedance distribution to control the noise level in a zone close to the barrier. Specific attention has been paid to the scattering of multiple line sources in order to model high-speed train noise sources more accurately.

4:00

1pNSc8. Model of a benefit/cost ratio analysis for comparison of environmental noise barriers. Antonio P. Carvalho and Pedro D. Oliveira (Dept. Civil Eng., Lab. of Acoust., College of Eng., Univ. of Porto, 4200-465 Porto, Portugal, carvalho@fe.up.pt)

The choice for an economically ideal solution of environmental noise barrier must acknowledge both the cost of its main components and the benefits it can provide through time. To achieve a systematic analysis tool an algorithm based on benefit/cost ratio analysis was created. It calculates the benefit/cost ratio for any potential noise barrier. The cost of a barrier can be described with known or quantifiable parameters such as barrier height, thickness, angle, material and initial investment costs, life-cycle costs as maintenance costs, replacement costs due to minor/major accidents, vandalism or defacement, etc. The benefits associated with a solution are defined by computable parameters such as sound absorption index (DLalfa) and airborne sound insulation index (DLr) defined in EN 1793, insertion loss (predicted or measured), and even intangible parameters such as visual intrusion (color and aesthetics) and environmental impact (sustainability). Each benefit is weighed regarding its importance. Using the necessary parameters it is possible to calculate the benefit/cost ratio for any number of years of a life expectancy. An analysis concerning several possible solutions with different life expectancies can therefore be conducted. A general example of application is also presented.

4:15

1pNSc9. Noise attenuation by two-dimensional sonic crystals made of rubber crumb. Jose Sanchez-Dehesa, Victor M. Garcia-Chocano, Daniel Torrent, Francisco Cervera, Suitberto Cabrera (Wave Phenomena Group, Polytechnic Univ. of Valencia, Camino de vera s.n., ES-46022, Spain, jsdehesa@upvnet.upv.es), and Francisco Simon (Instituto de Acustica, ES-28006 Madrid, Spain)

It is shown that sonic crystals consisting of cylindrical rods made of rubber crumb can be used as efficient structures to attenuate noise in a wide range of frequencies. A structure made of three rows of cylinders (3-m height) has been fabricated and its isolation properties have been characterized in a transmission chamber. Two different numerical algorithms have used to simulate the experimental characterization. A good agreement between theory and experiment is obtained and gives support to design barriers based on this technology. [Work supported by MICIIN of Spain.]

4:30

1pNSc10. Annoyance response to mapped noise from combined road-traffic and railway system. Jin-Hee Son, Tae-Ho Park, Joon-Hee Ko, Seo Il Chang (Dept. of Environ. Eng., Univ. of Seoul, Seoul 130-743, Republic of Korea), and Kun Lee (Univ. of Seoul, Seoul 130-743, Republic of Korea)

To study annoyance response to combined transportation noise from road-traffic and railway, a social survey has been performed in a highly populated residential area in the city of Seoul, South Korea. To determine the noise exposure level in an interviewed household, a noise mapping software package was utilized and the noise exposure level from each single source was calculated separately and combined to get total exposure level. The prediction was partially validated by measurements. The households in the study area are classified into acoustically differentiated groups which are named as the road-traffic noise dominant, railway noise dominant, and combined noise dominant, respectively. %HA (percentage of highly annoyed people) curves to noise exposure level are presented for the acoustically classified three groups. Comparison of the %HA curves shows that more people are highly annoyed to railway noise than road-traffic noise, but the curve for combined noise is much closer to the %HA curve for road-traffic noise rather than the %HA curve for railway noise. Multiple-regression and path analysis of the survey data give the direct and indirect quantitative relationships between annoyance and noise and non-noise factors. Personal sensitivity to noise and satisfaction of living environment are primary contributing factors.

4:45

1pNSc11. Noise mechanisms in motorcycle helmet noise. M. J. Carley (Dept. of Mech. Eng., Univ. of Bath, Bath BA2 7AY, United Kingdom, m.j.carley@bath.ac.uk), N. J. Holt (Bath Spa Univ., Bath BA2 9BN, United Kingdom), and I. Walker (Univ. of Bath, Bath, BA2 7AY, United Kingdom)

A unique set of results on the acoustics of motorcycle helmets has been gathered during road tests on a rider wearing a representative modern helmet. The data were collected during a study of the noise which can cause hearing damage and, possibly, distraction in riders. They consisted of simultaneous measurements of noise at the rider's ear and unsteady pressure on the helmet surface, combined with GPS measurements of rider position and speed. These signals have been analyzed to reduce the coherent structures in the turbulent flow responsible for noise generation. The identified structures appear to be produced by a vortex street shed by the motorcycle windscreen. The internal and external pressures proved to be poorly correlated over most of the frequency range, which has been identified as a result of the insertion loss of the helmet. The implications of these findings are that the majority of the variation in helmet noise is a function of such extrinsic factors as motorcycle configuration and rider build and posture. Efforts to reduce the harmful effects of noise in motorcycling should, then, move to studying the whole system of rider, helmet, motorcycle, and external environment.

1pNSd1. Calculating annualized sound levels for a wind farm. Kenneth Kaliski and Eddie Duncan (Resource Systems Group, 55 Railroad Row, White River Junction, VT 05001, kikaliski@rsginc.com)

Modeling done for wind farms usually focuses on calculating a worst-case short term average sound level. However, the impact to homes is not simply defined by a single meteorological condition. Rather, a more complete picture of the impacts is given by calculating sound levels under various meteorological conditions that occur during the year. The actual sound level at a receiver will depend on variations in atmospheric stability, wind speed, wind direction, and other parameters that change hourly. This paper will describe a method to calculate hourly sound pressure levels for individual receivers over the course of an 8760 h year and give examples of different wind farm configurations and how they affect annualized sound levels.

1:40

1pNSd2. Low frequency sound and infrasound from wind turbines: A status update. Robert D. O'Neal, Robert D. Hellweg, Jr., and Richard M. Lampeter (Epsilon Assoc., Inc., 3 Clock Tower Pl., Ste. 250, Maynard, MA 01754, roneal@epsilonassociates.com)

A common issue raised with wind energy developers and operators of utility-scale wind turbines is whether the operation of their wind turbines may create unacceptable levels of low frequency noise and infrasound. In order to answer this question, one of the major wind energy developers commissioned a scientific study of their wind turbine fleet. The study consisted of three parts: (1) a world-wide literature search to determine unbiased guidelines and standards used to evaluate low frequency sound and infrasound, (2) a field study to measure wind turbine noise outside and within nearby residences, and (3) to compare the field results to the guidelines and standards. The guidelines and standards evaluated were audibility including infrasound; ANSI S12.2 for interior sounds—both acceptability of low-frequency sounds in bedrooms, schools, and hospitals and perceptible rattles and vibration; ANSI S12.9 Part 4 for thresholds of annoyance and beginning of rattles; and certain European criteria for low frequency and infrasound. This paper presents the results of the detailed study and concludes that there should be no adverse public health effects from infrasound or low-frequency noise at distances greater than 1000 ft from the wind turbine types measured.

2:00

1pNSd3. Potential noise reduction from mast trailing vanes as downwind-design wind turbine retrofits. Mark Storm (URS Corp., 1615 Murray Canyon Rd., Ste. 1000, San Diego, CA 92108, mark_storm@urscorp.com)

Older wind turbine generators (WTGs) featuring rotors that are "downwind" of the nacelle mast structure have the reputation of being noisier than their "upwind" design counterparts on the argument that the aerodynamic wake from the mast introduces noise-producing turbulence at the interaction area of the passing rotor blades. Possible methods of improving the wake, for the purpose of reducing this blade-interaction turbulence and hence noise production, could include the addition of a flat plate or similar structure or device to the trailing side of a mast structural element. Realization of such a conceptual device would likely be a retrofit to a pre-existing downwind-design WTG—if mast-to-rotor clearance and other practical parameters allow. This study attempts to quantify the noise reduction potential of a sample retrofit concept, using an estimation technique similar to what one might find in the realm of commercial HVAC technology, where axial fan blade interaction with wakes from stators, vanes, pipes, grilles, or guards is a common noise-producing concern.

1:05

1pSP1. Acoustic sensing for urban battlefield applications. Tien Pham (US Army Res. Lab., 2800 Powder Mill Rd., Adelphi, MD 20783, tien.pham1@us.army.mil)

For years, acoustic sensor systems have been used effectively in a variety of battlefield applications due to its low-cost, low-power, non-line-of-sight and 360 deg coverage capabilities. Acoustic (only) systems can autonomously detect, track, and classify a variety of targets: personnel, ground vehicles, airborne targets, and transient events. In recent years, acoustics has become an important sensing technology due to its complementary sensing capability within multi-modal sensor systems, and its wide-area coverage capability to alert and point other hi-resolution sensors within a network of sensor systems for intelligent-surveillance-reconnaissance (ISR). For example, in a multi-modal sensor system, acoustic can provide enhanced detection and discrimination of targets and activities, and cue imaging sensors to capture the events of interest. Similarly, in a network of ISR sensor systems, acoustic can reduce the search space for other ISR sensors to autonomously track and locate events of interest in real time. In this discussion, we will present an overview of battlefield acoustic applications that are of current interest to military operations: (i) detection and localization of transients, (ii) sensing from mobile and aerial platforms, and (iii) sensing within a network of ISR sensor systems. We will then discuss the signal processing strategies and challenges associated with the applications.

1:25

1pSP2. Effects of atmospheric scattering and refraction on the performance of acoustic direction-finding arrays. D. Keith Wilson (U.S. Army Engineer Res. and Development Ctr., 72 Lyme Rd., Hanover, NH 03768-1290, d.keith.wilson@usace.army.mil), Sandra L. Collier (U.S. Army Res. Lab., Adelphi, MD 20783), and Vladimir E. Ostashev (NOAA Earth System Res. Lab., Boulder, CO 80303)

Refraction, turbulent scattering, and other atmospheric propagation effects complicate the performance of outdoor microphone arrays used to infer source bearings. In principle, with good knowledge of the atmospheric profiles, one can compensate for the refraction effects. However, the random angle-of-arrival variations induced by atmospheric turbulence limit array performance even when the signal-to-noise ratio is high. The turbulent scattering effect can be viewed as a coherence loss between elements of the beamforming array. Most research to date on acoustic signal coherence in the atmosphere has dealt with line-of-sight (LOS) propagation paths. A number of complications characteristic of real turbulence have been introduced; these include statistical inhomogeneity, anisotropy, and intermittency of the turbulent eddies. The LOS theory has also been extended to include sensor displacements longitudinal to the propagating wavefronts as well as transverse displacements. Formulations for the Cramer–Rao lower bound (CRLB) on the angle-of-arrival accuracy have been developed from the LOS theory. Based on limited experimental data and modeling, actual performance appears to be substantially worse than the CRLB. Recently, numerical methods have been introduced for solving second-moment parabolic equations, which offer the possibility of incorporating non-LOS effects into coherence calculations.

1:45

1pSP3. Associating acoustic transients for localization by multiple arrays. Tung-Duong Tran-Luu (2800 Powder Mill Rd., Adelphi, MD 20783, dtranluu@arl.army.mil)

This paper first presents two methods to estimate the location of an acoustic transient based on measurements of its time-of-arrival and direction-of-arrival at a set of microphone arrays. One is a least-square (LS) estimator, the other a maximum likelihood (ML) estimator. Both are compared to the Cramer–Rao lower bound for reference. They are then extended to associate detections (of the same event) at different arrays by a maximum *a posteriori* (MAP) formulation that can sort out outliers and multipath detections while reusing the likelihood values computed in the first part. Simulations show that the LS estimator performs slightly better than the ML estimator when the observation noise does not match the noise model. Both methods exhibit a bias in the range estimate, which accounts for most of the square error. The MAP estimator, applied to live fire data, was accurate and successfully resolved simultaneous multiple targets from outlier and multipath noise.

2:05

1pSP4. Comparison of noise levels measured on elevated acoustic sensor arrays mounted on various aerostats. Christian G. Reiff (2800 Powder Mill Rd., Adelphi, MD 20783)

The army has fielded acoustic systems for the detection of mortar, rocket, and small arms and it has been demonstrated that elevating the acoustic array by mounting the array on an aerostat can improve signal-to-noise levels. The elevated array receives a cleaner, higher amplitude signal while the noise level also increases. The performance of aerostat mounted acoustic sensor arrays for source detection and localization is limited by these increased noise levels caused by higher wind speeds and airship components. These shortcomings can be mitigated somewhat by using microphone windscreens, array location, and signal processing. Data from experiments on a large tethered rigid airship, a smaller tethered non-rigid aerostat, and a medium rigid motorized airship are compared for noise environment and effects on acoustic detection and source localization.

2:20

1pSP5. Refraction corrections in source localization with an elevated acoustic sensor array in the 2007 Yuma experiment. Vladimir E. Ostashev (NOAA/Earth System Res. Lab., 325 Broadway, Boulder, CO 80305 and Dept. of Phys., New Mexico State Univ., Las Cruces, NM 88003, vladimir.ostashev@noaa.gov), Christian G. Reiff, Michael V. Scanlon, Sandra L. Collier (U.S. Army Res. Lab., Adelphi, MD 20783), and D. Keith Wilson (U.S. Army Engineer Res. and Development Ctr., Hanover, NH 03755)

Performance of ground based acoustic sensor arrays for source detection is limited by several factors, including sound reflections by obstacles, irregular terrain, multipath sound propagation, absorption of sound waves in the ground, and formation of an acoustic shadow zone in the upwind direction. These shortcomings can be overcome by suspending acoustic sensor arrays below tethered aerostats. A comprehensive experiment in source localization was carried out in October of 2007 near Yuma, AZ. A sensor array was suspended below an aerostat, and ray refraction corrections were calculated for the apparent source coordinates. Significant bias errors in the source coordinates were found if a straight-line approximation for sound propagation in the atmosphere is used. However, by taking into account refraction of sound signals due to vertical profiles of temperature and wind velocity, it is possible to significantly reduce the localization errors even with a rough approximation of these meteorological profiles. If actual profiles were used in refraction corrections, localization errors would probably be further reduced.

2:35

1pSP6. Comparison of the performance of acoustic beamformers under differing atmospheric conditions. Sandra L. Collier, Leng Sim, Duong Tran-Luu (U.S. Army Res. Lab., RDRL-CIE-S, 2800 Powder Mill Rd., Adelphi, MD 20783, scollier@arl.army.mil), D. Keith Wilson (U.S. Army Engineer Res. and Development Ctr., Hanover, NH 03768), and Vladimir E. Ostashev (NOAA/Earth System Res. Lab., Boulder, CO 80305)

It is well known that atmospheric turbulence can negatively impact the performance of acoustic beamformers. While many beamformers, especially adaptive ones such as minimum variance distortionless response (MVDR), may be robust when the turbulent fluctuations are mild to moderate, they fail when the fluctuations are large. Other methods, such as maximum likelihood estimation, may be used to mitigate the effects of turbulence by directly incorporating the physics of the propagation medium into the assumed model of the acoustic signal (through the covariance and mean). When using synthesized data, the previously developed maximum likelihood estimator (MLE) for the azimuthal angle of arrival was found to outperform classical beamformers. However, in reality the atmosphere does not exhibit the exact behavior of the assumed atmospheric model, or all the required input parameters, such as the meteorological data, for the atmospheric model are not available. Therefore, we compare the performance of methods such as the MLE to that of classical and parametric methods, such as MVDR, multiple signal classification, and matched subspace detector, for data collected during a variety of atmospheric conditions. We critically examine the expense of gained accuracy over computational speed.

2:50

1pSP7. Impact of a collection of buildings on line-of-bearing estimates. John M. Noble, W. C. Kirkpatrick Alberts, II, and Mark A. Coleman (U.S. Army Res. Lab., ATTN: RDRL-CIE-S, 2800 Powder Mill Rd., Adelphi, MD 20783)

The urban environment presents a very complex environment for the propagation of acoustic signals. To study some of these effects, a series of field experiments was conducted looking at propagation around urban structures. The third experiment in the series involved propagation around a small collection of urban structures. As part of this experiment, a series of triangular arrays was scattered around the area to examine the effect of urban structures on the line-of-bearing calculation. This presentation will present the results of these measurements and discuss the observed effects and their causes.

3:05—3:20 Break

3:20

1pSP8. Acoustic and direct vibratory excitation, propagation, and scattering of Rayleigh waves at an air-ground interface. Thomas G. Muir (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, One Coliseum Dr., University, MS 38677), R. Daniel Costley (Miltec Res. and Technol., Oxford, MS 38655), Craig J. Hickey, and James M. Sabatier (Natl. Ctr. for Physical Acoust., University, MS 38677)

Finite element methods are utilized to model loudspeaker as well as shaker generation of sound, shear, and interface waves in an elastic solid containing an imbedded elastic scatterer. Results for steady state (continuous) and transient (pulsed) insonification, animated in the time domain, are presented to illustrate excitation, propagation, and scattering mechanisms and features. 1pSP9. Estimation of pointing vector using acoustic planar array. Thyagaraju Damarla (RDRL-SES-A, US Army Res. Lab., 2800 Powder Mill Rd., Adelphi, MD 20783, thyagaraju.damarla@us.army.mil)

Traditional use of acoustic array of sensors for estimation of azimuth and elevation of a target suffer from inaccuracies, especially in estimation of elevation angle, due to poor resolution in trigonometric functions. For example, a variation of angle 70×90 deg result in variation of sine of angle in 0.94–1. In the proposed approach, each pair of elements (sensors) in the array is used to estimate the direction of arrival (DoA) of the signal. This DoA forms a cone along the axis of the line joining the pair of sensors. Several such cones from different pairs of sensors would intersect giving the direction of the target. Since the phase angles between two sensors can be estimated accurately, the DoAs will be accurate and hence the intersection of the cones would result in accurate estimation of the pointing vector to the target overcoming the deficiencies of the traditional methods. In the case of transient events, the time difference of arrival at the pair of sensors gives the DoA. Mathematical formulation for estimating the pointing vector will be given. The technique will be used on some field data and the results obtained will be compared with the ground truth.

3:50

1pSP10. Near-ultrasound, broadband noise generated by low-speed airflow over wires. W.C. Kirkpatrick Alberts, II, Kevin J. Sanchez, Mark A. Coleman, Josh Gabrielse, and David A. Ligon (US Army Res. Lab., ATTN: RDRL-CIE-S, 2800 Powder Mill Rd., Adelphi, MD 20783)

Vortex shedding due to flow past a cylindrical object and its accompanying sound are well-described phenomena, though research has often focused on the sound broadcast in directions transverse to the wire and downstream in high-speed flows. Here, we investigate the sound broadcast in angles nearly opposite the direction of low-speed flows from nozzles of diameter similar to those of various wires. Also investigated are the effects that several parameters (tension, wire diameter, nozzle-wire separation, etc.) have on the level and frequency content of the recorded sound. It is found that a microphone approximately 3 cm above the outlet of a nozzle records broadband, near-ultrasound noise due to the flow over the wire. Signal levels as high as 20 dB above the nozzle background are observed. Recorded broadband noise spectra associated with vortex shedding from various wires and schlieren images of the interaction between the flow and the wire will be presented.

4:05

1pSP11. Matched field processing applied to diffraction of sound around 90 deg corners: Modeling and experiment. Victor Singh (W. E. Lay Auto Lab., Univ. of Mich, 1697 Broadway St. 303, Ann Arbor, MI 48105, victorsi@umich.edu), Katherine E. Knisely, Karl Grosh, David R. Dowling (Univ. of Mich, Ann Arbor, MI 48105), and Serdar H. Yonak (Toyota Motor Engr. and Mfg. North America, Ann Arbor, MI 48105)

Acoustic diffraction allows sound to travel around opaque objects and therefore may allow beyond-line-of-sight sensing of remote sound sources. This presentation reports simulated and experimental results for detecting and localizing sound sources at blind city-street intersections based on shadowed microphone array measurements. The generic geometry includes a point source, a solid 90 deg wedge, and a receiving array that lies entirely in the shadow defined by the source location and the wedge. Sound source detection and localization performance are assessed via matched-field (MF) ambiguity surfaces as a function of source frequency, receiving-array configuration, and received signal-to-noise ratio for the Bartlett and minimum variance distortionless MF processors. Here, the sound propagation model is developed from a Green's function integral treatment and the geometric theory of diffraction. The simulations suggest that sound sources may be localized by fully shadowed arrays for signal-to-noise ratios as low as 20 dB when ambiguity surfaces from several different source frequencies are incoherently combined. The experiments were conducted using an approximate 50-to-1-scaled tabletop model of a blind city-street intersection and chirp signals from 500 Hz to 30 kHz and suggest that the propagation model must be improved before the simulations' performance can be reached.

4:20

1pSP12. Revisiting isodiachrons as a solution for localization. Balaji Katlai and Jonathan Vallarta (Jasco Appl. Sci., 1496 Lower Water St., Halifax, NS, Canada)

Recently, there have been some new attemtps in source localization algorithms. In particular, Spiesberger *et al.* successfully introduced the notion of isodiachrons to localize a source. In this abstract, it is shown that the concept and notion of using an isodiachron can be understood in terms of mapping an unbounded trajectory (as in conventional hyperbolic fixing for localization) into a more closed form bounded surface. This is made possible by realizing a simple analytical continuation of the parameters in the algorithm. The resulting system is a bounded surface with isodiachrons as a solution. A simple proof-of-concept example is also demonstrated. This is a complementary solution/approach to the original idea of isodiachrons as proposed by Spiesberger. Additionally, other alternative approaches to translate (an unbounded) hyperbolic fixing technique to a source on a bounded surface are also discussed.

4:35

1pSP13. Optimal selection of weights for the linear total least-squares solution to impulsive source localization. Wm. Garth Frazier and Heath Rice (NCPA, Univ. of Mississippi, 1 Coliseum Dr., University MS 38677)

At a recent ASA meeting, Monte Carlo-based noise performance analysis of several formulations and solution algorithms for the time-of-arrival (TOA) based impulsive source localization problem were presented. That analysis included two algorithms for parameter estimation using the (exact) linear formulation for the localization problem. Those algorithms were standard linear least-squares (LLS) and linear total least-squares (TLS). Using systematically derived, but in no way optimized, choice of weights, the TLS algorithm clearly demonstrated the ability to overcome the bias associated with LLS under conditions associated with low signal-to-noise ratio. Unfortunately, the bias reduction was obtained at a cost of high variance as compared to solutions associated with nonlinear formulations. This presentation presents results from investigations into performance of optimally chosen (variance reducing) weighting schemes for TLS and compares them to the performance of nonlinear formulations.

4:50

1pSP14. Error analysis of locating arbitrary sound sources in three dimensional space in real time. Na Zhu and Sean F. Wu (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202, dv6930@wayne.edu)

This paper presents an error analysis in locating multiple incoherent sound sources in three dimensional space in real time by using a newly developed hybrid approach. The underlying principle of this hybrid approach consists of modeling of sound radiation from point sources in a free field, triangulation, and signal processing techniques. The impacts of target source locations and signal to noise ratio on the results are examined. Experimental results show that errors in source localization consist of primarily two components: biased and random errors. The former seems to be caused by the fact that the formulations used in acoustic modeling are for a free field, whereas the measurement environment is a non-free field. The latter is mainly caused by fluctuations in the source levels. To account for these errors, empirical formulations are developed and validated again in experiments with different settings. Results demonstrate that these empirical formulations can significantly improve the accuracy and spatial resolution of source localizations.

5:05

1pSP15. Coherence of low-frequency acoustic signals across a tetrahedral array. Geoffrey, H Goldman (U.S. Army Res. Lab., 2800 Powder Mill Rd., Adelphi, MD 20783-1197)

Many direction finding algorithms for acoustic applications require that the data collected at each microphone is coherent with respect to the data collected with another microphone in some frame. As the microphones are moved farther apart, the angular resolving power of the array is increased, but the coherence of the data is reduced. These factors are critical for designing the spatial configuration of acoustic arrays. The coherence of low-frequency acoustic signals was examined across tetrahedral microphone arrays elevated 1 m above the ground. The signal source was a UH-1 helicopter, which had strong harmonics between 10 and 100 Hz. The coherence was measured by tracking the harmonics of the signal, bandpass filtering each harmonic, cross correlating the filtered signals across all the microphone combinations, finding the maximum output, and then normalizing. The results indicate that the elevated microphone was less coherent than the non-elevated microphones. Multipath was determined to be a major factor affecting the coherency.

1pUW1. Oceanic noise: Mechanisms, radiation characteristics, and array results. William M. Carey (College of Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Noise produced by the oscillation of microbubble distributions and impacts (raindrops and splash) in the air-sea boundary zone results in doublet radiation patterns and noise fields with definitive temporal and spatial characteristics. Turbulence generated noise is quadrupole, and nonlinear wave-wave interactions are infrasonic. Plausible mechanisms provide a framework for a review of directional noise measurements in range dependent oceanic and bathymetric environments. Slope interaction converts higher angles to lower angles and results in a frequency dependent vertical directionality. Low-frequency (0.02–1 kHz) measurements reveal a temporally dynamic noise field with persistent directional characteristics. Higher frequency (1-kHz or greater) measurements exhibit a local stationary characteristic influenced by the boundary zone mixed layer. Beam noise cumulative distribution functions are shown to depend on the distribution of ships, basin size, and boundaries. Directional noise computations are presented along with the issues of shipping distributions, the air-sea boundary zone, and assimilated satellite observations of wind speed, white caps, and sea surface temperature. The computation of basin scale directionality basically estimates the persistent characteristic. Improved calculation with the directional radiation from modern ships and the inclusion of the dynamic ship distribution ships are presented to estimate the beam noise statistics.

1:30

1pUW2. Trends in low-frequency deep ocean ambient noise levels: New results from old data. Ross Chapman and Andrea Price (School of Earth and Ocean Sci., Univ. of Victoria, 3800 Finnerty Rd., Victoria, BC V8P5C2, Canada, chapman@uvic.ca)

Concern about effects of anthropogenic sound generated by ships, seismic exploration, naval operations, and ocean acoustic research on marine life has stimulated new studies of marine animal bioacoustics. An underlying issue in assessing the noise impact establishes the present-day background noise level and compares it to noise levels from previous times. The most generally accepted prediction of noise level trend at low frequencies (below 500 Hz) is due to Ross, who used noise levels from the 1950s and the mid-1960s to predict an increase of about 3 dB/decade. This paper addresses the issue of the trend in low-frequency ambient noise levels in the ocean and presents measurements taken in the intermediate years between the mid-1960s and the present time. The measurements were made using a calibrated multi-element volume array (MEVA) at deep ocean sites in the Northeast Pacific from 1978 to 1986. The array provided spectral noise levels and horizontal and vertical directionalities. Compared to the 1965 values, the MEVA values are 6–8 dB greater between 10–50 Hz and 1–3 dB greater from 50–400 Hz, respectively. The data presented here provide evidence that the trend predicted by Ross extended at least into the mid-1980s.

1pUW3. Noise cross-correlation and passive measurements of the sound speed profile in deep water. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Earth System Res. Lab., Boulder, CO 80305-3328, oleg.godin@noaa.gov), Nikolay A. Zabotin (Univ. of Colorado, Boulder, CO 80309-0425), and Valery V. Goncharov (Russian Acad. of Sci., Moscow 117997, Russia)

Ambient acoustic noise in the ocean contains extensive information about its sources and the propagation environment. Successful application of the noise observations to acoustic characterization of the environment depends on identifying the noise properties which can be reliably measured and are sensitive to variations in temperature and other physical parameters of the ocean. This paper focuses on two-point noise cross-correlation and the environmental information that can be retrieved from it without any *a priori* knowledge about properties and locations of the noise sources. A technique to retrieve deterministic acoustic travel times from cross-correlations of noise recorded on two vertical line arrays is described. Feasibility of environmental monitoring with ambient noise is illustrated by results of passive tomography of the water column using noise recordings of opportunity, which were obtained in the North Pacific Ocean as a by-product of a long-range sound propagation experiment. Conflicting requirements on the hydrophone separation and frequency band are analyzed that originate from the demands to improve the inversion accuracy and to decrease noise averaging time. Remaining challenges in retrieving oceanographically meaningful results from acoustic noise cross-correlations are discussed. [Work supported by ONR.]

1pUW4. Depth-profiling ambient noise in the deep ocean. David R. Barclay, Fernando Simonet, and Michael J. Buckingham (Scripps Inst. of Oceanogr., UCSD, 9500 Gilman Dr., La Jolla, CA 92093-0238, mbuckingham@.ucsd.edu)

Deep Sound is an untethered instrument platform designed to free-fall from the sea surface to a preassigned depth, at which point a burn wire releases a weight, allowing the system to return to the surface under buoyancy. The descent and ascent rate is 0.6 m/s. A Vitrovex glass sphere houses lithium-ion batteries and a suite of microprocessor-controlled electronics for data acquisition, data storage, power management, and system control. Outside the sphere, several hydrophones are arranged in vertical and horizontal configurations, a CTD returns environmental data, and motion sensors monitor pitch, roll, and yaw. Data may be downloaded, and the batteries may be recharged, via throughputs in the sphere. The hydrophones, with a bandwidth of 30 kHz, are rated to a depth exceeding 11 km, and the sphere itself has a depth-rating of 9 km. The system made three descents in the Philippine Sea in May 2009, to depths of 5100, 5500 and 6000 m; and in November 2009, two descents were made in the Mariana Trench to a depth of 9000 m. On all these deployments, ambient-noise time-series were recorded continuously, yielding the power spectrum and vertical coherence of the noise as functions of depth. [Research supported by ONR.]

1pUW5. The statistical interpretation of a simple ambient noise model. Richard Evans (College of Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, richard.evans.01@snet.net)

Theoretical analyses of the statistics of ambient noise levels can yield distributions that are either narrow and symmetric, or broad and nonsymmetric [I. Dyer, J. Acoust. Soc. Am. **53**, 564–570 (1973)]. Their standard deviations vary between nearly 0 and 5.6 dB. The assumptions regarding the nature of the noise source are the key in determining what distribution to expect. A simple computational model that exhibits both extremes, of the potential statistical distributions, can help in understanding what assumptions determine the statistics. The paper presents a simple ambient noise model that allows such a statistical interpretation.

2:45

1pUW6. Statistical properties of deep ocean noise. Brianne Moskovitz, Gerald D'Spain, John Hildebrand, and Achintya Madduri (Marine Physical Lab., Scripps Inst. of Oceanogr., 291 Rosecrans St., San Diego, CA 92106, bmoskovi@ucsd.edu)

The various arrays sea test (VAST) was conducted in July 1989 in the northeast Pacific Ocean. A 3000-m-long, 200-element hydrophone array was suspended for an 11-day period from R/P FLIP, moored about halfway between San Diego and Hawaii (34N, 140W). Simultaneously, 12 neutrally buoyant, freely drifting Swallow floats equipped with both infrasonic hydrophones and three-component geophones were deployed at various depths 150 km off the California coast (35N, 122W). The statistical properties of deep ocean noise recorded by these sensor systems, both single element and beam level, are examined quantitatively under a variety of conditions, including wind-dominated (15–18 kt), distant air gun operations, and marine mammal vocalizations. Non-parametric statistical tests applied to narrow band complex time series of the data include the Wald–Wolfowitz run test for mutual independence of the data samples, the Kolmogorov–Smirnov two-sample test for stationarity, and the Kolmogorov–Smirnov one-sample test for Gaussianity. Results are presented over a broad range in frequencies and time scales and show that the noise field at times and in certain directions displays non-stationary and non-Gaussian properties. In a few cases, these statistical characteristics can be associated with specific physical processes. [Work supported by the Office of Naval Research.]

1pUW7. Deep water ambient noise on the seafloor. Ralph A. Stephen (Dept. of Geology and Geophys., Woods Hole Oceanograph. Inst., 360 Woods Hole Rd., Woods Hole, MA 02543, rstephen@whoi.edu)

Long, continuous time series of ocean bottom seismometer (OBS) and co-located hydrophone data from the seafloor offer an unprecedented opportunity to study the physical mechanisms of seafloor ambient noise in the frequency band from 1 to 100 Hz. The Ocean Seismic Network Pilot Experiment (OSNPE) in 1998 compared noise and signal levels for a hydrophone at the seafloor with three-component observations from OBSs on the seafloor, buried 1 m into the soft sediment, and clamped in a borehole 10 m into basaltic basement. The Hawaii-2 Observatory (H2O) acquired over 3 years of nearly continuous, real-time data from a shallow-buried seismic and seafloor hydrophone system. On the North Pacific Acoustic Laboratory experiment in 2004 (NPAL04) three vertical-component geophone/hydrophones were deployed beneath vertical line arrays in the water column. In addition to ambient noise data, controlled source transmissions were received from ranges out to 3200 km. In the absence of shipping noise, whale calls, and local sea state, what controls the noise floor on the deep seafloor? Interesting observations include banded coherence structure between the vertical geophones and hydrophones, peaks in ambient noise levels due to resonances in the sediment layer, and Stoneley/Scholte wave particle motions. [Work supported by the NSF, ONR and WHOI.]

3:35

1pUW8. Long-time trends in low-frequency traffic noise for four sites off the North American west coast. Rex K. Andrew (Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105, randrew@apl.washington.edu), Bruce M. Howe (Univ. of Hawaii at Manoa, Honolulu, HI 96822), and James A. Mercer (Univ. of Washington, Seattle, WA 98105)

Measurements from four cabled-to-shore hydrophone systems located off the North American west coast permit extensive comparisons between "contemporary" low-frequency traffic noise (25–50 Hz) collected in the past decade to measurements made in the mid-1960s with the same in-water equipment at the same sites. An increase of roughly 10 dB over the band 25–40 Hz at one site has already been reported [Andrew *et al.*, ARLO Acoust. Res. Let. Online **3** (2002)]. Newly corrected data from the remaining three systems corroborate this increase. Simple linear trend lines of the contemporary traffic noise (duration 6–12+ years) show that the current levels either hold steady or decrease at three of the four sites. These results confirm the Ross prediction, at least at these sites, that the rate of increase in traffic noise would be far less at the end of the last century compared to that observed in the 1950s and 1960s.

3:55

1pUW9. Deep ocean noise measurements in the Philippine Sea. Matthew Dzieciuch and Peter Worcester (SIO/UCSD, 9500 Gilman Dr., La Jolla, CA 92039, mad@ucsd.edu)

In the spring of 2009, a newly developed distributed vertical line array (DVLA) receiver made up of two, 1000-m-long subarrays with 30 hydrophones each was deployed for approximately 1 month in the northern Philippine Sea. One subarray spanned the sound-channel axis, and the second subarray spanned the surface conjugate depth (about 4200 m). Twenty of the 30 hydrophones in the deep subarray were spaced 5 m apart (half-lambda at 150 Hz), allowing the vertical directionality of the ambient noise below the surface conjugate depth to be determined. The minimum omnidirectional ambient noise levels decreased significantly below the surface conjugate depth at frequencies from 50 to 500 Hz, similar to behavior previously observed in the central North Pacific Ocean. The minimum noise levels presumably correspond to times when wind speeds are low and surface conditions are calm so that there is little locally generated, low-frequency noise.

1pUW10. Model-data comparisons of deep water ambient noise. James J. Murray (OASIS, Inc., Fairfax, VA), Peter Worcester, Matthew Dzieciuch (Scripps Inst. of Oceanogr., 9500 Gilman Dr., La Jolla, CA), and Kevin D. Heaney (OASIS, Inc., Fairfax, VA)

During the North Pacific Laboratory (NPAL) Philippine Sea 2009 experiment, a distributed vertical line array (DVLA) was deployed for several weeks in the northern Philippine Sea. The array, described in detail in a previous talk, consisted of two 1000-m sections, one spanning the sound channel axis and the other covering the deep ocean, extending from above the surface conjugate depth down to within roughly 100 m of the bottom. In this paper, a hybrid propagation model for handling low-frequency ocean noise will be presented. The model uses analytic solutions (rays) for ranges to 5 km, the parabolic equation for ranges from 5 to 100 km, and normal modes for ranges beyond that. The model predicts ambient noise levels vs depth. The fall off of the ambient noise with depth below the surface conjugate has been reported. The level of the fall off and its frequency dependence are sensitive to the local geo-acoustics. A geo-acoustic inversion will be performed using a range-independent version of the acoustic model with Monte-Carlo realizations of surface ship distributions.

4:30

1pUW11. Horizontal noise directionality in deep water measurements and modeling. Richard Campbell, Kevin D. Heaney (OASIS, Inc., Fairfax, VA 22039), and Arthur B. Baggeroer (MIT, Cambridge, MA)

Low-frequency, less than 100 Hz, sound is dominated by surface shipping, particularly in the northern hemisphere. With low-volume attenuation sound can propagate significant distances. For periods of time not dominated by a particular nearby interferer, the low-frequency ambient noise field is dominated by distant shipping and is expected to be anisotropic due to various bathymetric effects such as downslope conversion and seamount or ocean ridge blockage. In this paper, the authors present horizontal array measurements from a 100 m towed line array (towed at 100 m) in very deep water in the Philippine Sea. The northern Philippine Sea has several ridges and seamounts and significant bathymetric interaction for surface ships in the main Singapore Shanghai shipping lane. A rapid range bearing dependent $N\times2$D parabolic equation approach will be described and used to evaluate the bathymetric effects on the horizontal directionality of low-frequency noise. Comparisons of measurements and models will be done using both Monte-Carlo realizations of surface ship positions (from the HITS database) as well as measured AIS from research vessels in the vicinity.

4:45

1pUW12. Characteristics and variability of ambient noise in the South China Sea basin. Ching-Sang Chiu, John E. Joseph, and Christopher W. Miller (Dept. of Oceanogr., Naval Postgrad. School, 833 Dyer Rd., Rm. 328, Monterey, CA 93943)

A hydrophone was moored at mid depth in the South China Sea basin from November 2005 to October 2006. Operated with a 1-min-on and 14-min-off duty cycle and sampled at 1.6 kHz, the measured time series captures the spectral characteristics and variability of the ambient noise in the 0–800-Hz band over an annual cycle. In this paper, we provide a description on the daily, monthly, and seasonal variabilities and variances in the measured noise spectrum and band levels. In order to gain insights into the predictability of the ambient noise field in this marginal sea, the interpretation of the data is facilitated with historical shipping density data and nowcast wind fields from the Navy Operational Global Atmospheric Prediction System (NOGAPS). Attention is made to the evolution of the ambient noise spectra during major storm events. Intermittent noises are also examined. The potential sources for these intermittent noises are discussed. [Research sponsored by the Office of Naval Research.]

1pUW13. Blue whale vocalizations and the seasonal variability of ambient noise levels at the Aloha Observatory. Orest Diachok (Appl. Phys. Lab., Johns Hopkins Univ., Laurel, MD) and Fred Duennebier (Univ. of Hawaii, Honolulu, HI)

In February, 2007 the Aloha Observatory added a cabled, bottom mounted hydrophone, which supplied a 20-month continuous recording of ambient noise from 0.02 Hz to 11 kHz. This observatory is situated at a depth of 4700 m, 100 km north of Oahu. This site is known to be close to (possibly within) one of the primary habitats of NE Pacific and NW Pacific blues, and other whales during the winter. Numerous previously reported measurements throughout the NE Pacific Ocean have demonstrated that the fundamental frequencies of NE blues vocalizations have systematically decreased from about 22.5 Hz in 1958 to about 16.5 Hz in 2007 (the cause of the frequency shift is unknown). Limited measurements suggest that the fundamental frequencies of NW blues vocalizations have also decreased with time and were about 18 Hz in 2007. Ambient noise levels from the Aloha site were analyzed in 1-Hz bands for 1 year to permit observation of the seasonal dependence of ambient noise levels as a function of frequency. The data reveal distinct peaks in noise levels at 16.5 and 18.5 Hz between November and March, consistent with observations of the fundamental frequencies of NE and NW blue whale vocalizations. Since blues and other whales repertoire of vocalizations cover a broad frequency range, the contributions of their vocalizations to noise levels at other frequencies will be considered.

5:15

1pUW14. Invariant features of deep ocean ambient noise. Zachary S. Guralnik (SAIC, 4001 N. Fairfax Dr., Ste. 175, Arlington, VA 22203)

Very low-frequency, deep ocean ambient noise is generated by nonlinear interactions (collisions) between surface waves with nearly equal frequency, propagating in nearly opposite direction. It is shown that the usual "standing wave" approximation used to compute this noise predicts that the ratios of entries in the power spectral density matrix, obtained from auto and cross-correlations of acoustic velocity and pressure fluctuations, are universal constants. This prediction is too strong and not observed. A careful consideration of bottom effects invalidates the standing wave approximation. Nevertheless a weak version of the standing wave approximation still holds and has interesting implications. While the ratios of entries in the power spectral density matrix due to surface wave generated noise are not universal constants, they are insensitive to the details of the surface wave spectrum. This theoretical prediction is borne out by data from the Hawaii-2 Observatory. [Work supported by ONR.]

Interdisciplinary: Tutorial Lecture on Animal Hearing

Micheal L. Dent, Chair
SUNY Buffalo, Dept. of Psychology, Buffalo, NY 14260

Chair's Introduction—7:00

Invited Paper

7:05

1eID1. Animal hearing. Robert J. Dooling (Dept. of Psych., Univ. of Maryland, College Park, MD 20742)

The auditory world of animals is, in many cases, quite different from our own due to evolutionary pressures that have created anatomical and physiological differences in auditory structures. However, there are a number of commonalities of function and mechanisms across many species that point to general concepts of auditory perception. This tutorial lecture explores the field of animal hearing, also known as comparative psychoacoustics. Because the diversity in hearing organs among animals is considerable, the hearing of many animals is quite different from our own. We will review some of these differences in hearing across animal groups, from household pets to more exotic animals. This tutorial also highlights the specific advantages of the comparative approach and illustrates the many creative methods used for behavioral testing of hearing in animals. Species comparisons contribute to our understanding of the evolution of the auditory system and can often clarify the relationship between structure and function in the auditory system as well as the effects of damage and repair. The study of animal hearing can lead to improved understanding of human auditory capabilities and invites speculation about how human speech is adapted for intraspecies communication.

2aAO1. Acoustic ducting and refraction by sea bottom relief in shallow water. James F. Lynch, Alexey A. Shmelev, Ying-Tsong Lin, and Arthur E. Newhall (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanograph. Inst., 98 Water St., Woods Hole, MA 02543, jlynch@whoi.edu)

Observations show that shallow water bottom relief often has a band-limited directional spectrum produced by various oceanographic and geological processes. This directional bottom feature is shown to have a noticeable effect on three-dimensional low-frequency acoustic propagation. An analytical study with an idealized model of straight sea bottom ripples has shown that acoustic energy can be partially ducted between neighboring ripples, and this ducting will affect acoustic propagation in shallow water. In our work, we also study ducting and refracting due to idealized curved sea bottom ripples. Previous research has shown that non-linear internal waves can also create acoustical ducts. Comparative analysis of these two different ducts is performed using our idealized model. The combined effects of internal waves and bathymetry are studied for various relative directions of internal wave front and bottom ripples. A numerical simulation of three-dimensional sound propagation across realistic bathymetry and internal wave fluctuations is performed. In conclusion, both water column fluctuations and bathymetry variability need to be taken into account when studying three-dimensional acoustic propagation in shallow water.

9:30

2aAO2. Three-dimensional sound propagation over submarine canyons. Ying-Tsong Lin, Timothy F. Duda (Dept. Appl. Ocean Phys. & Eng., Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, ytlin@whoi.edu), Jon M. Collis (Colorado School of Mines, Golden, CO 80401), James F. Lynch, and Arthur E. Newhall (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Submarine canyons are common features of continental shelf and slope regions, e.g., Hudson Canyon in the Mid-Atlantic Bight. In this paper, the impact of submarine canyons on low-frequency sound propagation is studied using a three dimensional (3-D) parabolic approximation numerical program, which is implemented in a Cartesian coordinate system and utilizes the split-step Fourier technique and a 3-D variant of the Thomson and Chapman wide-angle approximation. This program will be first benchmarked with a classic wedge problem, and then used to study an idealized canyon environment to understand distinct 3-D sound propagation effects. The idealized environment has a Gaussian shaped canyon incising a slope. Horizontal focusing of sound in the canyon and energy flow into the canyon from an off-axis sound source are observed. A realistic model using the Hudson Canyon bathymetry shows even more complex sound propagation situations. Propagation conditions over different seabed types are also compared, and the 3-D field sensitivity to bottom properties is investigated. [Work supported by the Office of Naval Research.]

9:45

2aAO3. Three dimensional parabolic equation modeling of an internal wave event during Shallow Water 2006. Georges A. Dossot, James H. Miller, Gopu R. Potty (Dept. of Ocean Eng., Univ. of Rhode Island, Narragansett Bay Campus, Narragansett, RI 02882), James F. Lynch, Ying-Tsong Lin (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), Mohsen Badiey (Univ. of Delaware, Newark, DE 19716), and Kevin, B. Smith (Naval Postgrad. School, Monterey, CA 93943)

During the Shallow Water 2006 (SW06) experiment, a J-15 acoustic source deployed from the Research Vessel Sharp transmitted broadband (100–500 Hz) chirp signals 15 km away from a vertical line array. The array was intentionally positioned near the shelf-break front and in an area where internal waves are known to occur. During the same time an internal wave, "Event 44," passed through the sound field such that the internal wave front was near parallel to the acoustic transmission path. Measured data show substantial intensity fluctuations that vary over time and space due to complex multimode and multipath (both two and three dimensional) interference patterns. Of specific interest are fluctuations of measured intensity preceding the internal wave's arrival. Additionally, depth variability of the measured acoustic intensities can be attributed to a warm water intrusion coinciding with the internal wave event. This presentation shows recent modeling results using the experimental geometry, acoustic signal parameters, and a simulated oceanographic environment based on environmental moorings and ship-born sensors. A new version of the three-dimensional Monterey–Miami parabolic equation code, which incorporates a user-defined sound speed field, is used. [Work sponsored by the Office of Naval Research.]

10:00

2aAO4. Horizontal focusing/defocusing due to shallow-water internal waves. Jing Luo, Mohsen Badiey (Univ. of Delaware, Robinson Hall 112B, 261 S. College Ave., Newark, DE 19716, luojing@udel.edu), and Ying-Tsong Lin (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

During the New Jersey Shallow Water 2006 (SW06) experiment, an acoustic source was towed by the Research Vessel Sharp and followed the front of an internal wave packet. The source was transmitting broadband acoustic signals (50–450 Hz) in different angles with respect to the internal wave front. The receptions of transmitted signal on a vertical hydrophone line array are analyzed to study the horizontal focusing/defocusing that occurred when the internal wave front and acoustic track aligned closely. Based on ship-board radar images and temperature data collected on the environmental moorings at various locations along the acoustic track, a detailed three-dimensional (3D) environment is reconstructed for a 3-D parabolic approximation model to study the unique propagation scenario. Construction of index of normal mode refraction for these data provides a clear picture of acoustic energy focusing for this event. Data and model comparison are in good agreement. [Work supported by ONR321 OA]

10:30

2aAO5. Spatial and temporal sound fluctuations in shallow water in presence of internal soliton in transition areas. Boris Katsnelson and Andrey Malikhin (Voronezh Univ., 1 Universitetskaya sq, Voronezh 394006, Russia)

Behavior of the sound field is considered in a 1–2-h time interval in presence of train of internal soliton (IS) crossing an acoustic track. During this period moving ISs pass through several stages: approaching an acoustic track, consequent covering source (receiver) only, both source and receiver, receiver (source) only, and receding from an acoustic track. Correspondingly there are different regimes of interaction of the sound field with IS: horizontal reflection, capture of signals in horizontal waveguide, adiabatic variations, and transition areas between these regimes. So, rather complex spatial and temporal structure of the sound field takes place, including frequency and modal dependence of its parameters. Theoretical analysis of variations in the sound field on the basis of techniques of vertical modes and horizontal rays (PE in horizontal plane) is carried out, and estimation of feasibility of an experimental setup is presented. [Work was supported by CRDF.]

10:45

2aAO6. Calculating the waveguide invariant for non-ideal waveguides. Kevin L. Cockrell and Henrik Schmidt (Dept. of Mech. Eng., MIT, Cambridge, MA 02139)

The waveguide invariant describes striations in a range versus frequency plot of a waveguide's Green's function. Analytic expressions for the waveguide invariant only exist for a few select waveguides, but experiments and simulations have shown that the waveguide invariant is approximately equal to unity for almost all realistic shallow-water waveguides. A quasi-analytic method will be presented for estimating the value of the waveguide invariant in waveguides with arbitrary sound speed profiles, including the effects of a bottom fluid halfspace. The method is approximate but allows for an intuitive understanding of why the value of the waveguide invariant does not strongly depend on the details of the sound speed profile.

11:00

2aAO7. Arrival structure variability of single-bounce paths for high-frequency transmissions during the experiment KAM08 (Kauai acoustics communications multidisciplinary research initative 2008). Joseph M. Senne, Aijun Song (Univ. of Delaware, 210 Robinson Hall, Newark, DE 19711, sennejm@udel.edu), and Kevin B. Smith (Graduate School of Eng. and Appl. Sci., Monterey, CA 93943)

During the summer of 2008 an experiment was conducted that included both chirp and M-sequence transmissions at 16-kHz center frequency. Source and receiver arrays were located west of Kauai Island HI, along an isobath of about 100 m. Moored thermistor strings and a wave-rider buoy provided detailed oceanographic data, while shipboard measurements recorded wind variations. Micro-multi-paths were observed from single surface bounces, and their variability has been examined for a variety of surface wave conditions. A surface wave model has been integrated into a parabolic equation model (MMPE) to approximate variations in the micro-multi-path structure over geotime. Model results are used to examine the correlation between environmental variability and observed single-bounce signal fluctuations. Comparisons are made with a variety of surface wave conditions, including both calm and rough seas. [Work supported by ONR 321OA.]

11:15

2aAO8. Impact of surface gravity waves on high-frequency acoustic propagation in shallow water. Entin A. Karjadi, Mohsen Badiey (College of Earth, Ocean, and Environment, Univ. of Delaware, 210 Robinson Hall, Newark, DE 19716, karjadi@udel.edu), and James T. Kirby, Jr. (Univ. of Delaware, Newark, DE 19716)

Sea surface roughness is one of several factors that significantly influences high-frequency (1–50-kHz) acoustic wave propagation in shallow water. The evolving sea surface introduces several variability effects including Doppler shift. Data analyses from high-frequency acoustic experiments show high-correlation between time, angle, and intensity fluctuations of received signals and varying sea surface conditions. In order to assess detailed acoustic signal interactions with the sea surface, a realistic wave model is developed and combined with an acoustic ray-based model. Model validity is evaluated by comparing the results with data from multiple experiments. [Work supported by ONR 321OA.]

11:30

2aAO9. Acoustic observations of subsurface instability. Justin M. Eickmeier, Mohsen Badiey (College of Earth, Ocean and Environment, Univ. of Delaware, Newark, DE 19716, jeickmei@udel.edu), and Tokuo Yamamoto (Rosenstiel School of Marine and Atmospheric Sci., Univ. of Miami, Miami, FL 33149)

A high-frequency (0.6–18-kHz), shallow water acoustic experiment (HFA2000) was conducted in Delaware Bay (15-m depth) during December 2000. Reciprocal transmissions of chirp signals (0.345-s duration) were radiated between three bottom mounted source-receiver tripod stations separated by 70–353 m. Environmental data were collected at a nearby oceanographic platform; simultaneously, a shipboard ADCP and CTD were deployed. Analysis of direct path station-to-station arrival times (between December 18th 00:00 and December 19th 10:00, during which 126 acoustic transmissions consisting of 29 chirps were radiated) revealed significant deviation from arrival time patterns established during previous tidal cycles. Examination of the corresponding signal intensity reflected this deviation. Independent ADCP data displayed current profile distortion during the period along the direction of the dominant flow channel. The mean slope of a wave number vs geo-time spectrum was calculated from each geo-time's respective chirp series. Slope changes correlate to variations in the total signal intensity's constituents, $I_{\mathrm{tot}}(t) = \langle |E(t)|^2 \rangle$, particularly the incoherent or scattered intensity, $I_{\mathrm{incoh}}(t) - I_{\mathrm{total}}(t) - I_{\mathrm{coh}}(t)$. Through comparison with a Kolmogorov power spectrum and calculation of the corresponding Richardson number, a profile of environmentally induced subsurface instability has been developed.

11:45

2aAO10. The three-dimensional acoustic field of primary arrivals from a seismic airgun array. Arslan M. Tashmukhambetov, George E. Ioup, Juliette W. Ioup (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, atashmuk@uno.edu), Natalia A. Sidorovskaia, Anca Niculescu (Univ. of Louisiana at Lafayette, Lafayette, LA), Joal J. Newcomb (Naval Oceanograph. Office, Stennis Space Ctr., MS), James M. Stephens, Grayson H. Rayborn (Univ. of Southern Mississippi, Hattiesburg, MS), and Phil Summerfield (ExxonMobil Corp., Houston, TX)

The Source Characterization Study 2007 (SCS07) measured the three-dimensional (3-D) acoustic field of a seismic airgun array. The Littoral Acoustic Demonstration Center (LADC) performed the experiment, collecting acoustic and related data on three moored hydrophone arrays and one ship-deployed hydrophone array which together spanned the full water column. Sensitive and desensitized phones were deployed at each position to extend the dynamic range. An ultra short baseline localization system was deployed with the EARS moorings to provide array shape. With postanalysis this results in time-dependent positions for each of the acoustic sensors. Every channel is calibrated. A seismic source vessel shot a series of lines designed to give detailed angle and range information concerning the field of the primary arrival. Peak pressures, sound exposure levels, total shot energy spectra, and one-third octave band analyses give important insights into details of the acoustic field. Images of these quantities are generated to show dependence on emission and azimuthal angles and range. 3-D visualizations and two-dimensional cuts through the data are shown. [Research supported by the Joint Industry Programme through the International Association of Oil and Gas Producers.]

8:10

2aBB1. Defense Advanced Research Projects Agency (DARPA) Blast Program–Preventing violent neurologic trauma. Geoffry Ling (Defense Advanced Res. Projects Agency, 3701 N. Fairfax Ave., Arlington, VA 22203)

DARPA is directing a comprehensive program to determine the causes of explosive neurological trauma. The current status of the program will be discussed.

8:30

2aBB2. Basics of blast physics. David Ritzel (19 Laird Ave. North, Amherstburg, ON N9V 2T5, Canada)

Blast science concerns the processes by which the energy of an explosion source becomes propagated into its surrounding environment, then interacts, loads, and damages materials, structures, and systems. Although explosive events have been chronicled for over 2000 yrs, and good empirical insights regarding blast phenomenology were established prior to WW-II, the advent of the nuclear bomb drove the first rigorous and concerted efforts to understand the detailed physics of blast propagation. Blast science merges with classical acoustic sciences in its far-field limits including phenomena such as atmospheric focusing. However, in the interaction of blast with composite structures including the human body, a wide range of transmitted, coupled, or overdriven mechanical waves of many types can be generated. There has been a significant resurgence of R&D in protective technologies against modern blast threats such as terrorist bombings and IED attacks against our armed services. The current paper presents a review of the basic of blast physics from the near to far fields, principles of blast simulation in the laboratory, as well as recent progress in the understanding of blast induced traumatic brain injury.

8:50

2aBB3. Blast associated traumatic brain injury. David F. Moore and Michael S. Jaffee (DVBIC-HQ, WRAMC, 6900 Georgia Ave., NW, Washington, DC 20309, david.f.moore@amedd.army.mil)

Blast tissue injury is familiar problem in military medicine for gas filled organ such as the lung and gut. Solid tissue organs such as the brain have more recently come into prominence in relation to blast through the current conflicts in Iraq and Afghanistan with blast injury regarded as the "signature injury" of these wars. Enhancements in personal protective equipment allowing survivability of abdominal and thoracic injury may have exposed a previously obscured brain vulnerability. Free field explosive detonation results in rapid conversion of chemical energy into the shock wave and pressure field, the kinetic energy associated with fragments and shrapnel, thermal energy, chemical products of detonation, and electromagnetic radiation. The variation and coupling of these physical fields result in a uniquely complex problem in understanding blast biological effects especially in such a functionally intricate organ as the brain. The clinical effects of concussion following blast exposure are still undergoing evaluation most notably in the military context. Significant effort is, however, underway to determine the relative contributions of shock wave stress, the effects of cavitation, and the effects of the electromagnetic field induced by the piezo-electric effect of the skull experiencing blast associated stress in brain injury and recovery.

9:10

2aBB4. Blast induced electromagnetic pulses in the brain from bone piezolectricity. Steven G. Johnson (Dept. of Mathematics, MIT, 77 Massachusetts Ave., Cambridge, MA 02139, stevenj@math.mit.edu), K. Y. Karen Lee, Michelle K. Nyein (MIT, Cambridge, MA 02139), David F. Moore (Walter Reed Army Medical Ctr., Washington, DC), John D. Joannopoulos, Simona Socrate, and Raul Radovitsky (MIT, Cambridge, MA 02139)

The mechanisms that might lead to in-brain electromagnetic pulses from an IED-scale explosive are considered, along with whether the resulting fields might have timescales and magnitudes relevant to neurological processes. In particular, due to known piezoelectric properties of bone, it is possible for a shock wave incident on the skull to directly induce large electric fields within the brain. Using

experimental data on the piezoelectric properties of bone combined with stresses from full-head-model blast simulations, the resulting in-brain electric fields shown to have timescales and magnitudes that exceed IEEE safety standards are comparable to procedures such as transcranial magnetic stimulation that are known to have neurological effects. Not only are such electromagnetic fields at least potentially relevant to the understanding of blast-induced traumatic brain injury but they may also lead to diagnostic tools in the form of blast dosimeters that measure blast-induced head stresses via the piezoelectric fields produced just outside the skull. [This work was supported by financial aid from the Joint Improvised Explosive Device Defeat Organization (JIEDDO) through the Army Research Office.]

9:30

2aBB5. Effects of low blast levels on the central nervous system. Annette Säljö, Berndt Svensson, Maria Mayorga, Hayde Bolouri, and Anders Hamberger (Dept. of Medical Chemistry and Cell Biology, Inst. of Biomedicine, Sahlgren Acad., Univ. of Gothenburg, SE 405 30 Gothenburg, Sweden, annette.saljo@gu.se)

Anaesthetized swine in crew positions were exposed to weapons in air or to explosives underwater. Blast parameters were correlated with those in the brain. The peak pressure in the brain (*P*max brain/air) was 0.7 for a bazooka (45 kPa), 0.5 for a howitzer (10 kPa), and 0.4 for a rifle (23 kPa). The brain/water *P*max for the detonation pulse of under water explosives was only 0.1, but 0.3–0.4 for the secondary pulses. The results indicate that low-frequency spectra penetrate easier into the brain. Histological examination revealed small hemorrhages in rear regions of the brain. In rats, we investigated the effect of shock tube blasts. After exposure to 10 or 30 kPa, cognitive performance (Morris Water Maze) decreased by 50%. The intracranial pressure (ICP) increased in a dose dependent fashion to reach peak levels 6 h after exposure at 10 kPa and 10 h after exposure to 30 or 60 kPa. An initial ICP elevation took place 30 min after exposure to 60 kPa, and 2 and 6 h after exposure to 30 and 10 kPa, respectively. A prophylaxis, consisting of a 2 week intake of hydrothermally fermented cereals, reduced significantly the blast effect both on ICP and cognitive performance. [The authors thanks Svante Hjer, Samba Sensors AB. The study was supported by the Swedish Armed Forces and FMV.]

Contributed Paper

9:50

2aBB6. Effects of a simulated blast pulse train on a simple neural model. Radia Wahab (radiaraian@yahoo.com), Yunbo Liu, Victor Krauthamer (U.S. Food and Drug Administration, Silver Spring, MD), Joseph McCabe, Chantal Moratz, Ryan Egan (Uniformed Services Univ. of the Health Sci., Bethesda, MD), Vesna Zderic (George Washington Univ., Washington, DC), and Matthew Myers (U.S. Food and Drug Administration, Silver Spring, MD)

In the treatment of traumatic brain injury (TBI) due to blast-wave exposure, an understanding of the mechanisms of injury is critical for proper intervention. One mechanism of particular importance is the interaction of blast waves with neurons. In order to investigate this interaction in isolation from other TBI mechanisms, blast waves were simulated on a local (approximately 1-mm) scale using high-intensity focused ultrasound (HIFU). The acoustic impulse of the HIFU blast wave was selected to approximate the impulse of an actual blast. As a first step in a chain of increasingly complex neural models, the giant axon in an earthworm was used in this study. Intact earthworms were exposed to simulated blast waves from an HIFU transducer, and axonal action potentials were stimulated and recorded. The action potential amplitude decreased continuously with increasing impulse, with the signal typically vanishing at about 8000 Pa s. The conduction velocity showed more of a threshold effect, decreasing minimally from control values until an impulse of about 4000 Pa s was reached, at which point the decline was more rapid. Results indicate that exposing isolated neurons to HIFU-simulated blasts is a promising approach for studying TBI.

10:30

2aBB7. Toward the non-invasive determination of cerebral perfusion pressure. Pierre D. Mourad (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, pierre@apl.washington.edu)

Brains subjected to blast from an explosive or other sources of trauma often develop intracranial hemorrhage or edema or loose their ability to autoregulate the blood flowing into the brain (cerebral autoregulation). Such damage can, in turn, lead to increases in intracranial pressure (ICP) and decreases in cerebral perfusion pressure (CPP=arterial blood pressure—ICP) that, in turn, can lead to ischemia and/or herniation, and brain death. This is not good for the patient. To assay ICP, of intrinsic value, and CPP—two variables of critical interest to the medical staff who treat and manage patients with head injury—requires a (invasive) neurosurgical procedure. Here I describe research performed over the last several years whose target is the prediction of ICP and CPP using arterial blood pressure data as well as data derived from transcranial Doppler. In particular, I will review the process by which we collected sufficient human-derived data in order to make a decent pass at predicting ICP for patients with closed traumatic brain injury (TBI) and a great effort at predicting CPP for these and a complementary group of patients.

10:50

2aBB8. Blast-induced traumatic brain injury research at Lawrence Livermore National Laboratory. William C. Moss and Michael J. King (Lawrence Livermore Natl. Lab., 7000 East Ave., Livermore, CA 94551, wmoss@llnl.gov)

Our blast-induced TBI research has computational and experimental components. Our numerical hydro-structural simulations show that non-lethal blasts can induce sufficient flexure of the skull to generate potentially damaging loads in the brain, even if no impact occurs. The possibility that this mechanism may contribute to TBI has implications for the diagnosis of soldiers and the design of protective equipment such as helmets. Our experimental work involves designing and testing blast dosimeters, which are needed to quantify the blast environment around the soldier, independent of the mechanism(s) causing TBI. One system that uses MEMS sensors incorporated into the helmet and suspension would record peak pressure, positive-phase duration, blast direction, loads directly on the

skull, and accelerations. Another system uses less sophisticated, inexpensive, small, lightweight, disposable, unpowered sensors that act as "yes-no" gauges that indicate the blast magnitude by visual inspection of the gauge. This system is a trade-off between quantity and quality of data, which may be viable, based on current DoD needs. [This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract No. DE-AC52-07NA27344.]

11:10

2aBB9. Experimental and numerical evaluation of the effect of shock waves on the brain. Albert I. King (Dept. of Biomedical Eng., Wayne State Univ., 818 W. Hancock, Detroit, MI 48202, king@rrb.eng.wayne.edu)

A combined experimental and numerical study was conducted to elucidate the mechanical response of a head surrogate under air shock loading. A gel-filled egg-shaped skull/brain surrogate was exposed to blast overpressure in a shock tube environment, and static pressures within the shock tube and the surrogate were recorded throughout the event. A numerical model of the shock tube was developed using the Eulerian approach and it was validated against experimental data. An arbitrary Lagrangian–Eulerian (ALE) based fluid-structure coupling algorithm was then utilized to simulate the interaction of the shock wave with the head surrogate. A comprehensive parametric study was carried out to assess the effect of several key parameters on model response. The curvature of the surface facing the shock wave significantly affected both peak positive and negative pressures. Biological experiments exposing anesthetized rats to shock waves, using the same shock tube, produced brain injury in the form glial cell activation which in turn can adversely affect the function of axons and neurons. This injury mechanism is not the same as that for blunt impacts to the head which causes direct diffuse axonal injury.

11:30

2aBB10. Numerical simulation of mechanisms of blast-induced traumatic brain injury. Jan Arild Teland (Norwegian Defence Res. Establishment, Postboks 25, 2027 Kjeller, Norway, jan.teland@ffi.no), Fredrik Arrhén (SP Tech. Res. Inst. of Sweden, Borås, Sweden), Anders Hamberger (Univ. of Gothenburg, Gothenburg, Sweden), Morten Huseby, Reza Rahimi (Norwegian Defence Res. Establishment, 2027 Kjeller, Norway), Annette Säljö (Univ. of Gothenburg, Gothenburg, Sweden), and Eirik Svinsås (Norwegian Defence Res. Establishment, 2027 Kjeller, Norway)

Blast-induced traumatic brain injury caused by road bombs has lately become a larger part of allied injuries. The same mechanisms may also be responsible for milder injuries of similar nature, resulting from training with large caliber weapons and explosives. In this paper, the blast effects from a weapon on the brain are investigated. Using the hydrocode AUTODYN, numerical simulations of shock wave propagation into the brain are performed. The shock wave is calculated from a complete numerical simulation of the weapon, including the burning gun powder gas inside the barrel, acceleration of the projectile, and the rapid gas flow out of the muzzle. An idealized head is placed in the simulation at the position of personnel firing the weapon. Here we focus on the qualitative mechanisms of the propagation of the shock wave through the skull and into the brain. The results are compared with experiments carried out on anesthetized animals. To simulate real training scenarios, pigs were placed in position of personnel and exposed to impulse noise generated from weapons. Blast parameters in the air were correlated with those in the brain.

11:45

2aBB11. Influence of skull microstructure on blast-induced pressures in the brain. Joseph A. Turner and Jinjin Liu (Dept. of Eng. Mech., Univ. of Nebraska-Lincoln, Lincoln, NE 68588, jaturner@unl.edu)

The interaction of blast waves with the human head is complicated by many factors including the geometry, material nonlinearities, and skull microstructure. In particular, the flat bones of the skull are comprised of the outer and inner tables (cortical bone) and the diploë (trabecular bone) on the interior. This microstructure results in both scattering and absorption of incident pressure waves. A clear understanding of these effects is needed if pressure profiles within the brain are to be accurately modeled. The focus of this presentation is on finite element wave simulations that have been developed to account for this complex organization. The models are first used to examine the scattering attenuation and coherency loss resulting from the microstructure as a function of incidence angle and frequency for plane wave incident pressure profiles. These models are then extended to more realistic pressure profiles representative of blast waves. The statistics of the microstructure are shown to play a key role in the peak pressures observed within the skull. It is anticipated that this work will lead to a better understanding of role of skull microstructure on blast-induced traumatic brain injury. [Work supported by ARO.]

Session 2aMU

Musical Acoustics: The Contemporary Traditional Violin

George A. Bissinger, Chair
East Carolina Univ., Dept. of Physics, Greenville, NC 27858

Chair's Introduction—8:00

Invited Papers

8:05

2aMU1. From Catgut to the Violin Society of America: The past 10 years of violin acoustics research. Fan-Chia Tao (595 Smith St., Farmingdale, NY 11735)

In the late 1990s, most of the original founding members of the Catgut Acoustical Society (CAS) had passed away and Carleen Hutchins had departed to concentrate on her new violin octet family. Nevertheless, violin acoustics research continued around the world. In 2002, the CAS and the Violin Society of America (VSA) co-sponsored a violin acoustics workshop at Oberlin College to bring together the world's leading violin acoustics researchers and violin makers. This annual VSA-Oberlin Acoustics workshop has spawned numerous collaborative projects such as George Bissinger's Strad 3D project. In 2005, the CAS merged with the VSA to become the CAS Forum. Members of the CAS Forum have continued to promote violin acoustics by organizing workshops, research projects, and presentations at international meetings of violin makers.

8:30

2aMU2. A finite element approach towards understanding violin structural modes. Colin Gough (School of Phys. and Astronomy, Univ. of Birmingham, Birmingham B15 2TT, United Kingdom)

A COMSOL finite element package has been used to model the structural modes of vibration of the violin treated as a shell structure with orthotropic arched plates. Such computations enable the physical properties of the plates, ribs, and soundpost to be varied over many orders of magnitude. This provides major insight into the nature of the coupling of the top and back plates by the ribs and the role of the soundpost in coupling the radiating "breathing" modes of the violin to the weakly radiating anti-symmetric modes excited by the bowed string induced rocking of the bridge on the central island area. Examples will be shown of the influence of such factors as plate thickness/density, anisotropy, arching, rib strength, and position of soundpost on the frequencies and excited strengths of the strongly radiating "signature" modes below 1 kHz. In addition to determining the mode shapes and frequencies of the excited modes, their contributions to the radiated sound are also computed. Comaparison will be made with experimentally observed mode shapes and frequencies.

8:55

2aMU3. The Strad 3D Project: Scientists, musicians, and violinmakers study three classic violins. Samuel Zygmuntowicz (565-A Third St., Brooklyn, NY 11215)

In 2006 the first ever three dimensional (3-D) modal laser scanning of violins was performed on three Guarneri and Stradivari violins, along with acoustic scanning and subjective evaluations. CT scanning was used to determine shape and density properties and to provide a 3-D model for future finite element analyses. These studies and images have been combined with empirical observation, photography, music recordings, and traditional documentation in an interdisciplinary survey of unprecedented scope presented in a two DVD set. From my violinmaker perspective acoustic studies of the violin have had remarkably little impact on the practice of violinmaking. Similarly, traditional empirical traditions continue to be effective in guiding violinmakers, without transferring clinically useful insights to the scientific researchers. This split is reflective of divergent vocabulary, goals, and the requirements of quantitative evidence. The Oberlin Violin Acoustics Workshops has attempted to bridge this gap by bringing together researchers, engineers, musicians, and violinmakers for interactive study, with equal weight given to these separate disciplines. The Strad3D project grows out of that ongoing collaboration and is intended to generate and collect images, documentation, and data that can be viewed and utilized from multiple perspectives and to further a mutually comprehensible dialog.

9:20

2aMU4. Global modeling of the violin radiativity profile. George Bissinger (Dept. of Phys., East Carolina Univ., Greenville, NC 27858, bissingerg@ecu.edu)

The violin's radiativity (pressure/force)profile maintains a consistent shape across quality classes, arguing for a quality-independent generalized global model. In the 196–660 Hz region the lowest cavity modes $A0$ and $A1$ and the two first corpus bending modes $B1$ generate almost all the radiativity, with the $B1$ modes treated as "pumps" for $A0$ and $A1$. The $B1$ modes have nodal patterns similar to the plate bending (primarily) modes 2 and 5, suggesting a link to the violin's critical frequency. The essentially serial character of the violin's sound chain leads naturally to a simplified expression for the averaged-over-sphere radiativity profile as a product of just two filters: (1) string-to-corpus through the tuned bridge substructure "gatekeeper") filter and (2) the "egress" filter for the vibration-radiation transformation, the latter reliably parametrized by the radiation-total damping ratio FRAD. FRAD incorporates the violin critical frequency as well as top and back plate properties in a generalized form. The gatekeeper filter on the other hand is considerably more complex; present bridge models must be augmented by systematic empirical measurements to understand the effects of varying bridge rocking mode frequency or "wing" mass. Recent three-dimensional vibration measurements provide additional insight into bridge-corpus impedance effects.

9:45

2aMU5. The violin: Perceptual studies and acoustical correlates. Claudia Fritz (Institut Jean Le Rond d'Alembert, Université Pierre et Marie Curie, UMR CNRS 7190, 4 place Jussieu, 75005 Paris, France, claudia.fritz@upmc.fr)

This talk discusses the results of experiments in which performances were replayed on different "virtual violins" in order to explore the relationships between acoustical characteristics of violins and perceived qualities. Specifically, it explores perceptual observations reported by Dünnwald [based on his measurements of over 700 instruments, J. Catgut. Acoust. Soc. (1991)] by modifying the amplitude of the resonance modes over five octave bands (thereby covering the violin's entire register). When using a subset of the most distinctive verbal descriptors of violin timbre [Fritz *et al.*, Conference of Interdisplinary Musicology (2009)] to study the relationship between human perception and these acoustical modifications, we ascertained results that partially conflict with Dünnwald's observations. In addition, the study investigated the manner by which one's perception of the violin's tone quality is affected by the magnitude of a player's vibrato as well as the damping of the violin's resonant modes. Our results do not support the conclusion that liveliness results from the combination of the use of vibrato and a "peaky" violin response. The talk concludes by discussing the limits of such psychophysical studies, suggesting future directions for psycholinguistic-based research in this domain.

10:10—10:25 Break

10:25

2aMU6. Optimizing the taper-camber relationship in bows for string instruments. John E. Graebner (2 Woodland Rd., Short Hills, NJ 07078, jegraebner@yahoo.com) and Norman C. Pickering (East Hampton, NY 11937)

A violin bow's taper (graduated diameter) and camber (inward or concave pre-bending of the stick) are important tools used by expert bow makers who know by intuition and experience how to match the two parameters. We have analyzed the static forces in bows and constructed a mathematical model that reveals a simple relationship between taper and camber. For any given taper, the model

predicts a preferred camber and vice versa. A machine has been constructed for accurately measuring the diameter and camber profiles, and measurements on several dozen bows of various degrees of playability provide support for the model.

10:50

2aMU7. Development of the *Titian* Stradivari finite element model. Michael A. Pyrkosz, Charles D. Van Karsen (ME-EM, Michigan Tech. Univ., 1400 Townsend Dr., Houghton, MI 49931), and George Bissinger (East Carolina Univ., Greenville, NC 27858)

As part of the continuing effort to understand the structural and acoustic behavior of one of Stradivari's masterpieces, a finite element (FE) model of the *Titian* Stradivari (1715) has been constructed from computed tomography (CT) scans. The CT data were used to extract high-fidelity geometry and density information specific to this violin. This violin is unique in that it is the only one of Stradivari's instruments that has been measured with a full three-dimensional mobility scan over the top and back plates and ribs as well as acoustic radiativity over a sphere. Hence this solid model can be updated and correlated with this comprehensive experimental data set. The current status of this solid modeling effort will be reviewed in the presentation.

11:15

2aMU8. The violin as a statistical energy analysis network. Evan B. Davis (Brugh Davis Acoustics, 8556 Burke Ave. N., Seattle, WA 98103)

This paper applies elementary statistical energy analysis (SEA) concepts to the violin. Modern makers have been experimenting with ultra-light violins trying to solve the problem increasing the overall output while maintaining the spectral balance of the classical violin. Anecdotal experimental evidence suggests the traditional bridge is not "appropriate" for the ultra-light violins. The ultra-light design problem is used as a case study for hybrid-SEA model. SEA modeling applies a high-modal destiny, high-frequency, approach which complements the low-frequency, low-modal density, finite element approach. The focus of the SEA modeling is the top plate or belly of the violin addressing the interaction of the cross-arching, plate thickness, wood material properties, and the dynamics of the bridge. The cross-arch of the violin is seen as a critical design feature in the violin. The current approach is more properly a "hybrid method" where the belly and box volume are represented as SEA subsystems and the bridge is represented with a two mode subsystem. The hybrid-SEA analysis demonstrates that the ultra-light's bridge mass must be in the same bridge-mass to belly-mass ratio as the traditional violin to maintain the spectral balance of the classical violin.

2aMU9. Computed cavity-air modes of Le Gruere violin and coupling to corpus modes. C. E. Gough (School of Phys. and Astronomy, Univ. of Birmingham, Birmingham B152TT, United Kingdom)

The internal cavity air modes of both a normal arched violin with f-holes and Calrleen Hutchin's Le Gruyère violin with additional holes around the ribs have been computed using COMSOL MULTIDISCIPLINARY ACOUSTICS software. The calculations underpin the need to take finite size corrections into account when evaluating the acoustically important Helmholtz or A0 air resonance. The computed modal shapes and frequencies are compared with the assumptions and predictions of the Shaw two degrees of freedom network model. This has been widely used to interpret the dependence of the A0 and A1 resonant frequencies on both cavity volume and the number of additional holes opened around the ribs. Finite size effects are shown to have a marked influence on such dependencies. They are shown to result in marked deviations from predictions based on an ideal Helmholtz resonator. The coupling of the air modes to the corpus modes that excite them is considered using a simple dynamic model. The pedictions of the model are compared with those of the Shaw network model and measurements of the dependence of A0 and A1 mode frequencies on the number and placing of additional holes opened around the ribs of the Le Gruyère violin.

2aNCa1. Noise and vibration phenomena in aircraft wheel and brake systems. Todd E. Rook (Aircraft Wheels and Brakes, Goodrich Corp., 101 Waco St., Troy, OH 45373, todd.rook@goodrich.com)

There is a wide variety of noise and vibration phenomena in aircraft brake systems for which must be accounted in the design process of such systems. These phenomena include such modes as whirl and squeal, the latter of which can be quite different from its counterpart in automotive systems and has likewise received much less attention in the literature than its automotive counterpart. Consequently, an overview of such phenomena with representative results from simulations and experiments will be presented to highlight the differences. Complicating matters is that brake-induced vibration often involves strong coupling with the aircraft structure, thereby necessitating a system level understanding beyond the brake itself. This aspect poses a particular problem to a brake component supplier in how to ensure favorable noise and vibration behavior for the full aircraft system, particularly early in the development cycle. To

accomplish this goal, Goodrich has developed a successful methodology combining simulation and testing to assess the noise and vibration behavior at an earlier stage. The methodology implements simulations to guide appropriate brake component tests that are more tractable for the brake supplier yet sufficiently mimic the full system environment. With the combined simulation and testing, a reduction in actual testing can be achieved while improving component noise and vibration performance.

2aNCb1. Enhancing accuracy in reconstruction of vibro-acoustic responses of a complex structure using Helmholtz equation least squares based nearfield acoustical holography. Logesh Kumar Natarajan and Sean F. Wu (Dept. of Mech. Eng., Wayne State Univ., Detroit, MI 48202)

In traditional nearfield acoustical holography, the acoustic pressures in the near field are measured, and the entire acoustic field including the normal component of the surface velocity are reconstructed. This type of approach may be appropriate for reconstructing the acoustic pressure field, but not for reconstructing normal surface velocity in practice because not enough nearfield information is collected to yield satisfactory reconstruction of the normal surface velocity. In this paper, we propose to supplement the acoustic pressure measurements with a few normal surface velocity measurements, which can be used as benchmarks in optimizing the reconstruction of normal surface velocity. These data are taken as input to the Helmholtz equation least squares method based NAH to reconstruct the acoustic pressure and normal velocity on the surface of a vibrating structure. The accuracy in reconstruction is examined experimentally on a baffled rectangular plate with clamped boundary conditions subject to random excitations. To validate the results, the reconstructed field acoustic pressures are compared with those measured by microphones, and the normal surface velocities were compared with the benchmark values collected by using a scanning laser vibrometer under the same condition.

9:30

2aNCb2. Planar nearfield acoustical holography in high-speed subsonic flow. Yong-Joe Kim (Dept. of Mech. Eng., Texas A&M Univ., 315 Eng./Phys. Bldg. Office Wing, College Station, TX 77843-3123), Hyu-Sang Kwon (Korea Res. Inst. of Standards and Sci.), and Seunghwan Jung (Texas A&M Univ., College Station, TX 77843-3123)

The objective here is to develop a nearfield acoustical holography (NAH) theory that includes the effects of high-speed, subsonic flow. Recently, the speed of a transportation means such as aircraft or vehicle has significantly increased, e.g., too close to the speed of sound. As a result, the NAH data measured with a microphone array fixed on an aircraft or vehicle entail significant airflow effects such as a Doppler shift in wave number domain. Here, a convective wave equation is used to define a mapping function. The mapping function is then used to derive a NAH theory that includes the Doppler shift effect by mapping the convectional NAH procedure in the wave number domain. A numerical simulation with a monopole is performed at the high-speed airflow of Mach = 0.7. The reconstructed acoustic fields obtained by applying the proposed NAH procedure to the simulation data match well with the exact fields. Through an experiment with two loudspeakers performed in a wind tunnel at the speed of Mach = 0.1, it is also shown that the proposed NAH procedure can be used to successfully reconstruct the sound fields radiated from the two loudspeakers.

9:45

2aNCb3. A method for measuring indoor noise levels from traffic with ulterior noise sources. Daniel Oldakowski (Polysonics Corp., 405 Belle Air Ln., Warrenton, VA 20186, danielo@polysonics.com)

This paper describes a measurement protocol used to determine indoor noise levels due to motor vehicle traffic traveling on Route 395/Route 295 flyover in southeast Washington, DC. Measurements were taken over a period of 24 h, in multiple locations of a 14-story high rise building, located in the vicinity of a baseball stadium. The challenge was to remotely measure the indoor noise due to traffic in the presence of unknown and unpredictable such as construction activity inside and outside the building during the day and nearby baseball field activity at night. Multiple sound level meters were employed, inside and outside the building. One-third octave band data, with a 1-min resolution, were taken for the duration of the measurement, as is typical for indoor noise measurements. Partial recordings of the sound field time history within the building were taken to document "loud" events. During postprocessing, loud events were manually inspected to determine if those events were due to traffic noise or due to other noises.

10:00

2aNCb4. Angle dependent effects for impulse noise reduction for hearing protectors. William J. Murphy, Amir Khan, and Edward L. Zechmann (CDC/NIOSH Hearing Loss Prevention Team, 4676 Columbia Parkway, MS C-27, Cincinnati, OH 45226)

The proposed U.S. Environmental Protection Agency regulation for labeling hearing protection devices (HPDs) includes an impulsive noise reduction rating . In 2009, the American National Standards Institute Subcommittee for noise approved a revised standard for measuring the impulsive insertion loss of HPDs, ANSI/ASA S12.42-2009. The exposure at the ear in response to a forward-propagating wave depends strongly on the orientation of the head with respect to the direction of propagation. Furthermore, the insertion loss varies with the peak sound pressure level. This paper reports the results of tests performed using an acoustic shock tube to produce peak impulses of approximately 160-dB peak sound pressure level. Two manikins were evaluated: the GRAS KEMAR manikin equipped with 1/2 and 1/4 in. microphone in a GRAS 711 IEC coupler and the Institute de Saint Louis manikin equipped with a Bruel & Kjaer IEC 711 coupler equipped with a

1/4 in. microphone. The manikin heads were rotated through ±90 deg relative to the direction of the oncoming wavefront and impulsive peak insertion loss was measured according to S12.42-2009. [Portions of the research were supported by U.S. EPA Interagency Agreement No. 75921973-01-0.]

10:30

2aNCb5. Development of NASA Glenn Research Center auditory demonstration laboratory facility and operational capabilities. Beth Cooper (NASA Glenn Res. Ctr., 21000 Brookpark Rd., MS 49-2, Cleveland, OH 44135, beth.a.cooper@nasa.gov), Jeff G. Schmitt (ViAcoust., Austin, TX), and David A. Nelson (Nelson Acoust., Elgin, TX)

The NASA Glenn Research Center Auditory Demonstration Laboratory (ADL) is a dual purpose facility, constructed in 2007 to support hearing conservation programs across the agency. Configured as a reverberant room, the ADL is an appropriate space for evaluating the performance of personal hearing protectors, using either human subjects or a test fixture. Hearing protector evaluations are conducted using NASA REATMASTER software, developed in partnership with the National Institute for Occupational Safety and Health. This software is available free on request to qualified laboratories, which are encouraged to participate in a collaborative program to fund continued software development. The ADL can also be configured as a free-field room to support the development of auditory demonstrations, widely used for a variety of training purposes within NASA and externally. The ADL provides an environment, sound system, and audio engineering tools for presenting and developing calibrated demonstrations of various acoustical and auditory phenomena that include fundamental acoustical and concepts, noise control principles, and simulations of hearing loss. Current work at the ADL will establish the capability of making three-dimensional surround sound recordings, which will expand the scope of the laboratory's educational products into additional areas of psychoacoustics such as binaural hearing and localization.

10:45

2aNCb6. Application of microphone frequency response and windscreen insertion-loss corrections on sound power determinations. Einar Ristroph, Michael Black, and John Phillips (1301 Arrow Point Dr., Cedar Park, TX 78613, einar.ristroph@ets-lindgren.com)

Engineering-grade product noise emission testing programs are qualified, and correction factors are applied to test results, based on "known" sound power levels of a reference sound source; i.e., a sound source that has been tested and qualified in accordance with ANSI S12.5/ISO 6926. The accuracy and uncertainty of ANSI S12.5/ISO 6926 test results are then transferred to the engineering-grade testing program and are thus of crucial importance. ETS-Lindgren recently commissioned the new Acoustic Research Laboratory at headquarters in Cedar Park, TX, and is developing an ANSI S12.5/ISO 6926 reference sound source testing program. This work included evaluation of factors contributing to accuracy and uncertainty. The application of microphone frequency response corrections (obtained from outside calibration laboratory) is discussed and data are presented. In addition, the use of windscreen insertion-loss corrections is discussed and data are presented.

11:00

2aNCb7. Anechoic chamber verification for calibration of reference sound sources. Kevin Herreman (Owens Corning Corp., 2790 Columbus Rd., R#16 Granville, OH 43023, kevin.herreman@owenscorning.com)

Confidence in the capability of a testing facility to perform repeatable /reproducible product testing mandates study of each test chamber utilized by the facility. The Owens Corning Acoustic Research Center (OCARC) provides product sound power level determination for many differing product types ranging from the power generation, appliance, automotive, to medical equipment industry utilizing a fully anechoic chamber with a removable horizontal reflecting plane. Recently the OARC completed a verification study identifying the performance of the chamber relative to the requirements of test standard ISO 6926: Requirements for the performance and calibration of reference sound sources used for determination of sound power levels and ANSI S12.5: Requirements for the performance and calibration of reference sound sources. These standards provide strict guidelines for the repeatability/reproducibility of test results. This paper will review the verification testing process and present results from the study.

11:15

2aNCb8. Developing a basis for efficient railroad horn testing. John Erdreich and Joseph Keefe (Ostergaard Acoust. Assoc., 200 Executive Dr., Ste. 350, W. Orange, NJ 07052, je@acousticalconsultant.com)

In response to complaints of excess noise from residents living in the vicinity of rail grade crossings, the Federal Railroad Administration promulgated regulations mandating minimum and maximum horn sound output levels. Older fleets require testing of horns to ensure compliance with these limits. Test requirements (no reflecting surfaces within 200 ft of the horn; wind less than or equal to 12 m/ph; no precipitation) severely limit the ability of urban commuter railroads to comply with the testing, especially in northern and coastal areas. To develop an alternate test protocol, measurements of horn sound levels were carried out in a semi-anechoic chamber and outdoors to determine if a reliable transfer function could be constructed to convert the chamber measurements to the outdoor measurements. Standard deviations of the *A*-weighted chamber measurements were smaller than standard deviations of the outdoor measurements. For one fleet, the differences between chamber measurements and outdoor measurements resulted in a consistent difference of about 41 dB(A). Locomotive supply air pressure differences at the horn were not a significant factor in sound output.

11:30

2aNCb9. Measuring recreational firearm noise. Per Rasmussen (G.R.A.S. Sound & Vib. A/S, 33 Skovlytoften, 2840 Holte, Denmark, pr@gras.dk), Greg Flamme (Western Michigan Univ., Kalamazoo, MI), Michael Stewart (Central Michigan Univ., Mount Pleasant, MI), Deanna Meinke (Univ. of Northern Colorado, Greeley, CO), and James Lankford (Northern Illinois Univ., DeKalb, IL)

Recreational use of firearms in the United States is commonplace. There are 28×10^6 Americans who consider themselves hunters and 13×10^6 went hunting in 2000. Participation in the shooting sports, without the use of properly worn hearing protection, exposes the involved persons to high levels of impulsive noise which may cause hearing loss and/or tinnitus (ear ringing). The present study was initiated to gain a better understanding of the noise exposure created by contemporary firearms using state of the art instrumentation and to ultimately increase our knowledge and awareness of this unique noise hazard. The sound pressure signal created by recreational firearms as used in hunting or target practice is characterized by a high-frequency, short duration impulsive noise. This signal is perceived by the human ear as one single, loud impulse or "shot." However, when the firearm sound level is measured with microphones capable of sampling wide frequency ranges and combined with high-speed data acquisition computer systems, the impulses can be resolved into a number of different acoustic signals related to different source mechanisms.

11:45

2aNCb10. Exposure to recreational/occupational shooting range noise versus industrial impulsive noise. Hale Marlund (Adv. Eng. Acoust., 663 Bristol Ave., Simi Valley, CA 93065-5402, noisedoc@aol.com)

Public shooting ranges are used primarily for recreational shooting. Certain occupations require periodic certification of firearms proficiency. Single gunfire noise is loud and impulsive. However, both recreational and occupational proficiency shooters are often exposed to firearm noise from other shooters. In such cases, the shooting noise exposure can include gunfire impulses less than 1 s apart. This situation changes noise exposure from "impulsive" to "continuous" during each open-fire session. A similar situation occurs in industrial applications when the work process involves impulsive fastening activities, such as pneumatic riveting. The similarities in high-intensity noise exposure at busy shooting ranges and production line riveting include time-weighted averages, under the current OSHA regulations, that are less than 90 dB(A) but consistently exceed 140 dB(C) peak. As a result, even though firing range and workplace rules require the use of hearing pro-

tection, it is not uncommon for recreational or occupational shooters and industrial workers to be casual about the fitting and proper use of their hearing protection devices. This paper describes the similarities in daily impulsive noise exposure at the shooting range and fastening production line. It also discusses the potential dangers in both situations with ill fitting and best practice use of hearing protectors.

2aNCc1. Transient in cab noise investigation on a light duty diesel passenger vehicle. Dhanesh Purekar (Cummins Inc., 2727 West 450 South Walesboro, Columbus, IN 47201, dhanesh.purekar@cummins.com)

A diesel engine in cab sound quality for passenger car market is scrutinized more closely than in the mid- to heavy duty diesel truck applications. This is obviously due to the increasing expectations from the customers for gasolinelike sound quality. This paper deals with a sound quality issue recently investigated on a light duty diesel engine for a passenger van application. The objectionable noise complaint occurred during the vehicle transient operating conditions and was found to be caused by the change in the pilot quantity over a very short period of time. The root cause of the noise complaint was investigated on the noise complaint vehicle as well as simultaneously on a standalone engine in the noise test cell. Several critical combustion and performance parameters were recorded for diagnosing the issue. In addition, various standard sound quality metrics were employed to differentiate the sound quality of the objectionable noise. The issue was resolved and verified by making appropriate changes to the engine calibration without affecting key requirements such as emissions and fuel economy. Finally, the findings from the experimental tests are summarized and appropriate conclusions are drawn with respect to understanding, characterizing, and resolving this transient, combustion related impulsive powertrain interior noise issue.

9:30

2aNCc2. Two-substructure, time-domain transfer path analysis of transient dynamic response of mechanical systems with nonlinear coupling. Wenwei Jiang and Teik Lim (Univ. of Cincinnati, 688 Riddle Rd., Apt. 800L, Cincinnati, OH 45220, jiangwe@mail.uc.edu)

The traditional frequency domain transfer path analysis has become a popular method to detect and diagnose vehicle NVH problems. Unfortunately, due to its reliance on frequency transfer functions, the approach is strictly effective only for linear time-invariant system and steady-state response. This limitation prevents the method from being applied to transient and/or nonlinear behavior such as clunk, shudder, and tip-in and tip-out. In this paper, a novel time domain transfer path analysis is proposed to deal with a class of non-linear transient response problems. It combines the versatility of the transfer path analysis for tracking transmission of vibratory energy between substructures and generality of the time domain analysis for treating transient response that is also nonlinear in nature. The formulation that is derived by combining the spectral-based substructure method and a discrete, piecewise convolution theory is applied to a lumped parameter system, and the results are compared with output from a direct numerical integration of the nonlinear equations of motion. Comparison results show significant promise and appear to be usable for solving real-life vehicle problems that are highly transient with moderate level of nonlinearity present.

9:45

2aNCc3. Refinement of vehicle interior noise by reduction of driveline vibrations. Okan Tandogan, Tarkan Yapici, Mert Doganli, and Caner Sevginer (Temsa R&D & Technol. Corp., Tubitak MAM Technol. Free Zone, 41470 Gebze-Kocaeli, Turkey, okan.tandogan@temsa-argetek.com.tr)

Driveline vibrations can be a significant vibration source, which require emphasis in vehicle NVH development studies. In the early design phases, it is usually not easy to predict the vehicle level NVH performance induced by the torsional irregularities of the driveline. Establishing a model with inertia, mass, and stiffness data taken from engine, transmission and driveline suppliers can be possible and useful to initiate preliminary cautions. However, it is first, a challenging job for OEMs to receive all relevant data from suppliers to create a reliable model. Second, driveline vibration-driven NVH response of a vehicle is mostly figured out in real-time testing. Therefore, it is of great importance to treat driveline vibrations as a potential source of customer concern in vehicles and should be investigated throughout the testing phase. In this study, a dissatisfying noise behavior of a coach is determined with objective data and defined by means of engine operating condition, frequency, and excitation orders. As a next step, the problem is cascaded to its possible sources by examining the exciters' inputs and the transfer paths. Finally, the important parameters in the reduction in driveline torsional vibrations and, as a consequence, the refinement of vehicle interior noise are discussed.

10:00

2aNCc4. Calculation of optimal damping placement in a vehicle interior. Craig Birkett (Daimler Trucks North America, 4747 N Channel Ave., C3B-EA Portland, OR 97217, craig.birkett@daimler.com), Poh-Soong Tang, and Dieter Featherman (Altair Eng.)

A study was performed of a heavy duty truck cab to reduce interior noise with the objective of using a minimum amount of damping material. Several complementary tools were applied to the problem of determining damping material layout. Candidate locations for damping material were first identified by summing *A*-weighted velocities over the frequency range of interest. These velocities could be additionally weighted by acoustic sensitivity. Then an automatic optimization was performed using structural inputs to determine the optimal damping treatment from the candidate damping patches given weight constraints. Results were confirmed with testing on a vehicle dyno. The study was significant because it compared various practical methods of optimizing a vehicle interior.

10:15—10:30 Break

10:30

2aNCc5. Vibration transfer path analysis on fender noise control. Paul Liang (Harley-Davidson Motor Co., 11800 W. Capitol Dr., Wauwatosa, WI 53222, paul.liang@harley-davidson.com)

The fender is one of the major noise radiators in motorcycles. The source of the fender noise comes primarily from the engine vibration through the vehicle frame. A rubber isolator between the engine and frame can effectively break the vibration path, thus reducing the fender noise. A finite element method will be used to analyze the vibration transfer paths of an engine and a boundary element method will be used to predict the radiated noise from the rear fender.

10:45

2aNCc6. Prediction of muffler insertion loss and shell noise by a hybrid finite element acoustic statistical energy analysis model. Terence Connelly (32605 W, 12 Mile Rd., Ste. 350 Farmington Hills, MI 48334-3379, tco@esi-group.com), Steve Mattson, Dave Labyak, and Jeff Pruetz (Great Lakes Sound & Vib.)

A reactive automotive style muffler was used to evaluate and experimentally validate the numerical predictions of muffler acoustic performance. A CAD model of the silencer was developed and an acoustic FE mesh created. The interior of the muffler included two sections of perforated pipe, which were included in the cavity mesh. A hybrid FE-statistical energy analysis (SEA) numerical model was created from the finite element acoustic mesh and was excited by a diffuse acoustic field at the inlet and coupled via hybrid junctions to SEA semi-infinite fluids on both the inlet and outlet. From the hybrid acoustic model different FE-SEA modeling approaches were investigated to predict the shell noise. The muffler insertion loss and shell noise was measured experimentally using a broadband acoustic source piped into a hemi-anechoic chamber. A straight pipe with simple bends to recreate the path from muffler inlet to outlet was fabricated for comparison. Muffler insertion loss was calculated by means of a simple level difference between the silencer and the straight pipe. Shell vibration and radiated noise were also measured to validate the shell noise modeling. Agreement between experimental measurement and numerical prediction was found to be reasonably accurate up to 3 KHz.

11:00

2aNCc7. Innovative quieter aspirator design for in-car temperature sensor. Niranjan G. Humbad, Dan Silaghi, and Matthew Morris (Behr America, Inc., Behr America, Inc. 2700 Daley Dr., Troy, MI 48083, niranjan.humbad@us.behrgroup.com)

Many vehicles use automatic temperature sensor mounted on dash [instrumentation panel (IP)] to sense the vehicle interior temperature for controlling the climate comfort. One type of design requires airflow over the sensor to correctly measure the interior vehicle temperature. This suction airflow over sensor is produced by various means. The present study deals with a widely used aspirator design to draw/suck interior airflow from ventury effect caused by discharging HVAC module flow. Such a design has an inherent drawback of bringing the HVAC module noise and flow noise (generated by aspirator) to an opening mounted on dash (via a connecting tube from sensor to aspirator). In one application, this caused a customer noise complaint; noise levels were higher at frequencies above 2 kHz. This required a separate muffler part between aspirator and sensor to reduce this noise. A new innovative aspirator design was developed to replace the aspirator and muffler by a single part. This one piece assembly was designed to be easy for manufacturing but still keeping the same performance targets of the two part aspirator and muffler design. Test results of the new design are compared to the current design and shows meeting both the airflow and noise targets.

11:15

2aNCc8. Passenger vehicle exhaust cool down noise measurement and sound assessment. Antoni Szatkowski and Brian Butler (Chrysler LLC, NVH Development & Eng., P.O. Box 21-8004, Auburn Hills, MI 48321-8004, as32@chrysler.com)

Passenger vehicle exhaust cool down is getting more attention as NVH vehicles quality is more and more refined. A new test procedure was developed and presented in this paper. Data acquisition, processing, and sound qualifying are presented. Four different metrics were developed that quantify the sound level and sound quality. A few examples of different exhaust systems were analyzed. Presented methodology is a great tool for different exhaust system ranking, benchmarking, comparison, and target setting.

Session 2aNCd

NOISE-CON and Physical Acoustics: Flow Noise

Dean E. Capone, Chair
Pennsylvania State Univ., Applied Research Lab., P.O. Box 30, State College, PA 16801

Contributed Papers

9:15

2aNCd1. The noise from flow over rough surfaces with small and large roughness elements. Stewart Glegg (Dept of Ocean and Mech. Eng., Florida Atlantic Univ., Bld 36, 777 Glades Rd., Boca Raton, FL 33431, glegg@oe.fau.edu) and William Devenport (Virginia Tech)

This paper will review theoretical and experimental results for the sound radiation from turbulent boundary layer flows over rough surfaces. Two distinctly different regimes will be considered. The first is hydrodynamically smooth surfaces for which the surface roughness does not impact the boundary layer turbulence. These surfaces have been shown experimentally and theoretically to radiate enhanced sound levels due to the scattering of the hydrodynamic pressure fluctuations by the roughness. The second regime considers large roughness elements that directly impact the boundary layer flow. Numerical calculations show that the flow separates around the large roughness elements and theoretically this implies that the roughness radiates sound in proportion to the unsteady force on each element. It is still an unresolved issue as to whether the unsteady loading is caused by the distortion of the turbulent flow around the element or the unsteady loading associated with the flow separation. This paper will describe the theoretical approaches which have been used to predict roughness noise levels in each of these two regimes and the transition from one regime to the other.

9:30

2aNCd2. Low wavenumber turbulent boundary layer fluctuating wall shear stress measurements from vibration data on a cylinder in pipe flow. William Bonness, Dean Capone, and Stephen Hambric (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804, wkb3@only.arl.psu.edu)

Fluctuating wall shear stress under turbulent boundary layer (TBL) excitation is studied in this experimental investigation. A cylindrical shell with

a smooth internal surface is subjected to TBL excitation from water in fully developed pipe flow at 6.1 m/s. The vibration response of the cylinder is used to inversely determine low-wavenumber TBL shear stress levels. Both the cross-flow and streamwise directions are examined using directionally uncoupled low-order cylinder modes in the circumferential and axial directions. These data address a critical gap in available literature regarding experimental low-wavenumber shear stress data. The low-wavenumber shear stress levels in both the cross-flow and streamwise directions are determined to be roughly 10 dB higher than those of normal pressure. As is the case for various models of TBL pressure, these measurements suggest that a nearly constant value for normalized shear stress at low wavenumber is valid over a broad range of frequencies. A simple wavenumber white model form established for low-wavenumber TBL surface pressure is also shown to be appropriate for shear stress.

9:45

2aNCd3. Analysis of sound measurements inside a finite length ducted rotor system. Scott Morris, Jason Tomko, and David Stephens (Univ. of Notre Dame, Notre Dame, IN 46556, s.morris@nd.edu)

The sound generated by a ducted rotor system leads to a complicated acoustic field inside the duct. The source can have both broad-band and tonal sound features. The interior Green's function will add additional complexity due to the cut-on modes and finite-length (organ pipe) effects. In this study, a simple ducted rotor was considered experimentally and analytically in order to obtain observations and predictions of these features. The results will be an important component of modeling the structural vibration in systems where the rotor operates in an elastic shell.

10:00

2aNCd4. Aero-acoustic predictions of automotive dashboard HVAC (heating, ventilating, and air-conditioning ducts). Stephane Detry (VISTEON Systémes Intrieurs Ctr., Visteon Interior System, Technique Rue Lon Duhamel, BP 87, 62440 Harnes, France, sdetry@visteon.com), Julien Manera, Yves Detandt, and Diego d'Udekem (Free Field Technologies)

The flow-induced noise generated by automotive climate control systems is today emerging as one of the main noise sources in a vehicle interior. Numerical simulation offers a good way to analyze these mechanisms and to identify the aerodynamic noise sources in an industrial context driven by permanent reduction in programs timing and development costs, implying no physical prototype of ducts before serial tooling. This paper focuses on a numerical aeroacoustic study of automotive instrument panel ducts to estimate the sound produced by the turbulent flow. The methodology is the following: the unsteady-flow field is first computed using a CFD solver—here FLUENT. Then, the acoustic finite element solver ACTRAN computes the acoustic sound sources from these time domain CFD results. The sources are finally propagated into the vehicle interior in the frequency domain. One advantage of the technique is that the CFD computations are completely separated from the acoustic computations. This allows reusing one CFD computation for many different acoustic computations. The theoretical background is presented in the first sections of this paper. Then, the accuracy of the method for real industrial cases is demonstrated by comparing the numerical results to experimental results available at VISTEON.

10:30

2aNCe1. Frequency-dependent propagation characteristics in and around forests. Michelle E. Swearingen (Construction Eng. Res. Lab., USA ERDC, P.O.B. 9005, Champaign, IL 61826, michelle.e.swearingen @usace.army.mil), Donald G. Albert (Cold Regions Res. and Eng. Lab., USA ERDC, Hanover, NH 03755-1290), Michael J. White, and Patrick Guertin (Construction Eng. Res. Lab., USA ERDC, Champaign, IL 61826)

Sound propagation in and around forests is highly influenced by the unique vegetative environment. The array of scattering objects represented can be parametrized by parameters such as tree height and diameter, spatial arrangement, and areal density. The array can be in a lattice or random configuration, depending on whether the trees were intentionally planted or naturally occurring. The trees themselves can be of uniform age and size or a mixture of sizes and types. Using data from three different study areas, this presentation will explore correlations between the physical structure of the forest and frequency-dependent attenuation of impulsive sounds.

10:45

2aNCe2. Meteorological influence on highway noise barrier performance: A case study. Paul Burgé (URS Corp., 1615 Murray Canyon Rd., Ste. 1000, San Diego, CA 92108, paul_burge@urscorp.com), Jon Sytsma, and Tom Zurburg (Michigan Dept. of Transportation)

Local meteorological conditions such as cross-winds and temperature gradients have long been recognized as factors that can negatively affect noise barrier performance. However, this relationship is seldom demonstrated with empirical data and neither are prevailing meteorological conditions routinely taken into consideration in the design of highway noise barriers. In this case study, a post-construction acoustical investigation was undertaken for a barrier that was installed as part of a recent highway improvement project and where neighborhood residents persistently complained that the barrier was not providing expected noise reduction. Several days worth of noise level measurements and meteorological data were collected and analyzed. The results of the analysis indicated that, while the area residents were not actually impacted under applicable federal and state noise policy, the noise barrier performance was indeed being significantly influenced by documented meteorological conditions. Interaction with area residents also revealed a remarkable example of the wide variation in different individuals' subjective response to virtually the same noise environment.

11:00

2aNCe3. Quasi-wavelet cascade models for intermittent random media and application to wave scattering. D. Keith Wilson (U.S. Army Engineer Res. and Development Ctr., 72 Lyme Rd., Hanover, NH 03768, d.keith.wilson@usace.army.mil), Vladimir E. Ostashev (NOAA Earth System Res. Lab., Boulder, CO 80303), George H. Goedecke (New Mexico State Univ., Las Cruces, NM 88003), Soren Ott (Risoe Natl. Lab. for Sustainable Energy, Roskilde, Denmark), and Donald G. Albert (U.S. Army Engineer Res. and Development Ctr., 72 Lyme Rd., Hanover, NH 03768)

Terrestrial environments often possess intermittent distributions of scattering objects. Examples include atmospheric turbulence, subsurface geology, vegetation, and buildings. A quasi-wavelet (QW) cascade process model for such intermittent random media is described, and the implications for wave scattering are examined. The QW model builds the random medium from randomly positioned and oriented, wavelet-like entities, which follow prescribed distributions for number density and energy vs spatial scale. Different types of QWs, including monopole and dipole scalar fields and toroidal and poloidal vector fields, can be combined with statistically preferred orientations to create multiple field properties possessing correlated properties and anisotropy. The spatially localized nature of the QWs facilitates construction of intermittent random fields in a manner that would be extremely challenging, if not impossible, with conventional Fourier approaches. To test the QW model, we conducted a seismic propagation experiment in the vicinity of a volcanic crater in the Mojave Desert. This site was chosen for its highly inhomogeneous, intermittent distribution of basalt and sand. Propagation of impulse signals was sampled along 864 distinct paths. Statistical distributions of seismic travel times were simulated with good success using a finite-difference, time-domain method applied to a QW model for the site geology.

11:15

2aNCe4. A numerical study of impulse propagation over a hill. Santosh Parakkal, Xiao Di, and Kenneth E. Gilbert (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

In preparation for a field experiment, a numerical study of impulse propagation over a hill has been carried out. The near side of the hill corresponds to downward refraction with the associated ducted propagation. The far side of the hill corresponds to upward refraction with the associated shadow zone. Thus conditions corresponding to nighttime propagation (downward refraction) and daytime propagation (upward refraction) can be studied in the same experiment. Of particular interest is the propagation of surface waves over the hill and into the shadow zone on the far side of the hill. For selected values of hill curvature and ground impedance, numerical predictions are presented and discussed in relation to the envisioned experiment. [Research supported by the U.S. Army TACOM-ARDEC at Picatinny Arsenal, New Jersey]

11:30

2aNCe5. Portable loudspeaker coverage capability for in-situ outdoor performance spaces. Juan Arvelo, Shawn Johnson, and Ronald Mitnick (Appl. Phys. Lab., The Johns Hopkins Univ., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099, juan.arvelo@jhuapl.edu)

Observations from daily experiences reveal that sound propagation in air is influenced by the ground topography, atmospheric stratification, winds, and turbulences. A ray-based outdoor loudspeaker coverage model was developed that accounts for terrain and atmospheric conditions. Loudspeaker coverage may be adjusted to various levels of sound or speech intelligibility. Comparison against benchmark closed-form solutions and wave-based approaches demonstrate the accuracy and computational efficiency of this Gaussian-ray bundle model at aural frequencies. This model is well suited as an acoustic design aid for outdoor performance spaces. This software was packaged into an ultra-mini notebook computer with an integrated GPS antenna and a 90-m resolution worldwide terrain database to account for *in-situ* terrain effects on sound propagation, a built-in microphone for calibrated measurement of the background noise level and the loudspeaker source level, and a USB real-time logger of temperature and relative humidity. The model is also capable of importing atmospheric measurement from balloon-launched radiosondes and various atmospheric models to accurately account for atmospheric stratification in temperature, pressure, relative humidity, wind speed, and direction in forensic investigations. Atmospheric turbulence has been shown to be another important factor that must be included in the next generation portable loudspeaker coverage capability.

2aNSa1. Modeling the acoustic interaction between components in ventilation ductwork. Ray Kirby (Mech. Eng., School of Eng. and Design, Brunel Univ., Uxbridge, Middlesex UB8 3PH, United Kingdom)

The modeling of sound propagation in ventilation systems normally focuses on understanding the acoustic performance of individual components within the system. For example, theoretical models have long been available for ventilation silencers, elbows, branches, and bends. However, to fully understand the overall acoustic performance of a system, it is necessary also to investigate the interaction between these components. This may be achieved by using numerical methods such as the finite element method and in principle current commercial packages may now be used to examine multiple components in ventilation systems. However, commercial packages normally rely on meshing the entire ventilation system and the computational cost of such an approach quickly becomes

prohibitive at higher frequencies. An alternative, and computationally more efficient, approach is to use a modal expansion for the sound pressure field in uniform duct sections and to apply a full finite element analysis only to non-uniform elements, such a corners and/or branches. Accordingly, predictions for a ventilation system that contains multiple components are reviewed here, and the acoustic interaction between these components is examined in order to gain a better understanding of the *in situ* acoustic performance of important components such as the ventilation silencer.

8:40

2aNSa2. Simulation of acoustic noise in duct systems. M.G. Prasad and B. Rajavel (Dept. of Mech. Eng., Noise and Vib. Control Lab., Stevens Inst. of Technol., Hoboken, NJ 07030, mprasad@stevens.edu)

Acoustical noise studies of automotive muffler, HVAC, and other duct systems are important in their design and performance. A methodology is developed for simulating the acoustical noise from a duct system which can be modeled in terms of source, duct element, and termination. In this methodology first the transfer function of the preliminary design of the duct system is obtained using system geometry, source, and radiation impedances. Then the impulse response of the obtained transfer function from the preliminary design is convolved with source signal to obtain the acoustic noise output of the system in frequency domain. In order to verify this methodology, the simulated noise is compared with experimentally measured noise for two types of duct systems, namely, a straight pipe and a simple expansion chamber. The results show good agreement between the simulated and measured noise spectra. The proposed methodology is then applied to obtain a simulation of noise reduced due to automotive muffler system. The methodology presented in this work provides the capability of simulating the noise of a duct and muffler system from its design stage before it is actually built. Further, this work could also be used for sound quality studies of duct systems.

9:00

2aNSa3. Acoustic propagation in three-dimensional, rectangular ducts with flexible walls. Jane B. Lawrie (Dept. of Mathematics, Brunel Univ., Uxbridge, UB8 3PH, United Kingdom)

Analytic expressions provide valuable benchmarks against which to check sophisticated finite element codes. In this talk some such expressions are presented for two duct configurations. Consideration is given first to the propagation of sound in a three-dimensional, unlined duct formed by three rigid walls, lying along $y - 0$, $-b \le z \le b$ and $z - \pm b$, $0 \le y \le a$ of a Cartesian frame reference, and closed by a thin elastic plate lying along $y - a$, $-b \le z \le b$. On assuming harmonic time dependence $e^{-i\omega t}$, the fluid-coupled structural waves are expressed in the form $B_n\psi_n(y,z)e^{\pm is_n x}$, $n=0,1,2,\ldots$, where $\psi_n(y,z)$ are an infinite set of non-separable eigenfunctions, s_n are the admissible wavenumbers, and B_n are the wave amplitudes. An exact, closed form expression for the eigenfunctions is presented. Various properties of the eigensystem are discussed. Second, the effect of incorporating a porous lining into the above model is considered. It is shown how the analysis is extended to include this modification. Numerical results are presented for both situations.

9:20

2aNSa4. Closed form calculation of reverberant sound propagation in a thin duct with flexible walls. Michael Panza (Dept. of Mech. Eng., Gannon Univ., 109 University Square, Eire, PA, 16541, panza@gannon.edu)

An analytical method for calculating the propagation of reverberant sound between two parallel perfectly reflecting planes in a thin duct with flexible side walls is presented. The flexible walls are modeled with a complex wave number to account for dissipation within the wall material. A mathematical model based on the Euler–Maclaurin sum formula provides an approximate closed form Green's function for the acoustic space. The method gives a set of two coupled integral equations in acoustic pressure and side wall displacement consisting of convolutions with respect to the spatial dimension along the duct. Laplace transforms for the spatial dimension are applied to the integral equations to solve for the acoustic pressure in terms of the spatial Laplace transforms of the Green functions for the reverberant acoustic space and the mechanical wave in the side wall material. A closed form solution is obtained by considering the first term of a binomial series in the Laplace domain and applying a partial fraction expansion leading to the solution in the spatial dimension along the duct. Numerical simulations show the behavior of the reverberant noise reduction provided by the flexible side walls along the duct.

9:40

2aNSa5. Exploration of a hybrid noise control system in a cylindrical duct. Gee-Pinn Too (Dept. of Systems and Naval Mechatronic Eng., Natl. Cheng Kung Univ., Tainan, Taiwan 701) and Shao-Rong Chen (Natl. Kaohsiung Marine Univ., Taiwan)

The purpose of this study is to explore the effects of sound elimination in a cylindrical duct by combining a reactive muffler and active noise control (ANC) system. Besides the exploration via experiment of the combined noise control system, predictions of desired signals in ANC system are proposed for this hybrid system. These predictions are Grey prediction based on Grey theory and signal processing for path impulse response function. In the experiment, the effects of sound elimination (such as transmission loss and insertion loss) are compared between cases with ANC systems installed before the muffler and after the muffler. The results indicate several conclusions that (1) the sequence of arrangement of muffler can influence the results of active noise control, (2) the effect of noise reduction in ANC system is influenced extremely by reference signal received, (3)the hybrid system has the advantages over a traditional muffler when the muffler is not designed for the frequency of the noise, and (4) predictions of the desired signals such as Grey prediction or path impulse response function could give a better control for the hybrid system.

10:00—10:25 Break

10:25

2aNSa6. Optimal microphone placement for active noise control in a forced-air cooling system. Raymond de Callafon and Charles Kinney (Dept. of Mech. and Aerosp. Eng., Univ. of California, San Diego, 9500 Gilman Dr., La Jolla, CA 92093-0411, callafon@ucsd.edu)

In active noise cancellation systems with relatively small acoustic coupling, feedforward compensation is an effective methodology to create a controlled emission for sound attenuation. Especially for small electronic systems where forced air-cooling is required to control the temperature of large power sensitive components in the system, an active noise cancellation (ANC) system is a viable solution to reduce acoustic emissions. In this paper we discuss the placement of the noise source microphone for feedforward based active noise control in a forced-air cooling system. Noise source microphone placement is directed by the ANC performance of an on-line output-error based affine optimization of a linearly parametrized generalized finite impulse response filter for sound compensation. For the computation of the optimal filter, generalized or orthogonal FIR models are used as they exhibit the same linear parametrization as a standard FIR filter. The procedure is demonstrated on a small portable NEC LT170 data projector. The data projector is equipped with a shielded internal directional pick-up microphone to measure the sound created by the forced-air cooling of the projector's light bulb. Non-invasive small directional speakers located at the inlet and outlet grill of the data projector are used to minimize acoustic coupling.

10:45

2aNSa7. Reflection and transmission across partial blockages in fluid-filled flexible, non-thin-walled pipes. Iain D. J. Dupere and Wenbo Duan (School of Mech., Aerosp. and Civil Eng., Univ. of Manchester, Manchester M60 1QD, United Kingdom)

A model is presented for propagation along a flexible pipe whose thickness is not small in comparison with its diameter across a partial blockage with varying sizes and material properties. Comparison is made with Flugge's well-known thin-shell theory for a propagation along a pipe where it is found that the additional computational complexity found in the current model becomes necessary when the thickness of the shell exceeds 10% of the pipe radius. Comparison is also made with experiment both for the propagation characteristics of the pipe and for the reflection from a partial blockage. Two reflection models are presented: a crude area change model with compensation for the mass of the blockage and a more accurate model using high-order modes and matching to a flexible blockage using co-location. Reasonable agreement is found for both with the more accurate model, giving better agreement but at the expense of computational efficiency. The work is useful both for blockage detection and for detecting stenosis in blood vessels.

11:05

2aNSa8. A cochlear analog bio-mimetic muffler. Sripriya Ramamoorthy (Dept. of Otolaryngol./Head and Neck Surgery, Oregon Res. Ctr., NRC 04, Oregon Health and Sci. Univ., 3181 SW Sam Jackson Park Rd., Portland, OR 97239, ramamoor@ohsu.edu)

A noise control device, the structural acoustic silencer, is designed by adopting the tailored structural acoustic filtering exhibited by the mammalian cochlea. In the cochlea, a flexible plate of gradually varying width and thickness separates the upper and lower fluid-filled ducts. Tailoring of the flexible plate properties enables frequency-specific localization of traveling waves, which are slowed down significantly at and near the site of resonance. While such slowing of the traveling wave leads to efficient energy coupling to the flexible plate thereby reducing transmitted acoustic fluctuations, the gradually varying impedance reduces reflections and allows the frequency-component to travel to its resonance site. The design of the bio-mimetic muffler employing non-biological materials is performed using three dimensional finite element analysis and validated against experimental data. The relation between coupled dispersion and transmission loss in the noise control device is explored. The coupled wave propagation in the engineered device is compared with the wave propagation in a passive cochlea.

11:25

2aNSa9. Shaped optimization of multi-chamber mufflers with open-ended perforated inlets using a simulated annealing method. Ying-Chun Chang (Dept. of Mech. Eng., Tatung Univ., Taipei, Republic of China, ycchang@ttu.edu.tw) and Min-Chie Chiu (Chungchou Inst. of Technol., Yuanlin, Changhua 51003, Taiwan, Republic of China)

Recently, research on new techniques of single-chamber mufflers equipped with a non-perforated intruding tube has been addressed; however, the research work on multi-chamber mufflers conjugated with open-ended perforated intruding inlet tubes which may dramatically increase the acoustical performance has been neglected. Therefore, the main purpose of this paper is not only to analyze the sound transmission loss (STL) of a multi-chamber open-ended perforated inlet-tube muffler but also to optimize the best design shape within a limited space. In this paper, the four-pole system matrix for evaluating the acoustic performance is derived by using a decoupled numerical method. Moreover, a simulated annealing method has been used during the optimization process. To appreciate the acoustical ability of the open-ended perforated intruding inlet-tube and chambers inside a muffler, two kinds of traditional multi-chamber mufflers hybridized with non-perforated intruding inlet tubes (one-chamber and two-chamber mufflers) have been assessed and compared. Results reveal that the maximal STL is precisely located at the desired tone. In addition, the acoustical performance of mufflers conjugated with perforated intruding inlet tubes is superior to traditional mufflers. Also, it has been shown that the acoustic performance for both pure tone and broadband noise will increase if the muffler has more chambers.

Contributed Paper

11:45

2aNSa10. Numerical and experimental investigation of sound transmission of a tee-junction in a rectangular duct at higher-order modes. Siu-Kit Lau (Architectural Eng. Program, 203C Peter Kiewit Inst., Univ. of Nebraska-Lincoln, 1110 S. 67th St., Omaha, NE 68182-0681) and Kwan-Hao Leung (The Hong Kong Polytechnic Univ., Hung Hom, Kowloon, Hong Kong)

Sound transmission and scattering properties in higher-order modes across the tee-junction of a rectangular duct used in ventilation and air-conditioning system were investigated numerically and experimentally. High-sound transmission of the fundamental mode and higher-order modes across the main duct is observed at eigen-frequencies of the main duct. The resonance of branch modes is suppressed by the weak modal coupling of the branch-modes and the traveling wave in the main duct at or very close to the eigen-frequencies of the sidebranch, which results in high-sound transmission of the fundamental mode and higher-order modes across the main duct and excitation of the branch modes at higher frequencies. Increases in sound scattering into higher-order mode are found when the non-planar or longitudinal branch-mode excited. In the case of co-excitation of the longitudinal branch-mode and non-planar branch-modes, a broader band-stop action in sound transmission has been observed. The results of numerical simulations were verified by experiments. A formulation of a transmission matrix based on the transfer function and a two-microphone method was shown. [The work described in this paper was supported by a grant from the Hong Kong Polytechnic University (Project A/C Code: G-U362).]

TUESDAY MORNING, 20 APRIL 2010 LAUREL A/B, 8:15 A.M. TO 12:00 NOON

Session 2aNSb

Noise, Animal Bioacoustics, and INCE: Effect of Noise on Humans and Non-Human Animals I

Hubbs Sea World Research Inst., 2595 Ingraham St., San Diego, CA 92109

Brigitte Schulte-Fortkamp, Cochair
Technical Univ. Berlin, Einsteinufer 25, Secr TA 7, Berlin, 10587, Germany

Chair's Introduction—8:15

Invited Papers

8:20

2aNSb1. Soundscape research in networking across countries: COST Action TD0804. Brigitte Schulte-Fortkamp (Inst. of Fluid Mech. and Eng. Acoust., Technische Universitt Berlin, 10587 Berlin, Germany) and Jian Kang (Univ. of Sheffield Western Bank, Sheffield S10 2TN, United Kingdom)

Soundscape, different from noise control engineering, is about relationships between human beings, sound environments, and society. Research in soundscape covers science, engineering, social science, humanity, and art, and it is related to many disciplines including among others acoustics, anthropology, architecture, ecology, landscape, noise control engineering, psychology, sociology, and technology. Soundscape research represents a paradigm shift in the field of environmental noise in that it combines physical, social, and psychological approaches and considers environmental sounds as a "resource" rather than a "waste." The COST Action has built a vibrant international network and delivers the foundations for soundscape indicators, an integrated database of experimental and field data, publications, and tools to support design and decision making. Therefore, the paper will discuss the underpinning science and practical guidance that supports the measurement tools and their implementation in "Soundscapes."

8:40

2aNSb2. A subject centered approach to environmental noise effects: revisiting old concepts and proposing new methods. Caroline Cance (INCAS3, Dr. Nassaulaan 9, P.O. Box 797, Assen, 9400 AT, The Netherlands, ccance@gmail.com) and Danièle Dubois (CNRS & Univ. Paris 6, Paris, 75015, France, daniele.dubois@upmc.fr)

Considering the effects of noise implies that "somebody" is affected by noise. If the noise itself is not problematic regarding its measurement (by physics), the question is less clear regarding WHO is concerned by noise? Humans, animals? Asking such a question entails some other ones: Is any living system similarly affected by noise? Generally as an organism? Or differentially as "subjects"? What scientific domains are concerned with such studies? We would address these questions from our experience and knowledge on soundscapes. Starting from psychophysics that remains within the "endemic antinomy of a world-less subject confronting a thought-less object: the antique dualism of mind and matter" [Shalins (1976)], we will consider the diversity of subjects (animal as well as human "experts" of different types, acousticians, urban planners, politicians, and inhabitants) to propose an alternative conception we name "semiophysics": it leads to reconsider the concepts of information versus meaning, as well as from a methodological point of view, the concepts of affordance versus Umwelt. Coupling field research and experimental work by accounting for meanings as relationships given to the world by the different subjects calls then for an ecological validity of laboratory investigations.

9:00

2aNSb3. Effect of combined noise sources on cognitive performance and perceived disturbance. Jin Yong Jeon and Pyoung Jik Lee (Dept. of Architectural Eng., Hanyang Univ., Seoul 133-791, Korea, jyjeon@hanyang.ac.kr)

An experiment was conducted to investigate the differences in cognitive performance and perceptions under road traffic noise and construction noise combined with road traffic noise. Under the conditions with individual noise and combined noise sources, an episodic memory task and semantic task were carried out in the laboratory. The subjects were asked to recall the presented words after the exposure to noises (episodic memory task) and to select the target word when the five words, including the target word and other words, were presented simultaneously (semantic memory task). Subjects also rated perceived annoyance and disturbance to the noise exposure during the experiment. The result showed that the percentage of correct answer significantly decreased with an increase in construction noise in an episodic memory task. In contrast, the semantic memory task was not impaired by the level of construction noise level. This indicates that only the retrieval task with a process of generating the internal cues was affected by the level of combined noise sources. And it was also found that the perceptions of combined noise sources were highly correlated with the result of the episodic memory task.

9:20

2aNSb4. Standardizing the measurement of natural and urban soundscapes. Robert Kull (Parsons, 7447 Central Business Park Dr., Ste. 100, Norfolk, VA 23513)

For the purpose of discussion, a simple model was presented to illustrate the contributions and interactions of various elements within an environment that make up soundscapes [Kull (2006)]. These elements should be considered when attempting to characterize a soundscape using acoustic measurements. For this presentation, the model will be used with the objective of creating a plan for taking sound measurements.

9:40

2aNSb5. Evaluating the prevalence of masking as a causal factor in wildlife responses to noise. Jesse Barber (Dept. of Fish, Wildlife and Conservation Biology, Colorado State Univ., 1474 Campus Delivery, Fort Collins, CO 80523, barber.jesse@gmail.com) and Kurt M. Fristrup (Natl. Park Service, Fort Collins, CO 80525)

Many protected natural areas are chronically exposed to noise. Noise exposure grows faster than the human populations whose activities generate noise. Data accumulate regarding masked hearing performance in animals, which can be coupled with models of sound propagation to predict reductions in the spatial extent of auditory awareness with elevated background sound levels. The emergence of predictive models of noise masking effects recommends a reassessment of field studies of wildlife responses to noise to identify the potential scope of this problem. A review of this literature reveals a substantial and diverse collection of scientific papers whose findings are plausibly related to masking effects and an increasing number of more decisive results from studies that were designed to control for other confounding factors.

10:00—10:10 Break

10:10

2aNSb6. Marine mammals and anthropogenic noise: Challenges from a management and regulatory prospective. Amy R. Scholik-Schlomer, Shane Guan, Jolie Harrison, and Craig Johnson (Natl. Marine Fisheries Service, Office of Protected Resources, 1315 East-West Hwy., Silver Spring, MD 20910)

Responsibilities of the National Marine Fisheries Service (NMFS) include conserving and recovering marine species protected under the U.S. Marine Mammal Protection and Endangered Species Acts. One of our primary objectives is to assess the risks anthropogenic noise in marine/coastal environments poses to animals in those environments and implement appropriate measures to reduce these risks. Many challenges to achieving these goals exist from both a scientific and a regulatory perspective. Accounting for the inherent complexity of source characteristics, noise propagation through the environment, and temporal/spatial overlap between sources and protected species, as well as understanding how noise exposure affects species are often quite difficult. Exposures typically are either high-level, short-term (e.g., seismic survey), or lower-level, long-term (e.g., construction project), with each presenting different risks. Establishing appropriate metrics for describing noise sources, assessing effects on individuals and on populations/stocks, as our statutes require, and ensuring the practicality of applying these metrics to real-world situations are essential. There are also often considerable data gaps, which require us to draw upon the knowledge gained from human and other terrestrial species. NMFS is currently re-evaluating and updating our acoustic criteria, which are used within our impact assessments, to reflect the best-available science on these issues.

10:30

2aNSb7. Predicting acoustic impact: Considering individuals versus populations. Brandon L. Southall (Southall Environ. Assoc., Inc., 911 Ctr. St., Ste. B, Santa Cruz, CA 95060), Adam S. Frankel, and William T. Ellison (Marine Acoust., Inc., Middletown, RI 02842, adam.frankel@marineacoustics.com)

Predictive models to assess the potential impacts of anthropogenic activities are increasing being used to assess environmental impacts. The most accurate models are, arguably, individual-based models that integrate species-specific biological and area-specific environmental data such as the acoustic impact model. These models simulate the movement of animals in four dimensions and typically include responses to both acoustic and/or non-acoustic environmental variables. The predicted exposures of individuals to sound sources may be assessed with a risk function; however, a recent meta-analysis of behavioral response and acoustic dose [Southall *et al.* (2007)] did not find meaningful linear relationships that were generally applicable between low to medium received sound levels and behavioral response. There appears to be significant variability in both species-specific and individual animal responses that are mediated by various contextual factors. Since regulatory requirements are often focused on population impact, the simplest approach to considering individual variability in behavioral response is that averaged over the population. Therefore, a mathematically linear dose-response function may be most applicable, at least within species for certain activity patterns, even if it is not supported for individual animals in all conditions.

10:50

2aNSb8. Harbor seals respond with aversion to 69-kHz pings: Implications for weighting procedures for marine mammal noise metrics. Ann E. Bowles, Stephanie K. Graves, Michael Shane (Hubbs-SeaWorld Res. Inst., 2595 Ingraham St., San Diego, CA 92109, abowles@hswri.org), and Samuel L. Denes (Penn State Univ., State College, PA 16802)

Author Shane tracked cultured white seabass (*Atractoscion nobilis*) instrumented with 69-kHz ultrasonic coded transmitters (UCTs) in the vicinity of harbor seals (*Phoca vitulina*), later finding the bones of fish associated with UCTs. This led the authors to suspect that seals had targeted and eaten instrumented fish. To determine whether seals could detect pings, four harbor seals and a ringed seal at SeaWorld San Diego were exposed to pings from two 69-kHz and one 83-kHz UCTs and their spontaneous responses observed. The seals were not expected to respond strongly because most of the energy in the pings was close to the upper limit of hearing, but three of the four harbor seals reacted with aversion to the 69-kHz pinger with the highest source level (147 dB *re* 1 μPa), swimming into a refuge pool or jumping out of the water. The received level at the closest point of approach was estimated at 20 dB above sensation level or less. The results suggest that seals may be especially responsive to high-frequency tonal signals, and that broadband weighting functions may not consistently yield efficient exposure metrics. [Funded by NOAA; in-kind support from SeaWorld San Diego.]

11:10

2aNSb9. Modeling the exposure of greater sage-grouse to noise from industrial gas drilling rigs. Stacie L. Hooper, Sean Hanser, and Gail Patricelli (Dept. Evolution and Ecology, Univ. of Calif., Davis, 1 Shields Ave., Davis, CA 95616, slhooper@ucdavis.edu)

Natural gas and methane extraction is a growing industry in Wyoming, and some greater sage-grouse leks appear to be declining in areas near industrial sites. The goal of this project is to develop a model for understanding whether industrial noise has played a significant role in these reductions in lek attendance. A software package called NMSIM, previously developed by Wylie Laboratories to measure noise exposure from aircraft for the National Park Service, is being used. NMSIM utilizes amplitude measurements, recorded a set distance from the noise source, topographic map data, and measurements of other factors affecting sound propagation such as temperature and humidity, to build a spatially explicit model simulating how noise from the industrial sites propagates over the surrounding terrain. Simulation results are then verified using a set of noise exposure measurements taken from known locations around the gas drilling rigs. In addition to explaining historic lek attendance patterns, this model will also be used to predict how noise from new industrial sites will impact nearby greater sage-grouse leks.

11:30—12:00 Panel Discussion

TUESDAY MORNING, 20 APRIL 2010 HERON, 7:55 A.M. TO 12:00 NOON

Session 2aNSc

Noise and Architectural Acoustics: Healthcare Acoustics/Noise and Occupant Perception and Performance

Erica Ryherd, Cochair
Georgia Institute of Technology, Dept. of Mechanical Engineering, 771 Ferst Dr., Atlanta, GA 30332-0405

Kenneth P. Roy, Cochair
Armstrong World Industries, 2500 Columbia Ave., Lancaster, PA 17604

Mandy Kachur, Cochair
Acoustics By Design, Inc., 303 Detroit St., Ste. 304, Ann Arbor, MI 48104

Chair's Introduction—7:55

Invited Papers

8:00

2aNSc1. Evidence-based medicine meets evidence-based design: An interdisciplinary study of acoustics and sleep disruption as a context for improving teamwork. Jo M. Solet (Div. of Sleep Medicine, Harvard Med. School, 15 Berkeley St., Cambridge, MA 02138, joanne_solet@hms.harvard.edu)

Hospital noise-induced sleep arousal probability curves were derived by exposing laboratory monitored sleeping human subjects to 14 common stimuli selected and scaled from a recorded inpatient hospital sound-scape. The research process in this recently published successful project, which informed the 2010 Guidelines for the Construction of Health Care Facilities, serves as a context for discussion of the promise and pitfalls of interdisciplinary teamwork, bringing together evidence-based medicine and evidence-based design, to solve real world problems. Revealing normally unspoken professional assumptions, work ethics, record keeping requirements, and conflict of interest concerns, this program seeks to make cross field boundary breaking collaboration easier and more successful and to improve possibilities for meaningful innovation. [Work supported by AAHF, FGI, and CHD.]

8:20

2aNSc2. Hospital soundscape modeling. Selen Okcu (College of Architecture, Georgia Inst. of Technol., 247 Fourth St., Atlanta, GA 30332, selen.okcu@gatech.edu), Erica Ryherd, and Craig Zimring (Georgia Inst. of Technol., Atlanta, GA 30332)

Effective soundscape solution considerations for hospital settings can be very complex. Some acoustic qualities of these soundscapes have been shown to have potential negative impacts on occupant outcomes. To enhance these qualities, different acoustic solutions are applied in the hospital settings. Testing the effectiveness of these implications is critical but not always practical in the real settings. In this study, we examined the soundspaces of critical care settings through acoustic models. This paper will discuss the preliminary results regarding the modeled acoustic qualities of various ICU settings such as noise levels and reverb qualities.

8:40

2aNSc3. An approach to making safe and secure indoor soundscape measurements. Kenneth Good and Kenneth Roy (Armstrong World Industries, 2500 Coulumbia Ave., Lancaster, PA 17601)

Outdoor soundscape measurements are being done for many types of noise sources and locations, and the monitor equipment must be both durable and secure from both the elements and physical disturbance. Indoor measurements require a somewhat more sophisticated setup since the measurement space is often an occupied space, and in the case of hospital corridors these will likely be very active spaces 24/7. A creative yet simple approach to setting up monitor stations in hospital hallways, nurses stations, and patient rooms was developed and is being used in a number of research programs. It is imperative that valid noise measurements be made in the designated spaces without arousing undue concern or interests on the part of the occupants (both medical professionals and patients /families), and that the equipment be unobtrusive and thus secure. Monitor system mounting technique and measurement performance will be illustrated and discussed.

9:00

2aNSc4. Description and comparison of healthcare sounds. Benjamin C. Davenny and Gladys L. Unger (Acentech Inc., 33 Moulton St., Cambridge, MA 02138, bdavenny@acentech.com)

Within the clinical literature and the popular press, the noise from particular pieces of healthcare equipment or certain clinical environments is described by giving an example that is supposed to orient the reader. But these examples are often very misleading and may be in inappropriate. Outdoor everyday sounds are compared with interior healthcare sounds and steady sounds are compared with impulsive sounds. This discussion will explore better descriptions of healthcare and everyday sounds with the goal of providing better comparisons. Illustrated by examples currently in the literature we will discuss what constitutes a useful comparison and what attributes of the sounds need to be considered. Better descriptions of healthcare noise sources will help in the control of hospital soundscapes.

9:20

2aNSc5. Impact of building design on inpatient nursing unit noise levels: A case study of evidence based design. Nathan Sevener (Acoust. By Design, Inc., 4001 Murvihill Rd., Ste. 2E, Valparaiso, IN 46383)

In spring 2006, the evidence-based design process was being applied to the design of the new inpatient pavilion at Lakeland Hospital. Because of survey feedback, the hospital was aware that noise detracted from patients satisfaction with the existing facility and therefore noise level became one of the 77 metrics used in the design of the new pavilion. To help create an improved acoustical environment, the sound levels in the existing facility were monitored, the design of the new pavilion was reviewed with respect to noise control, and follow-up measurements were made after occupation. The results of that effort are presented here.

9:40

2aNSc6. Controlling patient room reverberation with a thin acoustical wall treatment. Francis J. Babineau and Amy Sparks (SoundTech Inc., 3880 SoundTech Ct., Grand Rapids, MI 49512)

A study was conducted to explore an alternate method for reducing room reverberation time in a healthcare setting. Reverberation time (RT) is known to play an important role in overall noise levels and speech privacy, both of which are key factors in patient and staff satisfaction. However, RT is difficult to control in healthcare facilities, primarily due to durability and infection control requirements. A private patient room was treated with a thin, acoustically absorptive wall treatment. The wall treatment was not a typical acoustical finish, with absorption coefficients ranging from 0.05 to 0.6. However, several walls of the room were entirely covered with the treatment to achieve reverberation control. Reverberation times were measured before and after the installation, and results were consistent with predicted values. Despite being a small study, the results suggest that a thin acoustical wall treatment that meets durability and infection control requirements can be effective for controlling reverberation in healthcare facilities and creating a more comfortable environment for patients and staff.

10:00—10:20 Break

10:20

2aNSc7. Further studies in hospital noise control at the Johns Hopkins Hospital: Part 1. Colin Barnhill, James E. West (Dept. ECE, Johns Hopkins Univ., Baltimore, MD 21218, cb@jhu.edu), Timothy Hsu, and Erica E. Ryherd (Georgia Inst. of Technol., Atlanta, GA 30332-0445)

Hospital noise levels remain well above World Health Organization guidelines. One of the main difficulties in treating hospital noise is the inability to use conventional sound absorption techniques. In intensive care units, the hospital does not allow any materials that can harbor bacteria or produce a high level of dust. This criterion prohibits conventional drop ceilings and conventional sound absorbing panels and carpet. Based on our previous panel design [M. MacLeod *et al.*, "Weinberg 5C: A case study in hospital noise control, J. Acoust. Soc. Am. 119, 3327 (2006)] a lower cost version of our hospital noise panels was implemented by replacing the wrapping with DuPont™ Tyvek©. The lowered cost makes implementation of these new panels more feasible for hospitals. In this talk, it will be shown that this new implementation produces comparable results to the original panel design. The performance of a modified DL2 measurement will be investigated as a new way to characterize hospital noise.

10:40

2aNSc8. Further studies of hospital noise control at the Johns Hopkins Hospital: Part 2. Timothy Y. Hsu, Erica E. Ryherd (Woodruff School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0445), James E. West, Colin L. Barnhill (Johns Hopkins Univ., Baltimore, MD 21218), Marie Swisher (Sidney Kimmel Comprehensive Care Ctr., Baltimore, MD 21231), and Natalia Levit (DuPont, Richmond, VA 23234)

It has been shown through previous research that hospital noise levels continue to rise and that there exist potential health and occupational hazards due to the soundscape. Previous studies have examined parameters such as overall average sound levels, statistical distributions of levels, and frequency content in a variety of wards. However, studying the impact of sound absorbing materials in medical facilities is still very challenging due to strict infectious control requirements. We will present a case study on installing various sound absorbing treatments in four hematological cancer wards. Four units in the Weinberg Building of the Johns Hopkins Hospital were selected due to their identical geometries, similar staff activities, and similar patient acuity levels. Researchers installed different acoustical treatments in each ward, from untreated to fully treated with prototype materials. The prototype materials tested consisted of a layer of DuPont™ Tyvek® covering a panel of fiberglass acoustic absorbing material. In each ward, extensive acoustical measurements were taken and a questionnaire survey was administered to the registered nurses on staff. Preliminary results will be presented that compare and contrast attributes such as background noise, reverberation, speech intelligibility, and subjective perception in the four different wards.

11:00

2aNSc9. Acoustic privacy and health care. Neil Moiseev (Shen Milsom & Wilke LLC, 417 Fifth Ave., New York, NY 10016)

Acoustic privacy can be differentiated into two categories: freedom from intrusive noise, such as a person snoring or wheezing in the next bed, traffic outside the windows, carts in the hallways, and footsteps on the floor above; and speech privacy—the freedom from being overheard and of overhearing others. Providing the proper acoustical environment and the protecting privacy must be a joint effort between the facility designers and hospital staff. A brief discussion of the basic requirements for speech privacy and HIPAA privacy and a quality background sound will be presented.

11:20

2aNSc10. Two healthcare buildings get the power, the noise, and the vibration from a gas turbine generator system. Chad N. Himmel (1705 W. Koenig Ln., Austin, TX 78756)

A package gas turbine generator was installed at a small, 4.3-MW cogeneration power plant of a mixed use development with office, retail, hospital, residential, and other occupancies. Shortly after commissioning, noise complaints were received from nearby medical offices about undesirable tonal noise intrusions. At another nearby hospital building, a neurosurgery suite addition would include a new intra-operative magnetic resonance imaging (iMRI) unit. Ambient vibration measurements at that site indicated prominent discrete frequencies of disturbance that could affect iMRI image quality. Investigations found loud broadband noise and dominant ground borne vibration in the vicinity of the turbine, with strong tonal peaks relating to turbine and generator rotational rates. The intrusive noise in nearby medical offices and the structure borne vibration at the hospital included matching strong tonal peaks. Various noise- and vibration-mitigating measures were proposed and some were implemented with successful results for the medical offices and new iMRI suite. Mitigating measures are discussed, along with measurement results and photographs.

11:40

2aNSc11. Strengthening the healthcare guidelines: About the new online research community. David M. Sykes (Remington Partners, 23 Buckingham St., Cambridge, MA 02138, dsykes@healthcareacoustics.org), William Cavanaugh, Gregory Tocci, and Andrew Carballeira (Cavanaugh Tocci Assoc., Sudbury, MA)

Myriad challenges and opportunities exist for researchers in the 2010 edition of the Guidelines for the Design and Construction of Healthcare Facilities. The new edition, released in January, contains the first comprehensive acoustical criteria ever included in the 60-year-old Guidelines that are now being adopted as code by most states, federal agencies, and municipalities. Enforcement—and future strengthening—of these Guidelines will require a strong, organized, well-funded research community in acoustics willing to do transdisciplinary research. Since federal agencies do not actively support research on the human impacts of noise in healthcare facilities but some private foundations do, the drafters of the Guidelines recently launched an online research community to enable research teams across the country to interact directly with interested foundations, government agencies, policy groups, and healthcare organizations. The online community has a distinguished Advisory Board of interested professionals in acoustical science, medicine, healthcare architecture, and engineering. It hosts an open database of recent research on acoustics and human health, RFPs and announcements, links to interested groups such as ICBEN, the World Health Organization and UIA-PHG, and other features such as blogs and wikis.

Session 2aPA

Physical Acoustics and Engineering Acoustics: Ultrasonics, Nonlinear Acoustics, Acousto-Optics, and Engineering Acoustics in Honor of Mack Breazeale I

Lev A. Ostrovsky, Cochair
Zel Tech/NOAA ESRL, 325 Broadway, Boulder, CO 80305-3328

Nico F. Declercq, Cochair
Georgia Tech. Lorraine, 2 rue Marconi, Metz, 57070, France

Chair's Introduction—7:55

Invited Papers

8:00

2aPA1. Mack Breazeale and E. A. Hiedemann's group at Michigan State University. David T. Blackstock (Appl. Res. Labs., Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029 and Dept. M.E., UT Austin, Austin, TX 78712-0292)

Mack Breazeale received a Ph.D. degree in physics at Michigan State University in 1957. He was one of 19 doctoral students supervised by Egon A. Hiedemann, who headed a very active group in ultrasonics at Michigan State in the 1950s and 1960s. Mack's period there, 1954–1961, is reviewed and also the history of the Hiedemann group, which was well known for its contributions to physical acoustics. A particular interest in optical measurement of ultrasonic waves led to many theses and papers in nonlinear acoustics, at that time just beginning to enjoy a renaissance. Among those who, like Mack, went on to have very active roles in the Acoustical Society of America were Laszlo Adler, Bill Cook, Logan Hargrove, and Walter Mayer.

8:20

2aPA2. Impact of Mack Breazeale on the ultrasonic studies of interfaces. Laszlo Adler (Adler Consultants Inc./Ohio State Univ., 1560 Gulf Blvd., #1002 Clearwater, FL 33767)

Over the last 50 years, Mack Breazeale made very significant contributions to Physical Acoustics. He was a great influence to his students as well as to researchers all around the world who carried on, continued, and expanded the work which was initiated by him. His work is well known on nonlinear studies of liquids and solids, acousto-optics, ultrasonic interaction at liquid-solid interfaces at the Rayleigh angle generating leaky waves, and many others. Nonlinear acoustic techniques improved material characterization of complex materials and structures significantly. The generation and detection of leaky waves opened up several applications in nondestructive evaluation. In this presentation, several of these techniques which were recently developed will be discussed. One of this is the optical detection of leaky waves at an air-solid interface which can be used to evaluate elastic properties of solids as well as surface imperfections. A nonlinear ultrasonic method to study interfaces between solid layers will be also presented. Mack Breazele leaves a legacy of knowledge, wisdom, and kindness and will always be remembered by us.

8:40

2aPA3. Acousto-optics as the background of a long-lasting friendship with Mack Breazeale. Oswald Leroy (Interdisciplinary Res. Ctr., Katholieke Universiteit Leuven Campus Kortrijk, Meensesteenweg 453, 8501 Kortrijk, Belgium)

Ever since I have known Mack Breazeale, our friendship has come along with discussions and bilateral suggestions for further research in acousto-optics. Among many other topics we had a common interest in the application of acousto-optics for nondestructive testing. For layered structures all information concerning the structure is contained in the phase information of the ultrasound investigating the material. This phase information is obtained using two or only one laser beam depending on the kind of required information. Using the technique of two laser beams the measured phase difference between the incident and the reflected ultrasonic beam is influenced by the geometrical shape of a plate, the thickness of a thin layer on a substrate, as well as by the presence of defects inside a layered material. In addition different methods are discussed to describe the diffraction of light by monofrequent, pulsed, and adjacent superposed ultrasound. In the optical nearfield of a diffracted laser beam, it is even possible to reconstruct all of the acoustic wave parameters. The ability of measuring the amplitude and phase of reflected and transmitted waves is a powerful tool to discover information about the surface on which scattering of sound occurs.

9:00

2aPA4. Substructural organization and acoustic harmonic generation in fatigued metals. John H. Cantrell (NASA Langley Res. Ctr., MS 231, Hampton, VA 23681, john.h.cantrell@nasa.gov)

Since the discovery of acoustic harmonic generation in solids by Breazeale and Thompson [Appl. Phys. Lett. **3**, 77 (1963)] and Gedroits and Krasilnikov [Sov. Phys. JETP **15**, 122 (1963)], nonlinear acoustics has gained popularity as a tool for nondestructive materials evaluation. A longstanding problem has been the assessment of fatigue damage. Harmonic generation measurements are

shown to provide for the first time a quantitative, unambiguous means to assess the state of fatigue in metals from the virgin state to fracture. The salient features of an analytical model are presented that account for the microelastic-plastic nonlinearities resulting from the interactions of an acoustic wave with self-organized dislocation substructures and cracks that evolve during cyclic loading. The model predicts a monotonic increase in the nonlinearity parameter of several hundred percent over the life of the material. Generally, the increase in the nonlinearity parameter during the first 80%–95% of fatigue life is dominated by the evolution of organized dislocation structures, while the last 5%–20% is dominated by crack growth. Applications of the model to aluminum alloy 2024-T4, 410Cb stainless steel, and IN100 nickel-base superalloy yield excellent agreement between theory and experiment.

9:20

2aPA5. A diffraction correction for the nonlinearity parameter measured by the harmonic generation technique. William T. Yost (NASA-Langley Res. Ctr., 3B E. Taylor St, Rm. 285, MS231, Hampton, VA 23681-2199, william.t.yost@nasa.gov)

Practical applications of harmonic generation to determine the nonlinearity parameter Beta generally tend toward the lower drive (fundamental) frequencies. As a result, diffraction effects on Beta become more significant. Derivations of a number of different diffraction correction formulas, which are applied for a piston source and a receiver located some distance away, are in the literature. In the paper by Blackburn and Breazeale [J. Acoust. Soc. Am. **76**, 1755–1760 (1984)] the correction formulas were applied to the amplitude of the fundamental frequency and the results on Beta were experimentally tested. By building on this earlier work, a diffraction correction formula that includes a factor from a numerical integration algorithm applied to the harmonically generated wave is provided. The formulation of this algorithm is discussed. Experimental results are given for measurements of Beta in AA 2024 to illustrate the agreement.

9:40—10:00 Break

10:00

2aPA6. Nonlinear acoustics: A transition from laboratory to a practical fatigue assessment tool. Jeong-Kwan Na (SID, Univ. of Dayton Res. Inst., 300 College Park, Dayton, OH 45469, jeong-kwan.na@wpafb.af.mil)

The ultrasonic second harmonic generation technique measuring the nonlinearity parameter has been developed and used in laboratories for several decades throughout the world. Many students and visiting scholars from numerous countries devoted their passions at the physical acoustics laboratories led by Dr. Mack Breazeale for 50 years. During that period of time, nonlinear elastic properties of single crystals, polycrystalline alloys, superconductors, ceramics, and composites were measured. New measurement systems and techniques were also developed to understand temperature dependent linear and nonlinear elastic behaviors of these materials over a temperature range from the liquid helium to Curie temperatures of piezoelectric ceramics. It took years of research and development efforts with a persistent funding before a practical fatigue damage measurement technique was finally developed. The transition from a rack full of equipment to a portable fatigue damage measurement system, a continuous iteration process was inevitable. The current system, specifically designed for steam turbine blades fatigue inspections, consists of a probe fixture and an industrial grade lunch-box computer with custom designed signal processing cards.

10:20

2aPA7. Nonlinear interaction of ultrasonic waves: A tribute to Mack Breazeale. Murray S. Korman (Dept. Phys., U.S. Naval Acad., Annapolis, MD 21402)

While at Brown University (~1977), this graduate student was fortunate enough to learn about Mack Breazeale's important early work in nonlinear ultrasonic waves in solids [J. Appl. Phys. **36**, 3486 (1965)] through his thesis advisor (R. T. Beyer), who had friendly and most collegial interactions with Mack, through the ASA. When I met Mack Breazeale at ASA Meetings, he would discuss how he made some of his measurements and helped me understand some complexities involving the scattering of sound by sound. While Mack Breazeale was Associate Editor of nonlinear acoustics he gave a wealth of good advice (over a period of several years) on how to improve a manuscript on crossed beam scattering in turbulence and divide the material into at least two parts—which was done. When the paper was out, one agreed with Mack that it was much better and worth the effort. Years later, doing summer research at NCPA, Mack helped improve a manuscript on nonlinear acoustic landmine detection. As a tribute to Mack Breazeale, his work on "Quantum mechanical theory on nonlinear interaction of ultrasonic waves" (with I. L. Bajak) [J. Acoust. Soc. Am. **68**, 1245 (1980)] will be discussed in some detail.

Contributed Papers

10:40

2aPA8. Peculiarities of acoustic beam reflection from a fluid-solid interface. Oleg A. Sapozhnikov (Appl. Phys. Lab., Univ. of Washington, and Dept. Phys., Moscow State Univ., Russia, olegs@apl.washington.edu), Alexander A. Karabutov, Jr., and Vladimir G. Mozhaev (Moscow State Univ., Russia)

Mack Breazeale and his colleagues published several papers on experimental study of non-specular reflection of ultrasonic beam from a fluid-solid interface [Breazeale *et al.*, J. Acoust. Soc. Am. **56**, 866 (1974); J. Appl. Phys. **48**, 530 (1977)]. To study fairly unusual details of the reflected beam structure, Schlieren visualization was employed, which clearly confirmed theoretical predictions. The present talk was motivated by this elegant approach of Breazeale. One of the goals was to improve reflected beam imaging by using pulsed Schlieren technique. The second goal was to observe a growing interface wave. It is known that the secular equation for acoustic waves at fluid-solid interfaces yields the common leaky wave and its complement. This complementary wave grows instead of decays with propagation and is time-reversed compared to the leaky wave. Ultrasonic pulses and their reflections were visualized using Schlieren imaging and stroboscopic flashing of a semiconductor laser. The source was a broadband (0.5–3 MHz) single element plane transducer. Reflectors were aluminum blocks with fine angular adjustments in an optically transparent water tank. The wave reflection and transmission were also studied numerically using finite differences. [Work was supported by RFBR, NIH, and NSBRI grants.]

10:55

2aPA9. Fatigue damage evaluation using harmonic generation in polycrystalline copper. Brian Reinhardt and Bernhard Tittmann (Dept. of Eng. Sci. and Mech., Penn State Univ., 212 Earth Eng. Sci. Bldg., University Park, PA 16802)

A fundamental goal of ultrasonic nondestructive evaluation is to characterize material defects before failure. During material fatigue, dislocations tend to nucleate and become sources of stress concentrations. Eventually, cracks start to form and lead to material failure. Recent research has indicated that nonlinear harmonic generation can be used to distinguish between materials of high- and low-dislocation densities. This research reports nonlinear harmonic generation measurements to distinguish between those areas of high- and low-dislocation densities in copper bars. The copper bars were subjected to flexural fatigue. Periodic scans were taken in order to track dislocation development during the fatigue life of the material. We show that this technique provides improved early detection for critical components of failure.

11:10

2aPA10. Simulation of nonlinear acoustic waves based on the semi-Lagrangian method. Glauber T. Silva and Andre Nachbin (Inst. of Phys., Univ. Fed. Alagoas, Maceio, Alagoas 57072-970, Brazil, glauber@pq.cnpq.br)

In this work, we introduce the semi-Lagrangian numerical method for one-dimensional nonlinear wave propagation in acoustics. The method is suitable to simulate interacting waves in fluid media. In the method, the acoustic fields are expressed in terms of Riemann invariants. These variables are computed along the characteristic curves one step back in time. The unknown characteristics are obtained by the Runge–Kutta method. The Riemann invariants are evaluated in the grid points using cubic interpolation. The method is validated comparing the numerical solution to the Earnshaw solution for simple waves. Results show that the proposed method excels the Courant–Frederich–Lewy condition at least fourfold. The total numerical error is 12% and 3% using 16 and 32 points per wavelength, respectively. The proposed method is applied to simulate the interaction between a finite-amplitude tone with a Gaussian noise. Solutions are in qualitative agreement with earlier studies on tone and noise interaction [D. A. Webster and D. T. Blackstock, J. Acoust. Soc. Am. **64**, 687–693 (1978)]. [Work partially supported by CNPq.]

11:25

2aPA11. Ultrasonics in solids with frequency-dependent nonlinearity parameters. Paul A. Elmore (Naval Res. Lab., Marine Geosciences Div. Stennis Space Ctr., MS 39529, paul.elmore@nrlssc.navy.mil)

This paper reviews the current state of modeling the nonlinear generation of second-harmonic ultrasonic waves in heterogeneous solids. Experiments measure the rate in which the higher-order harmonics grow with wavenumber, k, and propagation distance, a. The lowest-order nonlinearity parameter, quantifying the growth rate of the second-harmonic amplitude, A_2, experimentally is $\beta \propto \lim A1 \rightarrow 0(A1/A22k2a)$, where A_1 is the fundamental harmonic amplitude. In crystals and amalgamated metals, β is constant, and the corresponding equation of motion can be written with one nonlinear term to a good approximation. In heterogeneous materials with granular contacts, however, such as lead-zirconate-titanate (PZT) and graphite-epoxy composites, β changes with wavenumber, and the corresponding equation of motion requires more nonlinear terms. An equation of motion updated from the one for crystals does provide predictions of β that appear to match the experimental results; however, it is inadequate for providing velocity predictions in graphite-epoxy composites, where there is significant dispersion, and does not explicitly account for the hysteric behavior of grain contacts. A recent model that accounts for grain contacts asserts that it can account for the frequency dependent β. This paper will review these models and compare predictions for β with PZT and composites data.

TUESDAY MORNING, 20 APRIL 2010 ESSEX A/B/C, 9:00 A.M. TO 12:00 NOON

Session 2aPP

Psychological and Physiological Acoustics: Application of Psychoacousticss to the Impaired Listener, Challenging Environments, Hearing Aids, and Cochlear Implants (Poster Session)

Sandra Gordon-Salant, Chair

Univ. of Maryland, Dept. of Hearing and Speech Science, College Park, MD 20742

Contributed Papers

All posters will be on display from 9:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 9:00 a.m. to 10:30 a.m. and contributors of even-numbers papers will be at their posters from 10:30 a.m. to 12:00 noon.

2aPP1. Comparison of central masking versus monotic masking in non-simultaneous masking conditions. Mahnaz Ahmadi and Lawrence L. Feth (Dept. of Speech and Hearing Sci., The Ohio State Univ., 110 Pressey Hall, 1070 Carmack Rd., Columbus, OH 43210)

The growth of non-simultaneous masking was compared in a central masking versus a monotic masking condition for the same masker and signal parameters. Detection thresholds of normal listeners were measured utilizing a 2AFC up-down adaptive-tracking procedure. Signal-to-masker time intervals were 0, 2, 5, 10, 20, and 50-ms. Brief sinusoidal signals at 0.5, 1, 2, and 4 kHz were masked by a two-octave band of noise of 200 ms duration. The masker was centered on and off the frequency of the signal. Detection thresholds were greater for signal-to-masker intervals less than 50 ms in forward masking using both central and monotic masking conditions. Backward central masking did not result in significant threshold shifts. High-frequency signals produced greater central masking effects; however, signals at lower frequencies were more effectively masked in monotic conditions. In contrast with monotic masking conditions, off-frequency maskers did not produce a clear central masking effect. Results of this study are consistent with neurophysiologic findings of medial olivocochlear bundle response characteristics and support the idea that central masking is mediated by efferent fibers in humans.

2aPP2. Comodulation masking release with signal-masker interactions represented in the envelope. Robert H. Pierzycki and Bernhard U. Seeber (MRC Inst. of Hearing Res., Univ. Park, Nottingham NG7 2RD, United Kingdom, rp@ihr.mrc.ac.uk)

In normal hearing, the threshold of a tone masked by a modulated narrow-band on-frequency masker (OFB) can be reduced if correlated modulation is present on spectrally distant flanking bands (FBs), an effect

known as comodulation masking release (CMR). Since electric hearing with current cochlear implants is based on envelope information, comodulation of envelopes on multiple electrodes might also be beneficial for detection in electric hearing. CMR was investigated with normal-hearing participants listening to unprocessed or vocoded stimuli. In Experiment 1, tone thresholds were determined when masked by a sinusoidally amplitude-modulated band of noise (SAM and OFB) and by zero to four FBs of noise whose envelopes were either co- or anti-modulated with the OFB envelope. In Experiment 2, envelopes of those signals were extracted in a vocoder and used to modulate noise or sinusoidal carriers, thereby replacing the original temporal fine structure (TFS). Significant CMR of 3–10 dB was found in unprocessed conditions and although reduced to 2–6 dB, CMR was still significant after vocoding. CMR did not differ significantly between the sine and the noise vocoder, suggesting that the applied SAM determined the magnitude of CMR. Since CMR withstands vocoding, comodulation is hoped to improve detection in electric hearing.

2aPP3. The speech-critical band for vowels in steady and fluctuating backgrounds. Eric W. Healy (Dept. of Speech and Hearing Sci., The Ohio State Univ., 1070 Carmack Rd., Columbus, OH 43210, healy.66@osu.edu), Kimberlee A. Crass (Univ. of South Carolina, Columbia, SC 29208), and Frederic Apoux (The Ohio State Univ., Columbus, OH 43210)

Previous work investigating the frequency resolution employed to process English vowels indicated that the speech-critical band (S-CB) for vowels was greater than the psychophysical critical band. This result suggests that the density of information in the acoustic signal is below the resolving power of the auditory system, and therefore functional resolution is limited by the signal. In the current investigation, the S-CB for vowels was measured in steady and fluctuating backgrounds. Thirty-six normal-hearing listeners heard vowels in /hVd/ context. The stimuli were restricted in overall bandwidth to 1.5 octaves centered at 1500 Hz and presented using vocoder-like processing as 1, 3, 5, 7, 9, or 11 low-noise noise carrier bands. Recognition increased and reached asymptote as the number of constituent bands increased. The carrier bandwidth at performance asymptote was again found to be larger than the psychophysical critical band. Moreover, the resolution of the acoustic signal at performance asymptote was similar across conditions in which the stimuli were presented (i) in quiet, (ii) in steady noise, or (iii) in four-talker babble at various signal-to-noise ratios. These results suggest that the current measure of speech frequency resolution is robust across a number of adverse listening conditions. [Work supported by NIDCD.]

2aPP4. Release from speech-on-speech masking under degraded signal conditions. Virginia Best (School of Med. Sci., Univ. of Sydney, Sydney, New South Wales 2006, Australia and Hearing Res. Cntr., Boston Univ., Boston, MA 02215, ginbest@physiol.usyd.edu.au), Nicole Marrone (Northwestern Univ., Evanston, IL 60208 and Boston Univ., Boston, MA 02215), Christine Mason, and Gerald Kidd, Jr. (Boston Univ., Boston, MA 02215)

Previously, Marrone *et al.* [J. Acoust. Soc. Am. (2008)] compared spatial release from masking (SRM) for a three-talker mixture of similar sentences in normal-hearing (NH) listeners and listeners with sensorineural hearing loss (HL). The HL group showed significantly less SRM. In an earlier study [Marrone *et al.*, J. Acoust. Soc. Am. (2008)] the NH group showed less SRM when the masker sentences were time-reversed while in the colocated case a large "reversed-masker release" (RMR) was also found. To investigate these findings, some listeners from the HL group were tested in the reversed-masker conditions. The difference in SRM between listener groups was much smaller for reversed speech. However, the HL group also had much less RMR. Both the overall target-to-masker ratios (TMRs) at which comparisons are made and the spectral smearing associated with sensorineural hearing loss were likely factors, perhaps affecting amounts of energetic and informational masking. We explored these factors in a new group of NH listeners in a similar task with both forward and reversed speech systematically degraded. Performance was measured at seven TMRs for unprocessed as well as 32-, 16- or 8-channel vocoder speech. The results provide qualified support for an influence of TMR and spectral degradation on both SRM and RMR.

2aPP5. Auditory stream segregation using amplitude modulated vocoder bandpass noise. Yingjiu Nie and Peggy Nelson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, Minneapolis, MN 55455, peggynelson@umn.edu)

We investigated the contribution of amplitude modulation (AM) rate and spectral separation to stream segregation of vocoder bandpass noises. Stimulus sequences were repeated pairs of A and B bursts, where bursts were white noise or vocoder bandpass noise carrying sinusoidal AM (100% modulation depth). Bursts differed either in the center frequency of the noise, or the AM rate, or both. Eight vocoder bands were used. The lowest four bands (1-2-3-4) were combined into one bandpass noise (B bursts) and the higher three bands (3-4-5, 4-5-6, and 6-7-8) were combined to constitute the A bursts. Results show that stream segregation ability increases with greater spectral separation. Larger AM rate separations were associated with stronger segregation abilities, but not when A and B bursts were both white noise. Significant inter-subject differences were noted. Results suggest that, while both spectral and AM rate separation separations could be cues for auditory stream segregation, stream segregation based on AM rate is more successful when combined with spectral separation. Correlations between segregation ability and understanding of vocoded speech will be discussed.

2aPP6. A test battery to assess localization ability in simulated complex acoustic environments. Stefan Kerber and Bernhard U. Seeber (MRC Inst. of Hearing Res., Nottingham NG7 2RD, United Kingdom, s.kerber@ihr.mrc.ac.uk)

In complex acoustic environments, following a target sound is made difficult by the presence of noise and reverberation and especially hearing impaired people struggle understanding speech in such settings. Localizing the speaker is important in such situations to follow discussions and to gain additional benefit from visual cues. A test battery is proposed to quantify localization performance in different realistic environments and with laboratory tests when noise and reverberation are present. The aim is to relate real-life performance to that in simplified tests. In the localization tests, participants indicate the sound location with a visual pointer. Sounds are played in an anechoic chamber from loudspeakers across the frontal hemifield. Localization performance is measured in quiet, in diffuse background noise, and with reverberation of simulated rooms. The ability to cope with a single reflection is assessed in a precedence effect paradigm where participants localize a sound and its delayed copy for various delays and levels. The test battery is completed by questionnaires (e.g., SSQ), a speech, and a cognitive test. By cross-comparing results from the tests, we attempt to predict the performance in real-world environments from outcomes of simplified tests particularly in the presence of hearing impairment.

2aPP7. On the possible influence of spectral- and temporal-envelope cues in tests of sensitivity to temporal fine structure. Christophe Micheyl (Dept. of Psych., Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455-0344, cmicheyl@umn.edu), Huanping Dai (Univ. of Arizona, Tucson, AZ 85721), and Andrew J. Oxenham (Univ. of Minnesota, Minneapolis, MN 55455-0344)

The role of temporal fine structure (TFS) in speech and pitch perception has attracted considerable attention. Recent studies have suggested sensitivity to TFS even at high frequencies (8 kHz), well beyond the known limits of phase-locking in mammals, and a reduced ability to use TFS in hearing-impaired listeners. These conclusions were based on tasks involving the discrimination of complex tones or iterated-rippled noise, which had different power spectra but were (a) bandpass-filtered in a way that reduced tonotopic excitation-pattern (EP) cues and (b) had random component phases to eliminate temporal-envelope (TE) cues. In this study, we examine the possibility that residual EP and/or TE cues may have been available to the listeners in these experiments. Analytical and computational analyses indicated that although systematic TE differences were absent at the level of the stimuli, they were likely present at the output of the cochlea. Empirical studies tested whether the available TE and EP information might have influenced

performance. Preliminary results suggest that although listeners may not have been sensitive to the available TE cues, performance may have been influenced by EP cues in a way that could also explain the deficits shown by hearing-impaired listeners. [Work supported by NIH R01 DC05216.]

2aPP8. Discrimination of repetitive intervals by younger and older listeners. Peter Fitzgibbons (Dept. Hearing, Speech, and Lang Sci., Gallaudet Univ., 800 Florida Ave., NE, Washington, DC 20002) and Sandra Gordon-Salant (Univ. of Maryland, College Park, MD 20742)

The study measured listener sensitivity to increments in the inter-onset intervals (IOIs) separating successive 20-ms 4000-Hz tone bursts in isochronous sequences. Stimulus sequences contained from 2–6 tone bursts, separated equally by IOIs in the range of 25–100 ms across stimulus conditions. Difference limens (DLs) for increments of all tonal IOIs were measured to assess listener sensitivity to changes in sequence rate. A DL was also measured for increments of a single IOI located at a fixed position within 6-tone sequences. Listeners included younger and older normal-hearing adults and older adults with high-frequency hearing loss. The results revealed that the relative DLs for sequence rate decreased as the magnitude of the reference IOI and the number of sequence components increased. The relative DL for a single interval embedded within a six-tone sequence was smaller than corresponding DLs measured with two-tone sequences, but only for brief reference IOIs. The discrimination performance of the older listeners was poorer than that of the younger listeners, especially for two-tone sequences with the shortest reference IOIs. The findings are interpreted within the context of multiple-look mechanisms and possible age-related differences in the sensory coding of signal onsets. [Research supported by the National Institute on Aging, NIH.]

2aPP9. Age-related differences in auditory spatial attention depend on task switching complexity. Gurjit Singh (Dept. of Psych., Univ. of Toronto, 3359 Mississauga Rd. N, Mississauga, Ontorio L5L 1C6, gurjit@psych.utoronto.ca), M. Kathy Pichora-Fuller, and Bruce A. Schneider (Univ. of Toronto, Mississauga, ON, L5L 1C6, Canada)

We investigated the role of simple and complex switching of auditory attention in a multi-talker, multi-spatial listening situation with target location uncertainty. In all conditions, a target sentence from an edited version of the CRM corpus was presented from one spatial location and competing sentences from two different locations, with cues specifying the target's callsign identity and the probability of its location. Four probability specifications indicated the likelihood of the target being presented at the left, center, and right locations (0-100-0, 10-80-10, 20-60-20, and 33-33-33). In conditions requiring simple switches of attention, the task was to report key words from the target sentence. In conditions requiring complex attention switching, when target callsigns were presented from one of the unlikely locations, the listener's task was to report key words presented from the other unlikely location. A total of eight younger and eight older adults who had normal audiometric thresholds below 4 kHz participated. The key finding is that, whereas both age groups performed similarly in conditions requiring simple switches of attention, older performed worse than younger listeners in conditions requiring complex switching. Switching complexity may explain, in part, why older adults with relatively good audiograms report difficulty communicating in complex listening situations.

2aPP10. Psychophysical tuning curves and recognition of highpass and lowpass filtered speech for a person with an inverted V-shaped audiogram. Vinay Nagaraj (Dept. of Electrons and Telecommunications, Acoust. Res. Ctr., Norwegian Univ. of Sci. and Technol. (NTNU), NO-7491 Trondheim, Norway) and Brian Moore (Univ. of Cambridge, Cambridge CB2 3EB, United Kingdom)

A single subject whose audiogram resembled an inverted V shape (good hearing at 4000 Hz, poorer hearing at other frequencies) was tested. Results of the TEN(HL) test suggested that a dead region (DR) in the cochlea was present at all test frequencies from 500 to 3000 Hz, but no DR was present at 4000 Hz. Psychophysical tuning curves obtained using signal frequencies of 2000, 3000, 4000, and 6000 Hz showed upward shifted tips for the lowest two signal frequencies and a downward shifted tip for the highest frequency. The results suggested a functioning region extending from 3900 to 5100 Hz, with DRs outside that range. The identification of nonsense syllables, amplified according to the Cambridge formula, was measured as a function of lowpass or highpass filter cutoff frequency. The results suggested that useful speech information could only be extracted from a limited frequency range around 4000 Hz.

2aPP11. The relationship between quiet threshold and the forward-masking temporal effect. Elizabeth A. Strickland (estrick@purdue.edu) and Yonit A. Shames (Dept. SLHS, Purdue Univ., 500 Oval Dr., West Lafayette, IN 47907)

Research in our laboratory has shown that the temporal effect (TE) in simultaneous masking is consistent with a decrease in gain, possibly mediated by the medial olivocochlear reflex (MOCR). The TE in simultaneous masking is a decrease in threshold signal-to-masker ratio for a signal at masker onset when a precursor is added. This work has been extended to a forward-masking paradigm. A growth of masking (GOM) function is measured with a short-duration off-frequency masker (which should not activate the MOCR) and a 4-kHz signal. Then the masker level is fixed at a point on the lower leg of the GOM function, and threshold is measured with a long-duration precursor which is intended to activate the MOCR. The estimated input-output function is compared for a precursor at and well below the signal frequency. The difference in thresholds is the TE, which is also a measure of the change in gain. In simultaneous masking, the size of the TE decreases with increasing quiet threshold. In the present study, this relationship was examined for the forward-masking TE. The TE was measured as a function of precursor level for listeners who had a range of quiet thresholds, including listeners with mild cochlear hearing impairment. [Research supported by a grant from NIH(NIDCD) R01 DC008327.]

2aPP12. Interaural time difference thresholds as a function of the duration of the beginning of a sound in hearing-impaired adults. Michael A. Akeroyd and Fiona H. Guy (MRC Inst. of Hearing Res., Glasgow Royal Infirmary, 16 Alexandra Parade, Glasgow, United Kingdom, maa@ihr.gla.ac.uk)

The precedence effect indicates that the auditory system places most weight on spatial information at the onset of a sound. In this experiment, we measured how well hearing-impaired adults can ignore what comes immediately after the onset of a sound, as any limitations in that should interfere with localization in environments with lots of reflections. The stimulus was designed to be a simplified analog of a room impulse response: it consisted of two bursts of speech-shaped noise concatenated together: the first was short and given some ITD (representing an ideal onset that marked direction correctly), but the second was far longer and was interaurally uncorrelated (representing later reflections and reverberation from all possible directions). We measured psychometric functions (over the ITD and duration of the first burst) to determine the minimum duration of the first burst needed to report its direction. Presently, 19 listeners have completed the task. No significant correlation was found between minimum first-burst duration and hearing loss (better-ear loss = 3–50 dB), but the individual variation was considerable, especially so in those listeners with larger hearing losses. The results indicate that some listeners will have difficulty in ignoring irrelevant information after a sound's onset.

2aPP13. The effects of development and hearing impairment on the ability to understand speech in temporally and spectrally modulated noise. Joseph W. Hall, III, Emily Buss, and John H. Grose (Dept. Otolaryngol., Univ. UNC Chapel Hill, CB 7070, Chapel Hill, NC 27599, jwh@med.unc.edu)

This study examines the ability of hearing-impaired children to receive speech recognition benefit from temporal modulation, spectral modulation, or combined spectral and temporal modulation of a background noise. The task involves identification of words within the context of meaningful sentences presented in a speech-shaped noise background. Control groups include normal-hearing adults and children and hearing-impaired adults. The age range of the children is approximately 5–10 years. In the procedure, the masker level is held constant and the speech level is adaptively varied to track a criterion percent correct. Preliminary data suggest that both hearing-impaired children and hearing-impaired adults show a poorer than normal

ability to benefit from temporal and spectral modulation. The hearing-impaired children require approximately 2-dB higher signal-to-noise ratio than the hearing-impaired adults for most conditions. The normal-hearing adults and children show better masked thresholds than their hearing-impaired counterparts, with normal-hearing adults generally performing 3–5 dB better than normal-hearing children across conditions.

2aPP14. Performance of phonemically targeted processing in conjunction with compression processing with spectral enhancement. Jeffrey J. DiGiovanni (Auditory Psychophysics and Signal Processing Lab., School of Hearing, Speech and Lang. Sci., Ohio Univ., Athens, OH 45701, digiovan@ohio.edu), Janet C. Rutledge (Univ. of Maryland, Baltimore City, Baltimore, MD 21250), and Chessy S. Umble (Ohio Univ., Athens, OH 45701)

Sensorineural hearing loss is strongly linked to poorer speech intelligibility, especially in noise. The goal of the present study is to test, individually and in combination, two signal processing strategies designed to improve both consonant and vowel perception. In the first strategy, specific consonants were targeted for processing to increase amplitude and duration. For consonants with a duration increase, the adjacent vowel was decreased proportionately in order to maintain overall word and sentence duration. Second, Col-SE, an adaptive compression processing strategy incorporating spectral enhancement, was used to process stimuli. Hearing-in-noise-test sentences were presented monaurally to normal-hearing and hearing-impaired adults through an insert earphone in the presence of speech-shaped noise. Preliminary results show that normal-hearing listeners benefited from Col-SE processing in conjunction with minimal phonemically targeted speech processing more than with either processing strategy individually. Increases in consonant amplitude and duration beyond a modest amount reduce intelligibility. These data suggest that the two processing strategies are viable to improve speech intelligibility, but that there is a limit to the processing whereby benefits are no longer observed.

2aPP15. Effects of independent bilateral compressive amplification on lateralization of a single source. Ian M. Wiggins and Bernhard U. Seeber (MRC Inst. of Hearing Res., Nottingham NG7 2RD, United Kingdom, ian@ihr.mrc.ac.uk)

Use of compressive amplification in bilateral hearing aid fittings can disrupt binaural cues important to spatial hearing. The head-related transfer function introduces direction-dependent interaural time and level differences (ITDs and ILDs) which are consistent with one another. Independent bilateral compression, however, reduces ILDs such that they suggest a different, conflicting direction than ITDs. The reduction in ILDs is a dynamic effect that depends on the characteristics of the compression and the sound. Single-channel compression was applied over a wide, high-frequency band. Two conditions were run, with the high-frequency channel presented to listeners in isolation or recombined with an unprocessed low-frequency channel. Stimuli included pink noise bursts with varied onset slopes and rates of amplitude modulation and speech. The effects of compression on the perceived auditory objects were assessed using a semantic differential method, in which listeners rated various spatial attributes on scales between two bipolar adjectives, for example, image width was rated on a scale between "focused" and "diffuse." Additionally, a lateralization task was performed. Initial results show that for sounds with slow onsets, compression tends to shift image location or causes the image to split. Interestingly, image location can also be affected for speech, particularly if high-pass filtered.

2aPP16. Horizontal localization and hearing in noise ability in adults with sensorineural hearing loss using hearing aids with binaural processing. Amy R. Mullin (Dept. of Commun. Sci. and Disord., The Univ. of Texas at Austin, 1 University Station A1100, Austin, TX 78712, amyruthie@mail.utexas.edu)

The purpose of the study was to determine whether hearing aids with binaural processing improve performance during a localization and a hearing in noise task. The study included 15 participants between the ages of 29 and 68 who had a bilateral symmetrical sensorineural hearing loss and who had no prior hearing aid experience. Participants were fitted with Oticon Epoq XW receiver-in-the-ear hearing aids bilaterally. The participants completed a horizontal localization task and a hearing in noise task with three listening conditions: (1) without hearing aids (NO), (2) with hearing aids that were not linked (BIL), and (3) with hearing aids that were linked (BIN). For the horizontal localization task, 1.5-s pink noise bursts were used as the stimulus. Sentences from the Hearing in Noise Test were used as target stimuli for the hearing in noise task. Continuous discourse by one male and two female talkers was recorded and used as maskers. The specific aim of the localization and hearing in noise tasks was to determine which of the listening conditions resulted in the best score for each task. Data are still being collected and data analysis will follow.

2aPP17. Effect of waveform shape and polarity on loudness and on place pitch for cochlear implant users. Robert Carlyon, Olivier Macherey, and John Deeks (MRC Cognition and Brain Sci. Unit, 15 Chaucer Rd., Cambridge CB2 7EF, United Kingdom)

It has been shown that, for pseudomonophasic pulses presented in monopolar mode, less current is needed to achieve the same loudness when the short-high phase is anodic than when it is cathodic. Experiment 1 extended that finding, obtained with the Advanced Bionics (AB) device, to waveforms that can be implemented in other devices, using 99-pps, 32-μs/phase pulse trains. For AB and MedEl devices, stimuli were triphasic pulses whose central phase had twice the amplitude of the first and third phases. For the Nucleus device, stimuli were pairs of biphasic pulses with opposite leading polarity, each with a 58-μs interphase-gap, separated by 8 μs—resulting in two adjacent same-polarity phases in the center of the waveform. The current level needed was always 1–2 dB lower when the central portion was anodic than when it was cathodic—including for electrode 1 of the MedEl device, which is inserted deep into the cochlea. Experiment 2 showed that, for pseudomonophasic pulses in bipolar mode, (a) pitch is lower when the "short-high" pulse is anodic relative to the more-apical than to the more-basal electrode and (b) intermediate pitches can be produced by variations in waveform shape and polarity applied to the same bipolar pair.

2aPP18. Pitch-ranking of electric and acoustic stimuli by cochlear implant users with the HiRes and Fidelity120 speech processing strategies. Benjamin A. Russell and Gail S. Donaldson (Dept. of Comm. Sci. and Disord., Univ. of South Florida, Tampa, FL 33620, barussel@mail.usf.edu)

Estimates of place-pitch sensitivity in cochlear implant (CI) users are typically obtained using electric pulse trains presented directly to the implanted electrodes. Such estimates may overestimate the place-pitch sensitivity available to these listeners through their speech processors due to spectral smearing by the analysis filters. To determine the influence of speech processing on place-pitch sensitivity, electric pitch-ranking (EPR) and acoustic pitch-ranking (APR) thresholds were compared in four users of the Advanced Bionics CI. EPR thresholds were obtained for single- and dual-electrode pulse-train stimuli presented to electrodes near the center of the array. APR thresholds were obtained for pure tones having frequencies corresponding to the tonotopic locations of the electric pulse trains, using both the HiRes and Fidelity120 speech processing strategies. Counter to expectation, APR thresholds were similar to EPR thresholds for three of four subjects, and APR thresholds were smaller than EPR thresholds for the remaining subject. APR thresholds did not differ systematically for the HiRes and Fidelity120 strategies, consistent with Nogueira *et al.* [(in press). EURASIP J Adv Signal Proc]. Findings suggest that CI users can make use of across-channel cues when performing an APR task and that such cues can compensate for spectral smearing by the analysis filters.

2aPP19. Lowering mean fundamental frequency to improve speech intelligibility in noise under simulated electric-acoustic stimulation. Christopher A. Brown and Sid P. Bacon (Dept. of Speech and Hearing Sci., P.O. Box 870102, Tempe, AZ 85287-0102)

We have previously demonstrated that much or all of the benefits of electric-acoustic stimulation (EAS) can be achieved when the low-frequency speech is replaced with a tone that is modulated in both frequency and amplitude with F0 and amplitude envelope cues derived from the target speech. One advantage of this approach is that the frequency of the carrier tone can

be lowered with little decline in benefit. Lowering mean F0 has the potential to provide EAS benefit to CI users who have very limited residual hearing. One drawback to this approach is that it relies on the efficacy of the pitch extraction algorithm. This is problematic because pitch extractors have trouble in background noise, an environment in which F0 is particularly useful. Here, an alternative way of lowering mean F0 that is unaffected by the presence of noise is examined under simulated EAS conditions. Speech intelligibility was measured using an algorithm based on resampling and compared to performance with the pitch-based method we have used previously, at frequency shifts of 0, 0.5, and 1 octave. At the 0.5-octave shift, the resampling-based approach provided more benefit than the tone. However, at the 1-octave shift, resampling was less beneficial. [Work supported by NIDCD.]

2aPP20. Effect of auditory deprivation on binaural sensitivity in bilateral cochlear implant users. Ruth Y. Litovsky, Gary L. Jones, and Richard VanHoesel (Waisman Ctr., Univ. of Wisconsin, 1500 Highland Ave., Madison, WI 53705, litovsky@waisman.wisc.edu)

Increasing numbers of cochlear implant (CI) users receive Implants in both ears in an effort to restore spatial hearing abilities. A known limitation of commercial CI devices is lack of synchrony to the signal fine timing cues arriving at the two ears. In addition to these hardware limitations, which may contribute in substantial ways to the gap in performance typically seen between bilateral CI users and normal-hearing people, there are considerable inter-subject differences in the type and history of hearing loss. We use a research processor which enables inter-aurally coordinated pulsatile stimulation of selected pairs of electrodes in the right and left ears. This project is concerned with the effects of the age at onset of deafness, and place of stimulation, on binaural sensitivity. Thresholds for discrimination of inter-aural time difference (ITD) and inter-aural level difference(ILD) and pointer-identification for perceived intracranial position were measured. Prelingually deafened subjects had no sensitivity to ITD but retained ILD sensitivity. People with childhood- or adult-onset of deafness retained sensitivity to both ITD and ILD, some within normal-hearing level of performance on some conditions. The role of auditory deprivation in the emergence and preservation of binaural sensitivity will be discussed. [Work supported by NIH-NIDCD.]

TUESDAY MORNING, 20 APRIL 2010 HARBORSIDE B, 8:20 TO 10:15 A.M.

Session 2aSAa

Structural Acoustics and Vibration, Noise, Underwater Acoustics, Animal Bioacoustics, and INCE: Noise Control of Small Marine Vehicles

Joseph M. Cuschieri, Chair
Lockheed Martin Corp., 100 East 17th St., Riviera Beach, FL 33404

Chair's Introduction—8:20

Invited Papers

8:25

2aSAa1. An overview of unmanned underwater vehicle noise in the low to mid frequency bands. Jason D. Holmes (Raytheon BBN Technologies, 10 Moulton St., Cambridge, MA 02138, jholmes@bbn.com), William M. Carey (Boston Univ., Boston, MA 02215), and James F. Lynch (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

Unmanned (autonomous) underwater vehicles offer a unique, cost-effective platform for performing ocean acoustic measurements and surveys because multiple systems can be deployed from a single research vessel. Various data surveys can be performed including on-the-bottom geo-acoustic surveys over large areas, sub-sea-surface turbulence and microbubble structure surveys, and bi-static fish population surveys. To take advantage of the autonomous survey capabilities of underwater vehicles, sufficient signal-to-noise ratio and acoustic aperture (resolution) are required for acoustic measurements. The most commonly used vehicle sonar systems provide images utilizing high frequency hull mounted arrays and sources. In the lower-frequency band (100 Hz–10 kHz), however, vehicle noise levels and aperture remain the two most significant challenges, especially for passive systems. Previous experimental and analytical work has shown that a towed array with synthetic aperture processing can be used to obtain the necessary aperture. The major challenge of vehicle radiated noise is the focus of this paper, and both measured and archival results on vehicle noise are presented including an overview of levels, spectral character, and noise mechanisms for several vehicles. In particular, fundamental vehicle propulsion system noise is discussed along with implications on measurement performance and possible mitigation strategies.

8:45

2aSAa2. Unmanned underwater vehicle self-noise and implications for low-frequency sonar design. Brian Houston (Naval Res. Lab., Code 7130, 4555 Overlook Ave., Washington, DC 20375)

Sonars configured on small unmanned underwater vehicles tend to be higher-frequency systems that are relatively insensitive to the dominating self-noise associated with low-frequency energy sources. These include the main propulsor, control surface actuators, and navigation components. A new generation of vehicles is required having reduced low-frequency signatures in order to support the growing interest in low-frequency broadband active and passive sonars. In the work presented here, we discuss the impact of vehicle noise

on the performance of both real and synthetic receiver arrays. Self-noise mitigation methods and their impact on vehicle architecture will be discussed as well as the use of signal processing techniques employing acoustic holographic projection to reduce the impact of structural-borne noise. [Work supported by ONR.]

9:05

2aSAa3. Decreasing the radiated acoustic and vibration noise of a mid-size, prop-driven, autonomous underwater vehicle. Richard Zimmerman, Gerald D'Spain, and John Orcutt (Scripps Inst. of Oceanogr., Univ. California San Diego, 291 Rosecrans St., San Diego, CA 92106, rzimmerman@ucsd.edu)

Previously published efforts at decreasing the radiated acoustic and vibration noise of the propulsion system of an Odyssey IIb autonomous underwater vehicle (AUV) manufactured by Bluefin Robotics, Inc. resulted in noise levels recorded by an AUV-mounted hydrophone array that were at or below typical background ocean noise levels across much of the frequency band from 300 Hz to 10 kHz [IEEE J. Ocean. Eng. **30**, 179–187]. The modifications required to achieve this 20–50-dB reduction in propulsion noise levels will be reviewed in this talk. Recently, these modifications have been incorporated into the Bluefin 21 AUV at the Scripps Institution of Oceanography. In addition, the stepper motors in the linear actuators used to steer this AUV's vectored-thrust tail cone in depth and heading have been replaced. At-sea measurements show that the high-level, broadband transients that previously occurred every 2–3 s due to these actuators are no longer visible in the hydrophone data. Eliminating these sources of self-noise allow the vehicle to be used in marine biological studies without vehicle noise disturbing either the acoustic measurements themselves or the habitats under observation. [Work supported by the Office of Naval Research and British Petroleum.]

9:25

2aSAa4. Acoustic noise estimates for a quiet unmanned underwater vehicle. Carl A. Cascio (50 Myrock Ave., Waterford, CT 06385-3008)

Acoustical Technologies Inc. (ATI) has been tasked by a number of clients to predict the radiated noise of unmanned underwater vehicles (UUVs). Laboratory, dockside, and at sea measurements have been taken on 21-in.-diameter, 20-ft-long prototype vehicles. Data were obtained during operation of the propulsion motors, control surfaces, and other UUV components. Structural impact hammer testing was also used to estimate propagation path transfer functions. Acoustic noise and structural vibration sensors were recorded on the ATI multi-channel data acquisition system and analyzed to produce narrow and broad bandwidth spectral estimates over the 10-Hz–100-KHz frequency range. Radiated noise predictions from the component source level data and transfer functions were made and illustrate the importance of selecting quiet components and appropriate noise control. This paper takes a look at how quiet a 21-in.-diameter 20-ft-long UUV could be using what is currently known about typical UUV component hardware. This is not an estimate for a real UUV but a radiated noise model based on an ATI concept using quiet components, practical noise control, and generic transfer functions. Radiated noise estimates will be presented at several operating speeds.

2aSAa5. Turbulent boundary layers over hydrophone arrays. Craig N. Dolder (Dept. of Mech. Eng., The Univ.of Texas at Austin, 1 University Station C2200, Austin, TX 78712-0292, dolder@mail.utexas.edu), Michael R. Haberman, and Charles E. Tinney (The Univ. of Texas at Austin, Austin, TX 78712-0235)

The speed at which naval vessels can operate sonar receiver arrays is limited due to the noise produced by the formation of a turbulent boundary layer (TBL) over the hull of the vessel. Despite efforts in the signal processing community to reduce these signatures, flow noise levels continue to surpass the signal to noise ratio needed for effective sonar operation at high-vessel speeds. This study focuses on the hydrodynamic signatures induced by the turbulence and the means by which energy can be removed from the TBL structures to reduce pressure fluctuations on the array elements. The research presented here employs an array of hydrophones with high-spatial resolution to measure the dynamic surface pressure while simultaneously acquiring time resolved single-point velocity field measurements at various positions above the array and within the TBL using laser Doppler velocimetry. Classical statistical quantities are then computed to determine the relationship between the pressure and velocity fields. Further, an analysis of the wave number frequency makeup of the surface pressure provides insight into the convective nature of the pressure filtered flow structures. The findings provide helpful guidance in developing active control methods for reducing the TBL noise.

2aSAa6. Estimation and measurement of the acoustic signature of unmanned surface and underwater vehicles. Joseph Cuschieri (Lockheed Martin MS2, Undersea Systems, Riviera Beach, FL 33404)

As the use of unmanned surface and underwater vehicles (USVs and UUVs) increases, the acoustic signature and self-noise of these vehicles become important for certain type of applications. For low-detection probability the UUV or USV must have a low-acoustic signature. Furthermore, the self-noise of the UUV or USV may interfere with on-board sonar sensors, especially as more sophisticated sonar systems are being developed. As the concept of the USV or UUV is to design for low cost and low weight, with low availability of power, it is important to address the mitigation of the acoustic signature during the design phase through estimation techniques based on modeling and component level selection. Additionally during the test and integration phase, methods to measure the acoustic signature without resorting to expensive offshore measurements in "quiet" acoustic test ranges are required. In this presentation some of the approaches available for modeling and testing are discussed, together with the challenges faced by noise control engineers working these type problems and the type of noise sources that have to be addressed.

Structural Acoustics and Vibration and INCE: Space Vehicle Vibroacoustics

Dean E. Capone, Cochair
Pennsylvania State Univ., Applied Research Lab., P.O. Box 30, State College, PA 16804

Stephen C. Conlon, Cochair
Pennsylvania State Univ., Applied Research Lab., P.O. Box 30, State College, PA 16804

Invited Papers

10:30

2aSAb1. Vibroacoustics in airplane design. Evan B. Davis (The Boeing Co., P.O. Box 3707, MC 67-ML Seattle, WA 98124, evan.b.davis@boeing.com)

Structural and structural-acoustic (vibroacoustic) tools are used to predict the future performance of systems in order to guide design trades and system optimization decisions. The key questions to be answered are (1) what needs to be known? (2) how well does it need to be known? and (3) how reliable are the tools that will be used to make the decisions?

10:50

2aSAb2. Vibro-acoustic analysis of aerospace structures and issues with the available commercial prediction tools. Ali R. Kolaini and Dennis L. Kern (Jet Propulsion Lab., California Inst. of Technol., 4800 Oak Grove Dr., Pasadena, CA 91109-8099)

The results of vibro-acoustic modeling using the boundary element method (BEM) that predicts the acceleration responses at critical locations and at the interfaces of selected test articles are discussed. High fidelity acoustic tests were performed in a couple of cases and the results are used to validate the BEM predictions. The accuracy of the BEM and its ability to correctly predict the acceleration responses of lightweight structures are discussed in some detail. Also a combined system level BEM, consisting of structures very responsive to acoustic pressures, and force-limited base shake random vibration analysis was performed. We will discuss how these results may be used to derive random vibration specifications for the purpose of qualifying large and lightweight structures for flight. In this paper, we also discuss the commercially available vibro-acoustic tools that are used to predict the acoustic transmission losses and vibration responses of flight structures for lift-off (assumed to be diffuse) and transonic (turbulent boundary layer) acoustic fields. The pros and cons of using the statistical energy analysis, finite element analysis, BEM, and newly developed hybrid methods within these vibro-acoustic tools are discussed in some detail.

11:10

2aSAb3. Noise control in Space Shuttle Orbiter. Jerry R. Goodman (SF/Habitability & Enviromental Factors Div., NASA-JSC, Houston, TX 77058)

Acoustic limits in habitable space enclosures are required to ensure crew safety, comfort, and habitability. Noise control is implemented to ensure compliance with the acoustic requirements. The purpose of this paper is to describe problems with establishing acoustic requirements and noise control efforts, and to present examples of noise control treatments and design applications used in the Space Shuttle Orbiter. Included is the need to implement the design discipline of acoustics early in the design process and noise control throughout a program to ensure that limits are met. The use of dedicated personnel to provide expertise and oversight of acoustic requirements and noise control implementation has shown to be of value in the Space Shuttle Orbiter program. It is concluded that to achieve acceptable and safe noise levels in the crew habitable space, early resolution of acoustic requirements and implementation of effective noise control efforts are needed. Management support of established acoustic requirements and noise control efforts is essential.

8:05

2aSC1. Noise-suppression algorithms for improved speech intelligibility by normal-hearing and cochlear implant listeners. Philipos Loizou (Dept. of Elec. Eng., Univ. of Texas-Dallas, Richardson, TX 75080, loizou@utdallas.edu)

Much research in the past few decades focused on the development of noise reduction algorithms that can suppress background noise. While these single-microphone based algorithms have been proven to improve the subjective speech quality, they have not been effective in improving speech intelligibility. This is partly due to the fact that most noise-suppression algorithms introduce speech distortion and partly because most algorithms are not optimized to operate in a particular noisy environment. Furthermore, none of the existing noise-reduction algorithms was designed to optimize a metric that correlates highly with intelligibility. This talk will present intelligibility data collected with normal-hearing and cochlear implant listeners who were presented with noisy speech processed by environment-optimized algorithms. It will also present algorithms that were designed using metrics that correlate highly with speech intelligibility. The data from these studies suggest that it is possible to develop noise reduction algorithms that improve speech intelligibility provided some constraints are imposed on the design of the suppression function and/or the intended listening environment. Research supported by NIDCD/NIH.]

8:25

2aSC2. Subjective evaluation of the speech quality from speech enhancement and segregation algorithms. Vijay Mahadevan, Srikanth Vishnubhotla, and Carol Espy-Wilson (Univ. of Maryland, 3180, A V W Bldg., College Park, MD 20770)

Automatic separation of speech from noise and segregation of overlapping co-channel speech are two of the most challenging problems in speech processing. In previous work, we have developed algorithms to both enhance noisy speech and segregate overlapping speech streams. Our single-channel speech enhancement and speech segregation algorithms have shown better performance than other reported algorithms for automatic speech recognition. Additionally, objective evaluation scores of perceptual quality have shown a significant improvement following processing by our algorithms. In this study, we focus on subjective evaluation of these algorithms for human listeners. We investigate the intelligibility and quality of speech from our algorithm on normal-hearing listeners, cochlear implant users, and hearing impaired subjects. Our preliminary results indicate a significant improvement in the perceptual quality of the speech signal after being processed by our algorithm and suggest that the proposed algorithms can be used as a pre-processing block within the signal processing in hearing aid devices.

8:45

2aSC3. Speech recognition in loud noise using an ear-insert microphone. Tarun Pruthi, Mihai Despa, and Amit Juneja (Think A Move, Ltd., 23715 Mercantile Rd. Ste. 100, Beachwood, OH 44122)

Think A Move, Ltd. has developed a patented ear-insert microphone which captures speech as acoustic vibrations inside the ear canal. These vibrations propagate to the ear canal through the flesh and bones in the human skull. A high density foam on the earpiece seals the ear canal when the earpiece is inserted. Tests show that this earpiece provides an average passive noise cancellation (PNC) of around 38 dB for noises in Aurora database. Using an in-house speech command recognizer, with a short enrollment phase, on a database of 19 speakers (11 females, 8 males), speaking a vocabulary of 56 commands, an average accuracy of 85% has been observed in 90 dBA of tank, military vehicle, and machine gun noises. To further demonstrate the noise robustness of the earpiece as compared to external microphones, pilot tests were conducted on a small set of speakers to recognize speech commands recorded simultaneously with an external microphone and our ear-insert microphone with our recognizer. Results show that while the accuracy of the recognizer drops to 27% in 90 dBA noise from 96% in quiet for external microphone, it only drops to 92% in 90 dBA of noise from 95% in quiet for internal microphone.

9:05

2aSC4. Voice conversion for enhancing various types of body-conducted speech detected with non-audible murmur microphone. Tomoki Toda (Graduate School of Information Sci., Nara Inst. of Sci. and Technol., Takayama-cho 8916-5, Ikoma-shi, Nara 630-0192 Japan, tomoki@is.naist.jp)

Our proposed statistical voice conversion approach to enhancing various types of body-conducted speech detected with Non-Audible Murmur (NAM) microphone is presented in this talk. NAM microphone, one of the body-conductive microphones [Nakajima *et al.*, IEICE Trans. Inf. and Syst., **E89-D**, 1–8 (2006)], enables us to detect various types of body-conducted speech such as extremely

soft whisper, normal speech, and so on. Moreover, it is robust against external noise due to its noise-proof structure. To make speech communication more universal by effectively using these properties of NAM microphone, body-conducted speech enhancement techniques have been developed with a state-of-the-art statistical voice conversion algorithm [Toda *et al.*, IEEE Trans. ASLP, **15**, 2222–2235 (2007)]. The proposed techniques would bring a new paradigm to human-to-human speech communication: e.g., the use of body-conducted voiced speech for noise robust speech communication, the use of body-conducted unvoiced speech for silent speech communication, and the use of body-conducted artificial speech for speaking aid [T Toda *et al.*, Proc. ICASSP (2009) pp. 3601–3604]. This talk gives an overview of these promising techniques and presents their applications. [This research was supported in part by MIC SCOPE.]

9:25

2aSC5. Synthesizing speech from surface electromyography and acoustic Doppler sonar. Arthur R. Toth (Yap Inc., 2414 Shady Ave., Pittsburgh, PA 15217, atoth@cs.cmu.edu), Michael Wand (Univ. Karlsruhe, Karlsruhe, Baden-Württemberg 76131, Germany), Szu-Chen Stan Jou (ATC, ICL, Industrial Technol. Res. Inst., Chutung, Hsinchu, Taiwan 31040), Tanja Schultz (Univ. Karlsruhe, Karlsruhe, Baden-Württemberg 76131, Germany), Bhiksha Raj (Carnegie Mellon Univ., Pittsburgh, PA 15213), Kaustubh Kalgaonkar (Georgia Inst. of Technol., Atlanta, GA 30332), and Tony Ezzat (Mitsubishi Electric Res. Labs., Cambridge, MA 02139)

Numerous techniques have been devised to process speech audio in noise, but automatic speech recognition is difficult when the noise is too great. An alternative approach is to collect data that represent the speech production process but is less affected by noise in the speech audio range. Two such types of data come from surface electromyography (EMG) and acoustic Doppler sonar (ADS). EMG records muscle activation potentials. ADS records reflected ultrasound tones. Both can be used to measure facial movements related to speech, but they present their own challenges for automatic speech recognition. This work investigates the alternative approach of using these data sources for speech synthesis. The synthesis techniques explored in this work are based on Gaussian mixture model mapping techniques, which are commonly used for voice transformation. Voice transformation is traditionally concerned with changing the identity of speech audio signals, but others have demonstrated that such techniques can be used to transform different types of signals, such as non-audible murmur and electromagnetic articulography, to speech. This work demonstrates that such techniques also show promise for transforming EMG and ADS signals to speech.

9:45

2aSC6. Dealing with noise in automatic speech recognition. Douglas O'Shaughnessy (INRS-EMT, Univ. of Quebec, 800 de la Gauchetiere West, Ste. 6900, Montreal QC H5A 1K6, Canada)

While automatic speech recognition (ASR) can work very well for clean speech, recognition accuracy often degrades significantly when the speech signal is subject to corruption, as occurs in many communication channels. This paper will survey recent methods for handling various distortions in practical ASR. The problem is often presented as an issue of mismatch between the models that are created during prior training phases and unforeseen environmental acoustic conditions that occur during the normal test phase. As one can never anticipate all possible future conditions, ASR analysis must be able to adapt to a wide variety of distortions. Human listeners furnish a useful standard of comparison for ASR in that humans are much more flexible in handling unexpected acoustic distortions than current ASR is. Methods that adapt ASR features and models will be compared against ASR methods that enhance the noisy input speech. Other topics to be discussed will include estimation of noise and channel parameters, RASTA, and cepstral mean normalization. TRAP-TANDEM features Vector Taylor Series, joint speech and noise modeling, and advanced front-end feature extraction. Single-microphone versus multi-microphone approaches will also be discussed.

10:05—10:25 Break

10:25

2aSC7. Using speech models for separation in monaural and binaural contexts. Daniel P. Ellis, Ron J. Weiss, and Michael I. Mandel (Dept. of Elec. Eng., Columbia Univ., 500 W. 120th St., Rm. 1300, New York, NY 10027, dpwe@ee.columbia.edu)

When the number of sources exceeds the number of microphones, acoustic source separation is an underconstrained problem that must rely on additional constraints for solution. In a single-channel environment the expected behavior of the source—i.e., an acoustic model—is the only feasible basis for separation. We have developed an approach to monaural speech separation based on fitting parametric "eigenvoice" speaker-adapted models to both voices in a mixture. In a binaural, reverberant environment, the interaural characteristics of an acoustic source exhibit structure that can be used to separate even without prior knowledge of location or room characteristics. For this scenario, we have developed MESSL, an EM-based system for source separation and localization. MESSL's probabilistic foundation facilitates the incorporation of more specific source models; MESSL-EV incorporates the eigenvoice speech models for improved binaural separation in reverberant environments.

10:45

2aSC8. Dual stage probabilistic voice activity detector. Ivan Tashev (Microsoft Res., One Microsoft Way, Redmond, WA 98052), Andrew Lovitt, and Alex Acero (Microsoft Res., Redmond, WA 98052)

Voice activity detectors (VADs) are critical part of every speech enhancement and speech processing system. One of the major problems in practical realizations is to achieve robust VAD in conditions of background noise. Most of the statistical model-based approaches employ the Gaussian assumption in the discrete Fourier transform domain, which deviates from the real observation. In this paper, we propose a class of VAD algorithms based on several statistical models of the probability density functions of the magnitudes. In addition, we evaluate several approaches for time smoothing the magnitude response to achieve a more robust estimate. A large data corpus of in-car noise conditions is then used to optimize the parameters of the VAD, and the results are discussed.

11:05

2aSC9. Speech enhancement beyond minimum mean squared error with perceptual noise shaping. Lae-Hoon Kim, Kyung-Tae Kim, and Mark Hasegawa-Johnson (Dept. of ECE, Univ. of Illinois at Urbana-Champaign, 405 North Mathews Ave., Urbana, IL 61820, jhasegaw@illinois.edu)

Residual error signal after speech enhancement through linear filtering can be decomposed into two disjoint portions: speech signal distortion and background noise suppression. Speech is known to follow a super-Gaussian probabilistic distribution function (PDF) such as Laplacian, while background noise follows Gaussian PDF. Minimum mean squared error estimation requires only second order statistics not only for the noise but also for the speech. Therefore higher-order dependence of observed speech on the original speech may cause leakage of speech information into the error residual. This talk will formulate an optimization problem minimizing higher-order statistics (HOS) as well as energy of the signal distortion constrained by a limit on the maximum audibility of the residual noise. Note that due to the non-stationary nature of speech, we perform the speech enhancement in short overlapping frames. Minimizing HOS of the speech distortion ensures that the speech distortion includes only noise terms, with minimum leakage from the speech signal. The constraint on the residual noise margin prevents over-suppressing, which may result in unwanted speech distortion.

11:25

2aSC10. The role of temporal modulation processing in speech/non-speech discrimination tasks. Hong You and Abeer Alwan (Dept. of Elec. Eng., UCLA, 405 Hilgard Ave., Los Angeles, CA 90095, alwan@ee.ucla.edu)

In this paper, temporal modulation characteristics of speech and noise from the point of view of speech/non-speech discrimination are analyzed. Although previous psychoacoustic studies have shown that temporal modulation components below 16 Hz are important for speech intelligibility, there is no reported analysis of modulation components from the point of view of speech/noise discrimination. Our data-driven analysis of modulation components of speech and noise reveals that speech and noise are more accurately classified by low-pass modulation frequencies than band-pass ones [H. You and A. Alwan, in Interspeech Proceedings (2009) pp. 36–39]. Effects of additive noise on the modulation characteristics of speech signals are also analyzed. Based on the analysis, a frequency adaptive modulation processing algorithm for a noise robust automatic speech recognition task is proposed. Speech recognition experiments are performed to compare the proposed algorithm with other noise robust front-ends, including RASTA and ETSI-AFE. Recognition results show that the frequency adaptive modulation processing algorithm is promising and is of low complexity. [Work supported in part by NSF.]

2aSC11. Relevant spectro-temporal modulations for robust speech and nonspeech classification. Sridhar Krishna Nemala and Mounya Elhilali (Dept. of Elec. & Comput. Eng., 3400 N. Charles St., Barton 105, Baltimore, MD 21218)

Robust speech/non-speech classification is an important step in a variety of speech processing applications. For example, in speech and speaker recognition systems designed to work in real world environments, a robust discrimination of speech from other sounds is an essential pre-processing step. Auditory-based features at multiple-scales of time and spectral resolution have been shown to be very useful for the speech/non-speech classification task [Mesgarani *et al.*, IEEE Trans. Speech Audio Process. **10**, 504–516 (2002)]. The features used are computed using a biologically inspired auditory model that maps a given sound to a high-dimensional representation of its spectro-temporal modulations (mimicking the various stages taking place along the auditory pathway from the periphery all the way to the primary auditory cortex). In this work, we analyze the contribution of different temporal and spectral modulations for robust speech/non-speech classification. The results suggest the temporal modulations in the range 12–22 Hz, and spectral modulations in the range 1.5–4 cycles/octave are particularly useful to achieve the robustness in highly noisy and reverberant environments.

9:15

2aSP1. Estimating the size and spatial distribution of bubble clouds in an underwater acoustic test tank. Fred D. Holt, IV (Appl. Res. Lab. and Graduate Program in Acoust., The Penn State Univ., State College, PA 16804), J. Daniel Park, R. Lee Culver (The Penn State Univ., State College, PA 16804), David Coles, and Timothy Leighton (Univ. of Southampton, Southampton S017 1BJ, United Kingdom)

The AB Wood Underwater Acoustic test tank at ISVR, University of Southampton, UK is outfitted with a Venturi-based apparatus for generating bubble clouds containing a large range of bubble sizes. Larger bubbles are allowed to rise out in a settling tank before the nearly opaque bubbly water is pumped into the acoustic test tank through a discharge manifold on the bottom. A series of acoustic attenuation measurements was made at AB Wood in July 2008 in order to estimate the size and spatial distribution of bubbles in the cloud. An acoustic projector transmitted 1-ms pure tones from 25 to 100 kHz, which were received at a co-linear three-element horizontal array. The receive hydrophones were spaced 0.5 m apart, with the center hydrophone placed directly over the bubble discharge location. Measurements were taken on-axis with the projector, and at three distances off-axis,

in 12-in. increments. The attenuation measurements were used to estimate the size and spatial distribution of bubbles within the cloud. The bubble size data will be used to support a study of the effect of nearby bubbles on array performance degradation. [Work sponsored by the Office of Naval Research, Code 321.]

9:30

2aSP2. Measurement and analysis of array gain degradation due to bubble scattering. J. Daniel Park, Fred D. Holt, IV, R. Lee Culver (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804), David Coles, and Timothy Leighton (Univ. of Southampton, Southampton, United Kingdom)

When an array is steered in the direction of a signal, array gain (AG) is maximum when the signal is coherent across the array, meaning that the signals add in phase for all elements and the noise or interference is incoherent across the array (i.e., it adds with random phase). For an acoustic array operating in the ocean, we would like to understand the degree to which scattering by nearby bubbles degrades AG. Bubble attenuation can also degrade array performance by attenuating the signal of interest, but that is separate from AG degradation. The degradation of AG due to scattering by nearby bubbles has been measured for different bubble densities. We have analyzed the relationship between bubble density at the array and the degradation in AG. We present probability density functions (pdfs) of signal amplitude and phase at the array elements. The amplitude pdfs can be approximated as a Rayleigh–Rice distribution, and the phase pdfs follow the von Mises distribution. With independence assumed between amplitude and phase distributions, simulated distributions generate array gain distributions closely matching the measured AG distribution. [Work sponsored by ONR Undersea Signal Processing.]

9:45

2aSP3. Array performance in a complex littoral environment. Steven L. Means (Naval Res. Lab., Code 7120, 4555 Overlook Ave. SW, Washington, DC 20375, steve.means@nrl.navy.mil), Richard M. Heitmeyer (Global Strategies Group Inc., Washington, DC 20375), and Stephen C. Wales (Naval Res. Lab., Washington, DC 20375)

In August of 2007 a long (~1-km), 500 phone linear array began collecting acoustic data in the waters (~260 m in depth) approximately 12 km off the coast of Fort Lauderdale, FL. The array consisted of four, 125-phone segments deployed closely along a line running nearly east and west. Marine-band radar data were collected concurrently so that shipping in the region of the array could be tracked. The data considered in this analysis were obtained over the month of August and contains ~19 days of measurements. Array performance is investigated by beamforming at a number of frequencies (up to ~420 Hz) and apertures then determining cumulative distribution functions as a function of bearing and noise window statistics. The results are compared for day, night, weekday, and weekend measurements during which the local shipping varies significantly. Additionally, ship tracks obtained from the acoustic array are compared against those obtained from radar. [Work supported by ONR base funding at NRL.]

10:00

2aSP4. Results of hermetic transform signal processing to enhance the resolution and array gain of underwater acoustic arrays. Harvey C. Woodsum (Bayshore Labs Div., Sonetech Corp., 10 Commerce Park North Unit 1, Bedford, NH 03110)

Results of applying the discrete hermetic transform (DHT) to the beamforming of underwater acoustic arrays are presented in terms of measured reductions in beam mainlobe width as well as the associated improvement in directivity index/array gain for practical cases of interest. Application of the DHT to array beamforming is shown to produce substantially enhanced resolution relative to the conventional beamforming diffraction limit as well as significant enhancement in array gain against ambient noise, without the use of data adaptive or nonlinear processing. As a result, enhanced sonar signal detection and/or the ability to use substantially smaller than normal arrays can be accomplished through the judicious use of DHT based beamforming algorithms. Results are favorably compared to theoretical predictions of algorithm performance.

10:15—10:30 Break

10:30

2aSP5. A mobile acoustic multiple-input/multiple-ouput communication testbed. Aijun Song, Mohsen Badiey, and Arthur Trembanis (College of Earth, Ocean, and Environment, Robinson Hall-114, Newark, DE 19716)

Underwater acoustic data communication is critical for naval and scientific underwater missions. For example, high-rate telemetry between underway autonomous underwater vehicles (AUVs) and surface platforms can facilitate adaptive sampling of the ocean. Multiple-input/multiple-output (MIMO) systems can deliver significant increased channel capacity for underwater communications. At the University of Delaware, an acoustic MIMO communication testbed on a Gavia AUV has been developed for digital communication measurements at the frequency band of 20–30 kHz. The Gavia AUV is a modular, small-size vehicle (20 cm in diameter, 77 kg in air) with a depth rating of 200 m. With advanced navigation systems (INS) and surface communication capabilities (WiFi and Iridium), it has been tested through various coastal-ocean missions. The MIMO system on board is designed for easy, low-cost deployment, and is capable of conducting acoustical sampling via a towed array with or without single-element or multi-element source transmission. In the presentation, the design concept, component detail, and engineering test results will be shown. [Work supported by ONR 321OA.]

10:45

2aSP6. Experimental validation of Helmholtz equation least squares when the Nyquist spatial sampling requirement is violated. Richard E. Dziklinski, III and Sean F. Wu (Dept. of Mech. Eng., Wayne State Univ., 5050 Anthony Wayne Dr., Detroit, MI 48202)

Previous numerical studies [Dziklinsky and Wu, J. Acoust. Soc. Am. (2009)] have shown that Helmholtz equation least squares (HELSs) enable one to violate the spatial Nyquist sampling frequency and stand-off distance requirements inherent in Fourier acoustics. A direct benefit of this severe under sampling using HELS is a significant saving in measurement and computational effort in locating acoustic point sources in practice without loss of the required spatial resolution. The presented paper aims at validating the previous numerical studies by conducting experiments on locating two incoherent point sources separated by a small distance of 6.25 mm via HELS. The acoustic pressures are measured by a 5×5 microphone array over a 50×50 mm square plane at varying stand-off distances with fixed microphone spacing of 12.5 mm. The considered source frequencies are well above the spatial Nyquist sampling frequency. Results show that HELS is capable of locating point sources when stand-off distance is 10 mm or less and SNR is 10 dB or higher. Similar results obtained by using planar Fourier acoustics are also presented for comparison purposes.

11:00

2aSP7. Implementation of sound ball with acoustic contrast control method. Min-Ho Song (Grad. School of Culture Technol., KAIST, Sci. Town, Daejon 305-701, Korea, godspd@kaist.ac.kr) and Yang-Hann Kim (KAIST, Sci. Town, Daejon 305-701, Korea)

It is well known that the problem of generating sound in the region of interest, by using finite number of speakers, is mathematically ill-posed. This problem can be well-posed; in other words, the way to drive the speakers to make desired sound field in the prescribed zone can be directly determined by using energy measure, which is called acoustic brightness, contrast control method. With the method, we can manuver sound ball or balls in space which can generate personal listening zone or virtual sound source. In this paper, a novel way that guides a way to design the speaker array in space to generate sound ball will be introduced. The signals between the zone of interest and the speakers are interpreted as vector spaces. The vector

space interpretation certainly provides insight to design the arrays for acoustic brightness or contrast control. Theoretical formulation in vector space and experimental results of generating the sound ball will be introduced.

11:15

2aSP8. Mode filters and energy conservation. Ilya A. Udovydchenkov (Dept. AOPE, MS#9, Woods Hole Oceanograph. Inst., 266 Woods Hole Rd., Woods Hole, MA 02543), Michael G. Brown (Univ. of Miami, Miami, FL 33149), and Irina I. Rypina (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

The discrete form of the mode filtering problem is considered. The relevant equations constitute a linear inverse problem. Solutions to problems of this type, including the mode filtering problem, are subject to a well-known trade-off between resolution and precision. But, unlike the typical linear inverse problem, the correctly formulated mode filtering problem is subject to an energy conservation constraint. This work focuses on the importance of satisfying, approximately at least, the energy conservation constraint when mode filtering is performed. [Work supported by ONR.]

2aUW1. Studies of acoustic particle velocity measurements in the ocean. Gerald D'Spain (Marine Physical Lab., Scripps Inst. of Oceanogr., 291 Rosecrans St., San Diego, CA 92106, gdspain@ucsd.edu)

This presentation reviews previously published results from applying various signal and array processing methods to the analysis of simultaneous measurements of acoustic particle velocity and acoustic pressure in the ocean. Particular focus is placed on interpreting the properties of the elements of the pressure/particle velocity data cross spectral matrix. These properties are used to evaluate measurements of the deep ocean infrasonic noise field during a period of rapidly changing wind speed. Numerical modeling of the evolution in directionality of the active and reactive acoustic intensity vectors during this time period demonstrates the influence of the continental slope on the flow of underwater acoustic energy. [Work supported by the Office of Naval Research.]

8:50

2aUW2. An ultra-low-frequency acoustic vector sensor. Dimitri M. Donskoy (Stevens Inst. of Technol., Hoboken, NJ 07030, ddonskoy@stevens.edu) and Benjamin A. Cray (Naval Undersea Warfare Ctr., Newport, RI 02841)

Passive underwater acoustic surveillance and oceanographic studies, for the most, have not been conducted at ultra-low frequencies (ULFs), from 0.01 Hz to a few hertz. One of the primary reasons for neglecting ULF has been the lack of sensitive, and directional, ULF acoustic sensors. Existing, and many prototyped, vector sensor designs are inertia based and thus not well suited to ULF, typically these sensors that operate at frequencies well above 100 Hz. A new type of acoustic vector sensor, capable of operating within the ULF range and possessing unsurpassed sensitivity (minimal detectable signal levels well below 1 nm/s) was built, tested, and calibrated at the Naval Undersea Warfare Center, Newport, RI. The measurements have validated the proposed detection concept, provided initial performance parameters, and have set forth the foundation for designing the next generation of fieldable prototypes.

9:10

2aUW3. Modeling the acoustic vector field using parabolic equation and normal mode models. Kevin B. Smith (Dept. of Phys., Naval Postgrad. School, Monterey, CA 93943)

Numerical algorithms for computing the acoustic vector field, i.e., particle velocity and pressure from an acoustic propagation model, are introduced. Implementation using both a parabolic equation and normal mode approach is considered. The parabolic equation model employed uses a split-step Fourier algorithm, although application of the technique is general to other parabolic equation models. Expressions for the normal mode equations are also presented for both coupled and adiabatic mode models. Results for a Pekeris waveguide are presented for a point source, prompting a brief discussion of multipath influence on the estimation of the direction of energy flow. Approximate analytic solutions are used to validate the general results of both models. Results for the range-dependent benchmark wedge are then presented and show generally good agreement between the two types of models. The results from the two-way, coupled normal mode model provide potential benchmark solutions for the wedge and a means of confirming the accuracy of other models. [Work supported by ONR 321OA.]

9:30

2aUW4. The cooperative array performance experiment: A joint China-US vector field experiment. Daniel Rouseff (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, rouseff@apl.washington.edu), Zhongkang Wang, Shihong Zhou, Hong Meng, and Lisheng Zhou (Hangzhou Appl. Acoust. Res. Inst., Hangzhou City, China)

The cooperative array performance experiment (CAPEx) was performed in Lake Washington near Seattle in September 2009. Acoustic transmissions in the 1.5–4 kHz band were recorded simultaneously on two vertical arrays: one a conventional 32-element pressure-sensor array and the other an 8-element array that measured both pressure and the three orthogonal components of acoustic particle velocity at each element. The present talk is an overview of both the data collected and the hardware used during CAPEx. Data were collected on the stationary arrays for both stationary- and towed-source scenarios in water 60 m deep. The source-receiver range varied between 10 m and 4 km. The data collected at short range demonstrate the relationship between the pressure and particle velocity fields. At more distant ranges, the particle velocity data are used to estimate the bearing to the source. Experimental results are compared to predictions generated using numerical models. [Work supported by ONR.]

9:45

2aUW5. Using the vector sensors as receivers for underwater acoustic communications. T. C. Yang and Alenka Zajić (Naval Res. Lab., Washington, DC 20375, yang@wave.nrl.navy.mil)

A vector sensor package (VSP) generally consists of three orthogonally oriented sensors and an omni directional hydrophone, all packed in a small compact housing. Because of its small size, the VSP might be more useful than a hydrophone array. In contrast to the hydrophone array, which has a non-negligible vertical aperture and is difficult to deploy on an autonomous underwater vehicle (AUV), the VSP can be easily deployed on the AUV and used for underwater acoustic communications (UAC). However, the usefulness of the VSP depends on whether it provides the same spatial diversity as a hydrophone array. Hence, to address this question, this paper investigates the spatial correlation characteristics of the VSP and the bit error rates and/or output SNRs, based on at sea data, between the VSPs and the hydrophone array. The data were collected in May of 2009 on the New Jersey shelf. A hydrophone array and a VSP were deployed close to the ocean bottom and used for UACs. The source was towed at a slow speed, transmitting signals of various modulations at distances 0.5 to a few kilometers from the receivers. Initial results will be presented. [Work supported by the Office of Naval Research.]

10:30

2aUW6. Sensitivity analysis of acoustic channel characteristics to sea surface spectral uncertainty. Allan Rosenberg and Qinqing Zhang (11100 Johns Hopkins Rd., Laurel, MD 20723)

The interaction of sound with the sea surface is important for underwater acoustic communications. The high-frequency sound used, 10 kHz and above, is sensitive to surface wave frequencies well above the ~0.5-Hz upper limit routinely measured by wave buoys. Accurately measuring the surface in the short gravity wave regime is difficult and even the general shape of the spectrum is uncertain. The primary measurement challenge is to disentangle the effects of the instrument, including its supporting structure, from what one is attempting to measure. There have been attempts to combine the copious data at low frequencies and the sparse data at higher frequencies to produce model spectra depending on a few parameters that describe the spectrum in the short gravity wave region and above. In this work we study the sensitivity of the acoustic channel characteristics such as the channel impulse response to our uncertain spectral knowledge. We merge low-frequency surface wave spectra measured at NDBC 44014, with various modeled higher-frequency spectra generated from measured environmental parameters to get unified spectra. For each unified spectrum we generate surface realizations, feed them into a rough surface parabolic equation model to compute a channel impulse response, and compare the impulse responses under different surfaces.

10:45

2aUW7. Determination of the location of a sound source in three dimensional based on acoustic vector sensors on the ground. Hans Elias de Bree (Microflown Technologies B.V., P.O. Box 300, 6900 AH Zevenaar, The Netherlands, debree@microflown.com)

An acoustic vector sensor (AVS) consists of three orthogonal particle velocity sensors in combination with a sound pressure microphone. In several publications it has been proven that multiple sources can be located in three dimensions with a single AVS. In this paper it will be shown that it is possible to measure the instantaneous location (this means bearing, elevation, and range) of a single dominant sound source in three dimensional space as well as the angle dependent local ground impedance. Theory as well as results of experiments will be presented.

11:00

2aUW8. A particle velocity gradient beam forming system. Hans-Elias de Bree (Microflown Technologies B.V., P.O. Box 300, 6800AH Zevenaar, The Netherlands, debree@microflown.com)

The topic of this paper is the determination of the acoustic source distribution in the far field with a small, three dimensional (3-D) system consisting closely spaced sound pressure sensitive microphones and particle velocity sensitive Microflown. Sound pressure sensors do have a zero order directionality (that is, no directionality). Particle velocity vector sensors have a first order directionality (this is a cosine shape directionality). With two closely spaced zero order sensors, a first order system can be created. Disadvantages are the low sensitivity for low frequencies and a limited high-frequency response. With two closely spaced first order sensors, a second order system is created. The directionality is a squared cosine shape. With this higher directivity it is possible to create a very small 3-D beam forming system with a reasonable resolution which is the topic of this paper. A second order system can be made with accelerometers or pressure sensors; however, the low-frequency response is very poor. The Microflown has a very high sensitivity at low frequencies so the velocity gradient signal is good. In this paper the velocity gradient method is presented, and a 3-D velocity gradient system is demonstrated.

11:15

2aUW9. An overview of underwater acoustic communication via particle velocity channels: Channel modeling and transceiver design. Ali Abdi (Dept. Elec. & Comput. Eng., New Jersey Inst. of Technol., 323 King Blvd., Newark, NJ, 07102, ali.abdi@njit.edu), Aijun Song, and Mohsen Badiey (Univ. of Delaware, Newark, DE 19716)

Over the past few decades, the scalar component of the acoustic field, i.e., the pressure channel, has been extensively used for underwater acoustic communication. In recent years, vector components of the acoustic field, such as the three components of acoustic particle velocity, are suggested for underwater communication. Consequently, one can use vector sensors for underwater communication. The small size of vector sensor arrays is an advantage, compared to pressure sensor arrays commonly used in underwater acoustic communication. This is because velocity channels can be measured at a single point in space. So, each vector sensor serves as a multi-channel device. This is particularly useful for compact underwater platforms, such as autonomous underwater vehicles (AUVs). Funded by the National Science Foundation, our research efforts focus on the research problems in two closely related categories: channel modeling and transceiver design. Channel modeling research aims at characterization of those aspects of acoustic particle velocity channels such as delay and Doppler spread, and transmission loss, which determine the communication system performance. Transceiver design addresses optimal use of vector sensors and particle velocity for data modulation and demodulation, equalization, synchronization, and coding. [Work supported by NSF.]

Session 2pAAa

Architectural Acoustics and Speech Communication: Speech Intelligibility and Privacy

Eric L. Reuter, Chair
Reuter Associates, LLC, P.O. Box 4623, Portsmouth, NH 03802-4623

Invited Papers

1:00

2pAAa1. Speech privacy: The new 2010 architectural guidelines. David Sykes (Remington Partners, 23 Buckingham St., Cambridge, MA 02138, dsykes@speechprivacy.org), William Cavanaugh, and Gregory Tocci (Cavanaugh Tocci Assoc., Sudbury, MA)

In January, speech privacy performance criteria were released in the 2010 Guidelines for the Design and Construction of Healthcare Facilities, which is accepted as code by ~42 states and many federal, state, and municipal agencies. This is the first acceptance by regulatory authorities of speech privacy and will impact healthcare facilities across the United States. The criteria have also been adopted as the reference standard for two environmental quality credits in LEED HC and GGHCv2. In addition new 1.5 million dollar penalties took effect on Nov 30, 2009 for violations of the HIPAA Privacy Rule, the first serious penalties since the law was written in 1995. The new speech privacy criteria simplify enforcement by accepting as "equivalent" all four of the established measurement systems (articulation index, privacy index and sound transmission index, and speech intelligibility index), thereby leaving regulators, courts, and professionals with a choice. The developers are working on the next edition (2014) when they hope to introduce the fifth and newest measurement system, S/N(A), which provides specific metrics for both "confidential" and "secure" privacy. Acoustical professionals will need to assist healthcare organizations, regulatory authorities, judges, lawyers, and consumer groups to understand the new criteria.

1:20

2pAAa2. Speech privacy in healthcare: A facility director's and staff. Nikki Rineer (Hope Within Community Health Ctr., 4748 East Harrisburg Pike, Elizabethtown, PA 17022)

Hope Within is a healthcare center that has gone the extra mile to have their architecture spaces evaluated for speech privacy. Once identified they have made accommodations to minimize the risk of overheard conversations and have an ongoing program in place to maintain and improve speech privacy performance. Much has been discussed regarding speech privacy in healthcare, but this paper will discuss the point of view from the director and staff.

1:40

2pAAa3. Measurement of speech privacy of closed rooms using the American Society for Testing and Materials ASTM E2638. Bradford N. Gover and John S. Bradley (Inst. for Res. in Construction, Natl. Res. Council, Ottawa, ON K1A 0R6, Canada, brad.gover@nrc-cnrc.gc.ca)

The degree of speech privacy between various locations in buildings has been of increasing concern, driven in part by legislative requirements and the desire for increased security. Until recently, ASTM E1130 "Standard Test Method for Objective Measurement of Speech Privacy in Open Plan Spaces Using Articulation Index" has been the only standardized measurement method available. This test method is, for a variety of reasons, not suitable for assessing speech privacy of closed rooms or conditions of very high-speech privacy. These issues are, however, addressed by the new ASTM E2638 "Standard Test Method for Objective Measurement of the Speech Privacy Provided by a Closed Room." ASTM E2638 describes a test method suitable for enclosed rooms of nearly all sizes and defines a measure called speech privacy class that can be used to accurately rate speech privacy over a very broad range, from no privacy to very high secrecy. The new E2638 measurement method will be described, and measurements in several real rooms will be presented.

2:00

2pAAa4. Setting speech privacy criteria for closed rooms in terms of speech privacy class values. John S. Bradley and Bradford N. Gover (Natl. Res. Council, 1200 Montreal Rd., Ottawa, Canada)

The new ASTM E2638 standard defines speech privacy class (SPC) as the sum of the measured average noise level at the position of a potential eavesdropper outside the room and the measured level difference between a source room average and the transmitted levels at the same potential eavesdropper location. For a given situation, the likelihood of transmitted speech being audible or intelligible can be related to the probability of higher-speech levels occurring in the meeting room. Increasing speech privacy criteria can be defined in terms of increasing SPC values. For a particular meeting room speech level, there is an SPC value for which transmitted speech would be below the threshold of intelligibility or even below the threshold of audibility. One can therefore create a set of increasing SPC values corresponding to increasing speech privacy and for each SPC value, one can give the probability of transmitted speech being either audible or intelligible. This paper describes a new procedure that makes it possible to specify degrees of speech privacy for meeting rooms and offices in terms of the expected risk of a privacy lapse and varying from quite minimal to extremely high-speech privacy.

2:20

2pAAa5. Low background noise is needed for good student-to-student classroom communication. David Lubman (DL Acoust., 14301 Middletown Ln., Westminster, CA 92683, dlubman@dlacoustics.com)

ANSI standard S12.60 requires that background noise not exceed 35 dBA in unoccupied lecture classrooms. Despite the strong and broad research basis for ANSI's 35-dBA requirement, some classroom noise guidelines permit 45 dBA (notably California Collaborative for High Performance Schools and Leadership in Energy and Environmental Design). How did this come about? The 45-dBA limit was a compromise between the 50-dBA guidelines then prevailing and ANSI's 35-dBA limits. There is no audiological basis for a 45-dBA BNL limit. With 45-dBA BNLs, the speech to noise ratio (SNR) in the rear of small classrooms is well below the 15-dB minimum required for sustained learning. With 35-dBA BNLs, the SNR approaches ANSI's 15-dB minimum. It is underappreciated that BNLs of 35 dBA or less also promote better student-to-student (STS) communication. For every 10 dB of background noise reduction, the physical range of STS communication increases by a factor of about 3.16, and the floor area encompassed increases by a factor of 10. As BNL is reduced, eventually all classroom occupants are within communication range.

2:40

2pAAa6. A primer on classroom acoustics. Gary W. Siebein (School of Architecture, Univ. of Florida, P.O. Box 115702, Gainesville, FL 32611), Reece Skelton, Keely M. Siebein, and Chris P. Jones (Siebein Assoc., Inc., Gainesville, FL 32607)

Research involving quantitative and qualitative evaluation of classroom activities has shown that speech perception and intelligibility in elementary, middle, and high schools can be measured, modeled, and simulated based on an impulse response-based theory. The theory combines the vocal production of the speaker, the hearing abilities of the listeners, the strength of the direct sound and early sound reflections from room surfaces, duration of longer term reverberation, and the level, type, information content, and frequency content of intruding sounds. Regression models relating measured intelligibility in classrooms to measured, modeled, and simulated sounds show model $r2 > 0.90$. A model relating speech perception score to the level, type, information content, and frequency content of typical classroom noise reaches $r2 > 0.90$ as well. The impulse response based measures are reduced to a series of architectural systems that can be implemented using alternate construction systems to meet budget requirements.

3:00—3:15 Break

3:15

2pAAa7. Assessing the potential intelligibility of assistive listening systems. Peter Mapp (Peter Mapp Assoc., Colchester, United Kingdom, peter@petermapp.com)

Approximately 14% of the general population suffer from a noticeable degree of hearing loss and would benefit from some form of hearing assistance or deaf aid. Recent DDA legislation and requirements mean that many more assistive listening systems are being installed, yet there is evidence to suggest that many of these systems fail to perform adequately and provide the benefit expected. There has also been a proliferation of classroom and lecture room "soundfield" systems, with much conflicting evidence as to their apparent effectiveness. This paper reports on the results of some trial acoustic performance testing of such systems. In particular, the effects of system microphone type, distance, and location are shown to have a significant effect on the resultant performance. The potential of using the sound transmission index and, in particular, STIPa for carrying out installation surveys has been investigated, and a number of practical problems are highlighted. The requirements for a suitable acoustic test source to mimic a human talker are discussed. The findings discussed in the paper are also relevant to the installation and testing of "soundfield systems."

3:35

2pAAa8. Effects of noise type and signal-to-noise ratio on speech intelligibility and the speech transmission index. Stephen D. Secules (Arup Acoust., 13 Fitzroy St., London W1T 4BQ, United Kingdom)

The STI metric is the most reliable measure we have for assessing the intelligibility of speech in public address/voice alarm or speech reinforcement systems. A good design for speech is based on an understanding of the room acoustics and electroacoustics of the system, with a consideration for the expected signal to noise ratios in the room. In modeling, most noise signals are assumed to be broadband, whereas in reality the noise signals can be significantly variable in the frequency and time domain, which may dramatically increase or reduce the intelligibility. This study compares the effects of type of noise on intelligibility as measured through both word scores and STI. It explores masking from both theoretical and real world signals. The determined relationships will help inform the design process by clarifying the effects of non-broadband and variable noise signals on intelligibility.

2pAAa9. Comparing head rotation angle, visual localization, and recall-proficiency of school-aged children 8–12 while listening to a story by multiple discreet talkers in a virtual classroom. Daniel L. Valente, Dawna E. Lewis, John M. Franco, and Elizabeth C. Heinrichs (Dept. of Res., Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

In general, children perform more poorly in speech intelligibility tasks than adults while in a noisy environment such as a classroom. This is especially true in discussion situations where the active talkers often are located to the side or behind the student. The purpose of this study was to obtain baseline data for normal hearing (NH) students who experienced multiple-talker stimuli in a controlled virtual classroom environment. Data were gathered using a gyroscopic head-tracker and a post-story comprehension task. Twenty elementary-aged students (ages 8–12, four students per year) were positioned in the center of the classroom and presented a story read by five talkers positioned around the student (reproduced by means of loudspeakers and LCD monitors). Students used different strategies in terms of head rotation over time while performing the experiment and individual differences were seen both across subjects within an age group and between age groups. The post-test comprehension task was used as a metric of performance in the environment. Results from the NH students are compared to a control group of adult NH listeners using head rotation angle over time, comprehension scores, and localization accuracy as salient metrics.

4:10

2pAAa10. Verifying speech intelligibility in classrooms. Roman Wowk (Papadimos Group, 818 Fifth St., Ste. 207, San Rafael, CA 94901)

Classroom speech intelligibility has undoubtedly become a hot topic and is capturing attention on all fronts. While there has been widespread adoption of many new guidelines and standards, even the most precise initiatives will not reach their full potential if speech intelligibility is not directly verified in classrooms after they are built. Performance verification ultimately encourages a better final product and provides crucial measured data for validating design methods. To ensure measurable performance, criteria would have to be established at the outset of the design using a metric directly related to speech intelligibility such as speech transmission index. Current guidelines generally focus on reverberation time (RT) and background noise for improving speech communication in classrooms. While low background noise is a necessary component for speech intelligibility, there is not always a direct correlation between RT and speech intelligibility. For instance, improper placement of absorptive treatments for reverberation control could eliminate early supporting reflections which are beneficial for speech intelligibility. With computer modeling becoming widespread and relatively inexpensive, designing directly for speech intelligibility is becoming more practical. This paper explores case studies and examines the overall process for optimizing speech communication in classrooms with an emphasis on performance verification.

4:25

2pAAa11. Ambient noise levels and reverberation times in Mississippi school rooms. Edward L. Goshorn, Megan N. Lucus, and Brett E. Kemker (Dept. of Speech and Hearing Sci., Psychoacoustics Lab., Univ. of Southern Mississippi, 118, College Dr. #5092, Hattiesburg, MS 39406)

Nine elementary school classrooms at three Mississippi public schools were selected at random for noise and reverberation time measures to monitor voluntary compliance with ANSI standard S12.60-2002 (Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools). 1-h equivalent dBA noise levels and reverberation times (T60) were measured with SPECTRAPLUS Version 5.0 software. Measures were taken on separate days at each school in unoccupied classrooms with the HVAC system operating. For ambient noise measures, an Audix TR40 omnidirectional microphone was placed in a 12 in. stand on a student's desk near the middle of the room and oriented toward the teacher's desk at a 45 deg angle. For the reverberation time measure a 400 W loudspeaker (Yamaha BR15M) was placed on the teacher's desk about 3 m from the microphone. Results showed that noise levels varied from 28 to 51 dBA with broad spectra containing peaks at 120 Hz and harmonics. Five of nine classrooms had noise levels that exceeded the ANSI recommended level of 35 dBA. Reverberation times varied from 0.21 to 0.62 s; only one classroom exceeded the recommended minimal reverberation time of 0.6 s. Acoustical modifications to reduce noise levels and reverberation times will be addressed.

4:40

2pAAa12. Voice privacy associated with raised floor law office: A case study. Christopher J. Pollock and Geoffrey Sparks (Shen Milsom & Wilke, LLC, 3300 N Fairfax Dr., Ste. 302, Arlington VA 22201, cpollock@smwllc.com)

Presentation and discussion of the acoustical transmission and voice privacy issues associated with raised floor office fit out construction. Many new LEED office fit out projects are using raised floor constructions for future flexibilty and use of underfloor plenum for HVAC systems and/or technology cable plant. Issues of user expectations of privacy versus capabilities of the system are becoming more common. Case study office fit out was completed with raised floor and the extent of voice transmission due to various construction conditions limited voice privacy and created noise disruption from offices, workrooms, and conference rooms. Case study involves a law office where privacy concerns are heightened due to sensitive discussions. Measurements of noise isolation and privacy were made both before and after modifications, and results will be presented and discussed and conclusions for practitioners will be discussed.

TUESDAY AFTERNOON, 20 APRIL 2010 1:00 TO 3:00 P.M.

Session 2pAAb

Architectural Acoustics and National Council of Acoustical Consulants: Student Design Competition

Andrew Miller, Cochair
BAi, LLC, 4006 Speedway, Austin, TX 78751

Byron Harrison, Cochair
The Talaske Group Inc., 1033 South Blvd., Ste. 101, Oak Park, IL 60302

Robert C. Coffeen, Cochair
University of Kansas, School of Architecture and Urban Design, Marvin Hall, Lawrence, KS 66045

.

The Technical Committee on Architectural Acoustics of the Acoustical Society of America, the Robert Bradford Newman Student Award Fund, and the National Council of Acoustical Consultants are sponsoring the 2010 Student Design Competition that will be professionally judged at this meeting. The purpose of this design competition is to encourage students enrolled in architecture, engineering, physics, and other university curriculums that involve building design and/or acoustics to express their knowledge of architectural acoustics in the design of performance hall primarily for opera on a college campus of moderate size.

This competition is open to undergraduate and graduate students from all nations. Submissions will be poster presentations that demonstrate room acoustics, noise control, and acoustic isolation techniques in building planning and room design. The submitted designs will be displayed in this session and they will be judged by a panel of professional architects and acoustical consultants. An award of $1250.00 US will be made to the entry judged "First Honors." Four awards of $700.00 US will be made to each of four entries judged "Commendation."

Session 2pAB

Animal Bioacoustics: Estimating Spatial Density of Animal Populations with Passive Acoustics

David K. Mellinger, Chair
Oregon State Univ., 2030 S.E. Marine Science Dr., Newport, OR 97365

Chair's Introduction—1:00

Invited Papers

1:05

2pAB1. Minke whale boing vocalization density estimation at the Pacific Missile Range Facility, Hawaii. Stephen W. Martin (Space and Naval Warfare Systems Ctr. Pacific, 53366 Front St., San Diego, CA 92152), Len Thomas, Tiago A. Marques (Univ. of St. Andrews, St. Andrews KY16 9LZ, Scotland), Ronald P. Morrissey, Susan Jarvis, Nancy DiMarzio (Naval Undersea Warfare Ctr., Newport, RI 02841), and David K. Mellinger (Oregon St. Univ. and NOAA Pacific Marine Environ. Lab., Newport, OR 97365)

Minke whales (*Balaenoptera acutorostrata*) seasonally visit the Hawaiian Islands with an apparent peak in activity in the February /March timeframe. Their presence is readily detected acoustically from their boing vocalizations, which are detectable on the Pacific Missile Range Facilities (PMRF) deep-water (3500 m to over 4500-m depth) bottom mounted hydrophones northwest of Kauai, HI. Automated techniques were developed to detect, classify, and associate the boings across 16 separate hydrophones. Over 13 h of data for each of 12 separate days from the 2006 whale season (February/March/April) were processed for detection and classification (D/C) of boing vocalizations. A sample set of the data (10 min from each day) was analyzed to characterize the detection function (probability of detection as a function of horizontal range) and the false positive rate of the boing D/C. Boings were associated across hydrophones, defining a capture history for each boing vocalization. Spatially explicit capture recapture methods were applied to the sample data associations to derive the detection function. Applying the parameters estimated on the sample data set toward the full data ser allows an estimation of the minke whale boing vocalization density in this area over these time periods in 2006.

1:25

2pAB2. Estimating density from single hydrophones by means of propagation modeling. Elizabeth T. Küsel, David K. Mellinger (Cooperative Inst. for Marine Resources Studies, Oregon State Univ., 2030 S. Marine Sci. Dr., Newport, OR 97365, elizabeth.kusel@oregonstate.edu), Len Thomas, Tiago A. Marques (Univ. of St. Andrews, Fife KY16 9AJ, Scotland), David J. Moretti, and Jessica Ward (Naval Undersea Warfare Ctr., Newport, RI 02841)

A density estimation method developed under the project Density Estimation for Cetaceans from passive Acoustic Fixed sensors is presented. It uses sound propagation modeling to estimate the probability of detecting an animal as a function of its distance from the receiving sensor. Two case studies involving Blainville's beaked whales (*Mesoplodon densirostris*) and sperm whales (*Physeter macrocephalus*) are analyzed. The study area is the Atlantic Undersea Test and Evaluation Center in the Tongue of the Ocean, Bahamas. A ray-tracing acoustic propagation model is used to estimate the environmental transmission loss as a function of depth and range in several directions away from a single hydrophone. The computed transmission loss is compared to ambient noise levels, source level, and beam pattern distributions available in the literature to estimate detection probability as a function of range. Detection threshold is characterized from the signal-to-noise ratio of detected clicks. Information on click production rate is also taken into account by the density estimation model. Beaked whale detection probability function provides a relevant comparison to both the detection function and the spatial density of whales derived empirically from the DTag data by Marques *et al.* [(2009)].

1:45

2pAB3. Population density of sperm whales in the Bahamas estimated using propagation modeling. David K. Mellinger, Elizabeth T. Küsel (Coop. Inst. for Marine Resources Studies, Oregon State Univ., 2030 SE Marine Sci. Dr., Newport, OR 97365, david.mellinger@oregonstate.edu), Len Thomas, Tiago Marques (Univ. of St Andrews, Scotland), David Moretti, Paul Baggenstoss, Jessica Ward, Nancy DiMarzio, and Ron Morrissey (Naval Undersea Warfare Ctr., Newport, RI)

The population density of sperm whales is estimated using an acoustic model to calculate the probability of receiving their clicks. The model uses estimates of (1) the source level of clicks, (2) the beampattern of the whales' emitted clicks, (3) the distribution of whale orientations, (4) the loss between source and receiver (derived from acoustic propagation modeling), (5) noise levels at the receiver, (6) the detector's rates of missed calls and false detections, and (7) sperm whales' average click rate. These data are combined in a model that propagates simulated clicks from whales at various simulated positions to the receiving hydrophone to estimate the detection function—the probability of receiving a click as a function of distance. This function is then combined with information on whale click rates (performed at a chosen time of day when sperm whales appear to click at a measurably predictable rate) to estimate the population density corresponding to the number of received clicks in a given period of time. Data from the U.S. Navy's Atlantic Undersea Test and Evaluation Center (AUTEC) in the Bahamas are used to estimate sperm whale population density there. [Thanks to ONR, NOAA, and the Navy's Environmental Readiness Division for funding.]

2:05

2pAB4. Density estimation of leopard seals using a single stationary passive acoustic sensor. Holger Klinck (Hatfield Marine Sci. Ctr., Oregon State Univ., 2030 SE Marine Sci. Dr., Newport, OR 97365, holger.klinck@oregonstate.edu), Nadine Constantinou (Univ. of New South Wales, Sydney, New South Wales 2052, Australia), David K. Mellinger (Oregon State Univ., Newport, OR 97365), and Tracey Rogers (Univ. of New South Wales, Sydney, New South Wales 2052, Australia)

The objective of this study is to estimate the spatial density of leopard seals using data recorded with a single stationary passive acoustic recording system in the Bransfield Strait, Antarctica, between 2005 and 2007. The most prominent vocalization of the leopard seal—the low double trill (LDT)—is used as a proxy for the presence of the species in the vicinity of the recording system. Because of the stereotypic nature and high frequency of occurrence of the LDT, a long-term spectrogram approach can be applied to the data sets to reliably detect the presence of the target species. Energy levels in the target frequency band (200–400 Hz) as derived by the long-term spectrogram analysis are related to number of manually counted calls extracted for selected periods. A linear regression analysis showed that energy levels are highly correlated with the number of manually counted calls. The number of recorded calls per unit time is converted into number of vocalizing animals per unit time by applying published calling rates for this species. In a last step of the analysis, the detection area is defined and leopard seal densities estimated. Opportunities and challenges of the method will be discussed.

2:25

2pAB5. Determining the spatial distribution of an Antarctic top predator using passive acoustics. Nadine E. Constantinou, Tracey L. Rogers (Evolution and Ecology Res. Ctr. (EERC), School of Biological, Earth and Environ. Sci. (BEES), Univ. of New South Wales (UNSW), Sydney, New South Wales 2052, Australia, n.constantinou@student.unsw.edu.au), Shawn W. Laffan, and David I. Warton (UNSW, New South Wales 2052, Australia)

The leopard seal (*Hydrurga leptonyx*) is one of four species of ice seals in Antarctica with each species occupying a distinct position in the Antarctic sea-ice ecosystem. Ice seals offer a potential source of information about ecosystem interactions and environmental variability integrated over a variety of spatial and temporal scales. During the austral spring and summer, leopard seals move within the pack ice to breed. Acoustic surveying is necessary to assess their distributions as male leopard seals vocalize underwater as part of their breeding display. During the 1999/2000 austral summer, the relative abundance of adult male leopard seals was determined using underwater passive acoustic point-transect surveys. The abundance data were combined with environmental data in a geographical information system, and a model was developed to determine what factors of the environment are correlated with their abundance and distribution. The model with the best predictive power showed a trend of increased abundance toward the pack ice edge. These regions are associated with areas of increased foraging potential suggesting that the distribution of leopard seals off Eastern Antarctica is influenced, in part, by increased availability of prey.

3:05

2pAB6. Combining visual and fixed passive acoustic methods to measure annual variability of cetacean occurrence at the NE-coast of Iceland. Edda E. Magnusdottir, Marianne H. Rasmussen (Husavik Res. Ctr., Univ. of Iceland, Hafnarstett 3, 640 Husavik, eem@hi.is), and Marc Lammers (Hawaii Inst. of Marine Biology, Kailua, HI 96834)

In order to measure cetacean occurrence at the NE-coast of Iceland, two seabed-mounted Ecological Acoustic Recorders (EARs) were deployed in Skjálfandi Bay in September 2008, deployments will continue throughout September 2010. To obtain species confirmation, visual observations were conducted from a lighthouse in October 2008 to September 2009 with total observation effort of 202 h. With visual observations, the aim was to acquire background information on the cetacean sighted in the area to improve the estimates of occurrence in continued long-term passive acoustic recordings in Icelandic and adjacent waters. Movements and locations of the animals were recorded using a theodolite and a real-time mapping program (CYCLOPS TRACKER). Visual observations included sightings of blue whales (*Balenoptera musculus*), Humpback whales (*Megaptera novaeangliae*), Minke whales (*Balaenoptera acutorostrata*), white-beaked dolphins (*Lagernorhynchus albirostris*) and killer whales (*Orcinus orca*). A custom MATLAB program is used to automatically detect and analyze target biological sounds produced by cetaceans or by pelagic fish recorded on the EARs. The visual data are compared to the occurrence of identified sounds in order to better understand the vocal activity and average silence periods of the cetaceans. Also, detected vocalizations are compared to the number, location, and behavior of simultaneously sighted animals.

2pAB7. Seasonal and diurnal presence of finless porpoises at the corridor to the ocean from a semi-closed bay habitat. Tomonari Akamatsu (NRIFE, FRA, Hasaki, Kamisu, Ibaraki 314-0408, Japan), Kiyomi Nakamura (Kujyu Kushima Aquarium, Sasebo, Nagasaki 858-0922, Japan), Ryo Kawabe, Seishiro Furukawa, Hiromi Murata (Nagasaki Univ., Nagasaki 851-2213, Japan), Akihiro Kawakubo, and Masayuki Komaba (Kujyu Kushima Aquarium, Sasebo, Nagasaki 858-0922, Japan)

Finless porpoises in Omura Bay is the smallest among five populations in Japanese waters. This is a newly established population after the global warming of 9000 years ago, consisting of approximately 300 individuals and believed to be confined in Omura Bay. At the major corridor to the ocean from this bay, presence of finless porpoises was monitored acoustically from November 2007 to May 2009. A stereo acoustic event recorder (A-tag) was deployed at this strait. A-tag stored the intensity and the sound source direction of biosonar signals that provides independent traces of sound source corresponding to each animal. During 1.5 year observation, 226 individuals of porpoises were detected. Of them, 76% were presented at night and 73% observed during March to April. In the same season, anchovy landings in the Omura bay was recorded. 70% percent of the porpoises were observed during the tidal current that went out of Omura Bay that suggests the porpoises swam back and forth around the monitoring station. Although finless porpoises have been known to be confined in a local area, occasional migration of this species induced by prey availability might extend their habitat at different waters in Asian coasts.

3:35

2pAB8. Are passive acoustics an appropriate method to accurately represent a soniferous Atlantic croaker (*Micropogonias undulatus*) population? Cecilia S. Krahforst, Joseph J. Luczkovich, and Mark W. Sprague (Dept. of Biology, East Carolina Univ., Greenville, NC 27858, csk1021@ecu.edu)

It was observed that the fundamental frequency of Atlantic croaker sounds is inversely correlated with the length of the fish. We used fundamental frequency as a method to estimate the average length of the croaker population at any given time. Croaker were collected using an otter trawl and simultaneously counted and measured acoustically with a 200-kHz split-beam echosounder at two sites within the Pamlico Sound estuary, NC from June to November 2008. Passive acoustic recorders [long-term acoustic recording system (LARS) recordings 10-s wave files $<$ 10 kHz at 15-min intervals] were deployed near each trawling site to obtain *in-situ* recordings of croaker over the same period. Based on captive fish recordings, a linear regression analysis related total length to fundamental frequency, where TL = 305.323 mm$-$(0.270 Hz^{-1})f_0(r^2 = 0.84). This equation was then used to estimate croaker lengths from LARS recordings. Lengths of fish collected in the trawls, compared with the estimate from the passive LARS recordings and the echosounder surveys, were significantly smaller ($P > 0.0001$). Thus suggests that size-selectivity of the trawl underestimates the average size of fish and that acoustic methods (active and passive) provide a more accurate size estimate for croaker populations.

2pBB1. A parallel algorithm for high-intensity focused ultrasound simulation. Joshua E. Soneson (Div. of Solid and Fluid Mech., U.S. Food and Drug Administration, 10903 New Hampshire Ave., Silver Spring, MD 20993, joshua.soneson@fda.hhs.gov)

The Khokhlov–Zabolotskaya–Kuznetsov (KZK) equation serves as today's workhorse for the modeling and simulation of high-intensity focused ultrasound. This approximation of the full nonlinear wave equation allows serial algorithms to compute the pressure distribution produced by circular transducers usually in several hours on a modern workstation. However, more complicated transducer geometries preclude axisymmetric modeling, and extending into the third spatial dimension requires significantly more computational power, making serial algorithms intractable. This presentation details a parallel implementation of a combination time and frequency domain algorithm for rapid solution of the KZK equation. A split step method is used in which the linear terms in KZK are solved in the frequency domain and the nonlinear term is solved in the time domain. In the frequency domain, each harmonic may be computed independently, so this task is distributed over the available processors. In the time domain, the transverse spatial domain may be partitioned and distributed for independent solution of the nonlinear term. Near-linear scaling (acceleration vs number of processors) using this algorithm is demonstrated.

1:25

2pBB2. Analytic and numerical modeling of ultrasonic B-scan and echo decorrelation imaging. T. Douglas Mast and Swetha Subramanian (Dept. of Biomedical Eng., Univ. of Cincinnati, 231 Albert Sabin Way, Cincinnati, OH 45267-0586, doug.mast@uc.edu)

An numerical model is presented for *B*-scan images of weakly scattering, lossy media, based on ultrasound array beam patterns calculated analytically under the Fresnel approximation. Given these beam patterns and a three-dimensional analytic or numerical tissue model, this method yields beamformed *A*-line signals from which *B*-scan images are constructed. This approach is further employed to model echo decorrelation imaging, a method for quantitatively mapping transient heat-induced changes in pulse-echo ultrasound images. In echo decorrelation imaging, a normalized decorrelation parameter is computed between *A*-line signals separated by milliseconds. Maps of this parameter comprise echo decorrelation images, which are potentially useful for monitoring of local tissue coagulation during thermal ablation treatments for cancer therapy. Following previous studies in which scattering cross section has been related to spatial-frequency spectra of tissue sound speed, density, and impedance variations, echo decorrelation is related quantitatively to the local decoherence of these spatial-frequency spectra. Decoherence estimates are validated by simulations employing analytic array beam patterns and random-media models for ablated tissue and are further applied to quantify tissue structure changes caused by thermal coagulation during radiofrequency ablation of *ex-vivo* bovine liver tissue.

2pBB3. A modeling tool for therapeutic and imaging ultrasound applications. Francesco Curra (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105)

The fields of therapeutic and imaging ultrasound have broad medical applications. However, the inherent complexity of biological media and the nonlinear nature of ultrasound propagation at therapeutic regimes make optimization and control of the therapy still a challenging task. An accurate modeling tool for solving multi-dimensional ultrasound-based problems in complex geometries that can greatly assist in the optimization and control of the treatment is presented. The model consists of 2-D, 2.5-D (cylindrical symmetry), and 3-D coupled solutions for acoustic and elastic wave propagation in heterogeneous, lossy media complemented by the bioheat transfer equation for temperature estimation. It includes linear and nonlinear wave propagations, arbitrary frequency power law for attenuation, and can account for multiple reflections and backscattered fields. Work is underway for the inclusion of cavitation effects and the extension of the model to adaptive grid refinement and unstructured, deformable grids. Sample results for therapeutic and imaging applications will be presented. [Work supported by US Army MRMC and NIH NIDDK.]

2:05

2pBB4. Modeling of high-frequency ultrasound contrast agents. John Allen, Fanny Cugnet (Dept. of Mech. Eng., Univ. of Hawaii-Manoa, 2540 Dole St., Honolulu, HI 96822, alleniii@hawaii.edu), Jonathan Mamou, Paul Lee, Parag Chitnis, and Jeff Ketterling (Riverside Res. Inst., New York, NY 10038)

High-frequency applications of ultrasound contrast agents continue to develop with their increasing use for imaging intravascular locations as well as dermal and ocular tissue. However, conventional ultrasound contrast agents were originally designed for traditionally lower diagnostic frequencies. The optimal contrast agent design and related acoustic forcing methods for high-frequency applications are important topics of on-going research. In this respect,ultrasound contrast agent models are reviewed and, in particular, the role of the shell is highlighted for novel high-frequency applications. Shell material and related stability issues are discussed in terms of the constitutive equation assumptions. The concept of auto-resonance, which may be achieved by a slowly varying forcing frequency, is introduced as a method for enhancing the subharmonic response of free or bound agents. The phase locking characteristics of auto-resonance are analyzed using an empirical mode decomposition of the scattered signal. This provides the intrinsic mode functions from which the associated instantaneous frequencies and phases can be determined. The Shannon entropy and the variance of the phase are used to quantify the behavior. Comparisons of the numerical results are made with current experimental data. [*Support from* NIH-EB006372 and NIH-2G12-RR003016121.]

2:25

2pBB5. Modeling of nonlinear shock wave propagation and thermal effects in high-intensity focused ultrasound fields. Vera A. Khokhlova (Ctr. for Industrial and Medical Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105 and Faculty of Phys., Moscow State Univ., Moscow 119991, Russia, vera@acs366.phys.msu.ru), Olga V. Bessonova, Mikhail V. Averiyanov (Moscow State Univ., Moscow 119991, Russia), Joshua E. Soneson (U.S. Food and Drug Administration, Silver Spring, MD 20993), and Robin O. Cleveland (Boston Univ., Boston, MA 02215)

Numerical simulations based on the Khokhlov–Zabolotskaya-type equation are currently used to characterize therapeutic high-intensity focused ultrasound fields in water and to predict bioeffects in tissue. Here results from three different algorithms that differ in calculating the nonlinear term in the equation are presented. Shock capturing schemes of Godunov type, exact implicit solution with further extrapolation of the waveform over a uniform temporal grid, and direct modeling in the frequency domain are tested. In the case of weak nonlinearity, all schemes give essentially the same solution. However, at high peak pressures around 50 MPa and strong shocks developed in the focal region, the predictions of acoustic variables and heat deposition become sensitive to the algorithm employed. The parameters of the schemes, such as number of harmonics or temporal samples and the inclusion of artificial absorption that provides consistent results, are discussed. It is shown that the spectral and Godunov-type approaches require about 6 points and implicit time domain approach needs more than 50 points in the shock to be accurate. In all schemes artificial absorption should be employed to obtain acceptable accuracy with fewer points per cycle. [Work supported by the NIH EB007643, ISTC 3691, RFBR 09-02-01530, and NSF 0835795 grants.]

2pBB6. Generalization of the iterative nonlinear contrast source method to realistic, nonlinear biomedical tissue. Martin D. Verweij (Lab. of Electromagnetic Res., Fac. of Elec. Eng., Mathematics and Comput. Sci., Delft Univ. of Technol., Mekelweg 4, 2628 CD Delft, The Netherlands)

Originally, the iterative nonlinear contrast source (INCS) method has been developed to compute the nonlinear, wide-angle, pulsed ultrasound field in a homogeneous and lossless medium. The method considers the nonlinear term of the lossless Westervelt equation as a distributed contrast source in a linear background medium. The full nonlinear wave field follows from the Neumann iterative solution of the resulting integral equation. Each iteration step involves the spatiotemporal convolution of the background Green's function with an estimate of the contrast source. Appropriate filtering provides accurate field predictions for a discretization approaching two points per smallest wavelength or period. The current paper first discusses the theoretical generalization of the original contrast source approach, e.g., to include tissue attenuation or inhomogeneity. Next, computational results are presented that show the directional independence (even for the nonlinear distortion) and the wide-angle performance of the original INCS method. Finally, results are presented for extensions that can deal with power law losses or inhomogeneity in the wave speed. The wide-angle capability and the versatility of the contrast source approach demonstrate that the INCS method is well-suited for modeling the various aspects of realistic biomedical tissue behavior. [Work supported by STW and NCF.]

3:05—3:35 Break

3:35

2pBB7. Fractional wave equation for compressional and shear waves. S. Holm (Dept. Informatics, Univ. of Oslo, P.O. Box 1080, NO-0316 Oslo, Norway) and R. Sinkus (Inst. Langevin, ESPCI ParisTech, F-75231 Paris Cedex 05, France)

This study has been motivated by the observed difference in the range of the power law attenuation exponent for compressional and shear waves. Usually compressional attenuation increases with frequency to a power between 1 and 2, while shear wave attenuation often is described with powers less than 1. Another motivation is the apparent lack of partial differential equations with desirable properties such as causality that describe such wave propagation. Starting with a constitutive equation which is generalized Hooke's law with a loss term containing a fractional derivative, one can derive a causal fractional wave equation previously given by Caputo (1967) and Wismer (2006). In the low $\omega\tau$ (low-frequency) case, this equation has an attenuation with a power law in the range from 1 to 2. This is consistent with, e.g., attenuation in tissue. In the often neglected high $\omega\tau$ (high-frequency) case, it describes attenuation with a power law between 0 and 1, consistent with what is observed in, e.g., dynamic elastography. Thus a unifying wave equation derived properly from constitutive equations can describe both cases. Recent results on fractional random media will also be discussed as they give similar characteristics from a microperspective.

3:55

2pBB8. Transducer models in the ultrasound simulation program FIELD II and their accuracy. J. A. Jensen and D. Bk (Dept. of Biomedical Eng., Ctr. for Fast Ultrasound Imaging, Tech. Univ. of Denmark, Build. 349, DK-2800 Lyngby, Denmark, jaj@elektro.dtu.dk)

The FIELD II simulation program can be used for simulating any kind of linear ultrasound fields. The program is capable of describing multi-element transducers used with any kind of excitation, apodization, and focusing. The program has been widely used in both academia and by commercial ultrasound companies for investigation novel transducer geometries and advanced linear imaging schemes. The program models transducer geometries using a division of the transducer elements into either rectangles, triangles, or bounding lines. The precision of the simulation and the simulation time is intimately linked through the choice of the fundamental elements. The rectangular elements use a far-field approximation, whereas the two other methods use the full analytic solution, leading to a higher precision at the price of a slower simulation time. The talk will describe the different compromises and solutions to obtain a fast simulation and still attain a high precision including a newly developed semi-analytic solution for a convex surface elements.

2pBB9. Beamforming for vibro-acoustography using a 1.75D array transducer. Matthew W. Urban, Mostafa Fatemi, and Azra Alizad (Dept. of Physio. and Biomedical Eng., Mayo Clinic College of Medicine, 200 First St. SW, Rochester, MN 55905, urban.matthew@mayo.edu)

Vibro-acoustography is an ultrasound-based imaging modality that maps the acoustic response of an object induced by acoustic radiation force. The method employs two ultrasound beams with frequencies separated by a small difference, typically in the kilohertz range. Using a 1.75D array transducer, which has multiple rows of elements, offers an advantage over linear array transducers because it allows for focusing in the elevation direction. We have performed simulations of different arrangements for the apertures assigned to the two ultrasound frequencies and evaluated resolution and sidelobe levels for different arrangements. However, the large size of the elements produces grating lobes in the transmitted fields. We will describe metrics for evaluating grating lobe levels compared to the main lobe of the transmitted field as a quantitative approach to optimize aperture design. We present experimental measurements of the transmitted field and compare with simulation results. Finally, we present imaging results from phantom experiments. This beamforming study is directed toward improving vibro-acoustography image formation using a General Electric Vivid 7 scanner for breast and thyroid imaging. [Mayo Clinic and two of the authors have potential financial interest related to devices or technology referenced above. Work supported by NIH Grant No. R21CA121579 and AIUM Award No. AIUM-EER#1.]

4:30

2pBB10. Calculations of intensities for radiation force modeling with the commercial software package FOCUS. Robert J. McGough, Donald J. Vanderlaan, Alexander Dutch (Dept. of Elec. and Comput. Eng., Michigan State Univ., East Lansing, MI), and Matthew W. Urban (Mayo Clinic College of Medicine, Rochester, MN)

Rapid calculations of the intensity are required for models of the radiation force generated by linear ultrasound phased arrays. To determine the computation times and numerical errors produced by two medical ultrasound simulation packages, namely, FIELD II and FOCUS, comparisons of the calculated pressures and intensities are performed using a simulated Vermon L5 phased array probe with 128 active elements. In these simulations, the array generates a fixed focus 25 mm from the array for a 5-MHz excitation, and the pressure field is computed on a $133 \times 133 \times 261$ rectilinear grid that is centered at the focus. Half wavelength sampling is employed in all three directions. In FIELD II, this calculation takes approximately 4 h on a 64-bit laptop running Linux, and in FOCUS, the same calculation takes less than 4 min on the same computer. The numerical errors are also much smaller with FOCUS. Details of the simulation approaches employed for this transducer model will be presented, including selection of FIELD II and FOCUS simulation parameters and calculations of the reference pressure field for error evaluations. The impact of numerical errors on shear wave calculations will also be discussed.

4:45

2pBB11. Strategies to improve conformal tumor heating with waveform diversity beamforming. Robert J. McGough and Matthew R. Jennings (Dept. of Elec. and Comput. Eng., Michigan State Univ., East Lansing, MI)

Waveform diversity is a phased array beamforming approach that, when applied to tumor heating with ultrasound, simultaneously maximizes the power at control points in the tumor while minimizing the power deposited in specified sensitive tissues. When waveform diversity calculations are combined with a rank deficient beamforming method, the optimal number of focal patterns is determined, and the optimal array excitations are also obtained. Previous results have shown that waveform diversity combined with mode scanning reduces problems with intervening tissue heating that otherwise occur when standard spot scanning approaches are applied. In an effort to extend these results and achieve a more conformal tumor heat deposition, variable weights will be applied to each of the focal points as a function of distance from the center of the spherical tumor volume. Modified focal point arrangements that decrease the focal point density along the array normal to further reduce normal tissue heating will also be evaluated. Simulations demonstrating the results of these and other modified beamforming strategies will be demonstrated for a large spherical section array using the FOCUS software package.

2pNCa1. Remote construction noise monitoring. Areg Gharabegian (Parsons, 100 W. Walnut St., Pasadena, CA 91124, areg.gharabegian@parsons.com)

Los Angeles was constructing an underground 12 ft in diameter sewage tunnel stretching 25 km. The project includes nine construction access shafts where tunnel boring machines, muck trains, and materials were lowered into the ground. The excavated tunnel material was transported from the tunnel head to the access shafts by muck train, removed by a crane, and carried away via heavy haul trucks. A state of art remote construction noise system was developed and installed near each of the shaft sites, which was collecting noise, audio, and video data 24 h a day. Noise levels were recorded whenever a noise limit threshold is exceeded. Data were then transmitted via modem to a central location where noise specialists review and analyze the data. A portion of these noise limit exceedances were correlated to the audio and video files to determine if the exceedances were due to the construction activities or other non-construction related events. Construction noise at the noise sensitive sites adjacent to each shaft were minimized by constructing sound walls as high as 10 m.

1:15

2pNCa2. Rising to the challenges of noise monitoring around construction sites. Douglas Manvell and Martin Alexander (Bruel & Kjaer, Skodsborgvej 307, 2850 Nrum, Denmark, dmanvell@bksv.com)

The construction of infrastructure and new buildings causes changes to the environment of the neighborhood both during and possibly after construction, particularly for major projects. These changes are often significant and result in concern among local population and government and often result in restrictions. To be effective and thus meet the demands on these restrictions, adequate enforcement is needed. Enforcement of noise limit compliance around construction sites needs to efficiently determine noise limit compliance, avoiding false positive exceedences, in order to provide a correct and true picture of the impact of the construction work. This paper describes some of the major challenges faced when designing, deploying, and operating a system to monitor compliance of noise regulations and limits around a construction site. It describes and compares alternative approaches to facing these challenges.

1:30

2pNCa3. Remote construction vibration monitoring at sensitive facilities. Marc Newmark, Jeffrey Zapfe, and Eric Wood (Acentech, Inc., 33 Moulton St., Cambridge, MA 02138, mnewmark@acentech.com)

Construction-related vibrations, while temporary, still have the potential to disrupt vibration- or noise-sensitive operations in adjacent facilities (such as hospitals, laboratories, and performing arts venues). Traditional construction vibration monitors are configured to measure levels corresponding to building damage thresholds. Unfortunately, vibration-sensitive equipment can be adversely affected at levels that are orders of magnitude lower than this. Furthermore, while most construction vibration monitors provide level information at a single dominant frequency, most criteria for sensitive equipment are specified over a range of frequencies. Generally, occupants of buildings near construction sites prefer to continue operations during the construction process. To do this, however, they need to know how the construction-related vibrations compare to their instrument criteria. To help provide this information, we have developed a remote monitoring system that provides real-time vibration and/or noise spectra in the sensitive facility. These spectra can be directly compared to instrument criteria with appropriate alarm notifications as needed. In this paper, we will present three case studies that show the evolution of this remote monitoring capability and discuss how the information has been used by the institutions where it has been installed.

1:45

2pNCa4. An approach to noise impact assessment for long-term construction. Frank Babic (AECOM, 105 Commerce Valey Rd., West, Markham, ON L3T 7W3 Canada, frank.babic@aecom.com)

Noise generated by construction is typically characterized as a temporary noise source. Due to its temporary nature, construction noise can generally be tolerated by the community at large more readily than long-term noise sources (for example, from industry). For some projects, construction may extend beyond a temporary period to become a more long-term noise problem—especially when the construction activity can last months or even years. When an extended construction period occurs, the community may be less tolerant of the noise, and the assessment of its impact on the community is more aptly characterized as a long-term noise source, similar to that of industry. This paper proposes an approach to assessing long-term construction projects, where a "worst-case" scenario can be modeled with utility factors, duty cycles, and barrier noise controls. From this modeling, a zone of influence can be determined which identifies the extent of the noise impact (i.e., potential complaints generated by nuisance from construction noise). Receptors within this zone of influence (including residences, hospitals, churches, etc.) can then be identified as part of the environmental noise impact assessment for long-term construction activity.

2:00

2pNCa5. Estimating construction noise using the Environmental Science Research Institutes geographic information systems program. Scott Noel (Parsons Brinckerhoff, Inc., 400 SW 6th Ave., Ste. 802, Portland, OR 97219, noels@pbworld.com)

ArcGIS is a series of Geographic Information Systems (GIS) programs and tools developed by the Environmental Science Reaserch Institue (ESRI). ArcGIS has many tools built in, however, no tools to extimate construction noise levels for either point sources or for a project construction footprint. PYTHON is a programming language that is becoming the preferred programming language for ESRI programs. Parsons Brinckerhoff, Inc. has modified the buffer tool in ArcGIS to estimate noise levels from a variety of construction equipment. The tool allows the user to choose what typical construction equipment will be used on their project. The tool then creates a noise contour showing what noise levels could be expected at certain distances from the project area or point source. The tool is useful for estimating construction noise at various distances to sensitive receptors. The tool also helps in graphics creation to aid in summarizing noise impacts. Parsons Brinckerhoff, Inc. has used this tool on transportation projects but it is applicable to other projects as well.

2:15

2pNCa6. Construction noise impact prediction using non-virtual simulation. Rob Greene (Parsons Brinckerhoff, 505 S. Main St., Ste. 900 Orange, CA 92868, greener@pbworld.com)

This paper presents a rarely used approach to predicting potential noise impacts from major infrastructure construction. The method includes the actual propagation of spectrally shaped pink noise into a community from locations within the proposed project's construction site, coupled with contemporaneous noise measurements at multiple in-community locations. Pretest source calibration measurements were performed and ambient noise levels were measured in the surrounding community during pre- and posttest periods. A Public Information program was part of the environmental assessment process. Yes, this novel/brave/are you crazy? approach was extensively covered in the local press. The community reaction to the methodology, the noise control mitigation that resulted from the test, the success of the construction, and lessons learned will be presented.

2:30

2pNCa7. Using the Federal Highway Administration Roadway Construction Noise Model for the Jerome Park reservoir construction project. Gabriella Yanez-Uribe and Erich Thalheimer (Parsons Brinckerhoff, 3340 Peachtree Rd, Ste. 2400, Tower Pl. 100, Atlanta, GA 30326, yanezuribe@pbworld.com)

The new Jerome Park Reservoir in the Bronx, NY, is a critical water supply source for the residents and businesses of New York city. This paper will describe the noise modeling work done in support of the project as well as an odd bug found in the FHWA's RCNM model. Noise associated with the various construction phases and equipment for the project were analyzed to evaluate the potential loudest hour during each month of work for the project's 50-month duration. Noise analyses were performed for expected weekday work conditions and Saturday work conditions at several receptor locations surrounding the reservoir using the FHWA's Roadway Construction Noise Model (RCNM), Version 1.0. During the analysis, an error was found with the output function of RCNM when exporting results for multiple receptors into CSV and TXT output files. The total L_{eq} and L_{max} levels were being reported as zeros even though the correct total noise levels were displayed on screen. This error was submitted to FHWA for review, and as a result, RCNM Version 1.01 was soon released addressing the problem. More importantly, the project was performed to the client's satisfaction and has allowed the necessary construction work to proceed.

2:45

2pNCa8. How good is the Roadway Construction Noise Model for predicting highway construction noise impacts? Marc Wallace (Tech Environ., Inc., 303 Wyman St., Ste. 295, Waltham, MA 02451, mwallace @techenv.com)

The reconstruction of the I-93/Route 110/Route 113 in Methuen, MA will be conducted over a 4-year period. As part of the project, a new I-93 bridge superstructure will need to be built. This bridge work will consist of constructing the center portion of new superstructure, which will include pile driving. The work will require shifting I-93 traffic lanes several times to accommodate bridge construction over a several months. The design engineers are also considering constructing the superstructure over a weekend by shutting down I-93 and re-routing over local roads to reduce construction impacts. The Federal Highway Administration's (FHWA) Roadway Construction Noise Model (RCNM) was used to assess potential construction noise impacts on nearby residential neighborhoods. The RCNM is a good screening tool to conservatively assess potential construction noise impacts. There are more sophisticated models, such as the Cadna A comprehensive three-dimensional (ISO 9613-2) model that takes into account topographic and atmospheric conditions. The goals of this paper will be to compare the RCNM and Cadna A model results to assess the accuracy of the RCNM model and to also assess the potential benefits or impacts of constructing the superstructure over a shorter period of time using the Cadna A model.

3:00

2pNCa9. Proactive regulation engenders creative innovation: Quieting the jack hammer. Eric Zwerling (Dept. of Environ. Sci., Rutgers Noise Tech. Assistance Ctr., 14 College Farm Rd., NB, NJ 08901, Zwerling@rutgers.edu), Charles Shamoon (New York City Dept. of Environ. Protection), and Stephen Szulecki (The Noise Consultancy, LLC)

In 2002, the New York City Department of Environmental Protection undertook to completely revise the city's Noise Code; it went into effect in 2007. The Mayor's Office made the reduction in construction noise a priority. Incentives were provided for the application of best management practices and the use of quieter equipment. DEP staff proposed the development of a remediation strategy for pneumatic pavement breakers. Working with KeySpan Energy (now National Grid), they approached Zo-Air Company, an industrial tool distributor, who developed the "No Racket Jacket." The key to developing a successful engineered solution is understanding the noise source. Most of the noise emissions from a pavement breaker come from internal components, not the tool bit hitting the pavement. Enclosing the source significantly reduces the noise emissions. The jack*et al.*so serves to insulate the operator from the exhaust air of pneumatic units, and the oil often spewed onto their legs. This paper discusses the development process which included four prototypes, and the results, with data from source sound level measurements and operator dosimetry. Three scenarios were tested: unremediated pneumatic hammer, pneumatic hammer with the "No Racket Jacket," and an electric pavement breaker.

3:15—3:30 Break

3:30

2pNCa10. Designing partial enclosures to minimize airborne sound transmission. D. W. Herrin, A.E. Carter (Dept. of Mech. Eng., Univ. of Kentucky, 151 RGAN Bldg., Lexington, KY 40506-0503, dherrin@engr.uky.edu), J., Shi, and D. C. Copley (Caterpillar, Inc.)

Enclosures are a very common way to reduce noise emissions from machinery. However, enclosures display complex acoustic behavior that is difficult to predict. Boundary element simulation was used to better understand the airborne transmission path for a partial enclosure. Sources considered included a point source and a diesel engine. Insertion loss was used as the performance measure to evaluate the effect of several different design considerations. Results indicate that the most important factors affecting enclosure performance are the opening size, amount of absorption, and the source-to-opening distance. It is notable that insertion loss was relatively insensitive to enclosure or source size.

3:45

2pNCa11. New York City western rail yard construction noise study. Erich Thalheimer (Parsons Brinckerhoff, 75 Arlington St., Boston, MA 02111, thalheimer@pbworld.com)

This paper will describe the technical approach, regulatory environment, and outcome of a construction noise study performed on behalf of a $2.5 billion private development to be built over the Western Rail Yards in Manhattan. Community noise modeling for the 9 year project was performed in accordance with New York City Environmental Quality Review (CEQR) Manual requirements using the CADNA-A and FHWA TNM models. The on-site noise analysis accounted for the staggered schedule of excavation, foundation laying, erection, and finishing of eight high rise residential and commercial buildings. Construction equipment source emissions used in the CADNA-A model were taken from the FHWA Roadway Construction Noise Model (RCNM) and the NYC DEP Construction Noise Regulations (Local Law 113, Chap. 28). Project-related trucking (mobile) noise was evaluated using the TNM model. Seventeen multi-story noise receptor locations surrounding the development site were evaluated with ambient noise measurements and predictive noise modeling. A construction vibration assessment for the elevated High Line park was also conducted. The results indicated that noise exceedance conditions were expected from pile driving, hoe ramming, and jackhammering operations during daytime, nighttime, and weekend periods, so noise mitigation measures were developed and incorporated into the project's construction permit.

4:00

2pNCa12. Report on mitigation of nighttime construction noise. Cliff Schexnayder (Arizona State Univ., P.O. Box 6700, Chandler, AZ 85246, cliff.s@asu.edu) and Jennifer S. Shane (Iowa State Univ.)

Nationally, the amount of road work being done at night appears to be significant. Data taken during the summer of 2001 suggests that one-third of the work zones present on National Highway Systems roadways were active primarily at night. Night work can have impacts on adjacent neighborhoods and businesses that would not be experienced or as disturbing if conducted during the daytime. Construction equipment is a major noise and nuisance generator on nearly all nighttime construction projects. This paper will report on an ongoing Transportation Research Board study that is seeking to identify best practices in terms of source control, path control, and receptor control of noise on transportation projects. Individual DOTs having specific experience and contractors are being queried about their experiences in mitigating nighttime construction nuisances.

4:15

2pNCa13. Noise control evaluation for a concrete batch plant. Robert D. O'Neal (Epsilon Assoc., Inc., 3 Clock Tower Pl., Ste. 250, Maynard, MA 01754, roneal@epsilonassociates.com)

As a result of neighborhood complaints, an Administrative Consent Order was issued to a concrete batch plant for violating the Massachusetts noise policy. The fact that the batch plant had been in business long before the residential subdivision was built did not factor in the State's decision. A detailed noise control study was conducted for the facility. All mobile and stationary sources of noise were measured in addition to measurements at the receiving property. The major sources included mixer trucks receiving concrete and prepping their load, concrete trucks climbing a hill, batch plant dust collector fans, and bulk cement truck deliveries. The measurements were analyzed, and a series of noise control measures was evaluated and recommended, some of which were implemented by the facility. Several rounds of controls and associated sound level testing were conducted to determine if the batch plant met the State noise requirements, and compliance was eventually achieved. This paper will discuss the key sources of noise at the facility and the techniques used to reduce noise at the source.

4:30

2pNCa14. Road construction noise inside a radio station. Sean Connolly (Big Sky Acoust., LLC, P.O. Box 27, Helena, MT 59624, sean @bigskyacoustics.com)

Construction noise limits are typically presented as noise levels not to be exceeded at the exterior of a building or a property line. However, when a building houses noise-sensitive uses, the possible construction noise impacts must be assessed inside the building. In 2004, a contentious legal dispute erupted between a radio station owner and the state highway department over the reconstruction of the highway directly adjacent to the station. The owner claimed that excessive road construction noise would disrupt live broadcasts from his studio. Therefore, the construction noise levels needed to be assessed inside the studio during the entire construction process, but legal maneuvering severely limited access to the station. This paper discusses the criteria and methods used to assess construction noise impacts inside the studio, the relationship between the measured noise levels inside and outside of the studio during various phases of road construction, and of course, if the construction noise interfered with radio broadcasts.

2pNCb1. German information technology-equipment noise categorization concept: Study on several data projectors. Gregor Feneberg (Mueller-BBM GmbH, Robert-Koch-Str. 11, 82152 Planegg, Germany, gregor.feneberg@muellerbbm.de)

An investigation project tendered by the German Federal Institute for Occupational Safety and Health (BAuA), with a planned duration of 1 1/2 years, has recently been awarded to Mueller-BBM. The existing concept of the quality classification of household appliances, where the energy efficiency categories A–F each represents a determined range of power consumption, is to be transferred to a system for the categorization of IT-equipment with regard to its noise emission. Currently it is almost impossible for a layperson to compare noise declarations provided by manufacturers even though there are standardized and very detailed specifications in ISO 9296 for the measurement and declaration of the noise emission of IT-equipment. One of the central issues of the project is the consolidation of existing procedures for noise emission measurements on IT-equipment with consideration of the impact of psychoacoustic parameters. A categorization proposal based on ISO 7779 will be presented. In order to check the neccessity of additional psychoacoustic metrics like tonality and transient loudness, 11 data projectors were measured according to the BAuA proposal. In addition, the annoyance of the operational noise was evaluated by a panel test. The results will be compared and contrasted with the current ISO /ECMA standard measurements.

1:15

2pNCb2. Development of the standard ISO 7779 3rd edition: Revised and new contents. Ikuo Kimizuka (IBM Japan, Ltd., 1623-14, Shimotsuruma,Yamato-shi, Kanagawa-ken 242-8502, Japan, kmzk@jp.ibm .com)

ISO 7779 is a noise test code for airborne noise emission of information technology and telecommunications equipment (so called, ITTE). Since its 1st edition of 1988, ISO 7779 has stated, in detail, the installation and op-

erating conditions for specific equipment categories. In nature of ITTE, however, changing of the product characteristics is much faster than the pace of standard document updates. For instance, most models of copy machines and printers (except some dedicated high speed machines) are almost being combined into new category, so called, multi-functional devices. To catch such rapid changes up timely, it becomes impractical to state specific condition within this International standard. Therefore, ISO/TC43/SC1 /WG23 which is responsible for ISO 7779 decided to propose new frame work so that 3rd edition should refer to ECMA-74, annex C, which has been the industrial counterpart and also pilot standard of ISO 7779. This paper introduces background of key changes from 2nd edition and new technical contents for ITTE noise emission measurement methodologies.

1:30

2pNCb3. Printer impulsive noise metrics: Sensitivity and repeatability analysis. Terry Baird and Katy Ferguson (Hewlett-Packard Comp., 11311 Chinden Blvd., Boise, ID 83714, terry.baird@hp.com)

The major cause of annoyance from impulsive noise is the impulsive amplitude. Many methods can characterize impulsive amplitude, such as time-averaged measures, peak amplitudes or real-time levels. For example, the "impulsive noise index" described by ISO 11201 or the "impulsive parameter" described in ISO 7779 are time-averaged metrics. Real-time metrics might include peak sound pressure level or peak loudness in the time domain. Impulsive metrics must be evaluated for effectiveness. That is, the metric must agree with the perceived impulsive amplitude. Impulsive metrics must also be practical. They must be insensitive to sample-to-sample variation while still providing the granularity between passing and failing results. This paper focuses on evaluating the sensitivity, measurement repeatability, and result granularity to determine the practicality of various effective impulsive noise metrics.

1:45

2pNCb4. Development of schemes to gauge the annoyance of time-varying sound. Menachem Rafaelof (Seagate Technol., 389 Disc Dr. Longmont, CO 80503, menachem.rafaelof@seagate.com)

Hard disk drives (HDDs) nowadays have use in many diverse applications. Examples include various types of consumer electronic devices that operate in extremely quiet environments and personal computers that integrate the HDD and other peripherals within the display very close to the user. Higher exposure to the HDD sound, either due to the lack of masking sound or close proximity to the user, require establishment of a scheme to identify features within the sound to decide on its acceptability. This paper describes an effort aimed at developing a scheme for identification of attention-grabbing or annoying features within time-varying sound that would point to its unacceptability by a typical user. In this first part, sample sounds were examined based on their perceived strength (loudness), duration, repetition rate, and higher order statistics to acceptability based on a jury study.

2:00

2pNCb5. Impact of personal video recorder/digital video recorder on hard disk drive acoustic requirements. Dave Ali (Western Digital, 5863 Rue Ferrari, San Jose, CA 95138, dave.ali@wdc.com)

In recent years the impact of the personal video recorder/digital video recorder market has grown substantially. This growth has a direct impact on the acoustic test laboratories that make sure the systems meet the manufacturer's specification for noise emissions. To date the standards have not addressed this growth and subsequently have not provided guidance as to standardized methods of test for these systems. This paper will show the impact of the market and provide a proposed addition to the appropriate acoustic test standards.

2:15

2pNCb6. Fan noise prediction for design. Charles Oppenheimer (Hewlett-Packard, 18110 SE 34th St., Vancouver, WA 98683, charles .oppenheimer@hp.com)

This paper develops a fan noise prediction model intended for use in the design of systems for cooling and drying. Airflow through a system is described by a dimensionless resistance parameter. Fan noise is predicted by a scaling relationship obtained from a dimensional solution of Lighthill's acoustic analogy. The scaling relationship contains unknown proportionality factors, which are determined empirically and compared for axial fans and centrifugal blowers. The dependence of fan and blower noise spectra on non-dimensional scaling parameters is also investigated.

2:30

2pNCb7. Constant acoustic fan curves for 92 mm axial fans. Willem Beltman (Intel Labs, Intel Corp., M/S JF2-86 2111 NE, 25th Ave., Hillsboro, OR 97124, willem.m.beltman@intel.com)

The noise emission of fans changes as a function of the operating point. Airflow and acoustic fan plenum experiments can be used to characterize these effects to estimate noise under installed conditions. Recently, the concept of iso-acoustic fan curves was introduced by various authors, and results were presented for small radial blowers and some axial fans. The current paper presents an analysis of the iso-acoustic fan curves for an extensive set of 92 mm axial fans. An analysis is presented of the airflow and acoustic performance of these fans, and expressions for the iso-acoustic fan curves are derived and presented. This allows a direct comparison between the various fans based on operating point conditions.

2:45

2pNCb8. Aero-acoustic simulations of small scale electronic cooling blowers. Jessica Gullbrand and Willem M Beltman (Intel Labs, Intel Corp., 2111 NE 25th Ave., MS JF2-86, Hillsboro, OR 97124, jessica.gullbrand @intel.com)

The noise emission of small radial blowers is important for the cooling of notebook systems. It has been demonstrated that airflow simulations for these radial blowers can be performed to predict the blower performance, even in the presence of inlet restrictions. The current paper presents an extension of this work to include predictions of the radiated acoustic noise. The calculated blower flow field is used as an input for a second stage aeroacoustic prediction. This paper outlines two methods. The first method uses a free field approach based on the Ffowcs-Williams and Hawkings analogy. The second approach constructs a rotating fan source, the magnitude of which is determined by integrating the pressure across a number of blade segments. The radiated field is then determined in a boundary element calculation, both for a free field and in the presence of the fan enclosure. Results for both methods are presented and compared to experimental data.

3:00

2pNCb9. A relation between flow, noise, and system impedance for notebook computers. Eric Baugh (Intel Corp., 15400 NW Greenbrier Pkwy., M/S CO5-166 Beaverton, OR 97006, eric.baugh@intel.com)

Performance of notebook computers is strongly limited by the ability to reject heat from the system. In a typical mainstream design, the airflow driven by the internal fan is responsible for about 80% of the maximum cooling capability, and this airflow impacts all the internal components (CPU, memory, radios, etc.) as well as the top and bottom skin temperatures. Fan flow, in turn, is limited by acoustics. It has been shown that the fan installation conditions inside a notebook computer have an adverse effect on both flow rate and noise. The market trend is toward thinner systems, which generally have a higher system impedance. As impedance increases, system airflow must decrease to maintain a fixed acoustic limit, holding all other variables constant. In order to demonstrate the effect of impedance, this paper describes a simple, two parameter model relating the flow rate in a notebook computer at a given operator position sound pressure level to the impedance index of the system. This relation is shown to reasonably approximate the behavior of about 20 different notebook computers.

3:15

2pNCb10. The dB[EQL]: An alternative sound pressure weighting according to the equal loudness contours of the international standard ISO 226-2003. Wade Bray (HEAD Acoust., Inc., 6964 Kensington Rd., Brighton, MI 48116, wbray@headacoustics.com)

The conventional spectral weightings applicable to sound pressure [dB (A), etc.] are fixed in spectral shape and intended for use over certain ranges

of unweighted sound pressure level: for example, the *A*-weighting from threshold of hearing up to 65 dB(SPL). In general, these weightings' spectral shapes match the sensitivity of hearing as a function of frequency within "use-level" ranges, although the strong effect of the cavum conchae resonance of the ear, apparent in the equal-loudness contours of ISO 226, is not considered except in the rarely Used *D*-weighting. Particularly for sounds with tonal content and within the general level range of the *A*-weighting, the authors propose a new spectral weighting assembled from the Phon values of the complete set of equal-loudness contours calculated for each frequency within the human auditory range. It will be shown that although giving values similar to those of the *A*-weighting, the dB[EQL] or equal-loudness weighting is situation dependent rather than fixed, and better represents subjective impressions at all frequencies. Although based on perceived loudnesses, the dB[EQL] sound pressure weighting is not a specific loudness measurement, does not consider critical band formation, and does not yield masking or psychoacoustic loudness data.

2pNCc1. Geothermal heat pump noise control (cont.): Its all in the details. Jeffrey Fullerton (Acentech, Inc., 33 Moulton St. Cambridge, MA 02138, jfullerton@acentech.com)

The installation of a geothermal heat pump in the basement of a 1900 era home introduced significant noise and vibration to a bedroom above, which was discussed in detail in a previous conference. After mitigating the noise and vibration using piping isolation products, lower levels of noise and vibration still remained. This paper will discuss pursuits that were implemented and the very effective resolution for mitigating the noise and vibration that was generated by the heat pump.

4:00

2pNCc2. Improving screw compressor housing design using simulation. D. W. Herrin, Z. Tao (Dept. of Mech. Eng., Univ. of Kentucky, 151 RGAN Bldg., Lexington, KY 40506-0503, dherrin@engr.uky.edu), A. J. Graybill, J.E. Bender, P.C. Marks, and C. Eichelberger (JCI Bldg. Efficiency)

The sound radiation from a rotary screw compressor was simulated using structural finite element and acoustic boundary element analysis. The modes of the housing were measured with and without the screws. Finite element modal analysis results were compared to the experimental modes with good agreement. Results demonstrated that the screws affected the bending modes but not the more important cylinder modes of the compressor housing. The sound radiation from the compressor housing was then predicted using acoustic boundary element analysis. The results indicated that the second and fourth pumping frequencies were close to two structural modes. Subsequent simulations investigated the effect of design changes on the housing. These changes included using a thicker cylinder and adding ribs.

4:15

2pNCc3. Vibro-acoustic model of an enclosed electric power generator. David C. Copley and Harvind Raman (Caterpillar Inc., Tech. Ctr. Bldg. E, P.O. Box 1875, Peoria, IL 61656, copley_david_c@cat.com)

A vibro-acoustic model of an enclosed diesel-powered electric generator was built using commercial vibro-acoustics software (primarily SEA) and empirical methods. The vibro-acoustic sources, including the engine, generator, cooling fan, and exhaust were characterized experimentally for several different operating conditions. The vibro-acoustic performance of the enclosure and sound suppression features were modeled and experimentally validated. Good agreement was achieved between experimental and simulated results.

4:30

2pNCc4. Passive noise control methods applied to a household icemaker. Richard Ruhala (Southern Polytechnic State Univ., 5735 Forest Ave., Evansville, IN 47712, rruhala@usi.edu)

Two icemakers were provided to the engineering program at the University of Southern Indiana for educational testing and development. Three students worked sequentially over 1 year to quantify and localize the noise sources using sound pressure and sound intensity methods, and then implement various design modifications in order to reduce the overall sound power by a goal of 3 dBA. Noise reduction was achieved during some machine operating cycles, although the overall noise reduction goal was not obtained. The students did learn one important finding in noise control engineering: that reducing the noise of a well developed and quiet product is a difficult task that requires expertise in noise assessment and control. This paper will also focus on findings from these studies that are pertinent to the development of quieter refrigerators, freezers, and icemakers.

4:45

2pNCc5. Acoustics of energy efficient hand dryers: Is this progress? Jeffrey Fullerton and Gladys Unger (Acentech, Inc., 33 Moulton St., Cambridge, MA 02138, jfullerton@acentech.com)

Recently there have been innovations in the technology of bathroom hand dryers with a particular focus on energy efficiency. The results have included some rather interesting methods for drying wet hands in different ways than previous generations of hand dryer models. The focus of this study will be to compare the sound levels from these different energy efficient models with previous models that have been used for years. The overall sound level will be compared to the rated efficiency of each unit.

2pNCd1. FAA noise impacts research roadmap. Raquel Girvin (FAA, 800 Independence Ave., SW Washington, DC 20591, raquel.girvin@faa.gov)

The Federal Aviation Administration's (FAA) continuing mission is to provide the safest, most efficient aerospace system in the world. Improving efficiency through airspace redesign, airport capacity expansion, and other initiatives of the FAA Next Generation Air Transportation System (NextGen) may be hampered without an aggressive program to address the environmental consequences of aviation. FAA's work toward mitigating such environmental consequences includes research to advance the state of knowledge on noise impact analysis. This paper describes the status of FAA's ongoing research efforts and the comprehensive research roadmap addressing critical noise impacts research needs.

1:15

2pNCd2. Overview of aircraft en-route noise prediction. Bill (Hua) He (Federal Aviation Administration, Office of Environment and Energy (AEE) —Noise Div., 800 Independence Ave., NW, Bldg. 10A, 900West Washington, DC 20591, hua.he@faa.gov) and Eric Boeker (US Dept. of Transportation Volpe Ctr.)

Community noise near airports is a major aviation noise concern, prompting the development of various modeling tools to predict the noise changes due to airport expansion and fleet changes. Once aircraft leave the terminal area and reach high altitudes, the aircraft noise received on the ground is assumed to be insignificant relative to urban ambient noise and is often neglected. However, this might not be the case, under either of the following conditions: (1) when aircraft fly over areas with very low ambient noise levels, such as in wildness areas, or (2) when an aircraft is powered by advanced propulsion systems that produces high noise levels. There is an increasing need to address both of these issues. Over the past 2 decades, some limited noise modeling capabilities and related research have begun to quantify the high-altitude aircraft noise or "en-route" noise. The purpose of this paper is to review and summarize related noise prediction research conducted through direct technical exchange with researchers, some simple data analysis as well as through a literature review. The authors will draw on experience in developing current aircraft community noise tools and formulate key future research questions and options.

1:30

2pNCd3. Application of atmospheric absorption models for aircraft enroute noise. Kieran Poulain, Victor Sparrow, Kenneth Brentner (201 Appl. Sci. Bldg., Univ. Park, PA 16802, kxp252@psu.edu), and Louis Sutherland (Los Angeles, CA)

Propagation of aircraft enroute noise for flights above 18 000 ft above ground level (AGL) (5.49 km AGL) is important for estimating noise impact in U.S. National Parks and other quiet areas. One key to the accurate estimation of noise impact is atmospheric absorption. In our atmosphere, it turns out that the absorption coefficient is dependent on altitude as well as frequency. The altitude dependent parameters include mean pressure, temperature, and relative humidity as well as the concentration of molecular species. This altitude effect can be important for certain frequency bands, and this point will be emphasized in this paper. In addition, an improved atmospheric absorption model for high altitudes of Sutherland and Bass [J. Acoust. Soc. Am. **115**, 1012–1032 (2004)] shows slightly different values of atmospheric absorption in important frequency bands for aviation noise at altitude compared to the typical ANSI Standard S1.26-1995 (R 2009). For certain situations, the updated atmospheric absorption coefficient could produce different enroute noise predictions on the ground. [Work supported by FAA/NASA/Transport-Canada PARTNER Center of Excellence.]

1:45

2pNCd4. Modeling propagation of aviation noise under range-dependent conditions, using a hybrid parabolic equation-fast field program method. Joyce Rosenbaum, Anthony Atchley, and Victor Sparrow (Graduate Program in Acoust., The Penn State Univ., 202 Appl. Sci. Bldg., University Park, PA 16802, jer262@psu.edu)

Based on the Parabolic equation method, a model for sound propagation over uneven terrain, with mixed ground impedance and range-dependent meteorological conditions, has been developed to improve prediction of the impact of aviation noise on communities. Intended to enhance the noise prediction capabilities for the Federal Aviation Administration's Aviation Environmental Design Tool in support of the Next Generation Air Transportation System (NextGen), the model uses a hybrid parabolic equation-fast field program approach for computing aviation noise contours. These methods ensure that the low-frequency content, a factor in community impact, is propagated accurately. The model can accommodate a broadband, moving sound source, traveling along a user-specified path, over three-dimensional terrain. A test case, designed to represent simple but realistic propagation conditions, is described, and results for a source traveling along a simple flight path are presented and discussed.

2:00

2pNCd5. Acoustic repropagation technique and practical source characterization for simulation noise model databases. Christopher Hobbs and Juliet Page (Wyle Labs., 241 18th St. South, Ste. 701, Arlington, VA 22202, chris.hobbs@wyle.com)

By utilizing the acoustic repropagation technique in conjunction with an open-source, platform-independent database, a robust noise source can be constructed that is well suited for use in simulation noise models. This paper describes a widely applicable methodology for creating a three dimensional noise source from measurements that can account for source directivity. It will be shown how the resulting data, known as noise spheres, may contain a variety of noise metrics representing the source at a fixed distance for all spherical angles. Such spheres can be combined to represent complex noise sources and depending on their metric content can be used to accurately predict the near and far field environment about the source. A case utilizing narrow band spectra with phase information will be explored. It will be shown how a collection of spheres can be used to represent different operating states of a source and how the use of an independent parameter such as speed or power can be used to interpolate non-exact states in a noise model. By way of example, an approach to incorporating non-linear sound propagation from a high amplitude noise source is explored in conjunction with the advanced acoustic model.

2:15

2pNCd6. Modeling of noise from aircraft taxiing operations. Juliet Page and Christopher Hobbs (Wyle Labs., 241 Eighteenth St. South, Ste. #701, Arlington, VA 22202, juliet.page@wyle.com)

This paper documents a study performed for the Airport Cooperative Research Program, investigating noise from aircraft taxi operations. A holistic approach is utilized, applying an understanding of the operations, the detailed aircraft motions, and the acoustic sources. A series of acoustic sensi-

tivity studies was conducted in order to develop a physical understanding of the relative importance of the various modeling elements within the framework of AEDT. The study is based on decoupling the modeling of taxi noise into the following three areas and exercising each element independently. (1) Engine source noise (level, spectra, and directivity); (2) aircraft movements and operating states (location, duration, and power setting); (3) environment/propagation (lateral attenuation, terrain, shielding, and ground impedance). Aircraft taxi noise sensitivity studies exercised each element independently. Limited opportunistic commercial aircraft taxi operation acoustic measurements were conducted. Independent taxi flight data recorder information was queried to determine statistical engine and aircraft operational parameters. The sensitivity studies reveal that the primary weakness for taxi noise modeling is related to item (#1), engine source noise modeling. This paper will discuss the sensitivity study findings and present an approach for development of a nominal taxi state noise noise-power-distance, spectral class, and directivity database for AEDT.

2:30

2pNCd7. Investigation of the use of lower frequency acoustic data in helicopter environmental noise modeling. Eric Boeker and Noah Schulz (USDOT Volpe Natl. Transportation Systems Ctr., 55 Broadway RVT-41 Cambridge, MA 02142, eric.boeker@dot.gov)

The current Federal Aviation Administration (FAA) aircraft noise modeling tools, Aviation Environmental Design Tool (AEDT) and Integrated Noise Model (INM), do not consider noise below 50 Hz in their computations. This paper describes a preliminary study to determine the effect of including low-frequency data on the accuracy of AEDT/INM results. Expanded aircraft noise spectra containing one-third octave band data to 12.5 Hz were analyzed using methods adapted from AEDT/INM. Results from expanded spectral data are compared with results from the historical AEDT/INM spectral data (one-third octave band data from 50 Hz to 10 kHz). This comparison showed a range of differences, from increases in overall un-weighted sound pressure levels, to negligible changes in *A*-weighted and time audible metrics. These changes may be particularly important for helicopters, with dominant low-frequency rotor noise below 50 Hz. Following the comparison, the potential implementation of expanded spectral data in AEDT/INM is discussed.

2:45

2pNCd8. Examination of the low frequency limit for helicopter noise data in aviation environmental design tool and integrated noise model. Eric Boeker and Noah Schulz (USDOT Volpe Natl. Transportation Systems Ctr., 55 Broadway RVT-41, Cambridge, MA 02142, eric.Boeker@dot.gov)

The current Federal Aviation Administration (FAA) aircraft noise modeling tools, Aviation Environmental Design Tool (AEDT) and Integrated Noise Model (INM), do not consider noise below 50 Hz in their computations. This paper describes a preliminary study to determine the effect of including low-frequency data on the accuracy of AEDT/INM results. Expanded aircraft noise spectra containing one-third octave band data to 12.5 Hz were analyzed using methods adapted from AEDT/INM. Results from expanded spectral data are compared with results from the historical AEDT/INM spectral data (one-third octave band data from 50 Hz to 10 kHz). 2pNCe1. Flanking noise transmission in condominiums via steel roof deck. Jim X. Borzym (Borzym Acoust. Consulting & Eng., LLC, 2221 Columbine Ave., Boulder, CO 80302, acoustics@columbine.net)

Noise was found to transmit horizontally via a structure borne path. A lightweight roof consisting of ribbed steel deck spanned two adjacent loft-style condominium residential spaces. This noise transmission path significantly flanked the demising partition wall with known high-transmission loss. Two remedies were attempted to reduce transmission, by adding concrete on top of the roof deck. One remedy was successful.

3:30

2pNCe2. Flanking paths associated with exposed roof decks in condominiums. Jeff Kwolkoski (D. L. Adams Assoc., Inc., 1701 Boulder St., Denver, CO 80211, jkwolkoski@dlaa.com)

An award winning residential/commercial condominium project featured two-story loft condominiums with an industrial look. The building was constructed with steel structure, exposed concrete on metal deck floors, and an exposed metal deck roof. Condominiums were separated by gypsum board on metal stud walls. A number of owners in the building complained of poor sound isolation from adjacent units. Field tests showed that sound isolation of the walls fell below expectations for the design. Subsequent investigation showed that a variety of structureborne and airborne flanking paths contributed to poor sound isolation. Improving sound isolation required a combination of conventional and creative methods.

3:45

2pNCe3. Concrete pier foundation and building design for electron microscope installations with vibration disturbances from train, truck, and bus traffic. Chad Himmel (1705 W. Koenig Ln., Austin, TX 78756, himmel@jeacoustics.com)

A university microscopy and imaging center housing nine instruments including scanning electron microscopes and transmission electron microscopes was proposed for a site near an active railroad and roadways. Low-frequency sound and vibration from trains, trucks, and buses can affect the performance and use of electron microscopes, by disturbing the stability and resolution of the specimen's image. On-site observations and spectrum measurements were conducted to determine the ambient and transient ground borne vibration conditions. Measurements showed that disturbances from trains as well as bus and truck traffic on campus roads significantly exceeded allowable floor vibration tolerances for many of the instruments. Soils exhibited response to disturbances at dominant frequencies around 5 and 10 Hz. This paper addresses the potential for concrete pier-supported floor vibration and structural resonance contributions to ground borne vibration levels and solutions proposed to mitigate the disturbances for sensitive

instrument installations. Graphic diagrams of structural design concepts and results from on-site measurements prior to construction will be discussed. The designs and effectiveness of the microscope rooms, structural treatments, and actively damped, pneumatic vibration isolation systems are discussed, along with post-construction vibration measurement results and photographs.

4:00

2pNCe4. Tri-axial measurement of roadway vibration in multiple research buildings located throughout an urban college campus. Scott Harvey and Josh Curley (Phoenix Noise & Vib., 5216 Chairmans Ct., Ste. 107, Frederick, Maryland 21701, sharvey@phoenixnv.com)

Plans are currently underway to run a mass transit rail line through the center of a major university. Concerns over this significant change to the school's infrastructure were raised by members of the university's faculty, particularly professors questioning whether their research projects and vibration sensitive equipment will be disturbed from vibration generated by all the new train passbys. A study was arranged to investigate the campus existing vibration levels and analyze the potential for a substantial increase in vibration once the rail line is constructed. This was primarily a measure of vibration from traffic sources, especially university buses which operate frequently throughout the campus during all hours. The project involved recording simultaneous tri-axial vibration measurements in numerous locations throughout the campus. This required designing methods to manage equipment, make measurements, organize data, and present results in an efficient, timely, and coherent manner. The data indicate the level of ambient ground and structural vibration already present from daily university activities while serving as a basis for comparison to the increased vibration levels, if any, the newly constructed train will cause.

4:15

2pNCe5. A method for determining the force spectrum produced by mechanical equipment. Andrew Gorton and Chris Papadimos (Papadimos Group, 818 Fifth Ave., Ste. 207, San Rafael, CA 94901, andrew@papadimosgroup.com)

Currently there is no standardized method for determining the force spectrum produced by a piece of mechanical equipment. This information is useful for conducting detailed vibration analysis in buildings, specifying proper vibration isolation for mechanical equipment, and comparing mechanical equipment vibration performance. This paper presents a method for estimating the force spectrum for a piece of mechanical equipment supported on spring isolators. The force spectrum is calculated from the measured vibration response of the sprung mass and the frequency response function of the system. For validation, this procedure was used to determine the force spectrum of a 21 500 CFM air handling unit externally mounted on nominally 1-in. static deflection spring isolators. The calculated force spectrum was then used as a force input to a finite element model of a mass-spring-damper system with the same properties as the sprung air handler. The predicted results compare favorably with the measured vibration response and tend to support that this is a viable method for characterizing the force produced by mechanical equipment.

4:30

2pNCe6. Shipboard structureborne noise by resonant interactions of two torsional vibration modes. Darrell Milburn (J&A Enterprises Inc., 16 Broadway, Salem, MA 01970, milburn@jandaenterprises.com)

In recent years several occurrences of a similar engine-firing rate structureborne noise resonance were observed in the passenger areas of different ships. All were 16V four stroke high speed diesel propulsion systems, including engine vibration isolation mountings and remote reduction gears. The engine firing rate noise path came through the reduction gear mounting feet. Interactions of two torsional vibration modes with nearly equal natural frequencies caused the noise: one mode with the maximum amplitude in the engine crank shaft, and the other in the propeller shaft/reduction gear. Over a narrow range of engine speed, the firing rate energy excited both modes. The resonant torsional vibrations were transmitted to the structure through the reduction gear bearing reactions. In the observed cases, the amplitudes of the torsional stresses at resonance were well within the safe limits of the driveline components, raising no concern to vibration analysts assessing only the risk for mechanical failure. This paper outlines the system parameters related to the occurrences of these resonances, permitting noise control engineers to diagnose this problem or to identify "at risk" installations during the design phase. Noise control recommendations are presented as case studies with examples of the achieved noise reduction results.

Session 2pNSa

Noise, Architectural Acoustics and INCE: Ventilation, Fan, and Duct Noise Control II

Lixi Huang, Cochair
The Univ. of Hong Kong, Dept. of Mechanical Eng., Pokfulam Rd., Hong Kong, P.R. China

Kirill V. Horoshenkov, Cochair
Univ. of Bradford, School of Eng., Great Horton Rd., Bradford, BD7 1DP, UK

Jian Kang, Cochair
Univ. of Sheffield, School of Architecture, Western Bank, Sheffield, S10 2TN, UK

Invited Papers

1:20

2pNSa1. Reduction of blade passing noise of a vertical take-off and landing (VTOL) aircraft. Jie Pan (School of Mehanical Eng., The Univ. of Western Australia, 35 Stirling Hwy., Crawley, WA, pan@mech.uwa.edu.au), Hongmei Sun (The Univ. of Western Australia, Crawley, WA, Australia, hongmei@mech.uwa.edu.au), B. S. Walsh, K. D. Do, P. ONeill, and J. Ranasinghe (The Univ. of Western Australia, Australia)

Rotor-stator interaction has been identified as the dominant noise source of a vertical take-off and landing (VTOL) aircraft developed by Entecho. This paper reports field measurement results of blade passing noise of the VTOL air-craft together with its analysis and control. The blade passing event was simulated in a wind tunnel experiment. The flow speed, rotor position, and rotor-stator spacing were varied with the chord-wise pressure distribution of the lead-ing surface of the rotor blade being measured by an array of six flush

mounted microphones. Results show useful features of the pressure distribution on the rotor blade influenced by an upstream stator, which are used for the analysis and prediction of the sound radiation from the VTOL aircraft. The preliminary result of the reduction in the blade passing noise using angled stator blades is also presented.

1:40

2pNSa2. Prediction of axial fan noise by linearized perturbed compressible equations with large eddy simulation. Young J. Moon, Hoyeon Kim, Youngmin Bae (Dept. of Mech. Eng., Korea Univ., Seoul 136-701, Republic of Korea, yjmoon@korea.ac.kr), Florent Ravelet, Sofiane Khelladi, Hussain Nouri, and Farid Bakir (ParisTech, Paris, France)

The seek for an efficient aerodynamic and aeroacoustic design of axial-flow fans is an important field of investigation for both academic and applied research. Improvements can only be made with a better understanding of the physical mechanisms arising in these machines that combine strong interactions between rotating and non-rotating parts of highly complex geometries. One way is to couple well-suited experimental investigations and innovative computational methods that overtake the weaknesses of methods based, for instance, on aeroacoustic analogy. In this paper we study an axial fan using a new numerical method based on large eddy simulation /linearized perturbed compressible equations with Brinkman penalization. This method is developed in the Department of Mechanical Engineering at Korea University. The experimental tests and validations are performed in the Laboratory of Fluid Dynamics at Arts & Métiers ParisTech in Paris. Detailed analysis of numerical and experimental results is in progress within the two partner teams.

2:00

2pNSa3. The near-field of spinning sources: Why source identification is hard. M. J. Carley (Dept. of Mech. Eng., Univ. of Bath, Bath BA2 7AY, England, m.j.carley@bath.ac.uk)

An asymptotic analysis is presented for the near field of spinning sources, based on a transformation into cylindrical coordinates centered on a line at a fixed radius from the source axis. This transforms the circular source into an equivalent finite length line source with a source distribution made up of "modes" given as Chebyshev polynomials of the second kind $U_n(s) = \sin[(n + 1)\cos^{-1} s]/\sin\cos^{-1} s$. These modes play a role like that of modes in ducts and the analysis shows that their acoustic field propagates or decays depending on whether $n + 1 < k$ or $n + 1 \geq k$, respectively, with k wavenumber, similar to the cut-on/cut-off behavior of duct modes. The analysis is used to examine the problem of identifying a source from field measurements. This has a wide range of applications in many industrial fields but is well known to be (very) ill conditioned. Using the information supplied by the analysis of the source near field, the reasons for this ill conditioning are explained and some possible methods to mitigate the problem are outlined.

2:20

2pNSa4. Toward the prediction of fan noise: From low-speed to high-speed turbomachineries. Stphane Moreau (Dept. of Mech. Eng., Univ. de Sherbrooke, 2500 Boulevard de l'Université, Sherbrooke, QC J1K2R1, Canada stephane.smoreau@gmail.com)

Environmental concern and comfort trigger more and more acoustic specifications and regulations on aircraft impact on airports and on ventilation systems in buildings or transportation systems (cars, trains, or airplanes), which in turn impose lower and lower maximum noise levels to such systems. For instance, turbofan engines have increased their bypass ratio in order to improve the aircraft performance while diminishing the nominal speed of rotation. The jet noise is then reduced, and the fan noise becomes a dominant source of noise, especially at approach. A quick calculation of the overall noise generated by a given fan geometry, either low speed or high speed, would be a valuable asset to any fan design designer and manufacturer prior to any installation in a building or an airplane, for instance. However, an accurate prediction of the sound by any full turbomachinery still remains a challenging goal and a daunting task to be achieved by a direct computation. In the present study, the noise predictions will then rely on a strip theory combined with an acoustic analogy based on the wall pressure fluctuations. For the low-speed fans, the model is an extension of the development by Schlinker & Amiet for helicopters. Turbofan engines induce two additional difficulties to noise modeling: the cascade effects and the duct configuration which are presently modeled.

2:40

2pNSa5. Sound generation mechanism in low speed axial fans. Stefano Bianchi, Alessandro Corsini (Dept. of Mech. and Aeronautics, "Sapienza" Univ. of Roma, Via Eudossiana 18, 00184 Roma, Italy, bianchi@dma.ing.uniroma1.it), and Anthony G. Sheard (Flakt Woods Ltd., Colchester, Essex CO4 5ZD United Kingdom)

Because of the global civil regulation concerning acoustic emission, the goal of the manufacturers is to substantially decrease the noise radiated by the low-speed fans, without degrading their aerodynamic performance. One of the main goal to accomplish this target is the evaluation of the unsteady aerodynamic sources in the fan rotor responsible for the noise emission. An experimental analysis, based on a cause-effect method, was carried out and the results are presented in this paper. The process focuses on the experimental comparison between the novel prototypes of a family of low-speed fans and enabled the evaluation of the noise sources in the rotor near-field domain. The near-field aerodynamic sources accounted in this work correspond to the zones with high pressure fluctuations amplitude, located in the wake region of the exhaust flow. The sources were measured along the rotor radius and then correlated with the noise emitted by the fan at the far-field domain, using a Fourier based methodology. The analysis was carried out looking at the cross-spectra polar form using the phase shift as revealing tool for aerodynamic noise sources. The results were compared to evaluate the merit of the aero-acoustic performance of each prototype.

3:00—3:15 Break

3:15

2pNSa6. Quiet, efficient fans for space flight: An overview of NASA's technology development plan. Danielle Koch (NASA Glenn Res. Ctr., 21000 Brookpark Rd., MS 54-3, Cleveland, OH 44135, l.danielle.koch @nasa.gov)

NASA has developed a Technology Development Plan for improving the aerodynamic and acoustic performance of spaceflight fans. The intent is to make broader use of the technology developed at NASA Glenn to improve the efficiency and reduce the noise of aircraft engine fans. The goal is to develop a set of well-characterized government-owned fans nominally suited for spacecraft ventilation and cooling systems. NASA's Exploration Life Support community will identify design point conditions for the fans in this study. Computational Fluid Dynamics codes will be used in the design and analysis process. The fans will be built and used in a series of tests. Data from aerodynamic and acoustic performance tests will be used to validate performance predictions. These performance maps will also be entered into a database to help spaceflight fan system developers make informed design choices. Velocity measurements downstream of fan rotor blades and stator vanes will also be collected and used for code validation. Details of the fan design, analysis, and testing will be publicly reported. With access to fan geometry and test data, the small fan industry can independently evaluate design and analysis methods and work toward improvement.

3:30

2pNSa7. Aerodynamic design and computational analysis of a space flight vehicle cabin ventilation fan. Daniel L. Tweedt (AP Solutions, Inc., 22526 Tammy Circle, Council Bluffs, IA 51503, daniel.tweedt@ap-solutions.com)

Quieter working environments for astronauts are needed if future long-duration space exploration missions are to be safe and productive. Ventilation and payload cooling fans are known to be dominant sources of noise, with the International Space Station being an important case in point. To address this issue in a cost effective way, early attention to fan design, selection, and installation has been recommended. Toward that end, NASA has begun to investigate the potential for small-fan noise reduction through improvements in fan aerodynamic design. Using tools and methodologies similar to those employed by the aircraft engine industry, the aerodynamic design of a new cabin ventilation fan has been developed, and its aerodynamic performance predicted using computational fluid dynamics (CFD) codes. The design, intended to serve as a baseline for future work, is discussed along with selected CFD results.

3:45

2pNSa8. Surface integration method used on semi-solid surface for fan noise prediction. Yoon-Shik Shin and J. Stuart Bolton (Ray W. Herrick Labs., Purdue Univ., 140 S. Martin Jischke Dr., West Lafayette, IN 47907-2031, shin31@purdue.edu)

As a continuation of previous work, the Ffowc-Williams and Hawkings model was applied to an axial fan that was operated under unfavorable inflow condition. A thin aluminum foam screen that is used as a treatment for disturbed inflow condition was included as a noise source in computational aeroacoustic simulation. The incompressible URANS model was used for the CFD simulation and the inflow foam was modeled as a homogeneous porous zone with permeability and inertial resistance factors found experimentally. Since the homogeneous porous zone defined in this way does not have a solid structure that could be used as a dipole noise source, the control surface integration method was applied to the surface of the homogeneous porous zone: i.e., to a surface right between the normal fluid zone and the porous zone. The unsteady pressure data on the control surface under the incompressible assumption was treated as representing pressure fluctuations on a semi-solid surface rather than as a representation of acoustic sources within the volume surrounded by the control surface.

4:00

2pNSa9. Cooling fan noise reduction by optimizing spacing of blades. John Wang (Volvo Construction Equip., 312 Volvo Way, Shippensburg, PA 17257, john.wang@volvo.com)

Cooling fan noise theories are briefly reviewed. A simplified model is derived from a rotating point source theory. Optimization was done using the simplified model. A fan with unevenly spaced blades was prototyped, tested, and compared with a fan with evenly spaced blades. Noise reduction data are presented.

4:15

2pNSa10. Suppression of ducted dipole noise by an expanded segment around the source. Lixi Huang (Dept. of Mech. Eng., Univ. of Hong Kong, Hong Kong, lixi@hku.hk)

Low-speed fan noise mainly features dipole sound radiation. For such a fan operating in a duct, the low- to medium-frequency radiation derives mainly from the unsteady, axial forces acting on the rotating blades. Recently, we have found, both theoretically and experimentally, that self-cancellation of sound can be achieved by placing the dipole in an expanded segment of the duct which provides a reverberating environment with a reduced radiation impedance. The insertion loss spectrum shows a very broadband appearance similar to but is better than the transmission loss spectrum of an expansion chamber silencers used for reflecting an incident plane wave. Parametric analysis reveals that the expansion ratio controls the peak insertion loss, while the chamber length controls the single-lobe bandwidth. Simple plane wave analysis implies that short chamber would give wider stopband with a chamber of vanishing length yielding the best result. It is shown here that such analysis fails when the chamber is too short. For a given finite frequency band, there exists an optimal chamber length. Spectral element analysis reveals details of such optimal length and the result is explained in terms of the known fundamentals of dipole radiation and duct acoustics.

4:30

2pNSa11. Active control of axial fan noise using a multiple-input multiple-output feedback controller. Cole V. Duke, Scott D. Sommerfeldt, and Kent L. Gee (Dept. of Phys. and Astron., Brigham Young Univ., N283 ESC, Provo, UT 84602, coleduke@gmail.com)

In the past, significant progress has been made in actively controlling the tonal noise of axial cooling fans using a digital, feed-forward controller. Progress has also been made in controlling broadband fan noise using an analog feedback controller due to the nondeterministic nature of the noise. Current work focuses on the control of broadband noise with a multiple-input multiple-output (MIMO) feedback controller using four control sources and four error sensors. To ensure stability of the closed-loop control system, the phase and magnitude characteristics of the controller must be chosen to produce attenuation in the target frequency band without augmenting the noise outside the band. A practical analog feedback controller will be presented, and performance results will be compared between a single-input single-output controller and a MIMO controller.

2pNSb1. Determining the effects of long-range missile noise on wildlife. Timothy Lavallee (LPES, Inc., 14053 Lawnes Creek Rd., Smithfield, VA 23430, tlavallee@lpesinc.com)

This is presentation on determining the sound levels from missile test and the potential effects on wildlife. The discussion will include an estimate noise from the launch, rocket motor splashdown, sonic boom, and detonation of long-range missiles. An overview of calculations and modeling to determine exposure to wildlife will be incorporated. The discussion will include overview of the ongoing development of noise threshold criteria for marine mammals and terrestrial wildlife, particularly, dolphins, pinnipeds, and avian species. A literature review and detailed review of the effects threshold will be included. A discussion of the benefits and the shortcoming associated with both the noise modeling and the limitations with respect to the existing effects thresholds will be included.

1:25

2pNSb2. Addressing concerns about ultrasound noise during expansion of a laboratory animal facility. Gary M. Glickman (Wilson, Ihrig & Assoc., Inc., 65 Broadway, Ste. 401, New York, NY 10006, gglickman@wiai.com)

Since 2002 the mouse has become the preferred model for biomedical research largely due to the ease with which it can be genetically engineered. The growth in genetic research has led many institutions to expand their animal holding and research facilities. Managing expectations of investigators during the process of construction and minimizing potential for noise impacts to research are critical for a successful expansion project. Noise in the ultrasound frequency range is often a concern among researchers due to limited data on its causes and response of mice to it and due to the fact that humans cannot perceive ultrasound and are therefore unable to detect when it occurs. Consequently, prior to and during construction, issues involving ultrasound are best given careful consideration so as to minimize it and at the same time address researcher's concerns. Work will be presented from a case study of an expansion project at a medical research facility involving transgenic mice. Issues surrounding the potential for construction noise to impact mice holding rooms will be examined. Particular attention will be paid to measurement and evaluation of noise at ultrasound frequencies and approaches for addressing the concerns of investigators.

Contributed Papers

1:45

2pNSb3. Animal magnetic resonance imaging and acoustic noise. Amanda M. Lauer (Dept. of Otolaryngol.-HNS, Johns Hopkins Univ., 521 Traylor Bldg., 720 Rutland Ave., Baltimore, MD 21205), AbdEl-Monem M. El-Sharkawy, Dara L. Kraitchman, and William A. Edelstein (Johns Hopkins School of Medicine, Baltimore, MD 21205)

MRI scanner noise can cause discomfort and potential damage to human hearing. MRI is used extensively in animal research and, increasingly, as a diagnostic tool in veterinary medicine, generally with no hearing protection. Effects of noise could be detrimental for research animals that will be used after scanning or for companion animals that will be returned to owners. Though safe exposure standards have not been determined for most animals, it is important to consider that animals exposed to scanner noise may suffer hearing damage. To study potential animal MRI adverse hearing effects, we measured sound levels produced by several animal scanning protocols in a commercial 3T scanner. Using hearing threshold data for research or companion animals, we estimate weighted sound pressure levels and compare these to levels at which damage occurs in humans. SPLs were above 90 dB on many scans and often exceeded 100 dB. Animals may be exposed to these levels intermittently for 1 h or more. Exposure to these sound levels could result in temporary or permanent hearing loss. Thus, it is important to use hearing protection, quieter pulse sequences, or quieter scanners for animal research or companion animal veterinary MRI.

2:00

2pNSb4. Comparison of impulse noise damage risk criteria using the chinchilla impulse noise exposures. William J. Murphy, Amir Khan (Hearing Loss Prevention Team, CDC/NIOSH, 4676 Columbia Parkway, MS C-27, Cincinnati, OH 45226, wjm4@cdc.gov), and Peter B. Shaw (CDC/NIOSH, Cincinnati, OH 45226)

The 1968 CHABA recommendations to limit impulsive noise exposure to levels below 140 dB sound pressure level form the basis of current United States occupational and military standards. The U.S. military standard, MIL-STD 1474D, estimates the number of allowable shots to which a person may be exposed using peak level, B-duration, for varying levels of hearing protection usage. The French Weapons Noise Committee has uses the 85 dBA *A*-weighted equivalent level, $L_{\mathrm{Aeq8\ hr}}$, as the limit for allowable exposures.

The U.S. Army sponsored a series of noise exposures with chinchillas to investigate the effects of level, number of impulses, and interstimulus interval. Several types of impulses were created ranging from acoustic shock tubes to narrow band impacts reproduced by a loudspeaker. The goodness-of-fit and the discrimination of five noise exposure metrics were evaluated in this study: MIL-STD 1474D, AHAAH model, $L_{\mathrm{Aeq8\ hr}}$, Pfander's C-duration metric, and Smoorenburg's D-duration metric. Goodness-of-fit was evaluated with a logistic regression and discrimination was evaluated using the area under the receiver operator characteristic curve. The $L_{\mathrm{Aeq8\ hr}}$ was found to best predict the temporary threshold shifts and the AHAAH model was found to best predict the permanent threshold shifts. [Partial funding provided by US Army Aeromedical Research Laboratories MIPR8J07586218].

2:15

2pNSb5. Extraction of hearing loss threshold levels and equal auditory risk metric curves of chinchillas from existing exposure data. Wonjoon Song, Steve Goley, and Jay Kim (Dept. of Mech. Eng., Univ. of Cincinnati, Cincinnati, OH 45221-0072)

An existing set of chinchilla noise exposure data has been re-analyzed using an advanced signal analysis tool and a statistical regression analysis. The data are comprised of 23 digitally recorded noise files and auditory damage indicators of the chinchillas measured at six frequency points, 0.5, 1, 2, 4, 8, and 16 kHz. From the relationship between the equivalent sound pressure level (Leq) of the six 1/3 octave frequency components of the noise and PTS of chinchillas, the Leq level that starts to cause auditory damage to chinchillas is identified as a function of frequency. These threshold levels of chinchillas, obtained for the first time in this study, will be useful information to design chinchilla exposure studies. The levels that will cause the same amount of PTS at the six frequencies are also obtained, from which equal auditory risk metric (EARM) curves are constructed. It is shown that a chinchilla version of an advanced noise guideline which enables quantitative, frequency-by-frequency assessment of the risk of a noise can be developed using the EARM curves. Possibility as well as difficulties of developing a human version guideline similar to this chinchilla prototype are discussed.

2:30

2pNSb6. Survey of ambient noise in aquariums. Colin W. Jemmott (Penn State Grad. Program in Acoust., P.O. Box 30, State College, PA 16804, cwj112@psu.edu)

Owning and maintaining an aquarium is a common hobby, but the ambient noise in aquariums resulting from pumps, filters, bubblers, and other equipment is not well studied. Elevated ambient noise levels have been shown to adversely affect wild fish and marine invertebrates, and anecdotal evidence suggests that this may be a problem in aquariums as well. Aquariums designed to maintain coral reefs require high water flow and pristine water conditions, which in turn require pumps and protein skimmers that contribute to underwater noise. A survey of ambient noise in both fresh and saltwater aquariums ranging in size from 5 to 550 gal was conducted. The aquariums differed in construction material, number, size and type of pumps, and presence of other equipment. The ambient noise broadband levels, spectrum levels, and time-frequency representations are compared, and general conclusions are drawn about noise characteristics of equipment and aquariums.

2:45

2pNSb7. A new tranquility rating tool and the role of audio and visual interactions. Kirill Horoshenkov, Robert Pheasant, Greg Watts (School of Eng., Univ. of Bradford, Bradford BD7 1DP, United Kingdom, k.horoshenkov@bradford.ac.uk), David Whitaker (Univ. of Bradford, Bradford BD7 1DP, United Kingdom), and Jian Kang (Univ. of Sheffield, Sheffield S10 1FL, United Kingdom)

Restorative environments which enable individuals to recover the sense of well-being are becoming increasingly important. These environments are characterized by an enhanced level of tranquility. Therefore, obtaining the optimum balance between the landscape and soundscape characteristics and measuring the resultant tranquility of these spaces are essential for their design and maintenance. In order to understand the key factors which affect the tranquillity construct, a large volume of audio and visual data has been collected across a representative range of landscapes in the UK. These data have been analyzed objectively by studying the temporal and spectral characteristics of the recorded sounds and the proportion of the natural and contextual features present in the video clips. The tranquility rating of these landscapes has been obtained from subjective experiments on 44 subjects to whom uni- and bimodal stimuli have been presented in a separate experiment. The results of these experiments make possible to objectively measure the key components of the tranquillity construct and determine their relative importance in the design of a restorative space. On this basis new relations between the tranquility rating, sound pressure level, loudness characteristics, and the visual quality of the scene have been derived.

3:00

2pNSb8. The effect of anthropogenic noise on the calling behavior of amphibians and birds in urban areas of Puerto Rico. Maria Isabel Herrera-Montes and Mitchell Aide (Dept. of Biology, Univ. of Puerto Rico, P.O. Box 70377, San Juan, PR 00936-8377, isahemontes@yahoo.com)

The bird and amphibian communities of Puerto Rico have high levels of diversity and endemism. Although Puerto Rico has a very high density of roads and high levels of noise pollution, presently 40% of the island is covered in forest. I will address the following questions: Do high levels of anthropogenic noise change species composition of amphibians and birds? Are amphibians and birds modifying the time of calling and/or characteristics of their vocalization in response to anthropogenic noise? I collected sound recordings in two habitats. For recordings I used the automated recording devices developed by our research group. Each recording device was programmed to record for 7 consecutive days; 1 min every 20 min. Previous results showed that noise influences the bird community composition in secondary lowland forest sites, but not in karst forest. Another possibility is that bird and amphibian use other strategies to minimize the effect of noise. This can involve evolutionary changes in signal characteristics, as a long term adaptation or the species may be adjusting signal traits in response to variations in noise levels as a short term adaptation. I will answer these questions when I do analyzing all data.

2pNSc1. Hearing protection devices: The regulatory journey to change. Catrice Jefferson (U.S. Environ. Protection Agency, 1200 Pennsylvania Ave., NW, Washington, DC 20460)

The regulation for the labeling of hearing protection devices (40 CFR Part 211, Subpart B) was promulgated in 1979 and has been the directive for 30 years. During this time, there have been significant changes in the industry with respect to newly developed products, which has resulted in the demand for various types of hearing protectors and an increased awareness of hearing loss in both occupational and non-occupational environments. The foundation of the newly proposed regulation of August 5, 2009 is based on these observations and those that were presented by industry, hearing conservation professionals, and the general public during the EPA Workshop on Hearing Protection Devices that was held in March 2003. While these observations will serve as the backdrop of the presentation, the scenery will be the key elements of the proposed regulation, such as the testing methodology, noise reduction rating range, label format and content, recurrent testing, and reporting requirements of testing data. The audience will journey through these scenic elements but will be delivered to its final destination, which are regulatory change and the prospects of withstanding another 30 years.

1:40

2pNSc2. Proposal for assessing the effectiveness of noise policies. Lawrence Finegold and Michiko So Finegold (Finegold & So, Consultants, 1167 Bournemouth Ct., Ctr.ville, OH 45459, lsfinegold@earthlink.net)

During the last half of the 20th century, most of the developed countries of the world have been addressing noise as an environmental and occupational problem, and have been working to develop noise control and exposure policies and related noise control technologies. Since the 1970s, the United States has been an international leader in these efforts, although more recently significant advances have been made elsewhere, particularly by the European Commission. However, little is known about how effective various noise policies and regulations have been in controlling the noise exposure of the populations which they are intended to protect. This paper proposes a national program to address this issue. The first phase involves the collection and cataloging of noise policy regulations and related guidelines and, for the most part, has already been completed by the International Institute of Noise Control Engineering, including a comprehensive index of U.S. noise policies. The second phase would involve developing a baseline of noise exposure estimates for various community environments. The third phase would determine the long-term effectiveness of noise policies in controlling noise exposure by examining the changes in various noise exposures and noise effects over time.

2:00

2pNSc3. Integrating disturbance ecology and public policy: A better framework for managing the effects of anthropogenic noise. Ann E. Bowles (Hubbs-SeaWorld Res. Inst., 2595 Ingraham St., San Diego, CA 92109) and Amy R. Scholik-Schlomer (Natl. Marine Fisheries Service, Office of Protected Resources, 1315 East-West Hwy., Silver Spring, MD 20910)

The Marine Mammal Protection Act and the Endangered Species Act are statutes designed to conserve and recover marine mammal species. In addition to language that restricts activities that could "take" individuals via death, they restrict activities that could harass marine mammals. By framing the problem in terms of harassment, these statutes acknowledge the potential for significant behavioral effects. However, predicting biologically significant effects of disturbance is often difficult. A better theoretical and technical framework is needed that accounts for the adaptive scope (both physiological and behavioral) of large, intelligent, wide-ranging, and long-lived marine mammals. While ASA members have debated policy statements on the inappropriate use of acoustic concepts in controversies over marine mammal exposure to noise, they have not effectively addressed the need for better integration of biological theory. Of particular importance are theories on cognitive function, adaptive defensive strategies, and allostasis that help explain why marine mammal responses can be intelligent and flexible in some cases and injurious in others. By integrating such biological concepts into its policy statements, the Society could foster more effective use of research resources and help stakeholders support regulatory instruments for noise that would effectively balance human needs with those of marine mammals.

2:20

2pNSc4. Disastrous decisions: Costs to natural quiet of Grand Canyon National Park. Dickson J. Hingson (275 S. River Run, Flagstaff, AZ 86001)

Noisy intrusions from air tour rides and other aircraft increasingly, adversely affect highly significant areas of the Grand Canyon National Park. These continue in the heart of the park, even though Theodore Roosevelt told us to "do nothing to mar its grandeur." Preserving the Canyon's numinous aura requires maintaining its emblematic silence. The requisite policy would be to severely restrict aircraft noise. Belated efforts for an aggressive noise policy began here soon after 1965 airport completion near the Park. Hard won Congressional mandates for restoration of natural quiet were nonetheless frustrated by an accelerating aircraft boom fed by still more bad decisions, FAA stonewalling/bullying, and industry selfishness. The NPS/FAA environmental outcome—being finalized now, under a "change" administration—is coming into focus via a detailed EIS under public comment. The still unmet national direction to curb this

noisy, commercial park "take-over" illustrates serial failures in group decision-making. A "road map" of contributing reasons for a veritable acoustic/soundscape "collapse" here gains strength from insights in Jared Diamond's recent book "Collapse":, i.e., failures to anticipate, to perceive, and to behave or obey. To right these wrongs, the concerned public must assertively guide the current Administration's implementation of substantial, enduring restoration of the Park's natural quiet.

2pNSc5. Sex, money, religion, and politics: Understanding noise policy in terms of what is left unsaid. Leslie D. Blomberg (Noise Pollution Clearinghouse, Box 1137, Montpelier, VT 05601-1137)

Sex, money, religion, and politics. We are not supposed to talk about these things. And when it comes to discussions of creating a comprehensive noise policy, we generally do not, and perhaps we should not. But we should at least understand their contribution to the mxe9;lange of laws and regulations that is our current noise policy. This paper examines the elephant in the room that people are not talking about.

3:20

2pNSc6. Would Western noise policies be effective in developing countries? Lawrence Finegold (Finegold & So, Consultants, 1167 Bournemouth Ct, Ctr.ville, OH 45459, Lsfinegold@earthlink.net) and Dieter Schwela (Swedish Environ. Inst.)

This paper examines the question of whether current and evolving Western noise policies would be effective and appropriate for use in developing countries. Differences in noise sources, available finances and noise control technologies, cultural norms, climate, views concerning the role of the government, etc., make it likely that different approaches might be needed in developing countries for their noise policies to be effective. Thus, it recommends that an international consortium of scientists and engineers, government representatives, and key stakeholders be organized to address this important topic. The noise policy needs of developing countries require an awareness of their typical noise problems, along with appropriate, affordable, and technologically feasible solutions, and how these might be incorporated into emerging Global Noise Policy concepts. This paper presents a concept for a Strategic Approach to Environmental Noise Management in Developing Countries, developed by the Swedish Environmental Institute (SEI), to form a foundation for the proposed international consortium. The next step is to now formalize an international consortium to provide additional technical input, to encourage participation by international agencies, professional societies and stakeholders, to organize workshops and special sessions at acoustics congresses, and to promote the evolving SEI concept with the governments of developing countries.

3:40

2pNSc7. There ought to be a law! Nancy S. Timmerman (25 Upton St., Boston, MA 02118, nancy.timmerman@alum.mit.edu)

This paper will examine some of the logical consequences of laws and policymaking as they relate to acoustics. In acoustics and noise control, "public policy" is used to try to legislate good behavior. Those who behave well do not need the laws. Those who do not will not obey the laws. Examples will be drawn from aviation and planning, examining the use of measures such as DNL. In particular, this paper will address how laws create unintended results, frequently not addressing the issue at all.

2pNSc8. New York City: The (E) designation and restrictive declaration. Benjamin Sachwald (AKRF, 440 Park Ave., South 7th Fl., New York, NY 10016, bsachwald@akrf.com)

Urban areas are typically associated with high-noise levels. With a population of more than 8×10^6 and growing, New York City is one of the largest cities in the world. In New York City, because of the population density and the wide variety of land uses (for example, residential, commercial, transportation, manufacturing, and industrial) that exist in close proximity, it is common for a residential building to be located in an area with ambient noise levels that would be considered unsuitable for residential use. To protect inhabitants of a planned building to be located in an area with high ambient noise levels, an (E) designation or a Restrictive Declaration may be used to ensure that the building's interior environment meet a certain acoustical design criterion. In this paper, the (E) designation and Restrictive Declaration are defined, their regulatory process is outlined, and specific case studies are discussed.

4:15

2pNSc9. Recommendations for the improvement of the management of noise from helicopter operations. Paul Kendrick, David C. Waddington, Geoff Kerry (School of Computing, Sci. and Eng., Univ. of Salford, Salford M5 4WT, United Kingdom, p.kendrick@salford.ac.uk), Matthew Muirhead, and Ray Browne (QinetiQ Ltd., Farnborough GU14 0LX, United Kingdowm)

This paper results from recent research commissioned by the Department for Environment, Food and Rural Affairs (Defra, UK) with the objective of identifying possible opportunities for the improvement of the management of noise from helicopter operations in the UK. Effected populations are not just those living close to heliports but include those exposed to noise from helicopters used by the military, emergency services, and commercial companies. A detailed report has been produced addressing the improvement of the management of helicopter noise. Also produced was a short nontechnical guide including the means of redress for perceived disturbance. The report also makes clear recommendations for future work and identifies particular areas where specific research is required. This paper discusses these recommendations and suggests a way forward for research into the improvement of the management of helicopter noise. [Work funded by the Department for Environment, Food and Rural Affairs (Defra), UK].

2pPA1. Highlighting the career of Mack Breazeale. James G. Miller (Dept. of Phys., Washington Univ., 1 Brookings Dr., St. Louis, MO 63130, james.g.miller@wustl.edu)

Mack Breazeale's creative work was respected and recognized by professional organizations including the Acoustical Society of America, the Institute of Acoustics (Great Britain), and the IEEE Ultrasonics, Ferroelectrics, and Frequency Control Society (UFFC), each of which honored him with the rank of Fellow. Breazeale served as the UFFC Distinguished Lecturer in 1987–1988, during which time he traveled extensively to deliver highly regarded presentations. In recognition of Breazeale's many contributions to the IEEE UFFC, including his many-year participation in the Technical Program Committee that sets the theme for the Annual IEEE Ultrasonics Symposium, Breazeale was honored with the Achievement Award in 2008, the highest Society-wide award presented to a member in special recognition of outstanding contributions. I had the pleasure of highlighting Breazeale's many contributions that led to this prestigious honor during the awards ceremony at the 2008 Ultrasonics Symposium in Beijing. When I wrote to Breazeale to express my congratulations on this award and to discuss how I might summarize his many achievements in a career spanning decades, Breazeale responded by saying, "The most important aspect of my career is the fact that I have served as Major Professor to 15 MS candidates and 16 doctoral candidates."

1:10

2pPA2. Training graduate students: The teaching philosophy of Mack Breazeale. Michael S. McPherson (Dept. of Phys. and Astronomy, 1906 College Heights Blvd. #11077, Bowling Green, KY 42101, mike.mcpherson@wku.edu)

Mack Breazeale's last Ph.D. student will comment on Dr. Breazeale's contributions to solid state acoustics, nonlinear acoustics, and acousto-optics. In particular, this talk will focus on Dr. Breazeale's approach to, and methodology for, training and teaching graduate students how to conduct research and mature into capable scientists. This talk will speak to Dr. Breazeale's unique gifts as a teacher and mentor and his approach to conducting scientific work in general.

1:20

2pPA3. Research on acoustical memory discovered in the laboratory of Mack Breazeale. Igor Ostrovskii (Dept. of Phys., Univ. of Mississippi and NCPA, University, MS 38677, iostrov@phy.olemiss.edu)

Research at Mack's Laboratory at NCPA has discovered that a $LiNbO_3$ single crystal can memorize an ultrasonic pulse for tens of microseconds, the frequency range was 17–28 MHz. Supposedly, the Acoustical Memory (AM) effect is connected to the oxide internal microstructures. This conclusion is based on frequency, thermal, and ultrasound attenuation data. Mack Breazeale's leadership, scholarly character, and gentle nature were clearly revealed through these experimental investigations, various meetings, and scientific discussions in his office and laboratory. However, a basic connection between the ceramic microstructures and AM formation is not revealed yet. Further development of AM investigations is done in the inversely poled ferroelectric wafers of $LiNbO_3$ and $LiTaO_3$. The speeds of different acoustic modes are altered in the presence of periodically poled ferroelectric domains. Calculations for a bulk periodically poled $LiNbO_3$ yield a similar result despite the uniform acoustic properties along the specimen. Distortions in the dispersion curves of ultrasound in non-homogeneous ferroelectrics with specific internal microstructures may be a physical cause of acoustical memory. Some applications are discussed. [Work supported by UM.]

1:40

2pPA4. Theoretical and experimental investigation of the backward beam displacement. Nico F. Declercq (UMI Georgia Tech, CNRS 2958, 2 Rue Marconi, 57070 Metz France and Woodruff School of Mech. Eng., Georgia Tech, Atlanta, GA 30332-0405)

The discovery of a backward beam displacement of ultrasound interacting with a periodically corrugated surface, dates back from 1976, when Breazeale and Torbett reported it [Appl. Phys. Lett. **29**, 456 (1976)]. Since 2002 new investigations have been undertaken partially motivated by Breazeales enthusiasm. An overview is presented of how the phenomenon was first discovered in 1976, how a theoretical explanation was found since 2002 [Declercq *et al.*, Appl. Phys. Lett. **82**, 2533 (2003); Declercq *et al.*, J. Appl. Phys. **96**,

6869–6877 (2004)] and what further verifications and discoveries have been made since then [Teklu *et al.*, J. Appl. Phys. **97**, 084904 1 (2005)]. The report also highlights new research showing the ubiquitous presence of the phenomenon and its importance for nondestructive applications [Herbison *et al.*, J. Acoust. Soc. Am. In press].

2:00

2pPA5. Breazeale legacy in Gaussian acoustics. Dehua Huang (NUWC, Newport, RI 02841)

Professor Breazeale is a great educator, an outstanding researcher, and scientist in many acoustic fields. This talk focuses professor efforts and leadership in pioneer Gaussian acoustics theory and practice. In 1992, instead of going by KZK or Helmholtz equations for theoretical Gaussian acoustic wave solution, a new path was discovered based on the far field approximation from the Rayleigh integral. By which, the mathematical solution matches with the other Gaussian wave equation results. Further, the design of the Gaussian acoustic transducer technologies is evolved. It was only possible for 2 MHz and above frequency band operating Gaussian transducers. This frequency band barrier was crossed over, and a set of kilohertz Gaussian transducers was fabricated in the laboratory by a new design. The definition for a qualified Gaussian transducer was also finalized. The propagation of a Gaussian wave in an ocean environment was also simulated.

2:20

2pPA6. Acoustic parametric oscillators: In the footsteps of Mack Breazeale. Lev A. Ostrovsky (Zel Technologies and NOAA Earth System Res. Lab., 325 Broadway, Boulder, CO 80305)

Parametric oscillators have been studied in physics since the 18th century. In acoustics, the effect of transformation of pump energy to a half-frequency subharmonic (or, more generally, to any lower-frequency signals) began to be studied in 1960s by Korpel and Adler and in the laboratory of Breazeale. They observed basic parametric effects such as half-frequency generation and generation of lower-frequency doublets. In early 1970s, our group in Russia began studies of acoustic parametric phenomena in dispersive systems (waveguide resonators), in which most of extra harmonics and subharmonics are suppressed so that generation at the desired frequencies occurs much more efficiently. Indeed, in these experiments the subharmonic mode was generated so intensively that it can even damp the pumping mode in resonance. Also the later experiments with "non-classical," strongly nonlinear solid materials, such as ferroelectrics and metals, should be mentioned. The more recent works include parametric phenomena in bubbles; moreover, the group of Lauterborn in Germany has demonstrated that the period-doubling scenario of transition to chaos can be realized in cavitation noise. This presentation outlines a brief history of acoustic parametric oscillators and relevant effects in the context of pioneering works of Professor Mack Breazeale.

2:40

2pPA7. Close encounters of the distinguished kind. Koen Van Den Abeele (Wave Propagation and Signal Processing, K.U. Leuven Campus Kortrijk, E. Sabbelaan 53, B-8500 Kortrijk, Belgium, koen.vandenabeele@kuleuven-kortrijk.be)

Mack Breazeale entered my life at the very start of my research career in Kortrijk, Belgium. At the 20th anniversary of the university campus, he was co-organizer together with Oswald Leroy of the Physical Acoustics Meeting. I had the honor to edit and compile the book containing all contributed papers. Since that moment we have met each other regularly in Kortrijk or at an international meeting. Later he was a member of the jury at the defense of my doctoral thesis, and the same evening he managed to persuade my wife and me to come to NCPA for a year as a post-doc. We will always remember Ole-Miss and the parties at the gentle Breazeale family. Upon returning to Belgium I immediately got an email from Paul Johnson, triggered by Mack Braezeale, asking me to apply for a post-doc at Lanl. Thanks to Mack (and Paul), we had an unforgettable experience there. I consider it the birth of nonlinear acoustics and ultrasonics in Belgium. Oh, and by the way, we have performed some great science together in acousto-optics and nonlinear acoustics.

2pPA8. Frequency dependence of the ultrasonic parametric threshold amplitude for a fluid-filled cavity. Alem A. Teklu (Dept. of Phys. & Astronomy, College of Charleston, 66 George St., Charleston, SC 29424, teklua@cofc.edu), Michael A. McPherson (Western Kentucky Univ., Bowling Green, KY 42101), Mack A. Breazeale (Natl. Ctr. for Physical Acoust., University, MS 38677), and Nico F. Declercq (Georgia Tech Lorraine, 57070 Metz-Technopole, France)

The excitation of fractional harmonics in a liquid-filled cavity by ultrasonic waves was described previously as a parametric phenomenon [L. Adler and M. A. Breazeale, J. Acoust. Soc. Am. **48**, 1077–1083 (1970)]. That is, by driving a transducer at one end of a fluid-filled cavity parallel to a rigid plane reflector at the other end, standing ultrasonic waves can be generated. Variations in the cavity length resulting from transducer motion lead to the generation of resonant frequencies lower than the drive frequency (known as fractional harmonics). The system was modeled by using a modified Mathieus equation whose solution resulted in the prediction of critical threshold drive amplitude for the excitation of parametric oscillation. The apparatus used by Adler and Breazeale was recently refined for accurate measurements of the threshold amplitude for parametric excitation at frequencies ranging from 2 to 7 MHz. The measurements showed that in this range the threshold amplitude increases with increasing drive frequency in apparent discrepancy with the results of Adler and Breazeale. Analysis of the theory indicates, however, that both past and current results lie in two different stability zones, and each is in agreement with the existing theory.

3:35

2pPA9. Optical Bragg imaging of acoustic fields after reflection. Michael S. McPherson (Dept. of Phys. and Astronomy, Western Kentucky Univ., 1906 College Heights Blvd. #11077, Bowling Green, KY 42101, mike.mcpherson@wku.edu), M. A. Breazeale (Univ. of Mississippi, University, MS 38677), Nico F. Declercq (Georgia Tech Lorraine, UMI Georgia Tech, 57070 Metz-Technopole, France), and Alem Teklu (College of Charleston, Charleston, SC 29424)

If visible light is incident at the Bragg angle on an acoustic wave of the appropriate frequency, the light will undergo Bragg diffraction from the acoustic wavefronts in a manner analogous to the Bragg diffraction of x-rays in a crystalline lattice. If the acoustic beam has previously passed through an object before having light diffracted from it, the structure of that object will be imaged in the optical diffraction orders. In traditional Bragg imaging applications, the sound is first transmitted through the object. In this presentation a new reflection-based method of Bragg imaging (where light is reflected from rather than transmitted through the object) will be discussed. This technique is capable of imaging structures at or near the surface of the object and may have potential industrial and biomedical NDT applications.

3:50

2pPA10. Infrasound-convection instability. Konstantin Naugolnykh (Dept. of Phys., Univ. of Colorado, 325 Broadway, Boulder, CO)

Heated below temperature stratified atmospheric layer is unstable and convection flow can be developed in such an area. Convection happens because warm less dense air goes up while cooler air comes down. Infrasound can initiate convection flow and being amplified by the flow. The process of infrasound-convection interaction is considered in the present paper. The model of convection in a compressible fluid is considered and analyzed. The conditions of infrasound amplification are obtained.

4:05

2pPA11. Ultrasonic imaging and characterization of objects submerged in highly attenuating fluids. Bart Raeymaekers, Cristian Pantea, Curtis F. Osterhoudt, and Dipen N. Sinha (Los Alamos Natl. Lab., MPA-11, P.O. Box 1663, MS D429, Los Alamos, NM 87545)

An ultrasonic scanning tool to image objects with high-spatial resolution submerged in highly attenuating fluids is described. The attenuation coefficient of the fluids used range over two orders of magnitude. For deeper penetration into the attenuating fluids, a parametric array with a difference frequency between 200 and 500 kHz was used. The primary frequencies that generated this difference frequency varied between 2 and 8 MHz. This parametric array provides a collimated beam for imaging. Both simple tone burst and frequency chirp signals were used for the measurement. Using this apparatus, the quality and accuracy of the image as a function of frequency, fluid attenuation coefficient, and fluid type (clear and suspensions) were investigated. It was found that imaging was possible over a wide range of attenuating coefficients and fluid types.

4:20

2pPA12. Batchelor's fourth order velocity correlation. John M. Seiner (Natl. Ctr. for Physical Acoust., The Univ. of Mississippi, University, MS 38677)

The Lighthill theory for aerodynamic noise relates far field sound pressure to complex fourth order two point two-time space-time velocity correlations. The Mani–Gliebe–Balsa (MGB) jet noise prediction code follows Lighthill's theory in the development of its algorithm. Since fourth order turbulence correlations are not modeled in the MGBs flow solver, it is necessary to resort to some form of approximation. The MGB invokes Batchelor's fourth order decomposition, which is exact for homogeneous and isotropic turbulence. For anistropic flow, like that of a jet, it is not known what the error is in adopting Batchelor's isotropic decomposition. The question here is can stereo particle image velocimetry (SPIV) provide a means to establish the error incurred with adoption of this decomposition. In an attempt to define the penalty for adopting the Batchelor's decomposition, a simple 2×94; diameter laboratory jet was operated at ambient temperatures at Mach 0.85. SPIV measurements were acquired of the fourth order two-point space correlation and all of the other second order correlations. A comparison was made to numerical plume simulations with an advanced numerical flow solver running in the RANS mode. This paper provides an explanation for observed variations between measured and predicted jet noise.

4:35

2pPA13. Multipole expansion for nonlinear acoustic scattering at the difference-frequency. Glauber T. Silva (Inst. of Phys., Univ. Fed. Alagoas, Maceio, Alagoas 57072-970, Brazil, glauber@pq.cnpq.br)

In this work, the scattering at the difference-frequency (DF) of two finite-amplitude plane waves by a rigid sphere in a fluid is studied. The DF-scattering is present in some acoustic imaging methods such as vibro-acoustography. This has motivated us to perform this study. We obtain for the first time the multipole expansion for the DF-scattered pressure in the farfield. Theory is based on the successive approximation and the Green's function methods. From the multipole expansion, we derive some quantities such as scattering cross-section and the total DF-scattered power. Furthermore, we show that the DF-scattered pressure increases with the observation distance r like $r \ln r$, while it varies almost linearly with the difference-frequency. Despite the amplification, we demonstrate that the DF-scattered pressure does not grow indefinitely because of absorption in the fluid. The theory is applied to the scattering in the Rayleigh limit (scatterer much smaller than the incident wavelengths). Only monopole and dipole moments are relevant in this limit. In conclusion, we believe that this theory can help to understand better the nonlinear scattering in acoustics.

4:50

2pPA14. A new form of Gaussian beam function as the base function for generic wave field analysis. J. J. Wen (VeroSound, Inc., 128 Powder Mill Rd., Sudbury, MA 01776)

Wave propagations are best described by three major approaches: the spherical wave approach represented by Rayleigh integral, the planar wave approach represented by spatial Fourier analysis, and the Gaussian beam approach. Spherical and planar wave approaches, both in form of double integrals, are analytically inconvenient and computationally expensive. In contrast, the Gaussian beam approach, with huge advantages in analytical operability and computational efficiency, has been quietly but firmly winning popularity. Dr. Breazeale's article: A diffraction beam field expressed as the superposition of Gaussian beams, co-authored with Wen, is not only a most representative work for Gaussian beam approach but also a most cited academic work in sound field analysis and computation. As a memory of Dr. Breazeale's pioneer role in the raise of Gaussian beam method, this article presents a new enhancement to the existing Gaussian beam method. A modified form of Gaussian beam function introduced as the base function set for wave field analysis greatly reduces the error rooted from the parabolic approximation, the number of Gaussian beams needed, and the run-time computation burden. The process for calculating the beam coefficients and beam parameters is also greatly simplified.

Session 2pPP

Psychological and Physiological Acoustics and Engineering Acoustics: Application of Auditory Models to Hearing Aids

Brent W. Edwards, Chair
Starkey Hearing Research Center, 2150 Shattuck Ave., Ste. 408, Berkeley, CA 94704

Invited Papers

1:00

2pPP1. The application of auditory models to hearing aid research. Brent W. Edwards (Starkey Hearing Res. Ctr., 2150 Shattuck Ave., Ste. 408, Berkeley, CA 94704, brent_edwards@starkey.com)

Audibility has been a focus of hearing aid research for much of the hearing aid field's existence. With modern hearing aids, audibility no longer limits performance for hearing aid wearers with moderate hearing impairment. Limitations in suprathreshold auditory-perception now need to be better understood in order to determine existing hearing deficits while aided. The ways in which hearing aids affect suprathreshold auditory function also need to be better understood in order to ensure that hearing aids provide maximal benefit in complex real-world situations. Auditory models can be used to address these needs. This talk will review current applications and future opportunities for the application of auditory models to hearing aid research.

1:20

2pPP2. Differentiating inner from outer hair cell damage: Measures and applications to model-based hearing aid design and fitting. Enrique A. Lopez-Poveda, Peter T. Johannesen, Patricia Prez-González, Jorge M. Mndez, and Almudena Eustaquio-Martín (Instituto de Neurociencias de Castilla y Leon, Univ. Salamanca, C/Pintor Fernando Gallego 1, 37007 Salamanca, Spain, ealopezpoveda @usal.es)

Hearing aids (HAs) are designed and fitted mainly to restore normal audibility and loudness growth. Unfortunately, after decades of research, many users still find them frustrating. We hypothesize that this is partly because HAs operate on the assumption that cochlear hearing loss is always associated with a reduction in cochlear gain and/or compression when this, in fact, need not be the case. Indeed, recent studies have shown that cochlear hearing loss frequently relates to selective or combined dysfunction of inner hair cells (IHCs) and outer hair cells (OHCs). Neither absolute thresholds nor loudness growth allows for a differential assessment of the type of hair cell damage, yet such assessment could be highly informative for optimizing HA design and fitting. In this presentation, we summarize our progress in designing a fast, universal method for inferring the degree of IHC and OHC dysfunction using distortion-product otoacoustic emission input/output functions. We also describe our progress in designing a HA based on these ideas and on a bank of dual-resonance non-linear filters inspired by computational models of healthy and impaired human cochlear responses. [Work supported by the MEC, Grant BFU2006-07536, and The Oticon Foundation.]

1:40

2pPP3. The use of a loudness model to derive initial fittings of multi-channel compression hearing aids. Brian C. J. Moore (Dept. of Experimental Psych., Univ. of Cambridge, Downing St., Cambridge CB3 9LG, United Kingdom, bcjm@cam.ac.uk)

A model of loudness perception applicable to hearing-impaired people has been used to develop three methods for the initial fitting of hearing aids with multi-channel compression, based on the audiometric thresholds. Method one, CAMEQ, has the goals of amplifying speech so that, on average, the specific loudness is the same for all frequencies within the range 500–4000 Hz, over a wide range of overall sound levels, giving about the same overall loudness as "normal" for speech covering a wide range of sound levels. Method two, CAMREST, determines the gains needed give normal specific loudness patterns for speech over a wide range of sound levels. Method three, CAMEQ2-HF, is similar to CAMEQ but differs from it in the following ways: (1) gains are recommended for center frequencies up to 10 kHz (as compared to 6 kHz for CAMEQ), (2) CAMEQ2-HF is based on the assumption that the user may wish to hear sounds from many directions and uses a diffuse-field-to-eardrum transfer function (as opposed to a free-field-to-eardrum transfer function for CAMEQ); (3) CAMEQ2-HF is based on recent wideband measurements of the average spectrum of speech. All of the methods can be applied to any multi-channel compression hearing aid.

2:00

2pPP4. Modeling of the auditory periphery for hearing aid evaluation and design. Ian C. Bruce (Dept. of Elec. & Comp. Eng., McMaster Univ., 1280 Main St. W., Hamilton, ON L8S 4K1, Canada, ibruce@ieee.org)

Amplification schemes and gain prescriptions for hearing aids have thus far been developed and evaluated based on perceptual criteria such as speech intelligibility, sound comfort, and loudness equalization. Finding amplification strategies that simultaneously optimize all of these perceptual metrics has proven difficult, despite decades of research. Furthermore, novel amplification schemes based on rough conceptual models of the normal and impaired auditory physiology have often proven to be unsuccessful. In this talk, I will describe studies directly employing physiologically accurate computational models to evaluate more rigorously what hearing aids are likely doing to the neural representation of speech. The results of these investigations indicate that (i) a physiologically accurate

auditory-nerve (AN) model can predict optimal linear and nonlinear amplification gains, (ii) optimal gains are dependent on both the spike-timing and mean-rate representations of speech in the AN, (iii) the proportion of outer hair cell and inner hair cell dysfunction in an impaired ear can affect optimal gains, and (iv) slow wide dynamic range compression (WDRC) or automatic gain control better restores the neural representation of speech than does fast WDRC.

2:20

2pPP5. Application of auditory models to assessing the sound quality of hearing aid signal processing algorithms. Volker Hohmann (Medizinische Physik, Universität Oldenburg, Oldenburg, Germany)

Advances in systems technology allow for increasingly complex processing algorithms in hearing systems addressing increasingly complex acoustic conditions. These developments have the potential of improving the rehabilitation of hearing impairment, but establishing reliable measures of benefit is quite difficult for these complex algorithms and conditions. Being the "gold standard" for algorithm evaluation, subjective testing of hearing-impaired subjects has some limitations in this context. It is very time consuming and the long acclimatization time needed when listening with new devices in complex acoustic conditions cannot easily be accounted for. Therefore, objective methods for estimating the benefit of an algorithm in a certain acoustic condition are desirable. They allow for identifying promising candidate algorithms and the acoustic conditions in which the algorithms might be applicable and thus identify critical acoustic conditions to be tested subjectively. In addition and in combination with technical measures such as segmental signal-to-noise ratio and distortion measures, perceptual measures based on auditory models might be useful for developing meaningful objective measures. This talk presents recent applications of auditory models to objective algorithm evaluation. Because of the growing importance of binaural and multi-microphone processing in hearing instruments, binaural/multichannel models for speech intelligibility and quality will be emphasized.

2:40

2pPP6. Auditory models of suprathreshold distortion in persons with sensorineural hearing loss. Ken W. Grant, Van Summers, Joshua G. W. Bernstein, Sandeep A. Phatak, Matthew J. Makashay, Elena Grassi, and Golbarg Mehraei (Army Audiol. and Speech Ctr., Walter Reed Army Medical Ctr., Washington, DC 20307-5001, ken.w.grant@gmail.com)

Hearing technology has advanced to where it is now reasonable to ask whether signal processing algorithms can be developed to compensate for an individual's hearing loss, thus allowing them to hear functionally in a manner similar to persons with normal hearing. Clinically, the pure-tone audiogram is the primary tool used to represent the patient's hearing status. However, it has been well established, experimentally and theoretically, that the audiogram cannot reflect fully all aspects of the hearing loss, most notably that part which pertains to suprathreshold distortion. Much has been written about the distortion component of sensorineural hearing loss, yet there is little agreement on estimating its importance to speech recognition, nor much consensus on which hearing factors (e.g., spectral and/or temporal resolution) most accurately represent the distortion. Recent attempts to use biologically inspired models of auditory processing to represent a patient's internal auditory experiences have shown promise as a way to understand the role that suprathreshold distortions might play in speech recognition. This talk reviews recent work to develop auditory models of {\it individual} hearing-impaired listeners to predict differences in the perception of speech and non-speech signals not readily explained by audiometric thresholds. [Work supported by the Oticon Foundation.]

3:00—3:10 Break

3:10

2pPP7. Real-world application of auditory models to hearing instrument design. Stefan Launer (Phonak AG, Laubisruetistrasse 28, 8712 Staefa, Switzerland)

Auditory models provide a powerful tool for designing and developing signal processing algorithms of modern digital hearing instruments and can even be integrated directly into these algorithms. Models for loudness perception have been applied directly in hearing instrument algorithms with two applications: to control the gain of a hearing instrument and to limit the maximum output power of a hearing instrument as a "loudness limiter." Another example is the application of a very simple model in a hearing instrument to help resolve localization problems due to the microphone position in BTE hearing instruments, resulting in reduced front/back confusions. Examples of the application of models to the development and analysis of hearing instrument performance in real-life environments include the use of auditory scene analysis models to better understand human sound source classification and to improve the performance of automatic control systems in hearing instruments. A last example is the application of models describing human localization performance under realistic acoustic environments to understand the impact that hearing instrument signal processing has on the ability of hearing impaired people to localize sounds with hearing instruments. This talk will explore and discuss the potential of these different approaches for hearing instrument technology.

2pPP8. Moving fluid loading to the basilar membrane in passive nonlinear cochlear model. Svetlana Kovinskaya (Mechmath LLC, Prior Lake, MN 55372, mechmath@mechmath.com)

The mechanical response of the cochlea to sound is a nonlinear phenomenon. Existing models (with either passive or active outer hair cells) do not include effect of the motion of fluid loading to basilar membrane (BM). Being extremely slow this motion will play significant role only if the traveling wave in BM is close to the point of ceasing of propagation. Two fluid channels corresponding to the scalae vestibuli and tympani, each filled with incompressible liquid, provide the fluid loading to BM. Equation describing BM vibration with contra-directed moving fluid loading (from opposite sides of BM) becomes nonlinear equation because of an additional force proportional to loading velocity squared and the local curvature of BM (the second derivative of BM displacement). The velocity of this mass-like fluid motion is proportional to the applied sound power. In the case of sinusoidal excitation, the equation for BM vibration becomes the Mathieus equation with the characteristic equation determining stable and (parametrically) unstable regions. The nonlinear equation gives a multi-frequency quasi-steady state solution. Suggested mechanism (additional forces in the equation for BM vibration) explains the compression of strong stimuli, explains the generation of distortion products, and is in qualitative agreement with other experiments.

2pPP9. Predicting the effects of compression incorporating signal-adaptive band allocation. James M. Kates (GN ReSound, Dept. Speech Lang Hear Sci., Univ. of Colorado, 409 UCB, Boulder, CO 80309)

This paper considers the effects of dynamic-range compression on speech intelligibility and quality for hearing-impaired listeners. The paper focuses on a modification of compression in which the compression behavior for each frequency band is controlled by the peak amplitude within a frequency region surrounding the band. The stimuli are sentences in a background of multi-talker babble. Speech intelligibility and quality indices are used to model the listener responses for mild, moderate sloping, and moderate/severe hearing losses. The indices predict the effects of varying the compression parameters and the width of the frequency region, thus giving an indication of the expected benefit of the modified compression system and the optimal parameter settings as a function of hearing loss and listening conditions.

4:00

2pPP10. Prediction of binaural speech intelligibility when using non-linear hearing aids. Nicolas N. Ellaham (School of Inf. Tech. and Eng., Univ. of Ottawa, 800 King Edward Ave., Ottawa, ON K1N 6N5, Canada, nellaham@uottawa.ca), Christian Giguère (Univ. of Ottawa, Ottawa, ON K1H 8M5, Canada), and Wail Gueaieb (Univ. of Ottawa, Ottawa, ON, K1N 6N5, Canada)

A new objective measurement system is proposed to predict speech intelligibility in binaural listening conditions for use with hearing aids. Digital processing inside a hearing aid often involves non-linear operations such as clipping, compression, and noise reduction algorithms. Standard objective measures such as the articulation index, the speech intelligibility index (SII), and the speech transmission index have been developed for monaural listening. Binaural extensions of these measures have been proposed in the literature, essentially consisting of a binaural pre-processing stage followed by monaural intelligibility prediction using the better ear or the binaurally enhanced signal. In this work, a three-stage non-linear extension of the binaural SII approach is introduced consisting of (1) a stage to deal with non-linear processing based on a simple signal separation scheme to recover estimates of speech and noise signals at the output of hearing aids [Hagerman and Olofsson, Acust. Acta Acust. **90**, 356 (2004)], (2) a binaural processing stage using the equalization-cancellation model [Beutelmann and Brand, J. Acoust. Soc. Am. **120**, 331 (2006)], and (3) a stage for intelligibility prediction using the monaural SII [ANSI-S3.5, 1997 (R2007)]. Details of the new procedure will be discussed. [Research supported by NSERC (Canada).]

4:15

2pPP11. Predict the intelligibility of individual consonants in noise for hearing-impaired listeners. Feipeng Li, Woojae Han, and Jont Allen (Beckman Inst., Univ. of Illinois at Urbana, 405 N. Mathews Ave., Urbana, IL 61801)

The performance of hearing-impaired (HI) listeners to understand speech often deteriorates drastically in cocktail-party environments. To understand why a particular HI listener can hear certain sounds and not the others, it is critical that we take the prior knowledge about speech cues into consideration and investigate the effect of different types of cochlear hearing loss on speech perception. In the last 2 years we have tested over 50 hearing-impaired ears on consonant identification in noise. To evaluate the impact of shift of hearing threshold on the intelligibility of individual consonants in masking noise, a consonant intelligibility index (CII) is developed to predict the perceptual scores of individual consonants. Results of preliminary study indicate that CII makes an accurate prediction for flat mild-to-moderate hearing loss, but fails for the cases of cochlear dead region and extremely unbalanced (e.g., severe high-frequency) loss, suggesting that audibility alone does not fully account for the hard of speech perception in noise for many HI listeners.

4:30

2pPP12. Evaluating hearing aid processing with an auditory model of modulation sensitivity. Frederick J. Gallun (Natl. Ctr. for Rehabilitative Auditory Res., U.S. Veterans Hospital Rd., Portland, OR 97239, Frederick.Gallun@va.gov), Pamela E. Souza, and Eric Hoover (Northwestern Univ., Evanston, IL 60208)

Amplitude modulation is one of the fundamental aspects of sound to which humans are sensitive. A number of auditory models based on this sensitivity have been successful at explaining other aspects of human behavior, both in the domains of psychoacoustics and speech perception. A constrained-parameter model of perceptual similarity based on modulation sensitivity (the spectral correlation index) has recently been developed for use in the prediction of perceptual confusions at the phonemic level [Gallun and Souza (2008)]. The relatively small parameter set of the model allows for efficient adaptation of the basic architecture to novel problems. With a single change in the range of one parameter, this model can be used for the evaluation of hearing aid processing by predicting the confusions that will accompany various choices of amplification parameters. This approach demonstrates the value of evaluating signal processing strategies in hearing aids through changes in perceptual similarity as predicted by auditory models. [Work supported by NIH NIDCD R01 DC0060014 and VA RRD CDA-2 C4963W.]

2pPP13. Modeling quality judgments of music stimuli reproduced by a simulated hearing aid. James M. Kates (Dept. Speech Lang Hear Sci., GN ReSound, Univ. of Colorado, 409 UCB, Boulder, CO 80309) and Kathryn H. Arehart (Univ of Colorado, Boulder, CO 80309)

The focus in hearing aids is generally on speech, but the ability to reproduce music is also important for listener satisfaction. This study uses a sound quality metric to predict judgments of music quality made by normal-hearing and hearing-impaired listeners. A simulated hearing aid was used to process music modified by (1) additive noise and nonlinear processing, (2) linear filtering, and (3) combinations of noise, nonlinear processing, and linear filtering. The music stimuli included jazz, classical, and vocalize selections. The quality metric incorporates a model of the auditory periphery that reproduces aspects of impaired hearing. The effects of noise and distortion on the signal are estimated by measuring the changes to the envelope time-frequency modulation pattern, and the effects of linear filtering are estimated by measuring the changes to the signal long-term internal spectral representation. The accuracy of the quality metric for music will be presented, and the performance of the metric for music will be compared to its accuracy in reproducing the quality ratings of speech stimuli processed under similar conditions.

Session 2pSA

Structural Acoustics and Vibration: Computer Modeling of Structural Acoustics and Vibration for Complex Structures

James E. Phillips, Chair
Wilson Ihrig and Associates, Inc., 5776 Broadway, Oakland, CA 94618-1531

Chair's Introduction—1:25

2pSA1. A multiphysics model of hearing aid vibroacoustics using finite elements. Thomas Burns and Dave Tourtelotte (Starkey Labs., Inc., Eden Prairie, MN 55344)

Electromagnetic balanced armature receivers [Hunt, *Electroacoustics*, Chap. 7] are used exclusively to generate acoustic output in hearing aids. These transducers are much more efficient than electrodynamic transducers and are capable of delivering upward of 140 dB of sound pressure to person. In an effort to maximize system gain in a hearing aid, vibroacoustical feedback paths originating from the receiver are modeled using finite elements. Given an electrical excitation, the electromagnetic-mechanical force on the armature is solved as a function of frequency. The force on this armature vibrates an internal diaphragm, which generates acoustic output while vibrating the entire hearing aid. Assuming that there are no acoustical leaks in the design, vibroacoustical coupling limits the usable gain of the aid. Using commercially available software, the fluid is modeled with full Navier–Stokes elements and is coupled to all structural boundaries. The armature is "kicked" with the aforementioned force, and spectral analysis is used to study mechanical transmissibility within and vibroacoustic reradiation around the hearing aid.

2pSA2. Finite element vibration analysis and measurement of a 255 ft vehicle ferry. Jesse H. Spence and Ron E. Dempsey (Noise Control Eng., 799 Middlesex Tpke., Billerica, MA 01821)

Finite element analysis (FEA) methods have become part of the standard repertoire when designing a ship. This is particularly true for static analyses, although FEA methods are becoming increasingly utilized for analysis of low-frequency vibration as well. This paper discusses the FEA modeling process that was used for analyzing low-frequency (less than 80 Hz) habitability vibration on a 255 ft vehicle ferry. Deck vibration levels were measured after the vessel was built. Measured versus predicted vibration data show good correlation, particularly when the various sources of potential error and uncertainty are considered. The subject ferry was designed to meet the ABS Comfort Class (COMF) vibration criteria. Calculations of deck vibration were performed using NEiNastran to verify compliance with the criteria. Excitations due to propeller hull pressure excitation are highlighted here as these forces created the largest deck responses. However, it is noted that the main propulsion engines were resiliently mounted subsequent to initial analyses using the FE model. This paper discusses pertinent details of the model (element types, properties, etc.), application of hull pressures, damping, analysis methodology, and interpretation of results. Areas of uncertainty and impacts to the results are discussed.

2:10

2pSA3. An evaluation of residual vectors in the commercial finite-element program NASTRAN. John B. Fahnline (Water Tunnel Bldg., University Park, PA, 16802)

MSC NASTRAN introduced residual vectors in 2005. They are used to improve solution accuracy by representing the static contributions of truncated modes in transient and frequency response calculations. This formulation is convenient because the residual vectors are added to the modal vectors to form an augmented basis set, where the residual vectors are orthogonal to each other and to the original mode set. Modal frequency response calculations then proceed as usual only with a few extra vectors in the basis set. This talk will focus on evaluating the improvements in accuracy that can be achieved using residual vectors for modal frequency response problems where two structures with truncated mode sets are joined together.

2:30

2pSA4. Derivation of a Ritz series modeling technique for acoustic cavity-structural systems based on a constrained Hamilton's principle. Jerry H. Ginsberg (School of Mech. Eng., Georgia Inst. of Technol., Atlanta, GA 30332-0405, jerry.ginsberg@me.gatech.edu)

Hamilton's principle for dynamic systems is adapted to describe the fully coupled interaction of a confined acoustical domain and a bounding elastic system in cases of imposed velocity or pressure fluctuations on the surface or forced excitation of the structure. A key part of the modified principle is the treatment of the surface traction as a Lagrange multiplier function that enforces continuity conditions at the fluid-solid interface. The structural displacement, fluid velocity potential, and traction are represented by Ritz series, where the usage of the velocity potential as the state variable for the fluid assures that the flow is irrotational. Designation of the coefficients of the potential function series as generalized velocities leads to corresponding series representations of the particle velocity, displace-

ment, and pressure in the fluid, which in turn leads to descriptions of the mechanical energies and virtual work. Application of the calculus of variations to Hamilton's principle yields linear differential-algebraic equations whose form is identical to those governing mechanical systems that are subject to nonholonomic kinematic constraints. Criteria for selection of basis functions for the various Ritz series are illustrated with an example of a rectangular cavity bounded on one side by an elastic plate and conditions that change discontinuously on other sides.

2:50

2pSA5. Acoustic color of viscoelastic objects in two-fluid environments: High-fidelity, high-speed, three-dimensional finite-element modeling. David S. Burnett (Naval Surface Warfare Ctr. Panama City Div., 110 Vernon Ave., Panama City, FL 32407, david.s.burnett@navy.mil)

NSWC PCD has developed a computer simulation system for modeling the acoustic color (target strength versus frequency and aspect angle) of realistic three dimensional (3-D) objects that are near to or straddling the interfaces between different fluids. It employs high-fidelity (fully 3-D physics throughout object and environment), finite-element (FE) modeling of acoustic scattering from viscoelastic objects. It is implemented in a scalable-architecture, multiblade rack system that automatically runs hundreds of thousands of FE models, changing the mesh resolution and outer fluid boundaries of the models as they sweep over frequency. This frequency-dependent modeling yields a frequency-independent modeling error for the acoustic color response. This, in turn, yields higher accuracy for subsequent signal processing of the acoustic color data. The first part of this paper will present a brief overview of the theoretical, numerical, and software issues. The second part will present verification and validation of the system: (1) ultra-high-precision correlation with *T*-matrix simulations for four canonical target/environment configurations and (2) experimental validation for objects in free space and straddling the interface between two different fluids. [Work supported by ONR and SERDP.]

3:10—3:25 Break

3:25

2pSA6. Energy finite element analysis of naval vehicles. Nickolas Vlahopoulos (Dept. of Naval Architecture and Marine Eng., Univ. of Michigan, 2600 Draper Rd., Ann Arbor, MI 48109, nickvl@umich.edu) and Kuangcheng Wu (Northrop Grumman Shipbuilding, Newport News, VA 23607)

Simulation methods can be used for meeting both the new acoustics and vibration initiatives for surface ship silencing. An energy finite element analysis (EFEA) formulation has been developed for computing efficiently the vibration of complex structures and the associated radiated noise at frequencies beyond the limits of conventional finite element methods. The EFEA provides a very attractive alternative to the statistical energy analysis (SEA) because it uses the same finite element model which is utilized for other simulations (i.e., structural analysis), while the SEA requires the development of a completely new model based on a lumped parameter approach. Further, the SEA requires estimates of modal densities for the various subsystems which introduce difficulties and approximations in the solution. Thus, the EFEA streamlines the structural-acoustic analysis within the ship design process due to modeling commonality with other disciplines. In this presentation, the main theoretical aspects of the EFEA will be presented first. Results presented for two 1/8th scale structures representing an advanced double hull design and a conventional hull design of a surface ship are analyzed. Results for the structural vibration induced on the outer bottom part of the structures are compared to available test data.

3:45

2pSA7. Engaging structural-acoustic simulations in multi-discipline design. Nickolas Vlahopoulos (Univ. of Michigan, 2600 Draper Rd., Ann Arbor, MI 48108, nickvl@umich.edu) and Jim He (Michigan Eng. Services, LLC, Ann Arbor, MI 48108)

In order to be effective and maximize the weight and cost savings, designing for noise and vibration attributes must be performed in parallel when designing a complex system for other disciplines (i.e., durability, crashworthiness, etc.). The system characteristics influence the performance in all the different attributes. Challenges arise when designing a system for improving mutually competing objectives, satisfying constraints from multiple engineering disciplines, and determining a single set of values for the vehicle characteristics. This presentation discusses an approach that conducts optimization analysis for a complex system by coordinating operations and exchange of data and information through a network of optimizations. A rotorcraft application is analyzed for structural-acoustic and crashworthiness. The hybrid finite element analysis (hybrid FEA) comprises the simulation method used for the structural-acoustic simulation. It combines conventional FEA with energy FEA for modeling the response of a system comprised by stiff, load bearing members, and flexible panels. The LS-DYNA solver is used for the crash-landing simulations. The weight of the gear box foundation is optimized while simultaneous improvements are pursued through parallel driven optimizations that address the input power into the system from gearbox excitation and the dynamic stresses encountered in the gearbox foundation from crash landing.

4:00

2pSA8. SALINAS: A massively parallel finite element code for structural dynamics and acoustics analysis. Jerry W. Rouse (Dept. Analytical Structural Dynam., Sandia Natl. Labs., Albuquerque, NM 87185, jwrouse@sandia.gov), Timothy F. Walsh, and Garth M. Reese (Sandia Natl. Labs., Albuquerque, NM 87185)

This talk shall present an overview of SALINAS, a massively parallel finite element code for structural dynamics and acoustics analysis that is being developed at Sandia National Laboratories. SALINAS allows for prediction of both the time and frequency domain responses of complex structural, acoustic, and fully coupled structural acoustic systems having millions of degrees of freedom. An overview of SALINAS capabilities shall be presented including development history, solver and element types, quadratic eigenanalysis and frequency response, direct frequency response, nonlinear acoustics, implicit transient dynamic analysis, and infinite elements with focus given to structural acoustics capabilities. The application of SALINAS to structural acoustics problems shall also be presented as well as future directions of research for the development of the code.

4:15

2pSA9. Numerical study of structural intensity for a model airframe structure in healthy and damaged states. Micah R. Shepherd, Stephen C. Conlon (Appl. Res. Lab., Penn. State Univ., P.O. Box 30, State College, PA 16804), and Fabio Semperlotti (Penn. State Univ., State College, PA 16804)

Structural damage due to fatigue or material flaws presents a major challenge for many engineering applications. To address this challenge, structural health monitoring techniques have been developed in an effort to determine the type, severity, and location of the damage. Many of these techniques are based on the nonlinear contact phenomenon. In this paper, structural intensity methods are used as a damage-detection metric on a simplified airframe structure. A finite-element model was created and the structural intensity field was mapped over the surface using individual element power flow estimates. Damage was then introduced into the model by removing connectivity between elements and including nonlinear stress-strain relationships and contact at the damage location. Structural intensity maps were then compared to the healthy case to correlate the changes with the damage state. More specifically, the increase in structural intensity at the sub- and super-harmonics was found to be indicative of the damage state. The results of this numerical study show the potential of surface structural intensity in autonomous damage detection for flight vehicles. The implications of this type of damage detection metric with respect to damage size and location will also be discussed.

Session 2pSC

Speech Communication: Speech Production (Poster Session)

Benjamin R. Munson, Chair
Univ. of Minnesota, Dept. of Speech, Language, Hearing Science, 164 Pillsbury Ave., SE, Minneapolis, MN 55455

Contributed Papers

All posters will be on display from 1:30 p.m. to 4:30 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:30 p.m. to 3:00 p.m. and contributors of even-numbers papers will be at their posters from 3:00 p.m. to 4:30 p.m.

2pSC1. A procedure for estimating gestural scores from articulatory data. Hosung Nam (Haskins Labs., New Haven, CT 06511, nam@haskins.yale.edu), Vikramjit Mitra (Univ. of Maryland, College Park, MD), Mark K. Tiede (Haskins Labs., New Haven, CT), Elliot Saltzman (Boston Univ., Boston, MA), Louis Goldstein (Univ. of Southern California, Los Angeles, CA), Carol Espy-Wilson (Univ. of Maryland, College Park, MD), and Mark Hasegawa-Johnson (Univ. of Illinois at Urbana-Champaign, Urbana, IL)

Speech can be represented as a set of discrete vocal tract constriction gestures (gestural score) defined at functionally distinct speech organs [tract variables (TVs)]. Using such gestures as sub-word units in an ASR system, variation in speech arising from coarticulation and reduction can be addressed. Since there is a lack of test corpora annotated with gestural scores, we develop a semi-automatic procedure for estimating and annotating gestural scores from natural speech databases using the Haskins speech production model (TaDA). We first describe the procedure's application to 500 words with unique phone sets found in the Wisconsin x-ray microbeam database, generating both gestural scores and synthetic speech. Second, we perform dynamic time warping (DTW) to align the TaDA-generated speech signals with respect to the microbeam data. The DTW time-scaling pattern is then used to adjust the gestural score originally input to TaDA to generate new time-warped TaDA acoustics. Third, we fine-tune the gestural timing patterns within the new gestural score in a constrained manner to generate the score whose associated acoustics are minimally different from the database acoustics. Finally, we evaluate the optimized gestural score's validity by comparing its associated TV trajectories to those from the original microbeam database.

2pSC2. Prosodic interaction between speakers of American and British English. Jelena Krivokapic (Dept. of Linguist., Yale Univ., 370 Temple St., 302, New Haven, CT 06520-8366, jelena.krivokapic@yale.edu)

Previous work has found that interaction between speakers influences their production, in that phonetic similarity of the speakers to each other increases [Sancier and Fowler, J. Phonetics **25**, 421–426 (1995); Pardo, J. Acoust. Soc. Am. **119**, 2382–2393 (2006); and Tobin, J. Acoust. Soc. Am. **125**, 2757 (2009)]. These studies have mostly focused on segmental properties of speech. Little is known, however, about how prosodic properties of speech are affected in conversational interaction. An experiment is presented that examines the interaction between native speakers of British English and American English. Using the synchronous speech paradigm [Cummins, ARLO **3**, 7–11 (2002) and Zvonik and Cummins, in Proceedings of the Eurospeech 2003 (2003), pp. 777–780] where two speakers read sentences at the same time, we examine how speakers influence each other at the prosodic level. Eight subjects (4 dyads), each consisting of one British and one American speaker, read the following: a short story that contained four words where the two dialects differ in stress pattern, 13 target words where the dialects differ in vowels, and 84 sentences with varying intonation patterns (question, statement, and focus). The goal was to examine how speakers adjust to each other's speech, and whether certain prosodic properties are more susceptible to adjustment to the co-speaker's production than others.

2pSC3. Prosodic boundaries in German: Final lengthening in spontaneous speech. Susanne Fuchs (ZAS, Schuetzenstrasse 18, 10117 Berlin, Germany fuchs@zas.gwz-berlin.de), Jelena Krivokapic (Yale Univ., New Haven, CT 06520-8366), and Stefanie Jannedy (ZAS, Schuetzenstrasse 18, 10117 Berlin, Germany)

Most theories of prosodic structure postulate at least two phrasal categories above the word level, a minor and a major one. One correlate of phrasal boundary marking is lengthening on the right edge of a phrase. To gain a theory neutral understanding of the nature of prosodic boundaries, a Gaussian mixed model (GMM) was applied to durational data, estimating the underlying clusters of a continuous distribution. Spontaneous speech data were collected with standardized interviews from 19 adolescent speakers of a multi-ethnolect (Kiezdeutsch, Hood German) spoken in Berlin, orthographically transcribed and added to a database that allowed for searches of the particle "so"(so or like) in different conditions. Acoustic durations of /z/ and /o/ of so in phrase final position (as determined by orthographical markings or by following pauses) were labeled and z-transformed per speaker. The

results show that a model including two clusters accounts best for the data. Nevertheless, there is an overlap between the two distributions supporting the gradient nature of boundaries. Further analyses with more tokens of so including word level junctures are currently under way. The impact of our data-driven results on theoretical models of prosodic boundaries is discussed. [Supported by a grant from BMBF.]

2pSC4. Prosodic analysis of subglottal pressure contours. Helen M Hanson (Dept. ECE, Union College, 807 Union St., Schenectady, NY 12308, helen.hanson@alum.mit.edu), Stefanie Shattuck-Hufnagel (MIT, Cambridge, MA 02139), and Angela McLelland (Union College, Schenectady, NY 12308)

In previous work the problems of identifying final fall and estimating declination of the subglottal pressure contour were addressed [Hanson *et al.*, J. Acoust. Soc. Am. **118**, 2027 (2005); **120**, 3090 (2006)]. Additional methods for identifying final fall have since been explored. These new methods will be described, and the identification of final fall will be compared across several of the methods. The use of these additional methods has meant that the complete data set for three subjects can be analyzed. Therefore it is worth revisiting the work presented in 2006. Objective measures of subglottal pressure declination will be evaluated with respect to subjective ratings of declination. The effects of phrase and boundary tones on declination rate will be re-examined, as will the effects of pitch accent distribution. [Work supported by NIH Grants DC00075 and DC04331 and by a Union College summer research grant to A.M.]

2pSC5. Effects of metrical structure on syllable timing II. Megan Tinius and Marios Fourakis (Dept. of Communicative Disord., UW-Madison, Madison, WI 53706)

Fourakis and Monahan [J. Linguist. (1988)] examined the effects of two different types of metrical foot (iamb and anapest) on syllable timing in 3 ft utterances. These utterances were comprised of three iambs, three anapests, and every possible combination of the two types. The present research follows the same paradigm but uses trochees and dactyls instead of iambs and anapests. A set of eight 3 ft long sentences was constructed. At one end there was the three trochee sentence: Auctions rescue business. At the other end was the three dactyl sentence: Auctions may rescue his businesses. The intermediate six sentences were formed by different combinations of the metrical feet. Five male and five female native speakers of Midwestern American English were recorded producing five repetitions of each sentence at a normal rate of speech. Segments were assigned syllable membership based on the maximum onset principle. Results will be presented on syllable durations as a function of foot type and sentence type. [Research supported by the University of Wisconsin Madison Graduate School.]

2pSC6. Temporal structure in the speech of persons with dementia: A preliminary study. Linda Carozza (Dept. of Commun. Sci. and Disord., St. John's Univ., 300 Howard Ave., Staten Island, NY 10301), Margaret Quinn, Jacqueline Palladino, and Fredericka Bell-Berti (St. John's Univ., Jamaica, NY 11439)

Although cognitive and language processes in dementia have been studied extensively, the question of motor speech degeneration in the course of dementing illness is a relatively unexplored area. The potential for early dissociation of motor functions of language at the level of speech production has not been explored; an interaction between motor speech and language production and perception changes should inform our understanding of the deterioration in dementia. If early motor declines are found, they may provide an additional early marker and contribute to early detection, giving further insight to the character of neurological deterioration in this disease. This study explores the temporal structure of speech in individuals in the mild-to-moderate stages of the disease. In this preliminary study, participants were asked to produce a series of four-word phrases containing target word in phrase-medial or phrase final position. The target words contained the vowel in "heed," "head," or "had," and began with a fricative or voiced or voiceless stop consonant and ended with either /t/ or /d/. Thus, we are able to examine four aspects of the temporal patterns of speech in these persons: intrinsic vowel duration, VOT, phrase-final lengthening, and the effect of final consonant voicing on vowel duration.

2pSC7. Japanese language learners' production of short/long vowel and single/geminate consonant contrasts: A longitudinal development. Yukari Hirata and Ian C. McNally (Dept. of East Asian Lang. and Lit, Colgate Univ., 13 Oak Dr., Hamilton, NY 13346, yhirata@colgate.edu)

This longitudinal study examined the development of native English speakers' production ability to distinguish between single/geminate consonant and short/long vowel pairs in Japanese over 4 months abroad in Japan. Seven participants, who had formal Japanese language classes for 2 years in the US, recorded rika(a) and ka(k)ko pairs in a carrier sentence three times each, at three speaking rates, before and after the study abroad (pre-/post-Japan). Seven measures, including the duration of contrasting segments, words, and sentences, were taken and various ratios were also calculated. Of the native Japanese speaker criteria used to evaluate participants' data, the vowel-to-word and closure-to-word duration ratios of 0.38 and 0.35 were used as boundary ratios between short and long segments [Hirata (2004); Hirata and Whiton (2005)]. Using these criteria, participants' data were classified at 66% accuracy at pre-Japan but improved to 85% at post-Japan for vowel distinction. In contrast, they improved from 73% to 74% accuracy for consonant distinction. Analyses of other durational measures also supported that participants made significant improvements in vowel distinction, but not in consonant distinction. These results support the claims of Toda (1997) and Han (1992) and extend to include intermediate language learners into their respective studies.

2pSC8. Modifying speech to children based on perceived developmental level: An acoustic study of adults' fricatives. Hannah M. Julien, Benjamin Munson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr., Minneapolis, MN 55455 julie006@umn.edu), Jan Edwards (Univ. of Wisconsin, Madison, WI 53705), Mary E. Beckman, and Jeffrey J. Holliday (Ohio State Univ., Columbus, OH 43210)

Recent acoustic studies have shown that children learning English gradually differentiate between the sounds /s/ and /ʃ/ [Li *et al.* (2009)]. Other studies have shown that adults can perceive different degrees of accuracy in these phonemes when given a non-categorical response modality, such as a visual-analog scale [Urberg-Carlson *et al.* (2008)]. This presentation combines a VAS rating task with a production task. Adults were presented with children's productions of target fricatives. They rated the accuracy, after which they were instructed to produce the target sequence as if they were responding to the child whose speech they had just rated. Ongoing analyses examine whether adults respond differently to productions that they have rated as intermediate between /s/ and /ʃ/ and whether adults produce hyperarticulated version of fricatives in response to productions that they rated as not canonically /s/ or /ʃ/ , as opposed to ones that they rated as adult-like. The results of this project will be used in supervised learning models of the acquisition of /s/ and /ʃ/ and will inform us on the extent to which adults calibrate their speech to children depending on the perceived level of speech mastery. [Work supported by NIDCD Grant 02932 and NSF Grant BCS0729277.]

2pSC9. Palatalization in infant-directed speech. Jenesia McCammon and Nan Bernstein Ratner (Dept. of Hearing and Speech Sci., Univ. of Maryland, 0100 Lefrak, College Park, MD 20742, jmccammon518@gmail.com)

Adult-directed speech (ADS) is characterized by frequent use of phonological rules such as palatalization ("did you" becomes "didju"). Use of such rules should blur word boundaries, making it more difficult for infants to identify words in the input. To date, there are conflicting data on the degree to which infant-directed speech (IDS) makes more or less frequent use of these rules [Shockey and Bond (1980) and Bernstein Ratner (1986)]. We are following a cohort of children from 7 months to 2 years. We examined whether rules such as palatalization are used more or less frequently in IDS by 20 mothers to their children and to an adult listener. To date, there are more opportunities for palatalization in the mothers' IDS than ADS to preverbal children, and the rule is more frequently applied in IDS. In this case, IDS is not more acoustically clarified than ADS. Research suggests that IDS

clarification may be a function of the child's language stage. We would therefore not expect reduction in palatalization, which primarily affects functors, until a later stage of the child's language development.

2pSC10. Voice onset time in infant-directed speech at 7.5 and 11 months. Anna Synnestvedt, Nan Bernstein Ratner, and Rochelle Newman (Dept. of Hearing and Speech Sci., Univ. of Maryland, 0100 Lefrak Hall, College Park, MD 20742)

Studies have reported differences between infant-directed speech (IDS) and adult-directed speech (ADS), suggesting that mothers adjust speech to their infants in ways that may help children better parse the incoming acoustical signal. One aspect of IDS that has been examined is voice onset time (VOT). Results have been inconsistent, revealing longer VOT in IDS [Englund (2005); Malsheen (1980)], shorter VOT in IDS [Sundberg & Lacerda (1999)], or no difference in VOT between ADS and IDS [Baran *et al.* (1977)]. Characteristics of IDS may also depend on the language maturity of the child and, therefore, clarity of speech may vary across stages of development [Englund & Behne (2006)] as well as vary among mothers. The present study examines 15 mothers' VOT in IDS to children at 7.5 months old and again at 11 months as compared to their VOT in ADS. Words with initial stop consonants that occurred in both IDS and ADS conditions are analyzed using PRAAT. Variability was observed among mothers and age effects: preliminary data suggest that VOT in IDS at 11 months is better differentiated than at 7.5 months. [Work supported by NSF BCS0745412.]

2pSC11. Mandarin and English initial stops produced by Mandarin-English bilinguals. Jia-Shiou Liao (School of Appl. Foreign Lang., Chung Shan Medical Univ., No. 100, Sec. 2, Daching St., South District, Taichung City 402, Taiwan, jsliao@csmu.edu.tw)

This study investigates the relationship between the way Mandarin-English bilinguals and native speakers of English pronounce English initial stop consonants, and between the way Mandarin-English bilinguals pronounce Mandarin and English stops, with respect to voice onset time. Twelve Mandarin subjects who had learned English as their second language and were studying at a US university were asked to read randomized lists of 72 Mandarin characters and of 72 English words; twelve English subjects read only the list of English words. The syllable structure of each Mandarin character and of each English word in this study was CV. The Mandarin consonants were initial aspirated and unaspirated /p, t, k/; the English consonants were initial /p, t, k/ and /b, d, g/. The vowels used in both lists were high vowels. Significant differences are found between the Mandarin-speaking subjects' articulation of all the Mandarin stops and their minimally paired English equivalents produced by the English-speaking subjects. Significant differences are found between Mandarin and English speakers' articulation of the same English stops, except for that of /t/. When comparing the Mandarin-speakers' articulation of Mandarin stops and their minimally paired English counterparts, a significant difference is found only between English and Mandarin aspirated /p/.

2pSC12. Phonetic adaptation in non-native speech: Insights from a distributional analysis of long-lag voice onset time. Marisa Pineda and Meghan Sumner (Dept. of Linguist., Stanford Univ., Margaret Jacks Hall, Bldg. 460, Stanford, CA 94305-2150, middyp@stanford.edu)

Speakers encountering long-lag voice onset time (VOT) for the first time in their L2 produce VOTs between their L1 and L2 values. Native-like long-lag productions are conditioned by speaker competency factors such as age of acquisition and experience, showing significant production differences between late bilinguals, early bilinguals, and native L2 speakers. Thus far, analyses have focused on average VOTs across speaker groups. This project investigates the full distributional properties of VOT in bilinguals (e.g., variation and skewness) in addition to averages, providing a more informative picture of bilingual acquisition. VOT production data were collected from French-English bilinguals (age of English onset 0–15 years) and submitted to a distribution-based analysis. Results show that while speaker groups differ predictably in mean VOT, the analysis discovers subgroups based on common production behaviors, eliminating the gross categorizations of early and late bilinguals and moving toward gradual, predictable shapes of VOT that are correlated with English schooling, time in an English-speaking country, and age of acquisition. Ultimately, these results may fill in some missing blanks between perception and production, suggesting, for example, that differences in perceived accent and comprehensibility diverge due to degree of overlap with native L2 VOTs.

2pSC13. A Bayesian model of voice-onset time production. Mark VanDam (Boys Town Natl. Res. Hosp., 555 N 30 St., Omaha, NE 68131, mark.vandam@boystown.org) and Noah Silbert (Indiana Univ., Bloomington, IN 47405)

Talkers performed a listen-and-repeat task to investigate temporal detail in voice-onset time (VOT) productions of American English word-initial stop consonants. Experimental factors included linguistic context (isolation, carrier phrase, unfamiliar phrase, and familiar phrase), usage frequency (high and low), lexical status (word and non-word), training (baseline and posttraining), and posttraining generalization (test words and novel words). For each context, frequency, and lexical status, baseline VOT production estimates were collected, then a naive training regimen conducted, then posttraining estimates of both test words and novel words were obtained. Testing novel words explored whether the effect, if obtained, generalized throughout the lexicon. A Bayesian linear model (analogous to analysis of variance) was used to model VOT means as a function of these factors. Posterior distributions of modeled VOT means were compared across six talkers, with a focus on probing the relationships between lexical frequency and status, linguistic context, and training. Preliminary results suggest that a number of these experimental factors influence fine-grained control of VOT production. As expected from speech production data obtained from multiple talkers and thousands of productions, the overall model fit was imperfect, but the results indicate that a Bayesian model can be productively deployed for data exploration into temporal aspects of speech production.

2pSC14. Priming at the level of phonetic detail: Evidence from voice onset time (VOT). Susannah Levi and Jennifer Bruno (Dept. of Communicative Sci. and Dis., NYU, 665 Broadway, 9th floor, New York City, NY 10012, svlevi@nyu.edu)

Priming studies have shown effects on the production of target words when the target and prime are identical and when the target and prime share some but not all phonological features. Variation at the level of phonetic detail has also been found to affect production in word shadowing tasks where speakers produce longer VOTs when the VOT of the sample word is artificially lengthened. In this study, we examine the effect of naturally produced, yet systematic within-category variability in the VOT of the prime on the production of a target word for visually presented words. Primes either contained a voiceless stop with a long VOT ("keen") or a short VOT ("pan"). The target words contained a voiceless alveolar stop followed by five vowels which varied in height and backness (e.g., "tune" and "ten"). Results showed that the same target word was produced with longer VOTs when the prime contained a naturally long VOT than when the prime contained a naturally short VOT. These results suggest that speakers are sensitive to natural within-category variability, and that this sensitivity affects production across different segments.

2pSC15. Why are Korean tense stops mastered early: Evidence from production and perception. Eun Jong Kong (Waisman Ctr., Univ. of Wisconsin at Madison, 1500 Highland Ave. #493, Madison, WI 53705, ekong@wisc.edu) and Mary E. Beckman (The Ohio State Univ., Columbus, OH 43210)

Transcription-based studies have found that Korean-acquiring children master tense stops earliest among the three different types of homorganic stops (tense vs lax vs aspirated) despite its phonologically marked status. Tense stops in Korean have a short-lag VOT, so this finding is consistent with previous cross-linguistic research on order of acquisition of stop phonation types. However, Korean tense, lax, and aspirated stops are also differentiated by the fundamental frequency and the voice quality at the vocalic onset in addition to VOT. This study examined how correctly these multiple acoustic cues (VOT, f0, and H1-H2) predict the mastery pattern of Korean stops. The effect of these acoustic parameters on 20 Korean adult listeners' assessments of children's (aged 2–6) productions of /t′/, /t/, and /th/ was analyzed. Listeners were asked to label the stimuli as one of three stop cat-

egories and then to rate their goodness using visual analog scaling. Both categorical and gradient assessments of children's stops were analyzed based on the three acoustic parameters in a mixed-effect regression model in order to quantify the relative effects of acoustic parameters on adult perception of phonation. [Work supported by NIDCD 02932 and NSF Grant 0729140.]

2pSC16. "Probably, OK, whatever!": Variability in conversational speech stops and flaps. Natasha Warner (Dept. Linguist., Univ. of Arizona, Box 210028, Tucson, AZ 85721-0028, nwarner@u.arizona.edu) and Benjamin V. Tucker (Univ. of Alberta, Edmonton, AB T6G 2E7, Canada)

In casual, conversational speech, speakers often do not fully realize all segments one would normally expect in a given word. For example, "better" may be pronounced with an approximant instead of a medial flap (if the tongue fails to make a complete closure at the alveolar ridge), the expected flap may be entirely deleted, or the segments may be so heavily overlapped that it is almost impossible to say which segments are present and which not. The current work investigates how much reduction occurs (including both changes and deletions), comparing casual conversations, connected reading, and isolated word-list reading. It compares the phonemes /p, t, k, b, d, g/, post-stress vs inter-unstressed, and six segmental environments. The results represent 13 native English speakers and comprise a dataset of more than 9000 tokens, with several acoustic measures. This provides very thorough data on phonetic variability in both natural and "lab" speech. The work finds relatively little effect of stress and complex effects of segmental environment attributable to places of articulation. It also provides insight into how variable speakers are in how much they reduce, both within a speaker and within the population, a topic not often addressed in phonetic research.

2pSC17. Functional anatomy of the human tongue: Review and implications for the development of speech production. Margaret Denny and Richard S. McGowan (CReSS LLC, 1 Seaborn Pl. Lexington, MA 02420)

To acquire speech children must attempt to reproduce adult acoustic models using immature vocal tracts which differ from those of adults in complex ways. Control of the tongue is crucial for acceptable speech, yet the tongue is an understudied articulator because it is anatomically complex and difficult to record from using kinematic or electrophysiological methods. Nevertheless recent advances in tongue anatomy and physiology, combined with knowledge of vocal tract development, promise to shed light on the problems that children must solve in learning to speak as well as the solutions available to them. This review aims to integrate and present these findings to an audience interested in the development of speech production. A striking finding is that the tongue shows an anterior-to-posterior gradient in muscle fiber sizes and types. In multiple muscles, faster fibers are more common anteriorly while slower fibers are more predominant in the posterior tongue. Within fiber type (fast or slow) smaller fibers are seen anteriorly and larger ones posteriorly. This implies that rapid fine positioning and shaping may be particularly challenging when it involves the posterior tongue. [Work supported by NIDCD-0001247 to CReSS LLC.]

2pSC18. Tracking muscle deformation during speech from tagged and diffusion tensor magnetic resonance imaging. Xiaofeng Liu (Dept. of Comput. Sci., Johns Hopkins Univ., 1600 N. Charles St., Baltimore, MD 20017, xiaofeng.liu@gmail.com), Sudarshan Ramenahalli (Johns Hopkins Univ., Baltimore, MD 20017), Hideo Shinagawa, Maureen Stone (Univ. of Maryland Dental School, Baltimore, MD 21210), Jerry L. Prince (Johns Hopkins Univ., Baltimore, MD 20017), Emi Z. Murano (Johns Hopkins Hospital, Baltimore, MD 21287), Jiachen Zhuo, and Rao Gullapalli (Univ. of Maryland Med. School, Baltimore, MD 21210)

Oral head and neck cancer is the sixth most common cancer worldwide. These tumors are usually treated by surgical removal of the affected tissue. The result of the surgery is a loss of muscle tissue, accompanied by scarring, reduced strength, and often reduced function. This paper explores the relationship between tongue muscle orientation and muscle deformation pattern in normal and post-cancer surgery speakers. Our motivation is the need to better understand the mechanisms that underlie tongue motion, in order to better interpret clinical observations and to provide data that can help predict optimal surgical outcomes. This study uses diffusion tensor imaging (DTI) to extract muscle fiber orientation, but it is not possible to image the muscle deformation in real-time using DTI. On the other hand, tagged MRI can track muscle fiber bundles in real time, but the original fiber bundle is not visible. Therefore, this work develops a method to overlay muscle bundles from the DTI onto the corresponding locations in tagged MR images and track muscle deformation. The mechanical properties of the muscles are calculated, such as translation and bending. Motion pattern differences between the normal and glossectomy tongue are detailed. [NIH R01-CA133015 and K99-DC9279.]

2pSC19. Dependency of compensatory strategies on the shape of the vocal tract during speech perturbed with an artificial palate. Jana Brunner (Res. Lab. of Electron., MIT, 50 Vassar St., Cambridge, MA 02139, jbrunner@mit.edu), Phil Hoole (Ludwig-Maximilians-Universität München, 80799 München, Germany), Frank H. Guenther (Boston Univ., Boston, MA 02215), and Joseph S. Perkell (MIT, Cambridge, MA 02139)

When adapting to an articulatory perturbation, different speakers may use different strategies. This study investigates the hypothesis that the choice of strategy depends on vocal tract shape. Vowel production was perturbed with prostheses that changed palatal shape. Three speakers had a prosthesis that effectively moved the alveolar ridge posteriorily; three others had a prosthesis that effectively flattened the palate. EMA recordings of speakers' adaptive behavior showed that during the production of the vowel /y/, the speakers with the alveolar prosthesis compensated by using increased lip protrusion. The speakers with the flat prosthesis used about the same amount of lip protrusion as without perturbation. We hypothesize that this is because for the first group of speakers the main constriction in the vocal tract was moved forward due to the changed palatal outline: the front cavity became too short, which was compensated for by more lip protrusion. This hypothesis is being explored by determining whether the DIVA speech production model will produce compensations like the subjects when the model's vocal tract is adapted to fit individual vocal tract shapes using detailed information about the subjects' vocal tracts from MRI recordings. Complete results will be reported and discussed. [Work supported by DAAD, NIH.]

2pSC20. Can an ultrasound tongue be overlaid on an MRI (magnetic resonance imaging) vocal tract? Jim Lee (jima@yahoo.com) and Maureen Stone (Dept. of Neural and Pain Sci. and Dept. of Orthodontics, Univ. of Maryland Dental School, Baltimore, MD 21210)

Ultrasound image sequences and cine-MRI time-frames provide intersecting but not identical data about the articulation of speech. It would be valuable to be able to combine ultrasound and MRI datasets in a way that maximizes their strengths. Midsagittal MRI images the entire vocal tract; ultrasound images the tongue surface. However, MRI is not portable, requires multiple repetitions, and supine subject positioning. Thus insertion of the tongue from ultrasound movies onto the MRI vocal tract would provide tongue motion in a head coordinate system. This study aligns supine ultrasound tongue contours with MRI tongue contours of the same tasks using (1) rigid alignment of the tongue contours frame-by-frame and (2) rigid alignment of palates, whose alignment parameters are then applied to tongue contours. rms differences compare the error between methods. The value of this study is that if palatal alignment yields a comparable error to tongue alignment, then palatal alignment could be used to insert an ultrasound data set into a vocal tract outline that has no tongue motion data associated with it. [Funding support: R01CA133015.]

2pSC21. An articulatory, acoustic, and perceptual study of the effect of a short lingual frenulum on flaps in late Korean-English bilinguals. Kyung-Ah Kim (Dept. of Linguist., Cornell Univ., 203 Morrill Hall, Ithaca, NY 14853, kk339@cornell.edu)

Having a short lingual frenulum is known to limit tongue mobility, often resulting in nonstandard pronunciations of certain coronal sounds. While previous studies have largely focused on the physical and linguistic characteristics of the most extreme cases and on the effects of surgical intervention [Hagiwara *et al.* (2002); Lee *et al.* (2008)], the current study investigates the articulatory, acoustic, and perceptual characteristics associated with Korean speakers with a relatively short lingual frenulum but not short enough to

greatly impede communication. The study focuses on the flap—the single most problematic sound for Korean speakers with short lingual frenula—produced in both Korean and English by both "short-tongued" and normal late Korean-English bilinguals. Flaps are studied through palatographic, linguographic, and spectrographic analyses, while a perception test is performed to pinpoint the categorical boundary between the normal and short-tongued flaps. Preliminary results suggest that the short-tongued speakers are better able to accurately produce the English flap than the Korean flap, due to language-specific phonetic and phonological characteristics. This finding bears on whether surgical intervention is necessary to help normal (and mildly short-tongued) speakers of Korean improve their English pronunciation [se Ko (unpublished)].

2pSC22. Resonance-based source-filter separation for speech. Ivan Selesnick (Dept. of Elec. and Comput. Eng., Polytechnic Inst. of New York Univ., 6 Metrotech Ctr., Brooklyn, NY 11201) and Chin-Tuan Tan (New York Univ., New York, NY 10016)

This paper proposes the application of resonance-based signal analysis to the decomposition of speech into "source" and "filter" waveform components. Resonance-based signal analysis, developed by Selesnick,[1] is a novel analysis method that decomposes a signal into high-resonance (oscillatory) and low-resonance (transient) components. The original signal is given as a sum of the two components. The method utilizes sparse signal representations in the domain of two invertible constant-Q transforms, having low- and high-Q-factors, respectively. The constant-Q transforms are implemented as rational-dilation wavelet transforms. Applied to speech, the method provides a separation that cannot be achieved with other known filtering techniques. Current source-filter modeling of speech assumes a known linear filter which sufficiently estimates vocal tract characteristics and can be derived from a segment of stationary speech. The source glottal waveform is then extracted by inverse filtering. In contrast, resonance-based signal analysis directly decomposes speech into its source and filter waveforms without such assumptions. The outcome may provide a new perspective in speech analysis, synthesis, recognition, and coding. This paper illustrates the efficacy of this signal analysis technique with vowels; further investigation with other speech elements is in progress.

2pSC23. Speech separation based on multi-level segmentation. Jose J. Lopez and Maximo Cobos (ITeam, Univ. Politecnica Valencia, Camino de Vera, 46022 Valencia, Spain, jjlopez@dcom.upv.es)

Speech separation is still a challenging issue in acoustic signal processing. To deal with this problem, sparse methods are usually employed when there are more sources than sensors (underdetermined problem). In this paper, a two-microphone separation method is presented. The proposed algorithm is based on grouping time-frequency points with similar direction-of-arrival (DOA) using a multi-level thresholding approach. The thresholds are calculated via the maximization of the interclass variance between DOA estimates and allow to identify angular sections wherein the speakers are located with a strong likelihood. Separation is finally performed by means of time-frequency masks. Several experiments conducted under different mixing scenarios are discussed, showing the benefits of the proposed approach.

2pSC24. Classification of gender based on cepstral coefficients and spectral moments. Laura Spinu and Jason Lilley (Univ. of Delaware, Newark, DE 19716)

Several gender classification methods based on acoustic information were compared. The data came from 31 native speakers of Romanian (10 males, 21 females). A subset of fricatives and vowels (7348 tokens) was divided by hidden Markov model training into three acoustically uniform regions. For each region, (a) a set of cepstral coefficients, specifically c0–c4 and (b) two sets of spectral moments, specifically bark-transformed and linear moments 1–4 plus rms, were extracted. The acoustic data were then used in a linear discriminant analysis to classify the tokens by gender. The findings show that cepstral coefficients perform better than spectral moments in gender classification, and that spectral moments are more successful than linear moments. The overall correct classification was 90% for the cepstral analysis, 78% for bark spectral moments, and 72% for linear moments. When the data from fricatives and vowels were examined separately, it was found that in all cases the vowel information yielded more accurate gender classification (e.g., 84% correct classification for cepstral moments based on vowels only), but the fricative information alone could account for 78% correct classification. These analyses provide insight into the differential distribution of acoustic features related to gender over segment types.

2pSC25. Manipulating the short time Fourier transform and cross-spectrum to estimate speech parameters. Douglas J. Nelson (Natl. Security Agency, 9800 Savage Rd., Fort Meade, MD 20755)

Presented are methods for automated estimation of speech parameters, including pitch, formant frequencies, and the instants of excitation of voiced speech. These methods are based on reassignment applied to the short time Fourier transform (STFT) and to the cross-spectrum computed as the product of the STFT and the complex conjugate of the STFT delayed in time. The cross-spectrum is a complex-valued surface whose magnitude is the conventional spectrogram and whose phase is the phase of the STFT differentiated with respect to time. It is demonstrated that this representation may be easily manipulated to detect and extract information, such as pitch and formant frequencies. Based on the cross-spectral representation, we present a peak representation that may be used to efficiently encode speech spectral features, and we demonstrate applications of this representation.

2pUW1. Modeling the acoustic channel for mixed pressure and particle velocity sensors. Paul Hursky and Michael B. Porter (HLS Res. Inc., 3366 North Torrey Pines Court, Ste. 310, La Jolla, CA 92037)

Looking at our repertoire of acoustic modeling techniques, ray tracing and Gaussian beams provide a good match to modeling the underwater channel for acoustic communications, given their fundamentally broadband nature. We will discuss how we have augmented existing acoustic models, including Gaussian beam and normal mode codes, to produce particle velocity predictions. In both of these cases, the modifications consisted of manipulating the components used to represent the pressure field, as opposed to relying upon a finite difference approximation of the predicted field itself. We will discuss further modifications to these codes that enable the dynamic features of the channel to be modeled, including source and receiver motion, and motion of the ocean surface due to ocean surface waves. It is important to model realizations of the channel, rather than averaged representations, because many of the high-speed, coherent modulation schemes that are the focus of continuing research use tracking loops in their design. These tracking loops must be stressed with realistically time-evolving channels. Acoustic channel predictions will be compared with experiment data from acoustic communications experiments off the coast of Kauai in Hawaii.

2pUW2. Geo-acoustic inversion with vector sensors in shallow water. Fenghua Li and Renhe Zhang (Natl. Lab. of Acoust., Inst. of Acoust., Chinese Acad. of Sci., Beijing 100190, China, lfh@mail.ioa.ac.cn)

Vector sensors have attracted much attention in recent years. However, relative few papers have been published on the geo-acoustic inversion with vector sensors. The data recorded with vector sensors in several shallow water acoustic experiments have been studied in this paper. The experimental data and theoretical analyses indicate that (1) the intensity of the vertical particle velocity decreases faster than that of the horizontal particle velocity; (2) the same normal modes of the horizontal particle velocity and the vertical particle velocity have similar transmission losses, but different amplitudes and phases; (3) the difference of the mode amplitudes between the horizontal particle velocity and the vertical particle velocity is dependent on the eigen-value and receiver depth. With those properties, two geo-acoustic inversion schemes employing vector sensors have been developed. The first inversion scheme uses a combination of matched field processing and the difference of transmission losses between pressure and particle velocity. The second estimates the bottom sound speed and attenuation from the amplitudes of normal modes of particle velocities. Experimental results show that the developed geo-acoustic inversion methods with vector sensors can decrease the uncertainty of inversion in comparison with that by hydrophones.

2pUW3. Modulated helicity for acoustic communications and helicity-selective acoustic receivers. Timothy M. Marston and Philip L. Marston (Dept. Phys. and Astronomy, Washington State Univ., Pullman, WA 99164 2814, marston@wsu.edu)

Helicoidal or vortex beams have an azimuthal phase gradient and an axial null in amplitude. The sign and magnitude of the azimuthal phase gradient determine the helicity and topological charge of the beam and the associated handedness. Beams with a unit-magnitude charge have been generated with a four-sector array, adjacent quadrants being driven with a 90 deg phase offset [B. T. Hefner and P. L. Marston, J. Acoust. Soc. Am. **106**, 3313–3316 (1999)]. The present work shows that the helicity can be rapidly modulated with an appropriately timed reversal of the excitation to a single pair of diagonal sectors. This reversal was demonstrated with an electronic commutator that inverts (at a zero crossing of the sine-wave excitation) two of the channels prior to amplification. While the wave helicity may be inferred with processed signals from a detection array, it may also detected with simple superposition of outputs from a four-element detector using appropriately offset elements. Digital communications was demonstrated where signals of the wrong helicity were suppressed. Scattering by symmetric objects on the axis of the beam preserves the helicity of the radiation [P. L. Marston, J. Acoust. Soc. Am. **124**, 2905–2910 (2008)]. [Work partially supported by ONR.]

2pUW4. Amplitude, phase, location, and orientation calibration of an acoustic vector sensor array, Part I: Theory. Hans-Elias de Bree (Microflown Technologies, P.O. Box 300, 6900 AH Zevenaar, debree @microflown.com)

An acoustic vector sensor array consists of multiple sound pressure microphones and particle velocity sensors. A pressure microphone usually has an omni-directional response, yet a particle velocity sensor is directional. Currently, acoustic vector sensor arrays are under investigation for far field source localization and visualization. One of the major practical issues in these applications, however, is to determine the accurate position, orientation, and complex (phase and amplitude) sensitivity of each sensor within the array. In this study, a calibration method is developed to determine each of those crucial parameters based on a limited number of measurements with a reference sensor and multiple sound sources located at known locations. The calibration method is also designed to be robust to mistakenly switched cable connections. Ideally, the calibration process should take place in an anechoic environment, but efforts have been made to compensate the effects of moderate background noise and reflections.

2:15

2pUW5. Amplitude, phase, location, and orientation calibration of an acoustic vector sensor array. Part II. Experiments. Tom Basten (Microflown Technologies B.V., Ruitenberglaan 26, 6800AH, The Netherlands, basten@microflown.com)

An acoustic vector sensor array consists of multiple sound pressure microphones and particle velocity sensors. A pressure microphone usually has an omni-directional response, yet a particle velocity sensor is directional and usually has a response pattern as a figure of number eight. Currently, acoustic vector sensor arrays are under investigation for far field source localization and visualization. One of the major practical issues in these applications, however, is to determine the accurate position, orientation, and complex (phase and amplitude) sensitivity of each sensor within the array. In this study, a calibration method, which is discussed in Part I, is verified with experiments. The method determines all the crucial parameters based on a limited number of measurements with a reference sensor and multiple sound sources located at known locations. The calibration method shows also to be robust to mistakenly switched cable connections. The experiments are performed in different acoustic environments including an anechoic room. The results will be presented in this paper.

2pUW6. Experimental study of vector array time reversal communication. Zhongkang Wang, Hongtao Zhang, and Xiaofan Yang (Hangzhou Appl. Acoust. Res. Inst., 96 Huaxing Rd., Hangzhou City, P.O. Box 1249, China)

The cooperative array performance experiment (CAPEx) was performed in Lake Washington near Seattle in September 2009 [Rouseff *et al.*, this session]. The experiment included a passive time-reversal communications component. A variety of communications signals in the 1.5–4 kHz band were transmitted including BPSK, QPSK, DSSS, and OFDM. The signals were recorded on an eight-element vertical vector array used as the receiving array at ranges up to 4 km. Results are given by using combined scalar and vector sensors. [Experiment supported by ONR.]

2pUW7. Proof of principle for geo-acoustic inversion of vector sensor array data. Robert A. Koch (Appl. Res. Labs., Univ. of Texas at Austin, 10000 Burnet Rd., Austin, TX 78758, koch@arlut.utexas.edu)

Acoustic data collected from an array with elements comprised of omnidirectional hydrophone sensors co-located with acceleration vector sensor triplets are analyzed for seabed geo-acoustic information. The data were collected during the passage of a surface vessel, the R/V Montague, in an August 2006 experiment conducted in Monterey Bay. Geo-acoustic inversion with the vector sensor acceleration components parallel to the array line of bearing produced a solution approximately identical to the solution obtained from the inversion of the hydrophone array data. [Sponsored by ONR.]

2pUW8. Concerning the null contours of vector sensors. Dean J. Schmidlin (2629 US 70 E, Apt. E2, Valdese, NC 28690-9005)

A common use of a vector sensor is to maximize the sensing of a plane wave coming from one direction while creating a null in regard to a plane wave coming from another direction. It is shown that when this is accomplished, there is a null not only in the desired direction but a whole contour of nulls. The shape of the contour is a function of a single parameter and is described by means of a contour plot in the azimuthal angle–elevation angle plane. Additional insight is found by mapping the contours onto a unit-sphere in the spatial domain. One byproduct of the notion of null contours is a method for selecting the coefficients of the vector sensor for the case of two interfering sources. Finally, it is shown that once the null contour is understood for the vector sensor, it is a simple matter to extend the concept to directional acoustic sensors of higher order.

2pUW9. Utilization of the pressure gradient along a sparse vertical line array to determine vertical arrival angle from partial reflections from a layered seabed. David R. Dall'Osto and Peter H. Dahl (Dept. of Mech. Eng and Appl. Phys. Lab., Univ. of Washington, Seattle, WA 98105)

Pressure signals measured by two four-element vertical line arrays, centered at depths 25 and 50 m, during an experiment off the New Jersey coast in Summer 2006 (SW06, depth 80 m) are combined to determine the pressure gradient of the received signal. The pressure gradient is converted to an estimate of vertical particle velocity, which combined with an estimate of the mean-squared pressure, and the plane wave impedance establishes a non-dimensional quantity. This quantity is inverted to determine arrival angle estimates from separate multipath arrivals of the transmitted signals (1 kHz). A geoacoustic model for the seabed [Choi *et al.*, J. Acoust. Soc. Am. **124** EL128–EL134 (2008)] includes a prominent sub-bottom reflector at depth 20 m below water sediment interface, which produces an energetic arrival time separated from the bottom arrival. The arrival angle estimates are examined as the source moves out in range from 50 to 300 m, and results are compared to arrival angle estimates derived from PE simulations. The performance of this gradient-based estimator is evaluated for various types of noise sources and levels, utilizing both real and PE-simulated time series. [Work supported by ONR.]

2pUW10. A characterization of scatterred acoustic intesity fields in the resonance region. Robert J. Barton, III (Sensors & Sonar, NUWC Code 1522, 1176 Howell St., Newport, RI 02841, robert.barton@navy.mil) and Kevin B. Smith (Naval Postgrad. School, Monterey CA, 93943, kbsmith @nps.edu)

In this study, we investigate the properties of the scattered acoustic vector fields generated by simple rigid and fluid-filled spheroids. Analytical solutions are derived from acoustic target strength scattering models in the near field region. Of particular interest is the understanding of the characteristics of energy flow of the scattered acoustic vector field in the near- to far-field transition region. We utilize the separable active and reactive acoustic intensity fields to investigate the structural features of the scattered field components. Numerical and in-air measured results are presented for the near and transition region scattered acoustic vector field of simple spheroids. A qualitative method is developed for characterizing submerged scatterer properties based on boundary condition and features of the scattered vector field.

4:15

2pUW11. Three dimensional sound source localization and sound mapping using a p-u sensor array. Jelmer Wind (Microflown Technologies B.V., 6800AH Zevenaar, The Netherlands, wind@microflown.com)

An acoustic sensor array, which consists of pressure and particle velocity sensors, is an attractive alternative to phased pressure array because knowledge of the three dimensional (3-D) particle velocity directly characterizes

the direction of the source. Hence, it is possible to localize sources in the low-frequency range, where the phase difference between pressure sensors is small, and in the high-frequency range, where aliasing occurs with pressure sensors. This article applies advanced source localization techniques from aeroacoustics to acoustic vector sensors. Several methods are simulated and tested with several configurations and validated using measurement data from an anechoic chamber. The setup to test the algorithms consists of 24 sources that are distributed in 3-D around the set ups in the anechoic chamber. The sources are uncorrelated driven with white noise. Conventional beamforming methods have been compared with acoustic vector based deconvolution methods and MUSIC algorithms. Four configurations are tested: (1) a planar array of sound pressure microphones, (2) a planar array of pu probes (pu probes are collocated sound pressure and particle velocity probes); the velocity probes where the velocity probes are oriented in randomly, (3) a velocity gradient array, (4) a quad array of three dimensional velocity probes plus collocated sound pressure. The different methods and algorithms

TUESDAY EVENING, 20 APRIL 2010 8:00 P.M.

OPEN MEETINGS OF ASA TECHNICAL COMMITTEES

The Technical Committees of the Acoustical Society of America will hold open meetings on Tuesday, Wednesday, and Thursday evenings. On Tuesday and Thursday the meetings will be held immediately after the Social Hours. On Wednesday, one technical committee will meet at 7:30 p.m.

These are working, collegial meetings. Much of the work of the Society is accomplished by actions that originate and are taken in these meetings, including proposals for special sessions, workshops, and technical initiatives. All meeting participants are cordially invited to attend these meetings and to participate actively in the discussions.

Committees meeting on Tuesday are as follows:

Acoustical Oceanography	Laurel C/D
Engineering Acoustics	Laurel A/B
Musical Acoustics	Galena
Noise	Grand Ballroom III/IV
Physical Acoustics	Grand Ballroom VII/VIII
Psychological and Physiological Acoustics	Grand Ballroom I/II
Structural Acoustics and Vibration	Dover A/B

Session 3aAA

Architectural Acoustics and Noise: Primary and Secondary School Special Function Spaces I

Robert C. Coffeen, Chair
Univ. of Kansas, School of Architecture and Urban Design, Marvin Hall, Lawrence, KS 66045

Chair's Introduction—8:00

Invited Papers

8:05

3aAA1. The rest of the school: An investigation into good acoustical design of non-classroom spaces in primary and secondary schools. Benjamin Markham and Jennifer Hinckley (Acentech Inc., 33 Moulton St., Cambridge, MA 02138)

The focus on acoustics in recent standards and guidelines such as the ANSI Standard S12.60, the Leadership in Energy and Environmental Design (LEED) for Schools system, and the Collaborative for High Performance Schools (CHPS) has rightly been on classrooms. Each of them does address other school environments also, although sometimes without particular specificity. After reviewing relevant American standards and guidelines for gymnasiums, libraries, lobbies, corridors, auditoriums, and other spaces that do not fit neatly into the classroom designation, this paper addresses good practices in the acoustical design of such critical environments through the use of a series of case studies. Specifically, the authors suggest room acoustics design parameters and appropriate background noise and sound isolation criteria for non-classroom spaces in primary and secondary schools.

8:25

3aAA2. Case study in cafeteria noise solutions. Kenneth Good and Sean Browne (Armstrong World Industries, 2500 Coulumbia Ave., Lancaster, PA 17601)

A recent case study was conducted addressing excessive occupant noise within a cafeteria in a Rhode Island school. A design requirement was to retain the open structure ceiling. This paper will discuss the before and after acoustic performance and the effect it had on the occupants.

8:45

3aAA3. The acoustical balancing act for music rehearsal spaces in schools. David L. Adams (D. L. Adams Assoc., Inc., 1701 Boulder St., Denver, CO 80211, dadams@dlaa.com)

Conflicting acoustical criteria are encountered in the design of music rehearsal spaces, particularly when a single space must serve both orchestra and band rehearsals, not to mention the situation when the space must also serve for chorus rehearsals. For example, the criterion commonly found in the literature for room volume or more explicitly ceiling height conflicts with the requirement for an appropriate reverberation time or design goal loudness level, which are also dependent on the group (band, orchestra, and chorus) that will use the space and for that matter on the individual music teacher. The degree of involvement of music teachers in the design of these spaces and their potential impact on the end result is discussed. Case histories are presented to illustrate the good, the bad, and the ugly with respect to music rehearsal spaces in schools.

9:05

3aAA4. Acoustical considerations for vocal music rehearsal rooms: A choir director's perspective. Jeremy Manternach (Div. of Music Education and Music Therapy, School of Music, Univ. of Kansas, 1530 Naismith Dr., Lawrence, KS 66045, jmanter@ku.edu)

What do vocal/choral instructors value in a rehearsal space? Along with logistical considerations, these instructors also desire particular room acoustic conditions. How might their input affect the decisions of architects and acousticians? This question is investigated through examination of several school rehearsal spaces. The study will include acoustical measurements from rehearsal spaces, opinions of vocal music instructors, and feedback from vocalists who rehearse in each space.

9:25

3aAA5. Acoustical compromises: Working with a design team for maximum isolation at minimal costs in high school music facilities. Pamela J. Harght (4006 Speedway, Austin, TX 78751, pam@baiaustin.com)

Texas Public High Schools place a large emphasis on their music and drama programs, often providing facilities for their students that are far superior than many 4-year college and universities. These high school facilities include several rehearsal rooms for band, choir, orchestra, percussion, ensembles, mariachi and individual practice. In addition, they also often have a drama classroom, a black box theater, and a Performing Arts Center. When working with the design team on these projects, there are often many obstacles to work

around in order to provide the best scenario possible for the end user. These "obstacles" often include (but are not limited to) school district codes, budgets, the "convenience" factor, city codes, and space planning. This paper will showcase many high school music facilities through the south and southeast and the compromises and obstacles that were overcome with the end result goal as satisfying the music department.

9:45

3aAA6. Helping clients realize superior room acoustics while achieving other facility goals. Rob Farion (Farion Architectural Acoust., 3749 43A Ave., Red Deer, AB T4N 3G2, Canada, rob@farion.ca)

Addressing the needs of a space often involves considering many competing objectives. When room acoustic performance is one of the priorities, there is potential to address other priorities in conjunction with acoustic considerations. Integrating interior design goals with acoustic requirements often allows more resources to ultimately be available for acoustic considerations. This presentation outlines two educational facility projects where clients were assisted in meeting their goals by incorporating interior design objectives and room furnishings with acoustic performance outcomes.

10:05—10:20 Break

10:20

3aAA7. The evolution of the gymatorium and cafetorium in primary schools. Felicia Doggett (Metropolitan Acoust., LLC, 40 W. Evergreen Ave., Ste. 108, Philadelphia, PA 19118, felicia@metropolitanacoustics.com)

Many primary schools do not have formal auditoriums, but the school still needs a space for performances and assemblies. The existence of "gymatoriums" and "cafetoriums" in these schools is essential to the student body and staff. Far from being just a gymnasium or cafeteria with a stage at one end, these rooms are fully functioning performance spaces with appropriate acoustics and audio systems. What many in the school may deem most important, however, is that they still function very well for their everyday uses of gymnasiums or cafeterias. This presentation explores several gymatoriums and cafetoriums and their acoustical and audio design elements.

10:40

3aAA8. Acoustical design of special purpose rooms in schools: Music rooms. Gary W. Siebein (Univ. of Florida School of Architecture, P.O. Box 115702, Gainesville, FL 32611), Hyun Paek, Chris, P. Jones, and Reece Skelton (Siebein Assoc., Inc., Gainesville, FL 32607)

Design strategies for music education rooms in elementary, middle, and high schools based on an impulse response-based theory are presented through a series of case studies of existing, renovated, and designed rooms. The strategies include providing sound reflections to allow the instructor to hear individual groups of students as well as to allow the students to hear each other, controlling room volume and absorption to allow early sound reflections for clear hearing, and simultaneously provide diffuse, low-level running reverberance to enhance musical qualities, providing for clear verbal communication between teacher and students and limiting background and intruding noise levels. The impulse response-based measures are reduced to a series of architectural systems that can be implemented using alternate construction systems to meet budget requirements. Standard design concept sketches communicate the intent of the acoustical design to Architects, School Board members, Design Builders and music faculty.

8:00

3aABa1. Modeling of precise onset spike timing for echolocation in the big brown bat, Eptesicus fuscus. Jason E. Gaudette (Ctr. for Biomedical Eng., Brown Univ., Providence, RI 02912, jason_gaudette@brown.edu) and James A. Simmons (Brown Univ., Providence, RI 02912, james_simmons @brown.edu)

The neuronal circuits enabling highly accurate sonar performance in bats are not well understood. In this research, a computational neuroscience model was developed based on Meddis' auditory peripheral model and a biologically plausible network of integrate-and-fire neurons. The stimuli presented to the model include acoustic simulations of target echoes using wideband FM echolocation calls recorded from Eptesicus fuscus. Synaptic connectivity of the neural network was varied to explore its effect on the precision of onset spike timing. Results show that precisely timed spike codes can relay sufficient information of echo time-frequency representations to account for performance observed in laboratory experiments. This research represents a portion of our overarching goal to reverse engineer the bat's critical auditory functions into a refined sonar signal processing algorithm. A necessary first component of this process is to understand the functionality of relevant circuitry in the auditory midbrain. Such biomimetic processing schemes may be useful in active sonar applications suffering from a high degree of environmental clutter, where man-made systems typically demonstrate poor performance.

8:15

3aABa2. Similarities in the echolocation beam pattern of vespertilionid bats. Lasse Jakobsen and Annemarie Surlykke (Inst. of Biology, Univ. of Southern Denmark, Campusvej 55, Odense C, Denmark)

Echolocating bats can navigate and fourage by sound, emitting short high-frequency sound pulses and listening to echoes reflected from obstacles and prey. Small insectivorous bats typically emit higher frequencies than larger bats. This correlation has been explained as an acoustic constraint by prey size since small bats feed on small prey and small objects only reflect echoes efficiently at short wavelengths, i.e., high frequencies. However, very small bats use higher frequencies than what is needed for effective reflection from their prey. Thus, we propose an alternative or supplementary hypothesis: Small bats emit high frequencies to obtain highly directional biosonar sound beams. Directionality increases with the size of the sound emitter relative to the wavelength. Hence small bats can counteract the decrease in directionality caused by their small size by increasing their emitted frequency. Echolocation calls were recorded from five species of echolocating bats of different sizes flying in the laboratory using a multimicrophone array and their beam pattern was calculated. The results show high similarity in beam patterns across species, indicating that directionality is indeed a constraint on echolocation frequency. [Funded by the Oticon Foundation.]

8:30

3aABa3. A comparison of biosonar beampatterns in bats. Rolf Müller (Dept. of Mech. Eng, Virginia Tech & Inst. for Adv. Learning and Res., 150 Slayton Ave., Danville, VA 24540, rolf.mueller@vt.edu) and Zhen Yan (Shandong Univ., 250100 Jinan, China)

The beampattern associated with a diffracting baffle around a sound receiver can be predicted efficiently using numerical methods. Here, such methods have been used to derive estimates for a large number of reception beampatterns from high-resolution digital models of the shapes of pinnae (outer ears) of different bat species. For each ear, beampatterns were obtained with a high-directional resolution (1 deg) and for a set of frequencies that sample the frequency band used by the respective species adequately. This allows the characterization of frequency-dependent features of the beampattern such as the number of lobes present, as well as their size, shape, orientation, and position. The resulting data set allows comparisons between different ecological groups, such as the continuous frequency (cf-fm) and frequency modulated bats (fm-bats) as well as an assessment of variability within such species groups. Comparisons across a larger number of species have facilitated the identification of outliers, i.e., species with unique beampatterns. Such unique beampattern features may be related to unique uses of the animals biosonar system or unique constraints under which these tasks have to be accomplished. Tentative links to unique features of the pinna geometry have also been established.

8:45

3aABa4. Ear deformations in the biosonar system of horseshoe bats. Li Gao, Weikai He (School of Phys., Shandong Univ., Hongjia Lou 5, 250100 Jinan, China, gl1231@mail.sdu.edu.cn), Sreenath Balakrishnan, and Rolf Müller (Virginia Tech. & Inst. for Adv. Learning and Res., Danville, VA 24540)

Many bat species exhibit conspicuous ear movements as part of their biosonar behaviors. The resulting transformations of the pinnae can contain rigid rotations as well as nonrigid deformations. Characteristic ear deformations are frequently observed in horseshoe bats (*Rhinolophidae*). In these animals, the pinna changes regularly between an upright and a bent configuration. In the bent configuration, the tip of the pinna tilts forward, down, and sideways, changing the curvature of large portions of the ear surface. Entire deformation cycles can be completed in as little as 200 ms. The time-variant geometry of the pinna deformations in the greater horseshoe bat (*Rhinolophus ferrumequinum*) was captured with a stereo pair of high-speed video cameras. Landmark points were marked on the pinna with dyes that were equally visible in the video frames as in x-ray micro-CT. The CT model was matched to the locations of the landmarks in the deforming ears inferred from stereo reprojection. Numerical predictions were obtained for the acoustic behavior of ear shapes at different phases during the deformation cycle. It was found that the pinna deformations seen in the animals can produce large changes in the directivity patterns. [Work supported by NSFC (Project No. 10774092) and CSC.]

9:00

3aABa5. A digital model for the deformation of bat ears. Sreenath Balakrishnan (Dept. of Mech. Eng., Virginia Tech. & Inst. for Adv. Learning and Res., 150 Slayton Ave., Danville, VA 24540, bsreenat@vt.edu), Li Gao, Weikai He (Shandong Univ., 250100 Jinan, China), and Rolf Müller (Virginia Tech & Inst. for Adv. Learning and Res., Danville, VA 24540)

In bats, the directivity patterns of the biosonar system are shaped by the surface geometry of the pinnae. Since many bat species are capable of large ear deformations, these beampatterns can be time-variant. To investigate this time-variance using numerical methods, a digital model that is capable of representing the pinna geometry during the entire deformation cycle has been developed. Due to large deformations and occlusions, some of the surfaces relevant to sound diffraction may not be visible and hence the geometry of the entire pinna has to be computed from limited data. This has been achieved by combining a complete digital model of the pinna in one position with time-variant sparse sets of three dimensional landmark data. The landmark positions were estimated using stereo vision methods. A finite element model based on elasticity was constructed from CT scans of the pinna *post mortem*. This elastic model was deformed to provide a good fit to the positions of the landmarks and retain values of smoothness and surface energy comparable to life. This model was able to handle ratios of data to degrees of freedom around 1:5000 and still effect life-like deformations with an acceptable goodness of fit.

9:15

3aABa6. Reanalyzing auditory sensitivity: The functional audiogram as modeled by the bat detecting moth ear. Matthew E. Jackson, Navdeep Asi, and James H. Fullard (Dept. of Biology, Univ. of Toronto at Mississauga, 3359 Mississauga Rd., N. Mississauga, ON L5L 1C6, Canada, matthereric.jackson@utoronto.ca)

Auditory sensitivity has often been measured by identifying neural threshold in real time (online) which can introduce bias in the audiograms that are produced. This was tested by recording auditory nerve activity of the Notodontid moth *Nadata gibbosa* elicited by bat-like ultrasound and analyzing the response offline. The offline audiogram was compared to a published online audiogram showing that the bias introduced can result in a difference in both the best frequency of this moth ear and the audiogram shape. The offline neural threshold audiogram was then compared to audiograms produced using behavioral threshold definitions based on (1) spike period and (2) the latency to first spike, showing that audiograms produced using these theoretical behavioral definitions to have a similar shape. Finally, predictions on the distance at which Notodontid moths may evade bats using negative phonotaxis or the acoustic startle response are made, using the number of spikes elicited as a proxy for distance.

9:30

3aABa7. Echolocation in a fresh water lake. Elizabeth vonMuggenthaler (Fauna Commun. Res. Inst., Hillsborough, NC, 27278 1@animalvoice.com), Joseph Gregory (NC), and Scott H. Mardis (Fauna Commun. Res. Inst., Vermont, Canada)

Lake Champlain is host to myriad interesting geological peculiarities, including the oldest Middle Ordovician reef bed in the world containing coral. Autogenic succession suggests animals adapt to modifications in climate. Eleven thousand year old Beluga whale skeletons have been found in Vermont and Beluga whales currently survive in the St. Lawrence Seaway. In 2003, 2005 and 2009 sites on Lake Champlain were explored using computers with National Instruments Polynesia real-time sound analysis, NI PCMCIA 6062-E cards, DAT recorders, GPS, amplifiers, three vector sensors, two hydrophones, and a Nagra IV-S5. ECHO Aquarium in Vermont facilitated recording of known lake inhabitants and non-biological signals studied formed the basis for the control. Neither recordings nor literature indicate that the known native creatures echolocate. Combining wavelet applications, aiding in reduction in ambient noise in this opposing environment along with conventional analysis, the experiments have been able to conduct far reaching, low-noise sound measurements and were capable of detecting signals the nature of which suggests the presence of some interesting and unexpected phenomena within the ranges and inherent structure of Beluga whale, killer whale, and dolphin echolocation. To protect Lake Champlain, further investigations into this acoustic anomaly is encouraged. [Work supported by the Radius Foundation.]

9:45

3aABa8. Identifying manatee location using dual-frequency sonar DIDSON. Christopher Niezrecki (Dept. of Mech. Eng., UMass Lowell, 1 Univ. Ave., Lowell, MA 01854)

Over the last several years there has been much interest in detecting the West Indian manatee (*Trichechus manatus latirostris*) in turbid waters. Even in clear waters, manatees can be difficult to detect at appreciable distances by looking from above at the surface of the water. The standard DIDSON sonar is a multibeam sonar that provides dynamic images and operates at two frequencies (1.1 and 1.8 MHz). It is capable of providing high-resolution images of objects underwater that are typically scanned from the side or from above. Within this work, the DIDSON sonar is used to detect manatees at Homosassa Springs, FL. The manatees are ensonified from the side and appear to be viewed from the top. The manatees are readily apparent at a range up to 23 m for the measurements acquired in this preliminary sample. The presentation will present some of the images of manatees using a handheld diver DIDSON unit and describes some of the challenges and implications in using the device to detect manatees.

10:00

3aABa9. Using active acoustics to assess habitat restoration in a freshwater lake. Laura E. Madden (Dept. of Wildlife and Fisheries Sci. and Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804-0030, lem230@psu.edu) and Jennifer L. Miksis-Olds (The Penn State Univ., State College, PA 16804-0030)

Artificial structures increase bottom complexity in man-made reservoirs and aim to increase fishery production by providing improved refuge, forage, and reproduction habitat. Electrofishing is typically employed to assess the effectiveness of these structures but is limited to shallow water sites. Active acoustic technology is a non-invasive sampling method that is more flexible than electrofishing, as it is operational in both deep and shallow water sites. Active acoustics also provides a continuous data series at one location to obtain high-temporal resolution information. An acoustic water column profiler was deployed for 1 week at each of two sites: (1) a control site with no introduced structure and (2) a treatment site with artificial refuge habitat. Difference in fish abundance, vertical distribution, and diurnal behavior between the two sites was assessed from the volume backscatter time series. Variation in fish activity between the two sites was compared. This work demonstrates the utility of active acoustics in assessing the effectiveness of freshwater habitat alteration beyond the scope of conventional techniques. A more comprehensive evaluation of habitat restoration is crucial in guiding the development of future conservation efforts.

3aABb1. Aerial audiograms of Steller and California sea lions measured using auditory steady-state response methods. Jason Mulsow (U.S. Navy Marine Mammal Program, SSC Pacific, Code 71510, 53560 Hull St., San Diego, CA 92152, jmulsow@hotmail.com), Colleen Reichmuth (Univ. of California, Santa Cruz, Santa Cruz, CA 95060), Frances Gulland (The Marine Mammal Ctr., Sausalito, CA 94965), David A. S. Rosen (Univ. of British Columbia, Vancouver, BC V6T 1Z4, Canada), and James J. Finneran (U.S. Navy Marine Mammal Program, SSC Pacific, San Diego, CA 92152)

Detection of aerial vocal signals by conspecifics is important in the reproductive behavior of the otariid pinnipeds. However, aerial hearing sensitivity measurements have only been obtained for a few otariid individuals that were trained to participate in behavioral experiments. In order to expand upon this small data set, auditory steady-state response (ASSR) methods were used to examine the aerial hearing sensitivity of Steller and California sea lions. Although ASSR thresholds were elevated relative to behavioral thresholds reported for otariids, the ASSR audiograms of the majority of individuals were similar to each other and to behavioral audiograms in terms of relative sensitivity. A marked reduction in sensitivity with increasing frequency regularly occurred between 16 and 32 kHz, indicating a consistent high-frequency cutoff. The reliability of the ASSR audiograms for both species suggests that behavioral aerial audiograms that exist for a few Steller and California sea lion individuals can be appropriately extrapolated to larger populations. The similarity of the ASSR audiograms among the Steller and California sea lions supports the notion that the otariid pinnipeds form a functional hearing group, with similar aerial hearing in terms of sensitivity and frequency range of hearing. [Work supported by ONR and NOAA Ocean Acoustics Program.]

10:45

3aABb2. Marine mammal auditory evoked potential measurements using swept amplitude stimuli. James J. Finneran (US Navy Marine Mammal Program, SSC Pacific, 53560 Hull St., San Diego, CA 92152, james.finneran@navy.mil)

Auditory evoked potentials are routinely used to characterize hearing in marine mammals for whom behavioral testing is not practical. For frequency-specific audiometry, the most popular evoked potential method has been the measurement of the auditory steady state response (ASSR). These tests normally entail measuring the ASSR to a sequence of sinusoidally amplitude modulated tones so that the ASSR input-output function can be defined and the auditory threshold estimated. In this study, an alternative method was employed, where thresholds were estimated in response to a single amplitude modulated stimulus whose sound pressure level varied linearly with time. The tone sound pressure was therefore swept over a range of levels believed to bracket the threshold. The input-output function was obtained by analyzing the resulting grand average evoked potential using a short-time Fourier transform. The swept amplitude technique was performed with bottlenose dolphins and California sea lions, with the resulting thresholds similar to those obtained with constant amplitude tones. The tradeoffs between the swept amplitude technique and the traditional, constant amplitude approach will be discussed. [Work supported by ONR.]

11:00

3aABb3. Relative salience of acoustic features in zebra finch song. Beth A. Vernaleo, Robert J. Dooling (Dept. of Psych., Neurosci. and Cognit. Sci. Program, Univ. Maryland, College Park, MD 20740, bgoldman@umd.edu), and Marjorie R. Leek (Natl. Ctr. for Rehab. Aud. Res., Portland, VA and Medical Ctr., Portland, OR 97239)

Zebra finch song consists of complex acoustic elements repeated over several hundred milliseconds with extreme vocal-motor precision. Much less is known about how song is perceived though previous work has shown that zebra finches easily discriminate between normal and time-reversed versions of song syllables. Here, we used operant conditioning, psychophysical methods, and various synthetic song models to assess the bird's sensitivity to local versus global temporal changes in song and to determine which cues are most salient in these complex syllables. Birds could discriminate syllable reversals in songs made up of the song envelope filled with noise, suggesting that syllable envelope cues can provide the basis for discrimination. However, birds could also discriminate syllable reversals in songs made up entirely of Schroeder harmonic complexes, stimuli that provide only phase (reversals of fine structure) cues without syllable envelope cues. Birds performed better on longer syllables, suggesting a window of temporal integration for fine structure discrimination. In contrast, humans could perceive few of the syllable reversals within these song modifications. This fine-grained perception in birds suggests that the machinery used for song perception is as precise as the machinery used for song production. [Work supported by NIH.]

11:15

3aABb4. Distance perception by non-territorial zebra finches (Taeniopygia guttata) and budgerigars (Melopsittacus undulatus). Kelly E. Radziwon and Micheal L. Dent (Dept. of Psych., Univ. of Buffalo, SUNY, 206 Park Hall, NY 14260, radziwon@buffalo.edu)

Birds use long-range acoustic signals to defend territories, attract mates, and locate conspecifics. However, long-range acoustic signals progressively degrade during their transmission from the signaler to the receiver. This degradation makes perceiving these signals more difficult, but receivers can use such information to estimate the signaler's distance. The perception of auditory distance cues (overall amplitude, frequency-dependent attenuation, and reverberation) has typically been studied in the field with territorial birds. The present study examined auditory distance perception in a non-territorial songbird, the zebra finch, and in a non-songbird, the budgerigar in a controlled laboratory setting. Three zebra finches and three budgerigars were trained to identify 1-m (undegraded) and 75-m (degraded) recordings of three budgerigar contact calls, one male zebra finch song, and one female zebra finch call. Test stimuli were then introduced on 20% of the total number of trials. These stimuli were created manually by manipulating the naturally recorded 1-m calls. By editing these calls, we could manipulate each distance cue separately to determine which cue was the most salient for the birds. Our results suggest that amplitude was the most important cue for these birds, similar to humans and other animals.

11:30

3aABb5. Direct measurements of subjective loudness in a bottlenose dolphin. Carolyn E. Schlundt (ITT Corp., 2376 Rosecrans St., San Diego, CA 92106, carolyn.melka@itt.com) and James J. Finneran (US Navy Marine Mammal Program, Space and Naval Warfare Systems Ctr. Pacific, San Diego, CA 92152)

Equal-loudness contours were measured in a bottlenose dolphin (*it Tursiops truncatus*) trained to perform a loudness comparison task. The subject was presented two sequential tones and whistled if the first tone was louder, and produced a burst pulse or "buzzed" if the second tone was louder. Approximately 70% of trials were "known" comparisons [e.g., tones of same frequency but different sound pressure levels (SPLs)] and allowed performance to be tracked within sessions. The remaining comparisons were probe trials, consisting of a 10-kHz standard tone with a fixed SPL (either 90, 105, or 115 dB *re* 1 μPa) and a comparison tone, whose frequency was fixed but whose SPL varied. Presentation order of probe trials was balanced. Eleven comparison frequencies ranged from 3.5 to 113.1 kHz. Logistic regression was used to derive curves relating the probability of the comparison tone being perceived louder. The 50% point represented the SPL at which the comparison and standard tones were equally loud. The data represent the first direct measurement of equal-loudness curves in any animal and show the relationship between the frequency and subjective loudness. Loudness contours may be more appropriate for assessing behavioral effects of sound, assuming behavioral reactions are more strongly related to *loudness* than *SPL*.

11:45

3aABb6. Vocalization in a neonatal Amur tiger cub. Edward J. Walsh, Adam B. Smith (Developmental Auditory Physio. Lab., Boys Town Natl. Res. Hospital, 555 North 30th St., Omaha, NE 68131, smithab1@boystown.org), Douglas L. Armstrong (Omaha's Henry Doorly Zoo, Omaha, NE 68107), and JoAnn McGee (Boys Town Natl. Res. Hospital, Omaha, NE 68131)

Although the acoustical features of a small number of calls representing the vocal repertoire of adult tigers have been studied and reported, calls produced by developing tigers representing any subspecies have not been described. In that light, the acoustical features of calls produced by an Amur cub during the first two postnatal weeks of life will be considered. The vocal repertoire of the cub observed during recording sessions was limited, consisting primarily of neonatal cries composed of three distinct types: an intense, harmonically rich phonation, an aperiodic cry (dysphonation), and a compound cry exhibiting both dysphonation and harmonically rich phonation segments. Overall acoustic power of the harmonically rich phonation was uniformly distributed across a frequency band ranging from approximately 0.6–2.0 kHz and that was centered on roughly 1.2 kHz on the second postnatal day. While the same basic pattern was observed on postnatal day 13, inter-harmonic differences were smaller, and between days 2 and 13 the mean fundamental frequency dropped from ~260 to ~200 Hz; typically, f0 varied during each utterance at each age studied. These findings will be considered in relation to the spectrographic character of calls produced by adult Amur tigers. [Funding was provided by NSF Grant 0823417.]

3aBB1. Numerical modeling techniques common to medical ultrasound and detection of undersea objects. David S. Burnett (Naval Surface Warfare Ctr., Panama City Div., Code T11, 110 Vernon Ave., Panama City, FL, david.s.burnett@navy.mil)

Acoustic scattering from gallstones, diseased tissues, and objects on the ocean floor and submarines are all governed by the same underlying partial differential equations describing wave propagation in fluids and viscoelastic solids. These objects differ in size by many orders of magnitude. However, they are all the same "acoustic size" when each is insonified at a frequency such that the ratio of object-diameter-to-wavelength is the same for all. Objects of the same acoustic size have two important characteristics: (1) they exhibit qualitatively similar physical-acoustic phenomenology and (2) numerical modeling consumes similar computational resources. Given these observations, many of the numerical modeling techniques developed by the U.S. Navy for acoustic scattering from undersea objects may be applicable to biomedical ultrasound applications. This paper explores these possibilities. NSWC PCD has developed a computer simulation system for modeling the acoustic color (target strength versus frequency and aspect angle) of realistic objects. It automatically runs hundreds of thousands of three dimensional FE models, changing the mesh and finite fluid boundaries of the models as they sweep over frequency and yielding uniform accuracy with frequency. This paper will present an overview of the technology and numerical verification and validation of the system. [Work supported by ONR and SERDP.]

8:20

3aBB2. Optimization of a 100 MHz fiber optic hydrophone for medical ultrasound applications using nanometer scale gold coating. Rupa Gopinath, Khushali Manseta, Vasileios Nasis, Afshin S. Daryoush (Dept. ECE, Drexel Univ., 3141 Chestnut St., Philadelphia, PA 19104), Mahmoud El-Sherif (Photonics Labs Inc., Philadelphia, PA 19104), and Peter A. Lewin (Drexel Univ., Philadelphia PA 19104)

This work describes a novel numerical model developed to optimize the design of a broadband, spatial averaging free fiber optic hydrophone probe (FOHP) for characterization of ultrasound fields in the frequency range 1–100 MHz. The design included minimization of the active sensor dimensions, so its cross-section is comparable with the half acoustic wavelength at the highest frequency of interest and improvement of voltage-to-pressure sensitivity of the probe measured in V/Pa. Initial simulations based on the assumption that bulk refractive index of sputtered material could be used indicated that a thin film gold coating (1–35 nm) could indeed enhance the voltage sensitivity of the FOHP by 16–30 dB; however, a follow up analysis revealed that determination of the coating thickness influence on the FOHP performance would require an introduction of the complex (as opposed to bulk) index of refraction of the sputtered film. The input parameters to the model, their selection criteria, and implementation of the coupled acousto-optic interaction of gold layer will be discussed. The measured prototypes produced unprecedented voltage sensitivity between −234 and −245 dB *re* 1 V per uPa or 2 and 560 mV/MPa, respectively. [The authors wish to acknowledge support of the NIH R01EB007117 grant.]

3aBB3. Acoustic streaming for direct delivery of therapeutics into tissue. Raghu Raghavan (1101 East 33rd St., Ste. B305, Baltimore, MD 21218)

Ultrasound has been used in medical drug delivery but largely for altering membrane permeability. We are investigating acoustic streaming for delivery of therapeutics, such as drug molecules or other particulates, into brain tissue, with other applications for the future. Acoustic streaming potentially can enhance fluid and particle flux in interstitial pathways in tissue. The conventional equations that describe streaming in fluids are not directly applicable to porous media such as the brain. In this study, a modified Biot equation is employed to develop a theoretical framework to account for the attenuation mechanisms dominant in acoustic streaming in porous media. The analytical solutions obtained for isotropic, homogeneous media are presented and compared with experiments conducted on gel phantoms, and with results reported for streaming in live monkey brains. The dependence of streaming-induced therapeutic transport on acoustic parameters and tissue properties are investigated. The theoretical framework was used to determine optimal operating parameters of ultrasonic devices for streaming-based drug transport in porous tissue with particular emphasis on two objectives: (1) reduction in backflow from catheters inserted into brain tissue for direct delivery and (2) delivering drugs into the margins of a resection cavity following surgery for brain tumor.

8:55

3aBB4. Phase synchronization and collective instability in oscillating bubble clouds. D. Sinden, E. Stride, and N. Saffari (Dept. Mech. Eng., Univ. College London, Torrington Pl., London WC1E 7JE, United Kingdom, d.sinden@ucl.ac.uk)

The effect of bubble interactions within a bubble cloud under ultrasonic forcing is investigated. Under certain conditions, phase synchronization is found, revealing parameter regimes where the dynamics of the bubble system are primarily determined by the interactions of the bubbles, rather than the applied ultrasonic acoustic field. Due to the Bjerknes interaction, the stability thresholds for critical pressure and size leading to unpredictable oscillations for bubble clouds are lower than the stability thresholds for single bubbles. Interestingly, numerical simulations confirm that in the regimes where bubbles exhibit chaotic oscillations, the dynamics are determined by a complicated geometric object called a low-dimensional strange attractor which is qualitatively the same as that for the chaotic oscillations of a single bubble. Thus an averaged equation may also be low-dimensional. The effects of synchronization on Landau damping are discussed. The effect of delays between the interactions is also investigated. The implications for applications in high-intensity focused ultrasound, harmonic imaging, and targeted drug delivery will be discussed.

9:10

3aBB5. Design and implementation of a cylindrical array for passive mapping of cavitation fields produced by clinical high intensity focused ultrasound transducers. Stuart Faragher, Miklós Gyöngy, Jamie Collin (IBME, Univ. of Oxford, ORCB, Oxford OX3 7DQ, United Kingdom), Mark Hodnett (Quality of Life Div. Natl. Physical Lab., Teddington TW11 0LW, United Kingdom), and Constantin-C. Coussios (Univ. of Oxford, Oxford OX3 7DQ, United Kingdom)

Key to the success of high-intensity focused ultrasound (HIFU) as a clinical tool is the development of standardized quality assessment procedures to assess the safety and efficacy of HIFU transducers. The present work details the development of a cylindrical sensor array to be positioned around the HIFU focus during pre-treatment quality assessment of clinical transducers, which is designed to localize cavitation activity in three dimensions by passive mapping of the broadband emissions arising from inertial cavitation. The propagation of sound from a collection of broadband sources was first modeled to determine the optimum size, number and distribution of array elements for accurate mapping, and characterization of the cavitation dynamics produced during HIFU exposure. The optimal array configuration was then manufactured from PVDF using a novel printed circuit board technique, and theoretical predictions of the spatial resolution that it could achieve were validated experimentally. Because inertial cavitation is a pressure driven phenomenon, the ability to map cavitation activity using this array could provide a novel tool for rapid mapping of pressure fields produced by clinical HIFU transducers, in addition to providing invaluable information about the evolution of cavitation dynamics during HIFU exposure.

9:25

3aBB6. Diffraction pattern recognition method for drastically improving image resolution and diagnostic sensitivity. J.J. Wen (VeroSound, Inc., 128 Powder Mill Rd., Sudbury, MA 01776)

Compared with the two other mainstream medical imaging methods, CT and MRI, the worst weakness of ultrasound imaging is poor resolution—the ability to resolve tiny variations in tissue structure or texture. Due to sound wave diffraction and the way imaging ultrasound signal is retrieved, a point target in object domain does not generate point image in image domain, but an image spot with sophisticate spot pattern and considerable spot size as functions of point target location relative to the transducer—the most direct cause of poor resolution. The mainstream techniques aimed at reducing the image spot, either by shortening the impulse signal or by sharpening the beam focusing, are unavoidably accompanied by the deteriorated sensitivity and depth of penetration. It is a common consent in medical ultrasound community that ultrasound imaging is very close to its theoretical resolution limit. This article presents a different approach we named E-mode imaging that uses a diffraction-theory-based spot pattern recognition technique to account for the effects of image spot pattern in image processing. With the same set of ultrasound data that *B* imaging is based on, E-mode imaging achieved five to ten times better resolution and diagnostic power in computer simulations.

9:40

3aBB7. A generalized formulation for scattering from arbitrary distributions of homogeneous cylinders or spheres. Andrew J. Hesford, Jeffrey P. Astheimer, and Robert C. Waag (Dept. of Elec. and Comput. Eng., Univ. of Rochester, UR Med. Ctr. Box 648, 601 Elmwood Ave., Rochester, NY 14642-8648, hesford@ece.rochester.edu)

A generalized form of spatial harmonic expansion suitable for calculation of scattering by arbitrary distributions of homogeneous cylinders in two dimensions and homogeneous spheres in three dimensions is presented. The method is applicable for general incident fields expressed as angular spectra of plane waves. The technique uses harmonic expansions, physical acoustic boundary conditions, and mode matching to represent scattering by each individual object as a diagonal operator. Interaction between objects is treated with a *T*-matrix approach in which scattering from one object is applied to another using translation operators that shift the origins of harmonic expansions between scatterers. The generalized form permits efficient calculations in both two and three dimensions. These calculations are used to assess the validity of two-dimensional approximations to three-dimensional scattering for volumes containing multiple interacting spheres that are illuminated by elevation-focused beams. Differences in the two-dimensional and three-dimensional results are attributed to out-of-plane scattering and partial-volume effects caused by significant variations in the scatterer cross section over the elevation width of the focused beam.

9:55—10:30 Break

10:30

3aBB8. Comparison of the Khokhlov–Zabolotskaya–Kuznetsov equation and Fourier-continuation for modeling high-intensity focused ultrasound beams. Theresa Cheung, Robin O. Cleveland (Dept. of Mech. Engin., Boston Univ., Boston, MA 02215), Nathan Albin, and Oscar P. Bruno (Caltech, Pasadena, CA 91125)

High-intensity focused ultrasound (HIFU) employs acoustic amplitudes that are high enough that nonlinear propagation effects are important in the evolution of the sound field. A common model for HIFU beams is the Khokhlov–Zabolotskaya–Kuznetsov (KZK) equation which accounts for nonlinearity and absorption of sound beams. The KZK equation models diffraction using the parabolic or paraxial approximation. For many HIFU sources the source aperture is similar to the focal length and the paraxial approximation may not be appropriate. Here we compare results obtained using the "Texas code" a time-domain numerical solution to the KZK equation to a new method of solving nonlinear differential equations: the Fourier-continuation (FC) method. Here the FC method solves the underlying fluid dynamics equations and does not invoke the paraxial approximation. Results were obtained for a 1.1-MHz focused HIFU source. The medium parameters were taken to either be hyperviscous water or to match human liver. For a low focusing gain transducer (focal length 50λ and radius 10λ) the KZK and FC models showed excellent agreement through the focal region. As the source radius was increased, discrepancies started to appear and for a radius of 30λ, the KZK model did not capture diffraction of the HIFU source accurately. [Work supported by NSF 0835795.]

10:45

3aBB9. Characterization of clutter in ultrasonic imaging using a nonlinear full-wave simulation method and *in vivo* human tissue. Jeremy J. Dahl (Dept. of Biomedical Eng., Duke Univ., Durham, NC 27708, jeremy.dahl@duke.edu) and Gianmarco F. Pinton (Laboratoire Ondes et Acoustique, ESPCI, Paris, France)

Clutter is a well known image degradation mechanism in ultrasonic imaging that is patient dependent. Despite widespread agreement on clutter sources, there are few studies on sources and their contribution to overall image clutter. We have performed simulations of clutter using a nonlinear, full-wave method to demonstrate the characteristics and sources of ultrasonic clutter. Representations of human abdominal layers, created from histological stains of human abdominal layers, were placed at the surface of the transducer. Point targets and anechoic cysts were simulated to demonstrate the characteristics of clutter resulting from these near-field layers. We have also performed matching *in vivo* experimental studies in human bladders and livers. The simulations and experiments show consistent results. Clutter resulting from near-field tissue layers is spatially coherent with respect to axial motion and incoherent in the sampled pressure field. The contribution of off-axis clutter resulting from the tails of the point-spread-function is shown to be relatively small ($<5\%$) compared to the contribution of clutter associated with near-field layers (approximately 68%). Thus, the dominating source of clutter is associated with multiple reflections in near-field tissue layers. Clutter due to off-axis scattering dominates only when an interfering target is close to the imaging target. [This work is supported by the NIH Grant R21-EB008481 from the NIBIB. Technical support was provided by the Ultrasound Division at Siemens Medical Solutions USA, Inc.]

11:00

3aBB10. Modeling nonlinear acoustic waves in media with inhomogeneities in the coefficient of nonlinearity. L. Demi (Lab. of Acoust. Imaging and Sound Control, Fac. of Appl. Sci., Delft Univ. of Technol., Lorentzweg 1, 2628 CJ Delft, The Netherlands, l.demi@tudelft.nl), M. D. Verweij (Delft Univ. of Technol., 2628 CD Delft, The Netherlands), and K. W. A. van Dongen (Delft Univ. of Technol., 2628 CJ Delft, The Netherlands)

The refraction and scattering of nonlinear acoustic waves play an important role in the realistic application of medical ultrasound. One cause of these effects is the tissue dependence of the nonlinear medium behavior. A method that is able to model those effects is essential for the design of transducers for novel ultrasound modalities. Starting from the Westervelt equation, nonlinear pressure wave fields can be modeled via a contrast source formulation, as has been done with the INCS method. An extension of this method will be presented that can handle inhomogeneities in the coefficient of nonlinearity. The contrast source formulation results in an integral equation, which is solved iteratively using a Neumann scheme. The convergence of this scheme has been investigated for relevant media (e.g., blood, brain, and liver). Further, as an example, the method has been applied to compute the one-dimensional nonlinear acoustic wave field in an inhomogeneous medium insonified by a 1 MHz Gaussian pulse propagating up to 100 mm. The results show that the method is able to predict the propagation and the scattering effects of nonlinear acoustic waves in media with inhomogeneities in the coefficient of nonlinearity. This motivates a similar extension of the three-dimensional INCS method.

11:15

3aBB11. Three-dimensional calculation of ultrasound propagation through a breast model. Jason C. Tillett (Dept. of Elec. and Comput. Eng., Univ. of Rochester, Medical Ctr. Box 648, Rochester, NY 14642, tillett@ece.rochester.edu), Gheorghe Salahura, Leon A. Metlay, and Robert C. Waag (Univ. of Rochester, Rochester, NY 14627)

A specimen of human breast comprised mostly of fat and connective tissue was imaged with a high-resolution magnetic resonance scanner. The volume of data was segmented to construct an acoustic model by assigning values of sound speed, density, and attenuation to voxels corresponding to fat and connective tissue. Propagation of a wavefront from a point source through the model was calculated using a three-dimensional finite-difference time-domain *k*-space method that included perfectly matched absorbing boundary conditions to eliminate reflections at the edge of the computational domain. Because of the large $557\times451\times289$ grid and computational demands of the three-dimensional FFT, the calculation was performed on a cluster of computers. The wave field was sampled in three orthogonal planes, one of which was offset from the origin to represent a receiving aperture. The aperture waveforms were corrected for geometry associated with the estimated location of the point source and used to calculate arrival-time and energy-level fluctuations. The root-mean-square arrival-time and energy-level fluctuations of the simulated propagation were consistent with measurements for comparable specimens of breast. The results demonstrate the feasibility of using the described combination of methods to provide insight about the way ultrasound beams are aberrated by tissue.

3aEA1. Middle-ear input impedance and middle-ear sound transfer. John J. Rosowski, Hideko H. Nakajima, Jeffrey T. Cheng, Mohamad A. Hamadeh, and Michael E. Ravicz (Eaton-Peabody Lab., Massachusetts Eye and Ear Infirmary, 243 Charles St., Boston MA 02114)

Measurements of the acoustic input impedance of the human eardrum, or tympanic membrane (TM), have been used as indicators of middle-ear sound transfer for over 70 years. Modern measurements include (i) middle-ear input impedance in single- and multi-frequency tympanometry, (ii) impedance-based estimates of ear-canal reflectance, a description of sound power absorption at the TM, and (iii) laser-Doppler measurements of the sound-induced velocity of specific points on the TM surface. The advantages and disadvantages of these techniques are discussed, and their use in identifying and estimating the effects of different middle-ear pathologies is illustrated. A new technique, opto-electronic holography, which allows measurements of the volume displacement of the visible surface of the TM, is also discussed. Common themes are (i) the impedance of the middle ear varies widely within populations of normal hearing subjects and (ii) input-impedance based estimates of sound transfer through the middle ear are hindered by the presence of flexibility within the ossicular chain. It is concluded that while middle-ear input impedance may adequately describe the acoustic load on hearing-aid receivers, this impedance, by itself, is not always an accurate indicator of pathological alterations in sound transfer through the human middle ear.

8:25

3aEA2. Effects of middle-ear disorders on ear-canal reflectance measures in human cadaver ears. Susan E. Voss (Picker Eng. Program, Smith College, Ford Hall, 100 Green St., Northampton, MA 01063, svoss@smith.edu), Gabrielle R. Merchant, and Nicholas J. Horton (Smith College, Northampton, MA 01063)

The development of acoustic reflectance measurements may lead to noninvasive tests that provide information currently unavailable from standard audiometric testing. Few systematic measurements exist on the effects of various middle-ear pathologies on the ear-canal reflectance, where reflectance is calculated from impedance measurements. This work uses a human cadaver preparation to examine how a variety of middle-ear pathologies affect power reflectance: static middle-ear pressures, middle-ear fluid, fixed stapes, disarticulated incudo-stapedial joint, and tympanic-membrane perforations. The change from normal in power reflectance, induced by the simulated pathology, generally depends on frequency and the extent of the pathology (except for the disarticulation). The largest changes from normal occur as increases in power reflectance near 1000 Hz with both large static pressures and large amounts of middle ear fluid. Disarticulation of the stapes results in reductions in power reflectance at the lower frequencies, while fixation of the stapes results in low-frequency increases in power reflectance. Tympanic membrane perforations generally produce reductions in power reflectance for frequencies below 1000–2000 Hz that are systematically related to the size of the perforation. These preliminary measurements may help assess the utility of power reflectance as a diagnostic tool for middle-ear disorders.

8:45

3aEA3. Modeling diagnosis of the human middle ear. Pierre Parent (Mimosa Acoust., Urbana IL) and Jont Allen (Dept. of ECE, Univ. of IL, Urbana IL, jontalle@illinois.edu)

Tympanic membrane (TM) and ossicular (OSC) models have been studied for many years. Most are implemented in the frequency-domain via Kirchhoff's equations. However, the frequency domain is less intuitive than the time-domain models and does not apply given non-linear phenomena. This research presents a human time-domain TM+OSC implementation, extending our cat model [J. Acoust. Soc. Am. **122**, 918–931 (2007)] as a cascade of slightly missmatched transmission lines. The canal plane-wave volume velocity is uniformly distributed across the canal cross-section, and updated at $\approx$1 MHz (to accurately simulate sound propagation). The time-domain model includes both forward and backward waves, enabling for the first time, the computation of one-way delays, thus explaining why multi-modal propagation observed on the TM are not critical. Results are validated with data from normal and pathological ears. Additionally, comparisons between the acoustic impedance in living and dead (temporal bones) ears shows significant temporal-bone artifacts. Because of ear-dependent impedance missmatch, canal standing waves are observed. It is frequently assumed that the umbo pressure is the best reference pressure. In fact the "forward-pressure" P_+ is a better estimate of the ideal reference, the cochlear pressure [J. Acoust. Soc. Am. **125**, 1605–1611 (2009)].

9:05

3aEA4. An eardrum impedance simulator for use with physical replicas of the human ear canal. Michael R. Stinson and Gilles A. Daigle (Inst. for Microstructural Sci., Natl. Res. Council, Rm. 307A, Bldg. M-50, Ottawa, ON K1A 0R6, Canada)

An eardrum impedance simulator has been incorporated into life-size replicas of the human ear canal. The simulator branches off from the ear canal at the center of the nominal eardrum position. It has been designed so that sound pressure distributions in an ear canal will have the same standing wave ratios as those measured previously in human subjects over the 4–10-kHz range. The key component of the eardrum simulator is a micro-perforated plate, whose holes provide damping through viscous and thermal boundary layer losses. The optimum design specifies 109 holes of 0.06 mm diameter in 0.003-in. shim stock. Measurements of sound pressure distribution in replica ear canals are underway to evaluate the acoustical performance of the eardrum simulator. The sound field is generated by an occluding hearing aid test fixture.

9:25

3aEA5. Forward-pressure level for in-the-ear calibration. Stephen T. Neely and Michael P. Gorga (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131, neely@boystown.org)

When acoustic impedance of the ear canal is known, sound pressure measured by a microphone in the ear canal can be decomposed into forward and reflected components. This decomposition provides a means to overcome problems associated with standing waves that may cause in-the-ear sound level calibration to be unreliable at high frequencies. Compared to total pressure measured at the sound source, we have demonstrated that forward pressure provides a more reliable estimate of sound quantity entering the ear, especially at frequencies above 4 kHz. Specifically, we have demonstrated increased reliability in measurements of distortion-product otoacoustic emissions (DPOAEs) when we use forward-pressure level (FPL) calibrations. Also, we have shown that behavioral threshold measurements for stimuli calibrated in FPL are more reliable than conventional calibration methods in the 4–10 kHz range. FPL calibration may provide advantages at high frequencies (1) for assessing hearing status with DPOAEs and (2) for fitting hearing aids using real-ear measurements. Objective methods of assessing hearing loss and fitting hearing aids at high frequencies are needed because the 6–12 kHz range is known to be important to young children for learning speech. [Work supported by Grants DC2251, DC8312, and DC4662 from the NIH/NIDCD.]

9:45

3aEA6. *In-situ* calibrated sound signals and hearing sensitivity. Robert Withnell (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405, rwithnel@indiana.edu), Pat Jeng (Mimosa Acoust., Champaign, IL 61820), William Shofner (Indiana Univ., Bloomington, IN 47405), and Jont Allen (Univ. of Illinois, Urbana, IL 61801)

The acoustic input impedance of the ear provides data on the acoustico-mechanical function of the ear and can be used diagnostically to assess outer and middle ear function. Sound signals delivered to the ear (canal) can be quantified *in-situ* if the complex reflectance of the ear has been determined. Hearing sensitivity can be expressed in terms of the forward-going sound pressure wave, or after correcting for acoustic delay, the fraction of the forward-going sound pressure wave transmitted to the middle ear. The latter is an estimate of the signal the cochlea receives. Data will be presented examining the virtues of expressing hearing sensitivity in terms of an *in-situ* calibrated sound signal.

10:05—10:25 Break

10:25

3aEA7. Simple models for hearing-aid vents and open fittings. James M. Kates (GN ReSound, Dept. Speech Lang Hear Sci., Univ of Colorado, 409 UCB, Boulder, CO 80309)

The effects of a vent or open fitting are determined by the vent and ear acoustics. The dominant effects are a high-pass filter applied to the hearing-aid frequency response and a low-frequency direct signal path through the vent into the ear canal. Because these effects occur predominantly at low frequencies, simple lumped-parameter acoustics can be used to model them. The vent is modeled as an acoustic mass, and the ear canal and middle ear impedances as equivalent acoustic volumes. The results of using these simple approximations will be compared to calculations using acoustic tube models for the vent and ear canal and the Zwislocki middle-ear impedance model.

10:45

3aEA8. A comparison of two methods for estimating sound pressure level at the tympanic membrane at high frequencies for hearing aids. Tao Zhang, Karrie Recker (Starkey Labs., Inc., 6600 Washington Ave. South, Eden Prairie, MN 55344-3405, tao_zhang@starkey.com), Janice LoPresti (Knowles Electrons LLC, Itasca, IL 60143), Matt Kleffner (Starkey Labs., Inc., Eden Prairie, MN 55344-3405), and William Ryan (Knowles Electrons LLC, Itasca, IL 60143)

For hearing aid fittings, it is important to know the delivered sound pressure level (SPL) at the tympanic membrane (TM) over a wide frequency range. Because it is infeasible to measure the SPL at the TM clinically, an indirect estimation based on measurements away from the TM is often used in practice. Furthermore, it is highly desirable that such a method does not require a clinician to use

extra accessories to perform extra calibration in a clinic. Two such methods were proposed in the past. One used a set of empirically derived correction factors to estimate the SPL at the TM (Recker *et al.* (2009), the other used a lumped-element model to estimate the SPL at the TM [LoPresti *et al.* (2009)]. In this study, both methods were evaluated using actual hearing aid prototypes. An ITC hearing aid was built for each of ten participants. For each participant, the SPL in the ear canal was measured using a hearing aid microphone. The SPL at the TM was estimated using each method separately. The results were compared with the measured SPL at the TM. The relative strength and weakness of each method were discussed with the implications for clinical applications.

11:05

3aEA9. Assess eardrum characteristics using standing wave technique. Weili Lin and Karrie Recker (Starkey Labs., Inc., 6600 Washington Ave. S., Eden Prairie, MN 55344, weili_lin@starkey.com)

It has been shown that eardrum reflection coefficients can be derived accurately up to 8 kHz based on standing wave patterns in the human ear canal, but not as reliably in higher frequencies [Lawton *et al.*, J. Acoust. Soc. Am. **79**, 1003 (1986)]. The primary purpose of this study is to investigate various factors affecting the accuracy of this type of measurements and extract important characteristics of ear canal and eardrum. In addition to reflection coefficients, eardrum impedance and the effect of loading on the eardrum are also examined. A model ear canal is constructed using a tube with variable loading conditions at one end. Measurements are taken along the center axis and contour of the tube when a stimulus is presented with frequency components up to 16 kHz, under both occluded and open situations. Results obtained from standing wave properties in the model ear canal are then compared to data acquired in real ear and in an ear simulator.

11:20

3aEA10. Capturing low-frequency cochlear impedance in time domain models: The role of viscosity. Michael J. Rapson and Jonathan C. Tapson (Dept. of Elec. Eng., Univ. of Cape Town, Private Bag, Rondebosch, 7701, South Africa, michael.rapson@uct.ac.za)

Viscous effects in the cochlear fluid have been shown to be negligible for frequencies greater than 100 Hz [M. Viergever, Ph.D. thesis]. However, they become important at lower frequencies; hence viscous damping is sometimes included in helicotrema models [S. T. Neely and D. O. Kim, J. Acoust. Soc. Am. **79**, 1472–1480 (1986)]. Modeling viscosity in time-domain computational cochlear models for wide-band input signals is problematic. Since the boundary layer thickness is inversely proportional to frequency, Navier–Stokes formulations require fine spatial resolutions, and fluid potential formulations are inherently inviscid models. Lumping all viscous effects into the helicotrema is not physiologically accurate as "the helicotrema does not appear to be a dominant constriction" [Lynch *et al.*, J. Acoust. Soc. Am. **72**, 108–130 (1982)]. An alternative is proposed whereby a fluid potential formulation is augmented with frequency dependent viscosity corrections that are based on prior analysis of the cochlear geometry and become negligible at higher frequencies. For simplified fluid boundary conditions, the predictions of this fluid model are compared to Navier–Stokes, potential, and lumped viscosity models for frequencies in the range 10 Hz–10 kHz. The simulations are also compared to physiological data for the input impedance of the cochlea.

3aMU1. What is known about banjo science and what is not yet known. Thomas D. Rossing (Stanford Univ., Stanford, CA 94305, rossing@ccrma.stanford.edu)

Banjos generally come in three differrent types: five-string banjo with a resonator, five-string banjo without a resonator, and four-string banjo with a resonator. Only recently have banjos been the object of much scientific study, and most of these studies have been directed at the American five-string banjo. These investigations have considered the modes of vibration of the principal parts, how they couple together, and how they radiate sound. In general, peaks in the driving point mobility correlate well with modes of vibration in the banjo head and with the radiated sound. Systematic modifications of some of banjo parts have been made by various investigators, and the effects of these modifications are considered.

8:55

3aMU2. A world beyond the banjo. Paul A. Wheeler (Dept. of ECE, Utah State Univ., 4120 Old Main Hill, Logan, UT 84322-4120, paul.wheeler@usu.edu)

The American banjo, a long-necked plucked lute developed by slaves from Africa and an important instrument in Bluegrass music, derives its characteristic timbre from the membrane belly of the instrument. Even though the banjo is the best known membrane-style lute in music of the western hemisphere, there are many musical traditions across the eastern hemisphere which have used their own version of the banjo long before the development of the American banjo. This paper will introduce some of these instruments and the musical cultures using them. These include the ngoni of western Africa (possibly the source of the American banjo), the cumbus and tar from the Middle East, the rawap of central Asia, the sarod of India, and the shamisen and sanxian of Japan and China. As diverse as these cultures may be, the characteristic timbre of the banjo is an important element in their music.

9:20

3aMU3. Time-resolved studies of banjo head motion. Thomas R. Moore and Laurie A. Stephey (Dept. of Phys., Rollins College, Winter Park, FL 32789)

Almost all of the radiated sound from a banjo can be attributed to the motion of the membranic head. This motion depends critically on the physical properties of the membrane as well as which string is plucked and the direction of the initial displacement. We present time-resolved studies of the motion of the membrane of an American five-string banjo after plucking and discuss the interaction between the string and the vibrating membrane.

9:45

3aMU4. The banjo: Developing a plausible model from first principles. Joe Dickey (3960 Birdsville Rd., Davidsonville, MD 21035, dickey@jhu.edu)

The banjo is one of the few musical instruments which is amenable to analytical modeling. It is fundamentally two connected canonical wave bearing systems, and as such, it can be solved. Furthermore, the requisite computer code runs quickly, making it practical to examine the instrument's response as functions of a variety of parameters. The parameters are the things banjo players tweek in their attempt to get the sound they want; things like head tension, bridge mass, and string gauge. This tutorial will start with first principles in both the physics and the mathematics and end with movies of the calculated head response and radiated sound as functions of time and frequency. Numerical models can never be exact. Real systems, and particularly musical instruments, are just too complex for this, but models can provide useful guidance by illuminating what might happen as parameters are changed.

3aMU5. The banjo, string theory for the rest of us. Joe Dickey (3960 Birdsville Rd., Davidsonville, MD 21035, dickey@jhu.edu)

An analytical model of a five string banjo is used to calculate the dynamic response of a plucked banjo and the subsequent radiation of sound. This is the easy part: the difficult part is to identify and quantify the subtle differences between bad and good sound, whether that sound is measured or calculated. As a step toward this, the author has defined figures of merit (FOMs) to quantify radiated sound characteristics related to loudness, brightness, and decay, and to examine these FOMs as functions of the tension and propagation loss factor of the membranic head, the mass of the bridge, and the location of the pluck on the string. The calculated response does exhibit dual decay constants for radiated sound and a diminution of the sixth overtone. Qualitative agreement between calculated and measured mode patterns will be presented.

10:55

3aMU6. Membrane modes and air resonances of the banjo using physical modeling and microphone array measurements. Florian Pfeifle and Rolf Bader (Musikwissenschaftliches Institut, Universitaet Hamburg, Neue Rabenstrasse 13, 20354 Hamburg, Germany, florian.pfeifle@haw-hamburg.de)

A fullscale physical model of a banjo is implemented using a finite-difference formulation. The model consists of strings, bridge, resonance membrane, and the air enclosed in the geometry. The resulting time series of plucked strings in the model radiated from the membrane is integrated with respect to a room position in front of the banjo membrane and analyzed. Furthermore, the modes of the membrane are displayed as two-dimensional mode shapes for the plucked string as well as for the free vibrating membrane. For verification and refinements of the model, measurements on a banjo were performed using a 11×11 microphone array. The recorded time series were back-propagated to the surface of the membrane showing its vibrational patterns. These measured modes are compared to the modeed mode shapes in the low- to mid-frequency range. Furthermore, the air modes of the open sound holes are investigated with respect to the their phase relations to the membrane. Radiation strength of these frequencies are strongly influenced by the opposite phase relations of these patterns. Also open-back and closed-back banjos are compared. The radiation behavior of these lower modes in the far field is then used to be implemented into the physical model of the banjo.

11:20—12:00
A short concert will follow the session in which techniques of Bluegrass 5-string banjos are demonstrated.

3aNCa1. Effects of building mechanical system noise on worker performance and perception. Lily M. Wang (Architectural Engr. Prog., Peter Kiewit Inst., Univ. of Nebraska-Lincoln, 1110 S. 67th St., Omaha, NE 68182-0681, lwang4@unl.edu)

This paper presents results from a number of studies that investigated the effects of noise from building mechanical systems on human task performance and perception. Three phases of research were conducted, each of which utilized a different set of noise signals produced by building mechanical systems: (1) broad-band noise at different levels and spectral qualities, (2) tonal noise conditions, and (3) noise conditions with time-varying fluctuations. In each phase, six different noise signals (many based on *in-situ* measurements) were reproduced in an office-like setting. Thirty participants completed tasks (e.g., typing, grammatical reasoning, and math) plus subjective questionnaires, while exposed to each noise condition for up to 1 h. In general, no statistically significant differences were found in task performance across the various noise signals tested. However, higher annoyance/distraction responses from the test subjects were often significantly correlated with reduced typing performance. These higher annoyance/distraction responses were also closely correlated to higher subjective ratings of loudness, followed by roar, rumble, and tones or fluctuations. Of particular interest is that a greater perception of low-frequency rumble was significantly linked to reduced performance on both the routine and cognitively demanding tasks. 3aNCb1. Sound transmission through double wall aircraft structures/ mounting effect. Neple Pascale (Airbus Operations SAS, 316 Rte. de Bayonne, 31060 Toulouse Cedex 09, France, pascale.neple@airbus.com), Atalla Noureddine, and Bolduc Maxime (GAUS, Univ. of Sherbrooke,)

In the context of noise control treatment identification for turbulent boundary layer excitation, the main objective of this work is to assess the impact of mechanical links on the sound transmission loss through a double wall aircraft structure. An assembly of a stiffened panel made of composite fiber reinforced plastic (with a critical frequency around 6000 Hz) and a trim panel with a honeycomb core (with a critical frequency around 3000 Hz) has been considered in the whole study. The transmission loss of this double panel filled with glass wool blankets has been measured under diffuse sound field and point force excitation in the 100–10000 Hz frequency range for a fully decoupled configuration and a totally coupled one (rigid mounting). Extensive simulation using transfer matrix methodology has been conducted on the double panel for different glass wool filling rates, density, sound barriers, and add-on damping patches, for fully decoupled and rigid configuration. The main result is that the rigid mounting decreases significantly (up to 10 dB at 1000 Hz) the double wall transmission loss compared to a fully decoupled mounting and the acoustic efficiency of the passive treatments as well, whatever the excitation field.

9:30

3aNCb2. Validation of a polyimide foam model for use in transmission loss applications. J. Stuart Bolton, Kwanwoo Hong (Ray W. Herrick Labs., Purdue Univ., West Lafayette, IN 47907-2031, bolton@purdue.edu), Tongan Wang, John Maxon (Gulfstream Aerosp. Corp., Savannah, GA 31402-2206), Brian Howerton (Lockheed Martin Exploration & Sci., Hampton, VA 23681-2199), Roberto J. Cano, Erik S. Weiser (NASA Langley Res. Ctr., Hampton, VA 23681-2199), Tyler Lorenzi (NASA Langley Aerosp. Res. Summer Scholars Program, Hampton, VA 23681-2199), Brian J. Jensen, and Richard J. Silcox (NASA Langley Res. Ctr., Hampton, VA 23681-2199)

In this paper, the use of polyimide foam as a lining in double panel applications is considered. Polyimide foam has a number of attractive functional attributes, not the least of which is its high fire resistance, thus making its use desirable in some sound transmission applications. The configuration studied here consisted of two 0.04×94 thick, flat aluminum panels separated by 5 in., with a 3 in. thick layer of foam centered in that space. Random incidence transmission loss measurements were conducted on this buildup, and conventional poro-elastic models were used to predict the performance of the lining material. The Biot parameters of the foam were determined by a combination of direct measurement (for density, flow resistivity and Young's modulus) and inverse characterization procedures (for porosity, tortuosity, viscous and thermal characteristic length, Poisson's ratio, and loss factor). The inverse characterization procedure involved matching normal incidence standing wave tube measurements of absorption coefficient and transmission loss of the isolated foam with finite element predictions. When the foam parameters determined in this way were used to predict the performance of the complete double panel system, reasonable agreement between the measured transmission loss and predictions made using commercial statistical energy analysis codes was obtained.

9:45

3aNCb3. Analysis of sound transmission through periodic structures typical for aircraft fuselages. Vincent Cotoni (ESI Group, 12555 High Bluff Dr., San Diego, CA 92130, vincent.cotoni@esi-group.com)

A novel numerical method is applied to calculate radiation properties and sound transmission loss of periodic structures typical for aircraft structures. The concept rests on that an accurate statistical energy analysis representation of the structure is determined from a small finite element (FE) model consisting of one or a few cells of the periodic structure. The FE model can be kept small and computationally efficient and can for this reason be used for parametric studies of the effect of design changes. Four different structures are analysed: a flat and a curved rib-stiffened panels typical of an aircraft fuselage, and an aluminium honeycomb inner floor panel. Calculated transmission loss results are found to compare well to measured data. Also mechanical power inputs due to point force excitations as well as radiation efficiencies are calculated and compared to measured data.

10:00

3aNCb4. Vibroacoustic characterization of a commercial airliner bulkhead. Albert Allen and Mark Moeller (Spirit AeroSystems, P.O. Box 780008, MC K95-79, Wichita, KS 67278, albert.allen@spiritaero.com)

The commercial airliner bulkhead design candidate of concern is an internal divider wall consisting of an aluminum forward panel and liner aft panel sandwiching an array of closely spaced interstitial aluminum I-beams. The main purpose of the bulkhead, which separates the cargo bay from the occupied area, is to protect the crew from being compromised by cargo during a hard landing. Occupied area noise requirements also affect the bulkhead design as it is a primary path of noise transmission from the cargo bay. Vibroacoustic performance of the bulkhead analyzed with statistical energy analysis is supported by coupon testing of a representative bulkhead test section. Fibrous acoustic treatments were also evaluated experimentally for noise reduction potential. The experimental methods, results, and component level modeling complement each other by demonstrating a vibroacoustically appropriate bulkhead design and good bulkhead modeling practices.

10:15—10:30 Break

10:30

3aNCb5. A semi-analytical method to predict the vibroacoustics response of composite and isotropic stiffened panels. Abderrazak mejdi and Noureddine Atalla (Dpartement de Gnie mécanique, Univ. of Sherbrooke, 2500 Boul. de l'Universit Sherbrooke, PQ J1K 2R1, Canada, abderrazak.mejdi@usherbrooke.ca)

The vibroacoustics behavior of aircraft-type stiffened panels is classically analyzed using deterministic methods such as the finite element and boundary element method at low frequencies or energy based methods at higher frequencies. In the present work, a general semi-analytical method based on modal expansion technique is developed to predict the vibration and acoustics radiation of both metallic and composite flat stiffened panels. Both unidirectional and bidirectional stiffened panels with eccentric stiffeners and various shapes are analyzed using the same matrix formulation. The presented model is also able to predict the response of both regular and irregular stiffened panels. The contributions of the force and moment modal coupling at each beam location are accounted for together with the effect of interaction between ribs in the case of orthogonal stiffened plate. The response to various types of excitations (point force, diffuse acoustic field, and turbulent boundary layer) are presented in terms of their joint acceptance. The model is numerically validated by comparison with the FEM/BEM and hybrid FEM/SEA methods for various configurations and excitations. Excellent agreement is found.

10:45

3aNCb6. Quiet honeycomb panel. Dan Palumbo and Jake Klos (NASA Langley Res. Ctr., MS 463, Hampton, VA 23681, d.l.palumbo@nasa.gov)

Sandwich honeycomb composite panels are lightweight and strong and, therefore, provide a reasonable alternative to the aluminum ring frame /stringer architecture currently used for most aircraft airframes. The drawback to honeycomb panels is that they radiate noise into the aircraft cabin very efficiently provoking the need for additional sound treatment which adds weight and reduces the material's cost advantage. A series of honeycomb panels incorporating different strategies aimed at reducing the honeycomb panels' radiation efficiency while at the same time maintaining its strength. The majority of the designs were centered around the concept of creating areas of reduced stiffness in the panel by adding voids and recesses to the core. The effort culminated with a reinforced/recessed panel which had 6 dB higher transmission loss than the baseline solid core panel while maintaining comparable strength. Attempts were made to damp the panels' vibration energy by the addition of lightweight particles to the honeycomb cells. These designs were very difficult to build given the particles' tendency to pollute the bond interface between the honeycomb and the face sheet. Well constructed panels exhibited very little benefit from the treatment that could not be attributed to the added mass alone.

11:00

3aNCb7. Prediction of the cabin noise of business jet using statistical energy analysis. Washington de Lima and Apoorv Ravindran (Cessna Aircraft Co., One Cessna Bldv., M.S. C3-353, Wichita, KS 67215-1424, washdelima@hotmail.com)

The application of deterministic method (FEM and BEM) to predict vibroacoustic response of complex system like an aircraft fuselage is limited to low frequency due to large size of computational model for high frequency and the high frequencies modes are very sensitive to variation in the system properties which introduces substantial uncertainty. Energy based method such as energy statistical analysis (SEA) is an alternative that avoid these difficulties. This paper presents the vibroacoustic response of business jet using SEA. The SEA model is validated using in-flight tests with the aircraft in various acoustic package configurations.

11:15

3aNCb8. Modeling freighter aircraft interior number. Mark Moeller and Albert Allen (Spirit AeroSystems Inc., Mark J. Moeller Spirit AeroSystems, Inc., M.S. K95-79, P.O. Box 780008, Wichita, KS 67278, mark.j.moeller @spiritaero.com)

A freighter version of a commercial passenger airplane platform was developed. The new architecture includes an occupied space immediately aft of the flight deck and forward of the cargo space. A bulkhead separating the occupied space from the cargo space is designed to protect people from being compromised by cargo during a hard landing. Occupied space noise requirements affect the bulkhead design as it is a primary path of noise transmission from the cargo bay. Statistical energy analysis (SEA) noise models were developed to evaluate the noise performance of the bulkhead. Models were developed for ground test, flight test, and component configurations, respectively. The component model is described in a companion paper. A fourth, requirements model, was developed to demonstrate bulkhead noise compliance. The model development and correlation efforts are detailed in this document. SEA model results are shown to correlate reasonably well with the test data.

11:30

3aNCb9. Impact of damping uncertainty on sea model response variance. Noah Schiller, Randolph Cabell (NASA Langley Res. Ctr., M.S. 463, Hampton, VA 23681, noah.h.schiller@nasa.gov), and Ferdinand Grosveld (Lockheed Martin Exploration and Sci.)

Statistical energy analysis is commonly used to predict high-frequency vibroacoustic levels. This statistical approach provides the mean response over an ensemble of random subsystems that share the same gross system properties such as density, size, and damping. Recently techniques have been developed to predict the ensemble variance as well as the mean response. However these techniques do not account for uncertainty in the system properties. In the present paper uncertainty in the damping loss factor is propagated through the analysis to obtain more realistic prediction bounds that account for both ensemble and damping variance. The analysis is performed on a stiffened composite cylinder representative of an aircraft fuselage. Realistic bounds on the damping loss factor estimates are determined using measurements acquired on the stiffened composite cylinder in the lab. The analysis demonstrates that uncertainty in system properties, such as damping, should be considered when computing the variance of the response.

11:45

3aNCb10. Hybrid characterization of engine isolator and its application to cabin noise studies. Marshall Downing (Lord Corp., 2000 W Grandview Blvd., Erie, PA 16509, mark_downing@lord.com)

Aircraft companies typically build a global acoustic model of the aircraft, engines, and engine attachments, which would allow for prediction of cabin noise related to engine operating conditions up to 500 Hz. The objective of the hybrid characterization method is to provide a matrix of stiffness (or mobility) for an isolator over a broad frequency range which is suited for use in the global model. The method is called "hybrid" because it aims at aligning viscoelastic material test data, isolator shaker testing, and a detailed finite element model. The result is a six degrees of freedom matrix of translational, rotational, and cross coupling terms for the engine attachment. This paper covers a case study showing how this method was used for the engine attachments on a business jet aircraft.

9:15

3aNCc1. From development to evaluating effectiveness in industry: Building a research model for noise control technology efforts. Dana Reinke and Adam Smith (NIOSH, 626 Cochrans Mill Rd., P.O. Box 18070, Pittsburgh, PA 15236, dreinke@cdc.gov)

The NIOSH mining hearing loss research program recognizes the importance of not only developing effective noise controls but also evaluating the technology transfer and industry usage of control technologies. As a way to focus on the direct impact of NIOSH-developed control technologies on reducing noise induced hearing loss, we have developed a structured research model with metrics that help to more accurately evaluate and measure the effectiveness of noise control technologies. Through the development of a process model, we are creating a more structured process to analyze the effectiveness of noise control products through development, refinement, promotion, and long term evaluation stages. With metrics identified at each stage, the model creates a more transparent and consistent process to evaluate control technologies. This presentation describes the architecture of the process model and its associated metrics to reduce occupational noise-induced hearing loss in the mining industry. Proven control technologies for roof bolter and continuous mining machinery will serve as examples of where current research gaps occur and how they are being addressed with this new model. This research structure for noise control development, dissemination, and evaluation of control technology effectiveness can serve as a model for noise control researchers and academics.

9:30

3aNCc2. Acoustic assessment of pneumatic and electric jackleg drills used in the mining industry. Hugo Camargo, J. Shawn Peterson, and Peter Kovalchik (NIOSH, 626 Cochrans Mill Rd., P.O. Box 18070, Pittsburgh, PA 15236, hcamargo@cdc.gov)

Hearing loss is the most prevalent disease among miners. A study of U.S. western hard-rock mines revealed that 96% of machine operators were overexposed to noise, with jackleg drill operators having the most rapid noise dose accumulation. Traditionally, jackleg drills have been driven by pneumatic power. However, there are currently available rotary hammer drills powered by electricity. This paper presents an acoustic assessment of pneumatic and electric jackleg drills that involved noise source identification (NSID), penetration rate and operator's cumulative noise dose measurements, and determination of sound power levels. NSID using microphone phased array technology revealed two dominant noise sources for the electric drill, one located at the drill and one located at the drill steel-rock interaction place. In contrast, NSID for the pneumatic drill showed only one dominant noise source located at the drill. Penetration rate and noise dose measurements were combined to estimate the accumulated dose and time required to drill a reference depth hole. Sound power level measurements

yielded overall 115 and 125 dB(A) for the electric and pneumatic drills, respectively. The results show that the acoustic performance of the electric drill, despite its slower penetration rates, overcomes the benefits of traditional pneumatic drills.

9:45

3aNCc3. A control suite to reduce roof bolting machine drilling noise. M. Jenae Lowe, J. Shawn Peterson, Lynn Alcorn, and David Yantek (Natl. Inst. for Occupational Safety and Health, 626 Cochrans Mill Rd., P.O. Box 18070, Pittsburgh, PA 15236, jli7@cdc.gov)

Among underground coal miners, hearing loss remains one of the most common occupational illnesses. In response, the National Institute for Occupational Safety and Health (NIOSH) conducts research to reduce the noise emission of various underground coal mining equipment, an example of which is a roof bolting machine. Field studies support the premise that, on average, drilling noise is the loudest noise that a roof bolting machine operator would be exposed to and contributes significantly to the operators' noise exposure. NIOSH has determined that the drill steel radiates a significant amount of noise during drilling. NIOSH in collaboration with Corry Rubber Corporation has developed a suite of controls to reduce drilling noise which consists of a bit isolator, chuck isolator, and a Collabsible Drill Steel Enclosure. This control suite effectively reduces the noise radiated by the drill steel. Laboratory testing confirms that the control suite reduces sound pressure levels generated during drilling by 13 dB(A) at the operator's location. As a result of this reduction in drilling noise, the noise exposure of the roof bolting machine operator is reduced.

10:00

3aNCc4. The development of a damped drill steel to reduce roof bolting machine drilling noise. J. Shawn Peterson, Hugo Camargo (Natl. Inst. for Occupational Safety and Health, P.O. Box 18070, Cochrans Mill Rd. Pittsburgh, PA 15236, JPeterson@cdc.gov), and Greg Goetchius (Mater. Sci. Corp.)

Among underground coal miners, hearing loss remains one of the most common occupational illnesses. In response, the National Institute for Occupational Safety and Health (NIOSH) conducts research to reduce the noise emission of various underground coal mining equipment, an example of which is a roof bolting machine. Field studies support the premise that, on average, drilling noise is the loudest noise that a roof bolting machine operator would be exposed to and contributes significantly to the operators' noise exposure. NIOSH has determined that the drill steel radiates a significant amount of noise during drilling. NIOSH has conducted research to evaluate a damped drill steel to reduce noise radiation. With this reduction in drilling noise, the noise exposure of the roof bolting machine operator is reduced. This paper documents the research to date of this damped drill steel. Laboratory testing confirms that the concept of a damped drilll steel reduces sound levels generated during drilling, and by extension, operator noise dose exposure.

10:15—10:30 Break

10:30

3aNCc5. Drill rod Coulomb friction damper. Anne Guthrie and Henry Scarton (Dept. of Mech., Aerosp. and Nuclear Eng., Rensselaer Polytechnic Inst., Troy, NY 12180-3590, scarton@rpi.edu)

The acoustical performance of a case-hardened Coulomb friction damper consisting of a case-hardened roll-threaded collar resting against a reverse taper segment of drill rod is discussed. Because of the axial impact, many transverse bending modes of vibration are excited in long prismatic drill rod, along with longitudinal and torsional resonances. The self-tightening nature of the collar that is caused to simultaneously move axially due to its inertia and rotate on the rolled thread and consequently press on the case-hardened tapered surface of the drill rod induces interfacial frictional rubbing which is conclusively shown to be present resulting in 30 dB of attenuation of the modes of vibration. These observations are experimentally shown and theoretically verified.

10:45

3aNCc6. Evaluation of stiffeners for reducing noise from horizontal vibrating screens. David Yantek (CDC-NIOSH-PRL, 626 Cochran Mill Rd., Pittsburgh, PA 15236, dyantek@cdc.gov) and Shawn Catlin (Mallett Technol., Inc.)

Sound levels around vibrating screens in coal preparation plants often exceed 90 dB(A). The National Institute for Occupational Safety and Health (NIOSH) is developing noise controls to reduce noise generated by horizontal vibrating screens. NIOSH determined the vibration mechanism housings and the screen body to be the dominant noise sources on a horizontal vibrating screen. Researchers used beamforming, experimental modal analysis, and operating deflection shape analysis to examine noise radiated by the screen body. Based on these results, finite element analysis and a NIOSH-written program were used to estimate the sound power level reduction resulting from adding rib stiffeners to key locations on the screen sides. Rib stiffeners made from two sizes of steel channel and two different cross-sections, C and T, were evaluated. In addition, the effects of orienting the stiffeners horizontally and vertically were examined. Finally, the stiffeners were evaluated with the ends welded to the existing ribs on the screen sides and with the ends free. The results indicate that for a broadband input, the smaller T cross-section oriented vertically with the ends welded to the existing ribs was the best option. This configuration reduced the predicted *A*-weighted sound power level by 7 dB.

11:00

3aNCc7. An investigation of the noise dynamics in a southern illinois underground coal mine. Marek Szary, Yoginder Chugh, William Bell (Carbondale College of Eng., Southern Illinois Univ., 1230 Lincoln Dr., Carbondale, IL 62901-6603, szary@engr.siu.edu), and Joseph Hirschi (Illinois Clean Coal Inst.)

Noise in an underground coal mine has dominant components generated mainly from three sources: (1) continuous mining machine (CMM), (2) roof bolters, and (3) cars/vehicles which are transporting personnel end/or coal. Each of these three noise sources also has a number of well defined subsources with their own noise characteristics. The CMM noise is comprised mainly of noise generated by coal cutting drum, wet scrubber for dust control, and coal transport conveyor (called also the CMM's tail). Roof bolter's noise is generated during the drilling of the roof bolt holes in the bolting process. Personnel and coal transportation vehicles generate noise from the power driven system. The personnel most exposed to these noises are operators of these machines and associated support personnel. Three selected techniques with appropriate instrumentation were used to monitor exposure of the personnel to the noise and noise energy over a period of time. The most common technique is based on the use of personal noise dosimeters. The sound level meters (both pressure and power) were also used to collect noise data in form of instantaneous readings and also to check calibration of other sound measuring instruments. Most useful information was obtained from continuous recordings of the noise over time. This paper discusses the variability or dynamics of the generated noise in both frequency and time domains

11:15

3aNCc8. Evaluation of noise exposures of miners operating highwall mining equipment. Link Bowers (U.S. Dept. of Labor, Mine Safety and Health Administration, P.O. Box 18233, Cochrans Mill Rd., Bldg. 038, Pittsburgh, PA 15236, bowers.link@dol.gov)

Modern highwall mining systems are starting to replace surface coal augers in some highwall mining operations because of their ability to increase coal production and recovery rates. Another benefit of using highwall mining systems instead of surface coal augers is the reduction in noise exposures to the affected miners extracting the coal from the highwall. Several surface coal augers and highwall mining systems were evaluated for full shift noise exposures of the machine operator and helpers during this investigation. Engineering noise controls were also evaluated for each piece of highwall mining equipment. The operator and helper working on a modern highwall mining system were exposed to average sound pressure levels

of 61.5 and 89.0 dBA, respectively, while the operator and helper working on a surface coal auger were exposed to higher average sound pressure levels of 95.4 and 94.0 dBA, respectively.

11:30

3aNCc9. Wave propagation characteristics in mud-filled drilling pipe. Abhay Patil and Yong-Joe Kim (Dept. of Mech. Eng., Texas A&M Univ., College Station, TX 77843, abhyapatil@neo.tamu.edu)

The objective of this study is to analytically and experimentally analyze the wave propagation characteristics of a mud-filled drilling pipe in terms of wave speed and spatial decay rate. Here, the pipe is modeled as an elastic hollow pipe and the inside mud as a fluid. A wave equation of the mud is then derived based on the assumption of one-dimensional plane wave propagation that is valid in low frequencies. This wave equation is coupled with the equation of motion of the elastic pipe. For the purpose of validating the analytical wave solutions of the wave equation, an experiment is performed with a mud-filled pipe. The pipe is driven by a piston at one end and the resulting dynamic responses are then measured with an array of strain gauges installed on the external surface of the pipe along the axial direction at the other end. A wave decomposition procedure is applied to the measured data to separate direct and reflective waves. The direct waves are then used to calculate their phase speeds and spatial decay rates. It is shown that the experimentally measured wave propagation characteristics are successfully used to validate and improve the analytical model.

Contributed Papers

9:15

3aNCd1. Deep dynamic compaction vibrations impacts on neighboring structures. Amir Yazdanniyaz and Sen Bui (Acoust. Eng. Services, Inc., 22801 Crespi St., Woodland Hills, CA 91364, amir.yazdanniyaz @aesacoustics.com)

This paper describes results from vibration study conducted for a construction of proposed building structures on a covered landfill site. Construction site is surrounded by various land uses, including mobile homes, single dwelling units, and infrastructures. Deep dynamic compaction (DDC) method is utilized to provide soil compactions necessary for the construction of the buildings and parking lot foundations. Concern with the potential structural damage and the human perceptions of the ground vibration exist because of close proximity of the existing structures (i.e., mobile homes, single homes, roadways, and bridges) to the compaction area. DDC induced ground-vibrations level were modeled using actual vibration measurements "pilot tests" and the site's soil dynamic characteristics. Vibration mitigation plan were developed to minimize the impacts.

9:30

3aNCd2. Vibration impact of 150 MW cogeneration power plant on a semiconductor fabrication facility. Ahmad Bayat and Jon Byron Davis (490 Post St., Ste. 1427, San Francisco, CA 94102, abayat@vaconsult.com)

A 150 MW cogeneration power plant construction was planned next to an extremely vibration-sensitive semiconductor fabrication facility in Taiwan. Both facilities were under construction simultaneously. We were asked to evaluate the impact of the power plant vibration sources on the semiconductor facility and determine that they can coexist at only about 30 m separation distance. Some of the power plant sources included large rotating equipment such as 7000-HP heat extraction blowers, turbines, and pumps. Dynamic forcing functions were extracted from a similar plant. *In situ* transfer function mobilities were obtained using seismic load drop equipment. Predictions were made which were in-line with the as-built results with the exception of two blowers. Their foundation design had to be retrofitted with deep pile foundations to transfer their vibration to deeper stiffer soil.

9:45

3aNCd3. Techniques for measuring the propagation speed of vibration waves in the ground. Anthony Nash (Charles M. Salter Assoc., 130 Sutter St., Ste. 500, San Francisco, CA 94104, anthony.nash@cmsalter.com)

Characterizing the transmission of ground vibration is important for assessing impacts upon buildings located adjacent to a rail right-of-way. This type ground-borne vibration transmission is typically dominated by surface or "Rayleigh" waves. When predicting the impacts, it is helpful to understand the attenuation of vibration from one location to another along the surface of the ground. In many cases, measuring the time-averaged rms vibration at spaced locations away from a line source is sufficient if one wishes only to quantify the reduction in ground borne energy density. For other purposes, however, it is essential to know the speed (and length) of the propagating wave front. This paper discusses successful (and not so successful) techniques for measuring the propagation speed of Rayleigh waves in the ground using both steady state and transient "point" sources. In terms of meaningful data, the steady state vibration method was found to be inferior to the transient vibration method. The steady state technique generated contradictory information on phase and amplitude at the spaced measurement locations. In contrast, the transient technique always indicated that (1) the Rayleigh wave propagated outward from the source and (2) the vibration amplitudes decreased between the near and far measurement locations.

10:00

3aNCd4. Modeling ground response functions in rock: A comparison of multiple methods. Gary Glickman and Richard Carman (Wilson, Ihrig & Assoc., 65 Broadway, Ste. 401, New York, NY 10006, gglickman@wiai .com)

Rail transit operations often produce groundborne vibration with energy that extends into the audible frequency range. It is often necessary to predict potential ground/structure-borne vibration and noise transmission in the design of new buildings in close proximity to existing rail lines or for new rail facilities/alignments. In a detailed analysis, key factors include source vibration characteristics (spectral force input to soil and/or track structure), ground vibration propagation characteristics (spreading and material damping losses), building foundation type (soil/structure interaction and coupling losses), and structural design of upper floors (floor and wall resonances and attenuation through the building). This paper focuses on methods for obtain-

ing vibration propagation characteristics in rock which is an efficient transmitter of vibration at audible frequencies. Three methods for obtaining one-third octave band response functions are compared: empirical methods, finite element analysis, and seismic modeling.

10:15—10:30 Break

10:30

3aNCd5. Observed frequency and depth effects on attenuation of ambient ground vibration. Hal Amick and Michael Gendreau (Colin Gordon & Assoc., 150 North Hill Dr., Ste. 15, Brisbane, CA 94005, hal.amick@colingordon.com)

This article presents observed relationships between depth and frequency with regard to ambient ground vibration. Typically, site vibration studies are conducted on undeveloped locations (grass fields, parking lots, etc.) to assess the ambient vibration conditions for a potential building site. However, the vibration-sensitive equipment of concern is frequently placed below grade, such that the final ambient vibration conditions it experiences might be quite different from that shown in the field survey. An earlier study [NoiseCon (2007)] presented data illustrating how several factors—including building foundation stiffness, ground stiffness, and building geometry—all have an effect on the propagation from "ambient" vibration sources. This presentation extends that work, specifically examining the relationship between depth, frequency, and extent of attenuation associated with below-grade spaces.

10:45

3aNCd6. Variation in measured force density levels of light rail vehicles. Shankar Rajaram and Hugh Saurenman (ATS Consulting, 801 S. Grand Ave, Ste. 575, Los Angeles, CA 90017, srajaram@atsconsulting.com)

The procedure recommended by the Federal Transit Administration for detailed predictions of ground-borne vibration is based on measurements at an existing rail system and measurements at the target site. A force density level (FDL) is derived from train vibration and line source transfer mobility (LSTM) measurements at the existing system. This FDL is then combined with the LSTM measured at the target site to develop predictions. This empirical procedure usually provides more reliable predictions than computer modeling procedures. FDL is assumed to characterize the trains and track support system and LSTM is assumed to characterize the effects of local geology. Implicit assumptions when applying this procedure are that FDL is independent of the local geology and that the vehicle and track support system will be the same at the target site as they are at the vehicle test site. This paper considers the differences in FDLs measured at light rail systems in Los Angeles, Minneapolis, Phoenix, and Portland. Issues discussed are how to adjust for train speed, why the speed adjustments are system specific, causes for FDL variations when the vehicles and track support systems are nominally the same, and procedures for obtaining consistent FDL measurements.

11:00

3aNCd7. Analysis and design of new floating slab track for special trackwork using finite element analysis. James Phillips (Wilson, Ihrig & Assoc., Inc., 5776 Broadway, Oakland, CA 94618, jphillips@wiai.com)

This paper discusses the development of a new vibration isolation system for tunnel crossovers in a future rail line extension. The previous design included ballasted track on top of continuous concrete slabs on rubber vibration isolators. The goal of the new design was to replace the ballast and tie track with rails fastened directly to discrete slabs similar to the vibration isolation system utilized on running portions of track within existing tunnels. Finite element analysis (FEA) was used to evaluate the dynamic interaction between the vehicle, rails, resilient rail fasteners and the vibration isolation system. The results of the analyses guided the design in determining the size and thickness of the inertia slabs, the stiffness and design of the rubber vibration isolation pads, and the rail fastener selection.

Chair's Introduction—8:05

Invited Papers

8:10

3aNSa1. Hearing loss mitigation through applied acoustics. Kurt Yankaskas (Office of Naval Res. (Code 342), 875 North Randolph St., Arlington, VA 22203-1995, kurt.d.yankaskas@navy.mil)

Hearing loss in the Navy and Marine Corps has been accelerating for decades, reducing combat effectiveness and creating hazardous conditions. This paper will discuss applied acoustics in current and future programs and its related challenges. Source noise reduction limits the amount of energy transmitted to the structure or into the environment. Acoustic modeling, insulation/isolation, and personal hearing protection are vital tools in this process, but often adding weight and complexity. Source noise solutions such as isotropic superfinishing treatment of gears increases transmitted power and reduces fuel consumption and lubricant temperatures while increasing gear life and maintenance intervals. Great strides are also currently being made in the arena of personal hearing protection to reduce hearing loss rates in environments where reducing source noise is not a viable option, such as the aircraft carrier flight deck. Technological advances in insulation and isolation and possible operational changes will also be discussed, adding to the tools required to approach this issue from an integrated systems approach. In conclusion, a systems integration approach to incorporating noise reduction into the design of vessels, vehicles, and platforms from the start of the design process will reduce life cycle costs, benefiting the Navy and Marine Corps.

8:30

3aNSa2. Navy aircraft carrier near-field jet noise and flight deck crew hearing protection. James A. Janousek (Naval Air Systems Command, 48110 Shaw Rd., Bldg. 2187, Patuxent River, MD 20670, james.janousek@navy.mil), Valerie S. Bjorn (Naval Air Systems Command, Arnold AFB, TN 37389-6000), Richard L. McKinley (Air Force Res. Lab., 2610 Seventh St., Wright-Patterson AFB, OH 45433-7901), and James K. Wilt (Naval Air Systems Command, Patuxent River, MD 20670)

Military jet operations on board US Navy aircraft carriers produce excessive acoustical noise fields in which personnel work. For those working in these noise environments, hearing impairment generally starts and worsens as they continue to perform countless high-stakes jet aircraft launch and recovery missions. Several noise measuring surveys were completed to characterize near-field jet noise on US Navy flight decks. These data set the foundation for numerous efforts to improve personal hearing protection and reduce jet engine noise.

8:50

3aNSa3. Near-field noise of high-performance military aircraft and required hearing protection. Richard L. McKinley (Air Force Res. Lab., 2610 Seventh St., Wright-Paterson Air Force Base, OH 45433-7901, richard.mckinley@wpafb.af.mil)

The near-field acoustic environment of a high-performance military jet aircraft is very complex and intense. The overall sound pressure levels at high-engine power settings can exceed 170 dB very near the aircraft and can be in the 130–150 dB range at personnel locations. This paper describes the measured near-field noise environments from several Air Force and Navy high performance aircraft such as the F-14, F-15, F-16, F-18, and F-35. This paper will also describe a technique of calculating the hearing protection requirements in octave bands using a baseline exposure criterion and noise dose.

9:10

3aNSa4. Characterization of near- and far-field nonlinearity in high-performance military jet aircraft noise. Tracianne B. Neilsen, Kent L. Gee (Dept. of Phys. and Astronomy, Brigham Young Univ., N283 ESC, Provo, UT 84602, tbn@byu.edu), J. Micah Downing, and Michael M. James (Blue Ridge Res. and Consulting, Asheville, NC 28801)

This study addresses the characterization of nonlinearity in military jet aircraft noise data in both the near and far fields. Previous work [Gee *et al.*, J. Acoust. Soc. Am. **123**, 4082–4093 (2008)] showed using a generalized Burgers equation-based model that nonlinear propagation effects were significant in far-field, ground run-up data from the F-22 Raptor for different engine powers and propagation angles. In this investigation, those findings are further vetted using data collected from the F-35 Joint Strike Fighter over greater propagation ranges and angles. The nonlinear nature of the near fields of the F-22 and F-35 jet noise is characterized through the calculation of maps of the waveform and waveform time derivative skewness as well as the crest factor. These results provide insights regarding short-range shock formation and the apparent origin of the nonlinearity-producing region of the plume. [Work supported by the Air Force Research Laboratory.]

9:30

3aNSa5. Weapon noise exposure of the soldier and its measurement. Karl Buck and Pascal Hamery (ISL Group APC, 5 r. du Gal. Cassagnou, 68301 Saint-Louis, France, karl.buck@isl.eu)

On the battlefield a soldier is continuously exposed to various types of noise. Much of this exposure is noise generated by his own weapon or by weapons of close by troops. The exposure levels are between 160-dB peak for small arms and 190-dB peak at the soldier's ear for some antitank weapons, with A-durations from 0.3 ms (small caliber) to 4 ms for large caliber weapons (e.g., Howitzers). As these parameters feed into the damage risk criteria which are in use by the armed forces of different countries, it is important that the recorded pressure time histories are as precise as possible. The paper will present the acoustic levels to which a soldier may be exposed by different types of weapon and under different circumstances. It also will present measurement techniques to use for reliable results.

9:50

3aNSa6. Measurement and characterization of army impulsive noise sources. Joel T. Kalb (U.S. Army Res. Lab., Aberdeen Proving Ground, MD 21005-5425, joel.kalb@us.army.mil)

Peak pressure levels in army noise environments range from 140- to 195-dB near soldiers firing energetic weapons and are all dangerous to unprotected ears. Blast reverberation in confined spaces and steady noise in armored vehicles is also hazardous, so complete assessment requires the widest possible measurement range. To accurately measure pressures in the free-field or under hearing protectors, microphone considerations include type, location, orientation, mounting, shape, and shielding from flash or mechanical shock. Blast-waves rise instantaneously and return to free-field ambient within 0.3–15 ms, while in enclosures this can increase to 100 ms, requiring wide bandwidth signal processing. In addition to hazard, acoustic detection and annoyance at greater distances from weapons involve propagation effects in the atmosphere and at the ground which alter the wave-shape.

10:10—10:25 Break

10:25

3aNSa7. Unique challenges for hearing protection in military noise environments. Douglas S. Brungart, Mary T. Cord, and Kim L. Block (Army Audiol. and Speech Ctr., Walter Reed Army Medical Ctr., 6900 Georgia Ave NW, Washington, DC, 20307, douglas.brungart@us.army.mil)

Military noise environments, and, in particular, the noise environments faced by dismounted soldiers on the battlefield, are characterized by wide variations in ambient level. Situations can quickly and unexpectedly change from quiet conditions where the sound of a snapping twig might alert the listener to hostile enemy activity to extreme noise conditions where firefights, explosions, or loud machinery create levels of noise that can cause hearing loss in a matter of minutes or seconds. This poses a unique challenge for the designers of military hearing protection, who must produce systems that provide enough comfort and acoustic transparency to convince users to consistently wear them in quiet conditions to ensure that they will be in place if an unexpected blast or other potentially damaging noise exposure occurs. In this talk, we discuss some of the issues that can influence the willingness of listeners to wear hearing protection for extended periods in quiet environments, including acoustic factors that have been shown to influence situational awareness while wearing hearing protection. Additionally, lessons on the factors impacting the comfort of hearing devices drawn from studies of how consistently hearing aids are worn by hearing impaired listeners will be discussed.

10:45

3aNSa8. Improved system for detection, localization, and classification of military impulse noise. Jeffrey Allanach, Justin Borodinsky (Appl. Physical Sci. Corp., 475 Bridge St., Ste. 100, Groton, CT 06340, jallanach@aphysci.com), Jeffrey Vipperman, and Matthew Rhudy (Univ. of Pittsburgh, Pittsburgh, PA 15261)

Impulse noise monitoring systems are needed for quantifying the magnitude and time of impulsive noise events to ensure compliance and to provide an archival record of noise emanating from military installations. Currently, there are several commercial systems; however, they report an overwhelming number of false events generated by windborne noise and distant non-military acoustic events. This can bias noise statistics to the point where a meaningful assessment of the acoustic sound levels from a site is not possible. APS, in collaboration with the University of Pittsburgh, have developed an improved noise monitoring system for mitigating windborne and other sources of non-military noise. This system includes a collection of remote sensors capable of detection, localization, and classification. Each sensor uses an acoustic array and real-time signal processing codes to estimate the noise source location. Mitigation of windborne events is accomplished using cross-channel correlation analysis, beamforming, and classification. A prototype of this system is installed at the Marine Corps Base Camp Lejeune where it has been automatically reporting and archiving detected impulse noise. In this paper, we will present the specialized array processing algorithms, system design, and its performance as determined by months of detection statistics accumulated in the field.

11:00

3aNSa9. Aircraft jet source noise measurements of a Lockheed Martin F-22 fighter jet using a prototype near-field acoustical holography measurement system. Michael M. James (Blue Ridge Res. and Consulting, 13 1/2 W. Walnut St., Asheville, NC 28801, michael.james@blueridgeres.com), Kent L. Gee, Alan T. Wall (Brigham Young Univ., Provo, UT 84602), J. Micah Downing, Kevin A. Bradley (Blue Ridge Res. and Consulting, Asheville, NC 28801), and Sally Anne McInerny (Univ. of Alabama at Birmingham, Birmingham, AL 35205)

Military jet aircraft generate high levels of noise which require innovative measurement and analysis methods to characterize the jet noise. A near-field acoustic holography (NAH) system is being developed to provide model refinement and benchmarking, evaluate performance of noise control devices, and predict ground maintenance personnel and community noise exposure. A prototype NAH system was used to perform jet source noise measurements of an F-22 at Holloman AFB, NM. This NAH system utilizes a patch and scan measurement approach using a 90 channel microphone array and over 50 reference microphones. The microphone array was used to make pressure measurements on a planar surface extending from the jet nozzle to 75 ft along the plume and over 6 ft in height. These measurements were made parallel either to the shear layer or to the nozzle center line of the jet plume at three different offset distances. Measurements were made every 6 in. on the surface which results in over 1800 measurements per offset distance. The ground based fixed reference microphones were located parallel to the nozzle center line. The measurement approach and pressure mea-

surements for four power conditions detailing the source size, frequency content, and ground effect will be detailed. [Work supported by AFRL SBIR.]

11:15

3aNSa10. Application of near-field acoustical holography to high-performance jet aircraft noise. Alan T. Wall (371 E 720 S, Orem, UT 84058), Kent L. Gee (Brigham Young Univ., Provo, UT 84602), Michael M. James (Blue Ridge Res. and Consulting, Asheville, NC 28801), and Michael D. Gardner (Graduate Program in Acoust., Penn State Univ., State College, PA 16802)

Near-field acoustical holography (NAH) measurements were made to visualize the sound field in the jet exhaust region of an F-22 Raptor. This is one of the largest-scale applications of NAH since its development in the 1980s. A scan-based holographic measurement was made using a 90-microphone array with 15-cm regular grid spacing for four engine power settings. The array was scanned through 93 measurement positions along three different measurement planes in a region near 7 m from the jet centerline and 23 m downstream. In addition, 50 fixed reference microphones were placed along the ground 11.6 m from the jet centerline, spanning 30.8 m. The reference microphones have been used to perform virtual coherence on the measurement planes. Statistically optimized NAH has been used to backpropagate the sound field to the source region for low frequencies and to identify jet noise characteristics. Ground reflection interference and other non-ideal measurement conditions must be dealt with. Details relating to jet coherence-lengths and their relation to reference microphone requirements will be discussed. Preliminary results of this ongoing work will be presented. [Work supported by Air Force SBIR.]

11:30

3aNSa11. Experiments on the directivity of sound emission from firearms. Morten Huseby and Haakon Fykse (Norwegian Defence Res. Establishment, Pb. 25, 2027 Kjeller, Norway)

Personnel firing weapons will be exposed to noise created by the expanding gunpowder gas escaping from the muzzle. The noise from a rifle is directive, up to 20 dB louder in the shooting direction than behind the weapon. Usually personnel firing a weapon is taking advantage of the lower noise level behind the weapon. However, today firearms will be used by soldiers in complex scenarios where the head of one soldier might be directly to the side or even slightly in front of the muzzle of another soldier's weapon. Most countries training regulations have not been updated to include all effects of the directivity of firearms in complex scenarios. Unexpected results were obtained from previous measurements on weapons with flash suppressors attached to the end of the barrel. The noise may be considerably larger in front of the weapon with flash suppressor fitted. The angular resolution of previous experimental data was not high enough to provide an explanation. This motivated us to design an experimental setup where the pressure wave from the weapon is measured, at 80 cm from the muzzle, in 180 directions relative to the firing direction. The measurements are done with and without a flash suppressor mounted.

11:45

3aNSa12. A hearing protector model for predicting impulsive noise hazard. Joel Kalb (Human Res. & Eng. Directorate, U.S.Army Res. Lab, Aberdeen Proving Ground, MD 21005-5425, jkalb@arl.army.mil)

Reduction in impulsive noise hearing hazard by earplugs and earmuffs is calculated with an electroacoustic lumped-parameter model of HPD attenuation using real ear attenuation at threshold (REAT) data. Energy flows into the occluded volume along three paths, each considered as a piston: (1) the rigid protector mass moving against the skin, (2) leakage at the support, and (3) transmission through the protector material (a second piston within the rigid piston). Circuit elements are adjusted so loss matches REAT data assuming path 1 is important at low, 2 at middle, and 3 at high REAT frequencies. Applying the model to 384 REAT data sets for ANSI S12.6 method B naive users gives statistical frequency distributions of occluded volume and leakage elements. For a given free-field impulsive noise, the model pressure predictions under the protector are compared to measurements on human and acoustical manikin ears to check validity of assumptions. The hearing hazards of the measured waveforms and the predicted waveforms are calculated with our previously developed auditory hazard analysis algorithm for humans ear model. The result is a cumulative frequency distribution of hazard based on user fit data useful in finding the best protector for a given impulsive noise.

Session 3aNSb

Noise, Architectural Acoustics, INCE, and ASA Committee on Standards: Standards in Psychoacoustics

Klaus Genuit, Chair
HEAD acoustics GmbH, Ebertstrasse 30a, Herzogenrath, 52134, Germany

Invited Papers

8:00

3aNSb1. Need for standardization of psychoacoustics. Klaus Genuit (HEAD Acoust. GmbH, Ebertstr. 30a, 52134 Herzogenrath, Germany, klaus.genuit@head-acoustics.de)

In the last decades, psychoacoustic parameters gained more and more importance in the context of sound perception and assessment in various applications. In particular, loudness was introduced as a better parameter than *A*-weighted level, because it shows a much better correspondence with the subjective impression of "volume" (loudness). This parameter was the object of standardization in the last years and few loudness standards were established (DIN 45631/A1, ISO 532, ANSI S3.4). The calculation of sharpness is also standardized (DIN 45692) and the standardization of roughness is recently under consideration by the DIN. These efforts have led to a global acceptance and a widespread use of psychoacoustic parameters in the automotive and IT-field. However, since the human signal processing is complex and the development of valid calculation models difficult, psychoacoustic phenomena must further be studied. Moreover, the validity, accuracy, and applicability of psychoacoustic parameters to specific noises must be determined. Especially, in the context of the description and classification of environmental noise, the potential of psychoacoustics has not been fully used so far. This paper will show the current status of standardization of psychoacoustics and will discuss the needs for the future.

8:20

3aNSb2. Comparative study of a proposed time varying loudness standard for common sounds. Colin Novak, Helen Ule (Dept. of Mech., Automotive and Mater. Eng., Univ. of Windsor, 401 Sunset Ave., Windsor, ON N9B 3P4, Canada, novak1@uwindsor.ca), and Tomasz Letowski (Army Res. Lab. Human Res. and Eng. Directorate)

Several calculation procedures exist and are standardized for the determination of loudness of steady sounds. While loudness models for unsteady sounds do presently exist, they differ in their outcomes and have not been yet sufficiently validated using round robin or other appropriate evaluation methodology. Recently, the Deutsches Institut fur Normung (DIN) announced that it will soon issue a new standard describing a method for calculation of loudness of time-varying sounds. However, the DIN 45631-A1 takes a less common approach in that it does not fully describe a methodology to calculate the unsteady loudness. It instead offers a more general procedure along with open-ended checks and balances for verifying the progress through the various calculation steps. The caveat of this is that while conditions specified by this standard may be satisfied, varying results may be achieved due to the procedures' open architecture. Conversely, the checks and balances may be enough such that identical results are achieved for the same sounds. This study investigates several commercial applications using this standard and compares their results for several common inputs. The results of the study will be discussed in terms of the extent to which compliance with DIN 45631-A1 results in identical loudness scores.

8:40

3aNSb3. An overview of issues concerning loudness measurement versus time. Wade R. Bray (HEAD Acoust., Inc., 6964 Kensington Rd., Brighton, MI 48116, wbray@headacoustics.com)

An overview of present methodologies for loudness measurement, especially considering time-varying sounds, is given. An ideal loudness-measuring method would mimic both the spectral and temporal acuities of human hearing including the relationship of those acuities at all audible frequencies. Due in part to practical considerations in their development history, none of the present set of loudness-measurement tools offers fully accurate representation of subjective time-frequency impressions. The most general limitations are insufficient spectral resolution and frequency-dependent time resolution. A recently standardized method well matches the temporal behavior of subjective loudness perception but only above a certain frequency due to lower-frequency time-resolution limits imposed by prior standards necessitating compliance. Examples will be shown of trade-offs and varying balances among several critical factors: time and frequency resolution at all audible frequencies, representation of temporal masking and growth/release effects, and appropriate spectral representations over varying combinations of broadband and narrowband signals.

9:00

3aNSb4. Loudness models applied to technical sounds. Roland Sottek (HEAD Acoust. GmbH, Ebertstr. 30a, 52134 Herzogenrath, Germany, roland.sottek@head-acoustics.de)

Loudness evaluation has become a central focus for assuring better consideration of subjective sound intensity phenomena than frequency-weighted levels such as dB(A). Different standards are available for evaluating loudness of stationary sounds (ANSI, ISO, and DIN). In principle, standards are very helpful in daily life, even if the method does not consider the most recent research results. But a variety of standards generating different results, at least for the most important technical or industrial sounds, may lead to confusion. Considering that most of these sounds are time variant, a single model of time-varying loudness is preferable. At present the recently

published extension of the German standard for time-varying loudness (DIN 45631/A1) is the sole standardized method, applicable also for stationary sounds. There are other models allowing for loudness evaluation of time-variant sounds. Some years ago, a Hearing Model was borne out of a widespread interest to have a single standardized psychoacoustic model describing and explaining many phenomena at once. The Hearing Model is based on the physiology of human hearing and has been validated by testing against previously conducted psychoacoustic research results. The different methods will be compared and validated with subjective tests using technical sounds.

Contributed Papers

9:20

3aNSb5. Safe lifetime occupational exposure-1 LONE (lifetime occupational noise exposure). Robert D. Bruce, Arno S. Bommer, Kimberly A. Lefkowitz, and Noel W. Hart (CSTI Acoust., 16155 Park Row, Ste. 150, Houston, TX 77084)

For many years, it has been recognized by those working in the field of industrial noise that understanding how much noise is needed to cause hearing loss over a lifetime is difficult to communicate to most people, even those who have an understanding of logarithms. The concept of expressing noise exposure in industrial situations without decibels is the focus of this paper. Eldred ("Sound Exposure without Decibels" Internoise-86) discussed this approach for community noise. ANSI Standard S3.44-1996 defines sound exposure with units of Pascals squared seconds, or PASQUES, as noted by Eldred. This paper proposes that a safe value for lifetime occupational exposure to noise be expressed in terms of PASQUES. The authors will discuss the pros and cons of such an approach and offer 11.5×10^6 million PASQUES as the upper limit for a safe lifetime exposure to occupational noise.

9:35

3aNSb6. Earmuff noise attenuation by microphone in real ear technique. Samir N. Y. Gerges (Mech. Eng., Federal Universit of Santa Catarina, Florianopolis, Sc, Brazil, samir@emc.ufsc.br), Danilo A. Agurto, Jorge Arenas (Universidad Austral de Chile, Chile), Jose Bento Coelho, and Miguel M. Neves (IST, Lisbon, Portugal)

When using a hearing protector at the workplace, it is necessary to quantify its noise attenuation by laboratory measurements. This paper aims at developing an objective methodology for measuring hearing protector noise attenuation of earmuff type using "microphone in real ear" (MIRE) method. The methodology uses the "insertion loss" (IL) as parameter, which is the difference between the sound pressure level with and without the hearing protector, using MIRE, and then calculating the hearing protector IL. The results for four different hearing protectors are compared with the subjective method "real-ear attenuation at threshold" (REAT). Factors such as physiological noise and bone conduction are quantified using the relation between MIRE and REAT method. Results are compared with values obtained from the literature.

3aNSc1. New options in microphones and instrumentation for making field infrasonic measurements. Kurt Veggeberg (Natl. Instruments, 11500 N. MOPAC C, Austin, TX 78759, kurt.veggeberg@ni.com)

There are many interesting man-made, animal, and other naturally occurring infrasonic signals. Typical measurement microphones and instrumentation systems are usually ac coupled and roll-off at various frequencies below 20 Hz since they were primarily designed for audible sound. Making infrasonic measurements has often used a variety of sensors or microphones that are not uniform or compliant with international standard IEC 1094 for dimensions of measurement microphones but offer capabilities for measuring to frequency ranges below 1 Hz. In addition, they typically are not compliant with ANSI or IEC standards for sound level meters. This is an overview of new IEPE/ICP condenser type measurement microphones and instrumentation capable of making measurements below 0.5 Hz and how they can be deployed in making precision acoustic field measurements compliant with acoustic standards at very low-frequency ranges.

10:30

3aNSc2. Laboratory measurements of sound transmission at low frequencies. Chris Fuller (Dept. of Mech. Eng., VaTech, 133 Durham Hall, Blacksburg, VA 24061), Kathleen Kondylas (NEVA Assoc., Newburyport, MA 01950), and Natalia Levit (DuPont, Richmond, VA 23234, natalia.v.levit @usa.dupont.com)

The ability of acoustic materials to attenuate sound is usually determined in accordance with ASTM E-90 or ISO 140-3, both based on the diffuse field theory. However, the reality is that the size of typical reverberant chambers does not provide a sufficiently diffuse field at low frequencies. As a result, there is significant variation in sound transmission data of tested materials below 150 Hz. Several attempts were undertaken to improve the accuracy of measuring TL such as increasing field diffuseness by using reflecting surfaces, installing near-field array of loudspeakers, and using sound intensity probes on the receiving sides. None of these proved totally satisfactory. This work presents studies on using various approaches to more accurately determine acoustic mitigation of low-frequency transmitted noise. A metal box consisting of a very rigid frame supporting elastic panels on all sides was acoustically excited by a loudspeaker suspended inside of the box. The panels and box interior were designed to have very low-fundamental frequencies. The box was suspended by its frame in an anechoic room. An intensity probe was used to measure the transmitted sound from the box panels. The acoustic performance of various acoustic materials was compared for frequencies below 500 Hz.

10:45

3aNSc3. Acoustic impedance of Earth's ground surface at infrasonic frequencies. Allan J. Zuckerwar (Analytical Services and Mater., Hampton, VA 23666, ajzuckerwar@yahoo.com)

The acoustic impedance of Earth's ground surface is known to have a significant impact upon measurements of outdoor infrasound, e.g., sonic boom rise times. Current acoustic impedance models assume a rigid frame, or a no-slip condition, and thus lead to unbounded values of the real and imaginary parts of the acoustic impedance as the frequency approaches zero. The model of Tarnow [J. Acoust. Soc. Am. **105**, 234–240 (1999)], on the other hand, considers relative motion between a porous frame (soil) and the air in the pores. It is shown here that this model yields finite values of the ground impedance in the limit to zero frequency. Further, extrapolation of selected experimental data to zero frequency by the method of the Richardson extrapolation also leads to finite values of the acoustic ground impedance. Finally, it is shown that the reflection of long-wavelength infrasound from bedrock may reveal resonance effects that will impact the ground impedance.

11:00

3aNSc4. Experience of the measurement and assessment of residential low-frequency noise complaints. David C. Waddington, Andrew T. Moorhouse, and Mags D. Adams (Acoust. Res. Ctr., Univ. of Salford, Salford M5 4WT,United Kingdom, d.c.waddington@salford.ac.uk)

The practical application of a procedure for the assessment of low-frequency noise (LFN) complaints is described. The development of the assessment method was published recently [J. Acoust. Soc. Am. **126**, 1131–1141 (2009)]. The procedure includes guidance notes and a pro-forma report with step-by-step instructions for field measurements, complemented with an interview-based questionnaire together with an event log completed by the complainant. It does not provide a prescriptive indicator of nuisance but rather gives a systematic procedure to help environmental health practitioners to form their own opinion. Examples of field measurements and application of the procedure are presented. The procedure and examples are likely to be of interest to environmental health practitioners involved in the assessment of LFN complaints. [Work funded by the Department for Environment, Food and Rural Affairs (Defra), UK.]

11:15

3aNSc5. Research into the human response to vibration from railways in residential environments. David C. Waddington, Andrew T. Moorhouse, James Woodcock, Nathan Whittle, Sharron Henning, Eulalia Peris, Gennaro Sica, Andy Steele, Phil A. Brown, and Mags D. Adams (Univ. of Salford, Salford M5 4WT, United Kingdom, d.c.waddington@salford.ac.uk)

This paper describes progress in research being carried out at the University of Salford to develop a method by which human annoyance to vibration in residential environments can be assessed. The objective of this study is to yield a robust relationship between vibration exposure and human response, therefore providing a reliable basis for the development of standards and guidance for the assessment of vibration in residential buildings. The vibration sources to be considered are those affecting residents that are outside their control, such as construction, road, and rail activities. Noise is also a consideration. The protocol involves the measurement of vibration outside and inside individual residences and a social study questionnaire based on face-to-face interviews with householders. Work so far has concentrated on the response of people in their own homes to railway noise and vibration. Approximately 1000 case studies have been obtained, and examples of early field measurements and results are presented. This work is likely to be of interest to acoustical consultants and environmental health officers involved in the assessment of vibration complaints and to planners and practitioners involved in the design of buildings. [Work funded by the Department for Environment, Food and Rural Affairs (Defra) UK.]

11:30

3aNSc6. Measurements of exploding balloon demonstrations. Julia A. Vernon, Kent L. Gee (Dept. of Phys. and Astronomy, Brigham Young Univ., Provo, UT 84602, julia.vernon@yahoo.com), and Jeffery H. Macedone (Dept. of Chemistry and Biochemistry, Brigham Young Univ., Provo, UT 84602)

Exploding balloons are popular demonstrations in introductory chemistry and physical science classes and as part of outreach programs. However, as impulsive noise sources, these demonstrations constitute a possible hearing damage risk to both the demonstrator and the audience. Measurements of various hydrogen, hydrogen-oxygen, and acetylene-oxygen balloons were made in both a large lecture hall and an anechoic chamber. Condenser microphones (6.35 and 3.2-mm diameters) were placed at various angles, and distances from the balloon and time waveform data were collected at a sampling frequency of 192 kHz. For all balloon sizes tried, hydrogen-only balloons were found to produce peak sound pressure levels less than 140 dB at distances greater than or equal to 2 m. On the other hand, large (but reasonably sized) hydrogen-oxygen and acetylene balloons can result in peak levels exceeding 160 dB at a distance of 2 m, which constitutes a significant hearing risk for unprotected listeners at typical distances.

11:45

3aNSc7. Ultrasonic noise from manmade electical devices. Trevor Jenny (tdwheats@hotmail.com), Brian E. Anderson (Dept. of Phys. and Astron., Acoust. Res. Group, Brigham Young Univ., Provo, UT 84602), and James A. TenCate (Los Alamos Natl. Lab., Los Alamos, NM 87545)

Measurements of ultrasonic noise emitted from manmade electrical devices have been made in an ultrasonic anechoic chamber. Until now, little has been published about the levels and frequency content of ultrasonic noise emitted from electronic devices such as laptops, cell phones, and other electronic devices. The most common source of ultrasonic noise in these devices is dc to dc power supplies. Measurements are made over the range of 20–200 kHz emitted by electronic devices (e.g., laptops). The results of these measurements and the challenges associated with making the measurements will be discussed (including anechoic chamber qualification in the ultrasonic frequency range). [This work has been funded by the Los Alamos National Laboratory.]

3aPA1. Sonic boom research in NASA's supersonic fundamental aeronautics project. Peter G. Coen (NASA Langley Res. Ctr., MS 264, Hampton, VA 23681)

The Supersonics Project of NASA's Fundamental Aeronautics Program is a broad based effort designed to address the technical challenges associated with flight in the supersonic speed regime. One of the key environmental challenges that must be overcome for successful commercial supersonic flight is sonic boom. The NASA Supersonics Project has chosen this challenge as a focus for its research activity over the next several years. In cooperation with the FAA and the ICAO Committee on Aviation Environmental Protection (CAEP) NASA has initiated the development of a roadmap for research into the community response to sonic booms with noise levels significantly less than those of the Concorde and current supersonic aircraft. The purpose of the roadmap is to define the key research that should be accomplished in order to provide a firm technical basis for future noise-based standards for sonic boom acceptability. This presentation will discuss the elements of this roadmap and outline some of the recent research contributions made by the NASA Supersonics Project.

8:20

3aPA2. Random focusing of nonlinear *N*-waves in fully developed turbulence: Laboratory scale experiment and theoretical analysis. Philippe Blanc-Benon (CNRS, LMFA UMR 5509 Ecole Centrale de Lyon, 69134 Ecully Cedex, France, philippe.blanc-benon@ec-lyon.fr), Mikhail V. Averiyanov (Moscow State Univ., Moscow 119991, Russia), S. Ollivier (CNRS, LMFA UMR, 69134 Ecully Cedex, France), and Vera A. Khokhlova (Phys. Faculty, Moscow State Univ., Moscow 119991, Russia)

The high-amplitude shock wave generated by a supersonic aircraft propagates through the atmosphere toward the ground and generates an acoustic field with non-uniform pressure distributions strongly influenced by atmospheric turbulence. Recent numerical simulations based on generalized KZK-type equation including the effects of moving inhomogeneous media will be discussed. Formation of multiple focusing and defocusing zones is predicted. Nonlinear effects are significant not only in the random focusing zones but also in shadow zones of lower-pressure levels due to scattering of high frequencies from the areas of focusing. A statistical analysis is performed, and the results are compared to experimental data obtained in the controlled laboratory scale experiments conducted in the ECL anechoic wind tunnel. A high-power spark source is used to generate *N*-waves. Correlation length scales and spectra of the turbulent velocity field are measured. Statistical distributions and mean values for peak positive pressure and shock arrival time are obtained and found to be in a good agreement with modeling. In focusing areas, waveforms with amplitudes more than four times higher than those measured without turbulence are observed. Pressure amplitude probability density distributions are shown to possess autosimilarity properties when changing the intensity of turbulence. [Work supported by RFBR, French Government.]

8:40

3aPA3. A comparison of wide-angle and narrow-angle progressive wave equations for modeling sonic boom propagation through turbulence. Andrew Piacsek (Dept. of Phys., Central Washington Univ., 400 E. Univ. Way, Elllensburg, WA 98926-7422, piacsek@cwu.edu), B. Edward McDonald (Naval Res. Lab, Washington, DC 20375), and Victor Sparrow (Penn State Univ., Univeristy Park, PA 16802)

The high-angle formulation of the nonlinear progressive wave equation model (NPE2) [McDonald, Wave Motion **31**, 165–171 (2000)] has been adapted for atmospheric propagation and is used to perform numerical simulations of sonic boom propagation through atmospheric turbulence. Turbulence is incorporated into the model as perturbations of the local ambient sound speed, which have a random spatial distribution determined by a von Karman energy spectrum. Wave forms, peak overpressures, and wavefront profiles computed at fixed ranges from the onset of turbulence are compared to corresponding solutions produced by the original (narrow-angle) version of the NPE in order to quantitatively assess the importance of wide-angle accuracy for sonic boom propagation.

9:00

3aPA4. The influence of non-standard atmospheric conditions on the potential number of acoustic signature occurrences in the continental United States. Joe Salamone (Gulfstream Aerosp., 500 Gulfstream Rd M/S R-07, Savannah, GA 31402)

The potential number of supersonic flight operations and their resulting acoustic signature occurrences are important components for assessing the overall impact of supersonic flight over populated areas. Gulfstream Aerospace has recently published estimates for the number of acoustic signatures that would occur per day, on average, over the continental United States based on actual flight movements from large cabin business jets. The previous analysis of the flight movement data assumed propagation from a supersonic vehicle flying at a constant altitude and Mach number through a standard atmosphere and also assumed great circle routing between the origin and destination airports. The present work will examine the influence that realistic flight profiles and non-standard atmospheric conditions have on the location and extent of the acoustic signature occurrences. The non-standard atmospheric conditions will consist of seasonally averaged, upper-air profiles from nearly 100 locations across the continental United States. The realistic flight profiles will be based on estimates for the climb capability of the supersonic vehicle and possible air traffic routing trajectories.

9:20

3aPA5. Prediction of shaped sonic boom focusing. Anthony R. Pilon (Adv. Development Programs, Lockheed Martin Aeronautics Co., 1011 Lockheed Way, Palmdale, CA 93599, tony.pilon@lmco.com)

The focusing effects of aircraft maneuvers and accelerations on shaped, or minimized, sonic boom signals have been investigated. The spectrally accurate boom prediction methodology of Pilon [AIAA J. **45**, 2149–2156 (2007)] has been enhanced to include the effects of focusing through an implementation of the nonlinear Tricomi equation solver of Auger and Coulouvrat [AIAA J. **40**, 1726–1734 (2002)]. The newly enhanced prediction tool was used to predict boom focus from aircraft accelerations, turns, and dives. Idealized near-field shaped boom signals were used as inputs to the code. Both fully resolved, continuous boom signals and booms containing zero-thickness shock waves were used as inputs to the focusing algorithm, in order to highlight the differences in perceived loudness on the ground. The new tool and results of the study will be used to help design accelerations and maneuvers for future supersonic cruise aircraft.

9:40

3aPA6. Three-dimensional finite-difference time-domain simulation of low-amplitude sonic boom diffraction around a rectangular test structure and building spiking effect. Sang I. Cho and Victor W. Sparrow (Grad. Prog. in Acoust., Penn State Univ., 201 Appl. Sci. Bldg., University Park, PA 16802, stc142@psu.edu)

A finite-difference time-domain (FDTD) approach is used for a three-dimensional numerical modeling of pressure loading on the exterior surface of a building due to an incident low-amplitude sonic boom. For these "low-booms," the linearized Euler equations suffice to describe the boom-structure interaction. A second-order centered-difference scheme and fourth-order Runge–Kutta time integration scheme are applied. The FDTD simulation models a field test performed by Virginia Tech in 2008, where a rectangular test structure representing a residential building was instrumented to measure its vibroacoustic response to a boom generated by detonation cord. By matching the geometries of the simulated structure to the actual test structure and using the waveform of a measured boom as the input to the simulation, a direct comparison of numerical and experimental data is made possible. The simulation result agrees well with the experiment and also shows expected pressure doubling and diffraction effects. An interesting observation is made in both numerical and experimental data and is called the "building spiking" effect, which can be attributed to frequency-selective diffraction by the building. [Work supported by NASA. The authors appreciate Virginia Tech and NASA making the 2008 detonation cord test data available for this work.]

10:20

3aPA7. A combined ray-tracing and radiosity method for propagation and diffraction of sonic booms in urban landscapes. Kimberly Lefkowitz and Victor W. Sparrow (Pennsylvania State Univ., State College, PA 16801)

Civil supersonic flight over land will only be allowed when sound levels are low enough to be acceptable to the public, and thus the sound field inside buildings needs to be well understood. To understand the field inside buildings, the sound field outside the buildings as well as the diffraction and loading on the building must be determined. A model to propagate sonic booms in urban landscapes was developed using a combined ray tracing and radiosity method. This model includes both diffuse and specular reflections for a single building configuration. The impact of diffuse reflections on the propagating and diffracting sound field will be examined, and multiple building configurations are also considered. The model results will be compared with data from NASA's SonicBOBS (sonic booms on big structures) experiment conducted in September of 2009. [Work supported by NASA.]

10:40

3aPA8. Vibro-acoustic response of a simplified residential structure exposed to sonic booms. Part I: Numerical model. Marcel Remillieux, Joseph Corcoran, Ryan Haac, Ricardo Burdisso (Virginia Tech, 142 Durham Hall, Blacksburg, VA, 24061, mremilli@vt.edu), and Georg Reichard (Myers-Lawson School of Construction, Virginia Tech)

This paper presents a numerical model to predict the vibro-acoustic responses of simplified residential structures exposed to sonic booms. The model is validated experimentally in a companion paper. The dynamics of the fluid-structure system, including their interaction, is computed in the time domain using a modal-decomposition approach. In the dynamic equations of the system, the structural displacement is expressed in terms of summations over the *in vacuo* modes of vibration. The pressures inside the interior volumes are expressed as summations over the acoustic modes of rooms with perfectly reflecting surfaces. The structural modes are computed nu-

merically using the finite element method. A shell element was specifically derived to model the structural components of typical residential buildings, e.g., plaster-wood walls, windows, and doors. The acoustic modes are computed for rectangular geometries using analytical expressions. Using modal decomposition, the dynamics of the fluid-structure system may be formulated by a finite set of ordinary differential equations (modal equations). These equations are then integrated with a Newmark algorithm to solve for the vibro-acoustic response of the system in the time domain. The system response may also be predicted in the frequency domain, by taking the Fourier transform of the time-domain response.

11:00

3aPA9. Vibro-acoustic response of a simplified residential structure exposed to sonic booms. Part II: Experimental validation. Marcel Remillieux, Joseph Corcoran, Ryan Haac, RicardoBurdisso Burdisso (Virginia Tech, 142 Durham Hall, Blacksburg, VA 24061, mremilli@vt.edu), and Georg Reichard (Myers-Lawson School of Construction, Virginia Tech, Blacksburg, VA 24061)

In a companion paper, a model was derived to predict the vibro-acoustic responses of simplified residential structures exposed to sonic booms. In the present paper, the experimental validation of the numerical model is presented. First, the experimental setup is described, including the structure, instrumentation, and external pressure loading. The structure was a single room made of plaster-wood walls and includes two double-panel windows and a door. The structure was extensively instrumented with accelerometers and microphones to record its vibro-acoustic response. Sonic booms with realistic amplitudes and durations were generated by an explosive technique. Subsequently, numerical predictions on the vibration of the structure and pressures inside the room are compared to experimental data, showing a fairly good agreement overall.

11:20

3aPA10. Distributed field measurements of low amplitude sonic booms. Joseph Gavin (Gulfstream Aerosp., 32 Lummus Dr, Savannah, GA 31408, joseph.gavin@gulfstream.com), Jack Arnold, Bryan Nadeau (Natl. Instruments, Austin, TX), Jacob Klos (NASA Langley Res. Ctr., Hampton, VA. 23681), and Edward A. Haering, Jr. (NASA Dryden Flight Reearch Ctr., Edwards, CA)

Quiet supersonic flight over land appears increasingly viable, based on significant advancements in aircraft shape optimization. One of the next critical milestones will involve community scale surveys, measuring the public response to events that sound as benign as distant thunder. The present paper describes a measurement infrastructure to reduce the field costs associated with those tests. Specifically, a scalable grid of NI CompactRIO data acquisition systems has been developed and deployed in a risk reduction test. Highlights of the system include communications via a wireless rf network and synchronization using low cost GPS receivers. This paper highlights some of the development challenges, solutions, and recent results from component and system level risk reduction testing at the NASA Dryden Flight Research Center.

11:40

3aPA11. Detailed finite element analysis of sonic boom transmission into residential building structures. Beom Soo Kim , W. Victor Sparrow (Graduate Program in Acoust., 201 Appl. Sci. Bldg., University Park, PA 16802, buk104@psu.edu), V. Natalia Sizov, and T. Ben Manning (Wyle Labs., Arlington, VA 22202)

Finite element modeling is a powerful and cost-effective tool for solving problems in structural dynamics and acoustics, particularly at low frequencies. In the present work the transient responses of the sonic boom transmission from outdoors to indoors were studied. Detailed finite element models of individual rooms from two residential structures were built. The simulated geometries were matched to the physical geometries of two houses exposed to sonic booms that were heavily instrumented by NASA in the summers of 2006 and 2007. The residential building walls were composed of studs and sheathing, and these were modeled using MSC NASTRAN/PATRAN software. To match the normal mode frequencies of the walls, it was necessary to not only match material coefficients but also the actual connections between the studs and the sheathing. The fluid structure coupling between the walls and the air was utilized to analyze the acoustic response of the sonic boom in the room interior. In order to verify the correctness of the model, the vibration responses of the structure and the acoustic cavity were compared with measured data. [Work supported by NASA.]

9:00

3aPP1. Sound source localization of a dipole by the plainfin midshipman fish (*Porichthys notatus*). David G. Zeddies (Marine Acoust. Inc., 41 Fairfax Dr., Arlington, VA 22203), Richard R. Fay (Loyola Univ.-Chicago, Chicago, IL 60626), Peter W. Alderks, Andrew Acob, and Joseph A. Sisneros (Univ. of Washington, Seattle, WA 98195)

Localization of a dipole sound source was studied in female plainfin midshipman fish (*Porichthys notatus*). Experiments were conducted and videotaped in a 3.65-m-diameter tank using a dipole underwater speaker system placed near the center of the tank. The sound was a 90-Hz tone, approximately the fundamental frequency of the male's advertisement call. Pressure and particle motion components of the sound field were mapped with 9-cm resolution. Pressure was measured using an eight-hydrophone array, and particle motion vectors calculated from the pressure gradients. Mapping confirmed that the projector was operating as a dipole. Gravid fish were released 70 cm from the sound source at two different positions relative to the dipole axis: one near the dipole axis and one near the pressure null axis. Twenty-five positive responses were recorded from each release site. The phonotactic response pathways along the dipole axis consisted of slightly curved tracks to the sound source, whereas pathways from the null axis consisted of greatly curved tracks to the source that followed the particle motion vectors. Results confirm that fish can locate a dipole sound source and are sensitive to the direction of acoustic particle motion. [Work supported by NSF.]

3aPP2. Generating correlated noise. William M. Hartmann and Yun Jin Cho (Dept. of Phys. and Astronomy, Michigan State Univ., East Lansing, MI 48824)

Research on binaural hearing frequently presents partially correlated noise to a listener's two ears. Experimentally, there are two classic methods to generate noise with a controlled amount of cross-correlation: the *two-generator* method and the *three-generator* method [J. C. R. Licklider and E. Dzendolet, Science, **107**, 121–124 (1948)]. Analytic formulas were developed and numerical experiments were done to study the properties of the two methods, particularly to determine how well the actual correlations approach targeted correlations. It was found that both methods give very similar results, with variance that is greatest when the targeted cross-correlation is zero and which decreases monotonically to zero as the targeted value increases to 1.0. The variance decreases inversely as the first power of the number of degrees of freedom in the noise, whatever the targeted correlation. Paradoxically, a far less popular method, the *symmetrical generator* method, is far more successful. The variance is zero when the targeted cross-correlation is either zero or 1.0, and the variance decreases inversely as the square of the number of degrees of freedom. The symmetrical generator method is a reasonable alternative to the summing of digitally orthogonalized noises. [Work supported by the NIDCD DC-00181.]

9:30

3aPP3. A binaural localization model that resolves front-back confusions through head movements. Jonas Braasch, John T. Strong, and Ning Xiang (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, braasj@rpi.edu)

It is well known that head movements are instrumental in resolving front/back confusions in human sound localization. A mechanism for a binaural model is proposed here to extent current cross-correlation models to compensate for head movements. The algorithm tracks sound sources in the head-related coordinate system (HRCS) as well as in the room-related coordinate system (RRCS). It is also aware of the current head position within the room. The sounds are positioned in space using an HRTF catalog at 1 deg azimuthal resolution. The position of the sound source is determined through the inter-aural cross-correlation (IACC) functions across several auditory bands, which are mapped to functions of azimuth and superposed. The maxima of the cross-correlation functions determine the position of the sound source, but unfortunately, usually two peaks occur—one at or near the correct location and the second one at the front/back reversed position. When the model is programed to virtually turn its head, the degree-based cross-correlation functions are shifted with current head angle to match the RRCS. During this procedure, the IACC peak for the correct hemisphere will prevail if integrated over time for the duration of the head movement, whereas the front/back reversed peak will average out.

9:45

3aPP4. Modeling the precedence effect for multiple echoes. Matthew J. Goupell and Ruth Y. Litovsky (Waisman Ctr., Univ. of Wisconsin-Madison, Madison, WI 53705)

A typical and controlled way to study the precedence effect has been to use two pairs of binaural click stimuli with different lead-lag delays. For lead-lag delays between 1 and 5 ms, interaural differences in the lead click pair are more easily discriminated than those in the lag click pair. This work attempts to move from the classic, but unrealistic, two-source paradigm to a more realistic situation, much like real rooms in which multiple echoes occur. Using a three-source paradigm, listeners were presented three click pairs (lead, lag1, and lag2) via headphones. Discrimination of directional changes in each of the three click pairs was measured with a 2AFC task for delays between 0 and 130 ms. Results show that due to interactions amongst the three sources "echo thresholds" were affected in a non-monotonic way. Temporal order effects were observed for long delays, which led to poorer lead discrimination, and better lag2 discrimination. Summing localization was observed for short delays between lead and lag1, and lag1 and lag2. A simple weighting model [Shinn-Cunningham *et al.*, J. Acoust. Soc. Am. **93**, 2923–2932 (1993)] was adapted to include this multiple source data and the complex relationships between the three sources. [Work supported by NIH-NIDCD R01 DC003083—R.Y. L.]

10:00

3aPP5. Investigation into and modelling of head movement for objective evaluation of the spatial impression of audio. Chungeun Kim, Russell Mason, and Tim Brookes (Inst. of Sound Recording, Univ. of Surrey, Guildford GU2 7XH, United Kingdom)

Research was undertaken to determine the nature of head movements made when judging spatial impression and to incorporate these into a system for measuring, in a perceptually relevant manner, the acoustic parameters which contribute to spatial impression: interaural time and level differences and interaural cross-correlation coefficient. First, a subjective test was conducted that showed that (i) the amount of head movement was larger when evaluating source width and envelopment than when judging localization

and timbre and (ii) the pattern of head movement resulted in ear positions that formed a sloped area. These findings led to the design of a binaural signal capture technique using a sphere with multiple microphones, mounted on a simulated torso. Evaluation of this technique revealed that it would be appropriate for the prediction of perceived spatial attributes including both source direction and aspects of spatial impression. Reliable derivation of these attributes across the range of ear positions determined from the earlier subjective test was shown to be possible with a limited number of microphones through an appropriate interpolation and calculation technique. A prototype capture system was suggested as a result, using a sphere with torso, with 21 omnidirectional microphones on each side. [Work supported by the Engineering and Physical Sciences Research Council (EPSRC), UK, Grant No. EP/D049253.]

10:30

3aPP6. Tuning of head-related transfer functions using principal component analysis. Kimberly J. Fink and Laura R. Ray (Thayer School of Eng., Dartmouth College, 8000 Cummings Hall, Hanover, NH 03755)

Modeling head related impulse responses (HRIRs) to determine head-related transfer functions (HRTFs) can be used to create a virtual auditory display through head phones. However, non-individualized HRTFs can create errors in sound localization and perception of the source as coming from inside vs outside of the head. We present a method, based on model-order reduction and principal component analysis, to "tune" generalized HRTFs derived from the CIPIC database of HRIRs in order to individualize an HRTF. The impulse response for each individual in the CIPIC database is modeled at given azimuth locations on the horizontal plane. Model order reduction is used to eliminate poles and zeros of the identified HRTF at high frequencies, while preserving the frequency response below ~8000 Hz. Principal component analysis is then performed on the reduced-order models in order to reduce the dimensionality of the dataset and identify a subset of weighting variables that are adjusted during HRTF customization. The sensitivity of weights on the frequency response is also studied in order to correlate weights with HRTF features. A prototype auditory display has been developed that allows a user to tune HRTFs in real-time, while listening to a 44.1-kHz source presented from a chosen azimuth.

10:45

3aPP7. Effects of individualized headphone equalization on front/back discrimination of virtual sound sources. Abhishek Guru, William L. Martens, and Doheon Lee (Faculty of Architecture, Design and Planning, Univ. of Sydney, New South Wales 2006, Australia, agur4608@uni.sydney.edu.au)

Individualized head related transfer functions (HRTFs) were used to process brief noise bursts for a two-interval forced choice front/back shift between virtual sound source locations presented via two models of headphones, the frequency responses of which could be made nearly flat for each of 21 listeners using their own individualized headphone equalization filters. In order to remove tone coloration differences between virtual sources processed using individualized HRTFs measured in front or in back of each listener, the spectral centroid of the "back" source was adjusted to more nearly match that of the source processed using the "front" HRTF. This manipulation resulted in chance levels of discrimination performance for 12 out of 21 listeners. For the remaining nine listeners showing good discrimination, the virtual sources presented using individualized headphone equalization supported significantly better front/back discrimination rates than did virtual sources presented without correction to headphone responses.

11:00

3aPP8. Reverberation disrupts spatial selective auditory attention. Dorea R. Ruggles and Barbara G. Shinn-Cunningham (Hearing Res. Ctr., Boston Univ., 44 Cummington St., Boston, MA 02215)

When there are multiple, competing speech streams, listeners can selectively attend to a desired target using spatial cues like interaural time differences (ITDs). However, reverberation smears fine temporal information needed to encode ITDs. Reverberation may therefore interfere with the ability to selectively attend to a target from a particular direction. Subjects were asked to report a stream of digits simulated to be directly in front of them in the presence of two masker streams symmetrically positioned at 15 deg left and right. Because the maskers were statistically identical to the target (except in direction), listeners had to focus spatial attention on the target while ignoring the masker streams. Three levels of reverberation were simulated using a rectangular room model to measure the influence of reverberation on performance. Initial results showed that spatial selective attention degraded as reverberation increased. However, overall performance varied dramatically from listener to listener in ways that were not predicted by age or memory span. The current study explores whether individual differences are predicted by performance on two discrimination tasks that rely on signal fine temporal structure: frequency modulation (a monaural task) and ITD (a binaural task). [NIDCD, ONR, and NSF provided funding to support this work.]

11:15

3aPP9. The effects of intervening interference on working memory for sound location. Aurora Grossmann, Dennis Ries, and Traci Hamilton (School of Hearing, Speech, & Lang. Sci., Ohio Univ., Grover Ctr., Athens, OH 45701, ag303003@ohio.edu)

Inter-aural phase differences were used to study working memory for perceived auditory position quantified as a change in the difference limen (DL) in equivalent auditory angle across 300-, 5000-, and 15 000-ms retention intervals. Data were obtained for the medium and long intervals both in the presence and absence of intervening tones. Intervening stimuli within the medium and long inter-comparison intervals produced a significant increase in the DLs compared those obtained in the corresponding quiet conditions. The DL for the 300-ms interval was roughly equivalent to that obtained for the medium interval without intervening tones while that obtained for 15 000-ms interval was significantly greater than that obtained for either of the shorter intervals. The results suggest that the temporal decay of information within AWM of a listerner regarding the location of a sound within their environment is so gradual that it can be maintained in trace memory for tens of seconds in the absence of intervening acoustic signals. Conversely, the presence of interpolated sounds within the retention interval may facilitate the use of context memory, resulting in a less detailed, but relevant representation of the location that is resistant to further degradation.

9:15

3aSA1. Damping in auxetic materials and structures. Fabrizio Scarpa (Dept. of Aerosp. Eng., Univ. of Bristol, 83 Woodland Rd., Bristol BS8 1US, United Kingdom, f.scarpa@bris.ac.uk)

Negative Poisson's ratio (NPR) (otherwise called auxetics) materials and structures feature enhanced energy absorption under cyclic loading both at low- and high-frequency excitations. We show in this paper experimental and simulation results related to open cell PU-PE foams, honeycombs, and composites, all exhibiting a negative Poisson's ratio value. The open cell auxetic foams provide a significant damping capacity at low frequency and high preload as well as under broadband excitation compared to the conventional foams from which they are derived. We show also that the acoustic absorption properties of the auxetic foams are significantly enhanced compared to conventional PU-PE under 500 Hz, and their loss factor increased using their specific shape memory property. We describe also the vibration damping properties of NPR honeycombs with different unit cell topologies and the damping capacity of NPR carbon fiber composites under flexural cyclic loading.

3aSA2. Intrinsic damping, relaxation processes, and internal friction in vibrating systems. Allan D. Pierce (Dept. of Mech. Engr., Boston Univ., Boston, MA 02215, adp@bu.edu)

Vibrations lose energy because of (1) coupling of the system to other systems or to the environment or of (2) intrinsic damping within the system itself. The present paper attempts to survey the current state of understanding for the principal mechanisms of the latter type with explicit physics (rather than purely phenomenological considerations), as simply as practical. Some mechanisms are evidenced in the attenuation of waves in unbounded homogeneous media, others are caused by the presence of boundaries. Some explicitly require quantum-mechanical concepts for their explanation, others can be explained in terms of classical mechanics and thermodynamics. Specific mechanisms that are to be discussed include those associated with thermal conductivity, grain and domain boundary effects, interstitial atom diffusion, relaxation by diffusion, inter-grain diffusion, micro-eddy current losses, hysteresis losses, thermoelastic internal friction, thermal damping associated with transverse vibrations of thin bodies, phonon-phonon interactions, phonon-electron interactions, internal fluids, and dislocations. The concept of relaxation often provides a convenient unified description. Rather than use the local averaged particle displacement as a sole description of the local vibrations, one considers additional local variables, loosely referred to as hidden variables. Each such variable, when disturbed, relaxes to its equilibrium value with a characteristic relaxation time.

9:55

3aSA3. Optimization of local damping treatments for plate vibrations. J. Gregory McDaniel (Dept. Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

This work considers passive damping treatments that dynamically interact with plates over areas that are much smaller than a flexural wavelength. Each treatment is modeled as a frequency-dependent admittance presented to the plate at a point. The frequency-dependence is required to satisfy the causality and minimum phase conditions, which are implicitly enforced via a specialized Fourier series in frequency. The Fourier coefficients, as well as the positions of the attachments, are regarded as optimization parameters to be varied so as to globally decrease plate vibrations over a frequency band of interest. Various cost functions are considered, such as the sum of modal loss factors over the band as well as acoustic radiation efficiencies. Examples involving a simply supported plate excited by a point force illustrate the approach. [Work supported by ONR under Grant No. N000140810531.]

3aSA4. Radiation damping and scattering reduction by transformation acoustics. Andrew Norris (Dept. of Mech. and Aerosp. Engng., Rutgers Univ., NJ 08854, norris@rutgers.edu)

The idea in transformation acoustics is to map one region into another so that the new region has the same acoustic appearance to observers as the original. It is analogous to transformation optics and is closely related to devices for cloaking, but it is not restricted to cloaking. This talk will explore the implications of transformation acoustics for radiation damping and scattering. Mechanisms for realizing transformed regions, which we call acoustic metafluids, will be described. The objective in these materials is to bend the waves so that energy can be steered around a given region, and thereby reduce the scattering strength. But it is not as obvious how these materials influence the radiation from an active source inside. In this talk we will discuss the implications of transformation acoustics on radiation using fundamental concepts, including acoustical reciprocity, mechanical impedance, and energy flux.

3aSA5. Radiation reduction using layers of three fluids. Adam J. Nagy and Andrew N. Norris (Dept. of Mech. and Aerosp. Engng., Rutgers Univ., Piscataway, NJ 08854, adnagy86@gmail.com)

Significant reduction in target strength and radiation signature can be achieved by surrounding an object with multiple concentric layers comprised of three acoustic fluids. The idea is to make a finely layered shell with the thickness of each layer defined by a unique transformation rule. The shell has the effect of steering incident acoustic energy around the structure and, conversely, reducing the radiation strength. The overall effectiveness and the precise form of the layering depend upon the densities and compressibilities of the three fluids. The best results are obtained if one fluid has density equal to the background fluid, while the other two densities are much greater and much less than the background values. Optimal choices for the compressibilities are also found. Simulations in two dimensions and three dimensions illustrate the effectiveness of the three-fluid shell.

11:05

3aSA6. Transmission loss of membrane-type locally resonant acoustic materials. Christina Naify (Dept. of Mater. Sci., Univ. of Southern California, 3651 Watt Way, VHE 602, Los Angeles, CA 90089), Chia-Ming Chang, Bill Carter, Geoff McKnight (HRL Labs., Malibu, CA 90265-4797), and Steve Nutt (Univ. of Southern California, Los Angeles, CA 90089)

Membrane-type acoustic metamaterials were fabricated, characterized, and analyzed. Thin plates which obey the acoustic mass law have low transmission loss at low frequencies. Acoustic metamaterials with negative dynamic mass density have been shown to demonstrate a significant (ten times) increase in transmission loss (TL) over mass law predictions for a narrow band (100 Hz) at low frequencies (100–1000 Hz). The peak TL frequency can be tuned to specific values by varying the membrane and mass properties. In this work, transmission loss magnitude as a function of frequency was measured for variations in the mass magnitude, mass placement on the membrane, membrane size, and membrane thickness using an impedance tube setup. The dynamic properties of membranes constructed from different materials and thicknesses were measured and compared to the results of coupled field acoustic-structural FEA modeling to understand the role of tension and element quality factor. In addition, the behavior and limitations of stacking multiple membranes in series to increase the reflection bandwidth were explored.

11:20

3aSA7. Damping mechanism concepts in ocean wave energy conversion: A simplified model of the Pelamis converter. Amadou G. Thiam and Allan D. Pierce (Boston Univ., Boston, MA 02215, thiam@bu.edu)

The conversion of mechanical energy to another energy form is often built into a structural acoustics model by adding some damping mechanism to the model. Also, in ocean wave energy conversion, one damping mechanism, which is occasionally of great importance in the determination of the limiting upper efficiency of a device, is the re-radiation of wave energy back into the ocean. Present paper focuses on a simplified model of the Pelamis wave energy converter, with the model consisting of a modified Euler–Bernoulli beam oriented head-on to incoming ocean waves and with energy conversion accounted for by a damping term, where the additional bending moment is proportional to the time derivative of the beam curvature. The wave energy converted is ideally equal to the energy dissipated by this term. The beam is taken as having circular cross-section with a mass density that is one-half that of water. An incident wave causes a transverse force along the bottom of the beam so that it heaves up and down in a snake-like fashion, and this heaving causes ocean waves to be re-radiated back into the ocean, causing an additional apparent damping. Consideration is limited to a linear analysis and to a deep-water ocean.

11:35

3aSA8. Rapid step response with limited ringing and light damping. Joseph Vignola and John Judge (Dept. of Mech. Eng., The Catholic Univ. of America, 620 Michigan Ave., NE Washington, DC 20064, vignola@cua.edu)

The time domain step response of an underdamped simple harmonic oscillator can be characterized as having two parts. The first is a transition from the initial position where the structure is accelerated toward a target position by a step force that introduces energy to the system. The second is a ringdown process, involving decaying oscillations about the target position as energy is removed from the structure. This study reports how an array of substantially smaller subordinate oscillators attached to the primary structure can dramatically reduce the time constant of the ringdown (the settling time) without slowing the first phase (rise time) in the way added classical damping does. In addition to having a more rapid initial response, a lightly damped oscillator with such an array of attachments requires less energy to change states than a more heavily damped structure. The approach is based on the concept of apparent damping, where vibration energy is transferred into and trapped by the set of attachments. Numerical results show that the distribution of the individual masses, isolated natural frequencies, and quality factors Q of the attachments, referred to as a subordinate oscillator array, can be tailored to achieve the rapid step response.

11:50

3aSA9. Application of time windowing to spatial maps of damping. Hande Öztürk and J. Gregory McDaniel (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Some of the most challenging vibration control problems involve the selection and placement of frequency-dependent damping devices, such as multilayered viscoelastic materials. In complex structures involving the simultaneous use of several passive damping devices, it is difficult to determine the effectiveness of each device directly from measurements. This question motivates the present analysis, which seeks to quantify the power being dissipated by the structure at selected locations for a given force distribution. The analysis begins with an expression for power flow to the structure from a specified force distribution. This expression involves the real part of the admittance matrix looking into the structure at a set of measurement points. By expanding this matrix as a sum over damping elements that mechanically connect measurement points, one can spatially map the power flow into the structure. While thermodynamics requires that this power flow to the structure be equal to the power dissipated by the structure, it does not require equality of the spatial distributions. In order to understand the spatial distribution of power dissipation, time windowing of the impulse responses is introduced. Examples are developed to explore the effects of the time window. Session 3aSC

Speech Communication: Exploring the Relationship Between Cognitive Processes and Speech Perception

Amee Shah, Chair
Cleveland State Univ., Speech and Hearing, 2121 Euclid Ave., Cincinnati, OH 44115

Chair's Introduction—8:00

Invited Papers

8:05

3aSC1. Perceptual expectations, attention, and speech recognition. Howard C. Nusbaum (Dept. of Psych., The Univ. of Chicago, 5848 S. Univ. Chicago, IL 60637, hcnusbaum@uchicago.edu)

Research has demonstrated substantial plasticity in the adult speech perceiver. When listeners receive feedback about the classification of a speech signal, this feedback can shape attention affecting phoneme perception. This demonstrates that it is possible to shape perceptual attention prospectively changing subsequent speech perception. These changes can also reduce the cognitive load of speech perception. The effect of expectations on speech perception has been reported for a wide range of studies from sinewave speech perception to phonetic categorization and effects of talker variability. Neural changes occurring during learning and the neural effects of expectations both appear to involve regions of motor cortex implicated in speech production. These neural changes suggest a model of speech perception similar to analysis-by-synthesis in which sensory processes are tuned by activity within the speech motor system. Although such sensory-motor interactions have been implicated in speech perception due to coarticulation and the encoding of speech into sound, the role of expectations in speech perception may extend beyond segmental perception. We consider evidence that the interpretation of prosodic signals also depends on perceptual expectations, suggesting that the role of expectations may be to constrain recognition given the many-to-many relationship that holds broadly in speech.

8:35

3aSC2. What do comparisons between younger and older adult listeners tell us about speech processing? Margaret K. Pichora-Fuller (Dept. of Psych., Univ. of Toronto, 3359 Mississauga Rd. N, Mississauga, ON L5L 1C6, Canada, k.pichora.fuller@utoronto.ca)

The perception of speech, the recognition of words, and the understanding of spoken language involve the dynamic and interactive processing of cues provided by the incoming signal and information stored in memory. Even when accuracy is high, the relative contributions of bottom-up and top-down processes may explain variations in the speed and effort required when listening to speech. Listening is fast when the quality of the incoming signal is optimal, but it is slowed as signal quality is reduced. Likewise, listening can be speeded when expectations constrain the likely alternatives or when priming implicitly facilitates the recognition of the signal, whereas it can be slowed if the context is incongruent with the signal or if context is used to resolve ambiguities or repair misperceptions in a compensatory fashion. Within-subjects comparisons on off-line and on-line measures in different listening conditions, including simulations of auditory aging and hearing loss, are used to investigate how listening effort varies and how listening is speeded or slowed depending on signal-driven and knowledge-driven factors. Comparisons between younger and older participants are used to evaluate how long-standing reductions in auditory temporal processing and compensatory changes in brain organization may alter how signal-driven and knowledge-driven processes interact.

9:05

3aSC3. The talker-specific nature of spoken language processing. Lynne C. Nygaard (Dept. of Psych., Emory Univ., 36 Eagle Row, Atlanta, GA 30322, lnygaar@emory.edu)

During spoken communication, listeners must contend with a physical speech signal that carries information not only about the linguistic content of a talker's utterance but also about a host of talker-specific attributes such as talker identity and emotion. Traditionally, the recovery of linguistic structure has been thought to be independent of the recovery of these indexical or surface characteristics of speech. Recent research, however, suggests that listeners remember the perceptual quality of spoken words, flexibly adapt to informative indexical variation in speech, and use this variation to guide their understanding of spoken words. This talk will review evidence for indexical specificity effects across a range of perceptual and memory tasks and will examine the linguistic, attentional, and cognitive constraints that may mediate the role of surface form in spoken language processing. Implications of these effects for accounts of linguistic representation and processing will be discussed. [Work supported by NIDCD.]

9:35

3aSC4. Interpreting speech in context. Mark Pitt (Dept. of Psych., Ohio State Univ., 1835 Neil, Ave., Columbus, OH, 43210, pitt.2@osu.edu)

One of the challenges in understanding how humans recognize spoken language is to reconcile the robustness of verbal communication with the many forms of ambiguity and variability in the speech signal. How much of the discrepancy is due to our incomplete understanding of the acoustics of speech (i.e., what is the critical information) versus the recruitment of mental processes (e.g., memory) to aid recognition? My approach to these explanations has been to study the processing of words that have been degraded in controlled ways (e.g., digital manipulation) and by using conversation-style speech that contains naturally produced ambiguities. Recognition is measured in isolation and in sentences using a variety of tasks whose purpose is to measure the source, magnitude, and time course of ambiguity resolution. I will present an overview of this work in the context of a few experimental settings, highlighting methodological issues along the way. Together, the findings suggest that word recognition is a highly fluid process that depends on the rapid integration of multiple sources of information.

10:05—10:20 Break

10:20

3aSC5. Investigating whether ease of lexical processing affects listeners' ratings of the strength of talkers' foreign accent. Amee Shah (Dept. of Health Sci., Cleveland State Univ., 2121 Euclid Ave., MC 429, Cleveland, OH 44115) and Conor McLennan (Dept. of Psych., Cleveland State Univ., 2121 Euclid Ave., CB 175, Cleveland, OH 44115)

Many research studies in spoken word recognition have examined the role that different types of surface variability have on listeners' perception of spoken words (e.g., influence of same versus different talker manipulations). In our ongoing research program, we are investigating the other direction of this relationship. Our initial two experiments investigated whether linguistic complexity affects listeners' overt subjective impressions of the strength of talkers' foreign accents. Ease of lexical processing was manipulated in two ways, namely, sentence context and long-term repetition priming. In the sentence context experiment, participants made accent ratings on the last word of each sentence presented to them; this word was either related or unrelated to the sentence context. In the long-term repetition priming experiment, participants made their accent ratings to isolated spoken words, which they either had (primed) or had not (unprimed) heard earlier in the experiment. Stronger accent ratings in the unrelated sentence context and unprimed conditions were predicted. Response time to provide their accent rating responses to sentence context and priming manipulations was also studied. Our results should lead to a greater understanding of the role that lexical processing plays in listeners' perception of foreign accents and perhaps other types of surface variability.

10:50

3aSC6. Interactive processing in speech perception: The facts of feedback. Daniel Mirman (Moss Rehabilitation Res. Inst., 1200 W. Tabor Rd., Philadelphia, PA, 19141)

Context plays a critical role in human speech processing. Rapid, efficient integration of context and input is accomplished by interactive processing: bottom-up input information and top-down context information work together to constrain the percept. One domain where this is most clear is the effects of word context on perception of speech sounds. Behavioral experiments and computational model simulations show that interactive processing confers both benefits (robust perception in noisy environments and tuning in response to changes in input patterns) and costs (errors and delays in perception when the input is inconsistent with the context). Context effects are also prevalent is the constraining effect of global communication context on activation of different meanings of ambiguous words (i.e., homophones): when only highly imageable meanings are consistent with the context (a word-to-picture matching task), concrete noun meanings (e.g., the tree-related meaning of bark) become more activate than less imageable meanings (e.g., the dog-related meaning of bark). These findings are consistent with an interactive graded constraint satisfaction view of speech perception in which bottom-up input and top-down context simultaneously constrain the final percept.

11:20—12:00 Panel Discussion

Session 3pAA

Architectural Acoustics and Noise: Primary and Secondary School Special Function Spaces II

Robert C. Coffeen, Chair
Univ. of Kansas, School of Architecture and Urban Design, Lawrence, KS 66045

Invited Papers

1:00

3pAA1. Acoustical design of special purpose rooms in schools: Cafeterias and cafetoriums. Gary W. Siebein (Univ. of Florida School of Architecture, P.O. Box 115702, Gainesville, FL 32611), Hyun Paek, Chris P. Jones, and Reece Skelton (Siebein Assoc., Inc., Gainesville, FL 32611)

Design strategies for cafeterias and cafetoriums in elementary, middle, and high schools based on an impulse response-based theory are presented through a series of case studies of existing, renovated, and designed rooms. The strategies include use of sound absorbing materials to control noise build-up for dining areas; integrated design of stage, canopy, shells (where used), and sound reinforcement systems to project sounds to the audience in a multi-use situation; controlling room volume and absorption to allow early sound reflections for clear hearing; providing for clear verbal communication between teachers and students with the audience; and limiting background and intruding noise levels. The impulse response-based measures are reduced to a series of architectural systems that can be implemented using alternate construction systems to meet budget requirements. Standard design concept sketches communicate the intent of the acoustical design to architects, school board members, design builders, and music faculty.

1:20

3pAA2. A new sound system in a reverberant high school gymnasium. Shane J. Kanter, Stephanie L. Hoeman, and Robert C. Coffeen (Dept. of Architecture, School of Architecture, Design and Planning, Univ. of Kansas, 1465 Jayhawk Blvd., Lawrence, KS 66045, shanekanter@gmail.com)

A new and well designed sound system was recently installed in a very reverberant high school gymnasium. While the new sound system performs much better than the previous system, would its performance be significantly better if the gymnasium reverberation time and undesirable sound reflections were properly controlled? This situation is investigated with binaural audio recordings of the new sound system with the existing room acoustics and by computer modeling and computer auralization with existing acoustical conditions and with improved room acoustics.

1:40

3pAA3. Design constraints and opportunites of two similar-function auditoria. Robert Lee and Andrew Miller (BAi, LLC, 4006 Speedway, Austin, TX 78751, robert@baiaustin.com)

Two high school auditoria are examined, one new construction and one renovation. The multi-purpose uses, size, and scope of both rooms are very similar, but they demanded very different design approaches due to the varying constraints and opportunities presented by the site, the owner, the existing building, and other factors.

2:00

3pAA4. Case studies: Auditorium, gymnasium, and gymnatorium. David S. Woolworth (Oxford Acoust., Inc., 356 CR 102, Oxford, MS 38655, dave@oxfordacoustics.com)

Three case studies of multipurpose rooms in schools with restricted budget. Areas covered include considerations with regard to function, re-use of materials, acoustic treatments fit under the school board's scope, hearing impaired provisions, noise issues, and electroacoustic design.

Session 3pAB

Animal Bioacoustics: General Topics in Animal Bioacoustics (Poster Session)

Peter Marvit, Cochair
Univ. of Maryland, Dept. of Psychology, College Park, MD 20742

Susan E. Parks, Cochair
Pennslyvania State Univ., Applied Research Lab., P.O. Box 30, State College, PA 16804-0030

Contributed Papers

All posters will be on display from 1:00 p.m. to 3:00 p.m. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 1:00 p.m. to 2:00 p.m. and contributors of even-numbered papers will be at their posters from 2:00 p.m. to 3:00 p.m.

3pAB1. Acoustic changes in the vocal signals of grasshopper sparrows, *Ammodramus savannarum*, during early development. Bernard Lohr and Lacey Laudick (Dept. of Biological Sci., Univ. of Maryland Baltimore County, Baltimore, MD 21250)

Grasshopper sparrows produce unusually high-pitched vocalizations for birds, with fundamental frequencies of species typical songs in the range of 7–9 kHz. The characteristics of vocalizations produced early in life, however, are relatively understudied in this and related species. In this study, the development of vocal signal structure and vocal behavior in grasshopper sparrows was investigated in the field immediately after birds hatched. Acoustic characteristics of nestling begging calls were measured throughout the course of the 8–9-day nestling period. Starting at day 6 post-hatch, nestling calls changed qualitatively, incorporating frequency-modulated elements that resembled some parts of the adult vocalizations. With increased nestling age, there was also an increase in the average duration, average acoustic frequency (pitch), and average amplitude of nestling calls. Overall, our results showed that the complexity of nestling vocal signals increased during early development, with vocalizations exhibiting some adult-like properties by the end of the nestling period.

3pAB2. Echolocation of moving objects by using the frequency modulated sound. Ikuo Matsuo (Dept. of Information Sci., Tohoku Gakuin Univ., 2-1-1 Tenjinzawa, Izumi-ku, Sendai, Miyagi 981-3193, Japan and Bio-Navigation Ctr., Doshisha Univ., 1-3 Miyakodani, Tatara, Kyotanabe, Kyoto 610-0321, Japan, matsuo@cs.tohoku-gakuin.ac.jp)

Using the echolocation, bats can capture moving objects in real three-dimensional space. Bats emit the frequency modulation sound and can identify objects with an accuracy of less than a millimeter. To determine delay times of multiple objects requires estimating the sequence of delay separations by extracting temporal changes in the interference pattern of the echoes. The models have been previously proposed to determine delay times of multiple objects by using the frequency modulation sound. In order to extract the temporal changes, Gaussian chirplets with a carrier frequency compatible with emission sweep rates were used and each delay time was estimated by using the temporal changes. It was examined that this model could estimate each delay time within the accuracy less than 1 mm in the case of measuring echoes from fixed objects. In this paper, the echoes were measured from moving objects, and it was examined that this model could estimate each delay times of these objects.

3pAB3. Auditory brainstem response in the lesser scaup (*Aythya affinis*), a species of diving duck. Sara C. Therrien, Catherine E. Carr (Dept. of Biology, Univ. of Maryland, College Park, MD 20742, therrien@umd.edu), Elizabeth F. Brittan-Powell (Univ. of Maryland, College Park, MD 20742), and Alicia M. Wells-Berlin (Patuxent Wildlife Ctr., Laurel, MD 20708)

The auditory brainstem response (ABR) is an effective approach to describing auditory sensitivity in a variety of animals. In this investigation, we used the ABR to estimate the auditory sensitivity of a species of diving duck, the lesser scaup (*Aythya affinis*). The typical lesser scaup ABR waveform showed two to three prominent peaks that occurred within the first 5 ms after onset of the stimulus. Peak amplitude increased and peak latency decreased with increasing stimulus sound pressure level (SPL). Threshold was defined as 2.5 dB below the lowest SPL that evoked a visual response (visual detection method). The best range of hearing for this species was from 500 to 5000 Hz, with sensitivity peaking between 1500 and 3000 Hz. Both the waveform morphology and response characteristics of the peaks to changing stimulus intensity are similar to those found in other avian species, such as screech owls (*Megascops asio*) and budgerigars (*Melopsittacus undulatus*).

3pAB4. Texture discrimination by echolocation in the big brown bat. Ben Falk (Neurosci. and Cognit. Sci. 1147 Bio/Psych Bldg., Univ. of MD, College Park, MD 20742, bfalk@umd.edu), Murat Aytekin, and Cynthia, F. Moss (Univ. of Maryland, College Park, MD 20742)

Echolocating bats emit high-frequency vocalizations and listen to the returning echoes to sense their environment. Echolocation transforms the physical environment into acoustic energy which bats use for navigation and prey capture. This study examined the capabilities of the big brown bat, *Eptesicus fuscus*, to identify and discriminate textured objects. The bat was trained to discriminate a smooth object from a textured object, both spherical, ~ 15 mm diameter, and tethered to the ceiling in a large flight room. The bat was free to fly and investigate the objects before making its decision (signaled by tapping one of the objects in flight − correct=smooth). The bat's discrimination performance was measured with a series of textured objects. Quantification of texture was made through acoustic recordings of the objects. High-speed video recordings allowed a reconstruction of the bat's three-dimensional flight path, full bandwidth ultrasound-sensitive microphones allowed recordings of the bat's sonar emissions, and an array of microphones positioned around the flight room allowed a reconstruction of the bat's sonar beam pattern. The relationship between the bat's performance and the acoustic recordings of the stimuli was examined. How the bat's motor behaviors contribute to its discrimination performance was investigated. [Work supported by NSF(REU), NIMH(R01MH056366.]

3pAB5. Repertoire and possible functions of social calls in foraging big brown bats (*Eptesicus fuscus*). Genevieve S. Wright (Dept. of Biology, Univ. of Maryland, College Park, MD 20742, gspanjer@umd.edu), Chen Chiu, and Cynthia F. Moss (Univ. of Maryland, College Park, MD 20742)

While the echolocation calls of big brown bats (*Eptesicus fuscus*) have been studied extensively, this species' communicative vocalizations have received little attention. Calls were recorded from pairs of bats flying in a laboratory flight room in a foraging context. Pairs consisted of naive bats flown with individuals that were either experienced about how to take a tethered insect or naive or of two experienced bats flying together. This situation elicited a variety of vocalizations with properties different from typical *E. fuscus* echolocation calls. Seven different call shapes that occurred only

when two bats were present were identified and categorized. These included chirp-like calls, rising frequency calls, calls that were longer than 20 ms in duration, and series of ultrasonic, chirp-like calls (or "songs") produced only by male bats and displaying individual variation. Some call types were only recorded when a juvenile was present or very rarely in adult-only pairs. Using high-speed video data collected in synchrony with the audio recordings, the contexts and possible functions of various calls are evaluated. The rate at which different call types were recorded with regard to bats' knowledge of the foraging task and the age and sex of bats flown together is also considered.

3pAB6. Behavioral sensitivity to interaural difference cues in the budgerigar (*Melopsittacus undulatus*). Thomas E. Welch, Kristen Garcia, and Micheal L. Dent (Dept. of Psych., Univeristy at Buffalo, SUNY, Buffalo, NY 14260)

Interaural time and level differences cues (ITDs and ILDs) allow organisms to localize sounds and detect and discriminate signals in noise. Behavioral sensitivity to these important cues has only been studied in humans and a few species of animals. Although the abilities of budgerigars to localize, detect, and discriminate a variety of sounds in quiet or noisy conditions are well known, this is the first study to equip birds with headphones so that their sensitivity to ITDs and ILDs can be measured using lateralization procedures. In one experiment, thresholds are measured behaviorally in budgerigars using pure tones (0.5–8 kHz) and broad-band noise as stimuli in a two-alternative (left-right) identification task. In another experiment, sensitivity to changes in ITDs and ILDs of binaural sounds within a repeating background (discrimination task) is measured using the same stimuli as the first experiment. Budgerigars appear to be less sensitive than humans to both ITDs and ILDs, but similar to cats and monkeys. Overall, these lateralization results are generally consistent with the free-field localization abilities of these birds, but their relatively acute sensitivity to interaural difference cues adds support to the idea that budgerigars may be using their connected interaural pathways to enhance directional hearing.

3pAB7. The effects of frequency content on auditory streaming in budgerigars and zebra finches. Kristen A. Garcia (Dept. of Psych., Univ. at Buffalo-SUNY, Buffalo, NY 14260, kgarcia@buffalo.edu), Siddharth Rajaram, Kamal Sen, Barbara G. Shinn-Cunningham (Boston Univ., Boston, MA 02215), and Micheal L. Dent (Univ. at Buffalo-SUNY, Buffalo, NY 14260)

Auditory streaming is a phenomenon that has been documented in a wide variety of animal species. Recently, space, intensity, time, and spectral composition were all found to be important factors for auditory streaming of birdsong by budgerigars and zebra finches, although the cues varied in importance. Those experiments were extended here to further examine the role of frequency characteristics on the auditory streaming of birdsong. The birds were initially trained using operant conditioning procedures to differentially peck keys in response to either a synthetic zebra finch song consisting of five syllables (whole song) or to the same song with the fourth syllable omitted (broken song). Correct responses were reinforced with millet, and incorrect responses were punished with a lights-off timeout period. Once the birds reached high-performance levels with the training stimuli, probe trials were inserted on a small portion of all trials. The probe stimuli contained either a white noise burst in the missing syllable's location or narrowband pieces of the original fourth syllable. Results show that the different cues are differentially effective in eliciting streaming of birdsong by zebra finches and budgerigars, similar to the previous experiments and results from human speech experiments.

3pAB8. Vocal behavior of North Atlantic humpback whales during reunion events on Stellwagen Bank. Kaitlin Palmer (Graduate Program in Acoust., 201 Appl. Sci. Bldg., University Park, PA 16802, kjp205@psu.edu), Susan E. Parks (Penn State Univ., State College, PA 16804-0030), David Wiley (Stellwagen Bank Natl. Marine Sanctuary, Scituate, MA 02066), Mason Weinrich , Jennifer Tackaberry (Whale Ctr. of New England, Gloucester MA 01931-0159), Alessandro Bocconcelli (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543-1050), and Ari Friedlaender (Duke Univ., Beaufort, NC 28516)

Humpback whales on their feeding grounds are typically found in small, ephemeral groups which have been hypothesized to form and separate to maximize foraging efficiency, but little is known about the functional mechanisms by which these groups change their composition. In this study, we test the hypothesis that specific vocalization types are associated with events where two or more individual humpback whales join to form a cohesive group on their summer feeding grounds. In the summer of 2008, 11 Dtags (a combined acoustic and movement recording tag) were attached to individual humpback whales on their feeding grounds in the Stellwagen Bank National Marine Sanctuary. Behavioral observations were collected from tagged animals at the surface and the timing of join events were recorded. Calls from the tagged whale and nearby associates were identified and analyzed to test for call rate changes between 10 min periods around joining events and 10 min control periods. Additional analyses included call type usage during joining events. Our results indicate a trend toward increased call rates during join events when compared to randomly selected control periods, with evidence of differential usage of specific call types during join events.

3pAB9. Measurement of Copepodid and Nauplii populations in the Golfo della Biodola using inverse acoustic methods. John Fornshell (NATO Undersea Res. Ctr., Viale San Bartolomeo 400, La Spezia 19126, Italy)

Acoustic observations and simultaneous collection of plankton were made in the Gulf of Biodola on the northern coast of the Island of Elba, Italy. The fieldwork was conducted on the 10th and 11th of October 2009 on the R/V LEONARDO. The acoustic measurements were made using the autonomous underwater vehicle, MUSCLE, at a working frequency of 300 kHz. Plankton samples were also collected simultaneously with a 1/4 m Nansen net with a 20 mm mesh size. The acoustic data were processed by scientists at the NATO Undersea Research Center and provided to the author. The waters of the southern Ligurian sea on this coast are exceptionally clear with very low plankton population densities. The plankton were sorted, identified, and enumerated at the National Museum of Natural History, Smithsonian Institution. It is assumed in this study that the volume back-scatter can be attributed to the plankton in the water column. The numbers in the net samples are compared with the values from the inverse acoustic methods.

3pAB10. Discovery of sound in the sea: An on-line resource. Kathleen J. Vigness-Raposa (Marine Acoust., Inc., 809 Aquidneck Ave., Middletown, RI 02842, kathleen.vigness@marineacoustics.com), Gail Scowcroft, Christopher Knowlton, and Holly Morin (Univ. of Rhode Island, Narragansett, RI 02882)

The scientific community and the public have become increasingly aware of, and concerned about, underwater sound. There is increasing interest in learning about sources and uses of sound, and potential effects of sound on the environment. Underlying this interest, however, is a need to provide scientific information at a level appropriate for the general public and for educational and media professionals. The discovery of sound in the sea website (http://www.dosits.org) provides scientific content introducing the physical science of underwater sound and how people and animals use sound to accomplish various tasks. It also includes three major resource sections. The Media Resources include a Facts & Myths quiz, Frequently Asked Questions, and PDF reprints of a tri-fold pamphlet and a 12-page educational brochure. The Teacher and Student Resources include structured tutorials and educational games. DOSITS recently launched a significantly redesigned site. The look and feel have been refreshed without losing functionality and content. The redesign includes an interactive front page, an interactive Audio Gallery, and a redesigned Scientist Gallery. DOSITS provides easy, efficient access to timely information on the science of underwater sound and the current state of knowledge of the effects of underwater sound on marine mammals and fishes.

3pAB11. Lake bottom forward scattering measurement and model/data comparison. Jinrong Wu and Li Ma (Inst. of Acoust., Chinese Acad. of Sci., No. 21, BeiSiHuan XiLu, Beijing, 100190, China, ymwjr@yahoo.com.cn)

The lake bottom scattering function depends, in general, on the grazing angles and the azimuthal angles of the incident and scattered energy. However, most measurements were for backscatter only. Little was understood about forward bottom scattering in shallow water. In order to address this issue, an experiment was conducted in Qiandao Lake using 16 element ver-

tical array and 8 element horizontal array. The measurement result indicated that there was relatively strong scattering in the forward direction near the specularly reflected ray, while the scattering was much weaker and relatively isotropic away from the specular ray. The Ellis and Crowe's three-dimensional scattering function was used to predict the forward scattered energy. Comparsion between model and measured data has shown that the model can explain the lake bottom scattering well, and the frequency dependence of bottom scattering function from 5 to 9 kHz can be neglected. [Work supported by the NSFC.]

3pAB12. Analyzing acoustic scenes in reverberant environments: A bird study. Sandra H. Blumenrath and Robert J. Dooling (Dept. of Biology & Psych., Univ. of Maryland, College Park, MD, shb@umd.edu)

In reverberant environments, the auditory system processes complex signals that are distorted and overlapped by tails of echoes of preceding sounds. These reverberation effects can be used to discriminate between different types of acoustic environments and to locate a sound source, but it also limits the transfer of biologically important information. To examine the positive impact of reverberation on acoustic scene analysis, we used psychophysical methods to test the ability of canaries, zebra finches, and budgerigars to discriminate between reverberation differences. Negative effects were investigated by asking whether birds can segregate reverberated songs from multiple individuals despite degraded auditory grouping cues. Birds were able to hear small changes in reverberation, although this ability was somewhat dependent on both the species and, in particular, the type of signal. Species-specific vocalizations as well as broadband signals posed the smallest difficulty. Interestingly, the non-oscine, flock-living budgerigar outperformed the other two oscine species. Moreover, birds were less able to "hear out" a target song among a cacophony of other songs when all vocalizations were reverberated. The results suggest both positive and negative impact of reverberant environments on the perception of vocal signals and the analysis of complex acoustic scenes in the tested species.

3pID1. Data-based speech synthesis: Progress and challenges. H. Timothy Bunnell (Ctr. for Pediatric Auditory and Speech Sci., Nemours Biomedical Res., 1600 Rockland Rd., Wilmington, DE 19803, bunnell@asel.udel.edu) and Ann K. Syrdal (AT&T Labs.-Res., Florham Park, NJ 07932)

In contrast to knowledge-based techniques such as articulatory or rule-based formant synthesis, data-based approaches to speech synthesis derive synthetic voices from a corpus of recorded human speech. Current "unit selection" data-based systems can produce synthetic utterances that rival human speech in intelligibility and naturalness by concatenating units of various sizes derived from large searchable corpora of speech aligned with tags that capture a rich set of segmental and prosodic features assigned to phonemic or subphonemic units. Emerging data-based techniques use machine learning algorithms to derive parameters automatically for parametric speech synthesis. Whatever the approach, because the extensive corpus of speech data used to construct most modern data-based systems is obtained from an individual talker, the synthetic output of the system captures much of the vocal identity of that individual. This latter feature has opened up new areas of application, such as personalized synthetic voices and "voice banking" for patients who might lose the ability to speak. This talk will trace the development of current data-based approaches, describe applications of this synthesis technology, and discuss some of the major challenges driving current research efforts. [Some work supported by NIDCD Grant R42-DC006193.]

1:20

3pID2. Hot topics in structural acoustics. Dean E. Capone (Appl. Res. Lab., Penn State Univ., State College PA 16804) and Matthew S. Allen (Univ. of Wisconsin-Madison)

In this paper, an overview of the many opportunities and new research focus areas that are hot topics within the structural acoustics community in the Society will be presented. The talk will discuss the topics within the general categories of computational, analytical, and experimental structural acoustics. In particular, numerical methods in structural acoustics are receiving considerable attention, and a variety of proposed new approaches to structural acoustic computational modeling will be reviewed.

1:40

3pID3. Hot topics in musical acoustics. Thomas D. Rossing (CCRMA, Stanford Univ., Stanford, CA 94305, rossing@ccrma.stanford.edu) and James P. Cottingham (Coe College, Cedar Rapids, IA 52404)

Musical acoustics deals with the production, transmission, and perception of musical sound, as well as the scientific study of musical performance. It interfaces with physics, music, psychology, engineering, architecture, audio engineering, and neurology, and it is often at these interfaces that some of the hottest topics occur. For example, functional magnetic resonance imaging (fMRI) and electro- and magneto-encephalography (MEG and EEG) have made it possible to study music and the brain and to localize neural processing of musical activity. Digital computers have made it possible to synthesize musical sound with every increasing refinement using such

methods as physical modeling, waveguide models, and commuted synthesis. Systems for real-time, high-quality, and low-latency audio over the internet have made it possible for performers at distant locations to play in concert. New acoustical musical instruments, as well as modifications of existing instruments, enrich musical performance, while new performing groups such as laptop and cellphone orchestras appear at many universities.

3pNS1. Speech intelligibility of air conducted and bone conducted speech over radio transmission. Phuong Tran and Thomas Letowski (U.S. Army Res. Lab., 520 Mulberry Point Rd., Aberdeen Proving Ground, MD 21005, ptran@arl.army.mil)

Personal radio-communication devices are traditionally used with built-in or external air conduction microphones. Recently, there have been some efforts to use bone conduction microphones mounted on the operator's head as a replacement for external air microphones. The goal of this study was to compare the intelligibility of speech transmitted through a boom-type noise-cancelling air microphone and a bone microphone using Thales multiband inter-intra-team radios. Eight participants were divided into four pairs with each participant serving as both a talker and a listener. The Callsign Acquisition Test was used to collect speech intelligibility data with the talker in quiet and in 100 dB(A) noise. The listener was always located in a quiet environment. Both types of microphones resulted in speech intelligibility scores ranging from 100% to 94% in quiet and from 100% to 90% in noise condition. There was no statistically significant difference in speech intelligibility between the two types of microphones. The advantages and disadvantages of using bone microphones under various civilian and military conditions are discussed.

1:15

3pNS2. Glass breakage by blasts: A prediction model and real-world validation. Louis C. Sutherland (LCS-Acoust., 27803 Longhill Dr., Rancho Palos Verdes, CA 90275-3908)

The structural elements most sensitive to blast damage are usually windows. A classic paper by Hershey *et al.* [J. Acoust. Soc. Am. **55**, 1009–1017 (1974)] developed a powerful statistical model for damage to windows from impulsive (sonic boom) pressure loads. The key part of the model depended on both the pressure load and failure stress having a log normal distribution; that is, the log of these variables was normally distributed. This basic concept, applied by the author in several studies on blast and sonic boom damage, is briefly reviewed here for application to blast damage to windows. Validation of the model is provided by data from an accidental explosion of an equivalent 20 lbs of TNT near a nearby nine-building apartment complex. 58 windows were broken, fortunately without any injuries. The predicted damage was augmented by results of a model study of diffraction around a cubical obstacle to approximate the changes in the net pressure loading on the apartment building windows located at various orientations to the blast wave front. The predicted window breakage rate, varying from 0.5% to 61% compared well with the observed values in the range of 0–64%. [Work supported by Wyle Labs.]

1:30

3pNS3. Assessing attitudes toward military blast noise. Edward T. Nykaza (Construction Eng. Res. Lab., U.S. Army Corps of Engineers, 2902 Newmark Dr., Champaign, IL 61822, edward.t.nykaza@usace.army.mil), Kathleen Hodgdon (Penn State Univ., State College, PA 16804-0030), George Luz (Luz and Assoc., Baltimore, MD 21212), and Peg Krecker (PA Consulting Group, Madison, WI 53719)

Existing impact assessment procedures for large weapon noise or blast noise do not fully meet the military's noise management needs. Military noise impacts currently are assessed in terms of the response metric annoyance as predicted by a long-term average noise level metric. This method has proven to be unsatisfactory for impulsive military noise. As a result, ERDC-CERL and SERDP have launched a series of field studies to enhance the understanding of human response to military blast noise. An overview of the four research protocols employed in this project will be presented, and the most recent findings from a qualitative personal interview study and a complaint and annoyance comparison study will be given. The preliminary results indicate that residents living near military installations adapt to the basic noise environment over time, notice unusually large noise events or events that produce house vibrations, and indicate that those who file complaints are significantly more annoyed on average than their neighbors who were exposed to a similar noise environment. All findings in this project thus far indicate that the number, timing, and level of discrete blast events are important for predicting the human response to blast noise.

1:45

3pNS4. Analysis of animal blast overpressure study data to compare current impulse noise criteria and propose some new criteria. Steve Goley, Wonjoon Song, Jay Kim (Dept. of Mech. Eng., Univ. of Cincinnati, Cincinnati, OH 45221-0072, steve.goley@gmail.com), and William J. Murphy (CDC/NIOSH Hearing Loss Prevention Team, Cincinnati, OH 45226, wjm4@cdc.gov)

The effects of high-intensity impulsive noise on the auditory system are complex and difficult to quantify in a simple criterion. Several impulse noise criteria (e.g., MIL-STD 1474D, Pfander, Smoorenburg, LAeq8hr, and a model-based method called AHAAH) are studied for their analytic structure to understand their underlying basic assumptions. Then, these criteria are compared for their performances based on animal blast overpressure data obtained from 905 chinchillas exposed to 137 exposure conditions. The noise exposures consisted of different impulse sources, peak levels, number of impulses with various temporal spacing, and presentations in reverberant and non-reverberant conditions. The noise data are analyzed using the analytic wavelet transform to study their time-frequency structures in relation to patterns of measured auditory damage of chinchillas. Based on these studies, a few new metrics are proposed by taking advantage of capabilities of the advanced signal analysis tool. The statistical correlations of the new metrics with the chinchillas' observed auditory damage are compared with the MIL-STD 1474D, Pfander, Smoorenburg, LAeq8hr, and the AHAAH model damage risk criteria. Possibility of developing a new impulse noise standard according to the approach adopted in this study as well as remaining challenges are discussed.

Invited Papers

12:45

3pPA1. Field experiment on vibration and acoustic responses of building to sonic booms using impulsive sound source. Yusuke Naka (Supersonic Transport Team, Japan Aerosp. Exploration Agency, 6-13-1 Osawa, Mitaka, Tokyo 181-0015, Japan, naka.yusuke@jaxa.jp), Tetsuya Doi, and Jiro Kaku (Kobayashi Inst. of Physical Res., Kokubunji, Tokyo 185-0022, Japan)

Annoyance related to sonic boom is believed to be enhanced in indoor spaces by vibration of building walls, window rattles, room acoustic effects, and so forth. For investigating such vibration and acoustic effects of sonic booms in buildings, both laboratory and field experiments have been conducted. Although propagation of sonic booms in space and relative phenomena such as diffraction around a building can be reproduced in field experiments, it is sometimes not straightforward to generate sounds similar to sonic booms in open space. In this study, an easy-to-handle, portable device suitable for simulating sonic booms in field experiments is developed. A device developed by some of the authors to generate impulsive sound with fair level of infrasonic components by using compressed air is modified to simulate the negative overpressure of sonic booms. The improved device is used in a field experiment to investigate vibration and acoustic responses of a small house. Results of this preliminary experiment will be reported.

1:05

3pPA2. Rattle laboratory testing of windows exposed to sonic boom excitation. Natalia V. Sizov and Christopher M. Hobbs (241 18th St., Ste. 701, Arlington, VA)

One of the major factors contributing to the annoyance indoor listeners experiencing sonic booms is window rattle. In earlier work the authors experimentally obtained a data set of responses of a large number of different window types installed in residential houses. Several of the windows studied were removed intact from tested houses and brought to a laboratory facility for further testing. They were affixed to a massive upright stand that simulated the house wall. These windows were acoustically excited using the same portable sonic boom simulator as in the *in-situ* tests. The results collected during the laboratory testing showed that rattle sources depend on window construction. Main rattle mechanisms were identified. Based on the knowledge gathered, a semi-empirical rattle model was developed defining the key parameters. Vibrational response of the window subjected to sonic boom excitation was modeled as a single degree of freedom system. The ratio between window element velocity and rattle-radiated sound pressure was obtained experimentally for the laboratory tested windows. The rattle-radiated sound level in the laboratory was compared with sound pressure levels received in front of house window exposed to typical and to low booms during NASA supersonic flight testing in 2007. [Work supported by NASA.]

3pPA3. Human response to sonic booms and rattle heard indoors. Alexandra Loubeau, Jacob Klos, Jonathan Rathsam (NASA Langley Res. Ctr., MS 463, Hampton, VA 23681, a.loubeau@nasa.gov), Brenda M. Sullivan (Lockheed Martin, NASA Langley Res. Ctr., Hampton, VA 23681), and Joseph R. Gavin (Gulfstream Aerosp. Corp., Savannah, GA 31408)

Human response to sonic booms heard indoors is affected by the generation of contact-induced rattle noise. The effect of sonic boom-induced rattle noise was studied in a series of psychoacoustics tests. In order to remove the effects of loudness, sounds were equalized to the same perceived level (PL) in each test. Stimuli were divided into three categories and presented in three different studies: isolated rattles at the same calculated PL, sonic booms combined with rattles at the same calculated PL, and sonic booms combined with rattles at three different PL. The sonic booms, both measured and synthesized, were filtered to simulate presentation inside structures with different transmission and reverberation properties. The rattle sounds due to sonic booms or mechanical loading were recorded in a residential home. Subjects listened to sounds over headphones and were asked to judge the level of annoyance of other factors, depending on the test. Annoyance to different rattles is shown to vary, and the combination of sonic booms and rattles can be more annoying than the sonic boom alone. These results show that the PL metric does not fully represent human annoyance to the selected indoor sonic boom and rattle sounds.

1:45

3pPA4. An examination of repeatability in physiological responses to simulated low amplitude sonic booms of various peak levels and rise times. Andrew Marshall and Patricia Davies (Purdue Univ., 140 S. Martin Jischke Dr., West Lafayette, IN 47907-2031, aimarsha@purdue.edu)

Findings from recent low-level sonic boom studies have shown that people's evaluations of startle could not be explained by loudness only and the startle evaluations were correlated strongly with evaluations of annoyance. A pilot study was conducted to examine how changes in physiological responses (skin conductance, pulse rate, and EMG) compared with subjective ratings startle. Analysis of this data was difficult because the intervals between stimuli were not long enough for some of the physiological measures to return to baseline before the next stimulus exposure. In addition, repeatability of responses was difficult to measure because of the complexity of the test which involved the subject doing several tasks while being exposed to the sounds. To examine what level of physiological response repeatability can be expected in these sonic boom experiments, another test was conducted in which subjects were exposed to simulated sonic booms. The interval required between boom exposures necessary to return to baseline was also examined. To examine the day-to-day repeatability of these measures, each subject completed several sessions on separate days. The variations in physiological responses within and between subjects will be described along with the trends observed related to signal characteristics.

2:05

3pPA5. Assessing sonic boom responses to changes in listening environment, signature type, and testing methodology. Denise M. Miller and Victor W. Sparrow (Graduate Program in Acoust., Penn State Univ., 201 Appl. Sci. Bldg., University Park, PA 16802, dmm503@psu.edu)

The aim of this research was to investigate human response to low-amplitude sonic booms, specifically focusing on listening environment, character variation in sonic boom signatures, and subjective test methods. Two tests were conducted in which subjects rated annoyance of numerous low-amplitude sonic booms using magnitude estimation and categorical line scaling methods. One test utilized Gulfstream Aerospace Corporation's Supersonic Acoustic Signature Simulator (SASSII), while the other was conducted in typical office and outdoor patio settings using a headphone playback system. The test stimuli consisted of indoor and outdoor recordings of low-amplitude sonic booms recorded by NASA researchers during flight tests at Edwards Air Force Base. The results include a comparison of subjective methods as well as the effect of listening environment on human annoyance of low-amplitude sonic booms. [Work sponsored by the NSF and the PARTNER Center of Excellence.]

Contributed Papers

2:25

3pPA6. Output-only modal testing of simple residential structures and acoustic cavities using the response to simulated sonic booms and ambient excitation. Joseph Corcoran, Ryan Haac, Marcel Remillieux, Ricardo Burdisso (Dept. of Mech. Eng., Vibs and Acoust. Labs., Virginia Tech, Blacksburg, VA 24061, jmc82@vt.edu), and Georg Reichard (Virginia Tech, Blacksburg, VA 24061)

Structural modal properties of single-room and two-room rectangular structures built with typical residential construction are extracted using only the vibration responses to (1) a sonic boom simulated with a linear distribution of detonating cord and (2) ambient excitation. Then, the acoustic modal properties of the cavities enclosed by the residential structures are extracted using the pressure responses to the same two types of excitation. The technique involves cross-correlating the responses measured at many points to the responses at a few different reference points on the structure or in the cavity. This allows for the calculation of impulse responses at many points around the structure or cavity due to excitation at the reference points. Structural natural frequencies, modal damping ratios, and mode shapes obtained from the output-only analyses are presented and compared to the results from conventional impact hammer modal testing and from a finite element model, demonstrating good agreement. Acoustic natural frequencies and modal damping ratios extracted in the output-only analyses are presented and compared with room pressure spectra measurements made with speaker noise excitation and analytically calculated results for the single room and the two room configurations, also showing good agreement between analyses. [Work supported by NASA Langley.]

2:40

3pPA7. Structural response to low-amplitude sonic booms. Joseph Gavin (Gulfstream Aerosp., 32 Lummus Dr., Savannah, GA 31408, joseph.gavin@gulfstream.com), Jacob Klos, Alexandra Loubeau (NASA Langley Res. Ctr., Hampton, VA., 23681), and Brenda Sullivan (Lockheed Martin, NASA Langley Res. Ctr., Hampton, VA., 23681)

Two highly instrumented homes have been ensonified by low-amplitude sonic booms. The resulting measurements have been analyzed (1) to gain insight to the dominant physical acoustics associated with sonic booms heard indoors and (2) to rank order the mechanisms needed for high-quality auralizations. The mechanisms turn out to be both clear and elegant. Diffraction loading on the exterior surface is as expected with an enhancement around on the incident side of the home and a strong shadow zone at higher non-dimensional frequencies. The resulting pressure loading induces modal vibration of the walls, ceiling, and windows; each of which show their first flexural modes at frequencies below 20 Hz. The walls themselves appear to break up into multi-layered wave bearing structures around 100 Hz, above which the nonlinear contact and sliding mechanisms take on a dominant role in the signature. These insights have been combined to motivate a low-dimensional tool for auralizing the complete audio bandwidth of booms heard indoors.

2:55

3pPA8. Synthesis of sonic boom noise inside structures: An innovative experimental approach. Patricio Ravetta, Ricardo Burdisso, and Nikolas Macko (AVEC, Inc., 3154 State St., Ste. 2230, Blacksburg, VA 24060, pravetta@avec-engineering.com)

Current approaches to evaluate the impact of sonic booms on structures are rather few and limited. In this work, an innovative approach was developed and experimentally validated. It consists in simulating the distributed boom load on the structure using an array of discrete forces. Each discrete point force is the integrated sonic boom pressure loading (from experimental data or a diffraction code) over an area associated with that force. Under the assumption that the structure behaves linearly, each discrete force is applied sequentially and the desired vibro-acoustic responses recorded simultaneously with the applied force. The vibro-acoustic responses due to all forces applied simultaneously (and simulating the sonic boom load) can then be obtained simply as a linear superposition of the individual responses. Since the actual force time history due to the sonic boom does not need to be generated, the approach can be implemented using a shaker or modal hammer. Thus, it is sufficient to measure the transfer function between the input force and the vibro-acoustic response of interest. The vibro-acoustic data are then synthesized using the measured transfer functions and the loading on the structure to estimate the time histories of the forces due to the booms.

3:10

3pPA9. Modification of the nonlinear wave progressive equation model for sonic booms in a stratified atmosphere. B. Edward McDonald (Naval Res. Lab., Washington, DC 20375, mcdonald@sonar.nrl.navy.mil) and Andrew A. Piacsek (Central Washington Univ., Ellensburg, WA 98926)

The nonlinear progressive wave equation (NPE) model [McDonald and Kuperman, J. Acoust. Soc. Am. **81**, 1406 (1987)] is modified to simulate sonic boom physics in a stratified atmosphere using a wave—following window whose dimensions are much less than atmospheric scale heights. (The NPE was originally formulated for time domain weak shock propagation in the ocean, where the ambient density is nearly constant.) This allows simulation of sonic boom propagation in a refracted ray tube in which the ambient density may vary considerably as the simulation window moves along. Energy conservation places a strong constraint on the form of the resulting nonlinear wave equation. Properties of the modified NPE and some illustrative solutions are presented. [Work supported by the Office of Naval Research.]

Session 3pPP

Psychological and Physiological Acoustics: Perception of Sounds in the Natural Environment

Robert A. Lutfi, Chair
Univ. of Wisconsin, Dept. of Communicative Disorders, Madison, WI 53706

Contributed Papers

1:00

3pPP1. A method for including manner of contact in the synthesis of impact sounds for perceptual research. Christophe N. J. Stoelinga and Robert A. Lutfi (Dept. of Communicative Disord., Auditory Behavioral Lab., Univ of Wisconsin, Madison, WI 53706)

Impact sounds synthesized according to a physical model have increasingly become the stimulus of choice in studies of sound source perception. Few studies, however, have incorporated manner of contact in their models because of the many parameters entailed in its description. Based on the work of Zener [Phys. Rev 669–673 (1941)], we show that the seven Hertzian parameters required to completely describe the contact can be reduced to just three: force of contact, duration of contact (t_c) and a non-dimensional parameter (λ). Using only these parameters for the contact, a simplified method is presented to synthesize the impact sounds of simply supported plates. The results of the method are shown to be in good agreement with those of the more comprehensive method of Chaigne and Lambourg [J. Acoust. Soc. Am. 1422–1432 (2001)], the only such method to receive validation through acoustic measurement of plates. Psychometric functions obtained from listeners for the discrimination of t_c and λ also show these parameters to be clearly discriminable over the range for which they would realistically vary. Potential advantages of using the simplified method over more comprehensive methods of sound synthesis in perceptual studies are discussed. [Research supported by NIDCD Grant No. 5R01DC006875-05.]

1:15

3pPP2. Acoustic analysis of perceptual sound categories. Laurie M. Heller (Dept. of Psych., Baker 254p, Carnegie Mellon Univ., Pittsburgh, PA 15213, laurieheller@cmu.edu) and Benjamin Skerritt (Brown Univ., Providence, RI 02912)

Acoustic analyses were conducted on several groups of sound events. The sound events were derived from a combination of physical analyses and perceptual data. The acoustic analyses utilized both low-level properties, such as spectral centroid, and higher-level properties. The higher-level properties were based on a combination of the physical source characteristics of basic classes of sound-generating events, statistical methods, and perceptual characteristics. A range of metrics are used to evaluate the success and generality of these acoustic properties, including classification performance and comparison to other results in the literature. (Work supported by NSF.)

1:30

3pPP3. A perceptive categorization of sounds produced the interaction of solid objects. Olivier Houix, Guillaume Lemaitre, Nicolas Misdariis, Patrick Susini (IRCAM, 1 place Stravinsky, 75004 Paris, France), and Isabel Urdapilleta (Universit Paris VIII, F-93526 Saint-Denis cedex, France)

The literature on the perception of environmental sounds often postulates that these sounds are perceptually organized according to their cause. In a previous study, we found experimental results consistent with this assumption by showing that, in the case of identifiable sounds and non-expert listeners, main categories of liquids, gases, electrical devices, and solids appear. We report here a study specifically exploring this latter category. Participants were required to categorize a set of sounds according to the actions causing the sound and to describe the resulting categories. We analyze the classifications with a specific hierarchal cluster analysis producing two dendrograms. The second dendrogram is used to highlight a possible secondary categorization that may add to the primary categorization. Therefore, this technique allows taking into account the multiple types of similarity that might occur in a categorization task. This statistical analysis of the classifications was complemented by a linguistic analysis of the descriptions of the categories (ALCESTE and LEXICO). This analysis shows two main categories of descriptions: those describing several objects in interaction and those describing modifications of an object. Eventually, we discuss how hierarchical cluster and linguistic analyses complement to provide a portrait of the perceptive categorization of sounds of solids.

2:00

3pPP4. Signal detection as a function of relative acoustic entropy. Christian E. Stilp (Dept. of Psych., Univ. of Wisconsin, 1202 W. Johnson St., Madison, WI 53706, cestilp@wisc.edu), Michael Kiefte (Dalhousie Univ., Halifax, NS B3H 1R2, Canada), and Keith R. Kluender (Univ. of Wisconsin, Madison, WI 53706)

Natural sounds are far from random. Instead, they possess structure that reflects physical constraints on sound-producing objects and events. Listeners likely exploit such structure (predictability and redundancy) when perceiving complex natural sounds. The present experiments investigate listeners' ability to discover and use structure in novel sounds to identify a repeating target sound against a competing background of sounds. Complementary signal-processing strategies independently varied acoustic entropy (complement to redundancy) in frequency or time. Novel sounds were generated by stretching the entropy in a restricted frequency band (instantaneous frequency dilation) or temporal slice (phase vocoding) of pink (1/f) noise across the bandwidth or duration, respectively, of an unstretched noise sample. Listeners matched a probe sound to a target sound (1%, 3.2%, or 10% entropy of pink noise) that repeats amidst distractor sounds (1%, 10%, or 100% entropy) at 0-dB SNR. In separate experiments varying entropy in frequency or time, identification of target sounds de-

pended critically on the difference in entropy across targets and distractors. Listeners were more proficient identifying lower-entropy targets against higher-entropy distractors but not lower-entropy distractors. Similarly, higher-entropy targets were better identified amidst lower-entropy distractors. Potential implications for cochlear implant processing will be discussed. [Work supported by NIDCD.]

3pPP5. How do listeners react to different urban soundscapes? A functional magnetic resonance imaging study of perception and emotion. Deborah Hall (School of Psych., Nottingham Trent Univ., Burton St., Nottingham, United Kingdom, deborah.hall@ntu.ac.uk), Amy Irwin (MRC Inst. of Hearing Res., Univ. Park, Nottingham, United Kingdom), and Christopher Plack (Univ. of Manchester, Manchester, United Kingdom)

This research formed one part of a multi-disciplinary positive soundscapes project investigating the perception of urban sound environments. To determine the neural correlates associated with perceptual and affective responses to such sounds, we have measured ongoing brain activity using functional magnetic resonance imaging. Sixteen participants were scanned while passively listening to a set of recordings made in urban spaces. In total, there were 150 recordings, each containing multiple sound sources. Soundscapes were matched in overall sound level [71 dB(A)] but differed in their ratings of pleasantness along a five-point scale. As expected listening to urban soundscapes evoked a significant response in a number of auditory brain regions (inferior colliculus, medial geniculate body, and auditory cortex). Crucially, those soundscapes evoking a strong emotional response (either pleasant or unpleasant) activated one of the main emotional centres in the brain—the amygdala. The perceived pleasantness of the soundscape also modulated the auditory response to the sounds. Our results confirm that that loudness is not the only factor that determines how people react to urban soundscapes.

3pPP6. Non-intrusive audio notification in emotion classified background music. Ralf Jung (German Res. Ctr. for Artificial Intelligence, Campus D3 2, 66123 Saarbruecken, Germany, ralf.jung@dfki.de)

In human-computer interaction, audio signals are generally used for warnings and acoustic feedback. Especially in environments with many people, such signals often affect intrusively and distractive because of their differentness compared to the natural sound environment. In this paper, a novel audio notification system is presented that provides methods to notify persons individually in multi-user environments. The used audio cues are unnoticeable for others since they can be embedded seamlessly in ambient background music. A novel notification hierarchy with three signal classes is introduced to realize a personalized and a context-aware notification within the background music. For the self-composed background music, perceptual constraints such as auditive Gestalt laws as well as results from musicology were taken into account to influence the listeners perception. A classification model for the emotional expression of non-vocal music is also introduced in this paper. The effectiveness of the novel notification method and the plausibility of the classification model are confirmed by empirical studies. This novel non-intrusive audio notification method let users become aware of individual events while at the same time other present persons will not get distracted by the notification.

3pSA1. Approaches for ultrasonic damage detection in aircraft components for structural health monitoring. Bernhard R. Tittmann (Dept. of Engr. Sci. & Mech., The Pennsylvania State Univ., 212 Earth-Engr. Sci. Bldg., University Park, PA 16802, brt4@psu.edu)

Characterization of flaws is an important goal of ultrasonic NDE in aircraft components, especially to meet the new demands for structural health monitoring to achieve retirement for cause. This presentation describes approaches and results for two classes of damage: (1) impact damage in fiber-reinforced composites and (2) cracks in jet engine components. In the application of impact damage on composites the use of non-contact laser based ultrasound with a NdYAG laser as transmitter and Mach–Zehnder interferometer as receiver was complemented by acoustic microscopy. Results are described for both hard and soft impacts on a variety of composites. In the application of crack detection of jet engine components the main emphasis was on the development for *in-situ* high-temperature piezoelectric sensors. In particular, high temperature operation in excess of 1000 °C is described with sol-gel spray-on coatings, thin AlN films and single crystals of aluminum nitride. Some of the sensors are geared toward wireless retrieval of crack detection in turbine disks and blades. Whereas these approaches in ultrasonic NDE are not routine they hold high promise for near-future applications in the aerospace.

1:50

3pSA2. Sensor network analysis for fatigue crack characterization in the vicinity of fastener holes. Cliff J. Lissenden, Hwanjeong Cho, and Chung Seok Kim (Eng. Sci. and Mech., Penn State, University Park, PA 16802, lissenden@psu.edu)

A network of surface mounted piezoelectric disk transducers is used to detect, locate, and eventually size a growing fatigue crack in an aluminum plate with multiple fastener holes. The results will be used as input to a probabilistic fatigue crack growth model in order to predict structural reliability and remaining useful life. The target application is built-up aircraft wing and fuselage structures. Since the transducers are bonded to the surface and available upon demand, this is structural health monitoring. A tomography algorithm based on *a priori* knowledge that a fatigue crack will initiate near to the centerline of the fastener holes is used to determine at which hole the crack initiated using Lamb wave modes. In that vicinity, both through-transmission and pulse-echo modes are then used to interrogate many guided wave propagation paths. Use of both modes enables evaluation of transmission and reflection coefficients. Training data are acquired from simpler geometries to facilitate characterization of crack length from received signal features. Characterization of fatigue crack size is in progress. The presentation will conclude with a description of the link to probabilistic modeling. [Support from the Ben Franklin Center of Excellence in Structural Health Monitoring is acknowledged.]

3pSA3. Ultrasonic nondestructive characterization of inhomogenieties and stress concentrations in the porous materials. Hasson M. Tavossi (Dept. of Phys., Astronomy & Geosciences, Valdosta State Univ., 1500 N Patterson St.,Valdosta, GA 31698.)

Ultrasonic nondestructive bulk testing of porous materials is difficult to achieve due to the high attenuation of ultrasonic waves in these materials. It is shown experimentally that ultrasonic wave attenuation and pass-band frequencies in the porous materials are some functions of average pore size, when other material parameters are kept constant. In most theoretical effective-media models for the porous materials, pore ratio is included but not their average size. The average pore size has a significant effect on both wave attenuation and pass-band frequencies of the porous materials. The goal of this study is to determine optimal criteria for nondestructive flaw detection in the porous materials. Experimental results are obtained on ultrasonic wave attenuation for different samples, as a function of frequency and the average pore size. Flaws in the form of inhomogenieties and localized stress concentrations are then introduced in the samples and the NDT techniques are applied to detect them. Experiments are performed to identify the type of flaw, size, and location in the porous samples. Data on location and sizing of the inhomogenieties and stress concentration will be presented. Results of this study can be used to determine the most effective ultrasonic NDT techniques for flaw detection in the porous materials.

3pSA4. Locating a small change in a multiple scattering environment (LOCADIF): Application to monitoring concrete. Thomas Planes, Eric Larose (LGIT-CNRS, BP 53, 38041 GRENOBLE Cedex 9, France, thomas.planes@ujf-grenoble.fr), Vincent Rossetto (LPMMC, CNRS, Grenoble, France), and Ludovic Margerin (CEREGE, CNRS, Aix En Provence, France)

Most conventional imaging techniques are operated in single scattering media where the Born approximation is found relevant. In the multiple scattering regime where this approximation does not hold, the wave forgets its initial direction after a few scattering events and we cannot have access to the precise trajectory of the wave. All waves are mixed together in phase, amplitude, and wavevector, which defines the diffuse regime. This paper presents an imaging technique to locate a weak perturbation in a multiple scattering environment. We derive a formula to predict the spatio-temporal decorrelation of diffuse coda waves induced by an extra-scatterer. Locating this new defect is then formulated as an inverse problem which is solved by a maximum likelihood approach. Using elastic waves in the 100–350-kHz frequency band, we show that the position of a millimetric hole drilled in a heterogeneous concrete sample can be retrieved with a precision of a few cm. We illustrate the robustness of the method and define an optimal time of propagation that depends on the geometry of the acquisition and the diffusion constant of the medium. Applications to monitoring civil engineering structure are discussed.

3:00

3pSA5. Semi-analytical study of wave propagation in wire waveguides. Manton J. Guers and Bernhard R. Tittmann (Dept. of Engr. Sci. & Mech., The Pennsylvania State Univ., 212 Earth-Engr. Sci. Bldg., University Park, PA 16802, mjg244@psu.edu)

Guided ultrasonic waves in wire waveguides are useful for various applications including position monitoring and *in-situ* measurements of specimens in harsh environments. In corrosive environments, it has been observed that the velocity of the guided waves changes due to the growth of an oxide layer on the waveguide. Previous work by Grossman [IEEE Trans. Sonics Ultrason. **31**, 25–31 (1984)] analyzed this phenomenon by calculating the change in rod velocity due to oxide thickness. In this paper, the semi-analytical finite element (SAFE) method was used to determine how the velocity changes with respect to oxide thickness and frequency. In addition, the effects of protective coatings on the waveguide have been considered. Results demonstrate that the SAFE method is effective for determining the dispersion characteristics of a waveguide comprised of two distinct materials.

Session 3pSC

Speech Communication: Speech Intelligibility (Poster Session)

Sarah Hargus Ferguson, Chair
Univ. of Kansas, Dept. of Speech Language Hearing Science Disorders, 1000 Sunnyside Ave., Lawrence, KS 66045

To allow for extended viewing all posters will be on display from 9:00 a.m. to 12:00 noon and 1:00 p.m. to 3:00 p.m. All authors will be at their posters from 1:00 p.m. to 3:00 p.m.

3pSC1. Coherent versus incoherent modulation filtering. Marc A. Brennan (Speech and Hearing Sci., Univ. of Washington, 1417 NE 42nd St., Seattle, WA 98105, mabrenn1@u.washington.edu), Pamela E. Souza (Northwestern Univ., Evanston, IL, 60208), Les E. Atlas, and Adam R. Greenhall (Univ. of Washington, Seattle, WA 98195)

Understanding how amplitude modulations are used for speech recognition is essential for improving speech signal processing techniques. Previous studies using vocoding or incoherent modulation filtering indicated that slow amplitude modulations are essential for speech recognition [e.g., Drullman (1994), Shannon (1995)]. Each method had limitations that constrain our understanding of how speech is decoded. These methods did not account for a product model which has the modulating signal multiply the carrier signal in speech or used modulation filtering which retained inherent carrier components. Coherent modulation filtering [C. & Atlas (2009)] is a modulation filtering method that uses a product model with more effective modulation filtering. The purpose of this study was to establish differences in speech recognition performance with coherent versus incoherent modulation filtering and assess the importance of slow amplitude modulations in speech recognition while preserving the carrier signal. Subjects were adults with normal hearing. Consonant recognition scores were measured for 16 nonsense syllables at different modulation filter cutoff frequencies. Speech was presented at a conversational level in a closed-set task. Recognition improved at high modulation filter cutoff frequencies for both conditions. At low-modulation filter cutoff frequencies, performance was substantially poorer with coherent compared to incoherent modulation filtering.

3pSC2. Age effects in the understanding of noisy speech denoised by estimated ideal binary masks. Pierre Divenyi, Nicholas Livingston (VA Northern California Health Care System and East Bay and Inst. for Res. and Education, Martinez, CA 94553, pdivenyi@ebire.org), Adam Lammert (Univ. of Southern California, Los Angeles, CA 90089), Ke Hu, and DeLiang Wang (The Ohio State Univ., Columbus, OH 43210)

An algorithm was developed to denoise speech presented in matching speech-spectrum noise by estimating the ideal binary mask (IBM) that retains the time-frequency (T-F) regions with favorable local signal-to-noise ratio (SNR) and removes the remaining regions [Hu *et al.*, in Proceedings of the 4th SAPA Workshop, Interspeech 2008]. With this method sentence intelligibility was tested in 20 elderly and 20 normal-hearing young listeners. The elderly group had, at worst, moderate SNHL between 0.5 and 4 kHz. Speech material consisted of IEEE sentences spoken by a single female talker. Intelligibility was tested at two SNRs in the elderly (-2 and -4 dB) and three SNRs in the young group (-4, -6, and -8 dB). Subjects listened to 50 sentences at each SNR in three conditions: denoising by the estimated IBM by the algorithm, denoising by the IBM calculated from premixed signals, and the sentences presented in the original noise without processing. With this last condition taken as the baseline, both keyword- and phonemic intelligibility of the sentences processed with the algorithm showed a slight improvement for the young but no improvement for the elderly listeners, while both groups performed substantially better than the baseline in the IBM condition. [Work supported by the VA Medical Research.]

3pSC3. Automatic scoring of responses to the hearing in noise test using utterance verification based on hidden Markov models. Jason Lilley (Dept. of Linguist., Univ. of Delaware, 46 E. Delaware Ave., Newark, DE 19711, lilley@asel.udel.edu), Justin M. Aronoff, Sigfrid Soli (House Ear Inst., Los Angeles, CA 90057), Tim Bunnell (Nemours A.I. duPont Hospital for Children, Wilmington, DE 19803), and Ivan Pal (Compreval, Inc., Grayslake, IL 60030)

The hearing in noise test (HINT) is widely used in clinical settings to measure patients' speech recognition thresholds (SRTs). The patient must repeat 20 sentences presented at signal-to-noise ratios (SNRs) that change adaptively throughout the test. HINT varies the SNR of the sentences according to the patient's responses, so each response must be scored by a human judge before the next sentence is presented. An utterance verification engine (UVE) would remove both the need for a human judge and the subjectivity of human judgments. 2000 HINT responses were used from 25 listeners to develop a UVE based on hidden Markov models (HMMs), a lexicon of observed and likely words, and a grammar that generates utterances classifiable as correct or incorrect. An evaluation study is in progress with a planned enrollment of 25 normal-hearing listeners. HMMs, lexicon, and grammar are updated after every five listeners. In results with ten listeners tested to date, scoring accuracy averaged 88% per subject (range 81%–95%). The mean SRT determined by the UVE differed from the mean SRT determined by human scorers by an average of 0.56 dB (range 0.04–1.91). Complete results will be presented at the conference. [Work supported by NIDCD Grant R43DC008212.]

3pSC4. Effects of semantic and syntactic cues in (non) native speech perception in noise. Bin Li and Ratree Wayland (Linguist. Program, Univ. of Florida)

Non-native listeners (NNLs) are reported to be less tolerant with the degradation of speech (e.g., speech in noise) than native speakers (NSs). In addition, benefits from clear speech in such conditions have been shown to be greater for NSs than for NNLs in speech perception. This study aimed to examine whether poor perception by NNLs is due to their limited usage of the contextual information or their abilities in processing acoustic-phonetic signals, by investigating Chinese listeners' ability in perceiving English sentences in varying linguistic contexts, such as semantic and syntactic cues, under different listening conditions. Sentences differing in degrees of semantic or syntactic acceptability produced by NSs of English were judged a different group of naive NSs of English on degrees of acceptability. All sentences were digitized and masked with white and babble noises with different signal-to-noise ratios (-4 and -8 dB). Listeners from three language backgrounds were recruited. Results showed that semantic and syntactic cues, as well as listening conditions, exhibited different degrees of facilitation in rewriting of keywords. Chinese speakers benefited more from marked syntactic structures, whereas English speakers found marked semantic contexts more facilitating.

3pSC5. Intelligibility of accented American English isolated vowel: Effects of fundamental frequency (F0) contour and formant structures. Sangeeta Kamdar, Chang Liu, Su-Hyun Jin, and Dasia Gonzales (Dept. of Commun. Sci. and Disord., Univ. of Texas at Austin, Austin, TX)

Our previous studies have shown that Chinese and Korean accented English vowels deviated in fundamental and formant frequency values and gross spectral shape properties when compared to English-native productions. The present study proposed to examine the intelligibility of accented English vowel by manipulating the fundamental frequency, formant frequencies, and/or entire spectrum shape in an effort to measure the specific contribution of each of these discrete acoustical parameters on accented vowel perception. There were six sets of vowel stimuli: original vowels produced by native and non-native speakers, flat F0 contour with original spectrogram of native and non-native speakers, hybrid vowels mixing non-native F0 contour and native spectrogram, and hybrid vowels mixing native F0 contour and non-native spectrogram. Preliminary results showed that intelligibility was significantly improved for foreign-accented vowels when the non-native spectrogram was replaced with native spectrogram. On the other hand, effects of F0 contour were dependent on talker intelligibility. For non-native speakers with low vowel intelligibility, replacement of F0 contour with native F0 contour slightly increased vowel intelligibility while for non-native speakers with high vowel intelligibility, replacement of F0 contour degraded rather than improved vowel intelligibility.

3pSC6. Speech intelligibility in cross-dialectal multi-talker babble. Robert A. Fox, Ewa Jacewicz, and Chiung-Yun Chang (Dept. of Speech and Hearing Sci., SPA Labs, Ohio State, 1070 Carmack Rd., Columubs OH 43210-1002)

This study examines speech perception in multi-talker babble by varying speaker dialect as a masker. Studies varying the language of the target speech and the babble masker show that the target is most intelligible when the masker is constructed from a non-native language and target represents exemplars from the listener's native language. Does variation in speaker and listener dialect has a similar effect on speech intelligibility? In this study, central Ohio listeners listen to target sentences spoken by either native Ohio or native North Carolina talker. The sentences are masked by multi-talker babble consisting of speech from either Ohio or North Carolina talkers presented at several sound-to-babble (S/B) ratios. The same material is also presented to listeners in North Carolina. The results for Ohio listeners show significant effects of dialect at 0 dB S/B ratio. Intelligibility improved when the background babble featured the dialect that was different from the dialect of the target speaker. The performance of Ohio listeners was more than 20% higher when the target was presented in the North Carolina babble than in the Ohio babble. Results for North Carolina listeners will be discussed. [Work supported by NIH.]

3pSC7. Fricative perception with and without hearing aids, an event-related potential study. Sharon Miller and Yang Zhang (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, Minneapolis, MN 55455)

The present study used auditory event-related potential (ERP) measures to investigate how the adult brain differentially processes fricative speech sounds with and without the use of a hearing aid. Synthetic stimuli for /sa/, /sha/, /as/, and /ash/ were created to control for the spectral cues in the vowel and consonant portions based on naturally recorded speech. ERP responses were recorded for each sound in an unaided and a hearing aid condition using a randomized block design. At least 160 trials per stimulus were averaged for each sound per subject. The results indicated that (1) the ERP responses in the unaided condition significantly differed from the aided condition, (2) N1 peak amplitudes and latencies to /s/ and /sh/ significantly differed in both unaided and aided conditions as well as in syllable-initial and syllable final positions, and (3) phonological context significantly affected N1-P2 responses. Despite some minor differences, these results are consistent with our previous ERP study using natural speech stimuli, which suggests that amplification through hearing aids alters neural coding of acoustic features in speech sounds. [This work was supported by the Graduate Research Partnership Program and Grant-in-Aid, University of Minnesota.]

3pSC8. Suprathreshold auditory processing and speech recognition in noise for hearing-impaired listeners. Van Summers, Joshua G. W. Bernstein, Matthew J. Makashay (Army Audiol. and Speech Ctr., Walter Reed Army Medical Ctr., 6900 Georgia Ave. NW, Washington, DC), Golbarg Mehraei (Univ. of Maryland, College Park, MD 20742 and Walter Reed Army Medical Ctr., Washington, DC 20307), Sarah Melamed, Marjorie R. Leek, Frederick J. Gallun, and Michelle Molis (VA Medical Ctr., Portland, OR 97201)

Suprathreshold distortions in auditory processing contribute to speech recognition deficits for hearing-impaired (HI) listeners in noise. Outer hair cell damage and attendant reductions in frequency selectivity and peripheral compression may contribute to these deficits. Reduced sensitivity to spectral or temporal modulations or temporal fine structure (TFS) information may also play a role. Eight normal-hearing and 18 HI listeners were tested in psychoacoustic tasks to assess frequency selectivity (notched-noise), peripheral compression (temporal masking curves), TFS sensitivity [frequency modulation (FM) detection in the presence of random amplitude modulation], and spectrotemporal modulation (STM) sensitivity (spectral-temporal "ripple" detection). Performance was examined at 500, 1000, 2000, and 4000 Hz at several presentation levels. Listeners were also tested on sentence recognition in stationary and modulated noise (92-dB sound pressure level signal level; −6-, −3-, 0-, and +3-dB SNRs). HI listeners with similar audiometric thresholds showed a wide range of speech scores. Estimates of FM and STM sensitivity at 500 and 1000 Hz were significantly correlated with speech scores and with each other. Frequency selectivity and compression measures were not clearly associated with speech performance. Implications for models of HI speech intelligibility are discussed. [Work supported by the Oticon Foundation.]

3pSC9. Effect of reduced audibility on masking release for normal- and hard-of-hearing listeners. Peggy B. Nelson, Elizabeth Anderson, Yingjiu Nie, and Bhagyashree Katare (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, Minneapolis, MN 55455, peggynelson@umn.edu)

Listeners with sensorineural hearing loss show reduced benefit from fluctuating compared to stationary maskers. Our hypothesis is that the representation of the signal in the dips is the most important predictor of performance [Jin and Nelson (2006)]. Because the audibility of the signal is the most critical factor, we tested normal-hearing (NH) and hearing-impaired listeners at similar reduced audibility levels. Listeners with normal hearing and hearing loss were presented IEEE sentences at a range of overall levels (from 30- to 80-dB sound pressure level), signal-to-noise ratios, and low-pass filter settings, resulting in a range of signal AIs that varied from 0.1 to 0.95. For the NH listeners, there was a very systematic relationship between AI and performance, but the slope of the function for the higher level stimuli was shallower than that for the low-level stimuli, suggesting that the active mechanism is at work at low levels both in quiet and in noise. The relationship between AI and performance was less systematic for listeners with hearing loss. [Work supported by NIDCD R01-DC008306.]

3pSC10. Relationships between the modified rhyme test and objective metrics of speech intelligibility. Gongqiang Yu, Anthony J. Brammer (Ergonomic Technol. Ctr., Uconn Health Ctr., 263 Farmington Ave., Farmington, CT 06030), Kara Swan, Jennifer B. Tufts (Univ. of Connecticut, Storrs, CT 06269), Martin G. Cherniack, and Donald R. Peterson (Uconn Health Ctr., Farmington, CT 06030)

Relationships between the modified rhyme test (MRT) and the speech transmission index (STI), and MRT and the speech intelligibility index (SII), have been obtained for additive stationary noise and nonlinear distortion of the speech signal. The former was speech-spectrum shaped noise, white noise, or −3-dB/octave noise presented at speech signal-to-noise ratios ranging from −25 to +10 dB. The speech distortions were peak clipping or center clipping, with clipping thresholds from 2% to 98% of the cumulative magnitude histogram. Subjects (4 male, 4 female) with normal hearing were seated in an anechoic chamber. Speech was reproduced by a small, high-fidelity loudspeaker located 2.4 m to the center-of-head and the inter-aural axis. Noise was reproduced by four-loudspeaker systems and processed to simulate a diffuse field at the ear in the horizontal plane. The revised STI

was computed using the standardized test signal [IEC 60268-16 (2003)] and the speech signal. The SII was calculated using coherence to estimate the effects of distortion. Results will be discussed in terms of the ability of each objective metric to predict intelligibility and adjustments to the metrics to improve performance. [Work supported by NIOSH Grant R01OH008669.]

3pSC11. Phoneme perception in temporally and spectrally modulated maskers: Effect of suprathreshold hearing impairment. Sandeep A. Phatak and Ken W. Grant (Army Audiol. and Speech Ctr., Walter Reed Army Medical Ctr., Washington, DC)

Normal-hearing (NH) listeners show better speech recognition in fluctuating maskers than in steady-state (SS) maskers. Hearing-impaired (HI) listeners do not show such benefit due to elevated thresholds. With amplification, HI listeners show some benefit, but significantly less than that for NH listeners. To investigate the reduced benefit in HI listeners at suprathreshold levels, we measured consonant and vowel recognition by NH and aided HI listeners in the presence of SS and modulated maskers. The modulated noises were generated by modulating the SS noise, in either one or six channels, by either one talker speech or four talker babble, resulting in four different modulated masker conditions. HI listeners were provided individualized gain according to the Cambridge formula. Both NH and aided HI listeners showed reduced intelligibility for consonants and vowels due to increase in the number of talkers. Increase in the number of channels provided more benefit to NH listeners than to HI listeners, and this benefit was greater for vowels than for consonants. This benefit due to spectral modulations for aided HI listeners was not correlated with audibility, but seems to be correlated with their ERBs. [Work supported by the Oticon Foundation, Denmark.]

3pSC12. Improvement of consonant identification in noise by spectro-temporal enhancement. Chang Liu (Dept. of Commun. Sci. and Disorder, 1 Univ. Station A1100, The Univ. of Texas at Austin, Austin, TX 78712) and David A. Eddins (Univ. of Rochester, Rochester, NY 14642 and Rochester Inst. of Technol., Rochester, NY 14623)

Our previous studies have shown that perception of vowels and consonants in long-term speech-shaped noise (LTSSN) by listeners with normal and impaired hearing is improved significantly by spectro-temporal enhancement resulting from modifications in the spectral modulation domain. The present study manipulated several parameters of enhancement processing including length of the analysis window and size of fast Fourier transform (FFT) analysis to determine which parameters produce the greatest improvement in stop consonant identification in the presence of LTSSN and cafeteria noise for normal-hearing listeners. The speech signals were presented at 70-dB sound pressure level and the signal-to-noise ratio was varied in fixed steps. Results indicated that identification of stop consonants increased by about 10 percentage points in LTSS noise and by about 25 percentage points in cafeteria noise when the length of analysis window was 200 ms and the FFT size was 512 points. Subsequent acoustic analyses showed that such perceptual improvement may be due to enhancement of formant transitions relative to background competition.

3pSC13. When noise vocoding can improve the intelligibility of sub-critical band speech. James A. Bashford, Jr., Richard M. Warren, and Peter W. Lenz (Dept. of Psych., Univ. of Wisconsin-Milwaukee, P.O. Box 413, Garland 224, Milwaukee, WI 53201, bashford@uwm.edu)

This study examined the redundancy of spectral and temporal information in everyday sentences, which were reduced to 16 rectangular spectral bands having center frequencies ranging from 250 to 8000 Hz, spaced at 1/3-octave intervals. High-order filtering eliminated contributions from transition bands, and the widths of the resulting effectively rectangular speech bands were varied from 4% down to 0.5% (Exp. 1) and from 40 Hz down to 5 Hz (Exp. 2). Intelligibility of these sub-critical bandwidth stimuli ranged from nearly perfect in the 4%- and 40-Hz bandwidth conditions, down to nearly zero in the 0.5%- and 5-Hz bandwidth conditions. However, a large recovery of intelligibility was obtained under adverse filtering conditions when the speech bands were used to vocode broader noise bands that approximated critical bandwidths (ERBn) at the 16 center frequencies. For example, the 0.5%- and 1%-bandwidth speech stimuli were only about 1% and 20% intelligible, respectively, whereas scores of about 26% and 60%, respectively, were obtained for the ERBn-wide modulated noise stimuli derived from the speech bands. These large intelligibility increases occurred despite elimination of spectral fine structure and the addition of stochastic fluctuations to the speech-envelope cues. Additional findings and their implications will be discussed. [Work supported by NIH.]

3pSC14. The perceptual organization of noise-vocoded speech under competitive conditions. Brian Roberts, Robert J. Summers (Psych., Sch. of Life and Health Sci., Aston Univ., Birmingham B4 7ET, United Kingdom), and Peter J. Bailey (Univ. of York, Heslington, York YO10 5DD, United Kingdom)

Research using sine-wave speech suggests that across-formant grouping depends critically on modulation of the frequency but not the amplitude contours of the formants. The generality of this finding was explored using noise-vocoded sentences. Sentences were filtered into six frequency bands, and the amplitude envelope of each band was used to modulate a matched noise-band carrier (N). Bands were paired, corresponding to F1 ($=N1+N2$), F2 ($=N3+N4$), and the higher formants ($F3'=N5+N6$), so that the frequency contour of a formant was implied by variation in the relative amplitudes of the corresponding pair of bands. Perceptual organization was probed by presenting stimuli dichotically (F1+F2C; F2+F3′), where F2C is a competitor for F2 that listeners must resist to optimize intelligibility. F2Cs were derived from F2 by time reversing the envelopes of $N3+N4$. Implied frequency variation in F2C was manipulated by varying the AM depth in the constituent bands (100%-0% of original depth) or by comodulating both bands with the same envelope (from $N3$, $N4$, or $N3+N4$). Competitor efficacy declined with AM depth. Comodulated competitors were less efficacious than their 100% modulated counterpart. The findings are consistent with the proposal that it is the time-varying frequency contours of formants that govern their grouping. [Work supported by EPSRC.]

3pSC15. Word perception, intelligibility, and simultaneous task performance. Nirmal Kumar Srinivasan and Thomas D. Carrell (Commun. Disord., Barkley Memorial Ctr., Univ. of Nebraska-Lincoln, Lincoln, NE 68583)

The relationship between speech intelligibility and simultaneous task performance was investigated in the present experiments. Specifically, the following indicators were measured: intelligibility, reaction time for word repetition, visual-motor performance, cognitive load, and visual word recall. These relationships were measured using natural, synthetic, and cell phone speech. It is clear from other reports that different patterns of results may be expected from different types of speech signals [Pisoni *et al.* (1985)]. Intelligibility was based on participant's accuracy in repeating the final word of a sentence. Visual-motor performance was measured as the average speed of rotation in adaptive pursuit rotor task [Srinivasan and Carrell (2007)]. Task load was measured using the NASA-TLX instrument [Hart and Staveland (1988)]. TLX was highly correlated with the simultaneous pursuit rotor task in the cell phone listening condition ($r = 0.41$, $p < 0.0001$). However, the pursuit rotor measure consistently demonstrated much lower variability than the TLX score. Perception was also measured in two attention conditions, consistent-mapping and variable-mapping [Schneider and Schiffrin (1977)]. In the consistent-mapping condition, cell-phone speech led to better performance at the pursuit rotor task than natural speech, whereas in the variable-mapping condition, the natural speech led to better performance.

3pSC16. Linguistic processing of vocoded signals. Susan Nittrouer and Joanna H. Lowenstein (Otolaryngol., Ohio State Univ., 915 Olentangy River Rd., 4th Fl., Columbus, OH 43212, nittrouer.1@osu.edu)

Tests of word discrimination show that listeners can accurately recognize speech with cochlear implants, but there is more to linguistic processing than these measures evaluate. We examined the possibility that other aspects of processing are hindered. Adults and 8-year-olds participated in two experiments. (1) Serial recall for words presented in each of three ways: natural, vocoded, and embedded in noise. Environmental sounds were control stimuli. (2) Judgments of whether words share the same final consonant using natural words, and those same words vocoded or embedded in noise. Serial recall was less accurate and responding was slower for vocoded than for natural speech, but not as poor as for environmental sounds. For final-consonant judgments, accuracy was not as greatly affected by use of vocoded signals, but response times were slowed. That was true even when only correct responses were considered. In both experiments, adults per-

formed better with speech-in-noise than with vocoded speech, but children performed similarly with the two kinds of signals. Conclusions were: as follows (1) linguistic processing of signals heard through implants can be hindered in ways not typically evaluated (2) that hindrance arises from impoverishment of signal properties required for recovering phonetic structure, rather than from general signal degradation. [Work supported by NIDCD Grant No. DC-00633.]

3pSC17. The speech scale. S. Umesh (Indian Inst. of Technol. Madras, Chennai 600 036, India), Leon Cohen (City Univ. of New York, New York, NY 10065), and Douglas Nelson (Dept. of Defence, Fort. Meade, MD, 20755)

Using the Timit database, we describe experimental results that lead to the concept that sounds made by different individuals and perceived to be the same that can be transformed into each other by a speech scale. The speech scale is empirically determined using only speech data. We show the similarity of the speech scale to the MEL scale of Stevens and Volkmann, which was derived only from hearing experiments. We thus argue that we have experimentally linked speech production and hearing.

3pSC18. Native and non-native speech database for children. Tessa Bent (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405, tbent@indiana.edu)

Language acquisition, performance in school, and social interactions all require the ability to compensate for the enormous amount of variability in the speech signal. Foreign-accented speech represents one common, real-world source of speech variability, which can be particularly challenging for accurate speech perception. Although maintaining perceptual constancy in the face of variability is necessary for effective communication, little is known about how listeners develop the skills to compensate for speech variability. As a resource for investigating this issue, I am developing a new database of foreign-accented speech with materials appropriate for children. The database includes 28 speakers with 4 from each of the following language backgrounds: American English, Spanish, Mandarin, French, German, Japanese, and Korean. In each language group, half of the talkers are female. Speakers were recorded reading words, sentences, and paragraphs in English, which have been used in previous research and clinical settings with children. The database also includes assessments of objective intelligibility, perceived comprehensibility, and strength of foreign accent by adult native listeners. With this database, I plan to assess the development of the cognitive-linguistic skills that underlie a listener's ability to compensate for variability in the speech signal. [Work supported by NIH-NIDCD R21-DC010027-01.]

3pSC19. A preliminary comparison of sound quality of maternal speech recordings in varied neonatal intensive care unit settings. Andi C. Petito, Jessica Jancek, and Charlene Krueger (Univ. of Florida, 911 NE 6th Ave., Gainesville, FL 32601, adest@ufl.edu)

Since the 1980s, research investigating the beneficial effects of exposure to maternal voice has been steadily increasing. This has been accomplished by playing back recordings of maternal voice to the preterm infants. It is not known, however, how variations in the typical NICU setting alter the sound quality of the original recordings. This is a sub-study to a larger study in which 58 preterm infants will hear a recording of their mother reciting a rhyme twice a day from 28–34 weeks post-menstrual. A pair of microphones will be placed at ear level of the preterm subjects while the original recordings of maternal speech are played. The sound recorded within the incubator will then be run through a sound analyzer (PRAAT) and compared to the same sound qualities of the original recordings. The purpose of this study is to compare the original sound spectrum of a maternal speech recording to spectra obtained while the recording is played within typical NICU settings (open vs closed crib, pillows vs no pillows, etc.) If it is observed that the sound quality is altered due to varied NICU settings, this information will be important in determining NICU sound regulations for future studies employing voice recordings.

3pSC20. Production of sibilant fricatives by children with cochlear implants. Ann E. Todd, Jan R. Edwards, Ruth Y. Litovsky (Univ of WI-Madison, 1500 Highland Ave., Madison, WI 53705, aetodd@wisc.edu), and Fangfang Li (Univ of Lethbridge, Lethbridge AB T1K 3M4, CA)

Children who use cochlear implants (CIs) are likely to show differences in speech production relative to children with normal hearing (NH) due to the suboptimal auditory input provided by CIs. The present study compared word-initial /s/ and /S/ produced by children with bilateral CIs and two comparison groups of children with NH (children matched for hearing age and children matched for chronological age). The first spectral moment (i.e., centroid), a measure which describes the mean frequency differences in the spectra of sibilant fricatives, was calculated at the midpoint of the fricative noise for /s/ and /S/. Results showed that the children with CIs produced less differentiation between /s/ and /S/, had lower centroid frequencies for /s/, and less variability for /s/ than both groups of children with NH. These results may be explained by the perceptual limitations of CIs; /s/ is a sound produced with more energy at higher frequencies, and CIs provide poor frequency resolution for higher frequencies. Currently the amount of coarticulation in productions of /s/ and /S/ with the following vowel is being examined to determine whether the groups show a difference. [Work supported by NIH Grant Nos. R01DC008365 to R.Y.L. and R01DC02932 to J.R.E.]

3pSC21. Discrimination of voicing on the basis of temporal envelope cues in 6-month old infants. Josiane Bertoncini, Laurianne Cabrera, and Christian Lorenzi (Lab. Psychologie de la Percept., CNRS-Université Paris Descartes, ENS, 45 rue des Sts Pères, 75006 Paris, France, josiane.bertoncini@parisdescartes.fr)

Several studies indicate that profoundly deaf children receiving a cochlear implant (CI) under the age of 2 years are able to develop linguistic skills at a rate equal to similarly aged children with normal hearing. CI devices deliver temporal-envelope (E) cues in speech over a small number of frequency channels. This suggests that infants are able to use efficiently E speech cues at an early age. However, little work has been done to investigate the developmental time course of the ability to use E speech cues. A recent study suggests that normal-hearing children are able to use such cues at adult levels by the age of 5 years, but information is lacking for younger children. The present study assessed the ability of 6-month old infants with normal hearing to discriminate between voiced and unvoiced stop consonants (/aba/ versus /apa/) on the basis of E cues, using a head-turn preference procedure and speech tokens processed via a tone or a noise E vocoder. The spectral and temporal resolutions of vocoders were varied to determine whether or not the ability to use E speech cues is similarly constrained in infants and adults. Preliminary results indicate that this method is applicable to young infants.

3pSC22. Infants' ability to recognize speech in the presence of amplitude-modulated background noise. Rochelle S. Newman and Giovanna Morini (Dept. of Hearing and Speech Sci. and Program in Neurosci. and Cognit. Sci., Univ. of Maryland, 0100 Lefrak Hall, College Park, MD 20742, rnewman@hesp.umd.edu)

Adults experience a release of masking when the amplitude level of a masker varies [Festen and Plomp (1990) and Wilson and Carhart (1969)], especially when the variation occurs in a slow, predictable manner [Gustafsson and Arlinger (1994)]. This pattern of performance has been described as "listening in the dips" of the signal and is a form of selective attention: focusing one's attention on those time periods of the signal that are likely to be most beneficial. Infants have poor selective attention abilities for different frequency regions [Bargones and Werner (1994)]; if they similarly are less able to attend to particular points in time, they should show no advantage when the amplitude level of a masker varies. We presented infants with either their own name or a foil name in the presence of white noise; the noise was either constant in amplitude or varied at a 10-Hz modulation at a depth of 12 dB. Infants showed a disadvantage when faced with amplitude-modulated background noise (that is, they showed stronger recognition of their name when the noise had a constant amplitude than a varying amplitude), suggesting that the modulation itself may have attracted attention away from the target speech. [Work supported by NSF BCS0642294.]

3pSC23. Cross-language perception of Mandarin affricates in conversational vs careful speech. Anna C. Woods and Natasha L. Warner (Dept. of Linguist., Univ. of Arizona, Douglass Bldg., Rm. 200E, Tucson, AZ 85721)

Two affricates "zh" and "j" in Beijing Mandarin are often confused by English speakers learning the language [Dow 1972]. An experiment based

on the work of Logan in 1989 training Japanese speakers to distinguish the difference between English /ɛvr/ and /l/ was modified to include training tokens taken from native Mandarin speakers' phone-conversational speech. "j" is described by Lee and Zee [2003] as laminal pre-palatal, and "zh" is described as apical post alveolar. In careful speech, the sounds are in complementary distribution, with "j" always followed by a high front vowel or a glide. A preliminary perception experiment shows whether native Mandarin speakers are able to distinguish between the pair of affricates simply by hearing the affricate alone, or if they are only able to distinguish them when hearing the vowel information as well. In conversational speech, the following high front vowel may be deleted, so natives' perception of the two affricates may differ for casual speech. English speakers with no Mandarin experience also participate in a perception task to show the effects of training with conversational speech tokens. This study elucidates how learners acquire categories despite the variability of natural speech.

3pSC24. Effect of age on clear speech intelligibility. Rajka Smiljanic (Linguist., Univ. of Texas at Austin, CAL 501, Mailcode B5100, Austin, TX 78712)

Previous work has established that elderly adult's comprehension is more detrimentally affected by noise, multi-talker babble and the absence of contextual cues compared to younger adult's comprehension. Elderly adult's abilities to understand fast speech and to detect/recognize brief non-speech and speech sound sequences (e.g., stop gaps) also decline with age. These effects seem to persist even when hearing loss is taken into account. In this study, we explored whether there are parallel effects of age on speech production, i.e., whether elderly adult's production patterns differ from those of younger adults. Specifically, we examined whether elderly and younger adult's hyper-articulation clear speech strategies provide similar intelligibility advantage for younger adult listeners. The sentence-in-noise perception results revealed that elderly adult's clear speech increased intelligibility for young adult listeners. Importantly, the overall elderly adult's speech intelligibility and the clear speech intelligibility gain were smaller compared to that provided by the speech of younger adults. Acoustic correlates of the differences in the observed clear speech gain provided by older and younger adults are explored. These results suggest that, in addition to perceptual problems, cognitive and hearing changes due to age can affect elderly adult's speech patterns and intelligibility.

3pSC25. Acoustic correlates of clear speech vowel intelligibility for elderly hearing-impaired listeners. Sarah Hargus Ferguson (Dole Ctr., 1000 Sunnyside Ave., Rm. 3001, Lawrence, KS 66045, safergus@ku.edu)

Earlier work on vowels in clear and conversational speech produced by a single talker suggested that the acoustic cues that underlie the superior intelligibility of clear speech for older adults with hearing loss may differ from the cues that young normal-hearing listeners find beneficial. In the present study, clear and conversational vowel stimuli produced by all 41 talkers from the Ferguson Clear Speech Database were presented in a background of 12-talker babble to 40 older adults with mild-to-moderately severe sloping sensorineural hearing loss. Acoustic analyses (vowel duration, steady-state formant frequencies, and measures of dynamic formant movement) were also performed for all stimuli. Vowel intelligibility scores for each talker in each speaking style as well as the magnitude of the clear speech vowel intelligibility effect for each talker will be compared to those obtained from young listeners with normal hearing in a previous study. Regression and other statistical analyses of intelligibility and acoustic data will also be performed to determine the acoustic correlates associated with improved clear speech vowel intelligibility for each listener group. [Work supported by NIHDCD-008886.]

3pSC26. American English adults' perception of Spanish-accented conversational and clear speech. Erika S. Levy, Paula B. Garcia, Dorothy Leone, and Jessica A. Lew (Dept. of Biobehavioral Sci., Teachers College, Columbia Univ., 525 W120th St., Box 180, New York, NY 10027)

Clear speech, an intelligibility-enhancing manner of speech production, has been shown to increase the transmission of information to various listener groups when uttered in the speaker's native language. When clear speech is used in a non-native language, it is not evident whether this mode will also improve intelligibility. The present study examined the accuracy with which adult monolingual native American English (AE) listeners identified Spanish-accented vowels produced in conversational and clear speech modes. Consonant-vowel-consonant (CVC) words were presented in the carrier sentence "Touch the CVC please," containing the AE vowels /æ, ʌ, ɑ, ɛ, i, ɪ/. The sentences were produced by a native speaker of AE and by a native speaker of Spanish judged as moderately accented by the AE listeners. Five pairs of photographs (cap-cup, map-mop, nut-knot; ship-sheep, pot-pet), representing the vowel pairs /æ-ʌ/, /æ-ɑ/, /ʌ-ɑ/, /ɪ-i/, /ɑ-ɛ/ were presented visually on a touch screen in a two-alternative forced choice paradigm. Listeners had the greatest difficulty with the /ɪ-i/ and /ʌ-ɑ/ contrasts. Clear speech mode was not as effective for non-native speech as it has been shown for native speech. Implications are considered for social and clinical settings in which a mismatch in language backgrounds is present.

Invited Papers

1:00

3pSP1. Distilled sensing for sparse recovery. Jarvis Haupt (Dept. of Elec. and Comput. Eng., Rice Univ., 6100 Main St., Houston, TX 77005), Rui Castro (Columbia Univ., New York, NY 10027), Robert Nowak (Univ. of Wisconsin-Madison, Madison, WI 53706), and Richard G. Baraniuk (Rice Univ., Houston, TX 77005)

The study of sparsity in data-rich applications has recently garnered significant attention in the signal processing, statistics, and machine learning communities. Generally speaking, sparsity quantifies the phenomenon where, in a large collection of data, only a small fraction is significant. Techniques that exploit sparsity are currently utilized in a wide variety of applications, including conventional and medical imaging, rf communications, signal intelligence, and bioinformatics, to name a few. Recently a renewed emphasis has been placed on identifying techniques that make judicious use of sensing resources, with the goal of extracting only the relevant information in high-dimensional but sparse signals. Among these techniques, the most promising approaches typically employ some form of active sampling, or sampling with feedback. Distilled sensing highlights how active sampling can result in rather surprising (and dramatic) improvements over traditional sampling methods.

1:30

3pSP2. Efficient and adaptive sparse time-frequency representations through superposition frames. Daniel Rudoy, Prabahan Basu, and Patrick J. Wolfe (Statistics & Information Sci. Lab., Harvard Univ., Oxford St., Cambridge, MA 02138, wolfe@stat.harvard.edu)

Sparsity in signal representation requires two aspects: a large dictionary of potential basis functions that can be adapted to a variety of waveforms and an efficient means of selecting these functions and reconstructing the corresponding signal representation. This talk introduces a family of time-frequency systems termed superposition frames that enable adaptivity and also, in contrast to many adaptive analysis systems, admit the property of fast overlap-add reconstruction. Several properties of this family are proved, and specific examples of adaptation criteria in the context of sparse audio processing are discussed.

3pSP3. Random encoding for robust recovery and channel identification. William E. Mantzel (801 Myrtle St., Apt. 1, Atlanta, GA 30308, willem@gatech.edu), M. Salman Asif, and Justin K. Romberg (801 Myrtle St., Apt. 1, Atlanta, GA 30308)

By encoding a signal in a randomly chosen subspace before transmission, this transmitted signal proves robust to sparse errors in the channel. In this talk, we will further demonstrate the robustness of such signals to unknown convolutive channels. In particular, we show that if the channel is not especially resonant at any given frequency (e.g., the channel is sparse or random), we are able to simultaneously recover both the transmitted signal and the channel characteristics by solving a rank minimization in X, the rank-1 outer product of the two unknown vectors, subject to the receiver observations. We demonstrate favorable simulated performance for sparse and random channels. Using a parallel approach to classical compressed sensing theory, we prove a restricted isometry property about our linear operator that guarantees a high probability of recovery when the number of observations is at least linear with the dimension of the message and the length of the channel.

2:15

3pSP4. Shallow water channel tracking using gradient-based mixed norm optimization techniques. Ananya Sen Gupta and James Preisig (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

The underwater acoustic channel is challenging to estimate and track due to channel dynamism, the ill-conditioned nature of the estimation problem, as well as the need to optimize over a complex field. An extension of previous work is presented where the sparse channel coefficients in the delay and delay-Doppler spread domains are estimated using mixed norm convex optimization. The estimation algorithm is extended to track the time-varying channel using a gradient descent approach, trading off optimality for tracking efficiency. A computationally inexpensive approximation of the dynamic gradient is used rather than re-computing the precise gradient every time. Results presented are based on field data collected over 15-m depth and a range of wave heights and distances using the normalized prediction error as the performance metric. Comparison of performance between tracking the delay-only and delay-Doppler coefficients is presented for different weightings on the mixed norm between L1 and L2 measures and over different lags. Performance and computational efficiency of the proposed

tracking algorithm are compared to conventional sparse estimation techniques. [Work supported in part by ONR Grants N00014-05-10085 and N00014-07-10184 and in part by Postdoctoral Scholar Program at the Woods Hole Oceanographic Institution, with funding provided by the Doherty Foundation.]

3pSP5. Convex hull method of acoustic field interpolation. Brian R. La Cour (Appl. Res. Labs., The Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029)

Empirical knowledge of the local acoustic field typically comes in the form of time samples at discrete points in space corresponding to the locations of, say, omnidirectional microphones or hydrophones on an underwater array. To determine the acoustic field at an arbitrary point in space requires either propagation modeling, signal interpolation, or some combination of the two. In this paper, a method of field interpolation is presented which estimates the acoustic field at any point within the convex hull of all sample points. This method is compared against more traditional inverse beamforming methods using both simulated and measured data.

2:45

3pSP6. Compressive sensing in underwater acoustics. Geoffrey F. Edelmann and Charles F. Gaumond (Naval Res. Lab., 4555 Overlook Ave. SW, Washington, DC 20375, geoffrey.edelmann@nrl.navyl.mil)

The performance of compressive sensing for determining frequency tonals is shown for several cases. The sampling requirements for infinite signal-to-noise ratio (SNR) is shown first. A detection threshold is developed for the case of additive noise with known noise level. The number of samples needed per tonal is shown as a function of SNR. The effects of temporal variability in the form of fading due to motion through an oceanic waveguide is discussed. [Work supported by the Office of Naval Research.]

3:00

3pSP7. Compressive matched field processing. William Maetzel, Justin Romberg (School of Elec. and Comput. Eng., Georgia Inst. of Technol., 777 Atlantic Dr. NW, Atlanta, GA 30332-0250), Karim G. Sabra (Georgia Inst. of Technol., Atlanta, GA 30332-0405), and William Kuperman (UC. San Diego, La Jolla, CA)

Sound source localization in shallow water environment is commonly done using matched field processing (MFP). MFP is usually implemented by systematically placing a test point source at each point of a search grid, computing the acoustic field (replicas) at all the elements of the array and then correlating this modeled field with the data from the real point source whose localization is unknown to determine the best-fit location. However, a direct implementation of MFP (i.e., brute force search) over a large grid space—or search area—is computationally demanding especially in the presence of complex propagation environments. We formulated instead the localization problem of a few acoustic sources as the sparse approximation of the measured signals in a specific dictionary of atoms obtained from discretization of this sparse search space. Spatial random projections are performed to efficiently span the search space. This compressive MFP approach allows for significant computation time savings with a computational cost increasing with the number of random projections instead of the number of search grid points. The performance of this approach will be illustrated using numerical and experimental data in a shallow water waveguide.

Session 3eED

Education in Acoustics and ASA Women in Acoustics Committee: Listen Up and Get Involved

Marcia J. Isakson, Chair
Univ. of Texas at Austin, Applied Research Labs., 10000 Burnet Rd., Austin, TX 78713

Chair's Introduction—5:30

Invited Papers

5:35

3eED1. Hands-on demonstrations for Project Listen Up: Education outreach. Hannah E. Allaire, Bethany L. Carlson, Julie Devlin, Alaina D. Dibiasie, Krysta L. Porterlott, Erica B. Renzhofer, Janet S. Voneiff, Jessie Carman, and Murray S. Korman (Dept. Phys., U.S. Naval Acad., Annapolis, MD 21402)

Midshipmen from the General Science Major will be getting involved in an ASA education outreach effort by presenting a number of acoustical demonstrations geared to promote a hands-on learning experience for middle- and high-school age girl scouts. The demos are designed to visualize certain sound wave effects that will be explained by the Midshipmen (role models) who hands-off the controls of the apparatus to the students who will be free to participate and make their own scientific discoveries. The demonstrations will be (1) sympathetic vibrations of matched xylophone bars or matched tuning forks mounted in quarter-wave resonant open-ended boxes, (2) tuning fork excitation of standing waves in a sound resonance tube with a variable water column, (3) small inexpensive speaker placed in a hole in a baffle or inside a megaphone generating enhanced sound by eliminating destructive interference effects, (4) interference from two separated loud speaker sources measured vs microphone location, and transverse wave visualizations using a (5) torsion wave machine and (6) a small ripple tank. The traveling and standing wave patterns in (5) and the reflection, refraction, interference, and scattering effects in (6) are helpful wave visualizations and aid in the understanding of longitudinal sound wave effects.

5:41

3eED2. How musical instruments make sounds: An exploration of standing waves and resonance frequencies. Tracianne B. Neilsen (Dept. of Phys. and Astronomy, Brigham Young Univ., N283 ESC, Provo, UT 84602, tbn@byu.edu)

A basic understanding of the production of sound waves can be obtained by studying standing waves and resonance frequencies. A vibrating string will settle into a steady, standing wave pattern when it is driven at one of its resonance frequencies. The resonance frequencies depend on the string length and the tension applied to the string. Similarly the resonance frequencies of tubes are determined by the tube length and whether the ends are open or closed. In a series of hands-on demos, we will explore the factors that influence the creation of standing waves by exciting the resonances of strings, tubes, rods, a metal plate, slinky, and a wine glass. These simple models provide insight into how musical instruments produce sound.

5:47

3eED3. Chlandi pattern demonstration. Marcia J. Isakson (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713, misakson@arlut.utexas.edu)

Chlandi patterns will be demonstrated using sand on a plate and an air acoustic source. As the source frequency is changed, different nodal patterns will become evident on the plate. In this manner, the different vibrational modes of the plate can be qualitatively determined.

5:53

3eED4. The singing shoebox: A $5 loudspeaker project. Scott P. Porter, Daniel J. Domme (The Graduate Program in Acoust., The Penn State Univ., 201 Appl. Sci. Bldg., State College, PA 16802), and Jeffrey S. Whalen (The Penn State Univ., State College, PA 16802)

Moving-coil loudspeakers typify the interdisciplinary nature of acoustics. In order to reproduce sound, these devices employ principles of electricity, magnetism, mechanics, and acoustics. The widespread use of loudspeakers has made them familiar to students and thus a valuable opportunity to introduce students to acoustics. In this paper, the authors demonstrate a loudspeaker-enclosure system that is easily built from scratch. The system is mostly constructed from common household supplies, making it low-cost and accessible to a wide audience. In addition, this project is well-suited for use by the K-12 educator as the content can be scaled to fit a variety of different academic levels. To this end, the speaker's design and construction will be presented and its relevance as an educational demonstration discussed. Finally, the loudspeaker will be auditioned and its performance demonstrated.

5:59

3eED5. Longitudinal wave demonstrations. Michelle E. Swearingen (Construction Eng. Res. Lab., USA ERDC, P.O. Box 9005, Champaign, IL 61826, michelle.e.swearingen@usace.army.mil)

In a wave, something always moves back and forth. A longitudinal wave is one that travels along the direction of propagation. In this demonstration, two different devices will be used to illustrate longitudinal propagation. An aluminum bar is used to produce transverse waves. A slinky will be used to visually show longitudinal propagation along the slinky. Finally, the aluminum bar is again used to show differences in longitudinal and transverse wave propagations.

6:05

3eED6. Demonstration of an air column resonance with a corrugated tube. Michelle C. Vigeant (Dept. Mech. Eng., Acoust. Prog. and Lab., Univ. of Hartford, 200 Bloomfield Ave., West Hartford, CT 06117, vigeant@hartford.edu)

Standing waves, or resonances, will occur in an open-ended tube when the air in the tube is excited at a particular frequency or its harmonics. The resonant frequencies are a function of the tube length. The first standing wave, fundamental mode or first harmonic, is set-up with antinodes at each end of the tube, as the air is free to move at the ends, with one node in the middle of the tube. Each successive standing wave has an additional anti-node and node, with the second harmonic containing three, antinodes and two nodes, the third containing four and three, respectively, and so on. This phenomenon of an air column resonance will be demonstrated using corrugated tubes. By spinning the tube overhead at a particular speed, the resonance frequencies will be excited. For slower speeds, lower frequencies will be heard, while the pitch will increase for faster speeds. Instrumental examples of open-ended tubes include the flute and organ pipes.

6:11

3eED7. Amplification. Ananya Sen Gupta (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

In this experiment the students will see a demonstration of how sound waves can be amplified. The setup of the experiment is simple: a tuning fork, a table, and a music box. First the tuning fork is struck by itself and the level of the sound emitted is noted. Then the tuning fork is struck again and held against a table. The amplification of the sound due to propagation of acoustic pressure waves through the larger surface area of the table is noted. The students are encouraged to participate and give their own reasoning for sound amplification. If time permits, students will experiment with the music box as well.

6:17

3eED8. Experiment on beats. Ananya Sen Gupta (Dept. of Appl. Ocean Phys. and Eng., Woods Hole Oceanograph. Inst., Woods Hole, MA 02543)

When two sounds of nearly the same frequency get together they will alternately add up or cancel out. If they start out together, after a while they will no longer be together, and the peak of the one will meet a trough of the other and they will cancel. The resulting fluctuations are known as beats. The beat frequency is just the difference of the two frequencies. The students will observe and experiment with beats generated by sounding an 880 tuning fork at the same time as an 883 tuning fork.

6:23

3eED9. The tin-can telephone: An example of sound propagation and communication for Project Listen Up. Jason D. Sagers, Andrew R. McNeese, and Preston S. Wilson (Mech. Eng. Dept. and Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78712-0292)

The tin-can telephone can be used to illustrate the basic concepts of sound waves and sound-structure interaction. It can also be used to illustrate advanced concepts of frequency response and speech intelligibility in acoustic communications. For the proposed demonstration, students will construct a tin-can telephone from household materials and observe its performance from a variety of acoustic tests. Students will observe sound transmission and discover that some sounds are transmitted with greater clarity than others. A measured frequency response function for several tin-can telephones constructed from different materials will be provided to the student to illustrate the concept of frequency response and speech intelligibility.

6:29

3eED10. Ultrasonic levitation. Cecille Pemberton Labuda (Univ. of MS/NCPA, 1 Coliseum Dr., Univ. MS 38677, cpembert@olemiss.edu)

Ultrasonic standing waves are set up between a horn and a brass plate. Because the wavelength is short, several wavelengths fit in the space between the horn and the plate. There are locations in the standing wave pattern where the forces associated with the sound pressure and the motion of the air molecules are opposite in direction to the gravitational force. A light ball placed at any of these locations will levitate if the mass of the ball is such that the gravitational force on the ball is equal and opposite to the forces associated with the pressure and the motion of the air molecules.

6:35

3eED11. Fourier synthesis. Kyoko Nagao (Ctr. for Pediatric Auditory and Speech Sci., Nemours A.I. duPont Hospital for Children, 1600 Rockland Rd., Wilmington, DE 19803, nagao@asel.udel.edu)

When two or more simple sound waves that differ in frequency and amplitude are added together, a complex wave is generated. This is called Fourier synthesis, named after a French mathematician Joseph Fourier. Many sounds we hear every day are complex waves. For example, the sound wave produced by the vowel "ah" is a complex wave. By combining simple waves with appropriate values, we can generate speech with a computer. In this experiment, you will synthesize a complex sound wave by adding two or more pure tones using a computer program. The ultimate goal here is to create a complex tone that sounds like the vowel ah. You will learn important acoustic components used in speech sounds.

6:41

3eED12. Acoustic demonstrations for the iPod generation. Shawn F. Johnson and Juan I. Arvelo (Appl. Phys. Lab., The Johns Hopkins Univ., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099)

Today's "iPod generation" can gain a unique and interactive exposure to physics by leveraging their musical interests, and their iPod, to explore the science of sound. Inside certain models reside a mini-computer and a suite of acoustic and vibration sensors, including loudspeakers, microphones, and accelerometers. Combined with free or inexpensive software applications or "apps," these highly portable devices can offer a tangible means to help students understand many physics, audio, and acoustics concepts that they can explore both inside and outside the classroom. We will demonstrate several apps that are currently available, for example, a seismometer, signal generator, noise level meter, spectrum analyzer, oscilloscope, and various musical instruments. Demonstrations utilizing an iPod Touch are guaranteed to excite students of all ages.

6:47

3eED13. Doppler effect. Megan S. Ballard (Appl. Res. Labs., Univ. of Texas, 10000 Burnet Rd., Austin TX 78758, meganb@arlut.utexas.edu)

The Doppler effect describes the change in frequency observed for a moving source and/or receiver. A common example of the Doppler effect involves a moving vehicle sounding a siren or horn as it approaches, passes, and recedes from an observer. The observed frequency (compared to the emitted frequency) is higher during the approach, is identical at the instant of passing by, and is lower during the recession. In this presentation, the Doppler Effect is demonstrated using a buzzer embedded in a Nerf ball. A difference in pitch can be heard when the ball is thrown to or from an individual. A second demonstration involves twirling a tuning fork from an attached string. An increase/decrease in frequency can be heard as the tuning fork moves toward/away from an observer.

6:53

3eED14. Phonation: Mickey Mouse and Darth Vader. Tessa Bent (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S. Jordan Ave., Bloomington, IN 47405, tbent@indiana.edu)

During voicing, the vocal folds are brought together and then caused to vibrate by air being pushed out of the lungs. In order to illustrate several phenomena regarding phonation, three demonstrations will be provided. First, an experiment with balloons will demonstrate how people can change the pitch of their voice by stretching their vocal folds. Second, the aerodynamic forces involved in phonation will be demonstrated with the use of soda cans and a straw. Last, high-speed videos of the vocal folds in action will be shown.

6:59

3eED15. Listen up and get involved: Standing waves—The unbalanced motor and musical string. Pamela J. Harght (4006 Speedway, Austin, TX 78751, pam@baiaustin.com)

The experiments that will be demonstrated are Standing Waves—The Unbalanced Motor and Standing Waves—Musical String. The unbalanced motor experiment involves a small electric motor that provides tension in the string. Students will observe the effect of holding the string and slowly sliding their hand toward the unbalanced motor. For the musical string experiment, students will observe musical intervals (do-me, do-sol, do-do, etc.) with a tensioned piano string and the science behind musical notes.

7:05

3eED16. Fourier synthesis. Helen M. Hanson (Dept. ECE, Union College, 807 Union St., Schenectady, NY 12308, helen.hanson@alum.mit.edu)

Fourier synthesis is the act of building a complex waveform from simple sine waves. Fourier analysis, on the other hand, decomposes a complex waveform into simple sine waves. Both Fourier synthesis and analysis are powerful tools in many scientific and engineering fields, allowing one to understand waveforms of all types in terms of their frequency content. In this experiment, Fourier synthesis will be brought to life as an acoustic waveform is built by combining several harmonic waves. A keyboard will generate the waves, which will then be observed using a computer.

7:11

3eED17. The energy flow for a spherical acoustic lens: Experimental results avoiding interference effects. Kendez C. Parker and Cleon E. Dean (Dept. Phys., Georgia Southern Univ., P.O.B. 8031, Statesboro, GA 30460-8031, cdean@georgiasouthern.edu)

A simple classroom demonstration consists of a weather balloon filled with carbon dioxide, a sound source, and a microphone. Since the speed of sound is slower in carbon dioxide than in air at room temperature and pressure, the balloon acts as a positive spherical acoustic lens. Preliminary experimental results have been presented previously [C. E. Dean and J. P. Braselton, "The energy flow for a spherical acoustic lens: ray and wave methods vs. experiment.," J. Acoust. Soc. Am. **125**, 2627 (2009)]. The possibility of interference effects from the reflection of sound off surfaces was brought up in the ensuing discussion. The current results have been measured in a way that minimizes the effect of interference due to reflections off walls, floor, or other surfaces.

7:17

3eED18. Standing waves on a vibrating string. Dorea R. Ruggles (Hearing Res. Ctr., Boston Univ., 44 Cummington St., Boston, MA 02215)

Most sounds are made up of many waves added together. These waves, called harmonics, are all related to each other because their frequencies are integer multiples of the lowest frequency, the fundamental. Adding together different amounts of each harmonic is part of what makes different sounds unique. The individual harmonics of a vibrating string are easy to see, one at a time, by creating a standing wave on the string and adjusting the driving frequency. The frequency where the fundamental, one-looped standing wave appears on the string depends on the string's length, mass, and tension, but if these factors are all kept constant while the driving frequency is increased, a new loop will be added to the standing wave for each multiple of the original frequency. This is an exciting way to see waves, observe their properties, and really understand how frequency, wavelength, and other properties are all interrelated.

7:23

3eED19. Ocean acoustic tomography: Live from the Philippine Sea. Lora J. Van Uffelen (Scripps Inst. of Oceanogr., Univ. of California San Diego, 9500 Gilman Dr., Mail Code 0225, La Jolla, CA 92093-0225) and Kathleen E. Wage (George Mason Univ., Fairfax, VA 22030)

In this live interactive video session, scientists onboard the R/V Roger Revelle in the Philippine Sea off the coast of Taiwan describe the basic concept of sound propagation in the ocean in the context of an ongoing acoustic mooring deployment. Six acoustic source moorings and a distributed hydrophone array will be deployed during the course of the month-long cruise. The scientists will give an introduction to how research is carried out at sea and will describe basic concepts and advantages of using acoustics as a tool to learn about the ocean environment. They will show examples of oceanographic instrumentation, including conductivity-temperature-depth sensors, acoustic sources, and hydrophone receivers, and will describe the process of deploying acoustic moorings and acquiring oceanographic data. The girl scouts will learn how sound is used to map the 6-km deep ocean floor as well as how tomographic moorings can be used to sense the ocean interior. There will be the opportunity to interact with scientists on the research ship and ask questions about ocean acoustics or life at sea. [Field work supported by ONR.]

7:29

3eED20. Standing waves on a spring. Holly A. Smith and Tara L. Tubbs (Grad. Prog. in Acoust., Penn State Univ., 201 Appl. Sci. Bldg., University Park, PA 16802)

This demonstration shows how standing waves on a spring can be generated by having two people simulate boundary conditions. If one person holds the end of the spring at rest while the other drives the opposite end in an up and down motion, the spring will begin to oscillate. By having the person driving the spring adjust her rate of motion, she will eventually find a rate of motion that produces a single standing wave on the spring. This rate is the fundamental frequency, and it is dependent upon the tension in the spring as well as the spring's mass per unit length. The fundamental frequency can be measured by timing the up and down motion of the standing wave for 20 cycles and dividing 20 by the recorded time, giving you the fundamental frequency in cycles per second. Other harmonics of the spring can be produced by increasing the driving rate to integer multiples of the fundamental frequency.

State of the Art of Supersonics Aircraft Technology–What Has Progressed in Science Since 1973

Victor W. Sparrow, Cochair
Pennsylvania State Univ., Graduate Program in Acoustics, 201 Applied Science Bldg., University Park, PA 16802

Laurette Fisher, Cochair
Federal Aviation Administration, 800 Independence Ave., SW, Washington, D.C. 20591

This panel discussion is an FAA public meeting on the advances in supersonic aircraft technology and related research in the noise generated during supersonic flight. The purpose of this session is to raise public awareness of the continuing technological advances in supersonic aircraft technology, and for the FAA, the National Aeronautics and Space Administration (NASA), and industry to get feedback from interested persons. The session will include presentations on current research programs and a question and answer session. Public involvement is essential in any future definition of an acceptable new standard that would allow supersonic flights over land. The discussion is open to all interested parties, and there are no fees to attend this session. [The FAA thanks the ASA for the opportunity to include this panel discussion as a part of the ASA's 159th meeting, joint with Noise-Con 2010.]

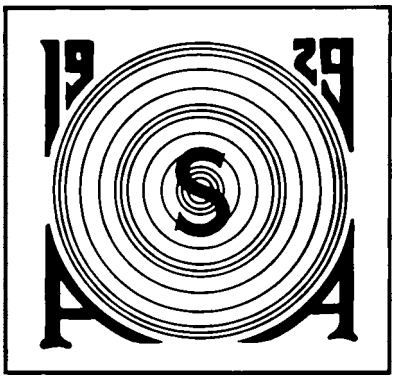
OPEN MEETINGS OF ASA TECHNICAL COMMITTEES

The Technical Committees of the Acoustical Society of America will hold open meetings on Tuesday, Wednesday, and Thursday evenings. On Tuesday and Thursday the meetings will be held immediately after the Social Hours. On Wednesday, one technical committee will meet at 7:30 p.m.

These are working, collegial meetings. Much of the work of the Society is accomplished by actions that originate and are taken in these meetings, including proposals for special sessions, workshops, and technical initiatives. All meeting participants are cordially invited to attend these meetings and to participate actively in the discussions. The Technical Committee on Signal Processing in Acoustics will meet tonight in Grand Ballroom III/IV beginning at 7:30 p.m.

ACOUSTICAL SOCIETY OF AMERICA

R. BRUCE LINDSAY AWARD



Kent L. Gee

2010

The R. Bruce Lindsay Award (formerly the Biennial Award) is presented in the Spring to a member of the Society who is under 35 years of age on 1 January of the year of the Award and who, during a period of two or more years immediately preceding the award, has been active in the affairs of the Society and has contributed substantially, through published papers, to the advancement of theoretical or applied acoustics, or both. The award was presented biennially until 1986. It is now an annual award.

CITATION FOR KENT L. GEE

. . . for contributions to the fields of jet noise propagation, nonlinear acoustics, and active control of fan noise

BALTIMORE, MARYLAND • 21 APRIL 2010

Kent Leonard Gee was born in Cleveland, Ohio and grew up in nearby Bay Village. A career in education seemed likely for him, as his father was a faculty member at Cleveland State University, and his mother was an elementary school teacher. In high school, Kent studied physics for two years, taught by a great instructor, and decided that he wanted to be a teacher. In 1994, Kent moved to Provo, Utah to attend Brigham Young University (BYU) on a full-tuition scholarship. After one year of schooling he took a two-year break to serve in southern Spain as a missionary for his church. He then returned to BYU to further pursue his education.

Kent is a well-rounded individual. He was blessed with speed and ran track for BYU for two years until injuries led him to give up that activity. Kent enjoyed playing the trumpet and piano, even composing some music occasionally. Most importantly for his future career, it was during this time that he discovered the field of acoustics. He realized he had a passion for the subject, and began taking graduate acoustics courses at BYU during his junior year in 1999-2000.

Armed with his new-found training in acoustics, Kent headed back home for the summer of 2000 for an internship at the Acoustical Testing Laboratory at NASA Glenn Research Center under the direction of Beth Cooper. Although he primarily worked on instrumentation and identifying flight-approved acoustic materials for the International Space Station, it was during also this internship that Kent was first exposed to the field of nonlinear acoustics.

Kent completed his BS in Applied Physics with an acoustics emphasis in 2001, graduating magna cum laude with minors in mathematics and Spanish. He immediately continued at BYU in their graduate program, working with Scott Sommerfeldt on developing a new approach for active noise control of small axial fans. Kent developed a novel compact control system that locates all acoustic control sources and sensors in the near field—very challenging for achieving global active control. This work was later published in the *Journal of the Acoustical Society of America* (*JASA*) and in the *Noise Control Engineering Journal* (*NCEJ*). The *NCEJ* paper was recognized in 2004 by the Institute of Noise Control Engineering (INCE-USA) with its biennial Martin Hirschorn IAC Best Paper award. Kent also developed his multitasking skills at BYU. In addition to his thesis research on axial fans, Kent took on the lead role in developing a three-dimensional intensity scanning system for NASA Glenn, which developed out of his earlier internship.

After graduating from BYU with his M.S. in Physics in 2002, Kent moved to Penn State to pursue a Ph.D. in the Graduate Program in Acoustics. Vic Sparrow was able to attract him with a University Graduate Fellowship in the Fall of 2002 and a Graduate Research Assistantship related to the propagation of high-amplitude jet noise beginning in the summer of 2003. During the joint Penn State/Wyle Laboratories project funded by the U.S. Department of Defense (DoD), Kent was able to rub shoulders with experts both in academia and industry. Penn State faculty members exposed him to different perspectives on jet noise and acoustical measurement techniques. Wyle staff members also provided sage advice and assistance, as well as the opportunity to participate in propagation measurements on an F-22 Raptor aircraft at Edwards Air Force Base to provide benchmark experimental data.

Kent's Ph.D. research focused on accurately predicting the far-field propagation of high-amplitude military jet noise—something not accomplished previous to Kent's work. This is an extremely important topic due to the rapid encroachment of populated areas around military air bases. Extending an approach originated by David Blackstock and his students, Kent was the first person to make accurate predictions based on the physics of the problem, rather than empirical guesses. The propagation of nonlinear jet noise is a challenging topic, but Kent makes it look easy. Multiple peer-reviewed publications have

come out of the work and his methods have been used directly by Wyle to produce a new DoD military jet noise prediction model. Certainly through this research, Kent has become a superlative young contributor to acoustics.

After graduating with his Ph.D. in the summer of 2005, Kent had several options to consider, but decided to return to BYU in a faculty position—first as a Visiting Assistant Professor and then in a permanent position since January 2006. He has been an important contributor to building the acoustics program at BYU, which currently has about 30 students enrolled—about half graduate and half undergraduate students. Kent has supervised four M.S. students, and is currently supervising an additional two M.S. students and one Ph.D. student. Perhaps equally impressive for the future of acoustics, he has supervised 16 undergraduates in acoustics research, at least half of whom have gone on to pursue graduate degrees in acoustics.

Kent's multitasking skills are evidenced in his research interests, where he has worked on studying high-amplitude jet noise and rocket noise, near-field acoustical holography, Gatling gun noise, active noise control, and acoustics demonstrations. He has published much of this work, with close to half of his papers appearing in *JASA*. Outreach in acoustics is important to Kent. He has given tours of BYU's acoustics facilities to hundreds of K-12 students and participates in the American Association of Physics Teachers to help educators understand how acoustics can be a wonderful mechanism to teach physics principles.

Kent has participated regularly in activities of the ASA since 2002. He has presented his work at the majority of the meetings since then, is a member of the Physical Acoustics and Noise technical committees, and has been particularly active in the Committee on Education in Acoustics. He received two student paper awards during his student years and the Noise Young Presenter award shortly after graduating. His students now regularly receive paper awards. Kent also serves as the Associate Editor for Noise for ASA's *Proceedings of Meetings on Acoustics*.

Kent and his wife, Alicia, are the parents of five children—one born while Kent was a student at BYU, two born while he was studying at Penn State, and two born since he returned to BYU. Again multitasking comes into play, as Kent balances his time between his family, which is very important to him, and the passion he feels for his chosen discipline.

CITATION FOR WILLIAM S. RHODE

. . . for discovering nonlinear basilar-membrane responses and for contributions to cochlear-nucleus functional circuitry

BALTIMORE, MARYLAND • 21 APRIL 2010

By 1960 the basic "tonotopic" pattern of vibrations set up in the mammalian cochlea by sound was understood, thanks to the life's work of Nobel-Laureate Georg von Békésy. His research showed that a pure tone produces a mechanical vibration on the cochlea's basilar membrane, at that sound's frequency, which propagates along that membrane from the cochlea's input port at the base toward its apex. The lower the tone's frequency, the further along the basilar membrane that traveling wave progresses until it hits an apparent "resonance," crests, and vanishes. Yet puzzles remained. These vibrations were uniformly linear over most of the audible intensity range, and they were tiny: the estimated peaks at hearing thresholds were on the order of 10^{-3} nanometers. Could such sub-atomic motion possibly stimulate receptors? Moreover, von Békésy's measurements, made with ordinary (wideband) light, showed only very shallow (low-Q) resonances on the basilar membrane. How then account for the exquisite frequency sensitivities displayed by mammalian auditory-nerve neurons and, psychoacoustically, by mammalian listeners?

Little further progress was made until 1967, when a brief paper in *Science* by Johnstone and Boyle of Australia introduced a more sensitive technique for measuring vibrations of the basilar membrane using a quantum-mechanical (Mössbauer) effect. William (Bill) Rhode, looking for a dissertation project at that time, decided to follow up that initial finding. This necessitated combining very exacting surgical techniques with mastery of unfamiliar gamma-ray equipment, while utilizing and programming one of the very first dedicated laboratory computers (a LINC). Displaying most extraordinary multidisciplinary skill and tenacity over scores of experiments, Bill succeeded in making reliable measurements of basilar-membrane vibrations in the basal (high-frequency) region to pure tones using the new technique. His initial results, published in the *Journal of the Acoustical Society of America* (*JASA*) in 1971, had a stormy reception. They showed, contrary to von Békésy's results, that the traveling-wave vibrations on the basilar membrane were markedly nonlinear, having peaks that were more sharply tuned at low sound intensities than at higher ones. It took almost 10 years for Bill's results to be generally accepted.

Since then, work in several laboratories, including his own, has confirmed that vibrations in the living and undamaged mammalian basilar membrane are indeed strongly nonlinear and sharply tuned at low intensities. In essence, each segment of the cochlear partition contains a "cochlear amplifier" that operates around its "resonant" frequency with amplifications at low intensities of up to 60 dB (compared to a post-mortem cochlea). Bill's pioneering role in discovering and exploring this "amplification" is well recognized. His 1971 paper alone has been referenced at least 625 times. More formally, he received the Samuel Talbot Award of the Institute of Electrical and Electronic Engineers for the best biomedical engineering Ph.D. thesis (1970), and in 2001 Bill received the Award of Merit from the Association for Research in Otolaryngology.

Parallel with his continuing work on cochlear mechanics, in the late 1970's Bill tackled the equally daunting task of understanding how neurons in the mammalian cochlear nucleus (CN), the first integrative stage of the auditory pathway, handle the information they receive from the auditory nerve. At the time, there existed substantial work on the anatomy of the cochlear nucleus. Anatomists had shown that it contains more than a dozen different types of neurons of which many are intermingled. Over the previous decade auditory electrophysiologists, too, had explored the cochlear nucleus, finding that the responses of its neurons to sounds were complex and quite varied. However, the fact that CN neurons with differing response patterns are not spatially segregated made it impossible in most cases to definitively associate particular response types with anatomical types in extra-cellular recordings. Bill reasoned that establishing such associations would require making intra-cellular recordings of responses to sounds of individual neurons and then labeling them so that the responses of individual neurons could be unambiguously assigned to particular anatomical types. Once again he tackled a fundamental

problem with a challenging technique: it is very difficult indeed to impale small neurons in animals whose every heartbeat and every breath threatens to pull the cell away from the electrode. With great experimental finesse, Bill and two junior colleagues succeeded in correlating anatomical cell types with the various response types to sound. Their pioneering work on both the dorsal and ventral divisions of the cochlear nucleus opened the door to major advances in our understanding of how the different sub-circuits in these nuclei process auditory information.

In addition to the twin peaks of his career, Bill has kept up a steady stream of publications on how auditory-nerve neurons and CN neurons respond to a wide variety of sound stimuli. He has been particularly interested in finding out to what extent the vibrations of the cochlear partition can account for the responses of these neurons. In the same vein, he has just recently published a paper showing correlations between (nonlinear) distortion-product otoacoustic emissions and related components in basilar-membrane vibrations.

Bill received his Ph.D. in Electrical Engineering from the University of Wisconsin-Madison (UW) in 1969, and has worked there ever since. During his tenure in Madison, where he rose to the rank of Professor of Physiology (now Emeritus), Bill was also a key player in the University's development of laboratory computing. He was first the Assistant Director (1970-72), then Director (1972-78), of the Laboratory Computer Facility, which introduced laboratory computing to the UW Medical School. He also was responsible for one of the first digital stimulus systems, which he built with the aid of the Medical Electronics shop and sent to many colleagues across the country.

In summary, Bill Rhode has made extensive and seminal contributions to the field of auditory physiology. Remarkably, he has done much of this work with his own hands, usually working, throughout his career, either by himself or with just one or two junior colleagues, most of whom have gone on to productive careers of their own in auditory physiology. For the truly stellar quality of his work, Bill's many friends join with me in congratulating him.

Physical Acoustics

Ronald A. Roy

2010

The Silver Medal is presented to individuals, without age limitation, for contributions to the advancement of science, engineering, or human welfare through the application of acoustic principles, or through research accomplishment in acoustics.

CITATION FOR RONALD A. ROY

. . . for contributions to the fields of biomedical ultrasound and nonlinear bubble dynamics

BALTIMORE, MARYLAND • 21 APRIL 2010

Ronald Aurele Roy grew up in Lewiston, Maine, a former mill town on the banks of the Androscoggin River, in a Catholic, Franco-American family. French was spoken at home and continued throughout the family's adult years. Ron's father worked in a shoe shop and his mother in a textile mill. Even though money was tight, Ron's mother bought him science kits, a microscope, helped him set up science experiments in his room, and accompanied him to science fairs all over Maine. It is apparent that Ron has been an avowed scientist since he was a child.

Ron attended St. Dominic Regional High School: Angela Mickalide, a classmate, recalls, "Even as a high school student Ron was brilliant. He grasped complex ideas quickly, and posed innumerable questions that his teachers could rarely answer. However, his Achilles' heel was his atrocious spelling [which continues to this day]. Ron would tutor me daily in physics. On tests, I often earned a hundred percent, but Ron only received ninety-nine percent because he would spell words like 'parallel' incorrectly. As a result, I was awarded the Physics Prize at the Senior Award Ceremony. But don't feel too badly for him—Ron earned the Mathematics Prize!"

After high school, Ron worked at General Electric for a year before attending the University of Maine (UM) in Orono. After his junior year, Larry Crum received a phone call from a friend at UM, Orono who asked whether Larry had any openings for a first-rate undergraduate physics student. Within a few days, Ron showed up at the University of Mississippi and began working in Larry's lab, starting a partnership that has continued to this day. Ron soon acclimated to the southern culture, but never to the southern weather—he would be soaking wet with sweat before he got to the lab from his dorm room—but by the end of the summer, he had not only performed some original research but had organized the lab, and assigned specific projects to all the graduate students.

After the urging of many of the Ole Miss Physics faculty, Ron returned to Oxford and entered graduate school in physics in 1981. It was soon obvious that Ron was an exceptional student. After he finished his MS degree, and having won an Office of Naval Research (ONR) Graduate Student Fellowship, Ron returned to the Northeast and the ivied halls of Yale University where he joined Bob Apfel's research group. His colleagues at Yale, Christy Holland and Carr Everbach, among many others, recall his tireless efforts to manage Apfel's cluttered laboratory and make progress on his Ph.D. research project: "The characterization of individual cell properties by ultrasonic scattering." Ron was also a compassionate mentor to his fellow graduate students, and was given the honor of teaching acoustics to both undergraduate and graduate students.

After graduation from Yale, Ron stayed on to run Bob Apfel's start-up company, Apfel Enterprises, Inc., exploring his entrepreneurial bent. Somehow the South had grown on Ron, so he returned to Oxford as one of the first employees of the National Center for Physical Acoustics. Ron was involved in a number of research projects, but soon set about trying to explain the acoustics associated with bubbles in the ocean. Ron conducted a multi-institutional experiment at Lake Seneca in New York to determine the characteristics of bubble cloud scattering. The experiment was difficult and initially failed; however, Ron was persistent and succeeded in the unique measurement of low frequency scattering from a submerged bubble cloud, the only free field measurement of collective scattering, which was published in the *Journal of the Acoustical Society of America* (*JASA*) in 1992. This experimental effort exhibited Ron's attributes: the ability to work arduous hours, his considerable experimental abilities, and his dogged persistence to see a project through to its conclusion.

In 1991, Ron decided to try out the West Coast for a change and joined the Applied Physics Laboratory (APL) in Seattle, where together with Larry Crum, they formed an acoustics research group at the University of Washington (UW). At APL/UW, Ron was involved in research in sonoluminescence, ambient noise in the ocean, acoustic cavitation

in liquids, and a number of widely diverse topics. Throughout his entire career, Ron is known for the rigor of his experimental studies and his insight into all sorts of physical phenomena. His publications soon attracted the attention of Allan Pierce who was building a strong acoustics group at Boston University and Ron circled back to the East coast. At Boston University Ron's work on sound scattering from microbubble distributions including the dynamics of bubbles, mutual bubble interactions and the properties of bubbly liquids had significant impact on underwater acoustics and sonar signal processing.

In 2006, Ron was selected as the 65th George Eastman Professor of Oxford University, which is a distinguished Chair appointed annually to a citizen of the United States who is deemed to be of great eminence in teaching or research in any field of study. Prior Eastman Professors include Deans, Distinguished Faculty Chairs, a Justice of the U.S. Supreme Court, and 12 Nobel Prize winners. Ron was the first engineer to hold this post in the long history of this prestigious award. Following his year in Oxford, he returned to Boston University where he is currently the Chair of the Department of Mechanical Engineering.

Ron has been an active member of the Acoustical Society of America, rarely missing a meeting, serving on numerous committees, including the Executive Council, and perhaps having the singular distinction of being the only individual who has served as Chair of two Technical Committees. With nearly 40 *JASA* articles and almost 100 others in similar journals, Ron is considered one of the world's experts in biomedical ultrasound, acoustic cavitation, and bubble physics.

Ron is married to Nancy Stone Roy and they have two children, Caitlyn and Sydney, both Boston University graduates.

CITATION FOR JIRI TICHY

. . . for contributions to acoustical intensity measurement, active noise control, education in acoustics, and for service to the Society

BALTIMORE, MARYLAND • 21 APRIL 2010

Jiri Tichy was born in the former Republic of Czechoslovakia. He studied electrical engineering and physics, received a doctorate in Technical Sciences (DSc) from the Czech Technical University in Prague in 1952, and was awarded the Diploma Habil in 1965. Later, he was appointed Associate Professor of Physics in the Department of Physics at the Czech Technical University. Early on he was interested in acoustics and published many papers on acoustics topics.

Jiri was acquainted with two American acousticians: Lawrence Batchelder and Leo Beranek who helped him to immigrate to the United States in 1968. He landed at the Pennsylvania State University, teaching architectural acoustics in the Department of Architectural Engineering and the Acoustics Graduate Program. His interaction with the large Penn State acoustics community, spread over six academic departments, and the Applied Research Laboratory allowed him to expand his professional work in acoustics. He was promoted to full professor in 1972 and was transferred to the Graduate Program in Acoustics where he was appointed the chairman of the Program. That program, which was initially an intercollege graduate program, was expanded later to become a full-fledged graduate department in the College of Engineering. It is the only program in the United States that awards M.S. and Ph.D. degrees in acoustics. Jiri served as the Program Head until his retirement in 1997, serving for 25 years.

Jiri's research expertise was primarily in audio engineering, noise, acoustic intensity, and active noise control. He is a pioneer in the measurement of acoustic intensity techniques, and has written seminal papers on the topic. These include "Measurement of the Complex Acoustic Intensity and the Acoustic Energy Density," with G. Elko in *Proceedings of Inter-Noise 84*, and "Instantaneous and Time-Averaged Energy Transfer in Acoustic Fields," with J. Mann and A. Romano in the *Journal of the Acoustical Society of America* (*JASA*) in 1987. He presented a Tutorial Lecture on this subject at the 115th meeting of the Acoustical Society of America (ASA) and delivered keynote speeches at the International Seminar on Noise Control, Rio de Janeiro, Brazil in 1989 and the Acoustical Society of Japan meeting in 1997.

Jiri Tichy's pioneering contributions in active noise control include the use of feed-forward control in signal processing techniques for the control of noise from many sources, within enclosures, rooms, halls, and ducts. Two of his seminal contributions are "Global Attenuation of Broadband Noise Fields Using Energy Density Control," with Y. C. Park and S. D. Sommerfeldt in *JASA* in 1997, and "Narrowband and Broadband Active Control in an Enclosure Using the Acoustic Energy Density," with J. W. Parkins and S. D. Sommerfeldt in *JASA* in 2000. He delivered keynote speeches on the subject at the tenth Brazilian Conference of Mechanical Engineers (1989), the Acoustical Society of Korea meeting in 1991, Acoustical Congress of Chile, as well as Internoise '95 and Internoise '01. These keynote speeches delivered at international meetings indicate the remarkable reputation and stature Jiri holds in acoustics in the national and international arenas.

Jiri has been a member of ASA since he came to the United States. He has devoted a major part of his entire professional society activities to ASA. He is a Fellow of the Society and has served in many positions. These include Chair of the Technical Committee on Noise, member of the Technical Council, Technical Program Chair for the ASA meeting in State College (1997), and Co-organizer and Co-chair of the ASA/EAA Meeting in Berlin (1999). He served very effectively as Vice-President of ASA (1992) and as its President (1993). He also served on various committees, such as publication policy, education, and medals and awards.

He has served as President of the Institute of Noise Control Engineering (INCE) (1986), and its Board of Governors (78-83), General Chair of Noise-Con '87, and '97, and General Chair of ACTIVE '95 and '97. He is also active in the Audio Engineering Society and is an Honorary Member of the Czech Acoustical Society. Such activities involving national and international societies point to a highly respected and acclaimed scientist and leader in acoustics.

Jiri Tichy has dedicated his life to education in acoustics. He has nurtured the Acoustics Graduate Program at Penn State since 1972. During those years, graduate enrollment increased from 30 to over 100 graduate students. He established a Continuing Education Program for industry, and a Certificate Program in Acoustics. He also mentored 28 M.S. and Ph.D. candidates in acoustics throughout his tenure at Penn State.

Jiri and his wife Dagmar, who passed away in 2003, were married in Prague in 1955. They had one daughter who is currently the head of the Oncology and Hematology Department at the Toledo Children's Hospital, Ohio. Jiri and his present wife, Iva, split their time between Toledo and Prague.

In conclusion, I am very happy that the Society has recognized Jiri's many accomplishments by awarding him the prestigious Gold Medal

SABIH I. HAYEK

Architectural Acoustics and Engineering Acoustics: Rooms for Reproduced Sound I

K. Anthony Hoover, Chair
McKay Conant Hoover, Inc., 5655 Lindero Canyon Rd., Ste. 325, Westlake Village, CA 91362

Invited Papers

9:00

4aAAa1. Design of critical listening rooms: A historical perspective. Peter D'Antonio (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774, pdantonio@rpginc.com)

Critical listening room design has progressed to follow loudspeaker evolution from mono to two-channel to multi-channel, as well as the advances in loudspeaker quality. There are basically two fundamental approaches to two-channel room design. The non-environment room, in which the contribution of the room is minimized, and versions of live-end-dead-end, in which early reflections were minimized creating a spatio-temporal reflection free zone and diffuse reflections from the rear of the room are used to create passive surround sound. This presentation will focus on an immersive design for multi-channel loudspeaker formats, which utilizes broad bandwidth absorption and diffusion. Research with low-frequency plate resonators and a broad bandwidth diffusion chamber has contributed to the proposed design and results will be discussed. The proposed multi-channel critical listening room includes the use of low-frequency control down to 40 Hz provided by 4-in.-thick metal plate resonators on a portion of the front wall and in all corners, broad bandwidth diffusion on all wall and ceiling surfaces, and strategically placed multiple subwoofers. The intent is to minimize monophonic reflections and create lateral enveloping energy by uniformly scattering sound from all of the active sound sources in the room.

9:20

4aAAa2. Work on the reproduction of sound at the Visualization Laboratories at the King Abdullah University of Science and Technology: A case study. Steve Ellison (Meyer Sound Labs, Inc., Berkeley, CA 94702, ellison@meyersound.com) and Peter Otto (Sonic Arts, CalIT2/UCSD, La Jolla, CA 92093, potto@ucsd.edu)

Researchers at the newly opened King Abdullah University of Science and Technology are developing new ways to visualize and auralize complex data sets in immersive environments. These environments include the Interactive Media Room, a 100-seat multi-purpose facility, and Cornea, a $10 \times 10 \times 10$ in.^{3} six-sided stereoscopic cave. Both facilities are equipped for multi-channel audio generation and playback in various standard and custom formats, as well as electronically variable acoustics utilizing electroacoustic architecture. Concurrent viewing and dialogue between participants in the two spaces is supported. Fully immersive environments present unique challenges due to physical properties of projection screens and the geometries that characterize these structures. Explorations of Cornea at KAUST and StarCave at UCSD are presented, along with strategies for reproducing sound and varying acoustics in these environments. Multi-use facilities such as the IMR also have conflicting acoustical goals. For instance, the optimal acoustic for multi-channel or cinematic reproduction is less reverberant than optimized classroom environments. The use of electroacoustic architecture to improve the listening and overall immersive experience at both Cornea and the Interactive Media Room is discussed. Examples are presented including an experimental VR emulation of the acoustics of the King Abdullah Grand Mosque on the KAUST campus.

9:40

4aAAa3. Seelos Theater: A case study for a renovated multipurpose room with multiple loudspeaker systems. Matthew J. Moore, Alexander G. Bagnall, and Aaron M. Farbo (Cavanaugh Tocci Assoc., 327 F. Boston Post Rd., Sudbury, MA 01776, mmoore@cavtocci.com)

The Seelos Theater at Holy Cross College has been renovated twice since starting out as a bowling alley in the main student center on campus. This most recent renovation provided an opportunity for the school and design team to update and modernize this heavily used lecture hall and cinema. The authors will show how two different loudspeaker systems and AV systems were integrated with the architectural acoustics design built for reproduced sound. The authors found that the resultant performance of the systems performed better than was expected in computer modeling. Existing mechanical system noise mitigation, integration of existing film equipment, short construction timelines, and serving the needs of different audience types will be discussed. The authors used lessons learned with this project to help with the design of spaces for future projects.

10:00

4aAAa4. Speaker coverage in active acoustic music practice rooms. Ronald Freiheit (Wenger Corp., 555 Park Dr., Owatonna, MN 55060, ron.freiheit@wengercorp.com)

Larger music practice rooms (>25 m^3) present unique challenges compared to smaller, traditional practice rooms (6–12 m^3) when employing active acoustics technology and integrated digital recording. An experiment was conducted comparing a ceiling array of 32 speakers in a large music practice room ($5.3 \times 5.7 \times 2.7$ m^3, 81 m^3) with that of eight speakers located in corners of that room (one at the

top and one at the bottom in each corner facing parallel to the walls). The goal was to determine which speaker configuration would be the most effective for creating even sound field coverage and uniform frequency response. Data were collected for both seated and standing positions in the room from a matrix of 42 locations. Frequencies from 40 Hz to 8 kHz were plotted for analysis. The data were compared to the qualitative preferences expressed by a number of musicians using the rooms for both practice sessions (with the active acoustics enabled) and listening to the playback of recorded practice sessions.

10:20

4aAAa5. Small music venues and amplified sound: High-sound pressure levels and architecture. David S. Woolworth (Oxford Acoust., Inc., 356 CR 102, Oxford, MS 38655, dave@oxfordacoustics.com)

This paper is a survey of typical popular live music venue sound pressure levels observed in Oxford, MS. An attempt is made to measure clarity and articulation in the venues with increasing sound pressure, and the results are correlated with previous observations of Knudsen and others. Additional analysis of challenges to sound operators and programs to control high-stage volumes are discussed.

10:40

4aAAa6. Mixing studio isolation. Anthony K. Hoover (McKay Conant Hoover, Inc., 5655 Lindero Canyon Rd., Westlake Village, CA 91362)

A new suite of mixing and teaching studios had been discussed for many years at Berkley College of Music in Boston. The authorization to proceed with design and construction of the studios finally came with a new Dean of the Music Technologies Department, who, without benefit of much of the background and previous discussions, contacted an old colleague for the final studio design, and then contracted with a reputable full-service contractor for construction services. Some unusual problems developed during construction, which sensitized the client to subsequent situations, in turn requiring acoustical consulting services. This paper will review some of the project history, outline the problems, and discuss solutions and recommendations, and will address some of the concerns with the specialized construction and unusual complications.

11:00

4aAAa7. Edison phonograph recording and reproduction in a concert hall. Alex U. Case (Sound Recording Tech., UMass Lowell, 35 Wilder St., Lowell, MA 01854, alex_case@uml.edu)

A recent recording session at the University of Massachusetts Lowell merged the birth of sound recording with the state of the art. A small ensemble performed an original piece of music—composed in the style of early 1900s American music—on stage in Durgin Concert Hall. It was recorded live to both high-definition digital multitrack and an original Edison wax cylinder phonograph. As the acoustical influence of the phonograph is substantial, several takes were needed to adjust the balance of the live performance to maximize the musical impact of the reproduced sound realized through wax cylinder playback. Multiple sonic viewpoints were simultaneously recorded: stereo, surround sound, close microphones, and Edison phonograph. The resulting recordings are played and discussed.

11:20

4aAAa8. Soul spaces: How acoustics influence the music production process and the recordings that result. Matthew B. Zimmern (8 Illsley Hill Rd., West Newbury, MA 01985, matthewzimmern@gmail.com)

Spaces in modern recording studios are quite different than those of 40 years ago. While today it is common for recording facilities to have various multi-purpose, acoustically designed spaces, many recordings from the middle of the 20th century were often captured in a single room, one that was not constructed with acoustical principles in mind and often times featured acoustical deficiencies. Soul music production practices of the late 1960s were researched, and an original composition was recorded in two different ways: by using past recording techniques and by using contemporary musical practices. Through listening to audio examples of the same song recorded in two different spaces, the sonic qualities of the different recording environments will be discussed, as well as how the different production techniques affected the recording, musical, and aesthetic attributes of the resulting audio recordings.

11:40

4aAAa9. Obtaining a frequency independent reverberation time in listening rooms. Niels Werner Adelman-Larsen (Flex Acoust., SCION-DTU, Diplomvej 377, 2800 Kgs. Lyngby, Denmark, nwl@flexac.com), Cheol-Ho Jeong, and Jiazi Liu (Tech. Univ. of Denmark, 2800 Kgs. Lyngby, Denmark)

High-frequency sound emitted from loudspeakers is very directive and can be easily aimed at the listeners. Investigations show that even a few people decrease the mid-/high-frequency reverberation time of a room significantly both due to actual absorption but also due to the scattering of the sound that they introduce which makes the placement of absorptive material important. People absorb approximately one-sixth of the sound at low frequencies than at high frequencies, but still much reproduced music contains very loud levels of bass frequency sound. In order to avoid loud, reverberant bass sounds masking the direct mid-/high-frequent sound, the room needs to be designed with quite large amounts of bass absorption in order to properly serve its purpose. Helmholtz and porous type absorbers need a large cavity in order to also achieve bass absorptive qualities and this is a challenge in many smaller rooms. Membrane absorbers require less space and due to the omni-directional behavior of bass sound their placement is not so critical. This paper will present new measurements of absorption coefficients of standing persons as well as a new type of modular bass absorber system: 2.6 in. deep, absorption coefficient of 0.6 from 50–125 Hz, and designed to readily incorporate into the architectural design.

8:05

4aAAb1. The Festival Hill concert hall. Richard Boner and Pamela Harght (BAi, LLC, 4006 Speedway, Austin, TX 78751 rboner@baiaustin.com)

The Festival Institute at Round Top, TX, was established in 1971, and began with ten pianists performing on an open stage, under the stars. Following the dream of the founder, Concert Pianist James Dick, Festival Hill has grown to be a premier summer venue for classical music, with over 30 concerts performed each June and July. The August-to-April Series, the International Guitar Festival, the Theatre Forum, The Poetry Forum, and the Herbal Forum bring the total number of year-round events to more than 50. This paper focuses on the excellent and visually unique 1000 seat concert hall, which was built in stages over a 26-year period from 1981–2007. Also discussed are the renovated 19th-century homes which have been moved to Festival Hill, serving as housing and practice spaces for musicians.

8:30

4aAAb2. Whispering arches as intimate soundscapes. E. Carr Everbach (Swarthmore College, Swarthmore, PA 19081) and David Lubman (DL Acoust., 14301 Middletown Ln., Westminster, CA 92683)

Whispering archways are whispering galleries. They are sometimes found around smooth arches, doorways, and even bridges. Persons positioned on opposite sides of a whispering arch communicate privately by whispering into the arch. In that way they function as private and even intimate soundscapes. Some whispering arches that have stood for centuries have inspired local folk legends. Such acoustical architecture can help to establish a sense of place and strengthen emotional ties. It is said that a whispering arch at the entrance to a 10th c. Gothic cathedral at the historic monastic site of Clonmacnoise in the Irish midlands figured in local courtship for centuries. There, shy young lovers are said to have uttered vows of love and proposals of marriage. The arch was also used by lepers to give confession without infecting the priest. Whispering arches were almost certainly unintended in the past but can also be created intentionally as an intimate form of public art. Recent measurements on a whispering archway at West Chester University show that high background noise levels from traffic or air handlers can ruin an otherwise intimate space; however, so modern architects should plan the entire soundscape carefully.

Contributed Papers

8:55

4aAAb3. A performers guide to venue acoustics. David J Zartman (Graduate Program in Acoust., Penn State Univ., 405 EES Bldg., State College, PA 16801)

Whether in high school or the Vienna Symphony, musicians have little control over their performance venues. An instrument can be upgraded or replaced if there is an undesirable aspect, but replacing a venue is often far too expensive to be a tenable solution. A musician's perfect venue will also change piece to piece—an incredible venue for lush Wagner operas can cause issues for someone performing an intricate Paganini concerto and vice versa. What then are these effects? Why do they take place? How can a performer anticipate and combat undesirable aspects of venues while drawing out their featured characteristics for an optimized performance?

9:10

4aAAb4. Vineyard shape variations of the Concertgebouw, Amsterdam. Weihwa Chiang (Natl. Taiwan Univ. of Sci. and Technol., 43, Keelung Rd., Section 4, Taipei 106, Taiwan, Republic of China) and Wei Lin (Hwa Hsia Inst. of Technol., Chung Ho, Taipei, Taiwan, Republic of China)

The Concertgebouw, Amsterdam is a unique one of its kind because of the extra width and size for a classical rectangular hall and the significant portion of seats behind the stage. These characteristics make the hall as "semi-surround" as the vineyard halls of the present day. Computer simulation was performed to analyze the possibility of deriving design variations out of the Concertgebouw. Clarity, strength, sectional balance, and stage support of various settings of stage position and overall proportion were compared as the first step. Variations that contain the geometrical features of vineyard shape halls were further developed to optimize the three acoustical qualities and to reduce the differences among seats. The architectural features evaluated included surface treatments, arrangement of individual seating blocks, and the geometry of upper walls and the ceiling.

Chair's Introduction—9:25

Invited Papers

9:30

4aAAc1. Back to vitruvius? James B. Lee (6016 S. E. Mitchell, Portland, OR 97206, cadwal@macforcego.com)

There is no generally accepted theory of acoustics of concert halls based on the physics of sound as waves. Lord Rayleigh, founder of the science, remarked but little about sound in rooms. Wallace Clement Sabine made an analogy of sound in rooms to the kinetic theory of gases; although this is theoretically untenable, Sabine designed the superb concert hall which is the subject of this session. Leo Leroy Beranek published the first systematic examination of concert halls, demonstrating that subjective evaluations of acoustic quality are consistent: everyone agrees which are good and which are poor; nonetheless Beranek encountered severe difficulty in applying his experimental results. What aspects of the physics of Rayleigh explicate the data of Beranek and the design of Sabine?

9:55

4aAAc2. Simple acoustic source radiation near a large wall. Michael J. Moloney (Dept. of Phys. and Optical Eng., Rose-Hulman Inst. of Technol., 5500 Wabash Ave., Terre Haute, IN 47803, moloney@rose-hulman.edu)

An acoustic simple source is predicted to radiate twice as much sound near an infinite rigid wall as it does in free space. As the simple source becomes more distant from the wall, its radiated power is predicted to decrease in an oscillatory way toward the value it has in free space. This behavior can be observed indirectly by fitting a 10-s signal of decaying amplitude from a tuning fork resonator box at various distances from a large unobstructed wall. Each fit determines the damping constant b, which reflects power losses, including radiated acoustic power. In a plot of b versus distance from the wall, the oscillatory part of the damping constant closely matches the theoretical curve of total radiated power from a simple acoustic source near an infinite rigid wall.

10:20—10:30 Break

10:30

4aAAc3. Evaluation of a boss model and subtraction technique for predicting wideband scattering phenomena in room acoustics. Georgios Natsiopoulos (WSP Acoust., Rullagergatan 4, 41526 Gothenburg, Sweden, georgios.natsiopoulos@wspgroup.se)

Scattering from a hard hemisphere on an infinite plane is studied experimentally and theoretically in a laboratory environment using a subtraction technique. With this technique, the scattered field is determined by subtracting the transient responses from the plane with and without the boss present. Scattering for different combinations of transducer and hemisphere positions are then classified into a number of cases, denoted in-plane/off-plane and back-/forward/mixed scattering. Theoretical and experimental results are compared and evaluated from an auralization point of view using a one-third octave band smoothing of the contribution from the hemisphere. With the smoothing used, average intensity level discrepancies typically less than 3 dB are obtained for a six octave wide ka-interval, where a equals the hemisphere radius.

4aAB1. Model-based signal processing approach to animal bioacoustics: A brief overview. James V. Candy (Lawrence Livermore Natl. Lab., P.O. Box 808, L-151, Livermore, CA 94551)

The model-based approach to signal processing is generally founded on the fundamental concept of incorporating any *a-priori* knowledge of the underlying phenomenology from which the signal evolved along with measurement instrumentation and uncertainty (noise, parameters, etc.) in the form of mathematical models that are embedded in the processor. In this way, the phenomenologist, experimenter, and signal processor combine all of their possible knowledge into a scheme enabling each to think within their own comfort zones while developing a powerful approach to extract the illusive information they desire. In this overview, we present the concepts required to develop mode-based processing schemes that can be used in a wide variety of animal bioacoustics applications ranging from signal estimation, tracking, identification, detection, and classification. We discuss the development of this approach incorporating acoustic applications that can be extrapolated to animal bioacoustics problems. We can express all of these techniques in terms of a model-based framework enabling the use of such powerful estimation techniques such as Kalman filters (Gaussian case) to Bayesian particle filters (non-Gaussian case) for solution to a wide variety of problems.

9:20

4aAB2. Detecting and identifying cetaceans species from their acoustic emissions. Whitlow Au and Julie Oswald (Hawaii Inst. of Marine Biology, Univ. of Hawaii, P.O. Box 1106, Kailua, HI 96734)

In the past decade, the use of autonomous remote passive acoustic recorders to detect the presence of cetaceans has grown enormously throughout the world. Since these devices digitize acoustic signals at sampling rates in the tens of kHz, a single device can quickly accumulate many Gbytes of data in a short time. Therefore, automatic detection and recognition algorithms must be developed to handle the large amount of data. There is no general signal method processing method that can be applied to all species of cetacean. The algorithm by the name of ROCCA (real-time odontocete call classification algorithm) developed by Dr. Julie Oswald is probably the most general one that has been applied to the whistles of dolphins. The program, extensible bio acoustics tool (XBAT) developed by Harold Figueroa, is probably the most general tool for use with baleen whales. However, investigators also tend to develop their own algorithms to suit their requirements. The problems and difficulties in developing automatic detection and recognition algorithms will be the focus of this presentation. General principles associated with the geography, biology, and the characteristics of sound emissions in relation to the development of algorithms will be discussed along with examples of different approaches.

9:40

4aAB3. Overcoming the idiosyncrasies of spectrogram correlation detection. Kurt M. Fristrup (Natural Sounds Program, Natl. Park Service, 1201 Oakridge Dr., Ste. 100, Fort Collins, CO 80525)

Spectrogram correlation has been widely used to detect animal sounds. Effective application of this method to identify Black-capped Vireo (*Vireo atricapillus*) sounds in 22 000 h of environmental recordings required the use of multiple spectrogram templates for each general type of sound to ensure that substantial subsets of these sounds were not missed by the detector. Over 5 million candidate sounds were identified, but the majority of these were not confirmed by expert review. Accordingly, acoustical features were extracted from a stratified random sample of 8284 candidate sounds that were identified by experts, and a random forest classifier was developed to winnow out the false alarms. The estimated classification error varied by site from 0.5% to 6%. When this classifier was applied to the entire data set, approximately 740 000 vireo sounds were identified. This project illustrates both the feasibility of monitoring birds over large spatial and temporal scales and the challenge of adequately sampling the range of variation in a very restricted class of biological signals.

10:00—10:15 Break

10:15

4aAB4. Individual identification using hidden Markov models for population monitoring and assessment. Michael T. Johnson (EECE, Marquette Univ., 1515 W. Wisconsin, Milwaukee, WI 53233) and Patrick J. Clemins (Assoc. for the Advancement of Sci., Washington, DC 20005)

Individually distinct acoustic features are present in a wide range of animal species, just as they are in humans, and the widespread success of speaker identification in humans suggests that robust automatic identification of individual animals from their vocalizations is attainable. Despite this, only a few studies to date have yet attempted to use individual distinctiveness to help assess population structure, abundance, and density patterns. Here we present an approach, based on individual identification and clustering using hidden Markov models (HMMs), which enables a more direct mechanism for using individual vocal variability to monitor and assess populations. Current results indicate that the new method is able to give good estimates of local abundance based on vocalization clustering, which can in turn be used in an acoustic mark-recapture framework to estimate population. Limitations to this approach currently include the need for explicit call-type separation prior to individual clustering, which is possible in many species but can create a problem in species with unknown or variable repertoires. Overall, it is hoped that this new technique may lead to a more accurate understanding of population structure and abundance on a larger scale.

10:35

4aAB5. Identifying delphinid whistle contours using graph search. Marie A. Roch, Bhavesh Patel (Dept. of Comp. Sci., San Diego State Univ., 5500 Campanile Dr., San Diego, CA 92182-7720), Shannon Rankin (NOAA SW Fisheries Sci. Ctr., La Jolla, CA 92037-1022), Yvonne Barkley (Bio-Waves Inc., Encinitas, CA 92024), Melissa S. Soldevilla (Duke Univ., Beaufort, NC 28516), and John A. Hildebrand (Univ. of California, San Diego, La Jolla, CA 92093-0205)

The automated characterization of delphinid whistle contours can lead to insights (both potential and realized) into biological questions such as habitat use and behavior. Prior to the 1990s, most measurements of whistle contours were conducted manually by trained analysts, and even today the noisy signal environment offers significant challenges to fully automated classification systems. In this talk, we provide an overview of challenges and historical approaches to this problem. We present our recent research using graph search algorithms to characterize complex auditory scenes involving numerous animals vocalizing simultaneously. We end by discussing techniques that have the potential to further advance this area of research. [Work sponsored by ONR.]

10:55

4aAB6. Wavelets: A comparison with the spectrogram and other methods for time-frequency analysis. Patrick Loughlin (Dept. of Bioengineering, Univ. of Pittsburgh, 745 Benedum Hall, Pittsburgh, PA 15261, loughlin@pitt.edu) and Leon Cohen (Hunter College, CUNY, New York, NY)

Many natural signals exhibit spectral content that changes over time. Methods for time-varying spectral analysis first emerged in the 1940s with the development of the "sound spectrograph" at AT&T Bell Laboratories. Since then, the spectrogram has become the primary method for time-frequency analysis. Originally implemented as a bank of band-pass filters, today the spectrogram is typically computed digitally via the short-time Fourier transform. Recently, wavelets have been proposed as a superior method for time-frequency analysis. The usual argument is that the spectrogram uses a fixed window length, whereas the wavelet approach uses windows that are longer for lower frequencies and shorter for higher frequencies. While the benefits of this approach are usually taken as self-evident, we explore in critical detail the aims of time-frequency analysis, and the benefits afforded by wavelets versus the spectrogram and modern methods such as the Choi–Williams distribution. In particular, since a primary aim of time-frequency analysis is to study the local spectral and temporal characteristics of signals, we examine the local moments of the various methods. Local moments are related to important signal features such as the instantaneous frequency and bandwidth. We show the effect of fixed windowing versus variable wavelet windowing on these features.

4aAO1. Variation of uncertainty and resolution with problem formulation in continuous geoacoustic inversion. Andrew A. Ganse and Robert I. Odom (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th, Seattle, WA 98105, aganse@apl.washington.edu)

In continuous geoacoustic inversion, the resolution and uncertainty of the estimated ocean bottom are inherently linked by a tradeoff with each other. They also depend on the experiment geometry and the choice of formulation for the data and for the bottom model. For example, the resolution and variance will differ if the data are represented by an intensity envelope timeseries or a tau-p timeseries, or if wave slowness or bottom impedance is estimated. Previous work by the authors investigated variations in resolution and uncertainty with geometry and problem formulation based on linearization of the geoacoustic problem at a given solution. However, the problem is further complicated by the fact that the solution point itself can also depend on the geometry and data and model formulation so that the resolution and uncertainty vary for that reason also. This aspect of the nonlinear geoacoustic inverse problem is explored here. [Work supported by ONR.]

4aAO2. The estimation of geoacoustic parameters via frequencies 25–100 Hz. A. Tolstoy (ATolstoy Sci., Inc., 1538 Hampton Hill Cir., McLean, VA 22101)

This work will discuss recent efforts to extend a previously discussed low-frequency (LF) geoacoustic inversion method to slightly higher frequencies. In particular, the earlier method was "successful" at frequencies 25–50 Hz where an exhaustive search was possible even in the presence of errors in other (assumed known) parameters. However, some of the test data analyzed offered only one appropriate frequency (53 Hz) and did not converge to a unique solution. In fact, thousands of data fits were found. Here, we shall examine efforts to improve convergence by allowing for slightly higher frequencies. Range may also be a consideration at these LFs.

9:00

4aAO3. Travel time inversion of broadband data from Shallow Water 2006 experiments. Yong-Min Jiang (minj@uvic.ca) and N. Ross Chapman (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC, Canada)

This paper presents geoacoustic inversions of broadband signals collected by the L-shaped array SWAMI32 during the Shallow Water 2006 Experiments. The L-shaped array was deployed in 70 m of water off the coast of New Jersey. The vertical leg of the array (VLA) has 10 even spaced sensors which expends 53.55 m in the water column, while the horizontal leg (HLA) has 20 uneven spaced bottom moored sensors that give 256.43 m of the aperture. An acoustic source was maintained at a depth of 35 m and towed along a circle around the VLA at a speed of 0.5 knots. The distance between the acoustic source and the VLA was around 190 m. Mid-frequency (1100–2900-Hz) chirps received at the VLA and HLA were analyzed for investigating the variability of the sea bottom properties around the circle. The data at the HLA were analyzed to assist the identification of the bottom layer structure while the data at VLA were employed to carry out the geoacoustic inversion. Environmental data collected in the vicinity were used in the inversion to account for the variable water column environment. [Work supported by ONR Ocean Acoustics.]

4aAO4. Low-frequency attenuation and sound-speed measurements in marine sediments using an impulsive source. Altan Turgut, Jeff Schindall, and Steven Means (Acoust. Div., Naval Res. Lab., Washington, DC 20375)

Low-frequency (200–1000-Hz) sediment attenuation and sound-speed measurements were conducted at a site on the New Jersey Shelf where additional data sets from a chirp-sonar bottom profiler (2–12 kHz) and an acoustic-probe system (10–80 kHz) are available. Impulsive sound signals, generated by automated light-bulb implosions, are received by a 16-element vertical line array at short ranges ($<$500 m). Precursor arrivals and signals reflected from the R-reflector are used to estimate sediment sound-speed and attenuation. Attenuation in dB/m/kHz is estimated using the spectral-ratio technique and sound-speed is estimated from the travel-time analysis. Frequency dependency of sound-speed and attenuation is also investigated within a wide frequency band (200 Hz–80 kHz) using the results from impulsive source, chirp-sonar, and acoustic-probe measurements. Measured attenuation and sound-speed values seem to be well predicted by an extended Biot theory for sediments with distributed pore sizes. [Work supported by ONR.]

4aAO5. Studies on the effect of shear on compressional wave attenuation. Gopu R. Potty and James H. Miller (Dept. of Ocean Eng., Univ. of Rhode Island, Narragansett, RI 02882)

Results of a modeling study to examine the effect of shear on compressional wave attenuation are presented. This study also investigates a shear inversion algorithm based on interface waves using synthetic data. Recent studies suggest that inclusion of shear speed is necessary to explain the correct frequency dependence of attenuation. Synthetic data will be generated for elastic bottom, with different shear speeds, and these data will be inverted for compressional wave attenuation. This could provide insight into the effect of shear speed on the attenuation coefficient obtained from inversion at various frequencies. In addition to investigating this effect, we also develop inversion algorithms for shear speed. One of the most promising approaches is to invert the relation between seismo-acoustic interface waves (Scholte waves) that travel along boundaries between media and shear wave speed. The propagation speed and attenuation of the Scholte wave are closely related to shear-wave speed and attenuation over a depth of 1–2 wavelengths into the seabed. The dispersion characteristics of the Scholte wave has been successfully used for inversion of sediment shear properties. Synthetic data will be used in our study to develop an inversion scheme. [Work supported by Office of Naval Research.]

4aAO6. Toward passive acoustic remote sensing of ocean-bottom gas seeps. Chad A. Greene and Preston S. Wilson (Dept. Mech. Eng. and Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78712-0292)

Cold seeps are gas vents that are found in the ocean, often along continental shelves near sediment-borne methane hydrates. Methane hydrates and methane gas seeps are of particular interest both for their potential use as an energy source and for their possible contribution to global climate change. This work is an initial step toward passively locating cold seeps and quantifying their gas flow rates using acoustic remote sensing techniques. Results are presented from laboratory experiments in which gas fluxes were determined from the radiated acoustic signature of a model seep. The physical principle that supports the technique and its accuracy will be discussed. [Work supported by ONR.]

4aAO7. The card-house structure of mud: Energy between particles and its effect on bubble formation. Joseph O. Fayton (Rensselaer Poly. Inst., Troy, NY 12180, faytoj@rpi.edu), Allan D. Pierce, William M. Carey (Boston Univ., Boston, MA 02215), and William L. Siegmann (Rensselaer Poly. Inst., Troy, NY 12180)

A model of mud as a lyophobic colloid [Verwey and Overbeek (1948)] leads to a card-house structure of platelets, typically kaolinite or smectite particles. Because of isomorphous substitution, each platelet carries a distributed negative charge. The structure is immersed in water which, especially so for sea water, carries positive and negative ions, and the positive ions tend to cluster on both sides of the platelets, so that the composite platelet charge is zero, but each platelet is analogous to a sheet of longitudinal electrical quadrupoles. The charge distribution causes parallel platelets to repel each other, but which can attach so that one platelet edge can touch the face of another platelet. The energy associated with such attachments is discussed, and it is conjectured that it is associated with van der Waals and London attraction forces. Recent sound transmission experiments by Carey at Dodge Pond in Connecticut support the contention that sediment mud invariably contains vapor bubbles, and other work such as that of Boudreau *et al.* (2005) suggests that the bubbles are considerably flattened, with shapes that have been described as corn-flakes. Present paper conjectures as to whether these shapes are associated with the card-house structure of mud.

10:30

4aAO8. An investigation of the combustive sound source. Andrew R. McNeese, Jason D. Sagers, Preston S. Wilson (Dept. of Mech. Eng. and Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78712-0292), and David P. Knobles (The Univ. of Texas at Austin, Austin, TX 78713-8029)

The combustive sound source (CSS) is a versatile impulsive underwater sound source with an adjustable bandwidth and output amplitude. Unlike typical impulsive acoustic sources, CSS can maintain a wide bandwidth at low amplitude; hence, it is a more environmentally friendly impulsive source for ocean acoustics experiments and surveys. The CSS consists of a submersible combustion chamber, open to the water, which is filled with a combustible fuel/oxidizer mixture. The mixture is ignited and a combustion wave propagates through the mixture. During this process the ensuing bubble expands due to an increase in temperature and can collapse to a smaller volume than before ignition. This bubble activity radiates acoustic pulses. The CSS can be used as a source for low-frequency sediment characterization and TL measurements, and when deployed on the bottom can produce seismic interface waves. In addition to stationary deployments in the water column, CSS can be deployed in a tow body and as an array. Discussion will focus on the latest CSS design including functionality, acoustic output, long-term operational stability, and future development plans.

10:45

4aAO9. Detection and classification of sub-surface features based on their seismo-acoustic signatures. Irena Lucifredi and Miaki Ishii (Harvard Univ., 20 Oxford St., Cambridge, MA 02138, irenav@alum.mit.edu)

Complex subsurface structure makes seismo-acoustic imaging difficult, raising the need for novel detection, classification, and imaging approaches. For the representation of range-dependent seismo-acoustic propagation, we employ a hybrid, coupled wavenumber integration approach to range-dependent seismo-acoustic modeling based on the OASES environmental modeling framework. In feature identification and classification, time series analysis frequently provides the sought-after recognition clues. Nevertheless, the geometry and the structure of the subsurface features generate a variety of complexities to the wave field caused by different physical mechanisms, geometric constraints, and intrinsic properties. Based on the time series attributes such as the time of arrival, waveform amplitude, and the frequency content, a set of identification features is extracted and a set of corresponding classes is formed. Using the simulated data scenarios, general rules incorporating the identification features of subsurface structures are deduced. This classification methodology is then applied to the data recorded by an array of seismographs and hydrophones on and off the coast of Japan. The results create a basis for classification and description of the structures of interest such as the presence or absence of very low-velocity range-dependent layers below the water-seabed interface.

11:00

4aAO10. Numerical experiments on weak shock propagation in marine sediments. B. Edward McDonald (Naval Res. Lab., Washington, DC 20375, mcdonald@sonar.nrl.navy.mil)

NRL is planning a set of laboratory and field experiments to investigate weak shock propagation in saturated marine sediments. Questions to be addressed are as follows: (1) How much does the granular content of the sediment increase the effective nonlinearity coefficient? (2) Does the 3/2 order Hertzian nonlinearity inherent to grain contacts play a significant role? Numerical and analytic solutions involving the Hertzian nonlinearity reveal maximum nonlinearity coefficient near zero stress, whereas in a fluid, nonlinearity increases with stress. Numerical experiments are presented using the NPE model [McDonald and Kuperman, J. Acoust. Soc. Am. 81, 1406 (1987)] to determine whether shocks resulting from Hertzian nonlinearity can be observed in the presence of nominal values of frequency-linear attenuation common to granular media. [Work supported by the Office of Naval Research.]

11:15

4aAO11. Tank experiments for validation of volume scattering models. Jorge E. Quijano and Lisa M. Zurk (Dept. Elec. and Comput. Eng., Portland State Univ., 1900 SW 4th Ave., Ste. 160, Portland, OR 97201)

Mid-frequency scattering from random media is of interest for active sonar applications and, in particular, in shallow water environments, where ocean bottom interaction may affect the performance. To estimate the contribution of volume scattering from the sea bed, models based on the wave equation have been developed and more recently, an approach based on transport theory was proposed [J. Acoust. Soc. Am. **126**, 1711–1723 (2009)]. Validation of this model is difficult to achieve in field experiments due to environmental uncertainties and in many cases to the lack of ground truth revealing the structure of the random media. As an alternative, tank experiments were implemented in a controlled environment at scaled frequencies to explore the range of applicability as a function of different input parameters such as frequency of operation, scatterer size, and concentration. For this work, gel slabs containing random distributions of micron-sized glass beads were manufactured, and broadband pulses at the frequency band 200–600 kHz were utilized to characterize the scatterer contribution. Acoustic propagation through this heterogeneous media is analyzed using the proposed radiative transfer method and the results are compared to the analytical solution of the wave equation for the long-wavelength approximation.

11:30

4aAO12. Inverting for surface displacement fields using directly measured point-to-point sensitivity kernels. Jit Sarkar, Shane Walker, Bruce Cornuelle, William A. Kuperman (Scripps Inst. of Oceanogr., UCSD, Mail Code 0238, 9500 Gilman Dr., La Jolla, CA 92093-0238, jit@mpl.ucsd.edu), Philippe Roux, and Christian Marandet (LGIT, BP 53, 38041 Grenoble Cedex, France)

The effect of surface perturbations on underwater acoustic fields has been directly measured in an ultrasonic tank experiment. High-frequency transducer arrays of 64 elements each are placed 600 mm apart, submerged in ~50 mm of water. A point perturbation is used to displace the surface sequentially in 1-mm steps between the two arrays. At each position a 3.8-MHz signal is transmitted from the source array (round-robin), and the response recorded on the receive-aray, both with and without the presence of the surface probe. The difference between these two measurements yields the point-to-point acoustic sensitivity to that perturbation. These data are explored with respect to inferring the surface structure through both linear full-wave inversions and double-beamforming.

4aBB1. Temporary modulation of vascular barriers with focused ultrasound and microbubbles. Nathan McDannold (Dept. of Radiology, Brigham & Women's Hospital, 221 Longwood Ave., Rm. 521, Boston, MA 02115)

The combination of focused ultrasound and preformed microbubbles (ultrasound contrast agents) circulating in the bloodstream provides an opportunity to utilize mechanical stimulation of endothelial cells to temporarily and locally modulate transvascular transport and permeability. This stimulation may directly alter the endothelium and increase free transport of agents out of the vasculature or it may trigger a physiological response and increase active transport. This talk will review recent work in the brain and kidney utilizing low-intensity focused ultrasound bursts and microbubbles to temporarily disrupt barriers to transvascular passage. In the brain, these sonications result in a temporary disruption of the blood-brain barrier and potentially enable a means for targeted drug delivery. Recent work will be shown demonstrating that the method is sensitive to anesthesia agent, perhaps due to differences in vasoactive effects. In the kidney, we have found that these sonications result in a temporary increase in glomerular filtration rate and urine production and the ability to temporarily pass larger molecules, potentially providing a new platform for the study, and perhaps treatments, of renal disease. Overall, the interaction between ultrasound, microbubbles, and the endothelium presents a unique means to interact with blood vessels and provides opportunities to develop novel treatments.

8:20

4aBB2. Study of sonoporation at the single cell level and cellular bioeffects associated with sonoporation facilitated by microbubbles. Cheri X. Deng (Dept. of Biomedical Eng., Univ. of Michigan, 2200 Bonisteel Blvd., Ann Arbor, MI 48109)

The interaction of ultrasound-driven microbubbles with cells results in multifaceted cellular bioeffects including physical disruption of cell plasma membrane and subsequent downstream effects. Microbubble facilitated sonoporation, the ultrasound-induced disruption of plasma membrane, enhances the transport of ions, other intracellular contents, and external agents through the membrane into the cytoplasm via diffusion, thereby making it useful for intracellular drug and gene delivery. Transport of these entities, which depends on the dynamic process of pore formation and resealing, plays important roles in many downstream cellular effects of sonoporation beyond the initial pore formation and subsequent diffusion-related transport. For example, extracellular calcium ions diffused into the cytoplasm initiate the process of membrane resealing. In addition, intracellular calcium transients are generated which may be related to many cellular processes triggered by the important second messenger molecule. Recent results of sonoporation at the single cell level and related bioeffects will be discussed. Electrophysiological techniques reveal the dynamic process of sonoporation. Real-time fluorescence imaging measurements of intracellular calcium concentration in mammalian cells subjected to sonoporation demonstrate the spatiotemporal evolution of sonoporation related calcium transients including the large influx of calcium in sonoporated cells and the complex dynamic calcium oscillations and waves. [Work supported by NIH.]

8:40

4aBB3. Photoacoustic delivery of molecules into cells. Mark R. Prausnitz, Prerona Chakravarty, Wei Qian, and Mostafa A. El-Sayed (Georgia Inst. of Technol., Atlanta, GA 30332, prausnitz@gatech.edu)

A major barrier to drug and gene delivery is crossing the cell's plasma membrane. This study presents a physically based mechanism to deliver molecules into cells with high efficiency and viability using photoacoustic effects generated by carbon nanoparticles. The results demonstrated intracellular delivery using this method in multiple cell types for uptake of small molecules, proteins, and DNA. At optimized conditions, calcein uptake was seen in up to 50% of cells with nearly 100% viability and in 90% of cells with ⩾90% viability. Uptake was not observed when cells were irradiated in the absence of carbon nanoparticles. These studies suggest that uptake occurs due to transient membrane permeabilization resulting from explosive photoacoustic forces generated by laser-induced carbon-steam reaction, C(s) + H2O(*l*) = CO$(*g*) + H2(*g*). This synergistic use of nanotechnology with advanced laser technology could provide an alternative to viral and chemical-based drug and gene delivery.

9:00

4aBB4. Ultrasound standing wave fields induce endothelial cell sprouting within three-dimensional engineered tissue. Kelley A. Garvin (Dept. of Biomedical Eng., 205 Goergen Hall, Univ. of Rochester, Rochester, NY 14627, garvin@bme.rochester.edu), Denise C. Hocking, and Diane Dalecki (Univ. of Rochester, Rochester, NY 14627)

The field of tissue engineering is working to develop fully functional replacement tissues and organs. To achieve this goal, methodologies aimed at controlling the growth of new vascular systems in three-dimensional (3-D) engineered tissues are needed. We hypothesized that organizing endothelial cells into multicellular, planar bands of cells within 3-D collagen gels using the radiation forces developed in an ultrasound standing wave field (USWF) would promote an angiogenic endothelial cell phenotype. Human umbilical vein endothelial cells were suspended in an unpolymerized type-I collagen solution and were exposed to continuous wave USWFs. The collagen solution was allowed to polymerize during the 15 min USWF treatment to maintain the USWF-induced banded pattern of cells within a 3-D collagen gel. Following a 24 h incubation period, endothelial cell sprouts were observed emerging from USWF-induced endothelial cell bands. The average length of these sprouts was ~100 μm. Sprouting was absent in sham samples where a rounded cell morphology was observed. The influence of acoustic exposure parameters on endothelial cell sprouting was investigated. These studies indicate that USWF technologies promote formation of capillary precursors in 3-D engineered tissue and thus, this technology has the potential to advance the field of tissue engineering.

9:20

4aBB5. Histological evaluation of continuous and pulsed high-intensity focused ultrasound induced vascular bioeffects in the presence or absence of contrast agents. Anna Tokarczyk, Ian Rivens, and Gail ter Haar (Joint Dept. of Phys., ICR: Royal Marsden NHS Foundation Trust, 15 Cotswold Rd., Sutton SM2 5NG, United Kingdom, anna.tokarczyk@icr.ac.uk)

A novel experimental model which uses an isolated, cannulated rat mesenteric artery (~ 400 μm diameter) has been used for the visualization of vessel behavior and damage during therapeutic ultrasound (US) exposures in the presence of contrast agents. The experimental setup includes a fluorescence microscope, ultrasound transducer, and a chamber in which the vessel, attached to micropipettes, can be perfused with a feeding buffer ± contrast agents and fluorescent dyes. A range of continuous and pulsed 1.7 MHz high intensity focused ultrasound (HIFU) exposures have been used at therapeutic and sub-therapeutic intensities (pressures). Vessel wall damage and leakage of intravascular buffer have been observed, predominantly in the presence of contrast agents. The observed lack of vascular constriction and expansion in response to phenylephrine and acetylcholine indicates smooth muscle and endothelial cell damage. This has been confirmed by histology (haematoxylin and eosin staining) and immunohistochemistry. Factor VIII and alpha-actin antibodies (which have receptors localised on endothelial, and smooth muscle cells respectively) have been used for accurate localisation of HIFU affected areas. This model will be also used to investigate the bio-effects induced by the exposure of vessels to diagnostic US exposures in the presence of contrast agents.

9:40

4aBB6. A pre-treatment planning strategy for high-intensity focused ultrasound treatments. Billy Andre (Dept. Mech., Boston Univ., 110 Cummington St., Boston, MA 02215, billy.andre@gmail.com), Phillip Jason White, Nathan McDannold, and Gregory L. Clement (Brigham and Women's Hospital, Boston, MA 02115)

High-intensity focused ultrasound (HIFU) therapy is a non-invasive treatment method for uterine fibroids patients. However, there exists focal distortion, due to inhomogeneous tissues, that can divert therapeutic dosage to non-targeted locations. A missing component of current HIFU protocols is a simulated pre-treatment planning, a procedure that can predict the efficiency of ultrasonic energy delivery pathways based on MRI scans using a simulated propagation model. To conduct this study, a 1.502-MHz transducer transmitted HIFU through five *ex vivo* bovine tissue specimens in an MR-compatible tank setup. A needle hydrophone (aperture = 0.2 mm) scanned the acoustic pressure field orthogonal to the axis of propagation for three different positions of the tissue specimens (0, 4, and 8 deg, about the rotation mounts). To quantify the level of distortion, the distortion index (DI = 1—ratio between local and total acoustic energy fields) were calculated. The data collected confirmed HIFU distortion due to tissue, where 48% of the focal acoustic intensity was redistributed away from the focal field. Focal distortion decreased on average by 7.2% (ranging from 5.6% to 12.3%, SD = 2.8%) upon optimizing the transducer-specimen orientation the default transducer orientation (0 deg). In addition, the propagation simulation model accurately predicted HIFU distortion from a specimen's MRI data.

10:00—10:30 Break

10:30

4aBB7. The harmonic motion imaging for focused ultrasound system for tumor detection and treatment: Simulation, *in vitro* and *in vivo* results. Elisa Konofagou, Caroline Maleke, and Yi Hou (Dept. of Biomedical Eng., Columbia Univ., 1210 Amsterdam Ave., New York, NY 10023, ek2191@columbia.edu)

Harmonic motion imaging (HMI) for focused ultrasound (HMIFU) is a novel, all-ultrasound-based system that can simultaneously detect and localize tumors as well as subsequently generate and monitor their ablation based on their distinct stiffness. In this paper, we present the results of a fundamental simulation study that is then validated using *in vitro* and *in vivo* findings. The same HMI and HMIFU parameters as in the experimental studies were used, i.e., the high-intensity focused ultrasound (HIFU) frequency was 4.68 MHz and the modulation frequency equal to 25 Hz. An HIFU-simulator was used to predict the lesion and its resulting time-dependent displacement field. Using the same parameters, *in vitro* bovine liver experiments were performed to validate the size of the simulated lesions. A transgenic mouse model of invasive adenocarcinoma was used for *in vivo* feasibility using the same parameters. Good agreement between the simulated lesion maps and pathology findings of the *in vitro* liver experiments was found. The lesion formation was identified by a 30% decrease in displacement amplitude in vivo. Tumor cell death was also confirmed by histology. Based on these results, the HMIFU system may offer a cost-efficient and reliable alternative for real-time monitoring of thermal ablation.

4aBB8. Controllable plasma membrane poration by pulsing tandem microbubble. Georgy Sankin, Fang Yuan, and Pei Zhong (Dept. of Mech. Eng. and Mat. Sci., Duke Univ., Box 90300, Durham, NC 27708)

Understanding the dynamic interaction of cavitation bubbles with biological tissue is central to the effective and safe application of therapeutic ultrasound in clinical medicine. Coupled oscillation of two laser generated microbubbles (maximum radius = 28 μm) in constrained media and associated shear stresses are investigated experimentally. Bubble-bubble interaction in a microchannel of 25-μm height is observed using high-speed video cameras and μPIV technique. Two liquid micro-jets moving in opposite directions can be generated when the second bubble is produced at the maximum size of the first one. The interaction of these tandem microbubbles with single cell leads to controllable poration of adjacent cell membrane and dye uptake. Micro-PIV data are compared with cell viability at various bubble-cell distances and azimuthal orientations. This method provides a new approach for highly selective cell treatment *in situ* applicable to targeted microinjection of macromolecules and gene vectors in microfluidics devices. [This work was supported in part by NIH.]

11:05

4aBB9. Ultrasound induced mechanical induction of mesenchymal stem cells. Jia-Ling Ruan, Yak-Nam Wang, and Stuart B. Mitchell (1013 NE 40th St., Seattle, WA 98105)

Low-intensity pulsed ultrasound (LIPUS) has been used to accelerate fracture healing and tissue regeneration but the biological mechanism of these responses is not completely understood. Stem cell activity can be induced through biochemical and mechanical mechanisms. Despite the common use of LIPUS in fracture healing and tissue regeneration, there are only a few studies that examine the mechanical induction of stem cells with ultrasound. The purpose of this study is to determine the effects of ultrasound-generated mechanical stimulus on the behavior of human mesenchymal stem cells (hMSCs) *in vitro*. In our preliminary studies low-intensity pulsed ultrasound was used to induce mechanical strains on hMSCs *in vitro*. Amplitudes, pulse durations, and pulse repetition frequencies were varied such that different radiation pressures were generated on hMSCs in culture. Results indicated a significant increase in cell proliferation after 4 consecutive days of treatment as well as a significant difference in the cellular response between treatment parameters. Results suggest that LIPUS can be used to influence mechanical mediated stem cell behavior; however, more research is needed to fully elucidate the relationship between ultrasound and hMSC response.

11:20

4aBB10. Local tissue-sparing due to blood flow in medium-size vessels. Simon Woodford, Ian Rivens, Gregory Vilensky, Nader Saffari, and Gail ter Haar (Dept. of Phys., Inst. of Cancer Res., Sutton, Surrey SM2 5NG, United Kingdom)

High-intensity focused ultrasound (HIFU) is a noninvasive surgical technique that uses ultrasound energy deposition to thermally destroy selected tissue. However, the cooling effect of blood flow can lead to unwanted tissue-sparing during HIFU treatment, particularly in the tissue immediately adjacent to the vessel wall. Regions where large (clinically detectable) vessels are present will require an increase in intensity or treatment time. However, there is a range of vessel sizes that are thermally relevant yet clinically undetectable. The treatment protocol must be chosen such that the spared region around these vessels is minimized or eliminated completely. Using numerical simulations, we have determined preliminary recommendations for suitable treatment protocols.

11:35

4aBB11. Dynamics and flow field produced by coupled oscillation of tandem microbubble. Fang Yuan, Georgy Sankin, Jaclyn Lautz, and Pei Zhong (Dept. of Mech. Eng. and Mat. Sci., Duke Univ., Durham, NC 27708)

Coupled oscillations of two adjacent laser-induced microbubbles have been shown to produce unique asymmetric bubble deformation and microjet formation. The resultant microstreaming and shear stress can cause localized cell membrane poration with potential application in targeted drug and gene delivery. In this study, we investigate the bubble dynamics and flow field produced by laser-generated tandem microbubble in a microfluidic device. Flow field around the tandem microbubble is analyzed with respect to phase delay, inter-bubble distance, and size ratio between the two microbubbles. In addition, micropatterning technique is used to control the adhesion site and growth pattern of HeLa cells in relation to the tandem microbubble. Flow vorticity is observed to be a key parameter that correlates with the strength of tandem microbubble oscillation and resultant macromolecule uptake efficiency. [Work supported by NIH Grant Nos. R01DK052985, R21CA135221, and S10RR016802].

11:50

4aBB12. Ultrasound-mediated nail drug delivery system to treat fungal disorders. Danielle Abadi and Vesna Zderic (Dept. of Elec. and Comp. Eng., The George Washington Univ., 801 22nd St. NW, Washington, DC 20052, zderic@gwu.edu)

This physiotherapy device treats nail fungal disorders by improving drug delivery to the nail bed using low frequency ultrasound to increase the permeability of the nail. Applying therapeutic ultrasound to the nail will allow pits to form on the surface through which more of the topical drug can be delivered. Transducers with corresponding matching networks are constructed in-house from 300-kHz and 1-MHz piezoelectric crystals. A software interface allows patients to select which toes to treat and at what intensity level (high, medium, or low). The highest-intensity setting supplies 1.5 W/cm^2 for a duration of 30 s to prevent damage to tissue below the nail. The software interface sends information to the electrical driving system,

which is composed of an amplifier for each intensity level and a signal generator. A Franz diffusion cell setup in combination with a spectrophotometer is used for experimental testing of nail permeability by measuring the amount of drug delivered through the membrane. Animal nails are used as a human nail model, and both drug-mimicking dye and Penlac (a topical prescription drug) are used for testing.

4aEA1. On the concept of transient directivity: Pipes and horns. Daniel Tengelsen, Brian E. Anderson, and Timothy W. Leishman (Dept. of Phys. and Astron., Acoust. Res. Group, Brigham Young Univ., Provo, UT 84602)

Directivity is a convenient way to represent how sound radiates from some arbitrary object in steady-state. The steady-state condition is implied when time harmonicity is assumed. Because all physical systems do not begin in steady-state, this directivity measurement is only valid after the transient portion of the solution has decayed. Transient directivity—a measure of sound radiation versus angle at a given instant in time and before the system has reached steady-state—is presented. Understanding an object's transient and steady-state radiation characteristics may be important in understanding the sound radiation from sources that are transient in nature. Results of transient directivity will be presented for pipes and horns from both numerical models and experimental measurements.

8:20

4aEA2. Modeling of transducer arrays for direct digital-to-analog conversion of signals. Jose Amado, Nikita Tkachov, and Charles Thompson (Dept. of Elec. and Comput. Eng., Univ. of Massachusetts Lowell, 1 University Ave., Lowell, MA 01854, jose_amado@student.uml.edu)

A binary weighted array of speakers will be used to reconstruct a decomposed sequence of delta functions. The idea of directly converting digital signals to an analog acoustic output was first proposed by J. L. Flanagan in 1979, in which he designed, fabricated, and tested digital transducers for 4-, 5-, and 6-bit PCM signals. Flanagan found that at 6-bit resolution, the system fell short of good quality, and that condenser transducers had a limited output sound level of about 85 dB. Simulations will be used to investigate experimentally developed models for transducers and apply the direct digital-to-analog approach.

8:35

4aEA3. A new loudspeaker design for the enhancemenet of sound image localization on flat display panels. Gabriel Pablo Nava, Keiji Hirata, and Yoshinari Shirai (NTT Commun. Sci. Labs., NTT Co., Hikaridai 2–4, Seikacho, Kyoto 619-0237, Japan, pablo@cslab.kecl.ntt.co.jp)

In most audio-visual multimedia applications, conventional stereo loudspeakers have been used to implement auditory displays. However, a fundamental problem with this kind of displays is that only the listeners situated at the sweet spot and over the symmetrical axis of the loudspeaker array are able to accurately localize the sound images. Although a number of audio signal processing algorithms have been proposed to expand the listening area, relatively less study on new loudspeaker configurations has been explored. This paper introduces a simple, yet effective, loudspeaker design to enhance the localization of sound images over the surface of flat display panels. In contrast to previous approaches, expansion of the listening space is achieved by attachment of rigid barriers which physically modify the sound radiation pattern of the loudspeakers. Moreover, numerical simulations, experimental sound measurements, and subjective tests have been preformed to validate a prototype of the proposed loudspeaker design using a display panel of an immersive teleconferencing system. Finally, an example of an interactive application was implemented involving real-time speaker tracking with a microphone and video cameras.

8:50

4aEA4. Head-tracking interface using a Wii remote. Megha Sunny, Ayse Kalkan-Savoy, and Charles Thompson (Dept. of Elec. and Comput. Eng., Univ. of Massachusetts Lowell, 1 University Ave., Lowell, MA 01854, megha_sunny@student.uml.edu)

In this work, we will examine the problem of detecting the angular motion of head in effort to build a head-tracking system to control sound. The head motion occurs in *X*, *Y*, and *Z* linear directions and three rotation angles, namely pitch, roll, and yaw. In the past, we had difficulties to detect the rotation angles, especially yaw. Our current work focuses on the detection of rotation angles using a software interface program. The distance between sound source and head, and angular rotation data is collected by the Wiiremote's built-in optical sensor and three-axis accelerometer. These real-time data will be used as input to our software interface. Results will be used in conjunction with head related transfer function to create the three dimensional sound source effects.

9:05

4aEA5. The influence of matching layer material loss on radiation impedance conversion in ultrasonic transducers. Minoru Toda (Measurement Specialties Inc., 135 Gedney Rd., Lawrenceville, NJ 08648, minoru.toda@measspec.com)

PZT based thickness mode ultrasonic transducers for both air and water /tissue typically have a quarter wavelength front matching layer with impedance *Zm*. It is widely known that the lower acoustic impedance Z_R of the propagation medium is converted to a higher impedance at the PZT surface by the relation $Z\max = Zm^2/Z_R$ (quarter wavelength conditions). In this work, the converted impedance was accurately calculated using a transmission line model incorporating the mechanical quality factor *Qm* of the matching layer material. In a medical transducer, it was found that the peak value is 20% or 28% lower than $Z\max = Zm^2/Z_R$ for $Qm = 15$ or 10, respectively. For air transducers, the peak value is one to two orders lower than *Z*max for the same range of *Qm*. These *Qm* values are typically ob-

served for the filled epoxy matching layer materials used in medical transducers and also for porous or air entrained materials used for air acoustic transducers. A simple impedance conversion equation for an air transducer has been proposed, making the design of air impedance matching layers easier and suggesting that neglecting material loss leads to serious errors.

9:20

4aEA6. Transitory response of an acoustic levitator. Sahir Shakir and Charles Thompson (Dept. of Elec. and Comput. Eng., Univ. of Massachusetts Lowell, 1 University Ave., Lowell, MA 01854, sahir_shakir@student.uml.edu)

This work will examine the transitory response of an acoustic levitator. Simulations will be used to ascertain the relationship between viscous and inertial forces on the vertical conveyance of a solid projectile. The objective is to use standing waves of strong intensity in a cavity to elevate a solid projectile. The projectile is suspended by nonlinear acoustic forces, and by rate of change in the frequency, amplitude, or cavity length, the transitory response will be determined.

9:35

4aEA7. Two driving constructions of loudspeakers for low-frequency range by piezoelectric ultrasonic motors. Juro Ohga (Ohga's Acoust. Lab., 2-24-3, Tamanawa, Kamakura, 247-0071, Japan), Takehiko Adachi, Hiroki Saito, Ryosuke Suzuki, Gen Takeda, Hajime Kubota (Chiba Inst. of Technol., Narashino 275-0016, Japan), Hirokazu Negishi (MIX Acous. Lab., Shiba, Minato-ku, Tokyo 105-0014, Japan), Kazuaki Maeda (TOA Corp., Takarazuka 665-0043, Japan), and Ikuo Oohira (Oohira's Lab., Aobadai, Aoba-ku, Yokohama 227-0062, Japan)

The loudspeaker driven by piezoelectric ultrasonic motors is characterized by a precise very-low-frequency reproduction due to its high-driving mechanical impedance. It has a lot of merits comparing to the conventional electrodynamic loudspeakers. One of the reason will be that this loudspeaker is a power flow modulator, not a transducer. In this presentation, two sorts of ultrasonic motors are compared as driver elements of the loudspeakers. One is an ordinary revolution-type motor and the other is a reciprocal linear motion type actuator. The authors constructed and improved practical low-frequency-range loudspeakers by using continuous revolution of ultrasonic motors. Its final model uses combination of two motors with same axis, which drive two cone radiators moving oppositely. This model shows a satisfactorily large output sound pressure and stable reproduction. However, its complicated elements for connection of the motors and the cone radiators cause a mechanical weakness. The authors, therefore, propose another new, completely different construction to avoid this defect. It applies linear motion of two ultrasonic actuators. A moving piece driven by piezoelectric ultrasonic vibrators is connected directly to a cone radiator. Comparison at various viewpoints and practical performance of these two constructions are presented at the meeting.

9:50

4aEA8. An ultrasonic vibrator constructed from laminated Galfenol steel. Scott P. Porter, Stephen C. Thompson, and Richard J. Meyer, Jr. (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA, 16804)

An ultrasonic vibrator has been developed to serve as the drive mechanism for an electroacoustic transducer. This design explores the unique characteristics of Galfenol, a recently invented giant magnetostrictive material. In addition to possessing competitive strain capabilities, strong mechanical properties, and a high-magnetic permeability, Galfenol does not require a prestress mechanism and can be laminated to effectively mitigate eddy current losses. Designing the vibrator required the authors to carefully engineer the magnetic circuit so that proper bias fields could be established using a permanent magnet. This step will be demonstrated with one- and two-dimensional models. Drive coil considerations will also be discussed and the fabrication and assembly of the vibrator will be shown along with in-air measurements.

10:05—10:15 Break

10:15

4aEA9. A preliminary analog circuit model of a balanced-armature transducer utilized for energy harvesting. Holly A. Smith and Stephen C. Thompson (Grad. Prog. in Acoust., Penn State Univ., 201 Appl. Sci. Bldg., University Park, PA 16802, has202@psu.edu)

This research investigates a balanced-armature transducer's potential to harvest ambient vibrational energy into electrical energy that could then be used to power small devices or recharge batteries. Such a device is desirable due to its compact size and environmentally friendly operation. An analog circuit model of a balanced-armature transducer was created in a version of SPICE. To ensure the model's accuracy, the electrical impedance predicted by SPICE was compared to experimental measurements. The model was then adjusted for energy harvesting. [Work supported in part by the Office of Naval Research.]

10:30

4aEA10. Modified single crystals for high-power, broadband underwater projectors. Nevin P. Sherlock and Richard J. Meyer, Jr. (Appl. Res. Lab., P.O. Box 30, State College, PA 16804)

When operating high-power electromechanical devices, the performance is often limited by self-heating within the active material. This is especially true in high-power, broadband underwater projectors using the piezoelectric single crystal $Pb(Mg_{1/3}Nb_{2/3}O_3$–$PbTiO_3$ (PMN-PT). Although PMN-PT crystals show an excellent piezoelectric response ($d_{33} > 1500$ pC/N) and high-coupling coefficient ($k_{33} > 0.90$), device performance is limited by the high-mechanical losses ($Q_M < 100$) and low-temperature phase transformation ($T_{RT} = 95$ °C). This work describes the material property enhancements of two compositional modifications and compares the performance of these crystals in high-power, broadband transducers. One such modification is the addition of $Pb(In_{1/2}Nb_{1/2}O_3$ (PIN) or $PbZrO_3$ (PZ) to the binary PMN-PT composition. The greater thermal stability of ternary PIN-PMN-PT and PZ-PMN-PT crystals is shown by comparing the dielectric permittivity, piezoelectric coefficient, and coupling coefficient to unmodified PMN-PT as a function of temperature. Additionally, the mechanical losses of PMN-PT have been decreased by doping with $Mn^{3,4+}$ ions. Using a laser Doppler velocimeter, the losses are evaluated under increasing ac electric drive. Using these data, high-power, broadband projectors were constructed from these modified crystals, and the results are compared to a projector using unmodified PMN-PT. [Funded by ONR under N00014-07-1-0336.]

10:45

4aEA11. Modeling thermal mitigation and nonlinear behavior in high-power single crystal 1-3 composite transducers. Tara L. Tubbs and Richard J. Meyer, Jr. (Appl. Res. Lab., State College, PA 16804)

The desire for high-precision sonar systems has forced 1-3 composite transducers to the forefront of sonar design. Single crystal, which has improved mechanical and dielectric properties over PZT, provides a variety of advantages, and their implementation into a 1-3 composite design makes them a great candidate for sonar transducers. Driving these transducers at high levels, we can get a broad bandwidth and high-power in a smaller device. However, high power introduces overheating and nonlinear behavior in the material properties. Using finite element software GID/ATILA from ISEN along with COMSOL MULTIPHYSICS, it is possible to incorporate these phenomena and solve thermal mitigation problems. This allows for improved high-power single crystal 1-3 composite transducers.

11:00

4aEA12. Use of compressively stressed zinc oxide to increase microspeaker response. Lukas Baumgartel (Dept. of Phys., USC MEMS Res. Group, 3737 Watt Way, PHE 621, Los Angeles, CA 90089, lbaumgar@usc.edu) and Eun Sok Kim (USC MEMS Res. Group, Los Angeles, CA 90089)

A micromachined piezoelectric speaker was fabricated on a 5×5-mm^2, 1-μm-thick silicon nitride diaphragm. A 4×4-mm^2 zinc oxide (ZnO) piezoelectric transducer sits in the middle of the diaphragm, providing

actuation. Two variations were fabricated: one with the compressively stressed ZnO covering the region between the transducer and diaphragm perimeter—causing wrinkling—and another with the ZnO removed in this region. In both variations, the stress gradient causes curvature in the active area, raising the resonant frequency to above 4 kHz. The displacement response is therefore approximately flat from 40 Hz to 4 kHz. The speakers are driven with a sinusoidal voltage, and the response is measured with a laser interferometer. The wrinkled device exhibits 11 times larger response and can be actuated by much smaller voltage, achieving lower THD while still having a larger deflection. The wrinkled device is driven at 2 $V_{0.t.p.}$ from 40 Hz to 4 kHz, demonstrating a response of 55 nm/$V_{0.t.p.}$ and an average THD of 5.1%. The unwrinkled device is driven at 15 $V_{0.t.p.}$ over the same range, yielding a response of 5 nm/$V_{0.t.p.}$ and an average THD of 8.6%. Measured sound output and displacement spectra match each other well.

11:15

4aEA13. Analysis and design of a MEMS (microelectromechanical system) directional microphone diaphragm with active Q control. Ronald N. Miles, Quang T. Su, Weili Cui, Dorel Homentcovschi (Dept. of Mech. Eng., Binghamton Univ., Binghamton, NY 13902-6000, miles@binghamton.edu), and N. Eva Wu (Binghamton Univ., Binghamton, NY 13902-6000)

The analysis and design of a MEMS directional microphone are described that incorporates electronic feedback to achieve active Q control. The microphone diaphragm consists of a 1 × 2-mm stiffened plate fabricated out of polycrystalline silicon that is supported on a central hinge. The sound pressure gradient incident on the diaphragm produces a rocking motion about the central hinge. Interdigitated comb fingers at each end of the diaphragm enable both capacitive sensing and electrostatic actuation. The diaphragm has been designed to have its dominant resonant mode have a frequency of approximately 1 kHz. By minimizing sources of passive damping, the thermal noise of the microphone has been shown to be lower than the noise floor of existing two-microphone systems used in directional hearing aids [Miles *et al.*, J. Acoust. Soc. Am. **125** (2009)]. However, this low-passive damping also results in an undesirable resonance within the audible frequency range. To minimize the adverse effects of this resonance, a simple analog electronic feedback system is designed that can result in acceptable performance in both the frequency and time domains. [Work funded by NIH Grant R01 DC009429.]

11:30

4aEA14. Response of a MEMS (microelectromechanical systems) directional microphone diaphragm with active Q control. Quang T. Su, Ronald N. Miles, Weili Cui (Dept. of Mech. Eng., Binghamton Univ., Binghamton, NY 13902-6000, quang.su@binghamton.edu), Mihir Shetye (Solteras, City of Industry, CA 91748), and N. Eva Wu (Binghamton Univ., Binghamton, NY 13902-6000)

Measured results are presented that demonstrate the use of proportional and derivative electronic feedback to improve the performance of a directional microphone. The microphone diaphragm consists of a 1 × 2 mm stiffened plate fabricated out of polycrystalline silicon that is supported on a central hinge. The sound pressure gradient incident on the diaphragm produces a rocking motion about the central hinge. Interdigitated comb fingers at each end of the diaphragm enable both capacitive sensing and electrostatic actuation. The sound pressure gradient near the diaphragm has been measured by numerically differentiating the pressure measured by a probe microphone at locations around the diaphragm. The sound-induced motion of the diaphragm was measured using a laser vibrometer. From these measurements, estimates of the mechanical parameters of the diaphragm were obtained. By applying a known quasi-static voltage across the interdigitated fingers and measuring the resulting diaphragm deflection, an estimate for the derivative of the capacitance with respect to the displacement is obtained for the comb fingers of the diaphragm. Using these experimentally determined parameters and a linearized dynamic model of the system, the measured response of the microphone system with feedback is accurately predicted. [Work funded by NIH Grant R01 DC009429.]

THURSDAY MORNING, 22 APRIL 2010 DOVER C, 8:40 A.M. TO 12:00 NOON

Session 4aED

Education in Acoustics and ASA Committee on Diversity: Diversity Issues in Education in Acoustics

Juan I. Arvelo, Cochair
Johns Hopkins Univ., Applied Physics Lab., 11100 Johns Hopkins Rd., Laurel, MD 20723-6099

Preston S. Wilson, Cochair
Univ. of Texas at Austin, Dept. of Mechanical Engineering, 1 University Station, Austin, TX 78712-0292

Chair's Introduction—8:40

Invited Papers

8:45

4aED1. "Future faces of physics" and other initiatives to broaden participation in science. Catherine O'Riordan and Kendra Rand (American Inst. of Physics, One Physics Ellipse, College Park, MD 20740, coriorda@aip.org)

Together, Hispanic-Americans and African-Americans make up over 25% of the US population, but they earn only 7% of physics bachelor's degrees. In order to help broaden the participation of underrepresented groups in STEM fields, the American Institute of Physics has several programs to work with students as well as to reach the general public. To engage physics undergraduates on the challenging subject of diversity, the Society of Physics Students (SPS), a society of over 4000 undergraduate physics students that is part

of the American Institute of Physics (AIP), has launched two new programs. SPS has developed a Physics Jeopardy-like game as part of a "Future Faces of Physics" kit that includes various materials that help engage students in conversations about diversity. These kits have been used at more than 20 regional and national meetings since 2008 with positive results. AIP has also worked with Research Corporation to launch a program that brings Nobel laureates to HBCU's and to SPS campus or regional events that include participation by Minority Serving Institutions. Another AIP program creates short TV science news segments and distributes them free of charge in Spanish. These programs and future directions will be summarized.

9:05

4aED2. What can we learn from statistics on acoustics? Rachel Ivie (Statistical Res. Ctr., American Inst. of Physics, One Physics Ellipse, College Park, MD 20740, rivie@aip.org)

This talk will present current statistics on acoustics degrees and employment in acoustics. The data come from the National Science Foundation's studies of degrees awarded and from the American Institute of Physics' surveys of members of our ten Member Societies (including ASA). Because acoustics encompasses many different disciplines, these statistics will be compared to data from larger fields such as engineering, physics, and life and earth sciences. Although the numbers are very small in acoustics, data will be shown on the participation of under-represented minorities and women where possible. Finally, implications for increasing diversity in acoustics will be discussed.

9:25

4aED3. What faculty say, and convey, matters: Interactions with underrepresented students in science, technology, engineering, and mathematics. Sharon Fries-Britt (Univ. of Maryland, 2203 Benjamin Bldg., College Park, MD 20742, sfries@umd.edu)

Join us for this invited presentation as we examine students perceptions of their interactions with faulty. The participants in this study were primarily undergraduate students; however, approximately one-quarter of the participants were graduate students and post-doctoral research assistants. The entire sample consisted of students from a variety of postsecondary institutions including public and private, predominantly White, historically Black and Hispanic serving institutions from across the United States. This research is part of a larger study conducted over a 5-year period (2004–2009) with the National Society of Black Physicists (NSBP) and the National Society of Hispanic Physicists (NSHP). The majority are physics majors; however, some students are pursuing dual degrees in other STEM disciplines such as math, astronomy, and engineering. The findings of this study indicate that their interactions with faculty in the classroom and in advising session are critical. When those interactions are positive students benefit tremendously; however, in many instances they are negative and the interactions can cause barriers to their engagement in learning process and in how supported students feel pursuing science. Join us as we discuss some of the challenges and opportunities that these students encounter in their interactions with faculty.

9:45

4aED4. Diversity in physics: Whose problem is this? What can I do? Theodore W. Hodapp (Dept. Education and Diversity, American Physical Society, One Physics Ellipse, College Park, MD 20740, hodapp@aps.org)

Physics has one of the lowest participation rates for underrepresented minorities and women of all science, technology, engineering, and mathematics (STEM) fields. Things are improving for women and, while still not representative of the population, the trends are encouraging. Underrepresented minorities, however, have not been as fortunate. I will describe the current status of participation in physics and discuss new initiatives planned to address the lack of involvement at all levels in the field. In particular, I will describe a new program by the American Physical Society (APS) that aims to significantly increase the number of minorities who receive Ph.D.'s in physics. Actions you can take within your community, university, or workplace will be discussed. I anticipate a lively discussion during the panel that follows to bring forward good ideas and possible actions we can collectively take to improve participation of *all* people in physics and the technical workforce. The APS has partnered with leaders in the community to address these issues, and we hope that members of the Acoustical Society will find ways to work collaboratively to attend to these problems. This is our responsibility.

10:05—10:30 Break

10:30

4aED5. Diversifying physics: Legal context, education action. Daryl E. Chubin (AAAS Capacity Ctr., 1200 New York Ave., NW, Washington, DC 20005)

Science education and career development are vital for (1) driving innovation and economic strength, (2) US leadership in producing research & development and the personnel responsible for its renewal, and (3) shaping federal investments in what universities do and K-12 schools teach. Yet the nation faces a demographic challenge: by 2042, the population will be "majority minority." Minorities represent less than 7% of the nation's STEM workforce and are grossly underrepresented in undergraduate and graduate degrees awarded in STEM fields. In addition, the US is flagging in STEM degree production compared to the nations of Europe and Asia. Regardless of one's political beliefs, the nation must prepare more of its citizens for careers in science and engineering. This lecture focuses on the legal climate for increasing participation of underrepresented groups (women and minorities) in physics education and careers. Review of student- and faculty-centered programs and practices that have been "effective" in research universities face another challenged: Can they be made "legally sustainable"? How to make progress "on the ground" in the face of what the law calls—for disciplines such as physics and specialties such as acoustics—a "pipeline problem" will be discussed.

10:50

4aED6. Vassar College-Bronx Institute acoustics workshop for low-income, ethnic minority, urban high school students. David T. Bradley (Dept. Phys. and Astronomy, Vassar College, 124 Raymond Ave., Poughkeepsie, NY 12604-0745, dabradley@vassar.edu) and Angela M. Kelly (Lehman College, City Univ. of New York, Bronx, NY 10468)

Recent studies continue to show that low percentages of women and members of underrepresented ethnic groups are pursuing careers in science, technology, engineering, and math fields. Acoustics is no exception to this trend. As national demographics change more rapidly, and globalization transforms the way we approach the scientific process, the need for diversity becomes even more essential. The inclusion of women and minorities not only changes the questions being asked but also changes how those questions are answered. For acoustics to grow as a discipline, barriers to participation and success of members from underrepresented groups must be eradicated, and we must address the leakage in the science pipeline for students and professionals at all stages in their careers. One key area of concern is the recruitment and retention of K-12 students. This presentation will detail the joint efforts of the Vassar College Physics and Astronomy Department and the Bronx Institute at Lehman College to establish a hands-on, inquiry based acoustic workshop series for urban, low-income, underrepresented ethnic minority students from a collection of high schools in the Bronx borough in New York City.

11:10

4aED7. Reinventing diversity. Howard J. Ross (Cook Ross, Inc., 8630 Fenton St., Ste. 824, Silver Spring, MD 20910, howardr@cookross.com)

Despite all of the efforts to find strategies to improve the way organizations are addressing diversity, inclusion, and cultural competency issues, some are still finding their goals unrealized. In response to this, we conducted extensive research within the field and focused on how to reinvent diversity for the 21st century. Our research points to the need for three major paradigm shifts: (1) A movement from the classic United States-based approach, which focuses too heavily on race and gender and an assimilation model of diversity, to one that incorporates a deep understanding of globalism and the impact of major changes in population demographics around the world, global business, and interactive communication and networking; (2) a shift from the "good person/bad person paradigm" of diversity, which has developed and permeated a corrective mindset about diversity; (3) a 'find them and fix them' approach, which escalates the "us vs. them" way that people approach the issue and makes it more rather than less difficult to address. We have to move away from the event-based way for we have approached diversity, a pattern that has given us many specific activities, but not enough emphasis on systems thinking and culture-based change, to one that is strategic, systemic, and culture based.

11:30—12:00 Panel Discussion

THURSDAY MORNING, 22 APRIL 2010 GRAND BALLROOM III/IV, 8:30 TO 9:45 A.M.

Session 4aPAa

Physical Acoustics: Nonlinear Systems

Matthew E. Poese, Chair
Pennsylvania State Univ., Applied Research Lab., P.O. Box 30, State College, PA 16804

Contributed Papers

8:30

4aPAa1. Dynamic stabilization of the ultradamped inverted pendulum. Randy Carbo (Acoust., Penn State Univ., University Park, PA 16802, rmc258@psu.edu), Matthew E. Poese, and Robert W.M. Smith (Appl. Res. Lab., University Park, PA 16802)

The dynamic behavior of the damped inverted pendulum is analogous to the modes of fluid systems with nonzero viscosity where a denser fluid is situated above a lighter fluid (e.g., the Rayleigh–Taylor instability). Thermoacoustic devices have such configurations whenever a hot heat exchanger is situated below a cold heat exchanger. It has been shown that such systems can be stabilized by effectively modulating gravity and can be described by a damped Hill equation. A numerical solver was developed that uses a stroboscopic technique to determine whether solutions are stable (bounded) or unstable (unbounded). While it is sometimes assumed that the stability boundaries of undamped systems bound the damped cases, for large values of damping ($Q < 0.05$, where Q is the quality factor), the numerical solution predicts that damping can destabilize the system for certain regions of the parameter space. Results of an experiment performed by the authors using a physical pendulum and eddy current damping to verify this rather counter-intuitive result are described. [Research supported by the Office of Naval Research and ARL Exploratory and Foundational Research Program.]

8:45

4aPAa2. Molecular dynamics of nonlinear and nonequilibrium effects in sound propagation. Takeru Yano (Dept. of Mech. Eng., Osaka Univ., Suita, 565-0871, Japan, yano@mech.eng.osaka-u.ac.jp)

Nonlinear and nonequilibrium effects on the propagation process of large amplitude and high-frequency sound waves are studied with the method of molecular dynamics, where the whole physical phenomenon is described in the numerical solution of Newton's equation of motion for hundreds of thousands of gas molecules. The frequency of sound studied here is so high that the wavelength should be comparable with the mean free path of gas molecules, and hence the continuum theory cannot be applied to the resulting phenomenon. The wave profiles are obtained by averaging the molecular motions, and the most conspicuous nonlinear effect in the result is the mass and energy transports by a shock-like wave, for which the origin can be attributed to a nonequilibrium effect caused by the high-frequency sound. The nonequilibrium effects are quantitatively examined with the velocity distribution function of gas molecules.

9:00

4aPAa3. Application of the chaotic cavity transducer concept for imaging in non-reverberant media. Koen Van Den Abeele, Bart Van Damme, Steven Delrue (Wave Propagation and Signal Processing, K.U. Leuven Campus Kortrijk, E. Sabbelaan 53, B-8500 Kortrijk, Belgium, koen.vandenabeele@kuleuven-kortrijk.be), and Olivier Bou Matar (Ecole Centrale de Lille, Villeneuve dAscq 59652, France)

The concept of chaotic cavity transducer utilizes a combination of a piezoelectric ceramic disk glued on a cavity of chaotic shape on the hardware side, with the time reversal (or inverse filter) technique on the software side. Using a two step procedure of direct excitation-reception and time reversed excitation-reception, it is possible to focus energy anywhere inside a non-reverberating sample, thanks to the ergodicity of the chaotic cavity. Moreover, the same basic concept can be used to create a virtual phased array using a single channel device. Both experimental data and simulations will be provided to illustrate the concepts. The goal is to use the chaotic cavity transducer concept to enhance the localization of micro-damage coupled to nonlinear elastic wave spectroscopy methods.

9:15

4aPAa4. Generation of sound by flow instabilities in a low-speed helium jet. W. C. Kirkpatrick Alberts, II and David A. Ligon (US Army Res. Lab., ATTN: RDRL-CIE-S, 2800 Powder Mill Rd., Adelphi, MD 20783)

Schlieren images of low-speed helium flow from a nozzle of circular cross section reveal instability in the jet occurring approximately 1 cm from the nozzle orifice. Accompanying this instability is a pronounced whistle. In this presentation, both qualitative and quantitative analyses of the observed phenomenon will be discussed.

9:30

4aPAa5. Parametrically excited oscillations: Where does the energy come from? Murray Strasberg (David Taylor Model Basin, 9500 MacArthur Blvd., West Bethesda, MD 20817-5000, murray.strasberg@navy.mil)

Recent discussions of parametrically excited oscillations seem to have overlooked an obvious question. How is energy transferred to a parametrically excited system to replace the energy lost to dissipative elements? The conventional analysis converts the linear differential equation representing the parametrically excited system into a Mathieu equation which is a lnear differential equation with a periodically varying coefficient, such as a periodically varying stiffness or length. This does not explain the physical mechanism involved in the energy transfer. To indicate how the energy is transferred, several systems are examined here, viz., (1) the simple pendulum where work is done when the length of the pendulum is varied periodically at half the period of the pendulum to increase the amplitude of its oscillation, (2) the taught string where work is done while sinusoidally varying the tension so as to excite transverse vibration at half the frequency of the varying tension, and (3) shape oscillations of gas bubbles in water excited by spherical volume pulsation at twice the frequency of the shape oscillation. These and other examples lead to the suggestion that more is required to excite parametric oscillation than being a solution of a Mathieu equation.

THURSDAY MORNING, 22 APRIL 2010 GRAND BALLROOM III/IV, 10:00 A.M. TO 12:00 NOON

Chair's Introduction—10:00

Invited Papers

10:05

4aPAb1. Materials science at extreme conditions. James Belak (Condensed Matter and Mater. Div., Lawrence Livermore Natl. Lab., P.O. Box 808, L-45, Livermore, CA 94550, belak@llnl.gov)

The response of a material to an extreme stress transient is sensitive to the loading path and the rate of loading. An extreme example is following a phase transformation, during which the microscopic structure of the material completely rebuilds itself. This microstructure, to a large degree, determines the further response of the material. Traditionally, microstructures have been measured by slicing up the pieces and looking inside with methods such as scanning electron micrsocopy and transmission electron micrsocopy. However, at extreme conditions, such as following a phase transformation, one cannot pick up the pieces and must resort to non-destructive probes such as x-ray scattering. Here, we review recent attempts to determine shocked microstructures using non-destructive diffuse and small-angle x-ray scattering and compare to large-scale molecular dynamics simulations. The talk will anticipate future experiments at emerging light sources such as the Linac Coherent Light Source. [This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.]

4aPAb2. High-pressure magnetically driven compression waves in condensed matter. Jean-Paul Davis (Sandia Natl. Labs., P.O. Box 5800, MS-1195, Albuquerque, NM 87185, jpdavis@sandia.gov)

The *Z* machine is a fast pulsed-power machine at Sandia National Laboratories designed to deliver a 100-ns rise-time, 26-MA pulse of electrical current to *Z*-pinch experiments for research in radiation effects and inertial confinement fusion. Since 1999, *Z* has also been used as a current source for magnetically driven, high-pressure, high-strain-rate experiments in condensed matter. In this mode, *Z* produces simultaneous planar ramp-wave loading, with rise times in the range of 300–800 ns and peak longitudinal stress in the range of 4–400 GPa, of multiple macroscopic material samples. Control of the current-pulse shape enables shockless propagation of these ramp waves through samples 1–2 mm thick to measure quasi-isentropic compression response, as well as shockless acceleration of copper flyer plates to at least 28 km/s for impact experiments to measure ultra-high-pressure (~3000 GPa) shock compression response. This presentation will give background on the relevant physics, describe the experimental technique, and show recent results from both types of experiments. [Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the United States Department of Energy's National Nuclear Security Administration under contract No. DE-AC04-94AL85000.]

11:15

4aPAb3. The influence of shock loading on material properties and dynamic damage evolution. Ellen K. Cerreta, George T. Gray, III, Darcie D. Koller, Curt A. Bronkhorst, Carl P. Trujillo, and Benjamin L. Hansen (T-3, Los Alamos Natl. Lab., MS B216, Los Alamos, NM 87545)

Many commercial and defense applications require structural metals for extreme environments. Specifically, automotive, aerospace, and infrastructure applications need materials with damage tolerance during dynamic loading. To this end, many studies have examined dynamic deformation and damage evolution. These studies have shown that kinetics of loading are critically important to damage evolution of bulk metals. Particularly, in dynamic loading environments in which a shock wave is imparted to the metal, kinetic and spatial effects based on shock wave shape play important roles in damage. These studies also show that depending on crystal structure, shock loading can alter the subsequent properties of a material significantly. However, while these phenomena are gaining acceptance in the dynamic damage community, the ability to predict these phenomena is limited. Here, the influence of dynamic loading across strain rates 103–106/s will be discussed. The role of test platforms and crystallography to examine the influence of kinetics will be tied to changes observed in deformation and damage evolution. It can be shown that isolating the influence of spatial and kinetic effects during dynamic loading is critical to understanding dynamic damage evolution and with this understanding, capabilities for predicting dynamic damage evolution can be advanced.

4aPAb4. Acoustical shock formation in highly nonlinear fluids. Cristian Pantea and Dipen N. Sinha (Mater. Phys. and Applications, MPA-11, Los Alamos Natl. Lab., Los Alamos, NM 87545)

Weak shock formation is investigated for plane sound waves of finite amplitude in fluids with high-acoustical nonlinearity. The shock formation length is related to the sound speed of the fluid c and its nonlinear parameter B/A. The use of fluids with low-sound speed and high parameter of nonlinearity has the advantage that the shock formation can be achieved at much lower pressures. Also, the experiments can be done on a smaller scale because the shock formation length is relatively small. The experiments are performed using short pulsed sound beams produced by a planar transducer with a resonance frequency of 0.5–1 MHz. The propagation medium consists of either different types of fluorocarbon or methanol. Direct pressure measurements of the acoustic waves in the fluid were obtained using a high-frequency calibrated hydrophone. For comparison, a relatively smaller acoustical nonlinear material like water is also investigated. Experimental results related to second and higher harmonics generated in the fluid and their evolution in time along the propagation axis are compared with theoretical time-domain predictions of the Khokhlov–Zabolotskaya–Kuznetsov equation.

4aPP1. Individual differences reveal the basis of consonance. Josh H. McDermott (Ctr. for Neural Sci., New York Univ., 4 Washington Pl., New York, NY 10003, jhm@cns.nyu.edu) and Andrew J. Oxenham (Dept. of Psych., Univ. of Minnesota, 75 E. River Rd., Minneapolis, MN 55455)

Some combinations of musical notes are consonant (pleasant), while others are dissonant (unpleasant), a distinction central to music. Explanations of consonance in terms of acoustics, auditory neuroscience, and enculturation have been debated for centuries. These debates have remained largely unresolved, in part, because the various theories are difficult to distinguish with conventional methods. This talk will describe our recent studies applying the method of individual differences to this problem. We measured preferences for musical chords as well as nonmusical sounds that isolated particular acoustic factors, including the beating and harmonic relationships between frequency components. Listeners preferred stimuli without beats and with harmonic spectra, but across over 250 subjects, only the preference for harmonic spectra was consistently correlated with preferences for consonant over dissonant chords. Harmonicity preferences were also correlated with the number of years subjects had spent playing a musical instrument, suggesting that exposure to music amplifies preferences for harmonic frequencies because of their musical importance. Preferences for stimuli lacking beats, in contrast, were not correlated with musical experience. Harmonic frequency relations figure prominently in many aspects of hearing, and our results indicate that they also underlie the perception of consonance. [Work supported by NIH Grant R01DC05216.]

4aPP2. Music on more than one note: Pitch perception and neural coding of concurrent harmonic tones. Christophe Micheyl and Andrew, J. Oxenham (Dept. of Psych., Univ. of Minnesota, 75 East River Rd., Minneapolis, MN 55455-0344, cmicheyl@umn.edu)

The basis of Western music lies in the combination of simultaneous (harmony) and sequential (melody) harmonic complex tones or notes. Listeners must "hear out" simultaneous pitches and "track" pitch sequences over time. Surprisingly few psychoacoustic studies have studied pitch perception under such "natural" conditions of more than one note at a time. Similarly, the neural mechanisms that support these abilities remain poorly understood. Here, we will review psychoacoustical and neurophysiological findings, which concur to suggest an important role for frequency selectivity in the ability of the auditory system to segregate concurrent notes. In particular, the ability to accurately discriminate changes in the fundamental frequency or, subjectively, pitch of a "target" harmonic complex tone in the presence of a "masker" tone occupying the same spectral region seems to covary with the limits peripheral frequency selectivity. Given that harmonic complex tones are an important class of sound for both music and speech and that frequency selectivity is usually adversely affected by cochlear damage, such results may have important implications for the current understanding of auditory scene analysis of concurrent music and speech sounds and of the listening difficulties experienced by hearing-impaired individuals. [Work supported by NIH Grant R01 DC05216.]

8:40

4aPP3. Auditory and tactile integration in music meter perception. Juan Huang (Dept. of Neurosci. and Zanvyl Krieger Mind/Brain Inst., The Johns Hopkins Univ., Baltimore, MD 21218 and Dept. of Intelligence Sci., Key Lab. of Machine Percept., Peking Univ., Beijing 100871, China), Darik Gamble, Xiaoqin Wang, and Steven Hsiao (Dept. of Neurosci., Dept. of Biomedical Eng., and Zanvyl Krieger Mind/Brain Inst., The Johns Hopkins Univ., Baltimore, MD 21205)

Meter is a fundamental temporal structure of music. The perception of meter is typically inferred from the occurrence of accents in the music surface. Under normal listening conditions, listening to or playing music is usually accompanied by vibro-tactile input which we hypothesize contributes to meter perception. Previous studies have shown that beat perception can occur via purely tactile stimulation. Whether vibro-tactile stimulation can give rise to meter perception and how it interacts with auditory meter perception is unknown. Here we used accent occurrence and strength as cues to study meter perception in subjects performing auditory only, tactile only, and combined auditory-tactile psychophysical discrimination tasks. We find that subjects can perceive meter through purely auditory only and tactile only stimulation. Furthermore, when stimuli were ambiguous, tactile stimulation was found to enhance meter perception when subjects were given weak auditory amplitude-accented cues. Similarly, auditory stimulation enhanced meter perception when subjects were given weak tactile amplitude-accented cues. These results indicate that meter perception is processed cross-modally, and that auditory-tactile integration plays an important role in the neural representation of temporal structures in music.

9:00

4aPP4. Imaging and inducing disorders in musical perception and production. Psyche Loui (Dept. of Neurology, Beth Israel Deaconess Medical Ctr. & Harvard Med. School, 330 Brookline Ave., Palmer 127, Boston MA)

To perceive and produce music accurately, the brain must represent, categorize, plan, and execute pitched information in response to environmental stimuli. Convergent methods from psychophysics, neuroimaging, and noninvasive brain-stimulation with normal and tone-deaf (TD) subjects were employed to show that neural networks controlling pitch perception and production systems include bilateral frontotemporal networks. First, psychophysical data showed that the perception and production of pitch are uncorrelated in TD subjects, suggesting a disconnection between perception and production brain regions. This disconnection was extended in a diffusion tensor imaging study in TD and control subjects: tractography revealed that the arcuate fasciculus, which connects temporal and frontal lobes, is reduced in TD subjects, especially in its superior division in the right hemisphere. This disconnection highlights the importance of frontotemporal interactions in music processing. Finally, to reverse-engineer the perception-production network, transcranial direct current stimulation was applied over superior temporal and inferior frontal regions. Results showed diminished accuracy in pitch matching after stimulation compared to sham control. Taken together, results demonstrate that intact function and connectivity of a distributed cortical network, centered around bilateral superior temporal and inferior frontal regions, are required for efficient interactions with sounds in the environment. 4aPP5. Neural substrates of spontaneous musical improvisation. Charles J. Limb (Dept. of Otolaryngol.-Head and Neck Surgery, Johns Hopkins Hospital, 601 N. Caroline St., Baltimore, MD 21287)

To investigate the neural substrates that underlie spontaneous musical performance, functional MRI was used to study improvisation in professional jazz pianists. The purpose of the study was to identify the neural substrates that give rise to spontaneous musical creativity, defined as the immediate, on-line improvisation of novel melodic, harmonic, and rhythmic musical elements within a relevant musical context. It was hypothesized that spontaneous musical improvisation would be associated with discrete changes in prefrontal activity that provide a biological substrate for actions that are characterized by creative self-expression in the absence of conscious self-monitoring. By employing two paradigms that differed widely in musical complexity, it was found that improvisation (compared to production of over-learned musical sequences) was consistently characterized by a dissociated pattern of activity in the prefrontal cortex: extensive deactivation of dorsolateral prefrontal and lateral orbital regions with focal activation of the medial prefrontal (frontal polar) cortex. Such a pattern may reflect a combination of psychological processes required for spontaneous creative behaviors such as improvisation, in which internally motivated, stimulus-independent behaviors unfold in the absence of central processes that typically mediate self-monitoring.

9:40

4aPP6. Musical experience impacts hearing speech in noise. Nina Kraus (Auditory Neurosci. Lab., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208, www.brainvolts.northwestern.edu)

Musical experience profoundly impacts how sound is transcribed by the nervous system. This influence is likely mediated by cognitive processes such as attention and memory through the corticofugal system [Tzounopoulos and Kraus, Neuron **62**, 463–469 (2009)]. Hearing in noise is difficult for everyone but especially for children with developmental dyslexia and older adults. We have identified objective neural signatures—from the human auditory brainstem—that reflect hearing in noise [Chandrasekaran *et al.*, Neuron **64**, 311–319 (2009) and Hornickel *et al.*, Proc. Natl. Acad. Sci. U.S.A. **31**, 13027 (2009)]. Musicians develop the ability to hear relevant signals embedded in a network of melodies and harmonies. This ability transfers to hearing a target speaker's voice in background noise. We are beginning to understand the biological basis for this perceptual advantage [Parbery-Clark *et al.*, J. Neurosci **29**, 14100–14107 (2009)]. Sensory processing of speech and music is tightly coupled with the cognitive abilities that underlie language and musical expertise; this knowledge can be used to advantage in the consideration of educational and remediation strategies. 10:15

4aPP7. Measuring and predicting the quality of nonlinearly distorted music and speech as perceived by hearing-impaired people. Chin-Tuan Tan (Dept. of Otolaryngol., School of Medicine, New York Univ., 550 First Ave., NBV 5E5, New York, NY 10016), Brian C. J. Moore (Univ. of Cambridge, Cambridge CB2 3EB, United Kingdom), and Mario Svirsky (School of Medicine, New York Univ., New York, NY 10016)

The goals of this study were to characterize and model the perception of nonlinearly distorted speech and music by hearing-impaired listeners. Hearing-impaired listeners were asked to rate the perceived quality of speech and music that had been subjected to various forms of nonlinear distortion, some of which are inherent to certain hearing aid designs including (1) hard and soft, symmetrical and asymmetrical clipping; (2) center clipping; (3) "full-range" distortion, produced by raising the absolute magnitude of the instantaneous amplitude of the signal to a power (8800;1), while preserving the signal of the amplitude; (4) automatic gain control (AGC); (5) output limiting. Stimuli were subjected to frequency-dependent amplification as prescribed by the "Cambridge formula" before presentation via Sennheiser HD580 earphones. The pattern of the rating was reasonably consistent across subjects with only two of ten subjects not making consistent ratings. The mean ratings were not lower with increasing amount of soft or center clipping or when the compression ratios of the AGC and output limiting were increased. The deleterious effects produced by these nonlinear distortions may have been offset by the beneficial effects of improving audibility and compensating for loudness recruitment. [Work supported by Deafness Research Foundation.]

4aPP8. Music through hearing aids: Perception and modeling. Kelly Fitz and Martin F. McKinney (Starkey Labs., 6600 Washington Ave. S, Eden Prairie, MN 55344, firstname_lastname@starkey.com)

Historically, the primary focus of hearing aid development has been on improving speech perception for those with hearing loss. Modern-day hearing-aid wearers, however, face many different types of acoustic signals, such as music, that require different types of processing. Music signals differ from speech signals in a variety of fundamental ways, and relevant perceptual information is conveyed via different signal attributes in the two types of signals. The research described here is an effort to improve music perception in listeners with hearing impairment. First, methods have been developed to quantitatively measure deficits in music perception for impaired and aided listeners. Second, specific perceptual features have been evaluated as to their relative importance in the successful perception of music and that information has been used to guide signal processing development. Finally, the relevant perceptual features have been modeled, and the models have been used to evaluate and compare signal processing algorithms designed to improve music perception through hearing aids. An overview of our research will be presented along with key recent results.

4aPP9. A novel physiological mechanism for pitch encoding in monkey primary auditory cortex. Yonatan I. Fishman (Dept. of Neurology, Albert Einstein Coll. of Med., 1300 Morris Park Ave., Bronx, NY 10461, yonatan.fishman@einstein.yu.edu) and Mitchell Steinschneider (Albert Einstein Coll. of Med., Bronx, NY 10461)

Pitch is a fundamental perceptual attribute of hearing. While auditory cortex is implicated in pitch perception, how pitch is represented at the cortical level remains unclear. The present study examines a novel hypothesis for how the pitch of pure tones and of harmonic complex tones, with or without the fundamental frequency, is encoded in primary auditory cortex (A1): pitch is represented non-topographically by the temporal distribution of population activity in A1. Sounds of lower pitch evoke a greater proportion of sustained multiunit activity (MUA), relative to initial onset MUA, than sounds of higher pitch, such that the temporal distribution of MUA systematically varies with pitch. Pure tones and harmonic complexes with the same pitch evoke a similar proportion of sustained MUA. The temporal distribution of MUA is largely invariant to changes in stimulus parameters (e .g., level and relative phase) that leave the perceived pitch unchanged. Timing of AEP components recorded in superficial layers of A1 parallels similar pitch-related changes in AEPs recorded in humans. Coding of perceptual qualities based on the time course of neural activity has been proposed in other sensory modalities (e.g., olfaction) and offers a novel alternative to topographic representations of pitch at the cortical level.

11:10

4aPP10. Neural correlates of sensory consonance and dissonance in primate primary auditory cortex. Mitchell Steinschneider (Dept. of Neurosci., Albert Einstein Coll. of Med., 1300 Morris Park Ave., Bronx, NY 10461, mitchell.steinschneider@einstein.yu.edu) and Yonatan I. Fishman (Albert Einstein Coll. of Med., Bronx, NY 10461)

The perception of consonance and dissonance of isolated chords (sensory consonance/dissonance) is fundamental to music appreciation. Consonant chords are composed of tones related to each other by simple frequency ratios (e.g., perfect fifth 3:2), whereas dissonant chords are composed of tones related to each other by complex ratios (e.g., minor second 256:243). Dissonance is thought to be due to the perception of beats (modulation frequencies $<$ 20 Hz) or roughness (modulation frequencies from 20–250 Hz), which occur when two or more components of a complex sound are separated from one another in frequency by less than the width of an auditory filter (i.e., critical bandwidth). These unresolved frequency components interact in the auditory periphery to produce amplitude-modulated (AM) fluctuations in the composite waveform envelope. We demonstrate that the magnitude of neuronal phase-locking to these AM fluctuations in primary auditory cortex of awake monkeys correlates with the perceived consonance/dissonance of musical chords and parallels human perception of roughness. This correlation is displayed by population activity, as measured by auditory evoked potentials (AEPs), current source density, and multiunit activity. We further demonstrate that phase-locking of AEPs in Heschl's gyrus of humans is similar to that seen in the monkey.

11:25

4aPP11. A biomimetic multi-resolution spectrotemporal model for musical timbre recognition. Kailash Patil and Mounya Elhilali (Dept. of Elec. & Comput. Eng., 3400 N. Charles St., Barton 105, Baltimore, MD 21218)

Timbre is usually defined as that property of sound that is neither pitch nor loudness that helps in identifying sounds. Such a definition of *what it is not* is in itself problematic and unsatisfactory. The complexity of characterizing a timbre space stems from the intricate interactions between spectrotemporal dynamics of sound, which overcasts the simple description of individual acoustic dimensions as usually captured by techniques such as multidimensional scaling. By contrast, sound encoding in the mammalian auditory system, and particularly its sensitivity to spectrotemporal modulations, offers a rich feature space to explore perceptual representations of timbre. In the present work, the problem of musical timbre modeling was casted as a generative model based on a reduced set of multi-resolution spectrotemporal features inspired from encoding of complex sound in the auditory cortex. A probabilistic system based on Gaussian mixtures was built to perform a timbre recognition task on a data set consisting of 12 instruments. The system was able to achieve an accuracy of 98%, hence corroborating the claim that physiologically inspired features are effective in properly outlining a timbre space. These results could have significant implications in terms of better understanding the neural correlates of timbre perception.

4aSA1. Comparison of techniques of acoustically interrogating a fluid-filled pipe. Curtis F. Osterhoudt, Christopher Dudley, and Dipen N. Sinha (MPA-11, Los Alamos Natl. Lab., Los Alamos, NM 87545, cfo@lanl.gov)

Through-transmission of sound in a fluid-filled pipe was experimentally investigated, with comparison to a one dimensional computational model. Pipe curvature is shown to be a contributor to deviations from the model, as is dynamical interaction between the finitely yielding pipe walls and the fluid contents. Various techniques of acoustically interrogating the system are considered. These include the different information which may be extracted via continuous-wave acoustical excitation, swept-frequency interferometry, and tone- and chirp-burst excitations. Each of these techniques has their advantages and disadvantages, especially in situations where short-time measurements must be made, and a version of the gain-bandwidth product must be taken into account. Some algorithms for automatically extracting fluid sound-speed are discussed, and it is shown that no one dominates under all circumstances. [This work was supported by Chevron USA.]

9:15

4aSA2. Sonar-induced strains and stresses in an absorbing solid elastic sphere. Kenneth G. Foote (Woods Hole Oceanograph. Inst., Woods Hole, MA, 02543), David T. I. Francis (Univ. of Birmingham, Edgbaston, Birmingham B15 2TT, United Kingdom), Mario Zampolli, and Tim van Zon (TNO Defense, Security and Safety, 2509 JG The Hague, The Netherlands)

The interaction of harmonic plane and spherical pressure waves with an absorbing solid elastic sphere is modeled. The analytic, boundary-element-method (BEM) and finite-element-method (FEM) solutions for the internal displacement, strain, and stress fields are evaluated numerically for 50-mm-diameter solid spheres of poly(methyl methacrylate) (PMMA) and high-density polyethylene (HDPE) in an immersion medium of mass density 1000 kg/m^3 and sound speed 1500 m/s. The mass density and longitudinal and transverse sound speeds of the PMMA sphere are 1191 kg/m^3, 2690 m/s, and 1340 m/s, respectively. The corresponding properties of the HDPE sphere are 957 kg/m^3, 2430 m/s, and 950 m/s. The two materials are assumed to have a hysteresis-type absorption, hence with constant product of absorption coefficient and wavelength. The respective values of this product for longitudinal and shear waves for PMMA are assumed to be 0.19 and 0.29 dB, and for HDPE, 0.40 and 1.20 dB. Each of two frequencies is considered, 10 and 100 kHz, for which the wavenumber-radius product is $\pi/3$ and $10\pi/3$, respectively. Results for the three solution methods are compared. [Work partly supported by NOPP through ONR Award No. N000140710992.]

9:30

4aSA3. On the cancellation of acoustic waves scattered from an elastic sphere. Matthew D. Guild (Appl. Res. Labs., The Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029, mdguild@arlut.utexas.edu), Andrea Alù, and Michael R. Haberman (The Univ. of Texas at Austin, Austin, TX 78713-8029)

Recent research has suggested the possibility of creating non-absorptive elastic covers that eliminate the acoustic field scattered from an elastic object, also known as acoustic cloaks [Norris, Proc. R. Soc. London, Ser. A **464**, 2411 (2008)]. The work presented here employs the scattering cancellation technique [Alù and Engheta, Phys. Rev. E **72**, 016623 (2005)] to investigate the effectiveness of a single isotropic elastic layer to cloak an elastic sphere. The presentation discusses the benchmarked analytical and finite element scattering models which were employed to explore the design space of the cloaking layer. Parametric studies showing the influence of cloak stiffness and geometry on the frequency dependent scattering cross section are then presented. These case studies clearly illustrate the fundamental physical behavior leading to the observed reduction in scattering cross section at design frequencies. Finally, material selection and the creation of composite materials required to produce a functional scattering cancellation layer are presented and discussed.

9:45

4aSA4. Effective mass density of a random configuration of cylinders. Francine Luppé (LOA-GOA, FRE CNRS 3102, Univ. of Le Havre, pl.R. Schuman, 76610 Le Havre, France, francine.luppe@univ-lehavre.fr), Jean-Marc Conoir (Univ. Paris 6, 75005 Paris, France), and Pascal Pareige (Univ. of Le Havre, 76610 Le Havre, France)

The dynamic effective mass density of a random distribution of $n0$ cylinders/m^2 in an ideal fluid is looked for. The Fikioris and Waterman approach is used to obtain the reflection coefficient of the random half-space at the plane interface with the ideal fluid. This coefficient is expanded into powers of $n0$, using Linton and Martin's expansion of the wavenumber of the coherent wave. The reflection coefficient is then compared to that obtained when a homogeneous viscous fluid replaces the random medium. When the two reflection coefficients are equal, the random fluid is acoustically equivalent to the viscous one, which is thus considered as the effective fluid. The coherent wave in the random medium is described as the acoustic mode in the effective fluid, with the shear viscosity of the latter being set to zero. Equating the two reflection coefficients provides an effective mass density that depends on frequency and on the incidence angle, except at low frequency. The angle dependence is discussed.

10:00

4aSA5. Coherent backscattering enhancement in cavities. Simple shape cavity revisited. Stefan Catheline, Thomas Gallot, Philippe Roux, Guillemette Ribay, and Julien de Rosny (Laboratoire de Gophysique Interne et Tectonophysique (LGIT), CNRS Universit de Grenoble, France, stefan.catheline@ujf-grenoble.fr)

Coherent backscattering effect (CBE) is classically introduced in disordered, random, or chaotic media. In this work, the attention is focused on simple parallepipedic cavities since, contrarily to a widespread idea, CBE can also be observed for a pure-tone source in a one-dimensional (1-D) cavity. This approach is of two-fold interest. First, analytical computations predict a dimensional dependence of the coherent backscattering enhancement according to a $^{(3/2)}d$ law, d being the dimensionality of the cavity, that have not yet been compared to experiments. Second, it opens a new ballistic interpretations for which each multiply reverberated path is associated with more (rectangle and parallelepipedic cavities) or less (1D cavity) than one single reciprocal counterpart. This paper is the first of two, the second paper dealing with some impacts of symmetry on CBE.

10:15—10:30 Break

10:30

4aSA6. Coherent backscattering enhancement in cavities. Highlight of the role of symmetry. Thomas Gallot, Stefan Catheline, and Philippe Roux (Laboratoire de Gophysique Interne et Tectonophysique (LGIT), CNRS & Universit de Grenoble, France, thomas.gallot@obs.ujf-grenoble.fr)

Through experiments and simulations, some consequences of symmetry on coherent backscattering enhancement (CBE) in cavities are reported here. First, CBE outside the source is observed (a) on a single symmetric point in a one dimensional cavity, in a tw0-dimensional (2-D) circular membrane, and in a 2-D symmetric chaotic cavity; (b) on three points in a rectangle; and (c) seven in a parallelepiped. Second, existence of enhanced intensity lines and plans in 2-D or three-dimensional cavities is demonstrated. Third, we show how antisymmetry is responsible for the existence of a coherent backscattering decrement with a dimensional dependence of (12)d law, *d* being the dimensionality of the cavity.

10:45

4aSA7. How does the scattering from an empty cylinder change with the level of filling? Duncan P. Williams (Dstl Physical Sci., Porton Down, Salisbury SP4 0JQ, United Kingdom), Richard V. Craster (Univ. of Alberta, Edmonton T6R 2Y9, Canada), and Samuel D. M. Adams (Imperial College, London SW7 2BZ, United Kingdom)

The acoustic scattering from elastic objects features in many tasks stretching from the use of sonar to search for underwater objects such as submarines and mines to the inspection of shipping containers and cargo screening. The properties of canonical objects, such as cylindrical and spherical shells, which are completely filled with fluid, or immersed in fluid, have been widely studied, but typically stop short of studying shells containing different levels of filling. Not knowing the extent of the effect of filling on the scattering from different objects can limit how well one can discriminate between similar objects or inspect the interior of objects and, for example, find contraband or other suspicious materials. This paper looks at the two-dimensional response of a partially filled elastic cylinder. A computational method to model non-uniform domains is introduced and the use of perfectly matched layers is discussed. Results are shown for combinations of cylinders and different levels of filling. In particular, we show how the response of the cylinder depends on the level of the filling. The results are used to comment on the usefulness, or otherwise, of the response to estimate the nature and level of filling based on short- or long-range observations.

11:00

4aSA8. Modeling of a two-transducer through-wall ultrasonic communication system. Sebastian Roa Prada, Kyle R. Wilt, Henry A. Scarton, Gary J. Saulnier, Jonathan D. Ashdown, Pankaj K. Das, and Andrew J. Gavens (Dept. of Mech. Eng., Rensselaer Polytechnic Inst., 110 Eighth St., Troy, NY 12180, sebastian-roa27@hotmail.com)

Ultrasound at 1 MHz is used as a carrier of information across solid walls without penetration. A communication channel is created by bonding two transducers on either side of a solid wall. The outside transducer transmits a continuous wave generating an acoustic field. The inside electronics are powered by harvesting the electrical output of the inside transducer. Digitized bits, representing the value of an analog signals measured on the inside (such as temperature), are used to alternate the electrical load of the inside transducer between two finite values. Changes in the electrical load of the inside transducer modify its acoustical impedance as seen by the incident waves coming from the wall, which in turn modulates the amplitude of the reflected signal. This modulated wave is detected at the electrical terminals of the outside transducer, where it is then demodulated to recover the data. The mechanical components of the system are modeled in connection to the electronic circuits by means of electro-mechanical analogies. Simulation of the communication system is performed using the electric circuit simulation package PSPICE. Simulation, finite element solutions, and experimental results are presented and discussed. Digital data communication rates exceeding 50 000 bits/s are achieved.

11:15

4aSA9. Relationships between structural energy density, power flow, and their influence on acoustic intensity. Jeff M. Fisher, Dan A. Manwill, Jon D. Blotter, Scott D. Sommerfeldt, and Kent L. Gee (Dept. of Mech. Eng., Brigham Young Univ., 435 CTB, Prov, uT jefffish@nm.byu.edu)

Power flow in structures has been a topic of research for the past few decades. Many different methods for determining structural power flow magnitude and direction have been developed and proven. Structural energy density methods have likewise been developed. In this paper, a study of both structural energy density and power flow in a plate and their influence on the acoustic field is presented. Structural energy density and power flow were determined using equations typically used with accelerometer arrays but adapted for use with a scanning laser doppler vibrometer. Experiments were performed from 25 to 100 Hz by exciting the plate at single frequencies but using different excitation points and methods at each frequency. In some cases two sources of excitation were used to alter the power flow response, giving a broader basis for concluding relationships. Both speaker and shakers were used as sources. The acoustic intensity in the room was calculated at approximately 3 in. from the vibrating plate. Relationships between structural energy density, power flow, and the acoustic field variables are presented.

11:30

4aSA10. Real-time active control of structural energy density and structural power flow. Daniel A. Manwill (dmanwill@byu.net), Jeff M. Fisher (Dept. of Mech. Eng., Brigham Young Univ., 435 CTB, Provo, UT 84602), Scott D. Sommerfeldt, Kent L. Gee, and Jonathan D. Blotter (Brigham Young Univ., Provo, UT 84602)

Structural energy density and structural power flow have long been used as metrics in the active control of vibrating structures. The greater portion of this previous work has focused on frequency-domain methods which incorporate assumptions about the relative contributions of near-field and far-field energy components. This paper describes the implementation of filtered-x-based time-domain control schemes which utilize 9- and 13-accelerometer arrays to estimate and control structural energy density and structural power flow, respectively. Experiments were performed on a clamped steel plate excited and controlled by various combinations of loudspeakers and electrodynamic shakers in a frequency range from 25 to 100 Hz. Analog circuitry was used to estimate spatial derivatives and reduce channel count. The development of control laws incorporating the effects of the analog circuitry is presented. Control attentuation results are given, sensor placement is discussed, and implementation challenges are addressed. [This work is supported by NSF Grant 0826554.]

Session 4aSC

Speech Communication: Speech Perception and Perceptual Adjustment (Poster Session)

Cynthia Clopper, Chair
Ohio State Univ., Dept. of Linguistics, 1712 Neil Ave., Columbus, OH 43210

Contributed Papers

All posters will be on display from 9:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors or odd-numbered papers will be at their posters from 9:00 a.m. to 10:30 a.m. and contributors or even-numbered papers will be at their posters from 10:30 a.m. to 12:00 noon.

4aSC1. Perceptual and production training of allophones and phonemes in Spanish. Wendy Herd (Dept. Linguist., Univ. of Kansas, 1541 Lilac Ln., Lawrence, KS 66044, wenherd@ku.edu)

American English learners of Spanish often do not acquire native-like pronunciation of intervocalic /d/, tap, and trill in words like CODO "elbow," CORO "choir," and CORRO "I run." The trill proves difficult because it does not exist in English. Although the tap exists as an allophone of /t/ and /d/ in English, students of Spanish must learn to process it as a phoneme rather than an allophone. Similarly, learners have difficulty acquiring the spirantization of voiced stops, where intervocalic /d/ is produced as a voiced dental fricative or approximant. This study investigates whether American English learners of Spanish can be trained to perceive and produce the intervocalic /d/, tap, and trill contrasts in Spanish. Both perceptual and production training methods were used. Past research has reported that perceptual training alone improves both perception and production, and that production training alone improves both as well; however, the production training studies have not been limited to production as trainees have been able to listen to the training stimuli. This study systematically controls both training modalities and introduces a third training methodology that includes both perception and production to discover whether perceptual, production, or combination training is most effective. [Research supported by NSF.]

4aSC2. Production and perception of Taiwan Mandarin syllable contraction. Grace Chen-Hsiu Kuo (Dept. of Linguist., Phonet. Lab., UCLA, Los Angeles CA 90095, gracekuo@humnet.ucla.edu)

Taiwan Mandarin syllable contraction is an optional lenition process which involves the elision of the intervocalic segments and the merger of the tonal elements of two syllables. Here it is shown that syllable contraction is gradient and non-neutralizing. In a production experiment, 20 subjects read a list of minimal sentence pairs, containing disyllabic contractable words and matched monosyllabic lexical words, at two speech rates (88 and 144 beats/min), three times each. Degree of contraction was measured as the depth of the intensity trough between two syllables [Mermelstein 1975], with a trough depth (TrD) of zero meaning fully contracted. 8% of disyllables were somewhat contracted (TrD between 0 and 2 dB) while 29% were fully contracted (TrD = 0 dB). Fully contracted disyllables were compared on several other acoustic measures to their monosyllabic counterparts and were found to differ most strongly in duration. In a perception experiment, items from the production experiment were presented to 35 listeners for forced-choice identification as disyllabic or monosyllabic words. Accuracy was generally high; reaction times were slower for lexical monosyllables, which were sometimes labeled as contracted. Thus, even when fully contracted syllables were produced, they remained acoustically and perceptually distinct from monosyllables.

4aSC3. Prosodic perception and production of English- and Chinese-native speakers. Amanda Rodriguez and Chang Liu (Dept. of Commun. Sci. and Disorder, The Univ. of Texas at Austin, 1 University Station A1100, Austin, TX 78712)

Our previous studies have shown that English-native adult speakers demonstrated categorical perception in tonal identification of speech and nonspeech sounds as typically as Chinese-native adult speakers. The purpose of this study was to investigate whether prosodic perception of English speech sounds was different between English- and Chinese-native listeners. F0 contour was manipulated from falling to rising patterns for the target word embedded in a short sentence. Listener's task was to identify the prosody of each sentence, either question or statement. Preliminary results suggested that both groups of listeners showed typical categorical perception, while the two groups had significant difference in categorical boundary. The difference in categorical boundary for prosodic perception between the two groups of listeners was similar to our previous findings in tonal perception, likely due to the difference in the listener's language background. English sentences with statement and question will be recorded for the two groups of listeners. The relationship between prosodic perception and perception will be discussed. [Work supported by The University of Texas at Austin, Undergraduate Research Fellowship.]

4aSC4. Influence of perceptual training of syllable codas for English consonants on sentences. Teresa Lopez-Soto (Dept. English Lang., Univ. of Seville, c/ Palos de la Frontera, s/n 41004 Sevilla, Spain, teresals@us.es) and Diane Kewley-Port (Indiana Univ., Bloomington, IN 47405)

This study extends our previous report suggesting that moderate amounts of speech perception training were associated with improved speech production. This study also examined perception in sentences. A new group of 8 Spanish speakers (<10 year residence in US) trained on 13 English final consonants in syllables using SPATS software. On days 1 and 7 the group participated in perception and production tasks with the 13 codas (pre- and post-tests). Perception tests included coda identification in both syllable stimuli and in 18 sentences extracted from the IEEE corpus (90 keywords). Results showed the following. (1)With 5-h training of the 13 codas in syllable stimuli, perception improved significantly (>10%) in the syllable post-test, with smaller improvement in the sentence post-test (>7%). (2) Although average improvement was small for codas tested in sentences, several improved substantially (>20%), while a few decreased considerably after perception training. (3) Absolute values in both post-tests show similar performance, near 90%, although interesting differences for specific consonants were noted. The results showed that perception of sounds when measured in different linguistic contexts (syllables versus sentences) rendered different results. The study lays ground for investigating how cross-language perception of individual sounds is influenced by the phonetic context.

4aSC5. Cue weighting and variability in perception and production. Jiwon Hwang (Dept. of Linguist., Stony Brook Univ., Stony Brook, NY 11794-4376)

The Korean single liquid phoneme shows an allophonic variation: lateral [l] occurs in coda and tap [r] in onset. Intervocalically, they may appear contrastive as tap or geminate lateral [ll] ([iri] wolf vs [illi] reason), differing in duration and laterality. Kim [(2007)] demonstrated that Korean listeners identified a shortened geminate lateral as geminate /ll/ rather than tap, despite the fact that the duration of edited stimuli was matched for tap. The current study examines whether the weighting of laterality cues over duration cues for [ll] vs [r] is motivated by the native language acoustics. Korean speakers produced 24 Korean words [(C)V_V], containing [ll] or [r] in two

speech modes (in a carrier sentence vs in isolation). The duration of [ll] was significantly longer than tap, but it varied greatly depending on the speech mode while tap did not. The intensity of tap was significantly lower than [ll] generally, but it showed a greater variability. However, F3 at the offset of the preceding vowel was lower for tap than for [ll] regardless of the speech mode. The consistent use of F3 in production supports the perceptual cue weighting pattern where Korean listeners rely more on spectral cues than duration for intervocalic [ll]-[r] contrast.

4aSC6. The production and perception of English consonant sequences by Japanese-speaking learners of English. Mieko Sperbeck and Winifred Strange (Dept. of Linguist., City Univ. of New York, the Graduate Ctr., 365 Fifth Ave., New York, NY 10016)

This study reports the second part of a study investigating vowel insertion phenomena among Japanese speakers. A previous study [Sperbeck (2009)] that measured categorial discrimination demonstrated that some contrastive CCV versus CəCV sequences were hard for Japanese listeners (72% correct overall). The current study explored difficulties in production and how production correlated with perception. Nonsense words were constructed as the stimuli. They were of the form/CC(C)ani/ and /CəC(C)ani/, where CC(C) combinations were /sp, sk, pl, kl, bl, gl, spl, skl/. A delayed imitation task was used to assess production. Participants heard a native speaker's productions (e.g., Say blani now) twice, produced the target word in isolation (e.g., blani), and then produced it in the carrier sentence (e.g., I said blani now). The latter was scored in this study. Two phonetically trained native English speakers perceptually transcribed the productions. Results showed that the overall percent correct was 66% (SE = 3.17) among Japanese speakers. There was a significant correlation between perception and production performance (rho = + 0.715. $p<0.01$). However, the major error type was vowel deletion, rather than vowel epenthesis in producing the CəCV tokens. The relationship between perception and production among L2 learners will be discussed.

4aSC7. The discrimination, perception, and production of two German /r/ allophones by two groups of American English speakers. Dilara Tepeli (Dept. of Communicative Disord., Univ. of Wisconsin-Madison, 1975 Willow Dr., Madison, WI 53706)

The German /r/ sound is one of the most difficult sounds for American English (AE) speakers learning German as a foreign language. Part of this difficulty may be due to its rich phonetic variation. The standard German /r/ variant [R] and dialectal variant [R′] are achieved by varying the tongue constriction degree while keeping place of articulation constant [Schiller and Mooshammer (1995)]. The close articulatory proximity of these allophones provides an opportunity for testing the relationship between perception and production in L2 sound acquisition. The aim of this study is to investigate how well experienced AE speakers and naive AE speakers can discriminate and produce the difference between the uvular fricative [R] versus the uvular trill [R′]. Two groups of AE subjects who participated in an imitation study were prompted to produce single words beginning with either [R] or [R′]. Subjects also participated in a discrimination and categorization test. Preliminary results suggest that inexperienced AE can discriminate [R] versus [R′] well. They often perceive the sounds as /h/ and are more successful at producing [R′] than [R]. Experienced speakers also discriminate the two sounds well, perceive both sounds as the German /r/ and struggle more with producing [R′] than [R].

4aSC8. Auditory feedback shifts in one formant cause multi-formant responses. Shira Katseff (Dept. of Linguist., Univ. of California, Berkeley, 1203 Dwinelle Hall, Berkeley, CA 94720-2650, skatseff@berkeley.edu), John F. Houde (Univ. of California at San Francisco, San Francisco, CA 94143-0444), and Keith Johnson (Univ. of California, Berkeley, Berkeley, CA 94720-2650)

Talkers are known to compensate for experimentally-induced shifts in auditory feedback. In a typical experiment, talkers might hear their F1 feedback shifted (so that [ɛ] sounds like [æ], for example), and compensate by lowering F1 in their subsequent speech. Typically, compensation is assumed to directly oppose the action of the feedback shift and is measured in terms of the shifted parameter. In this study, we instead find that sensitivity to altered auditory feedback is multidimensional: subjects respond to altered F1 feedback by changing their F2 production and vice versa. In particular, subjects whose [i] is heard as [ɪ], a shift primarily in F1, compensated by producing a higher F2, while subjects whose central vowel [ʌ] was heard as [ɛ] or [o], a shift primarily in F2, compensated by producing a higher or lower F1. We argue that it is insufficient to consider auditory sensitivity in terms of a single formant and suggest that this method of altering auditory feedback is a practical tool for investigating the psychological reality of formants and their combinations.

4aSC9. Perception of vocal imitations and identification of the imitated sounds. Guillaume Lemaitre, Arnaud Dessein (IRCAM, 1 place Stravinsky, 75004 Paris, France), Karine Aura (Universit de Toulouse le Mirail, 31058 Toulouse, France), and Patrick Susini (IRCAM, 75004 Paris, France)

We report two studies investigating how vocal imitations enable the recognition of the imitated sounds. First, we asked couples of participants to listen to series of everyday sounds. One of the participants ("the speaker") had then to describe a selected sound to the other one (the "listener"), so that he could "guess" the selected sound. The results showed that, spontaneously, the speakers used, among other para-linguistic cues, large numbers of vocal imitations. Moreover, they suggested that the identification performances were increased when vocal imitations were used, compared to only verbal descriptions. Second, we sampled 28 sounds across an experimental taxonomy of kitchen sounds and required laypersons to vocally imitate these sounds. Another group of participants was then required to categorize these vocal imitations, according to what they thought was imitated. A hierarchical cluster analysis showed that, overall, the categories of vocal imitations fitted well with the categories of imitated sound sources. By using finer analysis techniques, we also showed that some imitations inconsistently clustered. On the other hand, the consistent clusters of imitations were perfectly predicted by a few acoustical descriptors. We therefore conclude that vocal imitations of sounds contain enough information for the recognition of the imitated sounds.

4aSC10. The perception and acoustic features of Korean ditropic sentences. Seung-yun Yang, Ji Sook Ahn, and Diana Van Lancker Sidtis (Dept. of Communicative Sci. & Disord., NYU, 665 Broadway, Ste. 900, New York, NY 10003)

Ditropic sentences are utterances that convey either a literal or an idiomatic meaning (e.g., It broke the ice). This study investigated listener's ability to discriminate between literal or idiomatic meanings and examined the acoustic features contributing to this distinction. Ten ditropically ambiguous Korean sentences were audio-recorded by four native speakers of Korean. Each utterance was produced twice with either a literal or idiomatic meaning. Fifteen native Korean subjects listened to a randomized presentation of these utterances singly and in pairs without other context and identified each as literal or idiomatic. Listeners successfully discriminated the intended idiomatic or literal meanings (singletons = 70.65%, pairs = 75 .67%). These results were consistent with those of Van Lancker and Canter [(1981)] for English ditropic sentences. Each utterance was acoustically analyzed in terms of means and variations in fundamental frequency, duration, and intensity. Analyses of variance revealed significantly longer durations and greater variation in syllable duration for literal than idiomatic sentences, whereas idiomatic sentences were characterized by significantly greater variation in intensity than literal sentences. Some prosodic cues for Korean differed from those found previously for English [Van Lancker *et al.* (1981)] and French [Abdelli-Baruh *et al.* (2007)]. These results further understanding of use of prosody in sentential linguistic contrasts.

4aSC11. Discrimination and identification of synthetic [da]-[ga] sounds by adults and children 4–6 years of age. Kelly Richardson (Dept. of Communicative Disord. and Sci., Univ. at Buffalo, 3435 Main St., Buffalo, NY 14214, kcr2@buffalo.edu) and Joan Sussman (Univ. at Buffalo, Buffalo, NY 14214)

Identification of sounds along the alveolar-to-velar contrast has been shown to be different for children born with clefts of the palate compared to other children [e.g., Whitehill *et al.* (2003)]. However, little information concerning discrimination abilities of children, in general, is known. The current study used a seven-step continuum of synthetic consonant-vowel syllables changing from "da" to "ga" by the 40 ms third formant frequency transitions [Sensimetrics Corporation (1995)]. Each listener heard 180 trials of a "change no-change" discrimination paradigm with two, three, four, and

six-step comparisons to the endpoint, stimulus number 1 "da." Listeners were asked to verbally respond as to whether there was a "change" or "no-change" in the sounds presented. Results revealed that as the stimulus contrast increased, adults became better at discriminating the comparisons, whereas children's performance remained poor for all comparisons. Adults also showed less variability in their responses as the contrasts grew larger. In the identification task, young children displayed a much smaller velar category compared to the adult group. Furthermore, children were significantly poorer than adults at identifying the endpoint stimuli, as well as within-category exemplars. Results are compared to perception of other places of articulation by children and adults.

4aSC12. Misperceptions of foreign language phonology. Julia Yarmolinskaya, Colin Wilson, and Brenda Rapp (Dept. Cognit. Sci., Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218)

For many years it has been assumed that when hearing familiar sounds in unfamiliar combinations, listeners will perceive the sounds accurately. In the recent years, this assumption has been challenged [Halle *et al.* (1998) and Berent *et al.* (2006)]. The present study investigates what listeners actually hear when presented with familiar consonants in unfamiliar combinations. A group of monolingual native English speakers was asked to transcribe Russian words containing only consonants attested in English but presented in a two-, three-, and four-consonant combinations (CC, CCC, and CCCC clusters) which are not legal in English. The results indicate that the accuracy of response and the nature of errors depend on the type of cluster. CC clusters (e.g., /pn/) were most often misperceived as containing a vowel between the two consonants, and perception accuracy was well-explained by phonological principles, such as sonority. On the other hand, CCC (e.g., /vzb/) and CCCC (e.g., /fstr/) cluster transcriptions contained relatively few vowel insertions, but many deletions and substitutions and their accuracy were better explained by acoustic factors, such as voicing of the consonants. These results suggest that speech perception is influenced by both phonological and acoustic factors.

4aSC13. Effects of listener experience with foreign accent on perception of accentedness and speaker age. Paul Rodrigues (Dept. of Linguist., Indiana Univ., 1021 E, Third St., Bloomington, IN 47405, prrodrig @indiana.edu) and Kyoko Nagao (Nemours A.I. duPont Hospital for Children, Wilmington, DE 19803)

The current study examined the effects of foreign accent and listener experience on the perception of a speaker's age and native language. Ten audio stimuli were prepared from the recording of five Arabic speakers and five English speakers (18–79 years old) from the Speech Accent Archive [Weinberger (2009)] for the perception experiment. Thirty native speakers of English participated in the perception experiment through Amazon's Mechanical Turk website, estimated the speaker age, rated the speaker's accentedness, and estimated the native language of the speaker. The listeners were divided into two groups based on their experience with foreign accented English (experienced and inexperienced groups). Higher correlation was found between perceived age (PA) and actual chronological age (CA) for the native (English) stimuli than for the Arabic-accented stimuli in both listener groups. The correlation between PA and CA was higher in the experienced listeners than in the inexperienced listeners. Accentedness rating suggests that the inexperienced listeners tend to rate both native and non-native speakers neutrally on the scale. The results suggest that experiences with any foreign accented speech facilitates identification of age from speech and help to form the ability to perceive differences in the degree of foreign accented speech.

4aSC14. Word segmentation of American English /s/ in semi-spontaneous speech. Dahee Kim (Dept. of Linguist., The Ohio State Univ., 1712 Neil Ave., Columbus, OH 43210-1298, daheekim@ling .osu.edu), Christine Szostak, Colin Widmer, and Mark A. Pitt (The Ohio State Univ., Columbus, OH 43210-1287)

To comprehend spoken language, listeners need to find words from a continuous stream of speech sounds. Little work has explored whether there are reliable acoustic cues to word boundaries in conversational speech, which is highly reduced and under-articulated, potentially creating ambiguities at word boundaries. Segmentation may be even more difficult when the same segment repeats at a word boundary, ending the preceding word and beginning the following word (e.g., gas station). Segmentation in this environment was investigated by examining the production and perception of fricative /s/ in semi-spontaneous speech. Twenty talkers produced sentences containing ambiguous two-word sequences with /s/ between the two words. All sequences are interpretable in three ways (e.g., grow snails, gross snails, and gross nails) depending on how the frication is segmented. Acoustic analyses of the production data examined whether there are acoustic cues distinguishing the three versions of the ambiguous sequences. Listening experiments using the talkers' productions as stimuli evaluated the degree of ambiguity in the tokens and identified acoustic cues that listeners use to segment the two words. Results will be discussed in the context of theories of speech perception and word segmentation.

4aSC15. Perception of prosodic boundaries in spontaneous speech with and without silent pauses. Yoonsook Mo and Jennifer Cole (Dept. of Linguist., Beckman Inst., Univ. of Illinois, Urbana-Champaign, 1420 N. Mathews Ave., Urbana, IL 61801, ymo@illinois.edu)

In speech comprehension, listeners attend to variation in multiple acoustic parameters encoding prosodic structure. Given the multiplicity of acoustic cues, we ask whether prosody perception is dependent on any individual cue or whether acoustic redundancy encoding prosody supports robust prosody perception in the absence of an individual cue. The present paper reports on a study of boundary perception in spontaneous speech with and without silent pause as a boundary cue. Prior studies show that in read speech, silent pause is important for boundary perception, while in spontaneous speech, listeners can detect boundaries without pauses. Our study tests the role of pause in boundary perception with two versions of 36 short speech excerpts from the Buckeye Corpus: one with pauses intact and another with all pauses truncated to 20 ms. In real-time transcription tasks based only on auditory impression, boundary locations were marked by 74 subjects for the intact stimuli and by an additional 15 subjects for truncated excerpts. Inter-transcriber agreement was comparable across the intact and truncated conditions. Paired-sample t-tests show significantly higher rates of boundary perception for intact stimuli indicating that silent pause is an important but not necessary cue to boundary perception and cue redundancy allows for robust perception.

4aSC16. Dichotic digit listening in Mandarin and English by Mandarin-speaking adults. Shu-Yu Liu (School of Speech Lang. Pathol. and Audiol., Chun Shan Medical Univ., Chien-Kuo North Rd., Taichung 402, Taiwan, audio@csmu.edu.tw) and Jia-Shiou Liao (Chun Shan Medical Univ., Taichung 402, Taiwan)

This study examines Mandarin speakers' performance on Mandarin and English dichotic digit recognition tests (DDTs). The 60 right-handed subjects, whose primary language was Taiwan Mandarin, had started English as their second language no later than in seventh grade and continued with English through their freshman year in Taiwan. All the subjects were tested on their ability to pronounce and use English digits before participating in the experiments. Subjects took Mandarin one- and two-pair DDTs, and English one- and two-pair DDTs, in free-recall paradigms. In each DDT, subjects were asked to report the digits orally in any order no matter in what order they had heard the numbers in each ear. The scores were calculated from the number of digits the participants responded correctly to in each ear on one- or two-pair tests; they were then statistically analyzed. The English one- and two-pair recognition tests showed a significant right-ear advantage (REA) but not the Mandarin ones. The scores on the Mandarin one- or two-pair DDTs are higher than those on the English ones, suggesting REA or the influence of the non-native language on the subjects' performance.

4aSC17. Lexical recognition memory across dialects. Cynthia G. Clopper (Dept. of Linguist., Ohio State Univ., 1712 Neil Ave., Columbus, OH 43210, clopper.1@osu.edu) and Terrin N. Tamati (Indiana Univ., Bloomington, IN 47405)

Implicit recognition memory for spoken words is more accurate when words are repeated by the same or a similar talker than when they are repeated by a different talker. The current study explored implicit recognition memory for words repeated by the same talker, by a different talker from the same dialect, and by a different talker from a different dialect in a word recognition task in noise. Repetitions produced by the same talker facilitated word recognition performance. However, for target words originally pro-

duced by talkers from the Northern dialect of American English, repetitions produced by a talker from the Midland dialect of American English inhibited word recognition performance. No repetition effect was observed for repetitions produced by a different talker from the same dialect or for words repeated by Northern talkers that were originally produced by Midland talkers. These results suggest an asymmetry in how indexical information is stored and activated in lexical processing. The same talker repetition effect was observed for both dialects, but one variety (the Northern dialect of American English) inhibited the repetition effect across dialects and the other variety (the Midland dialect of American English) did not.

4aSC18. Perceptual similarity of unfamiliar regional dialects. Terrin N. Tamati (Dept. of Linguist., Indiana Univ., Bloomington, IN 47405, ttamati @indiana.edu)

Linguistic experience has been shown to influence the perception of regional dialect variation. Recent studies have found that the amount and type of experience with regional dialect variation affect performance in identifying or categorizing regional dialects. Experience also shapes the perceived similarity among regional varieties. To examine the effect of familiarity on the perceived similarity of regional dialects, a paired comparison perceptual similarity rating task was carried out with a group of unfamiliar regional dialects. Native speakers of American English made explicit judgments about the similarity of unfamiliar talkers from the United Kingdom and Ireland based on the regional dialect. Results show that listeners judged the regional dialects of pairs of talkers from the same dialect region as more similar than those of pairs of talkers from different dialect regions. A multidimensional scaling analysis revealed two dimensions of perceptual dialect similarity, both reflecting the geographic location of the cities of origins of the talkers (north versus south and east versus west). Thus, despite being unfamiliar with the regional dialects in the study, listeners were able to use dialect-specific differences in the acoustic signal to make judgments on the perceptual similarity of talkers based on regional dialect.

4aSC19. Identification of the place of articulation of trilingual postvocalic nasals and stops by native speakers of American English, Korean and Japanese. Takeshi Nozawa (College of Economics, Lang. Edu. Cntr., Ritsumeikan Univ., 1-1-1 Nojihigashi, Kusatsu, Shiga 525-8577, Japan) and Sang Yee Cheon (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Native speakers of American English and Korean produced postvocalic nasals and stops in /CVC/ frames in which the syllable final segment was a consonant with airstream blocking, and native speakers of Japanese produced more nasal /N/ and obstruent /Q/ in /CVNCV/ and /CVQCV/ frames. In Japanese stimuli, the consonant after the nasal or the obstruent was always a stop. Their utterances were recorded and edited to be used as stimuli for the experiment. The release burst of the English stimuli and the second syllable of Japanese stimuli were deleted. Native speakers of these three languages were recruited as listeners. They identified the place of articulation of the syllable-final nasals and stops of the three languages. As predicted, Japanese listeners performed most poorly because there are no phonemic contrasts between postvocalic nasals or stops in Japanese. Korean listeners outperformed the other two groups of listeners in identifying the place of articulation. Postvocalic stops in Korean are not released, so the Korean listeners may not depend on the release burst to identify the place of articulation of a syllable final stop. However, they made more voicing errors than American listeners probably because voiced stops in Korean cannot occur in a postvocalic position.

4aSC20. Why [spa] not [psa]? On the perceptual salience of initial /s/-stop and stop-/s/ sequences. Asimina Syrika (Dept. of Communicative Disord., Univ. of Wisconsin-Madison, Goodnight Hall, 1975 Willow Dr., Madison, WI 53706, syrika@wisc.edu), Jan Edwards, Marios Fourakis, Eun Jong Kong (Univ. of Wisconsin-Madison, Madison, WI 53706), Benjamin Munson (Univ. of Minnesota, Minneapolis, MN 55455), and Mary E. Beckman (Ohio State Univ., Columbus, OH 43210)

Initial /s/-stop clusters occur frequently in the world's languages, but initial stop-/s/ clusters are relatively infrequent. Furthermore, there appear to be no languages that contain initial stop-/s/ clusters, but not /s/-stop clusters, while the reverse is not true [Morelli, (1999) and (2003)]. This study aims at uncovering a perceptual explanation for these patterns by examining the salience of initial /s/-stop and stop-/s/ clusters in Greek, where both sequences are common. Twenty naïve Greek adult listeners identified syllables beginning with /sp/, /st/, /sk/, /ps/, /ts/, or /ks/, in two vowel contexts, /a/ and /i/, in real words spoken by ten Greek adult native speakers. The syllables were mixed with parts of Greek multitalker babble using SNRs of −6, 0, and +6 dB and presented to listeners for identification. Results showed significantly poorer identification for the /ps/ and /ks/ clusters than the /ts/ and /s/-stop clusters, particularly in the −6 and 0 SNRS. There was also a significant interaction with vowel, such that /sk/ and /ts/ were identified more accurately before /a/, whereas /ks/ was identified more accurately before /i/. The implications of these findings for phonological acquisition and speech perception are considered. [Work supported by NIDCD 02932 and NSF Grant 0729140.]

4aSC21. The perceptual acquisition of Korean fricatives by first language Mandarin listeners. Jeffrey J. Holliday (Dept. of Linguist., Ohio State Univ., 222 Oxley Hall, 1712 Neil Ave., Columbus, OH 43210, jeffh @ling.ohio-state.edu)

Despite numerous studies, it remains unclear how naive "foreign language" listeners become proficient L2 listeners, particularly in regard to difficult L2 contrasts. In an earlier study in which nine English-speaking L2 learners of Korean of varying proficiency and history of exposure to Korean identified Korean tense /s*/ versus non-tense /s/, listeners showed varying perceptual strategies. The results suggested that learners gradually learn to perceive differences in L2 contrasts by re-weighting useful cues and learning to ignore the "inefficient" cues that are initially relied on when the members of the L2 contrast are assimilated to L1 categories. This paper will report on the results of the same task (identification of CV sequences excised from real words), testing 30 L1 Mandarin speakers who have been in an intensive Korean language program in Seoul for about 2 months. The results of the present study will show whether there are as many inter-listener differences when the level and type of L2 exposure are much more controlled. In addition, because the acoustic cues relevant to the Mandarin sibilant fricative distinctions differ from those used in English the results will show to what extent the choice of perceptual strategy depends on acoustic properties of L1 contrasts.

4aSC22. Cross-linguistic perception of velar and alveolar obstruents: A perceptual and psychoacoustic study. Timothy Arbisi-Kelm (Dept. of Commun. Sci. and Disord., Augustana College, 639 38th St., Rock Island, IL 61201, timothyarbisi-kelm@augustana.edu), Jan Edwards (Univ. of Wisconsin-Madison, Madison, WI 53706), and Benjamin Munson (Univ. of Minnesota, Minneapolis, MN 55455)

It is well-known that velar stop consonants coarticulate more with the following vowel than stops at other places of articulation. The fine phonetic detail of this coarticulation is highly language-specific. For example, /k/ in Greek is more front before front vowels and more back before back vowels relative to /k/ in English [Arbisi-Kelm *et al.* (2008)]. The purpose of this study was to investigate how these cross-linguistic differences in production influence perception of place of articulation for lingual stops. The stimuli were word-initial consonant-vowel (CV) sequences excised from words produced by 2- to 5-year-old children and adults. The listeners were 20 adult native English speakers (tested in Minneapolis, USA) and Greek speakers (tested in Thessaloniki, Greece) who listened to these sequences combined across ages and languages in a visual analog scaling task [Urberg-Carlson *et al.* (2008)]. Listeners rated how alveolar or velar each sequence was by clicking on a double-headed arrow anchored with language-specific orthographic representations of the target consonants. Results showed that the two groups of adults perceived the sounds differently, as would be expected. We will report on the relationship between listeners' perception and psychoacoustic properties of the stop bursts. [Work supported by NIDCD 02932 and NSF BCS072914 and BCS0729277.]

4aSC23. Individual differences in use of English fricative perceptual cues. Elizabeth Casserly (Dept. of Linguist., Indiana Univ., Memorial Hall 322, Bloomington, IN 47405, casserly@indiana.edu)

This study examines individual variation as a potential explanation for contradictory and inconsistent reports of English speakers' use of acoustic cues in identification of the voiceless sibilants [s] and [ʃ]. While there is widespread agreement that the spectral shape of turbulent noise is key for

identification of these two categories, some studies find that formant transitions to and from the noise also influence identification [Whalen, J. Acoust. Soc. Am. **69**, 275–282 (1981)], while others do not [Harris, Lang. Speech **1**, 1–7 (1958)]. Similarly, the majority of studies investigating the effect of vowel context on fricative perception show that the presence of round vowels biases listeners toward perception of [s] [Kunisaki and Fujisaki, Ann. Bull. RILP **11**, 85–91 (1977)], but others show precisely the opposite effect, where round vowels favor [ʃ] responses [Nittrouer and Studdert-Kennedy, J. Speech Hear. Res. **30**, 319–329 (1987)]. In this study, 30 native English speakers participated in a labeling experiment that fully crossed all three factors—spectral noise shape, formant transitions, and vocalic context—for each subject. Every pattern of cue use found in the literature is also found in one or more of the individuals, which may explain why averaged results vary so widely across reports.

4aSC24. Learning and generalization of novel contrasts across speakers. Kyuwon Moon (kyuwon@stanford.edu) and Meghan Sumner (Dept. of Linguist., Stanford Univ., Stanford, CA 94305-2150)

This paper examines how listeners use a learned contrast when encountering novel speakers. Do speakers reset to their native perceptual biases or apply a learned contrast to new speakers? In two experiments, participants took a minimal pair decision pre-test (MPD), a training session in which a native Korean speaker contrasts stop release (e.g., [bEt] = BET, [bEt'] = BED) without any V/C duration differences, a post-test (identical to pre-test), and a generalization-test [identical to pre-test, but with a speaker of a different L1 (Arabic)]. In Experiment 1, the only difference between the post-test and gen-test was the L1 of the speakers. We found that a learned phonetic contrast generalizes across speakers of different L1s with equally strong effects for post-test and generalization-test independent of order of presentation. In Experiment 2, the post-test was identical to that in Experiment 1, but the learned contrast was paired with vowel durations consistent with native English. Listeners were slower and less accurate in both the generalization-test and post-test when the generalization-test was presented before the post-test. The resulting asymmetry between the two experiments suggests that listeners use learned contrasts, but quickly reset to native patterns when native cues are present.

4aSC25. Perceptual learning of talker-idiosyncratic phonetic cues. Alexandra Jesse (Max-Planck-Institut für Psycholinguistik, Postbus 310, 6500 AH Nijmegen, The Netherlands, alexandra.jesse@mpi.nl) and Rochelle S. Newman (Univ. of Maryland, College Park, MD 20742)

A number of recent studies have explored "perceptual learning," in which listeners use lexical knowledge to learn about a talker's idiosyncratic phoneme pronunciations and adjust their perception of other tokens from that talker accordingly. In a typical perceptual learning study, listeners might hear an item that is ambiguous between "crocotile" and "crocodile" during exposure. Since only crocodile is a word, listeners would learn (following several examples) that this talker has long VOTs, and subsequently at test show a shift in their categorization of a /d/-/t/ VOT continuum by the same talker. The present study explored perceptual learning through cues rather than through lexical knowledge. We used a phonetic contrast (s-th) in which there are both primary (spectral) and secondary (amplitude/duration) cues to phonetic identity. Listeners heard tokens of minimal s-th word pairs in which either the primary or secondary cue was ambiguous, but the alternative cue was unambiguous and thus disambiguated the phonetic identity of the word. We tested whether listeners use the unambiguous cue to learn about the speaker's production of the ambiguous cue (even though doing so was unnecessary for lexical identification) which would then influence later perceptual identification of a series based only on that cue.

4aSC26. Talker-specific accent: Can speech alignment reveal idiolectic influences during the perception of accented speech? Rachel M. Miller, Kauyumari Sanchez, Lawrence D. Rosenblum, James W. Dias, and Neal Dykmans (Dept. of Psych., Univ. of California, 900 Univ. Ave., Riverside, CA 92521, rmiller.ucr.grad@gmail.com)

Listeners use talker-specific (idiolectic) information to help them perceive and remember speech [e.g., Goldinger, J. Exp. Psychol. Learn. **22**, 1166–1183 (1998)]. However, recent research has shown that idiolectic information is not as helpful when listeners hear accented speech [e.g., Sidaras *et al.*, J. Acoust. Soc. Am. **125**, 5 (2009)]. It could be that listeners fail to encode idiolectic information when perceiving accented speech. To examine whether idiolectic is still encoded, experiments tested if subjects would display speech alignment to specific accented models. Speech alignment is the tendency to imitate another talker and can occur when shadowing heard speech [e.g., Goldinger, Psychol. Rev. **105**, 251 (1998)]. Native English subjects were asked to shadow a Chinese- or Spanish-accented model producing English words. Raters then judged whether the shadowed tokens were more similar in pronunciation to those of a shadowed model or of a different models with the same accent. In a second experiment, raters judged whether shadowed tokens were more similar in accent to those of (unshadowed) models with the same or a different accent. Preliminary results reveal that subjects align to the shadowed model, suggesting that idiolect is still encoded. Subjects also show moderate alignment to accent.

4aSC27. Initial acoustic-phonetic processing of competing verbal stimuli examined using dichotic verbal transformations. Peter W. Lenz, James A. Bashford, Jr., and Richard M. Warren (Dept. of Psych., Univ. of Wisconsin-Milwaukee, P.O. Box 413, Garland 224, Milwaukee, WI 53201, plenz@uwm.edu)

Initial studies with dichotic verbal transformations (VTs) of repeating words employed a cross-ear asynchrony of half the word's duration and listeners called out the independent perceptual changes at each ear as they occurred. In contrast to monaural and diotic VTs, the dichotic "immediate response" procedure is extremely difficult and tiring, requiring concurrent monitoring while remembering the word previously heard on each side. The present study employs a much less demanding task—a cued report procedure: the listener calls out what is heard on each side when prompted by a periodic light flash. When the asynchronous stimuli were statements of the same word, the transition rates on each side were the same as when presented monaurally, in contrast with the decreased rates reported with the earlier procedure. With different words on each side, the transition rates were diminished by an amount depending on the extent of their phonetic differences—rates were not influenced by either semantic relations or differences in the neighborhood density of the competitors. It is suggested that dichotic verbal transformations provide access to aspects of the acoustic-phonetic front end of speech analysis that may be obscured by subsequent levels of processing. [Work supported by NIH.]

4aSC28. PRESTO: Perceptually robust English sentence test: Open-set—Design, philosophy, and preliminary findings. Hanyong Park (Speech Res. Lab., Univ. of Indiana, 1101 E. 10th St., Bloomington, IN 40405, hanypark@indiana.edu), Robert Felty (Univ. of Colorado, Boulder, CO), Kelly Lormore (Indiana Univ. Cochlear Implant Program, Indianapolis, IN), and David B. Pisoni (Univ. of Indiana, Bloomington, IN)

Traditional clinical word recognition tests (e.g., SPIN and HINT) do not reflect variability in real world environments. These tests are often constructed with predictable short sentences spoken by a small number of talkers without dialect variation; thus, individual differences are difficult to uncover. To compensate for these shortcomings, PRESTO uses materials taken from the TIMIT database in order to incorporate variation in talkers, dialects, and number of words in a sentence. Familiarity and lexical frequency, syntactic structure, and semantic content are also considered. To provide normative data, normal-hearing young listeners performed an open-set identification task with the PRESTO materials in open field with six-talker babble mixed at different signal-to-noise ratios and also with no additional background noise. The HINT sentences were also used with the same listeners to assess the validity of PRESTO. Results indicate that listeners perform near ceiling for both the PRESTO and HINT materials in ideal listening conditions. However, under degraded listening conditions, the PRESTO shows much greater variability. Preliminary results from a clinical population also indicate that the more challenging PRESTO lists reveal individual differences among patients which are not apparent from scores on the HINT. 4aSP1. Bayesian approach to model-based signal processing: An overview. James V Candy (Lawrence Livermore Natl. Lab., P.O. Box 808, L-151, Livermore, CA 94551)

Although available for a long time with the advent of high-speed/high-throughput computing, the development of Bayesian processing techniques has evolved recently in acoustical signal processing. Bayesian signal processing is concerned with the estimation of the underlying probability distribution of a random signal in order to perform statistical inferences such as the conditional mean estimation. Knowledge of this distribution provides all of the essential information available required for problem solution. The usual limitations of nonlinear approximations and non-gaussian processes prevalent in classical algorithms (e.g., Kalman filters) are no longer a restriction to perform Bayesian inference. This approach enables the next generation of processors called particle filters that are sequential Monte Carlo methods providing an estimate of the underlying discrete probability distribution. In this overview, Bayesian signal processing is presented from a probabilistic perspective starting with Bayes rule and evolving to the development of a bootstrap particle filter perhaps one of the most common and simplest constructs available. The relationship of Bayesian processing to the concept of maximum entropy is discussed. Maximum entropy and its applicability in Bayesian processing is also mentioned briefly.

8:00

4aSP2. Defining uncertainty with maximum entropy method. David P. Knobles, Jason Sagers, and Robert Koch (Appl. Res. Labs., The Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029)

The maximum entropy (ME) method was strongly defended and advocated by E. T. Jaynes as a means to define uncertainty. Here, the ME method is applied to the estimation of ocean waveguide parameter probability distributions from measured acoustic data. An ME analysis produces a canonical distribution, well known from equilibrium statistical mechanics, which is the distribution that maximizes the entropy subject to constraints that reflect selected features of the measured data and a model. The ME method gives the most conservative distribution based only on the measured data and observed features. A Bayesian approach also has the goal of defining uncertainty, but starts from the specification of the likelihood function and the model priors. Data noise is naturally handled in the specification of the likelihood function. The discussion introduces simple examples, showing basic relationships between the constraints in ME and the maximum likelihood estimation. In special cases the form of the likelihood function used in Bayesian conditionalization can be derived from the ME approach. The form of the cost function is an important consideration in comparing ME and Bayesian methods of inferences. In general ME and Bayesian inferences lead to different results. 4aSP3. Automatic signal detection in noise using entropy. Christine Erbe (JASCO Appl. Sci., Brisbane Technol. Park, 1 Clunies Ross Ct, Eight Mile Plains, QLD 4113, Australia, christine@jasco.com)

Automatic detection of signals in noise is a common problem in many areas of acoustics. In the field of passive acoustic monitoring of marine mammals, the signals to be detected are vocalizations. The noise originates from natural (wind, waves, and rain) and man-made sources (e.g., shipping, construction, and seismic surveys). Signal characteristics vary broadly: frequency ranges from a few Hz to 200 kHz, duration from milliseconds to seconds to hours. Noise characteristics vary by similar orders of magnitude. While specific automatic detectors have been designed to successfully find specific calls in specific environments, the challenge is to find a large variety of calls in a large variety of noise. An exploitable difference between calls and noise is that most noise is a result of stochastic processes (wind, waves, rain, cavitating propellers + seismics generate gas bubbles underwater of varying size + resonance frequency), while many animal signals are a result of deterministic processes (vibrating strings & cavities of predetermined/fixed size). Shannon entropy was computed for power spectrum density functions of underwater recordings. Noise yielded high signal low entropy. Results are presented from passive acoustic surveys of marine mammals. The benefits and limitations of entropy applied to automatic signal detection are discussed.

8:40

4aSP4. The likelihood ratio and Bayesian signal processing. R. Lee Culver and Colin W. Jemmott (Appl. Res. Lab and Grad. Program in Acoust., Penn State Univ., P.O. Box 30, State College, PA 16804)

Over the past several years, we have been developing an architecture for classifying source depth associated with passive sonar signals. The classifiers utilize the statistics of a signal parameter which are estimated using knowledge of the environment and an acoustic propagation program. We have applied the likelihood ratio (LR) test to classify source depth using signal statistics from the SWellEx-96 and 1996 Strait of Gibraltar sea tests. More recently Bissinger developed a Hellinger distance classifier, and Jemmott is developing a histogram (discrete Bayesian) filter for this purpose. In this talk, we examine the relationship between the LR test and a processor that makes use of Bayes rule. We consider some of the fundamentals. It is useful to understand the underlying assumptions of the LR, the likelihood function, and how they are related to a Bayesian processor which makes use of prior information and computes a posterior probability distribution function. Under what conditions do the two processors produce the same answer? When would the Bayesian processor be a better choice? We compare the processors and apply them to the SWellEx-96 data. [Work supported by the Office of Naval Research Undersea Signal Processing.]

4aSP5. Bayesian bounds on passive sonar accuracy from binary performance metrics. John R. Buck (Dept. ECE, Univ. of Massachusetts Dartmouth, 285 Old Westport Rd., N. Dartmouth, MA 02747, johnbuck@ieee.org)

A passive sonar algorithm measures the pressure field at a sensor array then estimates the sound source location from these observations and an acoustic propagation model. Passive sonar performance is usually characterized by the mean squared error (MSE) between the estimated and true source locations. Consequently, passive sonar performance bounds typically provide lower bounds on the achievable MSE for a given array and environment. Such MSE bounds can be misleading in environments with strong sidelobes, as the optimal estimator may choose an unlikely location to balance the error among several highly likely locations. An alternative algorithm would be to partition the search space, then use the array observations to choose which block contains the source, but not its exact location in the block. The resulting binary performance metric is now the probability of choosing the incorrect block or error probability (P_e). Information theory allows us to formulate Bayesian bounds on the minimum achievable P_e for a given array, propagation environment, and search space partition. These bounds quantify the trade-off among SNR, P_e, and location estimation accuracy for passive sonar. [Work supported by ONR Code 321US.]

9:20

4aSP6. Using Bayesian inference for acoustic array design. Paul M. Goggans and Chung-Yong Chan (Dept. of Elec. Eng., Univ. of Mississippi, Anderson Hall, Rm. 302B, University, MS 38677)

Because inference and design are both generalized inverse problems, the tool and methods developed for Bayesian parameter estimation and model comparison can be adapted and used for the solution of design problems. As an example, this paper presents the use of the Bayesian inference framework for the automated design of linear transducer arrays [P. M. Goggans and C.-Y. Chan, "Antenna array design as inference," AIP Conf. Proc. **1073**, 294–300 (2008)]. Commonly, automated array design is cast as an optimization problem and solved using numerical optimization techniques. Here, the design of linear arrays is cast as an inference problem and solved using numerical Bayesian inference techniques. Compared to optimization-based methods, the inference-based method presented here has the advantage of being able to automatically determine the number of array elements required to satisfy design requirements and specifications. In addition, array design cast as inference can incorporate, as prior information, design requirements such as a minimum spacing between two adjacent elements, a maximum aperture width, and a necessary operating frequency bandwidth. Sample results are presented to demonstrate the application of the Bayesian inference framework in the automated design of linear arrays.

9:40

4aSP7. Recursive Bayesian state estimation for passive sonar localization. Colin W. Jemmott and R. Lee Culver (Penn State Appl. Res. Lab and Grad. Program in Acoust., P.O. Box 30, State College, PA 16804, cwj112@psu.edu)

A model-based recursive Bayesian signal processing framework is shown to localize a moving source emitting a low-frequency tonal signal in a shallow water environment. Source motion maps spatial variation in transmission loss into amplitude modulation of the signal received on a passive horizontal array. Acoustic propagation modeling predicts this variability, which is used to estimate source range, depth, range rate, and acoustic level. Uncertainty in transmission loss resulting from uncertainty in environmental parameters is predicted using Monte Carlo modal propagation modeling. Monte Carlo marginalization over environmental uncertainty provides robustness against data-model mismatch. The maximum entropy method is used to construct a probability density function (pdf) of transmission loss at each range depth location based on the Monte Carlo results. The resulting pdfs belong to the exponential family and result in an implementable recursive Bayesian processor. The physics of acoustic modeling determine the form of the processor through the transmission loss pdfs and are an intimate part of the localization technique. This processor is distinct from Bayesian matched field processing in that it neither relies on a vertical array nor computes modal amplitudes from received data. Results using SWellEx-96 will be shown. [Work supported by ONR Undersea Signal Processing.]

4aSP8. Bayesian geoacoustic inversion. Stan E. Dosso and Jan Dettmer (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC V8W 3P6, Canada)

This paper describes a general Bayesian approach to estimating seabed geoacoustic parameters from ocean acoustic data, which is also applicable to other inverse problems. Within a Bayesian formulation, the complete solution is given by the posterior probability density (PPD), which includes both data and prior information. Properties of the PPD, such as optimal parameter estimates, variances /covariances, correlations, and marginal probability distributions, are computed numerically for nonlinear problems using Markov-chain Monte Carlo methods. However, in many practical cases, both an appropriate model parametrization and the data error distribution are unknown and must be estimated as part of the inversion. These problems are linked, since the resolving power of the data is affected by the data uncertainties. Model selection is carried out by evaluating Bayesian evidence (parametrization likelihood given the data), or a point estimate thereof such as the Bayesian information criterion, which provides the simplest parametrization consistent with the data. The error covariance matrix (including off-diagonal terms, as needed) is estimated from residual analysis under the assumption of a simple, physically reasonable distribution form, such as a Gaussian or Laplace distribution. The validity of the above assumptions and estimates is examined *a posteriori* using both qualitative and quantitative statistical tests.

10:35

4aSP9. Particle filtering for sequential multipath arrival time and amplitude estimation. Rashi Jain and Zoi-Heleni Michalopoulou (Dept. of Math. Sci., New Jersey Inst. of Technol., Newark, NJ 07102)

Accurately estimating arrival times from acoustic time series in the ocean is essential for successful source and array element localization and estimation of the geometry of the sound propagation environment and environmental parameters such as sound speed in the water column and sediments. We have developed a sequential Monte Carlo method that characterizes multipath arrivals as moving targets, tracking them at spatially separated receiving phones. We focus on switching models that are suitable for unknown and varying numbers of arrivals at different phones. We also present approaches that efficiently and effectively extract amplitude information from received time series; such information can be then employed for sediment characterization. Our methods are applied to Haro Strait Primer and Shallow Water 06 data; their performance is evaluated through comparisons to conventional approaches. [Work supported by ONR.]

4aSP10. Sequential Bayesian strategies in geoacoustic inverse problems. Jan Dettmer, Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC V8W 3P6, Canada), and Charles W. Holland (The Penn State Univ., State College, PA)

This paper considers sequential Bayesian strategies for geoacoustic inverse problems which are difficult to solve simultaneously due to computational constraints. Bayesian inference provides a powerful approach to learning problems such as this since sequential inversions of multiple data sets [with the posterior probability density (PPD) of one inversion applied as prior information in the subsequent inversion] are equivalent to simultaneous inversion of all data. However, passing PPDs forward as priors has its own challenges when the PPD is sampled numerically for nonlinear inverse problems, particularly when the model parameter space is of high dimensionality and the data information content is high. In such cases, approximations are required to efficiently carry PPD information forward to subsequent inversions. The approach developed here represents numerically sampled PPDs in terms of discretized marginal probability distributions for principal components of the parameters, which minimizes the loss of information in representing inter-parameter correlations. The sequential Bayesian approach is applied to seabed reflectivity inversion with multiple data sets representing travel-time data and frequency-domain reflection coefficient data for a series of increasing penetration depths. Data information content is quantified by accounting for potential error biases as well as data error covariances. [Work supported by the Office of Naval Research.]

11:10

4aSP11. Three-dimensional source tracking in an uncertain environment via Bayesian marginalization. Dag Tollefsen (Norwegian Defence Res. Est. (FFI), Box 115, 3191 Horten, Norway) and Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC V8W 3P6, Canada)

This paper develops a non-linear Bayesian marginalization approach for three-dimensional source tracking in shallow water with uncertain environmental properties, with application to horizontal line array (HLA) data. The algorithm integrates the posterior probability density via a combination of Metropolis–Hastings sampling over environmental and bearing model parameters and Gibbs sampling over source range and depth, with a priori track constraints on source velocity. Two-dimensional marginal distributions for source range/depth and range/bearing are derived. The Viterbi algorithm is applied to obtain the most probable track, with uncertainties estimated from the marginal distributions. The algorithm is applied to simulated data in continental shelf environment and to towed-source and ship-noise data recorded on a HLA deployed on the seafloor in an experiment conducted in the Barents Sea.

11:25

4aSP12. Computation of normalizing constants in geoacoustic Bayesian inference. Jan Dettmer and Stan E. Dosso (School of Earth and Ocean Sci., Univ. of Victoria, Victoria, BC V8W 3P6, Canada)

This paper considers approaches to computing normalizing constants (Z) in Bayesian inference problems. Bayes' theorem combines the likelihood function, model prior, and Z to form the posterior probability density (PPD). Z (also known as evidence) is difficult to compute for general problems and a common approach is to avoid its computation entirely by calculating an unnormalized estimate of the PPD which is sufficient for moment estimates. However, estimating the normalized PPD, including Z, allows for moment estimates as well as quantifying the likelihood of the model parametrization. This is commonly referred to as model selection and poses a natural way to quantifying the most appropriate model parametrization for a given data set (Bayesian razor). Several approaches for computing Z have been developed in the statistics community, some of which are applied here to the geoacoustic inference problem. Annealed importance sampling follows an annealing approach and computes weighted averages along cooling trajectories. Nested sampling uses a likelihood constraint to move from the prior mass to the posterior. Both methods also give parameter estimates which are compared to Metropolis–Hastings results. [Work supported by the Office of Naval Research.]

4aUW1. Improving the parabolic equation solution for problems involving poro-elastic media. Adam M. Metzler, William L. Siegmann (Rensselaer Polytechnic Inst., Troy, NY 12180), Michael D. Collins, Ralph N. Baer (Naval Res. Lab., Washington, DC 20375), and Jon M. Collis (Colorado School of Mines, Golden, CO 80401)

Parabolic equation solutions for elastic media have undergone several modifications recently that increase their capabilities and accuracy. These include formulation in different dependent variables, approaches for handling range dependence such as coordinate rotations and single scattering, and treatment of media anisotropy. These advances are being extended to problems with heterogeneous and range-dependent poro-elastic media, which provide useful models of some shallow-water sediments. Other parabolic equation solutions for poro-elastic media [Collins *et al.*, J. Acoust. Soc. Am. **98**, 1645–1656 (1995)] are prior to recent progress. Vertical dependence is treated by applying heterogeneous depth operators from the equation of motion. Horizontal dependence is treated by incorporating single-scattering approaches. [Work supported by the ONR.]

8:15

4aUW2. Seismo-acoustic propagation near low-shear speed poroelastic ocean sediments using a hybrid parabolic equation solution. Jon M. Collis (Colorado School of Mines, Golden, CO 80401)

Accurate and efficient parabolic equation solutions exist for complex propagation environments featuring elastic and porous elastic sediment types. An area of concern has been low-shear wave speed sediments that become singular as their shear modulus tends toward zero. A historic approach for treating sediments of this type has been to assume that it is a fluid, and effects due to elasticity are negligible. This approach is limited in accuracy unless shear is accounted for. In this presentation, the ocean bottom sediment interface layer is treated as a porous elastic layer in which poroelastic momentum equations are solved and combined with an existing elastic parabolic equation implementation. Appropriate boundary conditions are enforced at the fluid-poroelastic and poroelastic-elastic interfaces. The new solution is tested on problems with a low-shear ocean bottom interface layer.

8:30

4aUW3. Improving the parabolic equation solution for problems involving sloping fluid-solid interfaces. Michael D. Collins (Naval Res. Lab., Washington, DC 20375, collins@noddy.nrl.navy.mil) and William L. Siegmann (Rensselaer Polytechnic Inst., Troy, New York 12180)

Several approaches are being investigated for improving the elastic parabolic equation for problems involving sloping fluid-solid interfaces. Approaches based on single scattering and energy conservation provide accurate solutions for problems involving sloping fluid-fluid and solid-solid interfaces, but the mixed-media problem has proven to be more challenging. The energy-conservation approach has been applied previously by deriving a linear equivalent to the nonlinear expression for energy flux. One of the approaches that are currently being investigated is based on going back to the nonlinear expression. Although it would not be practical to solve the full nonlinear scattering problem, promising results have been obtained for the fluid-fluid case with this approach by correcting the amplitude at only one grid point near the interface. With this approach, the nonlinear problem reduces to the evaluation of a quadratic function. Another approach that is being investigated is based on an alternative formulation that involves the vertical displacement and a quantity that is proportional to the normal stress on a horizontal interface. In these variables, the interface conditions across a horizontal interface are first order, and this may facilitate the extension of the single-scattering solution to the mixed-media problem. [Work supported by the Office of Naval Research.]

8:45

4aUW4. Dependence of the structure of the shallow convergence zone on deep ocean bathymetry. Stephen D. Lynch (slynch@mpl.ucsd.edu), Gerald L. D'Spain (Marine Physical Lab., Scripps Inst. Oc., San Diego, CA), Kevin Heaney (OASIS, Lexington, VA), Arthur B. Baggeroer (MIT, Cambridge, MA), Peter Worcester (Scripps Inst. Oc., La Jolla, CA), and James Mercer (APL/UW, Seattle, WA)

During an experiment in the northern Philippine Sea in 2009, low-frequency tones were transmitted from a shallow (15- and 60-m) source deployed from R/V Melville keeping station to a shallow (250-m) horizontal receiver array towed by R/V Kilo Moana approximately one convergence zone (CZ) away. Recordings were made during events in which the receiver ship maintained constant range in the convergence zone and during events in which the receiver ship transited radially through the CZ. The shallow CZ exhibits strong dependence on the bathymetry mid-way between the source and receiver array. In fact, the variability of the structure of the first CZ in this environment is significantly more strongly affected by the heterogeneous character of the bottom than water column fluctuations. Numerical modeling with a parabolic equation code is used to support the conclusions from the data analysis.

9:00

4aUW5. Range dependence in the level set method for underwater acoustics. Sheri L. Martinelli (Div. of Appl. Mathematics, Brown Univ., 182 George St., Providence, RI 02912)

The level set method due to Osher and Sethian [J. Comput. Phys. **79**, 12–49 (1988)] provides a way to obtain fixed grid solutions to the high-frequency wave equation. Instead of tracing rays from the source, the level set method embeds the wavefront implicitly in the phase space and propagates it according to the velocity field determined by the local ray direction, thus avoiding the complications involved in the spatial reconstruction of wavefronts from diverging rays. A level set method has been developed and implemented as a fixed-grid alternative to ray tracing to solve for the acoustic phase. One of the issues that arises with the increased dimensionality of posing the propagation problem in the level set framework is that the presence of reflecting boundaries produces a discontinuity in the phase space corresponding to a sudden change in propagation direction. When a reflecting boundary is range-dependent, further complications arise. To improve algorithm performance, specialized methods are applied to the level set equations that combine upwinding with higher-order spatial interpolation that avoid the generation of spurious oscillations that occur with most traditional finite difference methods. [Work supported by ONR 333 and the SMART Program.]

9:15

4aUW6. Two dimensional finite element propagation and reverberation modeling in shallow water waveguides. Marcia J. Isakson (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713, misakson@arlut.utexas.edu)

Finite element propagation models do not rely on approximations of the scattering at the interfaces and therefore provide excellent benchmark solutions to rough interface waveguide propagation and reverberation studies. In this study, two dimensional finite element solutions for reverberation and propagation are calculated for waveguides that have rough interfaces at the air/water boundary and the water/sediment boundary. The effects of upward and downward refracting sound speed profiles are also considered. [Work sponsored by Office of Naval Research, Ocean Acoustics.]

9:30

4aUW7. An algorithm to predict surface loss. Cathy Ann Clark (NUWCDIVNPT, B1320, R457, 1176 Howell St., Newport, RI 02841)

A semi-empirical surface loss algorithm is presented which is comprised of a rough scattering component derived from theory and a term which represents low-frequency, low angle loss from other mechanisms such as absorption and bubbles, based on a fit to measured data. A prediction of surface duct propagation using the semi-empirical algorithm and a current Navy standard propagation model is compared to measured data.

9:45

4aUW8. Boundary flattening transforms for acoustic propagation under rough and periodic sea surfaces. Roger Oba (Acoust. Div. Naval Res. Lab., Washington, DC 20375, roger.oba@nrl.navy.mil)

A conformal transform is presented that maps an acoustic domain with a one-dimensional, rough sea surface onto a domain with a flat top. The nonperturbative transform presented here broadly generalizes that of Dozier [J. Acoust. Soc. Am. **75**, 1415–1432] to include many wavelengths of the surface variation. A two-dimensional, flat-top domain permits the direct application of a parabolic equation model acoustic propagation model for the Helmholtz equation using a modified sound speed. Once the field is computed, the inverse transform permits the acoustic field interpolation in terms of the original coordinates. The mapping is derived from techniques in the classical theory of flow around an airfoil. Forward scatter test cases with periodic and rough sea surfaces provide verification of the method using a parabolic equation model. The periodic surface case demonstrates scattering from steep grazing angles to shallower ones. An extension to scattering to irregular cylinders is outlined following the scheme of DiPerna and Stanton [J. Acoust. Soc. Am. **96**, 3064–3076, (1995)]. [This research is sponsored by the Office of Naval Research.]

4aUW9. Three-dimensional scattering from pressure-release rough surfaces. Sumedh M. Joshi and Marcia J. Isakson (Appl. Res. Labs., 10000 Burnet Rd., Austin, TX 78758, sumedhj@mail.utexas.edu)

In order to compare a variety of three-dimensional (3-D) rough surface scattering theories, the scattering of a spherical wave incident on a pressure-release rough surface is modeled. Random surface realizations are computed from a spatial roughness power spectrum measured as part of the EVA sea test conducted in 2006. Scattering from these surfaces is computed using boundary and finite element methods. A singularity removal technique is applied to solve the Helmholtz–Kirchhoff boundary integral equation in 3-D. This integral solution is compared with 3-D finite elements and the 3-D Kirchhoff approximation, to determine the range of validity of the models.

10:30

4aUW10. Boundary roughness and the effect of internal waves on signal coherence for shallow water transmission. Harry, A. DeFerrari (Div. of Appl. Marine Phys., RSMAS - Univ. of Miami, 4600 Rickenbacker Cswy, Miami, FL 33149)

Broadband acoustic propagation experiments at three shallow sites allow for comparison of coherency of individual surface-reflected bottom-reflected modes of propagation. There appears to be a dependence of the correlation parameters of times and length on frequency and mode number that cannot be attributed to internal waves alone and likely depends on bottom and surface roughness. At low frequencies, f$<$100 Hz, during periods of quiescence internal waves, all modes of propagation have equally long coherence parameters. The coherency decrease equally for all modes as internal wave activity increases. For higher frequencies, 200 Hz $<f<$1000 Hz, the coherence parameters depend on mode number, with the lower order modes always more coherent than successive higher order modes. At still higher frequencies, $f>$1000 Hz, identifiable modes are not always observed; instead there is a continuum of arriving pulse energy with very low coherency even with minimal internal waves. Apparently, the randomizing effect of internal waves depends on bottom and surface roughness and frequency. At low frequencies, the boundaries appear flat and internal waves have a minimal effect. At the highest frequencies, phase coherence is already degraded by boundary roughness so that the slightest of internal wave activity completely randomizes the signals.

10:45

4aUW11. Horizontal Lloyd mirrors arising from propagation through straight and curved nonlinear internal wave fronts. Kara G. McMahon, Laurel K. Reilly-Raska (Dept. Math. Scis., Rensselaer Poly. Inst., Troy, NY 12180, mcmahk3@rpi.edu), James F. Lynch, Timothy F. Duda (Woods Hole Ocean. Inst., Woods Hole, MA 02543), and William, L. Siegmann (Rensselaer Poly. Inst., Troy, NY 12180)

Experimental observations and theoretical studies show that nonlinear internal waves (NIWs) occur widely in shallow water and cause acoustic propagation effects including mode coupling and ducting. Horizontal ducting results when acoustic modes interact with NIW fronts that comprise waveguide boundaries. For small grazing angles between a mode trajectory and a front, an interference pattern may arise that is hypothesized [Lynch *et al.*, J. Ocean Eng. **31**, 33–48 (2006)] to be a horizontal Lloyd mirror. We examine acoustic formulations for this feature and benchmark calculations for the acoustic intensity with those from the adiabatic mode parabolic equation. Results using different waveguide features are compared, including continuous-gradient and jump sound-speed profiles of varying strengths. We focus on differences in the location of the source relative to the NIW as well as the frontal curvature. The curvature influences both incidence angles and reflection characteristics. For sources oriented inside the front, as curvature increases the areas with interference patterns shrink, while sources beyond the front cause patterns to expand. [Work supported by ONR.]

11:00

4aUW12. Blind deconvolution of remote-source signals from ocean acoustic array recordings. Shima H. Abadi (shimah@umich.edu), David R. Dowling (Dept. of Mech. Eng., Univ. of Michigan, Ann Arbor, ML 48109), and Daniel Rouseff (Univ. of Washington, Seattle, WA 98105)

Reconstructing the signal originally broadcast from a remote source in an unknown multipath environment is a task commonly known as blind deconvolution. At frequencies of several kilohertz and above, multipath shallow-ocean sound propagation may be adequately described by ray acoustics. This presentation describes results from the application of ray-based artificial time reversal (ATR) to underwater sound propagation measurements. The receiving array was vertical and it recorded signals with center frequencies and bandwidths of a few kHz at source-receiver ranges up to 3 km in a water depth of approximately 60 m. Ray-based ATR uses a simple-beam-former-determined ray-arrival direction to construct a frequency-dependent phase correction at the receiving array that allows the Green's function of the sound channel and the original source waveform to be separately estimated. Here, the correlation coefficient between the original signal and the ATR-reconstructed signal is presented as a function of range and signal-to-noise ratio. In addition, the effect of reducing the number elements of the receiving array and the use of a coherent combination of reconstructed results for various ray arrival directions on cross correlation coefficient will be discussed. [Work supported by ONR.]

11:15

4aUW13. Experimental studies of underwater acoustic communication in Trondheim fjord. Guosong Zhang (Dept. of Electr. and Telecomm., Norwegian Univ. of Sci. and Tech., O.S. Bragstads plass 2B, NO-7491, Norway, guosong.zhang@iet.ntnu.no), Hefeng Dong, and Jens M. Hovem (Norwegian Univ. of Sci. and Tech., NO-7491, Norway)

Direct-sequence spread-spectrum signal was used for communication tests over underwater channels in Trondheim fjord. Differential binary phase shift keying was utilized between two adjacent symbols. To the receiver, a method uses a time updated channel impulse response estimation to recover differential phase modulated information, and it takes the estimation from the previous symbol as the match filter. The effectiveness of this method is ensured by the coherence between two consecutive symbols over time varying channels. This method is insensitive to multipath patterns, and it does not require time synchronization as precise as the convention de-spread method does. In our experiments, good performance was achieved, even in low SNR tests. The performance loss at high SNR in the experiments was caused by long time delay spread. Late-arriving paths from the previous symbol were buried in the current symbol during time-windowing process, and the late-arriving paths might decrease the magnitude of the differential phase information. In this situation, it is prone to cause errors.

11:30

4aUW14. Frequency dispersion of parametric array signal in shallow water. Igor Esipov (N. Andreyev Acoust. Inst., 4, Shvernik str., 117036 Moscow, Russia, igor.esipov@mail.ru), Sergey Tarasov, Vasily Voronin (Inst. of Technol. in Taganrog, Russia), and Oleg Popov (N. Andreyev Acoust. Inst.)

Results of experimental test of parametric array application for marine shallow water waveguide excitation by sweep frequency modulated signal are discussed. Parametrical sound signal is forming in shallow water environment, which is stimulated by intensity modulated high frequency power acoustical pump. As a result the end-fire parametric array is forming there, which excites sharp directional signal radiation at the modulation frequency. Such a low-frequency signal, generated in the virtual end-fire array by parametrical means, will propagate in shallow water waveguide independently from the pump radiation. Shallow water signal propagation obeys to waveguide dispersion. Sweep modulated signal compression is experimentally shown for single mode signal propagation in shallow water. Acoustical signal of 2-ms duration is generated in frequency band of 7–15 kHz by parametric array. This signal is transmitted in single lobe of 2 deg width along the path of 5.6 km long in water layer from 2.5- to 3-m depth. The directivity of the signal transmitted was constant in the whole frequency range. It was shown the single mode excitation of the shallow water waveguide takes place under this circumstance. [Work supported by ISTC, Project No. 3770.]

Meeting of Standards Committee Plenary Group

to be held jointly with the meetings of the
ANSI-Accredited U.S. Technical Advisory Groups (TAGs) for:
ISO/TC 43, Acoustics,
ISO/TC 43/SC 1, Noise,
ISO/TC 108, Mechanical vibration, shock and condition monitoring,
ISO/TC 108/SC 2, Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures,
ISO/TC 108/SC 3, Use and calibration of vibration and shock measuring instruments,
ISO/TC 108/SC 4, Human exposure to mechanical vibration and shock,
ISO/TC 108/SC 5, Condition monitoring and diagnostics of machines,
ISO/TC 108/SC 6, Vibration and shock generating systems,
and
IEC/TC 29, Electroacoustics

P. D. Schomer, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 43 Acoustics and ISO/TC 43/SC 1 Noise
Schomer and Associates, 2117 Robert Dr., Champaign, IL 61821

D. J. Evans, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108 Mechanical vibration shock and condition monitoring, and ISO/TC 108/SC 3 Use and calibration of vibration and shock measuring devices
National Institute of Standards and Technology (NIST), 100 Bureau Dr., Stop 8220, Gaithersburg, MD 20899

W. C. Foiles, Co-Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 2 Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures
BP America, 501 Westlake Park Blvd., Houston, TX 77079

R. Taddeo, Co-Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 2 Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures
NAVSEA, 1333 Isaac Hull Ave., SE, Washington Navy Yard, Washington, DC 20376

D. D. Reynolds, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 4 Human exposure to mechanical vibration and shock
3939 Briar Crest Ct., Las Vegas, NV 89120

D. J. Vendittis, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 5 Condition monitoring and diagnostics of machines
701 NE Harbour Terrace, Boca Raton, FL 33431

R. Taddeo, Vice Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 5 Condition monitoring and diagnostics of machines
NAVSEA, 1333 Isaac Hull Avenue, SE, Washington Navy Yard, Washington, DC 20376

C. Peterson, Chair
U.S. Technical Advisory Group (TAG) for ISO/TC 108/SC 6 Vibration and shock generating systems
200 Dixie Ave., Kalamazoo, MI 49001

V. Nedzelnitsky
U.S. Technical Advisor (TA) for IEC/TC 29 Electroacoustics
National Institite of Standards and Technology (NIST), 100 Bureau Dr., Gaithersburg, MD 20899–8221

The reports of the Chairs of these TAGs will not be presented at any other S Committee meetings.

The meeting of the Standards Committee Plenary Group will precede the meetings of the Accredited Standards Committees S1, S2, S3, and S12 which are scheduled to take place in the following sequence:

ASC S12, Noise	**22 April 2010**	**9:15 a.m. to 10:30 a.m.**
ASC S12, Noise	**22 April 2010**	**9:15 a.m. to 10:30 a.m.**
ASC S2, Mechanical Vibration and Shock	**22 April 2010**	**11:00 a.m. to 12:00 noon**
ASC S1, Acoustics	**22 April 2010**	**1:45 p.m. to 2:25 p.m.**
ASC S3, Bioacoustics	**22 April 2010**	**3:00 p.m. to 4:15 p.m.**
ASC S3/SC1, Animal Bioacoustics	**22 April 2010**	**4:30 p.m. to 5:30 p.m.**

Discussion at the Standards Committee Plenary Group meeting will consist of national items relevant to all S Committees and U.S. TAGs.

The U.S. Technical Advisory Group (TAG) Chairs for the various international Technical Committees and Subcommittees under ISO and IEC, which are parallel to S1, S2, S3, and S12 are as follows:

U.S. TAG Chair/Vice Chair	TC or SC	U.S. Parallel Committee
ISO		
P. D. Schomer, Chair	**ISO/TC 43** Acoustics	ASC S1 and S3
P. D. Schomer, Chair	**ISO/TC 43/SC1** Noise	ASC S12
D. J. Evans, Chair	**ISO/TC 108** Mechanical vibration, shock and condition monitoring	ASC S2
W. C. Foiles, Co-Chair R. Taddeo, Co-Chair	**ISO/TC 108/SC2** Measurement and evaluation of mechanical vibration and shock as applied to machines, vehicles and structures	ASC S2
D. J. Evans, Chair	**ISO/TC 108/SC3** Use and calibration of vibration and shock measuring instruments	ASC S2
D. D. Reynolds, Chair	**ISO/TC 108/SC4** Human exposure to mechanical vibration and shock	ASC S2/S3
D. J. Vendittis, Chair R. Taddeo, Vice Chair	**ISO/TC 108/SC5** Condition monitoring and diagnostics of machines	ASC S2
C. Peterson, Chair	**ISO/TC 108/SC6** Vibration and shock generating systems	ASC S2

Meeting of Accredited Standards Committee (ASC) S12 Noise

W. J. Murphy, Chair, ASC S12
NIOSH, 4676 Columbia Parkway, Mail Stop C27, Cincinnati, OH 45226

R. D. Hellweg, Vice Chair, ASC S12
Hellweg Acoustics, 13 Pine Tree Road, Wellesly, MA 02482

Accredited Standards Committee S12 on Noise. Working group chairs will report on the status of noise standards currently under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAG for ISO/TC 43/SC 1 Noise, take note - that meeting will be held in conjunction with the Standards Plenary meeting at 8:00 a.m. on Thursday, 22 April 2010.

Scope of S12: Standards, specifications and terminology in the field of acoustical noise pertaining to methods of measurement, evaluation and control, including biological safety, tolerance and comfort, and physical acoustics as related to environmental and occupational noise.

Meeting of Accredited Standards Committee (ASC) S2 Mechanical Vibration and Shock

A. T. Herfat, Chair, ASC S2
Emerson Climate Technologies, Inc., 1675 W. Campbell Road, P.O. Box 669, Sidney, OH 45365-0669

C. F. Gaumond, Vice Chair, ASC S2
Naval Research Laboratory, Code 7142, 4555 Overlook Ave., SW, Washington, DC 20375-5320

Accredited Standards Committee S2 on Mechanical Vibration and Shock. Working group chairs will report on the status of various shock and vibration standards currently under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAG for ISO/TC 108, Mechanical Noise, take note - that meeting will be held in conjunction with the Standards Plenary meeting at 8:00 a.m. on Thursday, 22 April 2010.

Scope of S2: Standards, specifications, methods of measurements and test, and terminology in the field of mechanical vibration and shock, condition and diagnostics of machines, including the effects of exposure to mechanical vibration and shock on humans, including those aspects which pertain to biological safety, tolerance and comfort.

4pAA1. Measuring and defining the sound quality of audio systems. Peter Mapp (Peter Mapp Assoc., Colchester, United Kingdom)

"High quality" is a term often employed as a requirement for the performance of an audio or sound system, yet what does it mean and can it be quantified? In particular, bass performance is an important aspect but again is extremely hard to define. Frequency response assessment alone is not enough to characterize sound quality as this does not provide information with regard to the temporal or transient characteristics of the room or system. The paper will look at a number of techniques that potentially can be used to help assess sound system performance including a new measurement method intended to quantify the transient and temporal characteristic of the bass sound in a room, whether this is via a sound system or an assessment of the room itself.

1:20

4pAA2. But how does it look? Deb Britton (K2 Audio, LLC, 4900 Pearl East Circle, Ste. 201E, Boulder, CO 80301, deb@k2audio.com)

As acousticians and audio professionals, we are constantly striving for the "optimum sound solution." Quite often our optimum solution is at odds with the room's architecture or the desired aesthetic. This paper will present some examples of spaces where high-quality sound, even coverage, speech intelligibility and visual aesthetics were all achieved.

1:40

4pAA3. Sweetness spotting. Sam Ortallono (zSam Ortallono MediaTech Inst., 3324 Walnut Bend Ln., Houston, TX 77042)

This paper investigates the traditional listening position for the mixing of stereo music in a near field-monitoring situation. Common sense and current practice reinforce the ideal listening post to be at the apex of an equilateral triangle formed by the two speakers and the observer's head. This experiment will put that notion to the test. Using white noise pink noise, sine waves, and program material we will compare listening positions to the left and right as well as closer and farther. Readings from several mixing studios at multiple facilities will provide the numbers. Results will be correlated with room size, shape, and room treatment. Will the data uphold the longstanding wisdom on phase coherency and stereo image or will the results surprise us all?

2:00

4pAA4. Critical listening research on reproduced sound in diffuse environments. William L. Martens (Faculty of Architecture, Design and Planning, Univ. of Sydney, New South Wales 2006, Australia, bill@arch.usyd.edu.au) and Peter D'Antonio (RPG Diffusor Systems, Inc., 651-C Commerce Dr., Upper Marlboro, MD 20774)

In critical listening rooms designed to monitor precisely small signal processing changes, what can be heard is influenced by the room's modal response and the degree to which reflections are controlled by absorptive, reflective, and diffusive boundary surfaces. In exploring the problem of room acoustics affecting the results of such important listening activities, it is informative to explore the boundary conditions. For example, the acoustics industry utilizes absorption and reverberation chambers to explore related auditory phenomena. Recently, a diffusion chamber was created with broadband diffusion on walls and ceiling. Modal frequencies were also controlled with dedicated plate resonators effective down to 50 Hz. Impulse response measurements in this diffuse chamber revealed a dense reflection pattern 30 dB or more below the direct sound. The initial perception in this room was precise sonic images, a comfortable sense of ambiance and an apparent transparency to the subtleties of reproduced imagery that support decisions of sound engineers. Related experiments being carried out in other controlled listening rooms will be reviewed to place the current work in context.

2:20

4pAA5. How reverberation degrades and aids source perception in auditory scenes. Barbara G. Shinn-Cunningham (Boston Univ. Hearing Res. Ctr., 677 Beacon St., Boston, MA 02215)

Reverberant energy (or reverberation) influences perception of source content (in addition to influencing perception of the environment and of source location). Moreover, reverberation can affect perception in different ways depending on whether a source is played in quiet or in a scene containing competing sounds. Reverberation smears spectro-temporal structure, which can interfere with estimation of duration, pitch contour, and other basic attributes. In the extreme, such spectro-temporal smearing (self-masking) can interfere with extracting the meaning of signals like speech or music. However, if the direct sound reaching a listener is nearly inaudible, re-

verberation adds energy, improving source detectability. While these in-quiet effects contribute to perception of sources in a complex acoustic scene, additional factors also come into play. For instance, if two otherwise similar sources have different levels of reverberation, the reverberation can make them more perceptually distinct, making it easier to focus attention on one and understand it. On the other hand, the same spectro-temporal smearing that can hurt perception of a source in quiet can also disrupt source segregation, making it difficult to selectively analyze a desired source. Examples of these different effects of reverberation on perception, taken from recent experiments, will be presented and discussed.

4pAA6. Optimal loudspeaker placement for sound field reconstruction in geometrically constrained environments. Joshua Atkins and James West (Dept. of Elec. and Comput. Eng., Johns Hopkins Univ., 3400 North Charles St., Baltimore, MD 21212)

The design of loudspeaker arrays for holographic sound reproduction systems involves sampling a given aperture by a set of loudspeakers. For full sphere apertures it can be proven that there are only five equidistant sampling methods (given by the five regular polyhedrons) which only allows for arrays with up to 20 elements. For larger arrays, non-equidistant design methods such as t-design and Gaussian sampling have been proposed. However, in realistic environments it is generally not possible to place loudspeakers on the floor or on walls at certain locations. Furthermore, it is not desirable to have the loudspeakers constrained to spherical radii. This work shows a method for loudspeaker array design that allows for consideration of these special cases. The method relies on the decomposition of the sound field into a spatially orthonormal basis of spherical harmonics. A heuristic method is used to minimize the eigenvalue spread of the spherical harmonic matrix. The loudspeaker weights are found by calculating the generalized inverse of this matrix. Constraints on the speaker positions, highest reproduction mode, and number of loudspeakers are imposed in the minimization. The results of a design for a 16 speaker array in our acoustics laboratory are discussed.

2:55

4pAA7. Acoustics in a home music listening room. Sergio Beristain (Acoust. Lab. E.S.I.M.E., P.O. Box 12-1022, Narvarte, 03020 Mexico Distrito Federal, Mexico, sberista@hotmail.com)

A room was designed with the sole purpose of listen all kinds of recorded music, with a high preference to classical and romantic music. It was decided to locate the room in the basement level of a large single family home, where the external noise control or the control of the sound going out were not the big issues, so that the internal acoustics became the main one. The acoustics was adjusted for clear and balanced sound, and the high-end audio system to be installed can handle monophonic, stereophonic, and surround signals, but stereo sources are paramount. The room is 4 m wide, 7 m long, and 2.8 m high, with the lower part of the walls used for the equipment and music source storage, while the floor, ceiling, and higher part of the walls are the places where the non-proprietary acoustic materials and the speakers are going to be located.

3:10

4pAA8. Acoustic calibration of the exterior effects room at the NASA Langley Research Center. Kenneth J. Faller, II, Stephen A. Rizzi, Jacob Klos (Structural Acoust. Branch, NASA Langley Res. Ctr., MS 463, Hampton, VA 23681, kenneth.j.faller@nasa.gov), William L. Chapin, Fahri Surucu (AuSIM, Inc., Mountain View, CA 94043), and Aric R. Aumann (Analytical Services and Mater., Inc., Hampton, VA 23666)

The exterior effects room (EER) at the NASA Langley Research Center is a 39-seat auditorium built for psychoacoustic studies of aircraft community noise. The original reproduction system employed monaural playback and hence lacked sound localization capability. In an effort to more closely recreate field test conditions, a significant upgrade was undertaken to allow simulation of a three-dimensional (3-D) audio and visual environment. The 3-D audio system consists of 27 full-range satellite speakers and four subwoofers, driven by a real-time audio server running a derivation of vector base amplitude panning. The audio server is part of a larger simulation system, which controls the audio and visual presentation of recorded and synthesized aircraft flyovers. The focus of this work is on the calibration of the 3-D audio system, including gains used in the amplitude panning algorithm, speaker equalization, and absolute gain control. Because the speakers are installed in an irregularly shaped room, the speaker equalization includes time delay and gain compensation due to different mounting distances from the focal point, filtering for color compensation due to different installations (half space, corner, and baffled/unbaffled), and crossover filtering.

4pAB1. Classification of marine mammal vocalizations using an automatic aural classifier. Paul C. Hines and Carolyn M. Ward (Defence R&D Canada, P.O. Box, 1012 Dartmouth, Nava ScotiaS B2Y 3Z7, Canada, paul.hines@drdcrddc.gc.ca)

Passive sonar systems are often used to detect marine mammal vocalizations in order to localize and track them. Unfortunately, transients generated by sources other than marine mammals can also trigger passive sonar systems which leads to a large number of false alarms. Furthermore, even in the case of a successful detection, classifying the genus is often required and this typically requires expertise not readily available on the vessel. Perceptual signal features—similar to those employed in the human auditory system—have been used to reduce false alarms in active sonar by automatically discriminating between target and clutter echoes. This contributes to improved sonar performance [Young and Hines, J. Acoust. Soc. Am. **122**, 1502–1517 (2007)]. Many of the features were inspired by research directed at discriminating the timbre of different musical instruments (a passive classification problem) which suggests it might be applied to classify marine mammal vocalizations. To test this hypothesis, the automatic aural classifier was trained and tested on a set of marine mammal vocalizations from a variety of species. This paper will provide an overview of the aural classifier's architecture, describe the preparation of the data set, including the attempt to provide ground-truth confirmation of the data, and present some preliminary results.

1:30

4pAB2. Processing burst pulse waveforms from odontocetes. Paul Hursky, Michael B. Porter (HLS Res. Inc., 3366 North Torrey Pines Court, Ste. 310, La Jolla, CA 92037), Tyler Olmstead, Marie Roch (San Diego State Univ., San Diego, CA 92182-7720), Sean Wiggins, and John Hildebrand (Univ. of California in San Diego, La Jolla, CA 92093)

A number of marine mammals produce an interesting vocalization called a burst pulse, which consists of a series of clicks whose repetition rate increases to the point that the entire waveform sounds more like a continuous buzz. These animals also produce individual clicks at a much less frequent rate, sometimes with a consistent inter-click interval, sometimes without. However, because these animals are often observed in groups that number in the hundreds at low rates, it is difficult to associate individual clicks with individual animals or to group multipath arrivals. A burst pulse waveform avoids these association ambiguities—the clicks making up a burst pulse are so frequent, and so consistent in amplitude and inter-click interval that they are easily associated with a single animal, and any multipath structure is consistently revealed. We will present results of processing a variety of burst pulses observed on array sensors from a series of experiments off the coast of California and discuss algorithms for detecting burst pulse waveforms and for extracting classification features from these waveforms.

1:45

4pAB3. Probabilistic bioacoustic signal extraction within spectrograms. T. Scott Brandes (Signal Innovations Group, Inc., 1009 Slater Rd., Ste. 200, Res. Triangle Park, NC 27703)

A methodology for probabilistic bioacoustic signal extraction within spectrograms of natural sound recordings is proposed. Probabilistic models of signal attributes are described for generating a host of likelihoods used to estimate the probability that individual pixels within a spectrogram represent part of a bioacoustic signal. The pixel probabilities result in a transformation of the spectrogram into a probability map of bioacoustic signal presence. It is shown that these probability maps create a dramatic increase in the bioacoustic signal-to-noise ratio within the spectrogram. These probability maps along with threshold filtering provide a means for image segmentation of the spectrogram, creating blocks of pixels that represent bioacoustic signals, facilitating feature and signal extraction. This methodology is applied to natural sound recordings of three quality types in a wide range of signal-to-noise ratios. In each instance, the probability mapping greatly increases the signal-to-noise ratio and, when applied as a threshold filter, is far more selective with pixel inclusion than threshold filtering applied based on sound level. Suggested applications include automated call recognition of birds, frogs, and insects from field recordings within a wide range of ambient noise.

2:00

4pAB4. Recognition of killer whale individuals from multiple stereotyped call types. Nicole Nichols, Les Atlas (Dept. of Elec. Eng., Univ. of Washington, Box 352500, Seattle, WA 98195, nmn3@u.washington.edu), Ann Bowles (Hubbs-SeaWorld Res. Inst., San Diego, CA 92109), and Marie Roch (San Diego State Univ., San Diego, CA 92182)

Recognition of marine mammal individuals will be an essential tool for obtaining demographic information of populations as habitat monitoring is increasingly being conducted with passive acoustics. Our previous research established the potential to identify killer whale individuals with passive acoustic recordings with up to 78% accuracy. The data for this result consisted of 75 vocalizations from four adult (two male, two female) killer whales of Icelandic origin in residence at SeaWorld San Diego. The stereotyped vocalizations used were all SD1a or SD1b, and caller identification was known to a high degree of certainty allowing for quantifiable validation. Classification was performed with 12 mel-frequency cepstral coefficients, and 12 delta and 12 delta-delta cepstral coefficients as inputs to a Gaussian mixture model. We initially chose to use one call type as the SD1 call was frequently produced by all four individuals and it eliminated potential ambiguity from identifying call type instead of individual. In the research we now present, we extend our prior methods to be used with multiple call types. Because individuals in the wild will not have a known frequency of call type usage, we propose a normalization method for training a classifier that is unbiased with respect to call-type frequency.

4pAB5. Autonomous underwater glider based embedded real-time marine mammal detection and classification. Tyler J. Olmstead, Marie A. Roch (Dept. of Comput. Sci., San Diego State Univ., 5500 Campanile Dr., San Diego, CA 92182, tyler.j.olmstead@gmail.com), Paul Hursky, Michael B. Porter (Heat, Light, and Sound Res. Inc., La Jolla, CA 92037), Holger Klinck, David K. Mellinger (Oregon State Univ., Newport, OR 97368), Tyler Helble, Sean S. Wiggins, Gerald L. D'Spain, and John A. Hildebrand (Univ. of California in San Diego, La Jolla, CA 92093)

Autonomous marine vehicles offer the potential to provide low-cost data suitable for passive acoustic monitoring applications of marine mammals. Due to their extremely low-power consumption and long range, gliders are an attractive option for long-term deployments. Challenges related to power availability, payload size, and weight have previously restricted the viability of marine mammal monitoring. As an example, the wide bandwidth of odontocete echolocation clicks requires a high sampling rate and poses challenges with respect to limitations in power, size, and weight of the deployed system. Recent developments in commercial off-the-shelf hardware driven by the mobile phone industry's need for multimedia-rich smart phones have resulted in low-power architectures capable of performing computationally demanding signal processing and stochastic recognition tasks in real time. We describe our work on a small form-factor, light-weight package used to perform real-time passive acoustic detection and classification. The system detects echolocation clicks using Teager energy. Echolocation clicks are then classified using cepstral features processed by a Gaussian mixture model. [Work sponsored by ONR.]

2:30

4pAB6. Analysis of cetacea vocalizations using ocean bottom seismic array observations, western Woodlark Basin, Papua New Guinea. Scott D. Frank (Dept. of Mathematics, Marist College, 3399 North Rd., Poughkeepsie, NY 12601, scott.frank@marist.edu) and Aaron N. Ferris (Weston Geophysical Corp., 181 Bedford. St., Lexington, MA 02420)

Over a 6-month period in 1999 an array of seven ocean bottom seismometers and seven bottom mounted hydrophones covered a 30-km^2 area at 2–3-km water depth in the western Woodlark Basin. The array's main task was the detection of microearthquakes associated with nearby active tectonics. However, it also made fortuitous broadband recordings of Cetacea vocalizations that we associate with finback whales. Each of these signals has a 10–15-s duration and they exhibit a repetitive pattern with 10–15-min period. The signals are well recorded across both the seismometers and hydrophones, which were sampled at 64 and 125 Hz, respectively. Time-varying spectral analysis demonstrates that the signals are frequency modulated in the 20–30-Hz band with most energy occurring at ~22 Hz. We employ array-based methods (e.g., optimal beam forming techniques) and acoustic transmission loss simulations to determine range and bearing of the acoustic sources. Preliminary analysis indicates that the acoustic sources originate near the array, and secondary signals may represent back-scattered energy from the short-wavelength, high-topographic features associated the active tectonics with in the basin.

4pAB7. Echolocation behavior of pairs of flying *Eptesicus fuscus* recorded with a Telemike microphone. Mary E. Bates (Dept. of Psych., Brown Univ., 89 Waterman St., Providence, RI 02912, mary_bates @brown.edu), Yu Watanabe, Yuto Furusawa, Emyo Fujioka, Shizuko Hiryu, Hiroshi Riquimaroux (Doshisha Univ., Kyotanabe, Japan), Jeffrey M. Knowles, and James A. Simmons (Brown Univ., Providence, RI 02912)

Four big brown bats (Eptesicus fuscus) were flown singly and in pairs in a room containing a sparse array of vertically hanging plastic chains as obstacles. Each bat carried a lightweight radio telemetry microphone (Telemike) that recorded their emitted echolocation sounds without artifacts from Doppler shifts, directional effects, and atmospheric attenuation. The broadcasts of both bats were also recorded with two stationary ultrasonic microphones located at the far end of the flight room. The echolocation broadcasts of bats flying singly were compared to those emitted when the bats were flown together. The principal change was shifting of harmonic frequencies very slightly (<5 kHz) away from each other and from frequencies used when flying alone. In contrast, the duration of emissions was more stable between single and double bat flights. Changes in ending frequency have been associated with a jamming avoidance response in big brown bats and could indicate attempts to avoid interference while flying with conspecifics in an enclosed space. [Work supported by ONR and NSF.]

4pAB8. Paradoxical reference frequency shifts during paired flights in Japanese horseshoe bats evaluated with a Telemike. Yuto Furusawa, Shizuko Hiryu, and Hiroshi Riquimaroux (Faculty of Life and Medical Sci., Doshisha Univ., 1-3 Miyakotani Tatara, Kyotanabe 610-0321, Japan)

In order to examine vocal behaviors for the echolocating bats to improve extraction of jammed echolocation signals, group flight experiments were conducted where two Japanese horseshoe bats were flown simultaneously in a flight chamber. Horseshoe bats are known to conduct Doppler-shift compensation, keeping their echo CF2 frequency constant to which their auditory system is sharply tuned. It was hypothesized that bats shifted their reference frequencies apart to avoid overlapping the reference frequencies. Echolocation sounds during sequential flights were recorded with an onboard wireless microphone, Telemike. Reference frequencies were investigated by measuring Doppler-shift compensated CF2 frequencies of the bats' own echoes. Recorded data show that the bats kept their echo CF2 frequency constant with a standard deviation (SD) of 50–80 Hz, indicating that they exhibited Doppler-shift compensation with the same accuracy as that used for flying alone (SD = 83.2 Hz). However, the bats did not shift their reference frequency toward increasing the frequency difference even when the initial difference in the reference frequencies between individuals was less than 100 Hz. Rather, the bats tended to make their reference frequencies closer during group flight compared to those for single flights. These findings suggest that multiple bats may squeeze their echo CF2 frequencies into a narrow frequency range. In addition, horseshoe bats may adapt to acoustic interference without expanding the frequency difference between individuals. [Work supported by ONR grant.]

4pAB9. Miniaturization of insect-inspired acoustic sensors. Erick Ogam (Laboratoire de Mcanique et d'Acoustique, CNRS, UPR7051, 31 chemin Joseph Aiguier, 13402 Marseille Cedex 20, France), Franck Ruffier (Institut des Sci. du Mouvement, 13009 Marseille France), Armand Wirgin (CNRS, 13402 Marseille Cedex 20, France), and Andrew Oduor (Maseno Univ., Maseno, Kenya)

Insects can navigate and follow sound sources with precision in complex environments using efficient principles based on particular and appropriate sensory-motor processing. It is precisely these principles, little understood at this point, that we want to understand, model, and validate by rebuilding them on a micro-flying device. To achieve this goal, a new bio-mimetic acoustic sensor inspired by the cricket's auditory system has been developed and tested in an anechoic chamber. The performance of the processing algorithm, the aperture of the auditory system, and interferences caused by the geometry of the sensor itself were first evaluated: synthetic signals were generated by a boundary element model taking into account the three-dimensional geometry of the sensor to characterize its performance in free space. A processing based on cross-correlation for localizing and tracking an acoustic source was also studied to assess whether the observed limitations were inherent to the geometry of the sensor or due to limitations of the cricket inspired processing algorithm. The sensor worked well with several synthetic chirped cricket songs. [Work supported by CNRS PIR Neuroinformatique grant SonoBot.]

4pAO1. Three-dimensional finestructure and vertical microstructure in thermohaline intrusions. Michael C. Gregg (522 Henderson Hall, Univ. Washington, 1013 NE 40th St., Seattle, WA 98105), Andrei Y. Shcherbina, Matthew H. Alford, and Ramsey R. Harcourt (Univ. Washington, Seattle, WA 98105)

Thermohaline intrusions have intrigued physical oceanographers since the first XBT section was published by Spilhaus in 1939. Characterized by vertical gradients of temperature and salinity having compensating density effects, intrusions are meters to tens of meters thick and extend laterally for hundreds of meters to many kilometers. Boundaries often have TS staircases produced by salt fingering or diffusive layering. Large diapycnal fluxes have been inferred from sections showing intrusions sloping across isopycnals, but these inferences are questionable, as isopycnal movements can give the illusion of diapycnal motion. To address these issues, in 2007 we used a depth-cycling towed body, a neutrally buoyant Lagrangian float, and microstructure profilers to map and follow intrusions in the subtropical front north of Hawaii. All intrusions were connected to the front, i.e., none was isolated lenses, some as long, thin folds, and others resembled tongues. About 10 m thick, the sheets protruded 10 km into the warm, saline side of the front, were coherent laterally for 10–30 km, and lasted at least 1 week, evolving at both inertial (23 h) and sub-inertial (~10 day) time scales. They appeared to be formed by advective deformation of the front driven by sub-mesoscale two-dimensional motions.

4pAO2. Internal waves, intrusions, and coastal zone acoustics. Timothy F. Duda, Andone C. Lavery (Dept. AOPE, MS 11, Woods Hole Oceanograph. Inst., Woods Hole, MA 02543, tduda@whoi.edu), and Jon M. Collis (Colorado School of Mines, Golden, CO 80401)

Ubiquitous linear internal waves are known to dominate fluctuations of long-range low-frequency sound in the deep ocean. In the coastal zone, however, variations in low-frequency-sound propagation caused by large episodic nonlinear internal waves are often dominant and have been studied in detail. Apart from this, sound-speed anomalies from smaller but pervasive linear internal waves can also influence propagation, as do density-compensated temperature/salinity intrusions found in areas near fronts. The physical nature of each of these two phenomena and existing models of their effects on propagation will be reviewed. The possibility of using high-frequency acoustics to remotely examine and map intrusions via double-diffusive microstructure scattering will also be examined. The anisotropy of the coastal internal wave field will be discussed, and subsequent acoustic propagation anisotropy will be examined using data from the multi-PI Shallow-Water 2006 experiment in the Mid-Atlantic Bight. [Research supported by the Office of Naval Research.]

4pAO3. Analysis of horizontal coherence during the transverse acoustic variability experiment. Peter C. Mignerey and David J. Goldstein (Acoust. Div. 7120, Naval Res. Lab., Washington, DC 20375)

The transverse acoustic variability experiment took place in the northern limit of the East China Sea in 65–80 m of water. 300-Hz and 500-Hz cw acoustic signals were transmitted over distances of 33 and 20 km to a broadside HLA where they were received at 22–27 dB SNR. Fourteen estimates of transverse mutual-coherence functions show high correlation with scale lengths on the order of 1000–1700 m. A towed CTD chain provided simultaneous measurements of the sound-speed fluctuation spectrum due to internal waves in an effort to determine whether the observed shallow-water coherence is understandable within the framework of a normal-mode formulation of path-integral theory. An important property of the mutual-coherence function is its behavior at small hydrophone separations. Here the phase-structure function is expected to follow a power law. Measured logarithmic phase-structure function have slopes that vary between 0.6 and 1.1, which disagree with path-integral solutions that predict slope 2. The discrepancy between observation and data is not currently understood. [Work supported by the Office of Naval Research.]

2:00

4pAO4. Performance of the transverse acoustic variability experiment horizontal line array. David J. Goldstein and Peter C. Mignerey (Acoust. Div. Naval Res. Lab., 4555 Overlook Ave. SW, Washington, DC 20375, david.goldstein@nrl.navy.mil)

The transverse acoustic variability experiment was designed to study the impact of shallow-water environmental fluctuations on acoustic coherence in the horizontal plane, transverse to the direction of propagation. The experiment was conducted during August 2008 in the East China Sea. A criti-

cal component to the success of the experiment was a two-segment 96-channel horizontal line array, moored on the sea floor at an approximate depth of 80 m. An analysis of the performance of this array is presented, including pulse arrival time statistics, beam patterns, gains, and signal-to-noise ratio. Methods used to determine the relative positions of array hydrophones are also discussed. [Work supported by the Office of Naval Research. We thank the staff at KORDI and the crews aboard the R/V Eardo and Sunjin for their assistance and bountiful hospitality.]

2:15

4pAO5. Mode-2 internal waves impact on acoustic signal properties. Marshall Orr (Acoust. Div., The Naval Res. Lab., 4555 Overlook Ave., SW, Washington, DC 20375)

The properties of mode-2 internal waves repeatedly observed on the New Jersey Shelf (USA) with high-frequency acoustic flow visualization systems will be overviewed. The impact of the mode-2 internal waves on the range/depth distribution of acoustic signal properties will be discussed.

2:30

4pAO6. Effects of anisotropic internal waves on acoustic propagation within the East China Sea. Chad M. Smith (cms561@psu.edu) and David L. Bradley (Graduate Program in Acoust., Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804-0030)

Using environmental and acoustic data from the TAVEX 2008 Korean /U.S. cooperative experiment, the anisotropic spatial properties of internal waves recorded during CTD tows and their connection to temporal variations in recorded acoustic data from a horizontal line array will be discussed. Structure of internal waves, wave travel speed and trajectory, as well as computational modeling of the acoustic field and its comparison with recorded data will also be covered. [Work supported by the Office of Naval Research Contract No. N00014-08-1-0455.]

2:45

4pAO7. Adjoint study of water column variability and propagation in the transverse acoustic variability experiment (TAVEX 2008). Michelle M. Kingsland and David L. Bradley (Appl. Res. Lab., Graduate Program in Acoust., Penn State Univ., 201 Appl. Sci. Bldg., University Park, PA 16801, mbm224@psu.edu)

Internal wave and other water column activity in the conductivity, temperature, and depth (CTD) data collected in the East China Sea as a part of TAVEX 2008 are used as a basis for analyzing acoustic propagation at 500 Hz between a fixed source and fixed horizontal line array placed on the seafloor. Because the CTD data were not taken coincident with the acoustic propagation path (in general), adjoint modeling methods will be used to study acoustic data and prediction misfit. Usefulness of the adjoint method for these experimental conditions will be discussed. [Work supported by ONR.]

3:00

4pAO8. Periodicity of intensity fluctuations in shallow water in the presence of solitary internal waves. T. C. Yang (Naval Res. Lab., Washington, DC 20375, tc.yang@nrl.navy.mil)

This paper investigates the intensity variation with time of a broadband signal in the presence of moving solitary internal waves. The autocorrelation of the received impulse responses summed over a vertical line array of receivers (the so called Q function) is measured from the SWARM95 data using broadband pulses received on the NRL array at a range ~42 km from the source. The signals are m-sequences centered at 400 Hz with a bandwidth of 100 Hz. The peak of the Q function shows a periodicity of 0.042 cycles/min, with a value changing with time depending on the position of the internal wave packets. Coupled mode equation is used to calculate mode coupling induced by the solitary internal waves and explain the observed periodicity of the intensity fluctuations. The results suggest that the positions and some parameters of the solitary waves could be remotely estimated from underwater sensors. [Work supported by the Office of Naval Research.]

4pAO9. Observed space-time scales of internal waves and finescale intrusions on the New Jersey Shelf and their likely acoustic implications. John Colosi (Naval Postgrad. School, Monterey, CA 93943), Tim Duda, Ying-Tsong Lin, Jim Lynch, and Arthur Newhall (Woods Hole Oceanograph. Inst., Woods Hole MA 02543)

It has been known for some time that ocean density surfaces possess multi-scale variations in temperature (T) and salinity (S), termed spice (hot and salty, cold and fresh) by Munk in 1981. Compensating T and S variations along a surface of constant density have reinforcing sound speed anomalies and thus have important acoustic implications. With the advent of new technologies to observe small scale, rapidly changing ocean thermohaline structure, spice variations, and their acoustic effects are just starting to be understood. Better known are the impacts of internal waves which vertically advect ocean sound speed structure. This talk will present analysis of moored T and S observations on the New Jersey Shelf region during the SW06 experiment in which the sound speed effects of internal waves and spice can be approximately separated. These results will be contrasted with similar measurements made in the deep waters of the Philippine Sea. Using recent results from coupled mode theory, some discussion of the acoustic implications of the internal wave and spice structure will be presented. In particular, the phase randomizing effects of linear internal waves and spice will diminish the mean acoustical influence of intense but localized nonlinear internal waves.

3:50

4pAO10. Characterizing water column variability and its impact on underwater acoustic propagation. Kyle M. Becker (Appl. Res. Lab., Penn State Univ., P.O. Box 30, State College, PA 16804-0030) and Megan S. Ballard (Appl. Res. Labs., Univ. Texas at Austin, 10000 Burnet Rd., Austin, TX 78758)

During the Shallow Water Experiment 2006 (SW06), a low-frequency acoustic source was towed out and back along radials from a receiver array located at the origin. Measurements were made along three radials, separated by 45 deg, with each track repeatedly traversed over a period of 6–10 h. Concurrently with the acoustic measurements, the water column sound speed field was estimated both along the source track and at the receiver location. The objective was to fully characterize the environment in the water column over the acoustic path during transmissions. In this way, variability in the acoustic field measured along the repeated tracks could be associated with variability in the water column. The variability in the water column, measured independently at the source and at the receiver, is

examined and related to variability observed in the acoustic fields. Spatial and temporal variability is characterized on transect-to-transect, radial-to-radial, and day-to-day basis. Over 3 days, variability in the water column could be attributed to thermohaline intrusions, linear and non-linear internal waves, as well as mesoscale variability. This talk will focus on the requirements for characterizing these features and understanding their impact on acoustic propagation and prediction. [Work supported by ONR.]

4:10

4pAO11. Reverberation clutter from combined internal wave refraction and bottom backscatter. Dajun Tang and Frank Henyey (Appl. Phys. Lab., Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, djtang@apl.washington.edu)

A hypothesis is proposed that one mechanism for clutter observed in shallow water reverberation measurements is due to the combined effect of forward scatter and subsequent backscatter. The forward scatter refracts part of the sound from low grazing angle to high grazing angle, then being backscattered by bottom roughness. The refracted sound impinges onto the bottom at higher grazing angle, resulting in higher backscatter because of elevated bottom scattering cross section as compared to that at lower grazing angles. The resultant reverberation will stand out as a target-like clutter. An example is presented as a non-linear internal wave propagates in a shallow water channel, resembling conditions found on the New Jersey Shelf. The effect on reverberation of the internal wave as clutter is investigated using a time-domain numerical model. The model uses parabolic equation for the two-way propagation and first order perturbation approximation for bottom backscatter. [Work supported by ONR.]

4:25

4pAO12. Acoustic propagation effects from saline intrusions across the shelfbreak front off the New Jersey coast in summer. Arthur E. Newhall, Ying-Tsong Lin, James F. Lynch, Timothy F. Duda, Glen G. Gawarkiewicz (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), and John A. Colosi (Naval Postgrad. School, Monterey, CA 93943)

In the summer of 2006, the multi-task, interdisciplinary Shallow Water 2006 (SW06) experiment was conducted on the continental shelf and shelfbreak regions off the New Jersey coast. During SW06 the shelfbreak front variability was clearly characterized by combined measurements of conductivity-temperature-depth casts, long-period (5 weeks) and quick sampling oceanographic sensor moorings, and surveys with a Scanfish, a ship-towed undulating vehicle carrying multiple sensors. This data set indicates that the slope water penetrated onto the shelf via neutrally buoyant intrusions. Due to the higher temperature and salinity, these frontal intrusions, seen as thin layers near the seasonal pycnocline, increased the local sound speed and accounted for variations in acoustic propagation. In this paper, we will use field data and PE numerical acoustic simulations to study the impact of these frontal intrusions. Specific examples on the creation of vertical acoustic double ducting and horizontal ducting formed by these intrusions and their modulation by linear internal waves are discussed. [Work is supported by the Office of Naval Research.]

4:40

4pAO13. Propagation of low-frequency sound through densely sampled internal waves. Megan S. Ballard (Appl. Res. Labs., Univ. of Texas, 10000 Burnet Rd., Austin, TX 78758, meganb@arlut.utexas.edu) and Kyle M. Becker (Appl. Res. Lab., Penn State, State College, PA 16804)

It is well known that nonlinear internal gravity waves can have a significant effect on acoustic propagation. In particular, horizontal refraction and ducting of sound can occur when the acoustic propagation path is aligned with fronts of internal waves. Additionally, more complicated effects are associated with internal waves that are curved and/or truncated. In this talk, observations of internal waves measured on the New Jersey shelf area of the north Atlantic and their effects on the acoustic field are presented. During the experiment, a low-frequency source broadcasting continuous tone was towed repeatedly out and back along radials with respect to a VLA. The ship's track was oriented parallel to the shelf break so that the acoustic propagation path was roughly aligned with internal waves propagating up the shelf. Internal waves were measured at the location of the receivers by temperature sensors on the VLA, at the location of the source by a towed CTD chain, as well as by a cluster of 16 environmental moorings located adjacent to experiment site. The high-spatial sampling of the environment allows for identification of range-varying features of internal waves.

4:55

4pAO14. Horizontal reflection of a low-frequency sound signal from a moving nonlinear internal wave front. M. Badiey (College of Earth, Ocean, and Environment, Univ. of Delaware, Newark, DE 19716), J. F. Lynch, Y.-T. Lin (Woods Hole Oceanograph. Inst., Woods Hole, MA 02543), and B. G. Katsnelson (Voronezh Univ., Voronezh 394006, Russia)

Simultaneous measurements of acoustical and internal waves are reported while an internal wave approaches an acoustic track during the SW06 experiment. The incoming internal wave packet acts as a moving layer reflecting and refracting acoustic waves in the horizontal plane. The mechanism of this interaction is shown in received acoustic data on a vertical hydrophone array using a modal approach. It is shown that the wave front of internal waves behaves as selective filter, depending on the mode number and frequency of the broadband signal. In other words the reflection coefficient in horizontal plane depends on mode number and frequency. Experimental data analysis shows good agreement with the theory. [Work supported by ONR 321OA.]

5:10

4pAO15. Acoustic wave propagation and scattering in turbulence and internal waves. Tokuo Yamamoto N (Div. of Appled Marine Phys., RSMAS, Univ. of Miami, Miami, FL 33149)

Acoustic wave propagation and scattering in turbulence and internal waves in Kanmon Strait and the outer New Jersey shelf are measured in a bistatic source-receiver configuration at frequency 5500 Hz. While internal wave dominates on the open New Jersey shelf, the turbulence dominates in the Kanmon Strait channel. Initially strong internal wave scattering is reduced rapidly due to strong mixing in the shallow strait. On the flat and open continental shelf, internal wave and warm water intrusion dominate while turbulence is near absent. The parabolic equation code predictions agree with data very well. The bistatic scattering data are processed for bistatic angles and the effects of Doppler shift on the mean flow and the broadening of peek spectra on the turbulent fluctuations. The mean flow and turbulence fluctuation obtained from the Doppler shift agreed with the two parameters obtained by the reciprocal acoustic transmission.

5:25

4pAO16. Using ocean ambient noise cross-correlations for noise-based acoustic tomography. Charlotte Leroy, Karim G. Sabra (School of Mech. Eng., Georgia Inst. of Technol., 771 Ferst Dr. NW, Atlanta, GA 30332-0405), Philippe Roux (LGIT, Grenoble, France), William Kuperman, William Hodgkiss, and Shane Walker (UC San Diego, La Jolla, CA)

Recent theoretical and experimental studies have demonstrated that an estimate of the Green's function between two hydrophones can be extracted passively from the cross-correlation of ambient noise recorded at these two points. Hence monitoring the temporal evolution of these estimated Green's functions can provide a means for noise-based acoustic tomography using a distributed sensor network. However, obtaining unbiased Green's function estimates requires a sufficiently spatially and temporally diffuse ambient noise field. Broadband ambient noise ([200 Hz–20 kHz]) was recorded continuously for 3 days during the SWAMSI09 experiment (next to Panama City, FL) using two moored vertical line arrays (VLAs) spanning the 13-m water column and separated by 150 m. The feasibility of noise-based acous-

tic tomography was assessed in this dynamic coastal environment over the whole recording period. Furthermore, coherent array processing of the computed ocean noise cross-correlations between all pairwise combinations of hydrophones was used to separate acoustic variations between the VLAs caused by genuine environmental fluctuations–such as internal waves–from the apparent variations in the same coherent arrivals caused when the ambient noise field becomes strongly directional, e.g., due to an isolated ship passing in the vicinity of the VLAs.

4pBB1. Cavitation and vaporization threshold of perfluorocarbon droplets. Kelly Schad and Kullervo Hynynen (Dept. Medical Biophys., Univ. Toronto, 2075 Bayview Ave., Toronto, ON, Canada)

Focused ultrasound therapy can be enhanced with microbubbles by thermal and cavitation effects. However, localization of treatment becomes difficult as bioeffects can occur outside of the target region. Spatial control of gas bubbles can be achieved with acoustic vaporization of perfluorocarbon droplets. This study was undertaken to determine the acoustic parameters for bubble production by droplet vaporization and how it depends on the acoustic conditions and droplet physical parameters. Droplets of varying sizes were sonicated *in vitro* with a focused transducer and varying frequencies and exposures. Simultaneous measurements of the vaporization and inertial cavitation thresholds were performed. The results show that droplets cannot be vaporized at low frequency without inertial cavitation occurring. However, the vaporization threshold decreased with increasing frequency, exposure, and droplet size. In summary, we have demonstrated that droplet vaporization is feasible for clinically relevant sized droplets and acoustic exposures.

1:20

4pBB2. Applications of acoustic droplet vaporization in diagnostic and therapeutic ultrasound. Mario L. Fabiilli, Oliver D. Kripfgans, Man Zhang, Kevin J. Haworth, Andrea H. Lo, Paul L. Carson, and J. Brian Fowlkes (Dept. of Radiology, Univ. of Michigan, 3225 Med. Sci. I, 1301 Catherine St., Ann Arbor, MI 48109, mfabiill@umich.edu)

Micron- and nano-sized colloids are being studied in diagnostic and therapeutic applications of ultrasound (US). Unlike clinically utilized microbubbles, emulsions possess unique physiochemical properties that could translate into distinct, clinical benefits beyond conventional contrast agents. Droplets, composed of a superheated liquid, can be phase transitioned into bubbles using US, a process known as acoustic droplet vaporization (ADV). Droplets, transpulmonary in size, transition into bubbles upon ADV and can reach diameters that occlude capillaries and arrest blood flow in the vascular bed. Examples of ADV in diagnostic and therapeutic applications will be presented. First, ADV has been used in phase aberration correction in transcranial US imaging. Second, ADV-generated microbubbles can reduce and occlude renal perfusion *in vivo*. Third, the effects of thermal therapy using high-intensity focused ultrasound (HIFU) has been enhanced and controlled more effectively using ADV. Fourth, ADV has been utilized as a release mechanism for therapeutic agents that are incorporated into the emulsion. In all applications, the physiochemical properties of the droplets coupled with the spatial and temporal control afforded by ADV-generated microbubbles are crucial to the success of each ADV development. [This work was supported in part by NIH Grant 5R01EB000281.]

4pBB3. Dodecaperfluoropentane emulsion for oxygen delivery. Evan Unger, Terry Matsunaga, Russel Witte, Ragnar Olafsson (Dept. of Radiology, Univ. of Arizona, 1501 N. Campbell Ave., Tucson, AZ 85724), Arthur Kerschen, Melissa Dolezal, and Jenny Johnson (NuvOx Pharma, LLC, 1635 E. 18th St., Tucson, AZ 85719)

Dodecaperfluoropentane emulsion (DDFPe) was prepared from DDFP and surfactant PEG-Telomer-B and studied for particle sizing, storage stability, acoustically *in vitro* at 37 °C, and for oxygen transport in porcine model of hemorrhagic shock and as radiation sensitizer in murine model of tumor hypoxia. DDFPe had mean particle size of about 200 nm stable on storage at room temperature for over 2 years. Compared to microbubbles of perfluorobutane (PFB), more than 100-fold higher DDFPe was needed for comparable acoustic backscatter compared to PFB. Acoustic reflectivity increased with higher MI ultrasound but was still much less for DDFPe than for PFB. DDFPe was highly effective oxygen therapeutic in models of hemorrhagic shock and tumor hypoxia. A dose of as little as 0.6 cc/kg of DDFPe was sufficient to prevent death from hemorrhagic shock. In hypoxic tumors a similar dose reversed tumor hypoxia and restored sensitivity to radiation therapy. No ultrasound was used in these experiments for *in vivo* oxygen delivery. Compared to liquid perfluorocarbons which have been studied as oxygen therapeutics, DDFPe uses a much lower dose, about 1%. DDFPe is a promising oxygen transport therapeutic. Additional work is underway to try to develop DDFPe for this application.

2:00

4pBB4. Phase change nanodroplet for sensitizer for thermal and cavitational effects of ultrasound. Ken-ichi Kawabata, Rei Asami, Hideki Yoshikawa, Takashi Azuma (Life Sci. Res. Ctr., Central Res. Lab., Hitachi, Ltd., Higashi-Koigakubo, Kokubunji, Tokyo 185-8601, Japan, kenichi.kawabata.ap@hitachi.com), and Shin-ichiro Umemura (Tohoku Univ., Aramaki, Aoba-ku, Sendai 980-8579, Japan)

Although HIFU therapy is very low invasive method for tumor treatment, its time inefficiency and the absence of focus detecting mechanism of current systems limit the number of applicable cases. For an improved HIFU tumor treatment system, we propose to utilize a non-echogenic liquid nanodroplet which turns into highly echogenic microbubbles upon non-therapeutic ultrasound pulses. Such a nanodroplet would give echographic information on the focus of HIFU when exposed to the pulse and accelerate HIFU treatment by enhancing the ultrasonic energy deposition as microbubble. As such a nanoparticle system, we developed a phase change nanodroplet (PCND) which consists of superheated perfluorocarbon nanodroplet coated with PEGylated phospholipids. Significance of PCND to enhance ultrasonically induced therapeutic effects was investigated on mice, rats, and rabbits. At frequencies of 2 and 3 MHz, it was found that the presence of PCND (and generated microbubbbles) halved the intensity threshold for inducing thermal damage. At frequency around 1 MHz, it was found that the PCND halved the threshold for inducing damage in murine tumor, and the damage was induced both by thermal and cavitational effects of ultrasound. [This work was in part entrusted by the New Energy and Industrial Technology Development Organization, Japan.]

4pBB5. Relationship between cavitation, rapid loss of echogenicity, and drug release from echogenic liposomes. Kirthi Radhakrishnan (Dept. of Biomedical Engg., Univ. of Cincinnati, 231 Albert Sabin Way, MSB 6155, Cincinnati, OH 45267, radhakki@mail.uc.edu), Jonathan A. Kopechek, Kevin J. Haworth (Univ. of Cincinnati, Cincinnati, OH), Shaoling Huang, David D. McPherson (Univ. of Texas Health Sci. Ctr., Houston, TX), and Christy K. Holland (Univ. of Cincinnati, Cincinnati, OH)

Echogenic liposomes (ELIPs), encapsulating air and drug, are being developed for use as vesicles for ultrasound-mediated drug release. Both calcein and a thrombolytic drug have been encapsulated in ELIP and released with 6-MHz color Doppler ultrasound in an *in vitro* flow system. To elucidate the role of stable or inertial cavitation in loss of echogenicity and drug release, ELIPs were insonified with 6-MHz pulsed Doppler ultrasound within the same flow system. A 10-MHz focused passive cavitation detector (PCD) was placed confocally with the pulsed Doppler sample volume. B-mode images and PCD signals were recorded during ELIP infusion (5 ml/min) and exposed to pulsed Doppler over a range of peak rarefactional pressure amplitudes (0–1.4 MPa) at two pulse repetition frequencies (1250 and 2500 Hz). The mean digital intensities were calculated on each image within two regions of interest placed upstream and downstream of the Doppler sample volume. The thresholds for rapid loss of echogenicity were ascertained from six B-mode images acquired over 30 s. These thresholds were compared to stable and inertial cavitation thresholds. The implications of these data on the mechanism of rapid liberation of gas and drug release will be discussed. [Work supported by the NIH R01 HL059586 and NIH R01 HL7400]

4pBB6. Bubble evolution in acoustic droplet vaporization. Adnan Qamar, Z. Z. Wong (Dept. of Biomedical Eng., Univ. of Michigan, 1101 Beal Ave., Ann Arbor, MI 48109), J. Brian Fowlkes, and Joseph L. Bull (Univ. of Michigan, Ann Arbor, MI 48109, joebull@umich.edu)

We present an overview of our recent theoretical and computational work on acoustic droplet vaporization within a confined tube and compare to our experimental data. This work is motivated by a developmental gas embolotherapy technique that involves injecting superheated transvascular liquid droplets and subsequently vaporizing the droplets with ultrasound to selectively form vascular microbubbles. The theoretical model describes the rapid phase transition from a superheated dodecafluoropentane (DDFP) droplet to the vapor phase via nucleation within the DDFP droplet. The theoretical results are compared to results from our computational models and high-speed camera experiments, and close agreement between the experimental bubble evolution and the prediction of the model is noted. Even though we consider bubbles that are small compared to the tube diameter, it is demonstrated that the tube affects the bubble evolution and resulting flow fields. 4pBB7. Ultrasound-mediated tumor chemotherapy with drug-loaded phase-shift nanoemulsions. Natalya Rapoport, Kweon-Ho Nam, Douglas A. Christensen, and Anne M. Kennedy (Dept. of Bioengineering, Univ. of Utah, 72 S. Central Campus Dr., Rm. 2646, Salt Lake City, UT 84112, natasha.rapoport@utah.edu)

This paper describes droplet-to-bubble transition in block copolymer stabilized perfluoropentane nanoemulsions used for ultrasound-mediated tumor chemotherapy. Three physical factors that trigger droplet-to-bubble transition in liquid emulsions and gels have been evaluated, namely, heat, ultrasound, and injections through fine-gauge needles. Among those listed, ultrasound irradiation was found the most efficient factor. Tumor accumulation of nanodroplets after systemic injections to tumor bearing mice was confirmed by ultrasound imaging. Efficient ultrasound-triggered drug release from tumor-accumulated nanodroplets was confirmed by dramatic regression of ovarian, breast, and orthotopic pancreatic tumors treated by systemic injections of drug-loaded nanoemulsions combined with tumor-directed therapeutic ultrasound. No therapeutic effect from the nanodroplet /ultrasound combination was observed without the drug, indicating that therapeutic effect was caused by the ultrasound-enhanced chemotherapeutic action of the tumor-targeted drug, rather than the mechanical or thermal action of ultrasound itself. The mechanism of drug release in the process ultrasonically activated droplet-to-bubble conversion is discussed. [The work has been supported by the NIH R01 EB1033 grant to N.R.]

4pBB8. Passive mapping of cavitation activity for monitoring of drug delivery. Costas D. Arvanitis, Miklos Gyongy, Miriam Bazan-Peregrino, Bassel Rifai (Dept. of Eng. Sci., Inst. of Biomedical Eng., Univ. of Oxford, Old Rd. Campus Res. Bldg., Headington, Oxford OX3 7DQ, United Kingdom), Leonard W. Seymour, and Constantin C. Coussios (Univ. of Oxford, Oxford OX3 7DQ, United Kingdom)

Acoustic cavitation has been recently shown to have tremendous potential as a mechanism for releasing and enabling improved uptake and biodistribution of therapeutic agents for the pharmacological treatment of cancer, cardiovascular, and neurodengenerative diseases. Passive cavitation mapping makes it possible to localize, characterize, and quantify cavitation activity by detecting the acoustic emissions produced by cavitating bubbles on an array of receivers, which are then back-propagated to form a cavitation-selective image with high spatio-temporal accuracy. In the present study, a 64-element diagnostic linear array was used to construct passive cavitation maps during pulsed HIFU exposure of a narrow channel transporting fluorescent dextran nanoparticles through a biocompatible porous hydrogel in the presence or absence of ultrasound contrast agents. Spectral analysis of the resulting acoustic emissions confirmed that different cavitation regimes were successfully instigated over the HIFU parameter range that was investigated. Superposition of cavitation selective images over the treatment course was used to construct maps of cavitation activity and dose as a function of location for treatment assessment and was found to correlate well with dextran extravasation. It is concluded that passive mapping of cavitation activity shows great promise for assessment and real-time monitoring of cavitation based drug delivery.

4pBB9. Combined ultrasonic and video-microscopic characterization of ultrasound contrast agents in a flow phantom. Parag V. Chitnis, Paul Lee, Jonathan Mamou (F. L. Lizzi Ctr. for Biomedical Eng., Riverside Res. Inst., 156 William St., 9th Fl., New York, NY 10038), Paul A. Dayton (UNC-NCSU, Chapel Hill, NC 27599), and Jeffrey A. Ketterling (Riverside Res. Inst., New York, NY 10038)

A high-frequency ultrasound pulse-echo system has been combined with a video microscope system for characterizing the response of two types of ultrasound contrast agents (UCAs). A focused-flow phantom was constructed using a glass micropipette (inner diameter 30 μm) mounted vertically in a test tank. The UCA solution was pumped using a syringe pump at a constant flow rate of 40 μl/min. A high-speed CCD camera operating at 10 000 frames/s with an exposure time of 4 μs was used to capture backlit images of individual UCAs. The camera was equipped with a 100× water-immersion objective with a field-of-view of 70×70 μm. A 40-MHz, focused transducer was aligned at the micropipette and used in pulse-echo mode to sonicate individual UCAs and receive the corresponding radio-frequency backscatter signals. The UCAs were subjected to ultrasound at varying incident-pressure levels (0.8–3 MPa) and pulse durations (10, 15, and 20 cycles). Echo signals from individual UCAs were windowed and spectra were calculated. The magnitude of the fundamental (40-MHz) backscatter was observed to increase monotonically with UCA diameter. Correlation between the magnitude of the sub-harmonic (20-MHz) response of UCAs and their size was investigated. [Work supported by NIH EB006372.]

4:15

4pBB10. Dynamic response of bubbles within a compliant tube. Neo Jang, Aaron Zakrzewski, Christopher Jensen, Robert Halm (Dept. of Mech. Eng., Univ. of Rochester, Rochester, NY 14627), and Sheryl M. Gracewski (Univ. of Rochester, Rochester, NY 14627, grace@me.rochester.edu)

The dynamic response of bubbles in a liquid that are partially constrained by a surrounding tube or channel is important in a variety of fields, including diagnostic and therapeutic biomedical ultrasound and for microfluidic devices. In this study, numerical simulations, lumped parameter models, and experiments are used to investigate the effects of a surrounding tube on a bubble's response to acoustic excitation. In particular, a coupled boundary element and finite element model and COMSOL MULTIPHYSICS models have been developed and used to investigate the nonlinear interactions of this three-phase system. Simulation results were compared to experimental measurements obtained using a scaled balloon model. The effects of tube parameters and bubble interactions on a bubble's natural frequency important for proposed clinical applications of ultrasound are investigated. Resonance frequencies agree well with one-dimensional lumped parameter model predictions for a bubble well within a rigid tube, but deviate for a bubble near the tube end. Simulations also predict bubble translation along the tube axis and the aspherical oscillations and induced tube stresses at higher amplitudes. [Work supported by NIH and NSF CMMI.]

4:30

4pBB11. Using optically activated nanoparticles to promote controlled lesion formation from high-intensity focused ultrasound exposures. James R. McLaughlan (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215, jmcl@bu.edu), Todd W. Murray (Univ. of Colorado, Boulder, Boulder, CO 80309), and Ronald A. Roy (Boston Univ., Boston, MA 02215)

The absorption of laser light in tissue can be enhanced through the use of gold nanoparticles. This enhancement can improve the signal-to-noise ratio of the thermoelastic emissions used for photoacoustic tomography (PAT) and photoacoustic microscopy (PAM). The ability to functionalize nanoparticles allows them to be used for the selective targeting and destruction of cancer cells through the formation of vapor bubbles. However, the laser fluence required to generate vapor bubbles from nanoparticles typically exceeds the maximum permissible exposure for *in-vivo* applications. In a previous study, it was found that the combination of laser light with high-intensity focused ultrasound (HIFU) significantly reduced the fluence and pressure thresholds for bubble formation. The presence of bubbles, or specifically inertial cavitation, in HIFU exposures is believed to locally enhance the heating, resulting in effective tissue ablation at lower HIFU intensities. Nanoparticle-doped tissue phantoms (polyacrylamide gels containing bovine serum albumin) were exposed to a continuous wave (5–30-s) 1.1-MHz HIFU field with and without pulsed laser light (532 nm, 1–10 Hz) to assess the potential for HIFU lesion enhancement from the controlled and repeatable generation of inertial cavitation. [Work supported by the Gordon Center for Subsurface Sensing and Imaging Systems, NSF ERC Award No. EEC-9986821.]

4:45

4pBB12. Effects of vaporized phase-shift nanoemulsion on high-intensity focused ultrasound-mediated heating and lesion formation in gel phantom. Peng Zhang and Tyrone Porter (Dept. of Mech. Eng., Boston Univ., 110 Cummington St, Boston, MA 02215, tmp@bu.edu)

In this study, we demonstrate the feasibility of using a phase-shift nanoemulsion (PSNE) as nuclei for bubble-enhanced heating and lesion formation during high-intensity focused ultrasound (HIFU) thermal ablation. In our experiments, different concentrations of PSNE (5%–15%) uniformly distributed throughout gel phantoms made from acrylamide and albumin were sonicated with a 1.1 MHz HIFU transducer. The PNSE at the transducer focus were first vaporized into bubbles and then acoustically driven with continuous wave HIFU at different amplitudes. Bubble-enhanced heating resulted in albumin denaturation and lesion formation. HIFU-mediated heating was conducted with and without vaporized PSNE, and the lesion size and location relative to the transducer focus were measured after HIFU exposure. In the presence of vaporized PSNE, lesions were formed more rapidly and reached a larger volume compared with no vaporized PSNE. We also noted that lesions formed due to bubble-enhanced heating were more often prefocal due to backscattering from the bubble cloud. Our results show that these effects were more pronounced at higher PSNE concentrations. Finally, a comparison between the effects of pulsed and cw exposure on cavitation activity and lesion shape was investigated.

4pBB13. Observations of microbubble translation near vessel walls. Hong Chen, Wayne Kreider, Andrew A. Brayman, Michael R. Bailey, and Thomas J. Matula (Ctr. for Industrial and Medical Ultrasound, Appl. Phys. Lab., Univ. of Washington, Seattle, WA)

To exploit the potential clinical applications of ultrasound contrast agents, it is important to understand the basic physics of bubble-vessel interactions. In this work, high-speed micrography was used to investigate

the dynamics of microbubbles inside vessels from *ex vivo* rat mesentery under the exposure of a single ultrasound pulse. The study included arterioles and venules. The ultrasound pulses were about 2 μs long with a center frequency of 1 MHz and peak negative pressures between 1 and 7 MPa. High-speed photographs reveal that interactions between microbubbles and vessels caused bubbles to move away from nearby vessel walls. The motion depended upon the standoff distance between the bubble and the nearest vessel wall, where a normalized standoff γ can be defined as the ratio of the standoff distance to the maximum bubble radius. For $\gamma < 1$, obvious bubble movement away from the nearby vessel wall was observed during collapse. At $\gamma = 0.3$, a bubble inside a venule was observed to translate over 16 μm during 1.5 μs, achieving velocities over 10 m/s. Bubble translation away from the vessel wall may be caused by the rebound of the vessel wall that was distended during bubble expansion. [Work supported by NIH Grants EB00350, AR053652, DK43881, and DK070618.]

4pBB14. Bubble-boundary interactions relevant to medical ultrasound. Wayne Kreider, Hong Chen, Michael R. Bailey, Andrew A. Brayman, and Thomas J. Matula (Ctr. for Industrial and Medical Ultrasound, APL, Univ. of Washington, 1013 NE 40th St., Seattle, WA 98105, wkreider@u.washington.edu)

Because bubble-vessel interactions have been implicated in vascular damage associated with medical ultrasound, such interactions remain a topic of interest. Recent photographs have shown that bubbles inertially oscillating in blood vessels tend to cause a vessel invagination (displacement toward the lumen) that exceeds the corresponding distention. To gain an understanding of such interactions, a Bernoulli-type equation was derived for conditions in which flow near a bubble is confined by a nearby planar boundary. This formulation assumes incompressible, inviscid flow within a locally cylindrical geometry between the bubble and boundary. Using spherical, radial bubble dynamics inferred from the aforementioned photographs, pressures generated by the bubble at the boundary were calculated. The assumed sphericity was based on observations of bubble collapses and jetting behaviors. In addition, the form of the equation was compared to that for unconfined flow around a spherical bubble. The main conclusion is that tensile stresses corresponding to vessel invagination will be asymmetrically larger than compressive stresses associated with vessel distention as the amplitude of oscillation increases and the distance between the bubble and boundary decreases. As such, these tensile stresses may be an important mechanism for vascular bioeffects. [Work supported by NIH Grants EB00350, DK43881, and DK070618.]

4pBB15. PiggyBac transposon-based gene delivery with cationic ultrasound contrast agents into SCID and CD-1 mice. Pavlos Anastasiadis (Dept. of Mech. Eng., Univ. of Hawaii at Manoa, 2540 Dole St., Holmes Hall 302, Honolulu, HI 96822, pavlos@hawaii.edu), Terry O. Matsunaga (Univ. of Arizona, Tucson, AZ 85724), Stefan Moisyadi, and John S. Allen (Univ. of Hawaii at Manoa, Honolulu, HI 96822)

Efficient integration of a functional gene, along with suitable transcriptional regulatory elements, poses a fundamental difficulty for the application of successful gene therapy. Though inducible gene expression after somatic cell gene transfer has been achieved by employing viral vectors, issues associated with cargo capacity, host immune response, the risk of insertional mutagenesis, and the requirement for separate viruses are limiting factors. Several researchers have used transposon-based approaches for gene delivery, and the piggyBac transposon system has recently been shown to be effective in human cell lines and for the transgenesis in mice. The use of engineering helper-independent plasmids with the mouse codon-biased piggyBac transposon (mPB) gene in combination with cationic ultrasound contrast agents (UCAs) is investigated for a range of insonification parameters. The plasmid pmGENIE-3 deactivates the mPB gene after insertion of the transposon, eliminating potentially negative effects which may occur from the persistence of an active piggyBac gene post-transposition.

5:45

4pBB16. Quantification of endothelial cell transfection as a function of permeability with targeted ultrasound contrast agents. Pavlos Anastasiadis (pavlos@hawaii.edu) and John S. Allen (Dept. of Mech. Eng., Univ. of Hawaii at Manoa, 2540 Dole St., Holmes Hall 302, Honolulu, HI 96822)

Gene and drug delivery have shown to be enhanced by the localized destruction of ultrasound contrast agents (UCAs). Moreover, deoxyribonucleic acid (DNA) is rapidly degraded by serum DNases following its injection into the bloodstream, and several studies have shown that DNA may be protected from such DNases if it is conjugated onto the shell of UCAs. The optimal acoustic parameters for transfection and delivery are not well understood. Likewise, the real-time monitoring of the related cell membrane permeability changes has only been recently attempted for these applications. This study evaluates the endothelial cell-to-cell and cell-to-substrate gaps with the electric cell-substrate impedance sensing system (ECIS, Applied BioPhysics, Troy, NY). ECIS can detect in real-time the nanometer order changes of cell-to-cell and cell-to-substrate distances separately. Targeted UCAs were conjugated with plasmid vectors and subject to ultrasound insonification, while continuous measurements of the electrical resistance across the endothelial monolayers were conducted in real-time for the determination of membrane permeability changes. The achieved transfection rate is investigated over a range of acoustic parameters. 4pEA1. Optimal spherical array modal beamformer in the presence of array errors. Haohai Sun (Dept. of Electrons and Telecommunications, Norwegian Univ. of Sci. and Tech., 7491 Trondheim, Norway, haohai.sun@iet.ntnu.no), Shefeng Yan (Chinese Acad. of Sci., 100190 Beijing, China), and U. Peter Svensson (Norwegian Univ. of Sci. and Tech., 7491 Trondheim, Norway)

Spherical array modal beamforming has become an attractive technique, since three-dimensional beampatten synthesis is more flexible than other array geometries, and the modal beamforming can be performed using the elegant spherical harmonics framework. However, the performance of a modal beamformer in practical situations is known to degrade in the presence of array errors caused by non-perfect spatial sampling, sensor sensitivity and phase variations, and sensor self-noise. Although the white noise gain constraint has been widely used to control the robustness of modal beamformers, it is not clear how to properly choose the constrained parameter set based on the known range of errors. In this paper, a worst-case performance optimization approach is formulated for the spherical array modal beamformer to improve its robustness against the above mentioned errors occurring in practice; thus the optimum performance can be obtained based on the known maximum level of errors. The robust optimal modal beamforming problem is reformulated as a convex optimization within the spherical harmonics framework, which can be efficiently solved by using second order cone programming.

1:25

4pEA2. Analysis of the high-frequency extension for spherical eigenbeamforming microphone arrays. Jens Meyer and Gary W. Elko (mh acoustics LLC, 25A Summit Ave., Summit, NJ 07901)

The em32 Eigenmike® spherical microphone array is constructed with 32 omnidirectional pressure microphones mounted on the surface of a 8.4-cm rigid spherical baffle. Beamforming is accomplished by the spherical harmonic decomposition eigenbeamformer and modal-beamformer concept. Due to the array size, geometry, and average element spacing, this approach yields fully controllable beampattern control up to approximately 8 kHz. Above this frequency, spatial/modal aliasing begins to interfere with beampattern control. However, professional audio applications require an operating bandwidth to much higher frequencies. One solution is to use a single microphone capsule that is closest to the main axis of the beampattern direction at higher frequencies. It will be shown that there are some problems to this solution. As an alternative implementation it is shown that using a small subset of microphone capsules at high frequencies allows one to smoothly transition the beampattern from eigenbeamformer processing to higher frequencies.

4pEA3. Audio visual scene analysis using spherical arrays and cameras. Adam O'Donovan, Ramani Duraiswami, Dmitry Zotkin, and Nail Gumerov (PIRL Lab., Univ. of Maryland, 3366 AVW Bldg., College Park, MD 20742, adamod@gmail.com)

While audition and vision are used together by living beings to make sense of the world, the observation of the world using machines in applications such as surveillance and robotics has proceeded largely separately. We describe the use of spherical microphone arrays as "audio cameras" and spherical array of video cameras as a tool to perform multi-modal scene analysis that attempts to answer questions such as "Who?,", "What?," "Where?," and "Why?." Signal processing algorithms to identify the number of people and their identities and to isolate and dereverberate their speech using multi-modal processing will be described. The use of graphics processor based signal processing allows for real-time implementation of these algorithms. [Work supported by ONR.]

2:05

4pEA4. A comparison of sound localization methods in a room environment using a spherical microphone array. Colin Barnhill and James E. West (Dept. ECE, Johns Hopkins Univ., Baltimore, MD 21218, cb@jhu.edu)

Enclosures are one of the most challenging environments for source localization, especially for teleconferencing where the main goal is to enhance desired speech signals while suppressing noise. This can be accomplished using beamforming but the speech source locations must be known. Three passive methods will be compared for room environment localization: generalized cross-correlation (GCC), spherical harmonic-based multiple signal classification (MUSIC), and spatial power signal characteristics and gradients (SPSGs). SPSG is a new localization algorithm designed for room environments based on wideband third order beamforming and power

signal characteristics, differences, and gradients. MUSIC is a subspace method that relies on an eigen-decomposition of the beam correlation matrix and GCC is a time delay estimation algorithm based on microphone signal correlation. MUSIC and GCC are methods that perform well in their optimal environments but suffer in noisy and reverberant conditions. Results will be shown for multiple source situations with reverberation and noisy interferers.

4pEA5. Microphone array sensor node for distributed wireless acoustic beamforming. Alaa A. Abdeen and Laura E. Ray (Thayer School of Eng., Dartmouth College, 8000 Cummings Hall, Hanover, NH 03755)

The presentation will illustrate the use of field programmable gate arrays (FPGAs) in microphone array digital signal processing for wireless acoustic beamforming in source localization. We have developed a prototype of a node composed of ten microphone channels interfaced with a Xilinx-based FPGA board. The methodology involves basic signal conditioning and delay-and-sum beamforming programmed by VHDL. The prototype results illustrate significant increase in the sensitivity to acoustic sources in the direction of a signal, while rejecting noise from other directions. The sensitivity is also enhanced in relationship to the number of channels. This node prototype is a building block for a wireless sensor network, capable of distributed beamforming at about 10-kHz sample frequencies. Each node is designed to maximize throughput so that broadband acoustic sources are accommodated. We are now performing parametric studies to optimize the node design and microphone array geometry to provide maximum bandwidth, dynamic range, and adequate special resolution, while preserving the ability to resolve time delays between the microphones.

2:40

4pEA6. MEMS (microelectromechanical systems) microphone array on a chip. Joshua S. Krause and Robert D. White (Mech. Eng., Tufts Univ., 200 College Ave., Medford, MA 02155, joshua.krause@tufts.edu)

The design, fabrication, and characterization of a surface micromachined, front-vented, 64 channel (8×8), capacitively sensed microphone array-on-a-chip are described. The element pitch is 1.3-mm center-to-center and is targeted at resolving the high-wavenumber components of the pressure spectra underneath the turbulent boundary layer. Care is taken to minimize package topology to reduce flow generated self-noise. The array was fabricated using the MEMSCAP PolyMUMPs® process, a three layer polysilicon surface micromachining process, with the addition of a Parylene-C coating in post-processing. An acoustic lumped element model, including mechanical components, environmental loading, fluid damping, and other acoustic elements, is detailed. Laboratory calibration indicates a sensitivity of 1 mV/Pa for each microphone over a 200–40 000 Hz band. A strong resonance occurs at 280 kHz in close accordance with modeled results. Spatial mapping of the array reveals minimal electrical and physical cross-talk between elements. Preliminary element-to-element sensitivity comparisons exhibit a standard deviation of 13%, 12%, and 25% at 250 Hz, 500 Hz, and 1 kHz. Phase matching showed a 9, 10, and 15 deg standard deviation difference at the same frequencies. A more in depth analysis of acoustic sensitivity is ongoing as well as element-to-element variability.

2:55

4pEA7. Ultrasonic calibration of MEMS (microelectromechanical systems) microphone arrays. Katherine E. Knisely, Victor Singh, Karl Grosh, David R. Dowling (Dept. of Mech. Eng., Univ. of Michigan, Ann Arbor, MI 48109, kknisely@umich.edu), and Serdar H. Yonak (Toyota Motor Eng. and Manufacturing, North America, Inc., Ann Arbor, MI 48105)

Ultrasonic microphone arrays have applications in imaging, scale model testing, and sound source localization. For these applications MEMS ultrasonic microphones are emerging as a natural choice because of their small size, low cost, and robustness to manufacturing treatments and environmental conditions. In this talk an array is constructed using commercially available Knowles SiSonic[TM] capacitive MEMS microphones. The absolute sensitivity and phase calibrations of the array elements in the 1–60-kHz frequency range are obtained through the use of replacement calibration and time-frequency analysis. For these results, a modulation in sensitivity and phase measurements for frequency ranges over 15 kHz is observed under certain conditions. The origin of this modulation is discussed as well as various techniques for its removal. Relative element calibrations are crucial for array performance and are obtained through a variety of sound source configurations, which vary in size and location relative to the array.

3:10

4pEA8. Characterization of a high-frequency pressure-field calibration method. Dylan Alexander (Mech. and Aero. Eng., Univ. of FL, 231 MAE-A, Gainesville, FL 32611, fhdpa86@ufl.edu), Casey Barnard, Benjamin A. Griffin, and Mark Sheplak (Univ. of Florida, Gainesville, FL 32611)

A method for the direct measurement of the pressure sensitivity of a microelectromechanical system (MEMS) microphone is developed for frequencies from 10 to 100 kHz. The use of a simultaneous pressure field measurement reduces the errors in calculating the pressure sensitivity from free field measurements, and it allows calibration of non-reciprocal and non-capacitive transduction schemes. An ionophone is used as a calibration source in an anechoic chamber. An aluminum plate is mounted in the anechoic chamber and contains a linear array of pressure field condenser microphones. Treatment of the plate edge is used to minimize diffraction within the pressure field. The microphone data are used to characterize the directivity of the ionophone and localize sources of acoustic diffraction that could impact future MEMS microphone magnitude and phase calibrations.

3:25

4pEA9. Experimental study of synthetic aperture microphone array on rotor blade noise. Jaehyung Lee, Wook Rhee, and Jong-Soo Choi (Dept. of Aerosp. Eng., Chungnam Nat'l. Univ., Daejeon 305-764, Republic of Korea aerojhl@cnu.ac.kr)

Recent development of signal processing technologies has encouraged the aero-acousticians to implement the state-of-the-art sensors and data acquisition devices. They sometimes cost too much; however, especially for the academic arenas, the efforts of reducing the expense of integrating a system and increasing performance of phased array have initiated the idea of designing the synthetic aperture microphone array. The application of beamforming technique in localizing rotor blade noise and the use of synthetic aperture array in wind tunnel testing are presented. To apply the synthetic aperture beamforming on rotating objects, three steps should be considered. The first step is to restore the original acoustic waveform radiated from a rotating sound source. The second step is to synthesize independent array measurement data by correcting phase information of the received acoustic signals. Finally, the beamformer calculates the power on each point of grid in the space. The paper describes the details of deploying the synthetic aperture microphone array and the data reduction methods associated with acoustic measurement in wind tunnel. The comparisons of various patterns of synthetic aperture array are made. The beampower maps for rotor blade noise of various flight conditions are presented.

3:40

4pEA10. Comparison of single-frequency monopulse techniques that mimic the results of multiple-frequency, single-aperture interferometry. Daniel S. Brogan and Kent A. Chamberlin (Dept. of Elec. and Comput. Eng., Univ. of New Hampshire, 33 Academic Way, Durham, NH 03824-2619, daniel.brogan@unh.edu)

The capability to resolve targets from each other and from noise is desirable in all target detection and tracking systems. In a previous presentation [G. R. Cutter, Jr. and D. A. Demer, J. Acoust. Soc. Am. **126**, 2232 (2009)] it was shown that single-frequency, multiple-aperture interferometry could be used to resolve multiple targets that could not be resolved using single-frequency, single-aperture interferometry. This was accomplished by using the phase differences from several pairs of subarrays with different

subarray spacing to mimic the operation of a multiple-frequency, single-aperture interferometric system. The differential-phase technique is one type of phase-comparison monopulse used in target bearing estimation. The current research compares the results of single-frequency, multiple-aperture interferometry to those of other single-frequency phase-comparison and amplitude-comparison monopulse techniques by using multiple receive subarrays and/or varying the receive arrays' elements' weights.

3:55

4pEA11. Non-uniform array synthesis concept and theory. Dehua Huang (NUWC, Newport, RI 02841)

Uniform or symmetric array is a common practice for most of the sonar array design, where the same performance transducer elements are used for numerical simulation and manufacture engineering conveniences. However, non-uniform array designs show their advantages for special array applications. This paper will theoretically address the non-uniform array synthesis concept and theory. A few numerical examples will also be presented for element hybrid and cluster special arrays. [The work is supported by the U.S. Navy.

4:10

4pEA12. Comprehensive development of the theory of nonuniformly spaced arrays. Jenny Y. Au and Charles Thompson (Dept. of Elec. and Comput. Eng., Univ. of Massachusetts Lowell, 1 University Ave., Lowell, MA 01854)

In this work, we will present the work of comprehensive development of the theory of nonuniformly spaced arrays. It will be shown that the position may be determined in terms of the Fourier transform of the objective function. Special consideration will be given to the objective function of G. J. van der Maas in 1954. These results will be compared with that presented by Wallace in 1982.

THURSDAY AFTERNOON, 22 APRIL 2010 HARBORSIDE B, 2:00 TO 3:25 P.M.

Session 4pID

Interdisciplinary: Science and Human Rights Coalition: The Interface Between the Human Rights and Scientific Communities

Edward J. Walsh, Chair

Boys Town National Research Hospital, 555 N. 30th St., Omaha, NE 68132

Chair's Introduction—2:00

Invited Papers

2:05

4pID1. The Science and Human Rights Coalition of the AAAS (American Association for the Advancement of Science): The interface between the human rights and scientific communities. Jessica Wyndham (AAAS, Sci. and Human Rights Coalition, 1200 Washington Ave., NW, Washington, DC 20005)

In July 2005, AAAS held a 2-day conference of scientific associations and human rights organizations to explore ways in which the scientific community could become more directly engaged in human rights. Born of a conference recommendation, the AAAS Science and Human Rights Coalition was officially launched in January 2009. Forty-two scientific membership organizations have since joined the Coalition which aims to build bridges and opportunities for collaboration within the scientific community and between the scientific and the human rights communities. Introducing the Coalition, Ms. Wyndham will answer four questions: What does the Coalition aim to accomplish? How will it do this? Who can join? How does it operate? One year young, the growing number of Coalition members reflects the commitment of scientific organizations to addressing human rights. This, however, is just the beginning. Building on the achievements to-date and lessons learnt throughout the course of the first year, Ms. Wyndham will outline the Coalition's plans for making a real and meaningful contribution to the realization of human rights.

2:25

4pID2. Aspects of participation in the Science and Human Rights Coalition of the AAAS (American Association for the Advancement of Science): Working groups and internal outreach. Clinton W. Anderson (American Psychol. Assoc., 750 First St., NE, Washington, DC 20002)

The goal of Dr. Anderson's presentation is to inform ASA members about two practical aspects of participation in the AAAS Science and Human Rights Coalition: Participation in the working groups that are at the core of the Coalition's activities and outreach by coalition member representatives internally within their organizations. The speaker will briefly introduce the missions and modes of operation of the five working groups that are currently active within the Coalition and focus more extensively on the operations and objectives of the Service to the Scientific Community Working Group. Based on the action plan of the Service to the Scientific Community Working Group and his own experience as an organization member representative for the American Psychological Association, the speaker will to explore ways in which ASA members might work to increase awareness and appreciation of human rights issues and alternatives within the ASA; to increase capacity of the ASA to address human rights issues through a variety of means, including the application of acoustical tools and techniques; and to increase engagement of ASA in human rights activities.

2:45

4pID3. The Acoustical Society of America and the Human Rights Coalition: An introduction. Edward J. Walsh (Boys Town Natl. Res. Hospital, 555 North 30th St., Omaha, NE 68132)

Technological developments in recent years have significantly improved the capacity of human rights advocates to monitor and document abuses of authority, including violations of human rights at home and in remote isolated regions of the world. Recognizing the need for a platform from which scientists and scientific Societies might speak with a common voice to promote human rights protect the professional and personal interests of threatened colleagues, cooperate with human rights organizations, and press for the practical implementation of the right of all persons to the benefits of scientific progress and its applications, the AAAS Science and Human Rights Coalition was launched in 2008. Operating through the Panel on Public Policy, the ASA accepted an invitation to participate as an affiliate member of the Coalition, and the purpose of the Special Session is to introduce the membership at large to the principles and goals of the organization and to offer insight into the mechanism of operation and cooperation through which an effective interface between the scientific and human rights communities might be developed.

3:05

4pID4. The role of science in the human rights movement. Leonard Rubenstein (Ctr. for Public Health and Human Rights, Johns Hopkins School of Public Health, 615 N. Wolfe St., Baltimore, MD 21205)

"Scientists have contributed valuably in making human rights a reality for all. Notable scientific contributions to human rights include the forensic exhumation of mass graves, the use of DNA evidence to identify victims of mass killings, the introduction of information management techniques to illuminate large-scale human rights violations, and, more recently, the use of satellite imagery to document the destruction of communities in remote locations." [Rubenstein and Younis 2008)]. As a human rights lawyer and a consumer of science, Mr. Rubenstein will discuss the contributions of science to human rights challenges, and the importance of the scientific community becoming a constituency for human rights. He will address head-on some of the greatest misconceptions about human rights work, including the charge that it is too "political" as well as steps needed to assure that scientific work undertaken with human rights organizations and is conducted consistent with scientific traditions of impartiality and independent inquiry. Finally, he will demonstrate how the AAAS Science and Human Rights Coalition can be used as a vehicle for the application of scientific skills, to reinforce the commitment, and to amplify the voices of scientists working toward the realization of human rights for all.

THURSDAY AFTERNOON, 22 APRIL 2010 ESSEX A/B/C, 3:15 TO 5:30 P.M.

Session 4pMU

Musical Acoustics: General Topics in Musical Acoustics

Thomas R. Moore, Chair
Rollins College, Dept. of Physics, Winter Park, FL 32789

Contributed Papers

3:15

4pMU1. Novel exploration of the vibration of the Caribbean steelpan in response to authentic excitation. Patrick O'Malley, Joseph F. Vignola, and John A. Judge (Dept. of Mech. Eng., The Catholic Univ. of America, 620 Michigan Ave., Washington, DC 20064)

A novel conformal scanning laser vibrometer was used to determine the vibrational modes of a C-lead tenor steelpan. The measurements provide a rich mechanical snapshot of the artistry involved in the marriage of metallurgy and music theory that goes into the creation of the instrument. The data represent the surface-normal motion of the entire face of the instrument in response to an impulsive excitation intended to mimic the strike of a mallet. A traditional scanning laser Doppler vibrometer is limited to measurement of planar geometries and therefore is of limited utility on the highly contoured surface of the steelpan. A description of the novel measurement system is presented, followed by the surface velocity data and a summary of response shapes and the frequencies at which those responses occur. The data show that individual note areas respond when adjacent or non-adjacent musically related notes are struck and clearly illustrate the complex vibration of the steelpan and the coupling between notes that produce the rich distinctive nature of the steelpan sound.

3:30

4pMU2. Vibrational characteristics of Balinese gamelan metallophones. Molly E. Jones (Dept. Phys., Univ. of Michigan, 450 Church St., Ann Arbor, MI 48109, jonesmo@umich.edu), Kent L. Gee, and Jeremy Grimshaw (Brigham Young Univ., Provo, UT 84602)

A study of the 16 metallophones from a Balinese gamelan has been conducted. Acoustical recordings of metallophone bars being struck were used to examine ratios of overtone frequencies to the fundamental. Results showed large variability in the number and ratios of overtones present. Scanning laser Doppler vibrometry measurements made on several bars also revealed great variability in mode shapes present. The distribution of prominent overtones and their modal shapes do not appear to match those of Western metallophones. Notably, the overall gamelan metallophone characteristics are quite dissimilar to the glockenspiel, which disagrees with previous studies. [This study was supported by the National Science Foundation through its Research Experiences for Undergraduates program.]

3:45

4pMU3. An introduction to the acoustics of playing the horn. David J Zartman (Graduate Program in Acoust., Penn State Univ., 405 EES Bldg., State College, PA, 16801)

In the art of music, a good performer can make a low-quality instrument sound passable, while a bad performer will not play well even on the best instrument in existence. Rather than merely focusing on the properties of the instrument, it is useful to provide the musician with some of the acoustical principles involved with playing the horn well. At the same time, this provides a medium to enable the acoustician to understand some of the intricacies a musician must balance well to create a pleasing sound.

4:00

4pMU4. Novel computer aided design of labial flue pipes. Brian Moss (CSRC/OFSRC, Univ. of Limerick, Limerick, Ireland), Elfed Lewis, Gabriel Leen, Kort Bremer, and Andrew Niven (Univ. of Limerick, Limerick, Ireland)

A labial flue pipe is a well known tone generator, which is familiar and easily recognizable as the organ pipes seen in many concert halls and churches. However, the design and understanding of the sounding mechanism of such pipes are fraught with difficulty. Traditionally labial pipes are constructed from age-old lookup tables that are closely guarded intellectual secrets. This paper discusses a novel computer program that facilitates the design and construction of such labial flue pipes. The computer program allows almost all aspects of the labial flue pipe design to be varied, the resultant frequency is generated, and in addition the Ising efficiency number is provided. Furthermore, a discussion is included related to the fact that even though an Ising number greater than 3 indicates that a pipe is overblown, the fundamental tone is still predominant. A comparison will also be made between a CFD simulation of the labial flue pipe jet mechanism and smoke trail plots typical of such analysis.

4:15

4pMU5. Acoustical studies on conch shells. M.G. Prasad and B. Rajavel (Dept. of Mech. Eng., Noise and Vib. Control Lab., Stevens Inst. of Technol., Hoboken, NJ 07030, mprasad@stevens.edu)

Sound from blowing a conch shell is known for its tonal quality. Its use in many cultures is known. In Hindu culture, conch shell is blown on several auspicious occasions such as festivals, worship, and rituals. A conch shell can be modeled as a horn in its acoustical behavior. This work presents an acoustical study in terms of the spectral characteristics of the shell. The study also presents the influence of parameters such as placing hand in the mouth of the conch shell and the size of conch shell on the spectral characteristics.

4:30

4pMU6. On the role of acoustics in the Vedic Hindu tradition and philosophy. M. G. Prasad and B. Rajavel (Dept. of Mech. Eng., Noise and Vib. Control Lab., Stevens Inst. of Technol., Hoboken, NJ 07030, mprasad @stevens.edu)

Acoustics has received a very high importance in the Vedic Hindu tradition and philosophy of ancient India. The Vedic literature which refers to both the Vedas and the subsequent literature based on Vedas emphasize that the roles of sound both as source signal and as hearing are important. This work presents the various ways such as chants, Sanskrit language, vocal, and instrumental music in which acoustics has played a major role.

4:45

4pMU7. The shape of musical sound: Real-time visualizations of expressiveness in music performance. Gang Ren (Dept. of Elec. and Comput. Eng., Edmund A. Hajim School of Eng. and Appl. Sci., Univ. of Rochester, Rochester, NY 14627), Justin Lundberg, Mark F. Bocko, and Dave Headlam (Univ. of Rochester, Rochester, NY)

Despite the complex multi-dimensional nature of musical expression in the final analysis, musical expression is conveyed by sound. Therefore the expressiveness of music must be present in the sound and therefore should be observable as fundamental and emergent features of the sonic signal. To gain insight into this feature space, a real-time visualization tool has been developed. The fundamental physical features—pitch, dynamic level, and timbre (as represented by spectral energy distribution)—are extracted from the audio signal and displayed versus time in a real-time animation. Emergent properties of the sound, such as musical attacks and releases, the dynamic shaping of musical lines, timing of note placements, and the subtle modulation of the tone, loudness, and timbre can be inferred from the fundamental feature set and presented to the user visually. This visualization tool provides a stimulating music performance-learning environment to help musicians achieve their artistic goals more effectively. Such visualizations and interactions with musical sound also will promote the semantic understanding of an expressive musical language.

5:00

4pMU8. Robust audio watermarking scheme based on spectral modeling synthesis. Pranab Dhar (School of Comput. Eng. & Information Technol., Univ. of Ulsan, Korea, pranab_cse@yahoo.com), Cheol Hong Kim (Chonnam Natl. Univ., Chonnam, Korea), and Jongmyon Kim (Univ. of Ulsan, Korea)

This paper proposes a new watermarking scheme based on spectral modeling synthesis for copyright protection of digital contents. In our proposed scheme, a short time Fourier transform (STFT) is applied to the original signal. Prominent spectral peaks of each frame are then detected and represented by sinusoidal parameters. The residual component is computed by removing all the prominent peaks from the spectrum, transforming the spectrum back to the time domain using inverse fast Fourier transform, and overlap-adding the frames in time. In addition, a peak tracking unit keeps the sinusoidal parameters and forms peak trajectories. Watermarks are then embedded into the most prominent peak of each frame in the peak trajectories. Watermarked signal is computed by the sinusoidal synthesis process and then adding the sinusoids with the residual signal. Watermarks are detected by using the inverse operation of watermark embedding process. Simulation results indicate that the imperceptible watermarks embedded into four different kinds of music sounds using the proposed scheme are robust against several attacks such as noise addition, cropping, re-sampling, re-quantization, and MP3 compression, showing similarity values ranging from 0.8 to 0.9. [Work supported by KOSEF, R01-2008-000-20493-0.]

5:15

4pMU9. Effects of tempo and other musical features on stress responses to college students. Wei-Chun Wang (Dept. of Digital Lit. and Arts, St. John's Univ., 499, Sec. 4, Tam King Rd., Tamsui, Taipei, Taiwan, vgnwang @hotmail.com)

It is believed that music has the power to soften emotions and alleviate pains. This study is aimed to explore the effects of tempo and other musical elements on stress-associated responses of college students when they listen to music. The effects of musical experience, preference, and awareness of music content on stress ratings are also investigated. College students were asked to listen to eight recorded musical excerpts and fill in a questionnaire to rate their relaxation and anxiety levels in a Likert five-point scale and to specify the musical elements. With a variety of tempo being considered, the musical excerpts were chosen from different types of music, including western classical music, Chinese pop music, Chinese traditional music, rock music, jazz blue, and new age music. Preliminary results showed that there was a correlation between relaxation and tempo, and the degree of personal music preference promoted stress reduction. It suggests that music used to enhance relaxation should match a person's musical taste.

4pPA1. Miniature thermoacoustic engine: Experiments and modeling. Konstantin I. Matveev and Sungmin Jung (MME School, WSU, Pullman, WA 99164-2920, matveev@wsu.edu)

A miniature standing-wave thermoacoustic engine was constructed and tested with four quarter-wavelength resonators having lengths in the range of 57–124 mm. 80-ppi reticulated vitreous carbon (RVC) foam was applied as a stack, and an atmospheric air served as a working fluid. The critical temperature difference between the stack ends, corresponding to the sound onset, was recorded in the range of 200–300 °C. A thermoacoustic model was developed to predict the critical temperature difference across the stack. The model allows for user-defined thermoacoustic functions for the stack. Results obtained with the capillary-based theory for tortuous media and thermoacoustic functions previously measured for RVC demonstrate a trend qualitatively consistent with our data, while the quantitative agreement is lacking. Modeling results obtained with thermoacoustic functions for a parallel-plate stack can approximate experimental data, if the appropriate plate spacing is selected. [Work supported by the NSF Grant No. 0853171.]

1:15

4pPA2. Characterization of the heat flux through the heat exchangers of a thermoacoustic cooler. Gaëlle Poignand, Philippe Blanc-Benon, Emmanuel Jondeau (LMFA, UMR CNRS 5509, Ecole Centrale de Lyon, 69134 Ecully Cedex, France, gaelle.poignand@ec-lyon.fr), Etienne Gaviot, Lionel Camberlein, Guillaume Penelet, and Pierrick Lotton (l'Universit du Maine, 72085 Le Mans, France)

A small-scale standing wave thermoacoustic cooler with a couple of stack and heat exchangers is studied. In addition to classical instrumentation in such a device, thermal heat flux sensors specifically developed using MEMS technology equipped the heat exchangers of this refrigerator. These sensors give the temporal evolution of the heat fluxes through the hot and the cold heat exchangers. Hence, they provide a better understanding of heat transfer between the stack and the heat exchangers. In this work, the temporal evolution of the temperature along the stack and of the heat flux through the heat exchanger is measured versus the acoustic pressure. The results show that for high-pressure levels, the heat flux extracted at the cold exchanger rapidly increases until a maximum value and then stabilizes at a lower value. The origin of this limitation may come from the formation of vortices behind the stack highlighted in the work of Berson *et al.* [Heat Mass Transfer **44**, 1015–1023 (2008)]. This work is supported by ANR (project MicroThermAc NT051_42101).

1:30

4pPA3. Inertial cavitation threshold dependence on high static pressures. Kenneth, B. Bader, Joel Mobley, Jason Raymond (Natl. Ctr. for Physical Acoust., Coliseum Dr, Univ., MS 38677, kbader@olemiss.edu), and D. Felipe Gaitan (Impulse Devices, Inc., Grass Valley, CA 95945)

The creation of a bubble in a liquid is energetically favorable when the liquid is subject to a net/an overall tension less than of its saturated vapor pressure. This gain is offset by the creation of a liquid-vapor/gas interface, and only bubbles larger than some critical size will spontaneously grow. The magnitude of the acoustic pressure required to produce a cavity of the critical size is termed the cavitation threshold of the liquid. The dependence of the cavitation threshold on hydrostatic pressure has previously been reported up to 130 bars in terms of electrical power applied to the acoustic driving transducer. These measurements used a standing wave set-up in a stainless steel spherical resonator (24.1 cm outer diameter, 1.9 cm thick) with a $Q >$ 10 000 when fluid loaded. This work will extend into higher pressure regimes and will be used to extrapolate the cavitation threshold at 1 kbar.

1:45

4pPA4. Determination of bubble size distributions in an ultrasonic cavitation field. Stéphane Labouret and Jacques Frohly (Département d'Opto-Acousto-Electronique, Institut d'Electronique, Micro-électronique et Nanotechnologies (IEMN), Université de Valenciennes et du Hainaut-Cambresis, le mont Houy, F-59 313 Valenciennes, France, labouret@laposte.net)

An electromagnetic method is proposed for determining bubble size distribution in the range 2–12 m in ultrasonic cavitation fields. The method is used to investigate the effect of the continuous and pulsed irradiations and of the presence of increasing concentration of a surfactant (sodium dodecyl sulfate) on the bubble size distribution in a standing wave ultrasound field. The electromagnetic sizing technique shows considerable promise as a means of tracking changes in the bubble size distribution during insonation and determining the role of such changes in transitioning from a field that contains a few discrete bubbles to one that exhibits widespread cavitation activity.

2:00

4pPA5. Pressure, temperature, and dissolved gas dependence of dielectric breakdown in water. Jonathan Sukovich and R. Glynn Holt (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

It has been shown experimentally that the optical breakdown strength of water is a pressure dependent quantity, growing with increasing pressure. The dependence of the breakdown strength on temperature and dissolved gas concentration over a larger range of pressures will be observed. Using a custom fabricated pressure vessel and high-power Nd:YAG laser, breakdown events will be generated and observed over a range of pressures from 0 to 25 kpsi. Observations of breakdown events will be made using a high-speed photodetector located behind the pressure vessel's optical windows. Dissolved gas concentration will be controlled and varied using a custom water preparation system over a range from water's vapor pressure (~20 torr) to atmospheric pressure. Temperature will be monitored using a thermocouple attached to the pressure vessel and the temperature dependence will be measured over a range from 20 to 35 °C. A comparison between current single detector methods and previous imaging methods of using breakdown to determine absolute pressure will then be made. [Work supported by Impulse Devices, Inc.]

2:15

4pPA6. A study on nonlinear ultrasonic waves in bubbly media: One and two-dimensional numerical experiments. Vanhille Christian (Escet, Univ. Rey Juan Carlos, Tulipan s/n, 28933 Mostoles Madrid, Spain, christian.vanhille@urjc.es) and Campos-Pozuelo Cleofé (Instituto de Acustica, CSIC, 28006 Madrid, Spain, ccampos@ia.cetef.csic.es)

Nonlinear ultrasonic waves are studied in bubbly media, typically liquids with gas bubbles. The acoustic behavior is modeled by a differential system which couples the acoustic pressure and the nonlinear dynamic of the bubbles. The differential equations are solved by means of a numerical model that gives the acoustic pressure and bubble volume variation as time traces (SNOW-BL code) in two configurations: one and two dimensions. Results are shown for one-dimensional progressive and standing waves as well as for two-dimensional progressive waves, with or without focus. Experiments are carried out with bubbles evenly distributed or forming clouds, for example, in the pre-focal zone. [This work is part of the research project DPI2008-01429.]

2:30—2:45 Break

2:45

4pPA7. Temporal evolution of laser-nucleated bubble clouds in an acoustic resonator. Phillip A. Anderson and R. Glynn Holt (Dept. Mech-Eng, Boston Univ., 110 Cummington St., Rm. 101, Boston, MA 02215)

Using high-speed digital imaging, the evolution of laser-nucleated bubble clouds over multiple acoustic cycles is observed. Five 7×7 custom phase gratings are employed to produce 245 beams, which are then focused into the center of a spherical resonator capable of high static and acoustic pressure. The dependence of the evolution of the bubble cloud on several system parameters is measured. Notably the resulting cloud(s) depend strongly on the phase of the laser firing, the laser energy per pulse, and the acoustic pressure. Number of bubbles, radius of individual bubbles, and effective radius of clouds will be reported as functions of time. The interplay between cloud dynamics and shock waves will also be discussed. [Work supported by Impulse Devices, Inc.]

3:00

4pPA8. Theoretical analyis of Schwinger's conjecture on sonoluminescence in relation to the boosting of sonluminescent transduction efficiency. Harvey C. Woodsum (Sonetech Corp., 10 Commerce Park North, Unit 1, Bedford, NH 03110)

In a previous paper [Spring ASA, Salt Lake (2007)], we have considered the potential viability of Schwinger's conjecture that sonoluminescent light radiation, which results from acoustically developed cavitation, derives from zero-point energy of the vacuum. In our prior paper, we considered the nonlinear interaction of zero-point electromagnetic modes in a cavitating bubble, through the Euler–Heisenberg theory for the scattering of light by light. Good agreement was found between theory and experiment with regard to both the efficiency and spectrum of the sonoluminescent radiation generated using a single acoustic frequency. We now consider a comparison of this theory with other experiments [Phys. Rev. Lett. **81**, 1961–1964 (1998)] which have demonstrated that cavitation bubbles created with acoustic waves having both first and second harmonics present, and having particular amplitude and phase arrangements, can result in sonoluminescent transduction efficiency increases of up to 300%. At this point in time, the predictive power of the current theory appears promising.

3:15

4pPA9. Nonlinear poroacoustic flow in rigid porous media. Pedro Jordan and Jim Fulford (U. S. Naval Res. Lab., Stennis Space Ctr., MS 39529)

An acoustic acceleration wave is defined as a propagating singular surface (i.e., wavefront) across which the first derivatives of the velocity, pressure, or density exhibit jumps. In this talk, the temporal evolution of the amplitude and the propagation speed of such waves are investigated in the context of nonlinear acoustic propagation in rigid porous media. By considering the exact conservation/balance equations, it is shown that there exists a critical value, the constant $\alpha^*(>0)$, of the initial jump amplitude such that the acceleration wave magnitude either goes to zero, as $t\to\infty$, or blows up, in finite time, depending on whether the initial jump amplitude is less than or greater than α^*. In addition, stability is addressed; a connection to traveling wave phenomena is noted, for which an exact traveling wave solution is obtained; and a comparison with the linearized case, i.e., the well-known damped wave equation, is also presented. Finally, the numerical solution of an idealized, nonlinear initial-boundary value problem involving sinusoidal signaling in a fluid-saturated porous slab is used to illustrate the finite-time transition from acceleration to shock wave, which occurs when the initial jump amplitude exceeds α^*. [Work supported by ONR/NRL funding.]

3:30

4pPA10. Different regimes of nonlinear pulse propagation in porous medium. Diego Turo and Olga Umnova (Acoust. Res. Ctr., Univ. of Salford, Salford, Greater Manchester M5 4WT, United Kingdom)

High-amplitude pulse propagation in rigid porous media has been investigated numerically and experimentally. At high-sound levels, strong interactions between different spectral components of the pulse make any frequency domain models difficult to use, therefore a time domain approach has been applied for the present research. The effect of Forchheimer nonlinearity (i.e., flow resistivity growth with particle velocity amplitude) in porous media is well studied. However, much less is known about the influence of memory effects on high-amplitude pulse propagation. The aim of this work is to study their relevance for high-amplitude pulses of different durations. A numerical finite difference time domain scheme has been developed which accounts for second order convection nonlinearity, Forchheimer correction, and memory effect simultaneously. It is shown that Forchheimer nonlinearity dominates for longer duration high-amplitude pulses, while convection terms and memory effect contribution become noticeable for shorter pulses of moderate amplitude. The numerical results are confirmed in a series of experiments with different duration pulses in the amplitude range from 120 Pa to 40 kPa.

3:45

4pPA11. Directivity and frequency control of an intense underwater laser acoustic source for navy applications. Melissa Hornstein, Theodore Jones, Antonio Ting, and Michael Nicholas (Acoust. Div., U.S. Naval Res. Lab., Washington, DC 20375)

We develop an intense laser acoustic source, in which a tailored laser pulse can compress underwater at a predetermined remote location. Optical compression results in laser-induced breakdown (LIB), localized heating, and acoustic shock generation. Recent experiments include near-field acoustic source characterization using lens-focused 400-, 800-, 532-, and 1064-nm pulses of Ti:sapphire and Nd:YAG lasers. Sound pressure levels over 215-dB were achieved using a compact laser. We have demonstrated control of the shape of the LIB plasma volume, and thereby control of the acoustic frequency spectrum and acoustic source directivity. By superposition of volume elements within the LIB, the acoustic pulse duration in a given propagation direction is determined by the parallel dimension of the LIB, divided by the parallel acoustic transit time across the LIB. Thus, the shape of the LIB strongly affects the acoustic pulse duration and directivity, and aspherical LIB volumes result in strongly anisotropic acoustic sources. In our experiments, the LIB volume shape was varied by laser pulse length, energy, optical bandwidth, and focusing angle. We also studied acoustic propagation in a 30 000-gal bubbly salt water tank. [This work is supported by the U.S. Office of Naval Research.]

4:00

4pPA12. Investigation of acoustic streaming in the cochlea. Katherine Aho, Elaine Vejar, and Charles Thompson (Dept. Elec. Eng., CACT, FA 203, 1 University Ave, Lowell, MA 01854)

In this work we will analyze acoustic streaming in the cochlea. A model will be developed to examine the steady flow induced by the harmonic excitation of a fluid in a rigid two-dimensional waveguide. The strength of the flow will depend on the time-phase between the axial velocity and the

boundary velocity. It was found in previous work that the amplitude of the flow is directly related to the streaming Reynolds number. These results will be used to compare with Bekesy's observations.

4:15

4pPA13. Acoustic performance predictions via a general theory for the scattering of sound by sound with experimental data from an operational parametric sonar system. Harvey C. Woodsum (Sonetech Corp., 10 Commerce Park North, Unit 1, Bedford, NH 03110)

In results previously described [J. Acoust. Soc. Am. 95, 2PA14 (1994)], a general theory for the scattering of sound by sound has been developed as an exact solution to the Lighthill–Westervelt equation of nonlinear acoustics. Most recently, a computer model based on this theory has been developed in order to support design analysis and performance prediction for parametric array echo-ranging systems and has been applied to a currently deployed operational parametric sonar. The present theory and model have the potential to support a wide range of analyses, including development of beam patterns, source levels, transient waveform effects, as well as the analysis of scattering of sound by sound from intersecting beams as well as the prediction of performance of parametric sources having multiple simultaneous transmit beams. Both the theoretical basis for the model and agreement with experimental data are presented.

4:30

4pPA14. Imaging multiple masked nonlinear scatterers applying a combination of time reversal principles and the selective source reduction method. Siegfried Vanaverbeke, Koen Van Den Abeele (Wave Propagation and Signal Processing, K.U. Leuven Campus Kortrijk, E. Sabbelaan 53, B-8500 Kortrijk, Belgium, koen.vandenabeele@kuleuven-kortrijk.be), Brian E. Anderson (Brigham Young Univ., Provo, UT 84602), and Marco Scalerandi (Politecnico di Torino, 10129 Torino, Italy)

Inherent limitations of the traditional time reversal process in the case of multiple sources or scatterers make it impossible to distinguish them individually. The selective source reduction (SSR) method employs a subtraction technique to selectively suppress in amplitude (and ideally eliminate) a time reversed focal signal that is masking another focus. In previous work, Scalerandi *et al.* and Anderson *et al.* successfully applied the SSR method to identify masked primary sources in a fully linear medium. Here, we extend the capabilities of the SSR method to deal with (i) secondary sources (for example, scattering caused by embedded defects) and (ii) nonlinear scattering generated during the ultrasonic wave propagation as well. We call this new method selective source reduction based on nonlinear time reversed acoustics (SSR-NLTRA). In the extended approach, the contribution of all primary sources is first eliminated by means of the scaling subtraction method. Subsequently, the SSR-TRA method is applied to the remaining nonlinear content of the signals. We show by means of two dimensional wave propagation simulations that the new method can be applied iteratively to successfully image multiple masked nonlinear defects.

THURSDAY AFTERNOON, 22 APRIL 2010 GRAND BALLROOM VII/VIII/IX, 2:00 TO 6:00 P.M.

Session 4pPP

Psychological and Physiological Acoustics: Physiology, Models, and Auditory Processing (Poster Session)

Monita Chatterjee, Chair
Univ. of Maryland, Dept. of Hearing and Speech Science, College Park, MD 20742

Contributed Papers

All posters will be on display from 2:00 p.m. to 6:00 p.m. To allow contributors an opportunity to see other posters, contributors or odd-numbered papers will be at their posters from 2:00 p.m. to 4:00 p.m. and contributors or even-numbered papers will be at their posters from 4:00 p.m. to 6:00 p.m.

4pPP1. Vacuum ear plug. Martin L. Lenhardt (Dept. of Biomedical Eng., Virginia Commonwealth Univ., P.O. Box 980168 MCV, Richmond, VA 23298-0168, lenhardt@vcu.edu)

A passive inexpensive hearing protection device (HPD) will be described that provides hearing protection, which is simple to use and comfortable over hours of use. Protection from impact sounds will be provided by creating a negative pressure between the plug tip and the eardrum (−100-mm H2O or −1 kPa). The negative pressure will be created by squeezing the peripheral plug end, evacuating a fixed amount of air from the canal. The aperture diameter is 0.010 in. In effect the pump plug will have a similar acoustical action on the eardrum as a normal stapedius muscle contraction, but without its limitations (too slow and fatigue). An external flexible bladder forms the end which is held in the fingers to be inserted into the ear canal. The vacuum mechanism consists of bulb on a polypropylene frame embedded in a closed cell urethane flanged housing. With a negative pressure of −2 kPa the transmission loss is 20–25 dB. It is estimated that a negative pressure of −1 kPa would result in a transmission loss of about 15 dB. The vacuum effect is maximal in the low frequencies which will also attenuate body conducted sounds by reducing ossicular inertial.

4pPP2. Development and validation of a computational model of bone-conducted sound transmission for improved hearing protection design. Odile H. Clavier (Creare Inc., 16 Great Hollow Rd., Hanover, NH 03755, ohc@creare.com), Margaret Wismer (Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801), Jed Wilbur, Anthony Dietz (Creare Inc., Hanover, NH 03755), and William O'Brien, Jr. (Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801)

Bone-conducted sound is the limiting factor in current hearing protection for very high-noise environments such as those encountered by maintainers of military aircraft. The University of Illinois has developed a three-dimensional acoustic wave propagation model for the computation of sound transmission into, around, and through fluid and solid-shell bodies. Creare has implemented experimental techniques to validate the computational

results. Three cases are presented. The first is a fluid sphere, for which experimental, computational, and analytical results were obtained. The second is a solid-shell, fluid-filled sphere, for which experimental and computational results were obtained to determine the effect of the solid shell. The third is a representative human head with and without passive hearing protection. For this case, the computational model and an experimental head simulator were both developed from a computed tomography scan of a living human head. The head simulator was built around a rapid-prototype instrumented skull using silicon organs and simulated tissue. Experimental, computational, and analytical results were all in good agreement for the fluid sphere test case. While general agreement was obtained for the other two cases, specific discrepancies in the results are outlined and limitations of the models are discussed.

4pPP3. Application of matched asymptotic expansions to the analysis of compressional bone conduction. David Chhan and Charles Thompson (Dept. of Elec. and Comput. Eng., Univ. of Massachusetts Lowell, 1 University Ave., Lowell, MA 01854, david_chhan@student.uml.edu)

In this work, we will investigate the compressional mode of bone conduction and its effect on the displacement of the cochlear partition. We will use the method of matched asymptotic expansions to obtain the velocity of the partition. In this mode of bone conduction, the cochlea is compressed alternatively due to an applied vibratory force. Velocity difference between the oval and round windows is shown to be critical in determining the amplitude of the partition motion. From this physical process, we will analytically derive equations that will be used to solve for the velocity of the cochlear partition due to the compressional velocity on the cochlear shell.

4pPP4. Exploring the traveling wave dispersion in the cochlea. Sripriya Ramamoorthy, Ding-Jun Zha, and Alfred Nuttall, L (Dept. of Otolaryngol ./Head and Neck Surgery, Oregon Hearing Res. Ctr., Oregon Health and Sci. Univ., NRC 04, 3181 SW Sam Jackson Park Rd., Portland, OR 97239, ramamoor@ohsu.edu)

In the measurements of the basilar membrane velocity as well as the auditory nerve responses to acoustic stimulation, it has been observed that low frequencies arrive at the measurement location (or the tonotopically located auditory nerve fiber) earlier and high frequencies arrive later, with significant delay noticed in the characteristic frequency component. In the derived impulse responses as well as click responses, this phenomenon manifests as the instantaneous frequency glide from low to high frequencies. The origin of these frequency glides has not yet been satisfactorily explained. In this paper, a simple elucidation along with experimental validation using measurements made on guinea pigs is presented for the plausible origin of the frequency glides observed in the cochlea.

4pPP5. Observing chartacteristic frequency shifts using chirp-evoked otoacoustic emissions. Luke Shaheen, Michael Epstein, and Ikaro Silva (Dept. Speech-Lang. Path. and Audiol., Auditory Modeling and Processing Lab. (AMPLab), Ctr. for Comm. and Digitial Signal Processing (Dept. Elec. and Comp. Eng.), Northeastern Univ., 360 Huntington Ave., Boston, MA 02115, m.epstein@neu.edu)

Otoacoustic emissions (OAEs) are often used to assess the integrity of specific regions of the cochlea. There is, however, evidence that the frequency that causes maximal response for a particular cochlear region shifts toward lower frequencies at high-stimulus levels. Therefore, OAE-based assessments of cochlear activity over a wide range of levels may need to take into account these shifts. The present study employed two experiments in order to confirm and characterize the extent to which this shift in cochlear excitation as a function of level can be observed in OAEs. In the first experiment, chirp-evoked otoacoustic emissions (ChOAEs) were used to track changes in the frequency spectra of each listener. The results showed a shift toward low frequencies in the spectral peak of ChOAE response in a majority of listeners (−9.1% average shift). This shift was then confirmed using a single-listener measurement of tone-burst otoacoustic emission input/output functions measured at three different frequencies. These results support the contention that it may be necessary to vary stimulus frequency to take the cochlear excitation shift into account when making assessments of the cochlear activity at a particular location across a wide range of levels.

4pPP6. Growth of otoacoustic emission suppression as a function of frequency and level in humans. Michael P. Gorga, Stephen T. Neely, Judy, G. Kopun, and Hongyang Tan (555 N. 30th St., Omaha, NE 68131)

DPOAE suppression was measured for 11 suppressor frequencies (f3) surrounding each of eight f2 frequencies (0.5–8 kHz) and six L2 levels (10–60 dB SL). A total of 63 normal-hearing subjects participated, with data from 20 subjects at each f2, L2 combination. Measurement-based stopping rules were used, such that averaging continued until the noise −25 dB SPL, the SNR 25 dB, or 210 s of artifact-free averaging had been completed. These stopping rules resulted in reliable measurements, even for conditions in which the SNR typically is poor (low f2 frequencies and low L2 levels). Suppression growth as a function of f3 was similar across f2 frequencies and L2 levels. Specifically, low-frequency suppressors relative to f2 had higher suppression thresholds but more rapid growth of suppression, compared to suppressor frequencies close to f2. Suppression growth for f3 frequencies above f2 was slow, even in comparison to suppression growth when f3 ¡Ö f2. This overall pattern was evident for all f2 frequencies and for a wide range of L2 levels. These findings suggest that suppression growth is similar across a wide frequency range in humans. [Work supported by the NIDCD R01 2251 and P30 4662].

4pPP7. Otoacoustic emission suppression tuning curves in humans. Michael, P. Gorga, Stephen, T. Neely, Judy, G. Kopun, and Hongyang Tan (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

DPOAE suppression data as a function of suppressor level (L3) for f2 frequencies from 0.5 to 8 kHz and L2 levels from 10 to 60 dB SL were used to construct suppression tuning curves (STCs). DPOAE levels in the presence of suppressors were converted into decrement versus suppressor level (L3) functions, and the L3 resulting in 3-dB decrements was obtained by transformed linear regression. These L3 levels were plotted as a function of f3 to construct STCs. STCs when f3 is plotted on an octave scale were similar in shape across f2 frequency. These STCs were analyzed to provide estimates of gain (tip-to-tail differences) and tuning (QERB). Both gain and QERB decreased as L2 increased, regardless of f2, but the increase with f2 was not monotonic. A roughly linear relation was observed between gain and QERB at each frequency, such that gain increased by 4–13 dB (mean xa1;xd6; 8 dB) for every unit increase in QERB, although the pattern varied with frequency. These findings suggest consistent nonlinear processing across a wide frequency range in humans, although the nonlinear operation range is frequency dependent. [Work supported by the NIDCD R01 2251 and P30 4662].

4pPP8. Influence of hair bundle configuration on biomimetic hair sensor sensitivity. Shuangqin Liu and Robert White (Mech. Eng., Tufts Univ., Medford, MA 02155, shuangqin.lin@tufts.edu)

Hair cells are the sensory receptors of the auditory system. When the stereocilia (hair buddles) sitting on top of the hair cells are stimulated, a current flows through the hair cell transducing mechanical stimuli into electrical response. For the outer hair cell (OHC), the hair bundles are stimulated by displacement of the tectorial membrane relative to the reticular lamina. For the inner hair cell (IHC), the hair bundles are stimulated by force due to motion of the fluid around the hair bundle. In addition, OHC and IHC hair bundles are shaped differently. In this paper, biomimetic micromachined hair sensors are designed, fabricated, and tested to investigate how the configurations of the hair bundles affect the sensitivity of the hair sensor. These hair sensors use a capacitive scheme and have different hair configurations including the W and U shape representing OHC and IHC hair bundles. Computational results achieved to date indicate that sensitivity can be strongly affected by the placement of the engineered hair bundles. Microfabrication and experimental work are ongoing.

4pPP9. Spatiotemporal coding of signals in the auditory periphery. Ramdas Kumaresan, Vijay Peddinti (Dept. of Elec. and Comput. Eng., Univ. of Rhode Island, Kelley Hall, Kingston, RI 02881), and Peter Cariani (Harvard Med. School, Newton, MA 02460)

Signal representation in the cochlea is often thought to involve either rate-place profiles or purely temporal, interspike interval codes. Spatiotemporal coding strategies based on phase-locking, cochlear delays, and coincidence detectors have also been proposed [Loeb *et al.*, Biol. Cybern. (1983); K. & Shamma, J. Acoust. Soc. Am. **107** (2000); and Carney *et al.*, Acoustica **88**, 334–337 (2002)]. In this view, spatiotemporal patterns of spikes locked to relative phases of the traveling wave at specific cochlear places at a given time can convey information about a tone. We propose a general mathematical basis for using such spatial phase/amplitude patterns along the frequency axis to represent an arbitrary (approximately) time and bandwidth-limited signal. We posit that the spatial pattern of phases and amplitudes corresponds to locations at which (real and/or imaginary parts of) the Fourier transform of the signal crosses certain levels (e.g., zero level). Given these locations, we show that we can accurately reconstruct the original signal by solving a simple eigenvalue problem. Using this approach, we propose an analysis/synthesis algorithm to represent speech-like signals. We conjecture that a generalized representation of the forms of signals can be inferred from spatial, cross-CF patterns of phase relations present in the auditory nerve. [Work supported by AFSOR FA9550-09-1-0119.]

4pPP10. Perception and discrimination of synchronous and asynchronous tones. Magdalena Wojtczak, Andrew J. Oxenham, and Anna C. Baird (Dept. of Psych., Univ. of Minnesota, Elliott Hall N218, 75 East River Rd., Minneapolis, MN 55455)

Studies of auditory-brainstem responses show that the response to a click is less synchronized than the response to an upward-chirp designed to compensate for the dispersion of basilar-membrane traveling-wave [Dau *et al.*, J. Acoust. Soc. Am. **107**, 1530–1540 (2000)]. However, upward-chirps are perceived as less compact than the clicks despite producing a more synchronized response along the basilar-membrane, suggesting the existence of a mechanism compensating for different traveling-wave delays [Uppenkamp *et al.*, Hear. Res. **158**, 71–83 (2001)]. This study evaluated synchrony and asynchrony perception and discrimination using tonal stimuli that excited remote places along the basilar membrane. Potential within-channel cues were masked using noise bands that were geometrically centered between the test tones. Level effects were investigated using two levels of the test tones, 20-dB SL and 85-dB sound pressure level (SPL). In addition, perception and discrimination of synchrony and asynchrony were measured for tones presented in noise bands at signal-to-masker ratio of 20 dB. The pattern of results for masked 85-dB SPL tones resembled that for unmasked 20-dB SL tones. The role of auditory-filter bandwidths and the existence of a compensating mechanism in the perception of across-channel synchrony and asynchrony will be discussed. [Work supported by NIH Grants R01DC03909 and R01DC010374].

4pPP11. Limiting factors in auditory discrimination of frequency ratios. Christophe N. J. Stoelinga and Robert A. Lutfi (Dept. of Communicative Disord., Auditory Behavioral Lab., Univ of Wisconsin, Madison, Wisconsin 53706)

Frequency ratios convey meaningful information for speech and many natural sounds. However, little is known regarding our ability to discriminate frequency ratios [see Fantini and Viemeister (1987). *Auditory Processing of Complex Sounds* (Lawrence, Hillsdale, NJ)]. The present study measured the relative contribution of two factors expected to limit discrimination: decision criterion and internal noise. In an adaptive, two-interval, forced-choice procedure with frequency rove, 11 highly trained listeners discriminated a change in the frequency ratio between two equal-intensity tones. The separate influence of decision criterion and internal noise was determined from scatter plots giving listeners' trial-by-trial responses as a function of the frequencies of the two tones. The plots reveal listeners to initially base their judgments on one tone alone (almost always the higher of the two) but after training to place greater reliance on both tones. Some listeners were able to achieve the optimal decision criterion of weighting both tones equally, so that the deviation from perfect performance was due only to internal noise. With continued practice over the course of many trials (at least ten 1000-trial sessions), listeners improved their performance by either improving their decision criterion or reducing internal noise. [Research supported by NIDCD grant 5R01DC006875-05.]

4pPP12. Diassociating spectral and temporal influences in an AM-QFM (amplitude modulated and quasi-frequency modulated) discrimination task. Ewa Borucki and Berg Bruce (Dept. of Cognitve Sci., Univ. of California, Irvine, 3151 Social Sci. Plaza, Irvine, CA 92697-5100, eborucki@uci.edu)

This study investigated temporal and spectral influences in a task used to investigate the bandwidths of phase sensitivity. Subjects discriminated amplitude modulated (AM) tones and quasi-frequency modulated (QFM) tones in a 2IFC. An adaptive threshold procedure was used to estimate modulation depth needed to make the discrimination as a function modulation frequency for a 2000-Hz carrier. Threshold functions were often nonmonotonic, with nonmonotonicities observed at higher-modulation frequencies. This is likely due to the effects of distortion products creating salient spectral cues. When stimulus duration is decreased from 200 to 50, 20, or 10 ms, thresholds for low-modulation frequencies decreased to near-chance levels, whereas thresholds in the region of nonmonotonicities were largely unaffected. The decrease in stimulus duration appears to hinder the listener's ability to use temporal cues in order to discriminate between AM and QFM, whereas spectral information derived from distortion product cues appears to be resilient. [Work supported by NSF BCS-07464003.]

4pPP13. The influence of practice on the discrimination of spectro-temporal modulation depth. Andrew T. Sabin (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60201, a-sabin@northwestern.edu), David A. Eddins (Univ. of Rochester, Rochester, NY), and Beverly A. Wright (Northwestern Univ., Evanston, IL 60201)

The pattern of sound energy spread across frequency and time (spectro-temporal modulation) is a crucial stimulus cue for sound identification. Improvements in the sensitivity to this modulation could potentially aid performance on numerous real-world tasks, yet it is unknown how practice influences this sensitivity. To investigate this issue, normal-hearing adults ($n=8$) were trained ~1 h/day for 7 days to discriminate between noises with the same spectro-temporal modulation drifting upward in audio frequency but with different modulation depths. Performance on the trained condition and on four untrained conditions was examined both before and after the training phase. Depth-discrimination thresholds improved significantly on the trained condition and on an untrained condition with a downward-drifting modulation. Discrimination thresholds also improved in subsets of listeners on untrained isolated component modulations (spectral or temporal) of the trained spectro-temporal modulation. Finally, the ability to detect the trained spectro-temporal modulation worsened significantly in proportion to the amount of improvement on the trained discrimination task. These data suggest that training on depth discrimination may be a means of improving sensitivity to spectro-temporal modulation depth in real-world stimuli, but potentially at the cost of the ability to detect these modulations. [Work supported by NIH/NIDCD]

4pPP14. Transient sex differences during development on two auditory tasks attributable to earlier maturation in males. Julia Jones Huyck and Beverly A. Wright (Dept. of Commun. Sci. and Disord., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60202, juliajoneshuyck@u.northwestern.edu)

Recent evidence suggests that the development of naïve performance on some auditory perceptual tasks can continue well into adolescence. Of interest here was whether there are sex differences in the maturation rate on three such tasks, temporal-interval discrimination, tone detection in forward masking, and tone detection in backward masking. To investigate this issue, performance was compared between males and females in multiple age groups on these three tasks (n per sex in each age group=9–20). There were no sex differences for backward masking. However, males reached adult-like performance earlier than females on the other two tasks: forward masking (males at ~12 years, females at ~15 years) and temporal-interval discrimination (males at 14 years, females at >14 years, on each of three

separate conditions). Surprisingly, the male advantage occurred only during adolescence. Thus, on two of the three late-developing auditory abilities examined, males matured more quickly than females, but did not differ from females either early in development or once mature performance had been reached. These results demonstrate that there can be transient sex differences during development owing to differences in maturational rate. [Work supported by NIH/NIDCD.]

4pPP15. Spectral weight analysis of commodulation masking release. Hisaaki Tabuchi and Bruce G. Berg (Dept. of Cognit. Sci., Univ. of California, Irvine, 3151 Social Sci. Plaza. Irvine, CA 92617-5100)

Spectral weight estimates are obtained in a commodulation masking release (CMR) experiment in which masking and flanking bands each consist of five equal-intensity tones spanning 20 Hz. The masking and flanking bands are centered at 1000 and 900 Hz, respectively, and the signal is an increment in the intensity of the 1000 Hz component. The phases for the five components of the masking band are randomly sampled on each trial and are identically assigned to the components of the flanking band, yielding commodulated bands. A small, random intensity perturbation is added to each component of the stimulus, and an analysis of trial-by-trial responses provides spectral weight estimates. Spectral weights are also obtained from simulations of two multiple channel models [Hall *et al.*, J. Acoust. Soc. Am. **76**, 50–56 (1984); S. Buus, J. Acoust. Soc. Am. **78**, 1958–1965 (1985)] and one single-channel model [B. G. Berg, J. Acoust. Soc. Am. **100**, 1013–1023 (1996)]. Data for most subjects show strong support for Hall's multiple-channel model. [Work supported by NSF BCS-07464003.]

4pPP16. Relationship between physiological and psychoacoustical sensitivity to amplitude and frequency modulation. Michelle Hsieh, Craig Champlin, and Su-Hyun Jin (Dept. of Commun. Sci. and Disord., Univ. of Texas at Austin, 1 University Station A1100, Austin, TX 78712, michellehsieh@mail.utexas.edu)

Various researchers have found a correlation between the auditory steady state response (ASSR) and corresponding behavioral measurements such as speech recognition scores [e.g., Dimitrijevic *et al.* (2001)]. However, relatively few studies have examined the sensitivity to small changes in amplitude and frequency modulation depths. In the present study, it was hypothesized that physiological individual differences in sensitivity to amplitude and frequency modulation depths would be reflected in corresponding psychophysical measures. Auditory steady-state responses were collected in response to amplitude- and frequency-modulated pure tone carriers (500 and 3000 Hz) in normally hearing listeners over a range of modulation depths at several different modulation rates. Participants also completed a psychophysical task in which they were asked to detect the modulated tone in a two-interval forced choice testing paradigm. The relationships between the ASSR and the psychophysical performance will be discussed.

4pPP17. A hybrid procedure for psychometric function estimation. Harisadhan Patra, Daniel L. Valente, and Walt Jesteadt (Boys Town Natl. Res. Hospital, 555 N 30th St., Omaha, NE 68131)

Threshold, defined as the stimulus level required for a predefined percent correct response, is often used to measure a listener's performance. Psychometric functions (PFs) provide better insight to the underlying decision process. Two parameters, threshold (α) and slope (β), are sufficient to define a PF. Estimation of α and β from individual trials of adaptive procedure tracks is time-consuming, costly, and dependent upon the step-size choice. A procedure has been developed and written in MATLAB, which provides stable PF parameter estimates of α and β and also their confidence intervals. The procedure consists of three stages. First, signals are presented adaptively to estimate levels corresponding to 71% and 87% correct. Second, the signal is pseudo-randomly presented at one of five fixed levels equally spaced over that range. Finally, the program implements a maximum-likelihood procedure updated after every trial to estimate signal levels corresponding to 63%, 71%, 76%, 79%, and 87% correct. After 140 trials, the program estimates α and β from the entire run and generates a PF curve that typically accounts for at least 90% of the total variance. The reliability and validity of the procedure are analyzed using simulations and observed data. [Work supported by NIH.]

4pPP18. Fundamental frequency and pitch shift discrimination. William A. Yost, Christopher A. Brown, and Farris Walling (Speech and Hearing Sci., Arizona State Univ., P.O. Box 870102, Tempe, AZ 85287, william.yost@asu.edu)

The pitch-shift of the residue has been used as an argument for the importance of temporal fine structure in pitch perception. Discrimination of a change in fundamental frequency (F0) for harmonic complexes was compared to discriminating a change in the shifted frequency (f) in pitch-shift of the residue stimuli. Patterson and Wightman [J. Acoust. Soc. Am. **59**, (1976)] showed that a linear relationship exists between matched pitch and the frequency of the lowest spectral component for pitch shift of the residue stimuli (stimuli for which the spacing between adjacent spectral components is constant, but all components in the complex are shifted up or down in frequency). Obtaining pitch matches for pitch shift of the residue stimuli is a difficult task because of the ambiguous nature of the pitch shift of the residue in several conditions. Using the two discrimination experiments allows for an estimate of the slopes relating matched pitch to the frequency of the lowest component. Slopes estimated from the discrimination experiments will be compared to those obtained by the previous authors to determine if the discrimination experiments provide a valid way to predict the matched pitch of pitch-shift of the residue stimuli. [Research supported by NIDCD.]

4pPP19. Extraction of fundamental pitch using Euclid's algorithm implemented through iterative demodulation. Ramdas Kumaresan, Jiun-yee Li (Dept. of Elec. and Comput. Eng., Univ. of Rhode Island, Kelley Hall, Kingston, RI 02881), and Peter Cariani (Harvard Med. School, Newton, MA 02460)

Strong periodicity or "virtual" pitches are heard at the fundamentals (F0s) of harmonic complexes. As an alternative to both spectral pattern matching and autocorrelation-like analysis, we propose a novel mechanism that extracts the pitch directly from the signal by iterative demodulation and low-pass filtering. In effect the mechanism computes the greatest common divisor (gcd) of component signal harmonic numbers, using a Euclid-like iterative subtraction algorithm. For example, F0 of 560- and 320-Hz tones is 80 Hz, obtained by iteratively subtracting smaller frequencies from larger ones until they converge, e.g., $560-320=240$ Hz, $320-240=80$, $240-80=160$, and $160-80=80$. This algorithm can be adapted to compute pitches of harmonic complexes. Consider two tones, 560 and 320 Hz. As in Euclid's algorithm, the tones are iteratively multiplied and low-pass filtered to obtain the first (240-Hz), second (160-Hz), and third (80-Hz) difference tones. At the end only F0 remains. For inharmonic tones, incomplete demodulation results if there is a lower-frequency limit to the process. The mechanism converges on one pitch rather than multiple subharmonics. Such repeated multiplication and low-pass operations could conceivably be implemented in the ascending auditory pathway via phase-locked spike trains with synchrony capture, successive cross-CF convergences, low-pass modulation tunings, and cumulative decline of phase-locking at successive stations. [Work supported by AFOSR FA9550-09-1-0119.]

4pPP20. Musical context affects detection of pitch differences in tones with different spectra. Elizabeth M. O. Borchert and Andrew J. Oxenham (Dept. Psych., Univ. of Minnesota-Twin Cities, 75 East River Rd., Minneapolis, MN 55455)

Pitch plays an important role in complex auditory tasks such as listening to music and understanding speech, yet pitch comparisons are more difficult when tones have different spectra. Since tones are rarely heard in isolation, the surrounding context may help or hinder pitch comparisons. The first study presented listeners with tone pairs in isolation or immediately following a tonal context, which consisted of a portion of a descending major scale with the target as the tonic. Listeners' performance improved in the presence of the tonal context, but only when the tones within a pair differed in spectral content. In the second experiment, a variety of contexts were used, with the goal of discriminating between effects of tonal hierarchy and effects of predictability. Even with maximal predictability, presenting tone pairs after an "atonal" context consisting of notes from an octatonic scale yielded poorer performance than tone pairs in isolation. The results suggest that any advantage listeners derived from the tonal context in our first experiment

was related more to placing the tone into an over-learned tonal hierarchy than to the likelihood of the target pitch within a predictable context. [Work supported by NIH Grant R01 DC 05216.]

4pPP21. Neural timing nets for fundamental frequency (F0)-based auditory scene analysis. Peter Cariani (Dept. of Otology & Laryngology, Harvard Med. School, 629 Watertown St., Newton, MA 02460) and Ramdas Kumaresan (Univ. of Rhode Island, Kingston, RI 02881)

Neural timing nets are idealized networks of delay lines, coincidence detectors, and adaptive processing elements that operate in the time domain on temporally coded signals to compare, extract, and separate auditory objects [Cariani, Neural Networks **14**, 737–753 (2001); J. New Music Res. **30**, 107–135; IEEE Trans. Neural Netw. **15**(5) (2004)]. Timing nets constitute an alternative, potential mode of neural signal processing in which information resides in neural signals rather than in patterns of activated elements. Recurrent timing nets with delay loops act as dense arrays of recursive, comb-like filters to effect a period-by-period analysis that builds up and separates component invariant time patterns with different fundamentals (F0s). Using both linear and nonlinear processing rules, the latter were used to process and separate synthetic double vowels, running speech, and polyphonic musical excerpts, with varying results. Relations to, and combinations with, processing strategies based on autocorrelation and all-order interspike intervals, adaptive comb filtering, correlogram duplex analysis, cancellation, Fourier zero-crossings, and demodulation, with and without prior bandpass filtering, are discussed. Bottom-up/top-down mechanisms for dynamic facilitation of lower level temporal processing loops are also considered. [Work supported by AFOSR FA9550-09-1-0119.]

4pPP22. The effect of stimulus context on cortical measures of pitch processing using functional magnetic resonance imaging. Daphne García (MRC Inst. of Hearing Res., Univ. Park, Nottingham, United Kingdom, daphne@ihr.mrc.ac.uk), Christopher Plack (Univ. of Manchester, Manchester, United Kingdom), and Deborah Hall (Nottingham Trent Univ., Nottingham, United Kingdom)

Many different paradigms and pitch-evoking stimuli have been used to study pitch. A growing body of neurophysiological evidence shows that cortical responses are sensitive to the context from which stimuli are presented. In this human fMRI study, we tested the hypothesis that the stimulus context influences the pattern of pitch-related auditory cortical activation. Fifteen listeners participated in a blocked design experiment. A diotic harmonic complex tone and a dichotic Huggins pitch stimulus were presented within either a noise or silent context and activation was contrasted with matched noise control conditions. Results revealed significant main effects of both context (noise/silence) and pitch stimulus (diotic/dichotic) ($p < 0.05$, corrected). While the response to context was primarily localized in primary auditory cortex, the response to pitch was more posterior. The context significantly modulated the pitch response, especially in subregions of planum temporal; non-primary auditory cortex. While the response to the diotic pitch was greater than the dichotic pitch, the overall results were broadly comparable. We therefore conclude that if the feature specificity of the pitch-related response is to be inferred from fMRI data, future studies should include careful controls for stimulus context.

4pPP23. Vocal pitch regulation depends on the baseline voice F0 feedback: An ERP study for investigating the role of auditory feedback for voice pitch error correction. Roozbeh Behroozmand and Charles Larson (Dept. of Commun. Sci. and Disord., Speech Physio. Lab., Northwestern Univ., 2240 Campus Dr., Evanston, IL 60208, r-behroozmand @northwestern.edu)

Voice production and control require neural interactions between the vocal motor and auditory mechanisms. The comparison between the incoming auditory feedback and the predicted sensory input (efference copies) from a self-produced vocalization allows the detection of feedback mismatches for voice error detection and correction. However, the sensitivity of the audio-vocal system for feedback mismatch detection seems to depend on the extent of feedback deviation from the predicted vocal output. The present study investigated this effect by examining event-related potentials (ERPs) in response to a +100-cent voice feedback pitch perturbation stimulus while the extent of pre-stimulus (baseline) feedback pitch deviation was randomly manipulated at 0, 50, 100, 200, and 400 cents. Results showed that the neural responses to +100-cent pitch-shift stimuli grew systematically larger as the extent of pre-stimulus baseline pitch deviation became smaller. This finding suggests that the extent of disparity between the predicted and incoming sensory feedback of self-produced voice can affect the neural tuning processes that adjust the sensitivity of the audio-vocal mechanisms for voice pitch error detection and correction. Lower sensitivity to larger feedback mismatches may imply robustness against the disruptive effect of highly deviant or externally generated sounds during vocal production and control.

4pPP24. Molecular analysis of the effect of onset asynchrony in the identification of a rudimentary sound source in noise. Robert A. Lutfi, Ching-Ju Liu, and Christophe N. J. Stoelinga (Dept. of Communicative Disord., Auditory Behavioral Res. Lab., Univ. of Wisconsin, 1975 Willow Dr., Madison, WI 53706, ralutfi@wisc.edu)

The threshold for detecting a target in noise is often greater when the target is gated on simultaneously with the noise than when it is gated on after some delay [Zwicker, E. (**1965**). J. Acoust. Soc. Am. **37**, 653–663]. One explanation is that the perceptual principle of grouping causes the target and noise with simultaneous onsets to be perceived as a single sound source. This idea was tested for a rudimentary sound source using perturbation analysis. In a two-interval, forced-choice procedure listeners identified as target the impact sound produced by the larger of two stretched membranes. The noise on each presentation was the impact sound of a variable-sized plate. Grouping predicts that the decision weights on the noise should be positive when target and noise have simultaneous onsets, but that they should approach zero when target and noise are gated on asynchronously. This prediction was confirmed when the noise preceded the target by a fixed interval (100 ms), but not when it followed the target by the same interval or when either interval was selected at random on each presentation (100 or −100). [Research supported by NIDCD Grant 5R01DC006875-05.]

4pPP25. Target enhancement and noise cancellation in the identification of rudimentary sound sources in noise. Robert A. Lutfi, Ching-Ju Liu, and Christophe N.J. Stoelinga (Dept. of Communicative Disord., Auditory Behavioral Res. Lab., Univ. of Wisconsin, 1975 Willow Dr., Madison, WI 53705, ralutfi@wisc.edu)

The identification of targets in noise is believed to entail two processes, one that acts to enhance the target and the other to cancel the noise [Durlach *et al.* (2003). J. Acoust. Soc. Am. 2984–2987]. The relative contribution of these processes in the identification of rudimentary sound sources is unknown. In the present study, perturbation analysis was used to determine the relative contribution in terms of the sign and magnitude of listener decision weights on the noise. In a two-interval, forced-choice procedure, listeners identified as target the impact sound produced by the larger of two stretched membranes. The noise on each presentation was the impact sound of a variable-sized plate. For four of five listeners showing significant interference, the weights were positive indicating enhancement; for the remaining listeners, they were negative indicating cancellation. In a second condition, the target was the membrane hit with harder force, and the noise was a plate hit with variable force. The noise weights for all listeners in this condition indicated cancellation. The results are consistent with an interpretation in which noise cancellation is the predominant strategy for identifying targets unless it is precluded by uncertainty regarding the spectral properties of the noise. [Research supported by NIDCD Grant No. 5R01DC006875-05].

4pPP26. The effect of binaural coherence on envelope interaural time difference thresholds. Jessica J. M. Monaghan, Katrin Krumbholz, and Bernhard U. Seeber (MRC Inst. of Hearing Res., Nottingham NG7 2RD, United Kingdom, jessica@ihr.mrc.ac.uk)

Room reflections alter the envelope of sounds differently at both ears, reducing binaural coherence. Experiment 1 measured interaural time difference (ITD) discrimination thresholds for broadband and transposed speech. A sentence was convolved with binaural room impulse responses for different source-receiver distances, and the envelopes extracted and multiplied with 4-kHz tones. Preliminary results indicate that envelope ITD thresholds increased from <100 μs without reverberation to >700 μs at four times the reverberation radius. ITD thresholds for unprocessed speech were more robust to the addition of reverberation, only rising above 350 μs at the same distance. To investigate whether reverberation is detrimental owing to re-

duction in binaural coherence, stimulus envelopes were created by temporally jittering raised cosine pulses around a 10-ms separation. Bilaterally independent jittering allowed variation in coherence while minimizing change in other envelope parameters. Preliminary results show ITD thresholds <100 μs for coherent envelopes, increasing to >700 μs for coherences of 0.6, a value consistent with the room simulations above. Envelope coherence strongly affects ITD discrimination, suggesting that ITDs extracted from high-frequency channels may not provide useful information in many realistic situations. This has implications for bilateral cochlear implant users, as current devices provide ITDs only in envelopes.

4pPP27. Tonotopic gradients in neural interaural time difference processing: A modeling study of the medial superior olive. Yoojin Chung (Eaton-Peabody Lab., Massachusetts Eye and Ear Infirmary, 243 Charles St., Boston, MA 02114, yoojin_chung@meei.harvard.edu) and H. Steven Colburn (Boston Univ., Boston, MA 02215)

The interaural time difference (ITD) is the primary cue for sound localization; yet many basic questions about the biophysical mechanisms remain. In the mammalian auditory system, neurons in the medial superior olive (MSO) are tuned to ITD as well as frequency. In this study, the effects of key parameters in MSO models, such as the membrane time constants and the number and strength of synaptic inputs on ITD sensitivity to pure tones, were explored with particular attention to the best-frequency dependence of these parameters. Results show that ITD tuning is dependent on neuron membrane characteristics (i.e., the shape and time constant of the membrane response), on the strength of individual synaptic inputs, and on stimulus properties such as frequency and intensity. Models with slow response times and weak synaptic inputs show good ITD sensitivity for low-frequency tones, whereas models with fast response times and strong synaptic inputs exhibit good ITD tuning for high-frequency tones. This dependence of ITD sensitivity on membrane properties in the model suggests that parameters important for ITD tuning depend on the best frequency of the neurons, in contrast to the view that the binaural mechanism is homogeneous along the tonotopic axis.

4pPP28. Level-dependent changes in perception of temporal envelope cues. Xin Wang, Jayne B. Ahlstrom, Amy R. Horwitz, and Judy R. Dubno (Dept. of Otolaryngol.-Head and Neck Surgery, Medical Univ. of South Carolina, 135 Rutledge Ave., MSC 550, Charleston, SC 29425-5500, wanxi@musc.edu)

Level-dependent changes in speech recognition may reveal effects of basilar-membrane nonlinearities on temporal envelope fluctuations. It is hypothesized that, as a result of the compressive effects of the active cochlear mechanism, the "effective" magnitude of speech envelope fluctuations will be reduced as speech level increases from lower (more linear) to conversational (more compressive) regions. With further increases from conversational levels (to a more linear region), temporal envelope fluctuations will become more pronounced. Accordingly, speech recognition will be maximized at conversational levels due to the optimal "flattened" envelope and then decline at lower or higher levels. To test these assumptions, speech recognition scores were measured as a function of level for adults with normal hearing. Speech stimuli were spectrally degraded using "noise vocoder" processing so that perceptual effects of modifications to the speech temporal envelope can be revealed. As vocoded speech level increased, background noise level also increased, maintaining a fixed signal-to-noise ratio to minimize sensation-level effects on speech recognition scores. Discussion will focus on level-dependent effects for different speech stimuli and the role of nonlinearities on perception of temporal envelope cues. [Work supported by NIH/NIDCD]

4pPP29. The use of confusion patterns to evaluate the neural basis for concurrent vowel identification. Ananthakrishna Chintanpalli (Weldon School of Biomedical Eng., Purdue Univ., 206 S. Martin Jischke Dr., West Lafayette, IN 47907) and Michael G. Heinz (Purdue Univ., West Lafayette, IN 47907)

Perceptual studies of concurrent vowel identification suggest that listeners with normal hearing (NH) are better able to use differences in fundamental frequency (F0) than listeners with sensorineural hearing loss (SNHL). However, the neural basis for this difference remains unknown. The present study sought to validate a neural model of concurrent vowel identification based on specific confusion patterns made by NH listeners. A standard set of five vowels was used. In each concurrent vowel pair, vowel 1 had F0 = 100 Hz, while the F0 of vowel 2 was varied between 100–126 Hz (4 semitones). NH listeners made similar confusions across all F0 differences, with a reduction in occurrence as F0 difference increased. F0 benefit varied significantly across concurrent vowel pairs. A phenomenological auditory-nerve model was cascaded with F0 segregation algorithms to predict the perceptual observations. Neural predictions showed similar confusion patterns to the perceptual data for many (but not all) concurrent vowel pairs. Validating a NH physiological model with specific confusion patterns will allow the model to be used to predict effects of specific physiological changes related to SNHL, which may be useful for improving cochlear-implant and hearing-aid signal processing strategies. [Work supported by Purdue University.]

4pPP30. Auditory channel weights for consonant recognition in normal-hearing listeners. Frederic Apoux and Eric W. Healy (Dept. of Speech and Hearing Sci., The Ohio State Univ., Columbus, OH 43210, fred.apoux@gmail.com)

The present study evaluated the relative contribution of various regions of the frequency spectrum to consonant recognition in normal-hearing listeners. The method used in this study was specifically designed to provide an estimate of the importance of each band (i) consistent with the frequency resolution of the auditory system and (ii) irrespective of the location of information elsewhere in the spectrum. Speech stimuli were divided into 30 adjacent bands with each band corresponding approximately to the bandwidth of an auditory filter. Listeners were presented with a subset of bands to avoid ceiling effects. The importance of each band was derived from the drop in performance observed when that particular band was omitted. The spectral location of the bands was always chosen randomly except for the one band whose importance was being assessed. The results indicated a fairly homogeneous contribution of all 30 bands to consonant recognition (i.e., a flat auditory channel importance function) with only the five lowest bands (below 300 Hz) having lesser weight. In contrast, additional analyses revealed a non-uniform contribution of the bands to the transmission of voicing, manner and place of articulation. [Work supported by NIDCD.]

4pPP31. Perception of temporally interrupted speech: Effects of two concurrent gating rates on intelligibility. Valeriy Shafiro, Stanley Sheft, and Robert Risley (Comm. Dis. Sci., Rush Univ. Med. Cntr., 1015 AAC, 600 S. Paulina St., Chicago, IL 60612, valeriy_shafiro@rush.edu)

Perception of temporally interrupted speech was investigated with either one or two concurrent square-wave gating functions. Sentences were interrupted at a single rate of 1, 2, 4, 8, 16, 24, or 32 Hz with a 50% duty cycle. For each rate between 1 to 8 Hz, stimuli were additionally gated at a secondary rate ranging from twice the primary rate up to 32 Hz. The secondary gating rate thus interrupted only the segments of speech which were left intact after application of the primary gating function to reduce by half the remaining speech content independent of secondary rate. With a single gating function, intelligibility scores increased with rate, reaching perfect accuracy at 8 Hz. Application of the second gating function led to a decrease in intelligibility which was greatest when the secondary rate was twice the primary rate, a condition equivalent to a 25% duty cycle of the primary rate. Further increase in the secondary rate generally led to an improvement in intelligibility, although never to the level achieved with the primary rate alone. The incomplete recovery of intelligibility scores at fast secondary gating rates suggest disruption of separate perceptual processes by each of the two concurrent interruption rates.

4pPP32. Noise robust representation of speech in the primary auditory cortex. Nima Mesgarani (Johns Hopkins Univ., Baltimore, MD, mnima@umd.edu), Stephen David, Jonathan Fritz, and Shihab Shamma (Univ. of Maryland, College Park, MD)

It is well known that humans can robustly perceive phonemes despite substantial variability across speakers, context and natural distortions. This study examines the responses of neurons in primary auditory cortex (A1) to phonetically labeled speech stimuli in clean, additive noise and reverberant conditions. Using a linear decoder [Bialek (1991)] to reconstruct the input stimulus spectrogram from the population response, we observed that

spectrograms reconstructed from the neural responses to noisy speech were closer to the original clean spectrograms than to the noisy ones. This indicates that sound representations in A1 serve to enhance information about natural speech signals relative to noise, thus extracting signal from noise. Examining the average reconstructed phoneme spectrograms in clean and noisy speech revealed a remarkable robustness in the encoding of features important for discrimination of different phonemes. In addition, it was found that the strict linear spectro-temporal receptive field (STRF) model of A1 neurons is insufficient to explain the noise robustness observed in the neural data. However, when a non-linear synaptic depression is integrated into the inputs for the STRF model, the noise was reduced in the reconstructed spectrograms similar to what observed with the actual neural data.

4pSA1. Wave propagation model for acoustic evaluation of polymeric thin films. Hyeong Sick Ju (Graduate Program in Acoust., The Pennsylvania State Univ., 201 Appl. Sci. Bldg., University Park, PA 16802, huj110@psu.edu) and Bernhard R. Tittmann (The Penn State Univ., University Park, PA 16802)

Polymeric thin films are fabricated on crystalline wafers to serve as a photoresist in lithography processes of semiconductors or MEMS. Essentially these film structures are viscoelastic layers on anisotropic substrates. Acoustic evaluation for these material structures requires an appropriate wave propagation model. This paper presents a leaky surface acoustic wave (LSAW) model for the evaluation of polymeric film integrity. Scanning acoustic microscopy (SAM) operating at relative high-frequency above 100 MHz is utilized to measure the LSAW velocity. For the use of SAM, the model modifies the pre-existing anisotropic layered model by employing hysteretic absorption in viscoelastic polymer and water-loading. The model produces the mean reflectance function and mean dispersion curve, which are specialized for spherical acoustic lenses. The predicted mean dispersion shows good agreement with LSAW velocities measured at several frequencies with spherical lenses.

2:15

4pSA2. Active vibration control modules for damping, compensation, measurement and dynamic testing. Vyacheslav M. Ryaboy (Newport Corp., 1791 Deere Ave., Irvine, CA 92606, vyacheslav.ryaboy@newport.com)

The active vibration control module was introduced previously as part of active vibration damping system for optical tables and other precision vibration isolated platforms. This paper describes steps to expand the application of those modules to other tasks, namely, compensation of forced vibration in local areas and dynamic testing of structures. Vibration damping of most significant structural modes had been achieved using a small number of properly placed active dampers. This did not affect forced tonal vibration. Current state of the art does not offer a practically feasible way to suppress all vibration, forced and normal, over the total table surface. However, by placing vibration control modules around a local area of the table supporting a vibration sensitive device, it is possible to abate forced tonal vibration in this area. Feedback control for vibration compensation will be discussed along with experiments demonstrating stable concerted work of several vibration control modules. In application to dynamic testing, the actuator is excited by white noise, and the sensor signal is processed to calculate the dynamic compliance. The test data show that the vibration control modules can be used to measure dynamic compliance with precision comparable to that of dedicated vibration measurement systems.

2:30

4pSA3. When is a system random? Richard H. Lyon (60 Prentiss Ln., Belmont, MA 02478)

Statistical energy analysis (SEA) is a method for estimating structural acoustic transfer functions based on a statistical model of the system. The SEA model assumes random noise excitation in frequency bands and an underlying ensemble of "similar" systems. However, since the results of a SEA calculation are nearly always applied to a single system, there is a natural question of in what sense a single system can be random. A particular structural acoustics system is considered that displays both deterministic and random behavior with a distinct transition between the two. System parameters (damping, modal density, and coupling factors) are examined to see how they might be controlling the transition from deterministic to random.

4pSA4. Novel lightweight vibration absorbers for marine structures. Ryan L. Harne and Chris R. Fuller (Virginia Tech Vib. and Acoust. Labs., 131 Durham 0238, Blacksburg, VA, 24061, rharne@vt.edu)

When combined with attached motors and rotating machinery, the lightly damped, thick plating required in maritime applications becomes a broadband noise and vibration control problem. A typical solution is to adhere heavy and dense damping materials for dissipation of the plate vibrational energy. In order to attenuate low frequencies, significant mass must be added to the structure. This paper will review the development of two, new passive treatments intended to resolve this issue. HG blankets are constructed using small masses embedded into poroelastic material. Together with the inherent stiffness of the poroelastic material, the masses become embedded mass-spring dampers and their presence is found to notably increase the low-frequency transmission loss of the host material. DVAs are compact vibration absorbers that distribute continuous mass and spring elements over the surface while generating ample reactive damping at low frequencies. This paper will overview the concepts and development of adapting DVAs and HG blankets for use on heavy plate structures, their testing for broadband control performance, as well as their versatility for thinner panels. A comparison with a conventional, marine noise control treatment will be considered. [This work was supported by Northrop Grumman Shipbuilding-Newport News.]

4pSA5. Bloch response of framed wings with upper and lower skins. R. Martinez and M. Eash (Alion Corp., 84 Sherman St., Cambridge, MA 02143)

Aircraft wings are typically composed of spanwise-periodic framing elements running from leading to trailing edge. Each frame is connected to the wing's upper and lower skins through continuity of motions among frames

and skins. This paper presents calculations of a generic wing's low-wavenumber Bloch response in global flexure per the following physical content: (1) the frames are mass controlled both in vertical translation and rotation; (2) the skins are plate-like, and respond dynamically to normal and compressional shears against each of the frames; (3) the two plates bend symmetrically with respect to the normal component of the virtual foces driving them, and antisymmetrically in compression with respect to their tangent component. The need for compressional forces and a corresponding in-plane response for each of the wing's two skins stems from the theory's lack of restrictions on frame height, which for our thick wing implies a neutral axis for global flexure that is far from the system's uppermost and lowermost material points. Our calculations showcase the effects of the skins' compression on the system's low-wavenumber response, as well as how compression defines the structure's low-frequency limit for a stiffness-controlled effective medium rendered anisotropic by its chordwise-running frames.

4pSA6. Noise and vibration transmission reduction using multi-element multi-path structures. Cassidy Palas and Donald Bliss (Mech. Eng. and Mater. Sci., Duke Univ., Hudson Hall, Durham, NC 27708, sid.palas@duke.edu)

Principles of structural acoustics are utilized in novel ways to cancel the transmission of sound and vibration through multi-element flexible barriers. Configurations analyzed include two and three layered plates with elastic interconnections. The substructures have different wave propagation properties and boundary conditions. Both continuous and periodic discrete elastic coupling methods are examined. This research demonstrates that flexibility and controlled resonant behavior can be used to block vibration and sound transmission, even with low structural damping. The main strategies utilized are structural wave cutoff with multi-element multi-path (MEMP) structures and relative phase changes due to boundary reflections. Examples of acoustic transmission loss through panel barriers are presented, and the potential advantages and possible shortcomings of the approach are evaluated. Practical configurations for layered sound reduction materials include designs allowing multiple substructural plates to produce radiation on a given surface, leading to net cancellations of transmitted sound in certain frequency ranges. Experimental results show vibration transmission reduction for several configurations. The work has particular application to the reduction in vehicle interior noise and addresses the need for good acoustic performance of lighter weight flexible structures.

3:45

4pSA7. An improved formulation for predicting low-frequency noise transmitted through double-pane windows. Dayi Ou, Cheuk Ming Mak (Dept. of Bldg. Services Eng., The Hong Kong Polytechnic Univ., Hung Hom, Kowloon, Hong Kong, 08900950r@polyu.edu.hk), and Kai Ming Li (Purdue Univ., West Lafayette, IN 47097-2031)

With superior sound insulation properties over a single-panel configuration, a double-panel structure with the presence of a cavity has found a wide range of applications for sound insulation. A classical method for combining a finite element method (FEM) with a boundary element method (BEM) is used to examine the transmission of low-frequency noise through double-pane windows in the present study. The technique of component mode synthesis is applied to adjust the stiffness matrix in the FEM formulation in order to examine the effects of elastic boundary conditions on the sound transmission through these structures. However, the Green function for predicting sound propagation in a rectangular long enclosure is used in favor of the free-field Green function for predicting the pressure inside the cavity of the window panes. The predicted pressure in the cavity is then coupled with the FEM formulation for the window panes and the BEM formulations for the sound fields at the outer surfaces of window panes. A parametric study is conducted systematically to allow a detailed examination for the characteristics of sound insulation of a double-pane window at different frequency bands especially for the low-frequency components.

4:00

4pSA8. Acoustic signatures of partial electric discharges in different thicknesses of Kapton. Daniel P. Hanley (US Naval Acad., P.O. 12571, Annapolis, MD 21412, m102592@usna.edu) and Edward J. Tucholski (US Naval Acad., Annapolis, MD 21401)

Thin polymer films in the presence of high electric fields undergo partial discharge and have characteristic acoustic emissions. It is hoped that studying these acoustic signals can aid in anticipating failure of the films, thereby providing a tripwire to reduce the electric voltage in high-energy capacitor applications before failure actually occurs and the capacitor is permanently damaged. This study compared the acoustic emission from a variety of thicknesses of Kapton film between 7 and 55 μm. A laser Doppler vibrometer with a frequency response from 0–22 kHz was used to study surface vibrations of a gold coated polymer sample as voltage was raised at a controlled rate of 500 V/s from 0 V to material failure. Emissions from partial discharges prior to failure are studied. The results of these tests demonstrate the relationship between characteristic frequencies for the acoustic emission and the polymer thickness.

4:15

4pSA9. Seismic surface wave method for near surface soil exploration. Zhiqu Lu (Natl. Ctr. for Physical Acoust., The Univ. of MS, Univ. MS 38677, zhiqulu@olemiss.edu)

There are many applications that require the information of near surface soil properties. The related areas include agricultural land management, levee/dam evaluation, landmines/UXO/tunnel detection, battle field condition assessment, and site foundation characterization, to name a few. To obtain soil properties in a non-invasive manner, a multi-channel analysis of surface wave (MASW) method based on laser-Doppler vibrometer was developed recently and reported in 157th ASA Meeting, Portland, OR. This talk will present the latest development. In particular, two methods of determination of the dispersive curve, i.e., the phase slope method and the two dimensional FFT transformation method, will be discussed. The emphasis will be given to demonstrate the capabilities of the two methods in identifying the fundamental mode and high modes of Rayleigh waves. An inversion algorithm using the measured dispersive curve can back calculate the soil profile, i.e., the shear wave velocity as a function of depth. Several case studies of the MASW method will be addressed.

4:30

4pSA10. Fault classification for rotating machines using neural network. Hyungseob Han and Uipil Chong (Dept. of Comput. Eng. and Information Technol., Univ. of Ulsan, Ulsan, Korea, overhs@naver.com)

When the rotating machines in the plants malfunction during operating, they can cause huge economic losses and many casualties. For these reasons, fault detection and diagnosis of rotating machines have become very important issues. This paper proposes a system to detect and diagnose abnormal states for induction motors. Through an effective combination of wavelet transform and neural network for measured vibration signals from the motors, successful fault detection and diagnosis can be achieved. This system is divided into two parts: analysis and classification. In the analysis part, vibration signals are divided into eight subbands by using wavelet transform. The most significant features of the signals are shown in the lowest-frequency band. For an efficient classification in the neural network, input samples chosen in that band were minimized. In the classification part, through one of the representative techniques, multi-layer perceptron, all kinds of vibration signals are trained and tested. From the experimental results, the proposed system perfectly classified input signals into each fault case. Furthermore, since it does not need reference data for classification, it can perform very quickly and be implemented to a real-time system.

Speech Communication: Speech for Tracking Human Health State, Performance, and Emotional State I

Suzanne E. Boyce, Chair
Univ. of Cincinnati, Dept. of Communication Disorders, Cincinnati, OH 45267-0379

Chair's Introduction—1:00

Invited Papers

1:05

4pSCa1. Speech analysis in accident investigation. Malcolm Brenner (Natl. Transportation Safety Board, 490 L'Enfant Plaza SW, Washington, DC 20594, brennem@ntsb.gov)

The NTSB investigates major transportation accidents in the United States to make recommendations to prevent their recurrence. The Safety Board also examines new technologies that might assist investigations. In conducting its work, the NTSB has found speech analysis a useful new technology for providing secondary evidence on operator state for issues such as psychological stress, alcohol impairment, physical straining, and hypoxia. This talk provides examples from two investigations: the grounding/oil spill of the Exxon Valdez tanker and the crash of a Boeing 737 airliner at Pittsburgh.

1:25

4pSCa2. Common voice measures as indicators of fatigue. Cynthia M. LaJambe (201 Transportation Res. Bldg., Penn State Univ., University Park, PA 16802, cml149@psu.edu), Frederick M. Brown (Penn State Univ., University Park, PA, 16802), Rebecca M. Reichardt (Towson Univ., Towson, MD, 21252), Malcolm Brenner (Natl. Transportation Safety Board, Washington, DC, 20594), and Robert A. Prosek (Penn State Univ., University Park, PA, 16802)

Unobtrusive, economical, and readily accessible fatigue-monitoring technologies are needed especially in transportation, military operations, and security industries. Voice analysis is compatible with operational settings, given its minimal interference with hands-on work duties. Controlled laboratory studies are underway to establish the sensitivity of this fatigue-monitoring method. A recent study evaluated sleep-deprivation consequences on basic voice attributes using multiple speech tasks. Twenty-six native English-speaking 18-26 year-old subjects were screened for physical and psychological problems. Several sleep/wake cycles were monitored with actigraphy prior to laboratory participation. Vocal measures were compared between 13 speakers sleep deprived for 36 hours and 13 non-sleep-deprived controls. In the laboratory, speech was recorded during baseline sessions and on the following day. Group differences varied by speech task and vocal measure, with more sleep-deprivation sensitivity found, for example, in speaking rate as compared to fundamental frequency. Fatigue-related changes in vocal measures were associated with decrements in psychomotor reaction times and cognitive performance. Results are compared with previous studies relating psycho-physiological states to basic voice measures. Design considerations are discussed.

1:45

4pSCa3. Speaker assessment: The impact of environment on speech systems and individuals. John H. L. Hansen (Dept. of Elec. Eng., CRSS: Ctr. Robust Speech Systems, Univ. of Texas at Dallas, Richardson, TX 75083, john.hansen@utdallas.edu)

Assessing speaker variability is critical in developing a scientific understanding or model of human speech production. The environmental context plays a significant role in how this variability plays out. In this study, recent findings are presented on the variability of speech production due to environmental factors that influence man-machine interaction as well as human-to-human interaction. Speech produced under task stress, emotional stress, and background noise (resulting in Lombard effect) all cause speech production changes. This impacts both speech processing algorithms intended for speech recognition/technology and human-to-human interaction. Specifically, two speech production domains are briefly considered including Part-1: speech production under varying types/levels of background noise and how this produces flavors of Lombard effect and impacts speaker recognition systems, and Part-2: assessing the stress/emotional state of parents/care-givers in quantifying the language learning exposure of children (ages 10–36 months). In Part-1: the UT-Scope corpus is employed with speech from 30 subjects (19M,11F) for analysis of duration and spectral tilt as well as developing an automatic Lombard effect classification scheme which is incorporated into speaker recognition. Next, Part-2: considers how neutral versus stressed/emotional state of adults impacts conversational turns and adult word-count in a child language learning environment (20 child-parent interactions).

2:05

4pSCa4. Intelligibility of speech produced under sleep-deprivation conditions. Suzanne Boyce (Dept. of Comm. Sci. Disord., Univ. of Cincinnati, 3202 Eden Ave., Cincinnati, OH 45267-0379, boycese@ucmail.uc.edu), Joel MacAuslan (S.T.A.R. Corp., Bedford, MA 01730), Sandra Combs, and Alexandra Blood (Univ. of Cincinnati, Cincinnati, OH 45267-0379)

In previous work, we applied the technique of acoustic landmark detection to speech produced under rested vs sleep-deprived conditions. We found significant differences for both the number and pattern of landmarks detected. In a parallel study we found significant differences in clear vs conversational styles of speech. While it has been shown by a number of investigators that clear and conversational speech styles differ in the degree to which intelligibility to listeners is preserved in noise, it is not clear whether the articulatory changes found in sleep-deprived speech affect the ability of listeners to understand what is said, especially in noise. In this paper, we present the results of a study in which normal-hearing listeners are asked to transcribe speech presented with and without background noise. Similar levels of background noise have been shown to reduce speech intelligibility for clear vs conversational speech presented to normal listeners. The speech in this study was produced under rested and sleep-deprived conditions. Results will be compared to effects of clear vs conversational speech presented in noise and in quiet.

2:25

4pSCa5. On the acoustics of emotion in speech: Desperately seeking a standard. Bjoern Schuller (Inst. for Human-Machine Commun., Technische Universitaet Muenchen, D-80333 Muenchen, Germany, schuller@tum.de)

Researchers concerned with automatic recognition of human emotion in speech have proposed a considerable variety of segmental and supra-segmental acoustic descriptors. These range from prosodic characteristics to voice quality to acoustic correlates of articulation and represent unequal degrees of perceptual elaboration. Recently, evidence has been reported from first comparisons on multiple speech databases that spectral and cepstral characteristics have the greatest potential for the task [B. Schuller *et al.*, Linguistic Insights **97**, 285–307 (2009)]. Yet, novel acoustic correlates are constantly proposed, as the question of the optimal representation remains disputed. The task of evaluating suggested correlates is non-trivial, as no agreed "standard" set and method of assessment exists, and inter-corpus substantiation is usually lacking. Such substantiation is particularly difficult owing to the divergence of models employed for the ground-truth description of emotion. To ease this challenge, using the potency-arousal-valence space as the predominant means for mapping information stemming from diverse speech resources, including acted and spontaneous speech with variable and fixed phonetic content on well-defined binary tasks is proposed. Among the various options for automatic classification, a method combining static and dynamic features representing pitch, intensity, duration, voice quality, and cepstral attributes is recommended.

2:45

4pSCa6. The detection of stress, emotion, and deception from speech: The intersection of phonetics, policy, and politics. James Harnsberger (Dept. Comm. Disord., Univ. of Florida, 68 Dauer Hall, Gainesville, FL 32611)

While prior research on the detection of stress, emotion, and deception from speech and language has shown limited progress, this has not prevented the marketing of commercial devices that purport to detect these states to a variety of customers, such as law enforcement agencies, the military, intelligence agencies, homeland security, and insurance companies. For the major products currently on the market, all independent studies to date have failed to verify their efficacy with a wide range of speech materials collected under various experimental conditions, ranging from laboratory studies with carefully controlled speech to "mock crimes" to speech produced under realistic levels of jeopardy. This literature (including two studies by the author) will be reviewed and discussed in terms of how their experimental design and results are shaped and used in policy debates by private manufacturers, elected officials and their staffers, academic researchers, and others.

3:05—3:20 Break

3:20

4pSCa7. Automatic methods to monitor the speech of Parkinson's patients with deep brain stimulators. Craig van Horne (Caritas Neurosurgery, 736 Cambridge St., CCP 8, Brighton, MA 02135), Karen Chenausky, Joel MacAuslan (STAR Corp., Bedford, MA 01730), Carla Massari, and Marianna McCormick (Caritas-St. Elizabeth's, Brighton, MA, 02135)

Parkinson's disease (PD) is a neurodegenerative disease causing hypokinetic dysarthria, associated with "blurred" or underarticulated speech, imprecise consonants, and, sometimes, irregular syllable trains. Within the past decade, deep brain stimulation (DBS) of the subthalamic nucleus (STN) has provided substantial benefit to PD patients. DBS treatment has largely been directed toward the motoric features of PD: bradykinesia, rigidity, and tremor, but its effects on speech vary. The speech of PD patients receiving DBS treatment, with or without accompanying medical therapy, was analyzed for rate (syllables per second), regularity (relative deviation of syllable length), stop consonant spirantization (a measure of stop consonant precision), vowel ratio (length of vowel to length of syllable), and other features using automatic routines written specifically for the purpose. Patients' speech is more variable on DBS stimulation than on medication or no treatment. It is possible to find a combination of DBS settings for each patient that relieves their motor symptoms and returns their speech to normal. These findings suggest that it is possible to improve speech along with the general motor symptoms of PD. Furthermore, automatic analyses show promise as sources of feedback for neurologists to use in optimizing DBS settings for speech.

4pSCa8. Impact of cognitive load and frustration on drivers' speech. Hynek Bořil (Erik Jonsson School of Eng. and Comp. Sci., The Univ. of Texas at Dallas, 2601 N. Floyd Rd. 75080, Richardson, TX 75083-0688, hynek@utdallas.edu), Tristan Kleinschmidt (Speech and Audio Res. Lab., Queensland Univ. of Technol., GPO Box 2434, Brisbane, Queensland 4001, Australia), Pinar Boyraz, and John H. L. Hansen (The Univ. of Texas at Dallas, Richardson, TX 75083-0688)

Secondary tasks such as cell phone calls or interaction with automated speech dialog systems (SDSs) increase the driver's cognitive load as well as the probability of driving errors. This study analyzes speech production variations due to cognitive load and emotional state of drivers in real driving conditions. Speech samples were acquired from 24 female and 17 male subjects (approximately 8.5 h of data) while talking to a co-driver and communicating with two automated call centers, with emotional states (neutral, negative) and the number of necessary SDS query repetitions also labeled. A consistent shift in a number of speech production parameters (pitch, first format center frequency, spectral center of gravity, spectral energy spread, and duration of voiced segments) was observed when comparing SDS interaction against co-driver interaction; further increases were observed when considering negative emotion segments and the number of requested SDS query repetitions. A mel frequency cepstral coefficient based Gaussian mixture classifier trained on 10 male and 10 female sessions provided 91% accuracy in the open test set task of distinguishing co-driver interactions from SDS interactions, suggesting—together with the acoustic analysis—that it is possible to monitor the level of driver distraction directly from their speech.

THURSDAY AFTERNOON, 22 APRIL 2010 GRAND BALLROOM V, 4:05 TO 5:05 P.M.

Session 4pSCb

Speech Communication: Speech for Tracking Human Health State, Performance, and Emotional State II (Poster Session)

Suzanne E. Boyce, Chair
Univ. of Cincinnati, Dept. of Communication Disorders, Cincinnati, OH 45267-0379

Contributed Papers

All posters will be on display and all authors will be at their posters from 4:05 p.m. to 5:05 p.m.

4pSCb1. Using temporal cycles in spontaneous speech to quantify linguistic impairments in patients with neurodegenerative disorders. Eden Kaiser (Prog. in Linguist., Univ. of Minnesota, 214 Nolte Ctr., 315 Pillsbury Dr. SE, Minneapolis, MN 55455, kaise113@umn.edu), Serguei V. S. Pakhomov, Angela K. Birnbaum, Daniel Boley (Univ. of Minnesota, Minneapolis, MN 55455), and David S. Knopman, (Mayo Clinic, Rochester, MN 55905)

Fronto-temporal lobar degeneration (FTLD) is a form of dementia which may manifest through symptoms similar to Alzheimer's, including language-specific impairment. Linguistic manifestations of the disorder are often described in subjective assessments of the disorder, but not always easily quantifiable using objective tests. This paper investigates a speech characteristic not yet assessed in FTLD patients, that of "temporal cycles" [Henderson *et al.* (1966); Butterworth and Goldman-Eisler (1979)]. Temporal cycles in the speech of healthy adults consist of alternating and roughly equal periods of fluent and hesitant speech [Roberts and Kirsner (2000)]. A time series analysis of temporal cycles was conducted using spontaneous speech from 45 adults diagnosed with FTLD. Patients' cognitive functioning was assessed using the language-specific clinical dementia rating (CDR) scale by board-certified neurologists. Periodicity of temporal cycles was quantified using the proportion of the energy in the highest peak to the total energy in the power spectrum. It was found that this measure was correlated with independent CDR assessments. The results of this study indicate that temporal cycles may be used to characterize the effects of neurodegenerative disorders on speech communication. [Work supported by US NIA Grants Nos. R01-AG023195, P50-AG16574, P30-AG19610, and NIH NIA-1R01AG026390, and Univ. of MN Academic Health Center.]

4pSCb2. Transition characteristics in speakers with dysarthria and in healthy controls: Part IV: Additional data on vital capacity transitions and stroke patients. Gary Weismer, Christina Kuo, and Phoebe Allen (Dept. of Communicative Disord., Univ. of Wisconsin-Madison, 1975 Willow Dr., Madison, WI 53706, gweismer@wisc.edu)

Formant transitions are known to provide important cues for speech perception, sound identification, and inferences to articulatory behavior. This study describes and examines three types of formant transitions [consonant-vowel (CV), vowel-consonant (VC), and diphthong transitions] in four groups of speakers: healthy, ALS, Parkinson's disease, and stroke. This is an extension from previous work by Weismer *et al.* [J. Acoust. Soc. Am. **121**, 3135 (2007)] and Weismer *et al.* [J. Acoust. Soc. Am. **124**, 2558 (2008)], who showed shallower slopes for CV and diphthong transitions in persons with dysarthria (ALS and PD). To better understand the characteristics of the different transition types in healthy and disordered populations, two questions are addressed here. First, are CV transitions associated with dysarthria different from those in healthy speakers in a way comparable to the observed differences in diphthong transitions? Second, do VC transitions show the same normal characteristics, and are the differences between healthy speakers and speakers with dysarthria the same as in CV transitions? Distributional analyses for 50-ms CV, 50-ms VC, and diphthong (highest-lowest/lowest-highest) F2 transition measures will be presented for 18 healthy speakers, 4 speakers with ALS, 4 speakers with PD, and 20 stroke patients. [Work supported by NIDCD R01 DC003723.]

4pSCb3. Measuring speech and language characteristics of effects of medications on cognition. Serguei Pakhomov, Susan Marino, Angela Birnbaum, Chamika Hawkins-Taylor, and Ilo Leppik (Serguei Pakhomov, Univ. of Minnesota, Minneapolis, MN 55455, pakh0002@umn.edu)

Many of the drugs prescribed for various diseases and syndromes, including chronic pain and epilepsy, significantly impair cognitive functioning with large individual variation. Language is a highly individualized and directly observable product of human cognition that is central to our everyday functioning. A system for automated language and speech analysis (SALSA) was developed that relies on using an automatic speech recognition engine (HTK 3.4) [Young *et al.* (2008)] to perform forced-alignment between the audio of spontaneous speech samples and their transcripts to measure a number of speech and language characteristics including fluency, speaking rate, change in fundametal frequency, and information content of spontaneous narratives. The system was piloted on a population of 14 healthy volunteers who participated in a randomized, placebo-controlled study of cognitive effects of an anti-epileptic medication (topiramate). Our preliminary results suggest that SALSA captures a number of fluency and lexical characteristics sensitive to the effects of topiramate, thus providing an objective mechanism to quantify the degree of cognitive impairment in individulas affected by medications. Our current results are consistent with prior work investigating speech and language correlates of mild cognitive impairment [Roark *et al.* (2007)] and fronto-temporal dementia [Pakhomov *et al.* (2009)]. [Work supported by a grant from the Univ. of Minnesota Academic Health Crt.]

4pSCb4. The differential effect of altered auditory feedback on speech in early- and late-onset of Parkinson disease. Emily Q. Wang (Dept. of Commun. Disord. and Sci., Rush Univ. Medical Ctr., 1653 West Congress Parkway, 203 SENN, Chicago, IL) and Leo Verhagen Metman (Rush Univ. Medical Ctr., Chicago, IL)

Advanced speech symptoms in Parkinson disease (PD), such as "festinating speech" or palilalia and frequent hesitations, are a clinical challenge. This report is a part of a larger study testing the hypothesis that the use of altered auditory feedback (AAF) would improve speech intelligibility in patients with PD and more advanced speech impairment. Our initial report showed that the use of AAF indeed improved speech intelligibility in these patient's spontaneous speech [Wang *et al.* (2008)]. In this report, the spontaneous speech samples produced by four older-onset (aged 72.4 SD 6.02 years) vs four young-onset PD patients (aged 54.2 SD 4.44 years), with and without the use of AAF, were analyzed. The results indicated that, regardless of the use of AAF, the older-onset patients performed poorer than the young-onset patients in many areas including the mean length of utterance in words, number of different word roots, within utterance pause time, and words per minute. These findings are consistent with the report that patients with an older age at onset had more rapid progression of PD than those with a younger age at onset in mentation, freezing, and activities of daily living. Possible underlying mechanism for the findings will be discussed.

4pSCb5. Temporal analysis of simultaneous nasopharyngoscopic and nasometric recordings. Wei Tian (Dept. of Hearing and Speech Sci., Univ. of Maryland, 0141D Lefrak Hall, College Park, MD 20742)

The velopharyngeal port closes and opens by the velar and pharyngeal wall motion during speech. Velopharyngeal dysfunction (failure to close or open appropriately) often involves insufficient motion or mistiming of the motion. Despite the fact that evaluation of the velopharyngeal port size by nasopharyngoscopy has been popular in clinical settings, the temporal pattern of velar and pharyngeal motion has never been studied. On the other hand, separate nasal and oral recording of speech acoustics with a Nasometer is reported to demonstrate speech nasality change in customized utterances. The present study aimed at investigating the correlations between velopharyngeal motion and speech acoustic change by simultaneous recordings of nasopharyngoscopy and nasometry. Kymographic analysis of the motion in the velum and lateral pharyngeal walls were performed in two female adult speakers during five repetitions of six VCVNVCV at a controlled speech rate. Although the velar and pharyngeal motions show the similar pattern, they do not initiate and end simultaneously. There is strong correlation between the physiologic motion and acoustic change, but they are not synchronized and have very different temporal patterns. There is also difference across speakers and phonemes.

4pSP1. Bayesian parameter estimation in adaptive psychometric procedures: Simulated and experimental results. Jeremiah J. Remus (Dept. of Elec. and Comput. Eng., Clarkson Univ., Box 5720, Potsdam, NY, 13699) and Leslie M. Collins (Duke Univ., Durham, NC 27708)

The wide use of psychometric assessments and the associated time required to conduct such experiments have motivated a substantial research effort focused on developing more efficient psychometric procedures to expedite the estimation of parameters of interest. Adaptive step size psychometric procedures, which have increasingly received attention as an alternative to fixed step size procedures, can be viewed as having two separate stages: estimation of the parameters of interest based on the available data and a selection of the experimental settings in order to maximize the information obtained from the next trial. Psychometric procedures that utilize a Bayesian framework for parameter estimation have become more prevalent in recent years. In this talk, we will present experimental results for Bayesian psychometric procedures from both psychoacoustics studies and computer simulations. Several com-

puter simulations explored the sensitivity of the procedure to different model parametrizations and evaluated performance using stimulus selection rules based on minimizing entropy and maximizing information gain. Psychoacoustic studies using two different listening tasks were used to investigate the robustness and stability of estimates provided by the Bayesian parameter estimation procedure. Collectively, the outcomes suggest that a Bayesian framework may be an important component in the development of more efficient psychometric procedures.

4pSP2. Nested sampling for room-acoustics energy decay analysis. Ning Xiang, Tomislav Jasa, and Jonas Braasch (Graduate Program in Architectural Acoust., Rensselaer Polytechnic Inst., Troy, NY)

Room-acoustic energy decays often exhibit single-rate or multiple-rate behavior in a wide variety of enclosures. There has been an ever increasing need to investigate where and under what conditions the single-rate and or multiple-rate energy decays occur and to quantify/characterize the energy decay process by estimating a set of decay parameters. In this architectural acoustics application, both energy decay model selection and decay parameter estimation are of practical significance. This paper discusses a model-based sound energy decay analysis within a Bayesian framework and applies the most recent Bayesian sampling method (nested sampling) to sound energy decay analysis. The nested sampling reverses the historical Bayesian computation approaches, yielding the Bayesian evidence as the prime target with representative posterior samples available as optional by-products. Bayesian evidence is crucial for model selection, while the representative posterior samples are of central importance for parameter estimation. Taking the energy decay analysis in architectural acoustics as an example, this paper demonstrates that two different levels of inference, decay model-selection and decay parameter estimation, can be cohesively accomplished by nested sampling.

Contributed Papers

4pSP3. Comparison of fading statistics for shallow and deep acoustic sources in a continental shelf environment. Alexander W. Sell, R. Lee Culver, Colin W. Jemmott, and Brett E. Bissinger (Graduate Program in Acoust., Penn State Univ., 201 Appl. Sci. Bldg., University Park, PA 16802, aws164@psu.edu)

Previous work has shown a noticeable difference in the effects of the ocean environment on signals from shallow and deep moving sources. These effects are seen in received amplitude statistics, and such statistics can be used in passive acoustic depth classification. This talk presents a statistical analysis of signals from a September 2007 shallow water acoustic transmission test performed along the continental shelf off the coast of southeast Florida. The data used include low frequency (between 25 and 450 Hz), continuous-wave signals from a towed source at 100 m depth, as well as tones from surface ships in the area. Using statistical class models in a Minimum Hellinger Distance Classifier, the usefulness of received signal amplitude statistics for passive acoustic source-depth classification is discussed. [Work supported by ONR Undersea Signal Processing.]

2:25

4pSP4. Depth discrimination in shallow water by matched-field tracking. Donald R. DelBalzo and James H. Leclere (QinetiQ North America, Hwy. 190 East, Slidell, LA 70461, donald.delbalzo@qinetiq-na.com)

Passive acoustic sonars have difficulty in detecting quiet sources in noisy shallow-water environments. The standard approach to improving detection performance is to use a large aperture linear array of horizontally distributed hydrophones and azimuthal processing to increase the signal-to-noise ratio (SNR) through beamforming. A newer approach is to apply matched-field correlation techniques and estimate source locations in depth and range using signals received on a linear vertical array. These localization techniques are not designed for detection of quiet targets and some potential applications preclude the use of vertical arrays for practical reasons, like damage caused by fish trawling. In this work, we examine the utility of matched-field processing on linear and planar horizontal arrays on the ocean bottom in shallow water. We employ a track-before-detect strategy to convert matched-field localizations into submerged source detections in various physical and acoustic environments. We show the advantages of planar compared to linear arrays to discriminate submerged from surface sources as a function of SNR.

2:40

4pSP5. A feasibility study on the low probability of intercept sonar. J. Daniel Park, David J. Miller, John F. Doherty (Dept. of Elec. Eng., The Penn State Univ., University Park, PA 16802), and Stephen C. Thompson (The Penn State Univ., State College, PA 16804)

The feasibility of low probability of intercept for sonar is explored. Using a noise-like active sonar signal, the transmitter (platform) employs a matched filter for echo detection while the target is assumed to use an energy detector. Decision statistic distributions are developed and detection performances are compared with a previous work (Gaussian distribution assumed). We then explore the detection advantage the platform can achieve by evasive on-off keying and by optimization of transmitted power. A favorable operating region of the platform in the (low power, small range) region of the (range, power) plane is identified. This suggests that the platform should start detection using a low-power probing signal, increasing power until a reliable detection rate is first achieved while ensuring that the detection rate at the target does not exceed a specified level. Second part of the feasibility study is about covert range estimation. Two matched-filter based algorithms were developed for the platform to obtain credible range estimations while ensuring the target fails to detect the platform. A platform-target encounter scenario was designed for detailed waveform-based Monte Carlo simulation. Characterization of variables in the model was performed to show the feasible conditions of covert range estimation. [Work sponsored by ONR, ULI.]

Meeting of Accredited Standards Committee (ASC) S1 Acoustics

P. Battenberg, Chair, ASC S1
Quest Technologies, Inc., 1060 Corporate Center Dr., Oconomowoc, WI 53066 4828

R. J. Peppin, Vice Chair, ASC S1
Scantek, Inc., 6450 Dobbin Rd., #A, Columbia MD 21045

Accredited Standards Committee S1 on Acoustics. Working group chairs will report on the status of standards currently under development in the areas of physical acoustics, electroacoustics, sonics, ultrasonics, and underwater sound, etc. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43, Acoustics and IEC/TC 29 Electroacoustics, take note - those meetings will be held in conjunction with the Standards Plenary meeting at 8:00 a.m. on Thursday, 22 April 2010.

Scope of S1: Standards, specifications, methods of measurement and test, and terminology in the field of physical acoustics, including architectural acoustics, electroacoustics, sonics and ultrasonics, and underwater sound, but excluding those aspects which pertain to biological safety, tolerance and comfort.

Meeting of Accredited Standards Committee (ASC) S3 Bioacoustics

C. A. Champlin, Chair, ASC S3
University of Texas, Dept. of Communication Sciences & Disorders, CMA 2-200, Austin, TX 78712

D. A. Preves, Vice Chair, ASC S3
Starkey Laboratories, Inc., 6600 Washington Ave., S., Eden Prairie, MN 55344

Accredited Standards Committee S3 on Bioacoustics. Working group chairs will report on the status of standards under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

People interested in attending the meeting of the TAGs for ISO/TC 43, Acoustics and IEC/TC 29 Electroacoustics, take note - those meetings will be held in conjunction with the Standards Plenary meeting at 8:00 a.m. on Thursday, 22 April 2010.

Scope of S3: Standards, specifications, methods of measurement and test, and terminology in the fields of psychological and physiological acoustics, including aspects of general acoustics which pertain to biological safety, tolerance and comfort.

Meeting of Accredited Standards Committee (ASC) S3/SC 1, Animal Bioacoustics

D. K. Delaney, Chair, ASC S3/SC 1
USA CERL, 2902 Farber Dr., Champaign, IL 61822

M. C. Hastings, Vice Chair, ASC S3/SC 1
6422 Crosswoods Dr., Falls Church VA 22044 1214

Accredited Standards Committee S3/SC 1 on Animal Bioacoustics. Working group chairs will report on the status of standards under development. Consideration will be given to new standards that might be needed over the next few years. Open discussion of committee reports is encouraged.

Scope of S3/SC1: Standards, specifications, methods of measurement and test, instrumentation and terminology in the field of psychological and physiological acoustics, including aspects of general acoustics, which pertain to biological safety, tolerance and comfort of non-human animals, including both risk to individual animals and to the long-term viability of populations. Animals to be covered may potentially include commercially grown food animals; animals harvested for food in the wild; pets; laboratory animals; exotic species in zoos, oceanaria or aquariums; or free-ranging wild animals.

THURSDAY EVENING, 22 APRIL 2010 7:30 P.M.

OPEN MEETINGS OF ASA TECHNICAL COMMITTEES

The Technical Committees of the Acoustical Society of America will hold open meetings on Tuesday, Wednesday, and Thursday evenings. On Tuesday and Thursday the meetings will be held immediately after the Social Hours. On Wednesday, one technical committee will meet at 7:30 p.m.

These are working, collegial meetings. Much of the work of the Society is accomplished by actions that originate and are taken in these meetings, including proposals for special sessions, workshops, and technical initiatives. All meeting participants are cordially invited to attend these meetings and to participate actively in the discussions.

Committees meeting on Thursday are as follows:

Animal Bioacoustics	Grand Ballroom I/II
Architectural Acoustics	Grand Ballroom III/IV
Biomedical Ultrasound/Bioresponse to Vibration	Kent A/B
Speech Communication	Laurel A/B
Underwater Acoustics	Laurel C/D

Session 5aAA

Architectural Acoustics, Noise, and INCE: Case Studies, Applications, and Integration of Architectural Acoustics in Building Information Modeling Three-Dimensional Modeling

Norman H. Philipp, Chair
Univ. of Nebraska-Lincoln, Peter Kiewit Inst., 1110 S. 67th St., Omaha, NE 68182-0791

Chair's Introduction—7:30

Invited Papers

7:35

5aAA1. Building information management: An acoustics consultant's perspective. Benjamin Markham (Acentech Inc., 33 Moulton St., Cambridge, MA 02138)

Architecture and engineering firms use building information management (BIM) software applications increasingly in the design process; similarly, building owners create BIM models for existing facilities both for internal use and to aid future tenants, facilities managers, and designers in planning for maintenance programs, restoration, or renovation. As for other design and engineering disciplines, these tools provide powerful opportunities to the acoustics community. The primary benefits to architectural acoustics consultants fall into two broad categories: first, in the construction process by providing a means of organizing the specifications for materials and constructions, and second, in the design process, by establishing a framework of data and acoustical attributes that in the future could potentially aid in acoustical calculation and analysis.

7:55

5aAA2. Building information modeling with revit architecture and acoustical coordination. Katherine LePage (GWWO, Inc. Architects, 800 Wyman Park Dr., Ste. 300, Baltimore, MD 21211, klepage@gwwoinc.com)

The adoption of BIM has provided a huge shift within the architectural design community. It provides an opportunity for more thoughtfully designed buildings as well as comprehensive coordination with consultants. This presentation will cover the basics of how programs like revit architecture are being used by the architectural community in general and more specifically for acoustical coordination. Topics covered will include visualization, basic modeling, consultant coordination, and construction administration. The work of GWWO Inc./Architects will be used as a basis for providing real world examples of how the program has been used through all stages of design and construction. The 70 000-sft^2 Daniel Z. Gibson Performing Arts Center at Washington University will be a featured project. The center provides a home for both the Music and Drama Departments and includes state of the art teaching and performance spaces. Challenges for the project included transforming an existing 600 seat house theater into a more intimate 440 seat theater with a balcony level, designing an acoustically pleasing 200 seat recital hall while minimizing the sound focusing of a concave glass wall along one side of the hall and the addition of a 175 seat flexible experimental theater.

8:15

5aAA3. Revit and the role of architectural acoustics in the design process. Jeff Larrick (Autodesk, West Palm Beach, FL 33401, jeff.larrick@autodesk.com)

A presentation by Autodesk discussing the role of Revit in the building information modeling design process and how it allows for collaboration between the architect and acoustical consultant.

Contributed Papers

8:35

5aAA4. Distilling the acoustical model from BIM (Building Information Modeling) Standard architectural, mechanical and structural models: Robust acoustical templates, limitations, and recommendations. Richard A. Vedvik and Jon W. Mooney (KJWW Eng. Consultants, 623 26th Ave., Rock Island, IL 61201, vedvikra@kjww.com)

The integration of architectural acoustics into building integration modeling (BIM) software and the implementation of such integration is discussed between available systems and platforms. The process of integrating the various platforms of building integration modeling software, in such a manner that the assigned properties can be shared, manipulated, and exported, is of great interest to acousticians. As the architectural model is created, a standardization of materials and generic construction methods is desirable so the relevant properties assigned to the various building components are able to be imported and adjusted by robust acoustical templates (RATs). Additional complications are identified as the acoustical model is detached from the live model. Standardization is also important between the architectural, structural, and mechanical models in order to create a common shared model that is able to maintain the relevant properties, both physical and analytical. Finally, the operation of a RAT prototype is demonstrated in the distillation of an acoustical model from standard BIM architectural, mechanical, and structural models.

8:50

5aAA5. Error estimation due to sample size effects of *in situ* surface impedance measurements. Eric Brandao, Erico Fulco, Arcanjo Lenzi (Federal Univ. of Santa Catarina, Joao Pio Duarte Silva St., 250, Bl3, Ap 201 Corrego Grande Florianopolis-SC, 88037-001 Brazil, eric@lva.ufsc.br), and Emiel Tijs (Microflown Technologies)

The boundary element method (BEM) is used to predict the effect of the sample size on *in situ* impedance measurements on a locally reactive sample

5a FRI. AM

at normal incidence. The BEM model is based on a direct measurement of the acoustic impedance above the sample (with a combined sound pressure and particle velocity sensor). As the sound source is placed close to the sensor, the acoustic waves cannot be considered plane anymore. Because of that, two models to obtain the surface impedance based on the acoustic field are presented and compared. It is also shown that the sample size, the thickness of the sample, and the positions of the source and receiver affect the measured surface impedance and the calculated absorption coefficient. Those effects are parametrized in a way that the user of the *in situ* measurement setup may have an estimate of the required sample size for a desired frequency range with a given error allowance.

9:05

5aAA6. Examining the relationship between total acoustic absorption and late lateral energy (GLL). David A. Dick and Michelle C. Vigeant (Dept. Mech. Eng. Acoust. Prog. and Lab., Univ. of Hartford, 200 Bloomfield Ave., West Hartford, CT 06117, vigeant@hartford.edu)

Listener envelopment, the sense of being immersed in the sound field, has been shown to correlate with the objective parameter late lateral energy (GLL). Barron proposed that GLL is primarily a function of the ratio of reverberation time to auditorium volume or the total acoustic absorption [Barron, Appl. Acoust. **62**, 185–202 (2001)]. An investigation has been conducted to examine this proposed theory with measurement data and predicted values from a room acoustics computer modeling program. Room impulse response measurements have been taken in the Belding Theatre in downtown Hartford, CT. Features of the hall include variable absorption in the form of curtains, both within the hall and also within small adjacent coupled volumes. Measurements were taken in several absorption configurations. A detailed room acoustics computer model of the hall has been created in ODEON v9.22 to examine the accuracy of the model's prediction of GLL. The model was initially validated using the measured parameters of reverberation time (T30), early decay time (EDT), and clarity index (C80). A comparison of the measured and predicted results will be discussed, along with an analysis of the relationship between GLL and total acoustic absorption. [Work supported by a University of Hartford Greenberg Junior Faculty Grant.]

9:20

5aAA7. Classroom acoustics in the developing world: A student project to develop simple assessments and treatments. Nathan McNeill, Matthew Blevins, Emily Drott, Alex Kremer, Mark Kusch, Brian Pluhar, Ashley Ringer, Valerie Sargent, and J. Stuart Bolton (Purdue Univ., Neil Armstrong Hall of Eng., Rm. 1300, 701 W. Stadium Ave., West Lafayette, IN 47907-2016, nmcneill@purdue.edu)

An inadequate educational system can be crippling to a developing country struggling to advance in the modern world. Poor classroom acoustics are a significant factor that can contribute to an inadequate education. Classroom acoustics is a mature field of research in the developed world; however, the classroom conditions and resources found in the developing world present new research challenges. A special project course was developed at Purdue University to give undergraduate students the opportunity to learn about and address classroom acoustics problems in underdeveloped regions. The goal of this special project course was to develop an evaluation and design manual that can be distributed to teachers and educational officials in those regions. The purpose of the manual is to help identify acoustic problems in classrooms, provide suggestions of simple noise control solutions, and outline best practices for the design of new classrooms. The manual specifically addresses problems related to excessive reverberation, poor signal-to-noise ratios, and noise transmission from outside the classroom. The ultimate intent of this project was to increase awareness of the unique classroom acoustic conditions in the developing world.

9:35

5aAA8. Experimental validations of the transport equation model for room-acoustic predictions in long spaces. Yun Jing and Ning Xiang (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., Troy, NY 12180)

This paper presents an experimental study on steady-state sound pressure levels and reverberation times in a tenth long-space scale model. The purpose of this work is to validate a recently developed one-dimensional transport equation model for acoustic predictions in long spaces. A series of measurements has been conducted in the scale model to reveal receiver-position dependence of measured and modeled parameters in the long spaces. Experimental results at different octave bands are obtained. This paper will compare the acoustically measured results with that of simulations.

9:50

5aAA9. An experimental scaled-model for coupled volumes with an automated high-spatial-resolution scanning system. Joonhee Lee, Craig Schaefer, and Ning Xiang (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., Troy, New York 12180, gi20plus@gmail.com)

This paper presents an experimental study of low-frequency behavior in coupled volumes. In order to examine low-frequency behavior in coupled volumes, an eighth-scale model of two coupled volumes with an automated high-spatial-resolution scanning system has been developed. The validated scanning system makes it possible to acquire thousands of room impulse responses on a designated planar grid with a fine grid size in the scaled model. The high-spatial-resolution scanning results are used to investigate the characteristics of acoustic wave propagation in both single-space and coupled-volume systems. This paper discusses some design issues relevant to high-quality, high-spatial resolution scanning, to diffusely reflecting interior surfaces, and to variable coupling aperture sizes. Some representative scanning results of sound pressure propagations and sound energy flows will also be demonstrated.

10:05—10:20 Break

10:20

5aAA10. Some preliminary investigations on the use of a diffusion equation model for room-acoustic parameters prediction. José Escolano (Dept. Telecommunication Eng., Univ. of Jaén, 23700, Linares, Spain, escolano@ujaen.es), Juan M. Navarro (San Antonio's Catholic Univ. of Murcia, 30107 Guadalupe, Spain), José J. López (Universidad Politécnica de Valencia, 46021 Valencia, Spain), and Ning Xiang (Rensselaer Polytechnic Inst., Troy, NY 12180)

Over the very recent years, an alternative model to describe sound fields in enclosures, based on the mathematical theory of diffusion, has been proposed. This model is based on the concept of sound particles traveling along straight lines and striking walls or scattering objects existing in a room. The scope of this work is to present some preliminary investigations in the prediction of objective room-acoustics parameters, such as reverberation time, clarity, and definition through the use of a diffusion equation. This paper will discuss modeling accuracy of the room-acoustics parameters using some numerical examples. Moreover, some issues concerning the numerical implementation by means of finite difference schemes for the diffusion equation are addressed.

10:35

5aAA11. Micro-perforated stretched foils as sound absorbers and barriers. Christian Nocke, Catja Hilge (Akustikbuero Oldenburg, Katharinenstr. 10, 26121 Oldenburg, Germany, nocke@akustikbuero-oldenburg.de), and Jean-Marc Scherrer (BARRISOL S.A.S, F-68680 Kembs, France)

A typical set-up of a micro-perforated sound absorber is a micro-perforated sheet or panel in front of a closed air cavity. The sound absorption coefficient of these set-ups can be easily calculated with a high accuracy according to the well-known approximation of D.-Y. Maa if all defining geometrical parameters (diameter of microperforation, distance between orifices, panel thickness, and air cavity depth) are known. Other applications are freely suspended sails of micro-perforated sheets as well as double layer structures mad of micro-perforated materials. In this contribution measured sound absorption coefficients of different set-ups as well as measurements of level decrease will be presented and discussed. For some of these assemblies

no closed calculation model exists so far. Comparisons between computer-based calculations of layered absorber set-ups show good results for some assemblies. Finally room acoustic applications of micro-perforated stretched sheets are shown.

10:50

5aAA12. Insertion loss estimation of an opened enclosure using a statistical ray-tracing model. Buye Xu, Scott D. Sommerfeldt, and Timothy W. Leishman (Dept. of Phys. and Astronomy, Brigham Young Univ., Provo, UT 84606, buye.xu@gmail.com)

Estimating the insertion loss (IL) of an enclosure with one or more openings is important for many noise control applications. In the low-frequency range (below the Schroeder frequency) where modal effects are dominant, numerical simulations based on modal expansions or the finite element method are feasible for obtaining the desired predictions. Above the Schroeder frequency, statistical room acoustics theories are more desirable because numerical simulations are not applicable or are computationally expensive. However, existing room acoustics theories can only deal with simple cases where a diffuse field can be assumed. The acoustic field inside enclosures is generally sufficiently complicated in practice such that the diffuse field assumption is not valid. Examples of the complex conditions include narrow spatial regions, non-uniform boundaries, and the existence of obstacles in the enclosure. In this paper, a model that adopts the basic ideas of both ray-tracing and Sabine's room acoustics theory will be introduced to deal with the difficulties mentioned. This new model greatly improves the ability to estimate acoustic performance when the enclosure conditions are not ideal, yet requires much less computation than the normal ray-tracing model. Comparisons of different models with experimental data will be presented.

11:05

5aAA13. High-resolution absorption mapping with a pu surface impedance method. Emiel Tijs (Microflown Technologies, 6826 CC Arnhem, Arnhem, The Netherlands, tijs@microflown.com)

The *in situ* method to measure the surface impedance with a pu probe documented is published in many publications. The method is based on the measurement of sound pressure (p) and particle velocity (u) close to an acoustic absorbing material. A loudspeaker at a defined distance is applied to generate a sound field with a known radiation impedance. The impedance of a small area (a few square cm^2) with a known impedance is scanned with an ultraminiature pu probe very close to the surface. The area is made of steel with a cut-out, behind this a material with a known impedance is placed. In this paper the method is explained, the spatial accuracy of the measurement is examined, and a visualization technique is presented with a display of the spatial distribution (two dimensional picture) of the damping properties as function of frequency. Finally the high-resolution measurements are combined and compared with a method that covers a larger surface area.

11:20

5aAA14. Is it 6 decibels? The effect of pressure doubling on exterior to interior transmission loss values. Noel Hart, Kimberly Lefkowitz, Arno S. Bommer, and Robert D. Bruce (CSTI Acoust., P.O. Box 218808, Houston, TX 77218-8808, noel@cstiacoustics.com)

When calculating sound levels inside a building due to external sources, should some value be added to the expected sound level? ATSM E966 recommends adding 6 dB to this level. It has been theorized that this is due to pressure doubling. The effect of pressure doubling on the calculated exterior to interior sound transmission in the direct field is, however, often misunderstood. Most texts on the subject simply list a 5- or 6-dB correction factor that is applied to the transmission loss value. The reasoning of this particular number is neither expounded upon nor explained. This paper investigates and explains this correction factor.

11:35—12:00 Panel Discussion

FRIDAY MORNING, 23 APRIL 2010 GRAND BALLROOM I/II, 8:45 A.M. TO 12:00 NOON

Session 5aAB

Animal Bioacoustics, Signal Processing in Acoustics, and Noise: Topical Meeting on Signal Processing of Subtle and Complex Acoustic Signals in Animal Communication III: Incorporating Contextual Features into Automated Detection and Classification Algorithms

Ann E. Bowles, Cochair
Hubbs Sea World Research Inst., 2595 Ingraham St., San Diego, CA 92109

Sean K. Lehman, Cochair
Lawrence Livermore National Lab., Livermore, CA 94550

Chair's Introduction—8:45

Invited Papers

8:50

5aAB1. Multipath features as a contextual clue for classification. Christopher O. Tiemann (Appl. Res. Labs., Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78731)

A single odontocete click is often heard as multiple click echoes due to the many paths sound travels between the source (whale) and receiver; these echoes are called multipath arrivals, and together they form an arrival pattern. Because each arrival can appear differently due to propagation effects, efforts to associate recorded clicks with individual whales can be frustrated by the presence of multipath arrivals, particularly when many whales click simultaneously. Automated classifiers may associate arrivals from one click event into many groups, even though they come from one source, thus overestimating the number of whales in a recording. However, collectively a multipath arrival pattern can be exploited to huge advantage when trying to do individual association. Typically, the relative spacing

of arrivals changes slowly over time (due to slow movement of the source) and is unique for a given source location. The persistence of stable arrival patterns over successive click events provides a contextual clue for associating many arrivals to a single individual or can validate automated classification techniques. Finding unique arrival patterns should provide an accurate estimation of the number of sources in an area and even serves as the first step in passive acoustic tracking of whales.

9:10

5aAB2. Contextual rhythmic analysis of beaked whale clicks for passive acoustic identification. Natalia Sidorovskaia, Philip Schexnayder (Dept. of Phys., Univ. of Louisiana at Lafayette, UL Box 44210, Lafayette, LA 70504-4210, nas@louisiana.edu), George E. Ioup, Juliette W. Ioup (Univ. of New Orleans, New Orleans, LA 70148), Christopher O. Tiemann (Univ. of Texas at Austin, Austin, TX 78713), Alexander E. Ekimov, and James Sabatier (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, Oxford, MS 38677)

The Littoral Acoustic Demonstration Center (LADC) has collected an extensive acoustic library of marine mammal phonations in the Northern Gulf of Mexico, including the Cuvier's and Blainville's beaked whale clicks. An automatic algorithm, which performs cadence frequency analysis, has been developed and successfully applied to sperm whale clicks to identify temporal evolution of individual rhythmic patterns in overlapping trains of simultaneously clicking whales in a group. In this study the results of the association of cadence frequencies with individual beaked whales in a group for the LADC 2007 Gulf of Mexico recordings are reported. The algorithm is a part of an integrated tool proposed by LADC for identification of individual animals in a group. The cadence frequency association results are compared to multi-attribute self-organizing map clustering and to time-of-arrival analysis and localization. A multi-band version of the algorithm is also presented. It provides species association cues for complex cluttered acoustic environments where different species phonate with similar inter-click intervals. The proposed approach is beneficial for passive acoustic studies of beaked whale populations and social behavior and may contribute to understanding acoustic communication of these evasive animals. [Research supported by ONR and SPAWAR.]

9:30

5aAB3. Using click change detection to modify cluster analysis for acoustically identifying individual sperm whales with changing aspect. George E. Ioup, Juliette W. Ioup, Lisa A. Pflug (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, geioup@uno.edu), Christopher O. Tiemann (Univ. of Texas at Austin, Austin, TX), and Natalia A. Sidorovskaia (Univ. of Louisiana at Lafayette, Lafayette, LA)

As described by Mohl *et al.* J. Acoust. Soc. Am. **114**, 1143–1154 (2003)], the acoustic properties of the received clicks of a turning sperm whale change as the whale rotates. These changing properties (the time signal, the discrete Fourier transform, and the discrete wavelet transform are studied here) confound cluster analysis attempts to identify individual whales by grouping like clicks in classes representing individuals. The 4th International Workshop on Detection, Classification and Localization of Marine Mammals Using Passive Acoustics has associated workshop data containing a sequence of sperm whale clicks which most likely come from the same individual (as shown by careful manual click analysis) turning with respect to the acoustic recording buoy. The time domain sequence of clicks indicates that the angle of a line from the head of the whale to the buoy appears to be changing from greater than 90 deg to less than 90 deg and back again. Time evolution and click change detection are applied to follow the whale and give correct automatic identification. This analysis is incorporated into the clustering process. [Research supported by ONR and SPAWAR.]

9:50

5aAB4. Acoustic identification of individual beaked whales using self-organizing maps for automated classification of clicks in Littoral Acoustic Demonstration Center (LADC) data. Juliette W. Ioup, George E. Ioup, Lisa A. Pflug (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, jioup@uno.edu), Natalia A. Sidorovskaia, Philip Schexnayder (Univ. of Louisiana at Lafayette, Lafayette, LA), Christopher O. Tiemann, and Alan Bernstein (Univ. of Texas at Austin, Austin, TX)

The Littoral Acoustic Demonstration Center (LADC) acquired underwater acoustic data from clicking sperm and beaked whales in the Gulf of Mexico during an experiment in July 2007. Analysis of sperm whale echolocation and coda clicks in the data has been presented at previous ASA meetings. Research emphasis is now on identifying individual beaked whales from their echolocation clicks. Again, clustering methods present one appropriate approach to the automated identification of these whales by computer. Self-organizing maps have the ability to limit the number of clusters automatically, and their successful use with sperm whales encourages the application to beaked whales as well. Results for time, frequency, and wavelet domain data allow comparison among clustering done using different signal representations and help highlight areas of concern in the analysis. As in the case of sperm whales, the beaked whale identifications are verified by comparing to cadence analysis (as presented in an accompanying abstract) and to a limited extent by manual analysis and localization. [Research supported by ONR and SPAWAR.]

10:25

5aAB5. Automated detection of sperm whales (*Physeter macrocephalus*) creaks and association with depredation events. Delphine Mathias, Aaron Thode (Marine Physical Lab., Scripps Inst. of Oceanogr., 9500 Gilman Dr. La Jolla, CA, 92037-0238, delphine.mathias@gmail.com), Jan Straley (Univ. of Alaska Southeast, Sitka, AK 99835), John Calambokidis, Gregory S. Schorr (Cascadia Res. Collective, Olympia, WA, 98501), and Bill Burgess (Greeneridge Sci. Inc., Goleta, CA 93117)

Sperm whales have been depredating black cod (*Anoplopoma fimbria*) from demersal longlines in the Gulf of Alaska for decades, but the behavior has now become pervasive enough that it is starting to affect government estimates of the sustainable catch, motivating further studies of this behavior. In July 2007 and June 2009, bioacoustic tags were attached to adult sperm whales off Southeast Alaska under both natural foraging conditions and situations wherein the animals were depredating sablefish from commercial longlining vessels. Tags remained attached for a cumulative hours, yielding more than 100 h of depth, orientation, and acoustic data. Results show that when depredating, sperm whales often dive at depths shallower than 50 m, compared to natural foraging depths of 300–400 m in the area. Dive durations, pitch, and roll rates are also distinctively different. Techniques such as spectrogram cross-correlation and cepstral analysis are used to automatically detect creak events, which have lower intensities and narrower frequency ranges than conventional clicks. Acoustic measurements such as creak production rate, duration, and intensity are then extracted. Correlations are derived between creak events, sudden changes in body orientation and depredation rate, with a goal of determining an acoustic measure of depredation activity and efficacy. [Work conducted under the SEA SWAP Program, supported by the North Pacific Research Board and the National Geographic Society.]

Invited Paper

10:40

5aAB6. Detecting sequences of calls. David K. Mellinger (Coop. Inst. for Marine Resources Studies, Oregon State Univ., 2030 SE Marine Sci. Dr., Newport, OR 97365, david.mellinger@oregonstate.edu)

Many sound-producing animals make vocalizations with predictable timing patterns. In some cases, animals produce long, regular sequences of sounds, either for breeding (e.g., many baleen whales) or for foraging (e.g., most toothed whales and dolphins); in other cases, different call types are produced in succession with the intervals between calls following certain timing patterns. Here I describe methods for detecting these timing patterns. Both of these methods operate on a "detection function," the estimated likelihood at each instant of time that a call is present. Long, regular sequences can be detected using an autocorrelation of the detection function that significantly increases the detectability of sequences compared to single calls. Different call types occurring in irregular but predictable timed patterns can be detected using methods similar to dynamic time warping; again, the detectability of the patterns is notably higher than the detectability of single calls. [Work funded by ONR and the Navy's Environmental Readiness Division.]

11:00—12:00 Panel Discussion

Biomedical Ultrasound/Bioresponse to Vibration: Ultrasonic Characterization of Bone I

Keith A. Wear, Chair
Food and Drug Administration, 10903 New Hampshire Ave., Silver Spring, MD 20993

Chair's Introduction—8:25

Invited Papers

8:30

5aBB1. Extracting bone strength information from x-ray image data and applications in clinical research. Thomas J. Beck (Dept. of Radiology, Div. Medical Imaging Phys., Johns Hopkins Univ. School of Med, Baltimore, MD 21287)

Osteoporosis is a symptomless disease that reduces bone strength so that bones fracture easily, but it is often undiagnosed until fractures occur. Because effective treatments exist, it is important to detect the disease before fractures occur. Current diagnostic methods measure some observable parameter that is statistically correlated with the presence of disease. Most commonly the parameter is a form of bone density although ultrasonic parameters have also been used. Engineers have designed some excellent instruments that measure parameters with high accuracy and precision but even the best methods identify less than half of those at risk of fractures. This is not surprising when discrimination is based how average patients differ from normal rather than on what is actually wrong with them, i.e., reduced bone strength. Mechanical engineering methods can be used to predict bone strength if the material strength and the structural geometry can be measured. Currently there are no reliable non-invasive methods for measuring bone material properties so current mostly x-ray based methods measure structural geometry alone. A review of current methods will be presented together with an overview of what they tell us about osteoporosis as well as what we still need to know.

8:45

5aBB2. Quantitative ultrasound in the management of osteoporosis. Marc-Antoine Krieg and Hans Didier (Ctr. of Bone Diseases, CHUV, Av. Pierre-Decker 4, 1011 Lausanne, Switzerland)

Bone mineral density (BMD) is one of the major determinants of bone strength and fracture risk (FR), but it is not the only determinant, and overlap exists in BMD values between patients with and without fractures. It is therefore important to improve the strategy in better detecting patients at high FR who will benefit from treatments (TT). Quantitative bone US(QUS) are portable and less expensive than DXA. Only few QUS measuring the heel have reached a sufficient level of validation to be routinely used. They usually measure the attenuation (BUA) and the velocity (SOS) of the US wave. It is well established that valid heel QUSs predict fragility fracture in PM women and men >65, independent of BMD. Then, heel QUS can be used in combination with other clinical risk factors (CRFs) in a model of risk assessment. Then, when DXA is available, the primary clinical use of heel QUS is to identify, in conjunction with CRF, a population at low FR in which no further diagnostic evaluation is necessary. On the other hand, if central DXA cannot be done, pharmacologic TT can be initiated if the probability, as assessed by heel QUS in conjunction with CRF, is sufficiently high.

9:00

5aBB3. New developments in x-ray micro-computed tomography technology and its applications to study bone micro-architecture. Rasesh Kapadia (Scanco USA, Inc., 985 Old Eagle School Rd., Ste. 511, Wayne, PA 19087)

Developments in hardware and software capabilities, along with a significant increase in access to equipment and awareness of the methods, over the last 10 years have enabled micro-computed tomography (CT) technology to establish itself as one of the basic tools to study bone micro-architecture in the laboratory. A wide range of equipment is now available ranging from synchrotron based facilities to compact desktop scanners for small to large specimens and scanners for *in vivo* pre-clinical imaging. The various scanners offer the ability to acquire images with resolution ranging from sub-micron to 100 μm in acceptable scan times and where applicable, with acceptable x-ray doses. More recently, high-resolution scanners (under 100 μm) have become available for clinical research. Micro-CT is now widely used to investigate bone from pre-clinical models of various aging and pathologic conditions (osteoporosis, osteoarthritis, and arthritis) as well as models for tissue regeneration and bone fracture repair as well as high-throughput skeletal phenotyping. Pre-clinical *in vivo* imaging methods are now routinely used as a screening tool in drug discovery and development processes. The availability of sophisticated software for analyses and visualization of these images has made micro-CT a very versatile research tool for the pre-clinical laboratory and promises to do the same for clinical research.

9:15

5aBB4. Bone diagnostics using dual frequency ultrasound measurements. Jukka S. Jurvelin, Janne Karjalainen, Ossi Riekkinen, Markus Malo, Hanna Isaksson, and Juha Tyräs (Dept. of Phys. and Mathematics, Univ. of Eastern Finland, P.O. Box 1627, 70211 Kuopio, Finland, jukka.jurvelin@uef.fi)

Diagnosis of osteoporosis is made at skeletal sites composed mainly of trabecular bone. Calcaneus has been the first location for through transmission (TT) ultrasonic measurements of trabecular bone. Similarly as with the DXA, the best prediction of the hip fractures could be obtained by making the measurements at hip. To realize axial pulse-echo (PE) ultrasound measurements, e.g., in hip we have introduced the dual frequency ultrasound (DFUS) technique to minimize the effects of soft tissues overlying the bone and to correct the PE-parameters [Riekkinen *et al.*, Ultrasound Med. Biol. **34**, 1703–1708 (2008)]. Based on our experimental measurements at frequencies of 2.25 and 5.0 MHz and finite difference simulations, the DFUS technique detects minor changes in bone density, despite variable composition of soft tissue. For TT-geometry, the composition of the interfering soft tissues may also be solved with the DFUS, e.g., by measuring the reflection from the bone surfaces at both sides of the bone. The measurements with phantom materials indicated that accuracy of TT-parameters, such as broadband ultrasound attenuation, were significantly improved by DFUS. Potentially, the DFUS could also benefit the *in vivo* TT-measurements of trabecular bone. [Support from Academy of Finland is acknowledged.]

9:30

5aBB5. Comparison of conventional ultrasonic phase velocity and attenuation measurements of cancellous bone to estimates obtained using Bayesian probability theory. Christian C. Anderson (Washington Univ. in St. Louis, 1 Brookings Dr., St. Louis, MO 63130), Michal Pakula (Kazimierz Wielki Univ., Bydgoszcz, Poland), Pascal Laugier (Université Pierre et Marie Curie, Paris, France), G. Larry Bretthorst, Mark R. Holland, and James G. Miller (Washington Univ. in St. Louis, St. Louis, MO)

Cancellous bone supports the propagation of two compressional waves, commonly referred to as fast and slow waves, which can overlap in the acquired time-domain data. When such data are processed using conventional techniques, interference effects may cause artifacts to be present in the speed of sound and broadband ultrasound attenuation (BUA) measurements. Bayesian probability theory is a proposed method for extracting the ultrasonic properties of the individual fast and slow waves, even in the presence of substantial interference. In the current study, data were acquired *in vitro* at sites on a cancellous bone, and the acquired signals were used as input to a Bayesian probability approach for estimating parameters characterizing the fast and slow waves. For comparison, the signals were also processed using conventional methods. Although the conventionally obtained phase velocity and BUA frequently exhibited anomalous features, including negative dispersion, those estimated using probability theory exhibited no aberrant behavior. Hence, material properties obtained using Bayesian probability theory may provide more reliable estimates of bone quality and fracture risk than the apparent properties derived from the non-causal mixed mode signals. [Work supported by NIH R01HL40302 and R01AR057433, NSF CBET-0717830.]

9:45

5aBB6. Transfer functions for one-dimensional bone models. James L. Buchanan (Dept. Mathematics, US Naval Acad., 572C Holloway Rd., Annapolis, MD 21401, jlb@usna.edu), Robert P. Gilbert (Univ. of Delaware, Newark, DE 19711), and Miao-Jung Ou (Oak Ridge Natl. Lab., Oak Ridge, TN 37831)

A system for calculating wave pulses through one-dimensional layered media via a series of transfer functions is developed. This system obviates the need for numerical approximation beyond the use of discrete Fourier transforms, whence it is not necessary to deal with the poor numerical conditioning of the linear systems that arise in multi-layered models. A one-dimensional model of bone as a cancellous segment between two cortical segments insonified by an ultrasonic pulse is considered. For the cancellous

segment the Johnson–Dashen–Koplik modification of Biot's model for a poroelastic medium is used. The cortical segments are modeled both as dense fluids or porous media and the results compared.

10:00—10:15 Break

10:15

5aBB7. Fabric dependence of wave attenuation in anisotropic poroelastic media. Luis Cardoso and Stephen Cowin (Dept. of Biomedical Eng., CCNY, New York, NY 10031, scowin@earthlink.net)

The governing equations for wave motion in the linear theory of anisotropic poroelastic materials have been developed and extended to include the dependence of the constitutive relations upon fabric. Fabric is a quantitative stereological measure of the degree of structural anisotropy in the pore architecture of a porous medium. This anisotropic poroelastic theory is then applied to cancellous bone architecture to study the role of both porosity and fabric on the wave attenuation due to reflection, absorption, and scattering. The analysis of the fast and slow wave attenuation is performed as a function of the porosity of the medium and the frequency of the wave. This study demonstrates that the attenuation ratio between fast and slow waves strongly depends on the porosity and fabric of the trabecular structure. Wave attenuation predictions from this model confirm our previous experimental observations indicating that either the fast or slow wave may be the predominant wave mode in trabecular bone depending on the bone architecture. [This work was supported by grants from NSF (NSF/CUNY AGEP 0450360, NSF-MRI 0723027, and PHY-0848491). The authors also acknowledge the support from PSC-CUNY Research Award Program (PSC-CUNY-60014-38-39, 69486-00 38, and PSCREG-39-1103) and NIH 1SC2AG34198-1A1.]

10:30

5aBB8. Fabric dependence of tortuosity in poroelastic wave propagation. Stephen Cowin and Luis Cardoso (Dept. of Biomedical Eng., CCNY, New York, NY 10031, scowin@earthlink.net)

The governing equations for wave motion in the linear theory of anisotropic poroelastic materials have been developed and extended to include the dependence of the constitutive relations on fabric. Fabric is a quantitative stereological measure of the degree of structural anisotropy in the pore architecture of a porous medium. With the addition of the second order symmetric tensor fabric variable, the formulation of wave motions in the poroelastic theory is consistent with the presentations of Biot and later authors. In this work we show that tortuosity is a function of the fabric tensor. This relationship between tortuosity and fabric is employed to provide a geometric understanding of tortuosity in terms of pore space architecture. This geometric understanding is then applied to cancellous bone architecture. [This work was supported by grants from NSF (NSF/CUNY AGEP 0450360, NSF-MRI 0723027, and PHY-0848491). The authors also acknowledge the support from PSC-CUNY Research Award Program (PSC-CUNY-60014-38-39, 69486-00 38, and PSCREG-39-1103), and NIH 1SC2AG34198-1A1.]

10:45

5aBB9. Inverse problem of recovery of poroelastic parameters of cancellous bone by inversion of transmitted ultrasonic data. Zine El Abiddine Fellah, Erick Ogam (Laboratoire de Mecanique et d'Acoustique, UPR 7051 CNRS, 31 Chemin Joseph Aiguier, 13402 Marseille, France), Catherine Masson (INRETS-UMR T 24 LBA UFR de Medecine, 13916 Marseille Cedex 20, France), and Robert Gilbert (Univ. of Delaware, Newark, DE 19716)

This investigation addresses the inverse problem (IP) of the retrieval of the macroscopic poroelastic parameters of cancellous bone using transmitted ultrasonic waves. The IP is solved by minimizing the objective functional (OF), which is a measure of the discrepancy, in the least squares sense, between the trial and measured data pertaining to the transmitted USW. In this study the Biot–Johnson–Koplik was employed as the interaction model (IM). A close examination of the OF computed using this IM and measured ultrasonic data transmitted through the cancellous bone showed that it exhibited several local minima and maxima. Most off-the-shelf iterative nonlinear least squares optimization algorithms (such as the Levenberg–Marquadt or Nelder–Mead simplex methods) could not retrieve a nonambiguous solution. A simple method for resolving this problem without ambiguity by using two distinct transducer central frequencies is proposed. Finally the recovered acoustic parameters are compared with those obtained using classical methods.

11:00

5aBB10. Frequency dependence of phase shifts in human calcaneus *in vitro*. Keith A. Wear (FDA Ctr. for Devices and Radiological Health, Bldg. 62, Rm. 3108, 10903 New Hampshire Blvd, Silver Spring, MD 20993)

If dispersion in a medium is weak and approximately linear with frequency (over an experimental band of frequencies), then it can be shown that the constant term in a polynomial representation of phase shift as a function of frequency can produce errors in measurements of phase velocity differences in through-transmission, substitution experiments. A method for suppressing the effects of the constant phase shift in the context of the single-wave-model was tested on measurements from 30 cancellous human calcaneus samples *in vitro*. Without adjustment for constant phase shifts, the estimated phase velocity at 500 kHz was 1516 +− 6 m/s (mean +− standard error), and the estimated dispersion was −24 +− 4 m/sMHz (mean +− standard error). With adjustment for constant phase shifts, the estimated mean velocity decreased by 4–9 m/s, and the estimated magnitude of mean dispersion decreased by 50%–100%. The average correlation coefficient between the measured attenuation coefficient and frequency was 0.997 +− 0.0026 (mean +− standard deviation), suggesting that the signal for each sample was dominated by one wave.

11:15

5aBB11. Computing bone fragility using transient ultrasonic waves. Robert P. Gilbert and Philippe Guyenne (Dept. Mathematical Sci., Universirty of Delaware, 317 Ewing Hall, Newark, DE 19711)

In this paper, we determine bone fragility of cancellous bone *in vivo* by using a simple one-dimensional model of a muscle-cortical bone-cancellous bone sample, by measuring the refracted sound when the sample is exposed to impulses from a transducer. From these data, the bone parameters can be determined. Such a procedure is referred to as solving an inverse problem. A transducer is placed on one side of the skin of the member to be interrogated and a receiver is place diametrically opposed in contact with the member. The muscle will be modeled as an elastic material, whereas the the corrical and cancellous bone may be modeled by modified Biot equations albeit with different porosities. However, because of the known frequency dependence of the viscous term, we propose that the standard Biot equations, which are not well posed, be replaced by adding a convolution term. The form of the kernel $b(t)$ in the convolution integral is suggested by frequency domain representation of the dissipation term in the Biot–Johnson–Koplik–Dashen model.

11:30

5aBB12. Ultrasonic characterization of cancellous bone using three models of trabecular structure. Jerzy Litniewski, Andrzej Nowicki, and Janusz Wojcik (Dept. of Ultrasound, Inst. of Fundamental Tech. Res., Pawinskiego 5b, 02-106 Warsaw, Poland, jlitn@ippt.gov.pl)

The semi-empirical scattering models of trabecular bone were developed and examined for their abilities to mimic the frequency dependent backscattering coefficient measured in the cancellous bone. In the simulation of the bone, rf echoes the real properties of the bone and experimental conditions were taken into account. Tree types of trabeculae mimicking scatterers were considered. First, the bone consisted of cylinders with varying thickness (Gamma distributed) within the population was assumed. The next two cases accounted for the contribution of thick and thin trabeculae to the total backscattered signal. The second model assumed existence of two populations of the cylindrical scatterers significantly differing in the average value of Gamma distributed diameters. Finally, the mixed model composed of thick and thin trabeculae modeled, respectively, by cylindrical and spherical scatterers was examined. The last selection resulted from the similarity found between scattering on small sphere and finite cylinder. Calculated echoes demonstrated the usefulness of the mixed model. Frequency dependence of backscattering coefficient agreed well with the experimentally de-

termined dependences. The study also showed that the amplitude histograms calculated using demodulated rf echoes deviate from the Rayleigh distribution when the variation in scatterers' diameters increase.

11:45

5aBB13. Quantitative evaluation of articular cartilage using a minimally invasive ultrasound method. Tuomas Viren, Simo Saarakkala, Jukka S. Jurvelin, and Juha Tyräs (Dept. of Phys. and Mathematics, Univ. of Eastern Finland, P.O. Box 1627, 70210 Kuopio, Finland, tuomas.viren@uef.fi)

Quantitative ultrasound imaging is a potential method for the evaluation of the integrity of articular cartilage. A quantitative minimally invasive intra-articular ultrasound (IAUS) technique has been developed for *in situ* and *in vivo* diagnostics of articular cartilage [Virén *et al.* Ultrasound Med. Biol. **35**, 1546–1554, (2009)]. In IAUS, a high-frequency (40 MHz) intravascular ultrasound device is used and reflection coefficient (R), integrated reflection coefficient (IRC), apparent integrated backscatter coefficient (AIB), and ultrasound roughness index (URI) are calculated for cartilage. A set of experiments was conducted for the validation of the technique. For example, significant differences were observed in ultrasound parameters between intact, spontaneously and surgically repaired rabbit articular cartilage. The parameters revealed abnormal surface roughness and internal collagen structure by decreased R and IRC and increased values of URI and by increased AIB. Furthermore, the poor integration of the repair and surrounding native tissue was visible in the ultrasound images. As a reference, histological images revealed that repaired tissue exhibited abnormally organized collagen network, rough surface and lower collagen, and proteoglycan contents. Based on the present experimentation using IAUS, tissue structure and properties, not diagnosable by present clinical techniques, may be quantitatively evaluated with the minimally invasive ultrasound technique.

Session 5aEA

Engineering Acoustics: Electret Condenser Microphones

Allan J. Zuckerwar, Cochair
4909 Camberley Cir., Williamsburg, VA 23188

Qamar A. Shams, Cochair
NASA Langley Research Ctr., 4 Langley Blvd., Mail Stop 238, Hampton, VA 23681

Chair's Introduction—8:00

Invited Papers

8:05

5aEA1. Electret condenser microphones. James E. West (Dept. of Elec. and Comput. Eng. and Dept. of Mech. Eng., Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21231, jimwest@jhu.edu)

For more than 4 decades electret microphones have dominated most transducer applications in the audio frequency range for three main reasons, linearity, simplicity, and they are inexpensive. E. C. Wente invented the condenser microphone in 1916 searching for a replacement for the carbon microphone used in most telephones, but it was impractical until the high-voltage battery was replaced with a permanently charged polymer. Electret microphones have been the workhorse for most microphone applications including microphones for professional sound level measurements, telephones, hearing aids, professional audio recordings, games, and toys. Recent worldwide estimates of the electret microphone market suggest that over 2 billion units are made annually. Electret condenser microphones are available in a variety of sizes from very small (a few millimeters in diameter) to about 2 in. in diameter. The use of multiple microphone elements in arrays and the use of digital signal processing provide interesting prospects for improving signal-to-noise. A variety of microphone arrays and some important historical facts will be discussed in this talk.

8:25

5aEA2. Piezoelectret microphones. Gerhard M. Sessler and Joachim Hillenbrand (Dept. of Elec. Eng., Univ. of Technol., Merckstrasse 25, 64283 Darmstadt, Germany, g.sessler@nt.tu-darmstadt.de)

Piezoelectret microphones, a recently described new class of electret microphones, are based on the strong piezoelectric effect of internally charged, cellular polymer films. Such piezoelectret films have a large number of internal voids within the polymer. The upper and lower walls of these voids are oppositely charged. Films of this kind, when metallized on both sides, show high-piezoelectric activity and can be directly used as microphones. Recent work on these transducers has concentrated on stacking of piezoelectret films to improve sensitivity, on directional microphones, and on investigations of new film materials with improved charge stability at elevated temperatures. Stacked transducers have sensitivities proportional to the number of piezoelectret layers. With six layers, values of approximately 15 mV/Pa can be achieved. Directivities include omnidirectional, bidirectional, and cardioid patterns as well as dimensional characteristics. The new materials are based on fluoropolymers. These are, as opposed to the originally used polypropylene, not available in suitable cellular form. However, useful films can be made by fusing thin fluorocarbon films such that an array of small air voids is created between the layers. Transducers consisting of charged films of this kind withstand temperatures of 90 °C without significant loss of sensitivity.

8:45

5aEA3. Temperature characteristics of electret silicon microphones. Yoshinobu Yasuno (Appl. Piezoelectricity Div., Kobayasi Institut of Physical Res., 3-20-41, Higashi-motomachi, Kokubunji, Tokyo 185-0022, Japan, yasuno@kobayasi-riken.or.jp)

The electret condenser microphone (ECM) has become an important component for various consumer equipment systems because of its stable sensitivity and frequency characteristics and its success in achieving small size and high sensitivity. A previous report described the method to design a microphone with stable temperature characteristics. The quality of the silicon material for the diaphragm was pointed out as important for improving robustness. Recently, microphones using micro-electro-mechanical systems (MEMS) have been practically applied and widely used for mobile equipment, such as cellular phones. The major reason for adopting MEMS is that a re-flow soldering process can be used in production, in addition to having desirable features such as being small and thin. However, almost no electret types have been commercialized since a guaranteed 300°C heat resistance is required. This report presents a new trial electret silicone microphone that contains a SiO_2 thin-film electret. The report also evaluates the heat resistance of a SiO_2 electret, the temperature stability of a silicon diaphragm, and the temperature change in sensitivity and frequency characteristics compared with those of a conventional ECM and the microphone for measurement.

9:05

5aEA4. Prepolarized measurement microphone properties: 30 years of experience. Johan Gramtorp and Erling Sandermann Olsen (Brüel & Kjær Sound & Vib. Measurement A/S, Transducers R&D, Skodsborgvej 307, 2850 Nærum, Denmark jgramtorp@bksv.com)

30 years ago, Brüel & Kjær launched the world's first prepolarized condenser measurement microphones. These microphones combined the high-performance construction of the normal measurement microphones with a polarized electret layer placed on the back electrode. Since then, prepolarized microphones have gained an increasing share of the measurement microphone market. Prepolarized microphones are flexible in use because they do not need the external polarization, in particular, they can be used with constant current supply preamplifiers (Deltatron, ICP) that are widely used for many purposes in the industry. In order to be used for measurement purposes, the microphones and thereby the electret polarization must be highly stable and reliable. That is indeed achievable, and that is the main emphasis of this paper. A short historical overview of the development of the Brüel & Kjær prepolarized microphone types is given. The properties of prepolarized microphones are discussed and compared to those of externally polarized microphones. These will include stability with respect to time, temperature, humidity and the chemical environment, as well as distortion and dynamic range.

9:25

5aEA5. Electret condenser microphones in hearing aids. Daniel Warren, David Schafer, and Kiran Konde (Knowles Electron., 1151 Maplewood Dr., Itasca, IL 60143, daniel.warren@knowles.com)

As sensors small, high-gain devices, hearing aid microphones must be tiny, have high signal-to-noise ratios, be relatively insensitive to vibration from the nearby speaker, and operate at low hearing aid battery voltages. The subminiature backplate-electret condenser microphone was developed in the early 1970s specifically for hearing aids, with a very lightweight mechanical system for lower vibration sensitivity and somewhat improved signal-to-noise compared to previous designs. Although the design has been refined over several generations, the basic technology of electret films has proven to be very robust over the last 40 years, enabling continual size reductions while maintaining high signal-to-noise ratios. Noise generation and vibration sensitivity continue to be competitive dimensions for hearing aid microphones. Some of the mechanisms for noise generation and vibration pickup are intrinsic to the design of these microphones. Other mechanisms may be caused by interaction between the microphones and the hearing aid system of which they are a part. In this presentation, we will discuss both types of mechanisms and some design guidelines for minimal noise application of microphones in hearing aids.

9:45—10:00 Break

10:00

5aEA6. Ringing the changes: The potential for push-pull electret transducers in cell phones. Tim Mellow (Devices R & D, Nokia, Summit Ave., Farnborough GU14 0NG, UK, tim.mellow@nokia.com) and Leo Kärkkäinen (Nokia Res. Ctr., 00180 Helsinki, Finland)

Electret microphones are very common in mobile devices, but are invariably single-ended in configuration. For moderate dynamic conditions this is not a problem, but under high-sound pressure levels, better linearity can be obtained using a push-pull arrangement. Recent progress in nano-porous electret materials also opens up possibilities for electret loudspeakers. Such loudspeakers would offer potential benefits such as high-conversion efficiency, no magnetic field, and an ultra-thin package. However, there are product integration challenges. The authors describe a simulation model of a push-pull electret transducer and discuss the conditions under which it is linear. It turns out that the relationship with a non-electret electrostatic transducer is relatively simple.

10:20

5aEA7. Airframe noise flight test measurements using an electret condenser microphone array. William M. Humphreys, Jr., David P. Lockard, and Mehdi R. Khorrami (NASA Langley Res. Ctr., Hampton, VA 23681)

An extensive collection of airframe noise flight test data has been acquired for a regional jet class of aircraft using a ground-based electret condenser microphone phased array system. The measurements were conducted at the Wallops Flight Facility for the NASA Aeronautics Research Mission Directorate Fundamental Aeronautics Program. Gulfstream G450 and G550 aircraft were used as the test beds for the study. The phased array employed for the measurements consisted of a spiral clustering of 167 Panasonic WM-61A quarter-inch, omni-directional electret microphones. The innermost 49 sensors of the array were flush mounted on an aluminum plate with the remaining sensors flush mounted on individual 16-in. circular Plexiglas platters. The aluminum plate and platters were deployed on the overrun area of runway 4 at Wallops. Airframe noise measurements were performed with the aircraft flying a racetrack pattern simu-

lating the approach path to landing as it passed over the array. A distributed data acquisition system was used to acquire simultaneous time histories from the array and was synchronized with instrumentation onboard the aircraft. This presentation will discuss the design of the phased array, the calibration and deployment of the microphones, a sampling of the measurements obtained from the system, and lessons learned from the deployment.

10:40

5aEA8. A method for free-field transfer calibration of electret microphones at ultrasound frequencies in air using a stable broad band ultrasound source. Angelo J. Campanella (Campanella Assoc. and Acculab, 3201 Ridgewood Dr., Hilliard, OH 43026, a.campanella@att.net)

A rotating turbulence screen wheel sound source, now in use in the air ultrasound instrument industry for product quality control, provides a steady source of broad band ultrasound. This source is broad band through at least 100 kHz. It is calibrated as a secondary standard, using a one-quarter inch condenser microphone, grid removed, normal incidence, and corrected for free-field conditions per the microphone manufacturer free-field response. Sound pressure amplitude is measured at a distance of 500 mm and from 1 to 100 kHz in 1-kHz FFT bins. Calibration site sound absorption by humid air is calculated to correct the emitted sound pressure values to be reinserted for the user test site air temperature and humidity. Transfer calibrations of two electret condenser microphones are shown. Microphone phase response measurement methods will also be investigated and discussed.

Contributed Paper

11:00

5aEA9. Acoustic field of air-coupled transducers made with electroactive polymer foams. Louis Satyanarayan and Yves Berthelot (Woodruff School of Mech. Eng., Georgia Tech Lorraine, GT-CNRS UMI 2958, 2 rue Marconi, 57070 Metz, France)

Electroactive films made of soft cellular polypropylene (PP) foams containing electric charges have high piezoelectric coupling coefficient and good matching impedance with air over a broad frequency range. They offer interesting capabilities in the design of new air-coupled ultrasonic transducers. A prototype transducer has been designed and tested in our laboratory. The amplitude displacement on the surface of the transducer was measured by laser vibrometry by vibrating the PP foams with a continuous wave sinusoidal excitation. The transducer was mounted with a needle-type PVDF hydrophone on a high-precision polar C-scan apparatus. The receiving hydrophone was translated along and across the axis of the source transducer and data were recorded. A quantitative characterization of the acoustic field of the transducer was carried out by plotting the on-axis and cross-axis variations in the pressure field, at various separation distances between the source and the receiver in pulsed transmit-receive mode. The results indicate that simple and relatively efficient air-coupled ultrasonic transducers can be made with electroactive polymer foams. [Work supported by CNRS and by the Conseil Rgional de Lorraine.]

FRIDAY MORNING, 23 APRIL 2010 KOZMOS, 8:20 A.M. TO 12:00 NOON

Session 5aMU

Musical Acoustics: Extended Instrument Techniques

Jonas Braasch, Chair

Rensselaer Polytechnic Inst., School of Architectue, 110 8th St., Troy, NY 12180

Invited Papers

8:20

5aMU1. Instrumental analysis of extended saxophone techniques for live electronics. Jonas Braasch and Doug Van Nort (Graduate Program in Architectural Acoust., School of Architecture, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, braasj@rpi.edu)

The development of automated music transcription systems focuses predominantly on polyphonic musical instruments. At the same time, the analysis of a monophonic instrument is usually much simpler wherein pitch, loudness, and duration of individual notes may be tracked robustly. When using extended techniques, however, many more parameters than the aforementioned three can be meaningful for the performed music. This paper explores the challenges that extended techniques pose for music recognition systems using the example of the saxophone. The goal is to correctly identify extended techniques over the whole range of the instrument, including subtones, multiphonics, growl, and other voice-enhanced tones, as well as tones where the reed is supported by the lower teeth. The feature analysis is based on cepstrum, spectral moments, pitch, and roughness, among other features. A hidden-Markov model is used to recognize the trajectory of the various extended techniques based on the given feature space. Finally, it is demonstrated how the recognizer can be integrated into an intelligent live electronics system to control its parameters. For example, the characteristics of a virtual acoustic enclosure (room size, reverberation time, etc.) can be adapted this way. [Work supported by NSF 0757454.]

8:40

5aMU2. Pitch bending and higher-mode reed vibration in mechanically blown free reed instruments. James P. Cottingham (Dept. Phys., Coe College, 1220 First Ave. NE, Cedar Rapids, IA 52402, jcotting@coe.edu)

Pitch bending in the harmonica, in which manipulation of vocal tract resonances plays an essential role, has long been a common practice. Pitch bending in free reed instruments with mechanically driven air supplies, such as the reed organ and the accordion, is a different matter. At least two methods of pitch bending in such instruments have been studied and demonstrated. The first, likely to be musically useful only in certain special circumstances, involves partial opening of the pallet valve combined with variations in blowing pressure. The second, recently described and implemented in the accordion by Tonon [J. Acoust. Soc. Am. **126**, 2217 (2009)], involves modifying the construction to include a resonating chamber in addition to the standard reed chamber. It is also possible to construct air-blown free reed instruments in which the reed vibrates mainly in the second transverse mode. In one case the reed is coupled with a pipe resonator that provides a suitable mismatch in frequencies with the fundamental frequency of the reed. In another case the second or higher-mode vibration of the air-driven reed can be mechanically induced. The musical possibilities of these hypothetical reed-pipe instruments have yet to be explored.

9:00

5aMU3. Extended techniques of the contrabass. Michael T. Bullock (15 Channel Ctr. St., Apt. 403, Boston, MA 02210, michaeltbullock@gmail.com)

Contrabass improvisers, composers, and performers of contemporary contrabass repertoire rely on a broad vocabulary of extended contrabass techniques. This vocabulary is continuously developed primarily through a kinesthetic engagement with the acoustics of the contrabass, and many new discoveries are made in the act of playing. This presentation will include live performance, by the presenter, of a series of extended techniques on the contrabass. Spectrograms and video clips will be used to illustrate how these techniques are related to the unique acoustic properties of that instrument. Principles demonstrated will include the following: (1) *Overtone bowing and fingering*: The low fundamental register of the contrabass means that each string has a many upper overtones within the audible range. Using various bowing and fingering techniques that exploit these upper partials, the timbre and pitch of a string can be radically altered and continuously transformed while playing. (2) *Activating the contrabass body*: Striking the contrabass body with hands and soft objects, rubbing the instrument's back with the fingers, and manipulating feedback through amplification are ways to activate the complex resonances of the contrabass. [Thanks to Professor Jonas Braasch of the RPI School of Architecture.]

9:20

5aMU4. Extending and abstracting sitar acoustics in performance. Curtis R. Bahn (Dept. of the Arts, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180-3590, crb@rpi.edu)

There is a very close relationship between the acoustic design of instruments of the Hindustani classical music tradition and the structure of raga. The sitar and other related string instruments have sympathetic strings which are tuned to prominent notes of a raga. These strings resonate sympathetically in performance, creating a rich and hauntingly beautiful sonority. In creating a computer extended electronic sitar, the first step was to model and extend this resonant quality of the instrument, allowing for new tunings and extended resonances not possible with a traditional instrument. The extended sitar also uses performance analysis and a variety of sensors to control various signal processing techniques that further extend the quality of the instrument. This sonic analysis and subsequent sound synthesis/computer generated compositional schemes relate directly to structures of raga. This presentation will detail the development and performance of the computer extended sitar in relationship to traditional raga structure and in new contexts not directly related to traditional notions of the sitar.

9:40

5aMU5. Simulating, mirroring, morphing, and blurring acoustic space as an extended instrumental technique. Pauline Oliveros (Dept. Arts, Rensselaer Polytechnic Inst., 110 8th St., Troy NY 12080)

The paradigm for musical performance is the sound of musical instruments in a fixed acoustical space. Ordinarily space does not shift and change during performances. An ideal space for performing classical composers such as Mozart is the Shaffy Theater in Amsterdam with a relatively short reverberation time 1.5 s. Instruments couple to the space, and space is part of the instrument and vice versa. Players develop special relationships with favorite spaces. After experiencing many different types of acoustics this leads to the desire to change the space during performance in order to hear the different qualities that emerge from spatial coupling. Spatial progressions can be made so that rather than moving sound in space, space can be moved around the sound and produce a variety of qualities.

10:00—10:15 Break

10:15

5aMU6. Extending the acoustic ensemble through spectral and temporal transformations in real-time. Doug Van Nort (Dept. Architectural Acoust. and Dept. Arts, Rensselaer Polytechnic Inst., 110 8th St., Troy, NY 12180, vannod2@rpi.edu)

The paradigm of live performance mixing acoustics and electronics has predominantly focused on simple background "tape music," human players performing highly structured sample-based music (e.g., using the ABLETON LIVE software), or reactive systems that respond to player qualities such as timing, pitch, and so on. In this talk I will present my approach to improvised "laptop performance" that focuses on the transformation of acoustic players in real-time. Rather than simply altering the acoustic content in the manner of an effect processor, the goal is to capture notes and phrases in short-term memory and to re-articulate the material so that it presents a new gestural inflection and timbral content that can be completely novel or suggestive of other players' sound. The system presented utilizes

a hybrid system combining spectral analysis and feature extraction with block-based temporal processing and a feedback delay network. The interaction paradigm of "scrubbing" the intermediate time/frequency representation is used to generate the ultimate output. The result in an ensemble context is an extended palette that can "keep up" with the musical dialog while eliciting the subtle textural qualities of acoustic players. [This work was supported by NSF Grant 0757454 and CIRMMT/McGill University Fellowships.]

10:35

5aMU7. The digital audio player as aleatory musical instrument. Adam Di Angelo (SIA Acoust., 75 Rockefeller Plaza, 26th Fl., New York, NY 10019, diangelo@gmail.com)

The digital audio file player is an ideal instrument for the performance of aleatory music. The near-instantaneous seek time coupled with random track playback yields the possibility of nonlinear musical arrangements. In this is the potential to create unique and unrepeatable listening experiences—music that constantly renews and reinvents itself, free from the static limitations of the recorded medium. This study examines the history of chance as a compositional and performance tool from 18th century musical dice games to contemporary stochastic methods. It presents examples of works which are designed to be structurally random and outlines the process of employing the digital audio player in the production of variable music. Through such considerations, the role of the conventional mp3 player can expand from passive playback device to become an engine integral to a new kind of listening.

10:55

5aMU8. The physics of pitch bending on the vibraphone. Randy Worland (Dept. of Phys., Univ. of Puget Sound, 1500 N. Warner, Tacoma, WA 98416, worland@pugetsound.edu)

The vibraphone is a member of the keyboard (or mallet) percussion family, with tuned aluminum bars typically spanning three chromatic octaves (F3–F6). Extended performance techniques include the use of harmonics and bowing of bars, as well as the pitch bending effect discussed here. After first striking the middle of a bar with a soft mallet in the normal manner, the pitch bend is obtained by pressing a hard mallet onto the bar at a nodal point and then sliding it away from the node as the note sustains. The audible result is a descending pitch, typically of about one semitone. Experimental data on frequency versus location of the hard mallet along the bar are presented. The mass, hardness, and orientation of the sliding mallet relative to the bar are discussed. Interferograms of the lower frequency modes of the bar are also shown. Results are interpreted using a mass perturbation model.

11:10—11:15 Break

11:15—12:00
Participants will give informal demonstrations of several of the techniques discussed.

5aPAa1. Green's function for the scattered field near the surface of a dissipative elastic medium. Evgenia A. Zabolotskaya, Yurii A. Ilinskii, and Mark F. Hamilton (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713-8029)

The problem of scattering in bounded elastic media is relevant to medical ultrasound imaging and detection of buried objects. A method was developed that takes into account the propagation of longitudinal, shear, and Rayleigh waves in an elastic medium. The approach is based on solving the inhomogeneous momentum equation for the Green's function. The forcing function is modified to accommodate different kinds of excitation that are important for shear wave imaging and seismic wave generation. The solution for the Green's function is presented as a Fourier integral, and coefficients in the Fourier expansion are calculated by applying boundary conditions on the solid surface and matching conditions in the plane parallel to the surface that contains the source. The method permits the scattered bulk and surface waves to be distinguished from one another. The Green's function has been presented previously in both the frequency and time domains for a lossless medium. The model is generalized here for elastic media with losses. Besides reducing the amplitude of the response, losses also impair ability to distinguish between the bulk and surface modes of propagation. [Work supported by NIH DK070618.]

8:15

5aPAa2. Image method for acoustic reflections from a wedge. Ambika Bhatta, Max Denis, Mira Raspopvic, and Charles Thompson (ECE Dept., Univ. Mass. Lowell, 1 Univ. Ave. (CACT), FA 203, Lowell, MA 01854)

In this paper we will present the analysis of reflected waves of a point source from a two dimensional wedge. Exact method of images is used to calculate the position and strength of image sources. It is shown that the traditional fractional order Bessel function series for the total pressure can be replaced by quadratures of elementary functions.

8:30

5aPAa3. Transition matrix (T-matrix) of circular cylinders embedded in a viscous fluid. Edgar Reyes-Ayona, Daniel Torrent, and Jose Sanchez-Dehesa (Wave Phenomena Group, Polytechnic Univ. of Valencia, Camino de vera s.n., ES-46022 Valencia, Spain)

The present study concerns the scattering of a plane sound wave by a cylindrical scatterer of circular cross section. An infinitely long cylinder embedded in a viscous fluid is here considered. The linearized equations of viscous fluid and the scalar and vector potentials are employed to obtain the T-matrix for two different types of material cylinders: (i) a rigid cylinder and (ii) a fluidlike cylinder with losses. Both cases are also studied and discussed in the limit of long wavelengths. [Work supported by MICIIN of Spain and ONR.]

8:45

5aPAa4. A numerical model for acoustic scattering from an inhomogeneous medium. Max Denis, Jing Tsui, Jessica Piper, Kavitha Chandra, and Charles Thompson (Dept. of Elec. and Comput. Eng., Univ. of Massachusetts Lowell, 1 Univ. Ave., Lowell, MA 01854, charles_thompson @uml.edu)

In this work, a numerical method for evaluating the scattering of acoustic waves from an inhomogeneous medium is presented. The internal resonant and multiple scattering effects are modeled by the Padé approximants of a perturbation expansion of the contrast properties between the medium constituents. Due to the local divergence in the Padé approximant solution, a local expansion method about any convergent solution is performed. This allows one to extend the numerical model to higher frequencies. The results show good agreement for geometrically simple scatterers. Based on the simulations, analyses are made of inhomogeneous media micro-structural effects on the scattered field. Of particular interest is the frequency dependence relationship.

9:00

5aPAa5. Single-channel time reversal with Lanczos iterations. Zachary J. Waters (Naval Res. Lab., Code 7130, Washington, DC 20375-5320) and Paul E. Barbone (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215)

Recent investigations of array-based time reversal techniques employing Lanczos iterations have demonstrated convergence properties superior to equivalent methods using power iterations [A. A. Oberai *et al.*, "Efficient time reversal by Lanczos iterations," J. Acoust. Soc. Am. **123**, 3596 (2009)]. In numerical scattering simulations, time reversal techniques developed for a single-channel transducer are applied to study echoes from a thin-walled spherical shell. When power iterations are employed, a narrowband waveform corresponding to the dominant scattering mode of the target is selected. Lanczos iterations converge to this waveform in fewer transmissions and simultaneously identify additional higher-order target scattering features. The performance of both techniques is studied in the presence of varying levels of stochastic and deterministic noise. [Work supported by the Office of Naval Research.]

9:15

5aPAa6. Modeling of acoustic propagation to capture finer-scale features of bounding objects. Sandra L. Collier, W.C. Kirkpatrick Alberts, II, and John M. Noble (U.S. Army Res. Lab., RDRL-CIE-S, 2800 Powder Mill Rd., Adelphi, MD 20783, scollier@arl.army.mil)

One of the limiting factors of performing high-resolution modeling of outdoor sound propagation in the time domain is the treatment of the boundary conditions. Impedance ground boundary conditions have been successfully modeled in the time domain for a variety of porous ground types via the use of recursive convolution methods; however, the applications were for a flat ground. The modeling of sound propagation around buildings (or other obstacles) is usually accomplished by drastically simplifying the building geometry, thereby failing to account for fine-scale, or even some larger-scale, details. Experiments conducted at a fire training facility found that external building features, such as facets and fire escapes, can effect the sound field significantly enough so that standard acoustic diffraction models fail to accurately predict the sound field. Here we develop numerical models that allow us to capture the effects of finer-scale features. Such treatments are necessary for the development of source localization algorithms in urban or other multifarious environments.

9:30

5aPAa7. Energy flux streamlines vs the alternatives for the visualization of energy coupling inside and outside the surface of an ensonified spherical acoustic lens: Preliminary results. Cleon E. Dean (Dept. Phys., P.O.B. 8031, Georgia Southern Univ., Statesboro, GA 30460-8031, cdean@georgiasouthern.edu) and James P. Braselton (Georgia Southern Univ., Statesboro, GA 30460-8093)

Energy flux streamlines are compared with alternative presentations of the energy flux vector field to visualize energy coupling inside and outside the surface of an insonified spherical acoustic lens. The emphasis is on the energy flux streamline as a natural bridge between necessarily approximate ray solutions and full-fledged wave solutions. The present work is the wave solution for the experimental work performed by Kendez C. Parker and Cleon E. Dean also being presented at this meeting that primarily used ray methods in its theoretical analysis; thus a comparison between energy flux representations and ray analysis results is made. Difficulties in the interpretation of the energy flux streamline representation due to the spherical geometry of the scatterer are noted.

5aPAb1. Transmission of acoustic-gravity waves through air-water interface. Iosif M. Fuks (ZelTechnologies LLC and NOAA/Earth System Res. Lab., Mail Code R/PSD99, Boulder, CO 80305-3328) and Oleg A. Godin (Univ. of Colorado, Boulder, CO 80305-3328, oleg.godin@noaa.gov)

It was demonstrated recently that air-water interface, which is usually an almost perfect reflector of acoustic waves, becomes anomalously transparent and the power flux in the wave transmitted into air increases dramatically, when a compact sound source in water approaches the interface within a fraction of wavelength [O. A. Godin, Phys. Rev. Lett. **97**, 164301 (2006)]. Powerful underwater explosions and certain natural sources, such as underwater landslides, generate very low-frequency waves in water and air, for which both fluid buoyancy and compressibility simultaneously serve as restoring forces. In this paper, analysis of sound transmission through air-water interface is extended to acoustic-gravity waves (AGWs). It is found that, as for sound, the interface becomes anomalously transparent for sufficiently shallow compact sources of AGWs. Depending on the source type, the increase in wave power flux into air due to diffraction effects can reach several orders of magnitude. Physical mechanisms responsible for the anomalous transparency are discussed. Excitation of an interface wave by an underwater source is shown to be an important channel of AGW transmission into atmosphere, which has no counterpart in the case of sound.

10:30

5aPAb2. Sound control by temperature gradients. Jose Sanchez-Dehesa, Mitko I. Angelov, Francisco Cervera (Wave Phenomena Group, Polytechnic Univ. of Valencia, Camino de vera s.n. ES-46022 Spain, jsdehesa@upvnet.upv.es), and Liang-Wu Cai (Kansas State Univ., Manhattan, KS 66506)

The acoustic mirage, like the optical mirage, is a consequence of temperature gradients existing in the air above Earth surface. Here, we report experiments showing that temperature gradients can be used to collimate an airborne ultrasonic beam. A very simple system consisting of two glass tubes heated by an internal resistive coil is used to create a temperature gradient producing the desired effect. Numerical simulations are also performed and results are in agreement with the experimental findings [Work supported by MICIIN of Spain.]

10:45

5aPAb3. Characterization of a lossy elastic plate thanks to the relationships between its reflection and transmission coefficients. Serge Derible and Alain Tinel (LOMC GOA, FRE CNRS 3102, Univ. Le Havre, 76600 Le Havre, France)

The normal reflection and transmission coefficients of a lossy elastic plate are measured and associated according to the outcomes of resonance scattering theory (RST) and S-matrix theory (SMT). The sum and the difference of those coefficients provide valuable tools, the transition terms, we use to characterize the plate. The absorption in the plate can be expressed via different manners recalled in the following. By means of a dimensionless loss factor, the velocities of the longitudinal and transverse waves of the studied aluminum plate are no more real but complex. The width of a resonance is the sum of two parts: the elastic width and the absorption one. In the vicinity of a resonance frequency, the transition terms obey the Breit–Wigner resonant form which makes it possible an easy determination of the two parts of the resonant width. There is a good experiment/theory agreement when an imaginary part is added to the Lamé coefficients of the aluminum plate. The loss factor is of the order 5.10–4. On the whole, the effect of the attenuation rises with frequency and reaches a maximal importance at the vicinity of a resonance frequency.

5aPAb4. Constraining the acoustic energy radiated from collisions of polypropylene balls. Joshua Riner and Andi Petculescu (Dept. of Phys., Univ. of Louisiana at Lafayette, P.O. Box 44210, Lafayette, LA 70504, riner@louisiana.edu)

Measurements of sound radiation from binary collisions of polypropylene balls were performed in order to study the collision dynamics and constrain the fraction of incident energy radiated as sound. In the experiments, one ball is released from directly above a stationary target ball. In the first experiment, the incident energy of the incident ball is varied by changing the drop height. The sound is recorded at an angle of 55 deg below the impact plane. Data from this experiment, fitted with a theoretical model, show a possible deviation from Hertzian behavior. The second experiment concens the radiation pattern of the collision process. The sound pressure was measured as a function of the polar angle θ. It is assumed that the problem is azimuthally symmetric, i.e., independent of the angle ϕ. The results are somewhat surprising: they show a dipole-like pattern that is asymmetric with respect to the impact line. The acoustic energy radiated during the impact, obtained by multiplying the collision time by the sound intensity integrated over a spherical surface centered at the impact point, is estimated as four orders of magnitude smaller than the incident energy. [The work was supported by the Louisiana Board of Regents.]

5aPAb5. Acoustical probe of the density fluctuations in a binary fluid mixture. Curtis F. Osterhoudt and Dipen N. Sinha (MPA-11, Los Alamos Natl. Lab., Los Alamos, NM 87545, cfo@lanl.gov)

Silicone oil was found to be fully miscible in "segregated" perfluorinated hydrocarbon (Novec fluid, by 3M) above a critical temperature slightly above room temperature and at atmospheric pressure. This constitutes a binary fluid mixture, and these have long been used as examples of continuous phase transitions, especially in regard to the phenomenon of critical opalescence [T. Andrews, Philos. Trans. R. Soc. London **159** (1869) and M. Smoluchowski, Ann. Phys. **21** (1906)]. During a phase transition in these mixtures, the fluids become spatially segregated, and the density fluctuation correlations are known to span a large number of length scales [L. Landau and E. M. Lifshitz, *Statistical Physics*, 3rd ed., Part 1]. This behavior is reflected in massive fluctuations in sound speeds and viscosities in the mixtures near the critical point, and the resulting scattering behavior is probed by actively acoustically interrogating the mixture with techniques including swept-frequency acoustical interferometry and pulse-echo measurements. It is shown that with higher-power acoustical probes, the transition from unary to binary mixture may be prevented or enhanced. [This work was supported by Chevron USA.]

11:30

5aPAb6. Acoustic behavior of large encapsulated gas bubbles with resonance frequencies in the 50–100 Hz range. Mark S. Wochner, Kevin T. Hinojosa, Kevin M. Lee (Appl. Res. Labs., The Univ. of Texas at Austin, Austin, TX 78713-8029), Theodore F. Argo, IV, Preston S. Wilson (The Univ. of Texas at Austin, Austin, TX 78712-0292), and Richard S. Mercier (Texas A&M Univ., College Station, TX 77843-3136)

A one-dimensional resonator technique was used to investigate the acoustic behavior of water containing large spherical and toroidal encapsulated air bubbles. Tethered balloons and inner tubes, respectively, were used to create the bubbles, which had effective spherical radii of approximately 5 cm. The number of balloons or inner tubes varied from 3 to 6, which resulted in void fractions from 1.5% to 5%. Effective mixture sound speeds for both shapes were inferred from the resonances of a water and bubble-filled waveguide 1.8 m in length. For the spherical bubbles, the Commander and Prosperetti (CP) model [J. Acoust. Soc. Am. **85**, 732–746 (1989)] quantitatively described the measured sound speed dispersion approaching the individual bubble resonance frequency and qualitatively predicted the frequency range of high attenuation, even in this regime of high-void fractions and discrete bubble distribution within the waveguide. Qualitative agreement was found between the CP model and the toroidal bubble measurements. Finite-element simulations of both experiments were performed, which help explain the discrepancy between the CP model and the measurements. [Work supported by Shell.]

5aPAb7. The characteristics of thunder on Titan. Andi Petculescu (Dept. of Phys., Univ. of Louisiana at Lafayette, P.O. Box 44210, Lafayette, LA 70504)

Even though *Huygens* has not detected acoustic signatures of Titanian lightning, electric discharge processes are thought to be very plausible in Titan's thick atmosphere dominated by nitrogen and methane. When correlated with electromagnetic signatures, thunder will very likely confirm the occurrence of lightning, both during a probe's descent and/or once it has landed. The presentation has two parts. In the first part, the mechanisms of Titanian thunder *generation* are discussed, in the context of the most up-to-date predictions of lightning on Titan, as well as relevant *Cassini-Huygens* data. In the second part, the *propagation* of thunder in Titan's troposphere is addressed. Here, the structure, composition, and ambient conditions of the satellite's atmosphere will be presented and accounted for. Current Titan lightning models predict cloud-to-ground discharge channels of ~20 km. Long-range Titanian thunder simulations are developed based on the far-field superposition of approximately 7000 *N*-waves arising from 3-m "elementary" sources. Two lightning geometries will be considered: linear and tortuous. (Tortuous channels are synthesized as a Gaussian distribution in the orientations of the 7000 elementary sources.) For illustrative purposes, to show the effects of atmospheric filtering, the thunder waveform described above will also be propagated in Venus' atmosphere.

5aPP1. Effects of training in increment-detection and intensity-discrimination tasks. Walt Jesteadt, Harisadhan Patra, Melissa Krivohlavek, and Cynthia Rutledge (Boys Town Natl. Res. Hospital, 555 N. 30th St., Omaha, NE 68131)

Subjects use different cues when asked to detect a brief increment in a longer duration tone (increment detection) than when asked to discriminate between two tones of the same duration that differ only in level (intensity discrimination). To determine whether experience in one task would generalize or interfere with performance in the other, a group of six subjects completed 4000 trials in an increment detection task, followed by 800 trials of intensity discrimination, and final 800 trials of increment detection. A second group of subjects was tested in the reverse pattern, beginning with 4000 trials of intensity discrimination. The increment or signal was a 90-ms, 4-kHz tone. The pedestal or standard was a 490- or 90-ms, 4-kHz tone presented at 70-dB sound pressure level. A two-interval, forced choice adaptive procedure was used to estimate the level of the increment required for 71% correct. The results showed modest improvement over time for two subjects in increment detection and one in intensity discrimination, but at least one subject showed the opposite effect in each task. There was no generalization or interference between the two tasks and no correlation between increment detection and intensity discrimination across the 12 subjects. [Work supported by NIH.]

9:15

5aPP2. The relative contribution of adaptation and temporal integration in forward masking. Naveen N. Nagaraj and Jeffrey J. DiGiovanni (Auditory Psychophysics and Signal Processing Lab., School of Hearing, Speech and Lang. Sci., Ohio Univ., Athens, OH 45701, nn328108@ohio.edu)

Forward masking has been studied extensively, but the mechanism underlying forward masking is still being debated. The aim of this study was to understand the relative contribution of adaptation and temporal integration on forward masking. In the first experiment, gap detection thresholds were measured for symmetrical and asymmetrical noise markers ranging from 10- to 30-dB SL in 5-dB increments. Further threshold measurements were made while keeping the level of the noise marker before the gap at a constant 30-dB SL while varying the level of noise marker after the gap between 10- and 25-dB SL. Noise marker sets with gap detection threshold of 20 ms or less were selected for the second experiment. In the second experiment, participants adjusted gap durations within an asymmetrical noise marker to be perceptually equal to that of symmetrical noise markers. The results will be discussed in the context of a temporal integration model, an adaptation model, and a hybrid model including both temporal integration and adaptation components.

9:30

5aPP3. Perceived continuity and pitch shifts. Christopher J. Plack (Human Commun. and Deafness Div, Univ. of Manchester, Manchester M13 9PL, United Kingdom, chris.plack@manchester.ac.uk) and Rebecca K. Watkinson (Univ. of Essex, Colchester CO4 3SQ, United Kingdom)

If a noise burst is introduced into the gap between two brief complex tone bursts, pitch discrimination improves to the level observed when the bursts really are continuous. In the experiment described here, it was shown that perceived continuity also affects sensitivity to envelope phase across the gap. Two complex tone bursts with unresolved harmonics and five regular envelope peaks ("pitch pulses") were presented sequentially, separated by a gap of two periods. When the relative phases of the two bursts were varied, such that the inter-pulse interval (IPI) across the gap was varied, the pitch of the whole sequence was little affected, consistent with previous results suggesting that the pitch integration window may be "reset" by a discontinuity. However, when the gap between the two bursts was filled with a noise with the same spectral envelope as the complex, variations in IPI had substantial effects on the pitch of the sequence. It is suggested that the presence of the noise causes the two tone bursts to appear continuous; hence resetting does not occur, and the pitch mechanism is sensitive to the phase discontinuity across the gap.

9:45

5aPP4. Frequency-specific measurements of the temporal modulation transfer function using narrowband noise. Yi Shen and Jennifer Lentz (Dept. of Speech and Hearing Sci., Indiana Univ., 200 S Jordan Ave., Bloomington, IN 47405, shen2@indiana.edu)

Interpretation of frequency-specific measures of temporal acuity is often confounded by the coexistence of spectral and temporal cues. The current study presents a new experimental technique to measure the temporal modulation transfer function (TMTF), in which inherent envelope modulations in narrowband noise are used as the detection target. Modulation depths of the stimuli were manipulated using a signal processing algorithm that introduced no change in the stimuli's power spectra. In this way, spectral cues cannot cue the presence of modulation. TMTFs were measured using these narrowbands of noise [TMTF-NS (no spectral cues)] at four center frequencies (2, 4, 6, and 8 kHz) and bandwidths of 16, 24, 32, 48, 64, 96, and 128 Hz. TMTFs using low-pass-noise modulated puretones (TMTF-NBM) were also measured for comparison. In cases where the spectral cues are limited in TMTF-NBM (at low-modulation rates or at high-carrier frequencies), thresholds are very similar between the TMTF-NS and the TMTF-NBM, providing validation that this new technique measures temporal acuity similar to standard TMTF methods. In conditions where spectral cues are available in TMTF-NBM (high-modulation rates and lower carrier frequencies), higher thresholds are measured for TMTF-NS and a more reasonable estimate of temporal acuity is obtained.

10:15

5aPP5. Another indication that information in "off-frequency" filters enhances sensitivity to envelope-based interaural temporal disparities. Leslie R. Bernstein and Constantine Trahiotis (Depts. of Neurosci. and Surgery (Otolaryngol.), Univ. of Connecticut Health Ctr., 263 Farmington Ave., Farmington, CT 06030, les@neuron.uchc.edu)

A recent study, [Bernstein, L. R., and Trahiotis, C. (**2009**). J. Acoust. Soc. Am. **125**, 3234-3242] employing "raised-sine" stimuli centered at 4 kHz revealed three outcomes concerning discriminability of envelope-based interaural temporal disparities (ITDs). First, graded increases in raised sine exponent led to graded decreases in envelope-based threshold-ITDs. Second, threshold-ITDs decreased with increases in modulation depth. Third, when the modulation depth was 25%, increasing the exponent led to especially large decreases in threshold-ITD. Overall, an interaural correlation-based model including stages mimicking peripheral auditory processing was shown to capture quite well most of those outcomes. Left unexplained, however, was the interaction between modulation depth and raised sine exponent. Here, we report new threshold-ITDs obtained while varying, factorially, depth of modulation (25% or 100%), raised-sine exponent (1.0 or 8.0), and modulation frequency (32, 64, 128, or 256 Hz). Those stimulus parameters were chosen specifically to shed light on the unexplained interaction. A quantitative theoretical analysis of the new data suggests that listeners can enhance their sensitivity to envelope-based ITDs by utilizing "off-frequency" filters centered above 4 kHz. [This research was supported by research grant NIH DC-04147 from the National Institute on Deafness and Other Communication Disorders, National Institutes of Health.]

10:30

5aPP6. Masker modulation regularity and its effects on comodulation masking release. Emily Buss, Joseph W. Hall, and John H. Grose (UNC School of Medicine, Chapel Hill, NC 27599, ebuss@med.unc.edu)

Several authors have suggested that comodulation masking release is largest when performance in the narrowband masker condition is poor due to perceptual similarities between masker fluctuations and an added signal. The present study tested this hypothesis by manipulating the regularity of masker modulation between but not within listening intervals. The signal was a 500-Hz tone burst, and the masker was a continuous band of noise, either 25- or 1050-Hz wide. After filtering, the masker was amplitude modulated with one of three envelope patterns. The regular envelope was a smoothed 20-Hz square wave, composed of 10-ms raised-cosine ramps and 15-ms steady states. In the irregular envelope conditions, either the duration of the steady state or the modulation depth was randomly selected prior to each modulation period, with one exception: modulation was not randomly perturbed during listening intervals, when the signal might be presented. There were large individual differences, but masker envelope irregularity tended to elevate thresholds, particularly for the 25-Hz masker bandwidth. Results were consistent with more CMR under conditions for which there is greater informational masking in the narrowband masker condition.

10:45

5aPP7. Effects of modulated noise on detection of formant-like stimuli. Peggy B. Nelson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, Minneapolis, MN 55455), Magdalena Wojtczak (Univ. of Minnesota, Minneapolis, MN 55455), and Yingjiu Nie (Univ. of Minnesota, Minneapolis, MN 55455)

One problem reported by listeners with hearing impairment (HI) might be that formant transitions in noise are not as salient as for listeners with normal hearing (NH). We hypothesize that a reduced ability to perceive formant transitions in noise could contribute to reduced masking release seen in HI listeners. In this study, we used pure-tone glides and harmonic complex simulations of formant transitions (shifts in intensity increments across frequency range of a formant transition over the transition duration) to test this hypothesis. Pure-tone glides were 30- or 60-ms long and were centered at 1250 or 2500 Hz, frequencies representing second formants in speech. They were presented in isolation or with unmodulated flanking tones (simulating F1 and F3) in quiet, steady noise, and gated noise. NH listeners were only slightly better than HI listeners at detecting the single gliding tone in quiet. Flanking tones adversely affected performance of the HI but not NH listeners. Performance of the NH listeners was somewhat better in gated than in steady noise, whereas the HI listeners performed similarly in steady and gated noise. The role of perception of formant transitions in masking release will be discussed. [Work supported by NIDCD R01-DC008306.]

11:00

5aPP8. The fluctuating-masker benefit for word identification with spectral or fine-structure distortions. Joshua G.W. Bernstein (Army Audiol. and Speech Ctr., Walter Reed Army Med. Ctr., Washington, DC 20307, joshua.g.bernstein@us.army.mil)

Normal-hearing (NH) listeners presented with speech processed to reduce spectral detail or remove temporal fine-structure (TFS) information show a reduced benefit from momentary dips in the level of a fluctuating masker. This has been interpreted as evidence that related deficits may underlie the reduced fluctuating-masker benefit (FMB) observed for the hearing impaired. However, the reduced FMB for processed stimuli could be attributable to the greater signal-to-noise ratio (SNR) required to yield performance levels equivalent to the unprocessed case for unmodulated noise (the reference condition). NH listeners were tested in the identification

of isolated words presented in stationary-noise, interfering-talker, and speech-modulated noise maskers. Different response-set sizes were used to offset performance differences between processed and unprocessed conditions. A validation experiment showed no effect of set size on the FMB when compared at a common stationary-noise SNR. A second experiment compared the FMB for unprocessed, spectrally smeared, and noise vocoded speech. When compared at the same SNR and percent-correct level (but different set sizes), processed and unprocessed stimuli yielded similar FMB. This suggests that for the conditions tested here, spectral or TFS distortions do not directly impair the ability to listen in the gaps of a fluctuating masker. [Sponsored by the Oticon Foundation.]

11:15

5aPP9. Psychometric properties of the coordinate response measure corpus with various types of background interference. David A. Eddins (Dept. of Otolaryngol., Univ. of Rochester, Rochester, NY 14642 and the Int. Ctr. for Hearing and Speech Res., Rochester Inst. of Technol., Rochester, NY 14623 USA.) and Chang Liu (Univ. of Texas at Austin, Austin, TX 78712)

The coordinate response measure (CRM) corpus has gained broad acceptance as a research tool for investigating speech intelligibility in background competition and has been widely used in studies of informational masking. Beneficial properties of the CRM include closed set format, limited linguistic content, and inclusion of target items that promote sound stream segregation based on the voice-identify of the target talker. Extensive research has demonstrated the psychometric characteristics of CRM target-word identification in the presence of one, two, or three competing talkers from the same corpus as well as long-term speech-shaped noise (LTSSN). Percent correct identification varies non-monotonically with signal-to-background ratio for one and two CRM-talker interference and is monotonic when the number of talkers exceeds 2 or is LTSSN. The CRM has even broader applicability when used with other types of background competition. The purpose of this study is to establish the psychometric characteristics of CRM target-word identification in various backgrounds with the goal of being able to determine when it is appropriate or not to use adaptive threshold procedures with the CRM corpus. Psychometric functions and thresholds based on adaptive tracking for identification of CRM target words presented in multi-talker babble and cafeteria noise will be discussed.

FRIDAY MORNING, 23 APRIL 2010 GRAND BALLROOM VII/VIII/IX, 8:00 A.M. TO 12:00 NOON

Session 5aSC

Speech Communication: Vowels, Phonation, and Tones (Poster Session)

Susan N. Nittrouer, Chair
Ohio State Univ. Medical School, Dept. of Otolaryngology, 915 Olentangy River Rd., Ste., 4000, Columbus, OH 43312

Contributed Papers

All posters will be on display from 8:00 a.m. to 12:00 noon. To allow contributors an opportunity to see other posters, contributors of odd-numbered papers will be at their posters from 8:00 a.m. to 10:00 a.m. and contributors of even-numbered papers will be at their posters from 10:00 a.m. to 12:00 noon.

5aSC1. Phonetic learning *in utero*. Christine Moon (Dept. of Psych., Pacific Lutheran Univ., Tacoma, WA 98447, mooncm@plu.edu), Hugo Lagercrantz (Neonatology Unit, Karolinska Inst., Stockholm, Sweden), and Patrica K. Kuhl (Inst. for Learning & Brain Sci., Univ. of Washington, Seattle, WA)

The prevailing view is that newborn phonetic perception is *tabula rasa* because of poor transmission of the acoustic features of phonemes to the fetus. However, vowel information may be at least intermittently clear *in utero*. We tested 80 neonates (M = 32.8 h old, range 7–75) in the US and Sweden with English and Swedish vowels using an infant-controlled sucking procedure. Sucking activated 1 of 17 stimuli (a prototype and 16 variants) from the same vowel category, either the English /i/ or the Swedish /y/. Infants sampled through all 17 stimuli, presented randomly, one time. The dependent measure was mean number of sucks per stimulus. Results showed that the Foreign Vowel Group had significantly greater means to the prototype than the Native Group. A within-group analysis showed another Foreign-Native Group difference. Infants in the Foreign Group had significantly more sucks to the prototype compared to the variants, whereas the Native Group treated the prototype and variants equivalently. These results require us to re-evaluate assumptions about availability of speech sounds to the fetus and the state of speech perception at birth.

5aSC2. Longitudinal analysis of vowels in infant-directed speech. Kerry E. McColgan, Nan Bernstein Ratner, and Rochelle Newman (Dept. of Hearing and Speech Sci., Univ. of Maryland, 0100 Lefrak Hall, College Park, MD 20742, kmccolgan@hesp.umd.edu)

Adult-directed conversational speech (ADS) is characterized by a high level of acoustic imprecision which should theoretically cause problems for infant language learning. Whether infant-directed speech (IDS) is clearer than ADS is disputed. However, differences in prosody [Fernald (1989)], utterance length [Cooper (1997)], and acoustic features [Bernstein Ratner (1984) and Malsheen (1980)] have been found. Such differences have the potential to assist children in decoding language input [Fernald (1985)]. In prior research, the child's age and language ability appear to affect speech clarification [Bernstein Ratner (1996)]. This study examines whether vowel clarification is a function of the infants' age. More than 75 mother-infant dyads are being followed from 7 months to 2 years of age. Data reported here are from 10 dyads whose data have been fully analyzed. Plots of the first and second formant values for vowels in words spoken in IDS and ADS were compared at 7 and 11 months of age. Vowels to 7-month-old infants appear to show less clarification than those to 11-month infants, although individual patterns of clarification are evident. This study analyzes whether such variability in vowel clarification affects the rate of early infant vocalizations prior to language production. [Work supported by NSF BCS074512.]

5aSC3. Vowel space of 3- and 4-year-old children. Rebecca W. McGowan, Margaret Denny, Richard S. McGowan (CReSS LLC, 1 Seaborn Pl. Lexington, MA 02420), and Susan Nittrouer (The Ohio State Univ., Columbus, OH 43212)

Children learn to produce speech within the constraints of vocal tracts that are smaller and configured differently from those of adult speakers. To study children's speech development in relation to their vocal tract growth, the acoustic characteristics of vowels spoken by ten children, recorded at 6 month intervals between the ages of 36 and 48 months and a subset between 18 and 48 months, are analyzed. The first three formant frequencies of each token are measured and tokens are categorized by intended vowel. Formant frequencies are compared both among vowel categories at each age and

within categories over time to give an understanding of the development of children's vowel space. Changes in children's ability to differentiate among vowels in F1-F2 space over time are investigated. The development of vowel space is considered in the context of growth of and changes in the proportions of the vocal tract and improved control of the articulators. [Work supported by NIDCD-0001247 to CReSS LLC.]

5aSC4. Neural coding of formant-exaggerated speech in infants and adults. Yang Zhang, Sharon Miller, Tess Koerner, and Edward Carney (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillbury Dr. SE, Minneapolis, MN 55455)

Speech scientists have long proposed that formant-exaggerated speech plays an important role in phonetic learning and language acquisition. However, there have been very little neurophysiological data on how the infant brain and adult brain respond to formant exaggeration in speech. We employed event-related potentials (ERPs) to investigate neural coding of formant-exaggerated speech sounds. Two synthetic /i/ vowels were modeled after infant-directed speech data and presented in alternating blocks to test the effects of formant exaggeration. The fundamental frequencies of the two sounds were kept identical to avoid interference from exaggerated pitch level and range. For adult subjects, non-speech homologs were also created by using the center frequencies of the formants to additionally test whether the effects were speech-specific. In the infants (6 to 12-month olds), ERP waveforms showed significantly enhanced N250 and sustaining negativity responses for processing formant-exaggerated speech. In adults, enhancement was observed in the N100 component for the speech stimuli but not the homologous non-speech sounds. Collectively, these results provide the first evidence that formant expansion in infant-directed speech enhances neural activities for phonetic encoding, which may facilitate phonetic learning and language acquisition regardless of the age factor [Zhang *et al.* (2009). Neuroimage 46, 226–240].

5aSC5. Development of vowel production in young children with cochlear implants. Kyoko Nagao, Allegra Cornaglia, and H. Timothy Bunnell (Ctr. for Pediatric Auditory and Speech Sci., Nemours A.I. duPont Hospital for Children, Wilmington, DE 19803, nagao@asel.udel.edu)

Past research on children with cochlear implants (CIs) focused on improvements in speech perception, but few speech production studies have been reported. The literature on speech development in prelingual children with CIs is particularly sparse. This is partially due to difficulty transcribing young children's productions. The aim of this study was to examine whether developmental changes in vowels can be captured without phonetically transcribed data. The subject, a prelingually deaf child 22 months old at the start of the study, is one of six children with CIs participating in an ongoing longitudinal study. Audio and video data were collected once or twice per week during auditory/verbal therapy at the Alfred I. duPont Hospital for Children. One author perceptually categorized the child's vowel-like vocalizations in terms of broad height (HIGH, MID, and LOW) and place (FRONT, MID, and BACK) features. Acoustic features (barkscale cepstral coefficients) were then used to train linear discriminant functions on the same vowel data and used to predict perceptual vowel categories. In preliminary results 62% of the tokens were correctly classified for place and 67% for height. Results on generalizability of the features will be presented. [Work supported by NIDRR Grant H133E080003 to the RERC on Hearing Enhancement.]

5aSC6. Sensorimotor maps and vowel development in English, Greek, and Korean: A cross-linguistic perceptual categorization study. Benjamin Munson (Dept. of Speech-Lang.-Hearing Sci., Univ. of Minnesota, 164 Pillsbury Dr., Minneapolis, MN 55455, munso005@umn.edu), Lucie Mnard (Universit du Quebec, Montreal, QC 3C 3P8, Canada), Mary E. Beckman (Ohio State Univ., Columbus, OH 43210), Jan Edwards, and Hyunju Chung (Univ. of Wisconsin, Madison, WI 53705)

Learning to speak involves learning the association between different articulatory maneuvers and their associated auditory-perceptual characteristics. These associations may change over the course of development as a consequence of the nonlinearities inherent in vocal-tract growth. A set of recent studies by Ménard and colleagues has examined these developmental changes by studying adults' categorizations of synthesized vowels based on an articulatory model of the growing vocal tract. These have shown that vowels modeled on younger vocal tracts tend to be perceived as more front than those modeled on older vocal tracts. They have also shown language-specificity in the vowels that are identified in growing vocal tracts, with French listeners labeling fewer sounds as /u/ than English ones, presumably because the high-vowel space of French includes three vowels /i y u/, while English has only two. The current experiment expands on this by examining the perception of synthesized vowels based on seven vocal-tract growth stages by speakers of three languages with very different vowel systems, American English, Korean (seven vowels), and modern Greek (five vowels). Preliminary analyses show language-specific patterns in the perception of vowels in developing vocal tracts. [work supported by NIDCD 02932 and NSF grants BCS0729140 and BCS0729277]

5aSC7. Korean listeners' sensitivity to language-specific phonetic details of children and adults' vowel production in five different languages. Hyunju Chung, Jan Edwards, Gary Weismer, Eunjong Kong (Dept. of Communicative Disord., Univ. of Wisconsin-Madison, 1500 Highland Ave., Madison, WI 53705, hchung23@wisc.edu), Benjamin Munson (Univ. of Minnesota, Minneapolis, MN 55455), and Mary E. Beckman (Ohio State Univ., Columbus, OH 43210-1298)

Systematic differences in vowel production across languages have been demonstrated, even for so-called "shared" vowels. Starting from 10 months of age, language-specific vowel production patterns emerge in babbling [Boysson-Bardies *et al.* (1989)]. Vowel production data from a word repetition task in our laboratory also showed language-specific patterns emerging at 2 years of age. While there is research on adult and infant perception of non-native vowels produced by adults, there is little work on adult perception of children's non-native vowels of different languages. The current study examined Korean adult listeners' perception of vowels from five languages, Cantonese, English, Greek, Japanese, and Korean, produced by 2-, 5-year-old children, and adults. Consonant-vowel and vowel only stimuli were extracted from our vowel production data. Target vowels included /i/, /a/, and /u/, following velar and alveolar stops. Twenty native Korean adult listeners were asked to identify the vowels and rated their goodness. Results will be analyzed using both the formant frequencies and listeners' judgments using a mixed effect model. [Supported by a Fulbright fellowship, NIDCD Grant 02932, and NSF Grant 0729140.]

5aSC8. Coordination of the first and second formants of the Mandarin triphthong /iau/ revealed by adaptation to auditory perturbations. Shanqing Cai, Satrajit S. Ghosh, Frank H. Guenther, and Joseph S. Perkell (Speech Commun. Group, Res. Lab. of Electrons, MIT, Cambridge, MA 02139)

Investigations of auditory feedback control of supra-glottal articulatory movements traditionally have focused on quasi-static speech sounds like monophthongs. Only recently has attention been directed toward time-varying sounds. To study the role of auditory feedback in the formation of formant trajectories in time-varying vowels, we perturbed the second formant frequency (F2) trajectory as 20 native speakers produce the Mandarin triphthong /iau/ and measured their patterns of auditory-motor adaptation. The subjects changed F2 in directions opposite to the perturbations, not unlike adaptive responses seen in previous studies. Surprisingly, concurrent with the F2 compensations, the subjects significantly altered the first formant (F1), the unperturbed formant, in ways that assisted cancellation of the perturbations to the location and orientation of the formant trajectory in the F1×F2 space. Care was taken to rule out that the F1 changes were byproducts of the F2 compensations. These observations indicate that F1 and F2 are planned in a coordinated fashion for the triphthong /iau/, a property of the speech system not yet revealed through studying quasi-static sounds. The implication of this F1-F2 synergy for the spatiotemporal nature of vowel auditory targets will be discussed. The patterns of generalization to a set of unperturbed vowels will also be presented.

5aSC9. Position and height asymmetries in hiatus resolution: Are they phonetically driven phenomena? Hijo Kang (Dept. of Linguist., Stony Brook Univ., Stony Brook, NY 11794-4376, hikang@ic.sunysb.edu)

Hiatus is not preferred in many languages and is resolved in various ways. Two typological patterns have been found in hiatus resolution. When hiatus is resolved by a weakening (deletion or gliding) of one vowel, (1) V1 is more likely to be the target than V2 [Casali (1996)] and (2) high vowels are more likely to be the target than non-high vowels [Rosenthall (1997)]. If

these patterns are due to human articulatory and/or auditory mechanisms [Ohala (1993)], the patterns would be expected to reflect variations in ordinary speech. In this study Korean CV1V2 nonce words produced by six Korean speakers are analyzed to test whether V1 and high vowels in a realized hiatus are actually weakened in terms of duration. The results showed that V1 is shorter than V2 irrespective of speech rate [$F(1,5)=12.90$, $P<0.02$], which was not found in CVCV or CVGV words. It was also found that high vowels are shortened in fast speech to a more degree than non-high vowels [$F(1,5)=7.16$, $P<0.05$]. The formant analysis showed that vowel-to-vowel coarticulation effects are greater in CV1V2 than in CVCV, which means that vowels in hiatus are more vulnerable to misperception and consequently, sound change.

5aSC10. Lexical frequency and Japanese vowel devoicing. Kuniko Nielsen (Dept. Linguist., Oakland Univ., 320 O'Dowd Hall, Rochester, MI 48309, nielsen@oakland.edu)

The current study aims to examine the relationship between Japanese vowel devoicing and lexical frequency in light of the probabilistic reduction hypothesis [Jurafsky *et al.* (2001)], which predicts that more probable words are (phonetically) reduced more than less probable words. In Tokyo Japanese, high vowels become devoiced when they occur between two voiceless consonants. Similar devoicing processes occur in many languages and are generally considered to be part of the vowel reduction processes [e.g., Dauer (1980); Kohler (1990)]. Although Japanese vowel devoicing has been studied extensively from both phonetic and phonological viewpoints, its lexical property, namely, the effect of lexical frequency, is as of yet unknown. If Japanese devoicing is a phonetic reduction process, we would expect to see a stronger degree of devoicing among words with higher lexical frequency. Twenty-four speakers of Tokyo Japanese recorded 60 words which include various devoicing environments. Contrary to the prediction by the probabilistic reduction hypothesis, our preliminary results revealed a significantly higher rate of devoicing [$F(1,22)=24.89$, $p<0.01$] as well as shorter vowel duration [$F(1,22)=4.61$, $p<0.05$] among low-frequency words than high-frequency words. The implications of these results on the nature of Japanese vowel devoicing will be discussed.

5aSC11. Comparison of the formant frequencies F3 and F4 on a three-dimensional vowel chart. Toshio Isei-Jaakkola (Dept. of English Lang. & Culture, Chubu Univ., 1200 Matsumoto, Kasukagi, Aichi 487-8501, Japan, tiseij@isc.chubu.ac.jp), Takatoshi Naka (Chukyo Univ., Toyoda, Aichi 470-0393, Japan), and Keikichi Hirose (Univ. of Tokyo, Bunkyo, Tokyo 113-8656, Japan)

We have developed a three-dimensional vowel chart that should fit into a quadrilateral IPA vowel chart better and later we have added more visually effective functions to it. On the chart we can see not only the locations of F1 and F2 with two scales of *x* and *y*, where *x* is F1 and *y* F2, but also F1, F2, and F3 as well, with three scales of *x*, *y*, and *z*, where *x* is F1, *y* F2, and *z* F3. Thus, this enables us to compare the vowel locations of any language (multilingual vowel presentations), vowels uttered by male with those of female (thus, gender difference), vowels of adults with those of children (thus, age difference), foreign language learners with target vowels, or vowels uttered by the same language learners. This time, we focus more on the roles of the respective formants, particularly on the roles of F3 and F4. It has been clarified that F3 is more related to lip-spreading. We want to show that F4 may be more related to lip-protrusion. For this purpose, we have further added a selection of F3 and F4 functions to the chart. [Work supported by JSPS and Chubu University Grant (A).]

5aSC12. Psychometric functions of vowel detection and vowel identification in multi-talker babble. Maggie Miller, Jessica Walker, Kayla O'Brien, and Chang Liu (Dept. of Commun. Sci. and Disorder, The Univ. of Texas at Austin, 1 Univ. Station A1100, Austin, TX 78712)

Psychometric functions of vowel detection and vowel identification were measured in multi-talker babble for young normal-hearing listeners. A four-interval forced-choice procedure was used to examine the accuracy of vowel detection in babble with speech level presented from 0- to +15-dB sensation level relative to vowel detection thresholds obtained with method of limits. The accuracy of vowel detection was significantly influenced by vowel category and sensation level. The threshold of vowel detection for each vowel and each listener was defined as the speech level at which 71% accuracy of vowel detection was reached. Vowel identification was then measured in babble with vowel levels presented from 0- to 12-dB sensation level relative to individual thresholds of vowel detection, using a close-set 12-choice procedure. Results suggest that vowel identification was significantly affected by vowel category and sensation level. Altogether, the results of vowel detection and vowel identification indicate that, given the same signal-to-noise ratio, vowels are not equally audible and identifiable, possibly due to the fact that some vowels are more audible than others, and that the slope of psychometric functions of vowel identification is vowel-dependent.

5aSC13. Vowel-inherent spectral change in isolated vowels and consonant vowel consonants. Peter F. Assmann (School of Behavioral and Brain Sci., The Univ. of Texas at Dallas, Richardson, TX 75083), Terrance M. Nearey (Univ. of Alberta, Edmonton, AB T6G 2E7, Canada), and Michael Kiefte (Dalhousie Univ., Halifax, NS B3H 1R2, Canada)

To study the interaction of vowel inherent spectral change (VISC) and consonant context on vowel formant patterns, we recorded 15 vowels /i ɪ eɪ ɛ æ ʌ ɑ ɔ oʊ ʊ u ɝ ɑɪ ɑʊ ɔɪ/ in each of 14 consonant environments (pVp, pVb, bVb, bVp, tVt, tVd, dVt, dVd, kVk, kVg, gVk, gVg, hVd, and V) spoken by 10 men and 10 women from the north Texas region. Analysis of vowel formant frequency trajectories confirmed the reliable presence of VISC across talkers for a range of consonant environments. Vowels showing stable patterns of VISC included those acknowledged as diphthongs in most North American English dialects, /ɑɪ/, /ɑʊ/, /ɔɪ/, /eɪ/, /oʊ/, as well as /ɪ/, with more variable movement patterns for /ɛ/, /æ/, and /u/. Of particular interest were cases where the formants F1 and/or F2 showed a "switchback" pattern of movement, with initial movement in the expected direction for the vowel (as observed in isolated vowels) and subsequently toward the"locus" for the final consonant. Parallel analyses of VISC in three dialects (north Texas, Nova Scotia, and Alberta) are currently underway and will be reported at the meeting along with statistical modeling results [Nearey (this meeting)].

5aSC14. Assessing acoustic measures of the spontaneous phonetic imitation of vowels. Molly E. Babel (Dept. of Linguist., Univ. of British Columbia, 2613 West Mall, Vancouver, BC V6T 1Z4, Canada, mbabel@interchange.ubc.ca) and Benjamin Munson (Univ. of Minnesota, Minneapolis, MN 55455)

It is well established that people imitate fine phonetic detail of another talker in shadowing tasks [Goldinger, Psych. Rev. **105**, 251–279 (1998)] and in interactive conversation [Pardo, J. Acoust. Soc. Am. **119**, 2382–2393 (2006)]. That is, the acoustic characteristics of a model talker's production (MTP) are more similar to a participant's shadowed production (PSP) than they are to that participant's baseline production (PBP), typically elicited in a reading task. This presentation compares two methods of assessing the acoustic distance between the vowels in PSP and PBP monosyllabic words taken from two previous studies [Babel, thesis, University of California (2009); Kaiser & Munson, (unpublished)]. One of these measures is the F1/F2 Euclidean distance between PSP and PBP vowels. This measure does not take into account the direction of the difference. The other [adapted from Titze, *Principles of Voice Production* (1994)] compares the distance and direction of the F1 and F2 values in the PSP and PBP vowels relative to those of the MTP. The merits of each of these methods are assessed by comparing them to measures of listener judgments of the similarity of PSPs and PBPs to the MTPs in AXB perception tasks.

5aSC15. The relationship between fundamental frequency and vowel quality. Santiago Barreda and Terrance M. Nearey (Dept. of Linguist., Univ. of Alberta, 4-32 Assiniboia Hall, Edmonton, AB T6G 2E7, Canada, sbarreda@ualberta.ca)

There is disagreement over the role fundamental frequency (f0) plays in the determination of vowel quality. Some claim [e.g., D. Smith *et al.*, J. Acoust. Soc. Am. **117**, 305–318 (2005)] that changes in f0 do not affect vowel quality at all. Others claim there is relationship between f0 and vowel quality, whether direct or indirect [see T. M. Nearey and P. F. Assmann, in *Experimental Approaches to Phonology*, edited by M. J. Solé and P. S. Beddor (Oxford University Press, Oxford, 2007), pp. 246–269 for a review]. To test these theories, a series of experiments was carried out in which participants were asked to make simultaneous speaker and vowel quality judgments. Participants were presented with a synthetic vowel continuum

spanning from [æ] to [ʌ] matched with several different f0s and higher formants. Participants were asked to rate vowel quality on a continuous scale ranging from completely [æ] to completely [ʌ] and to indicate the size and gender of the speaker. Results indicate that there is a complicated, indirect relationship between f0 and vowel quality, and that shifts in vowel quality caused by changes in f0 are a result of changes in assumed speaker properties.

5aSC16. Improved representation of variance in measures of vowel merger. Lauren Hall-Lew (Phonet. Lab., 41 Wellington Square, Oxford OX1 2JF, UK)

Current measures of vowel merger, such as the Euclidean distance between averages, have only been able to capture some of the variability between two given vowel clusters. Reliance on averages obscures the amount of variability within a given vowel class, while other techniques, such as calculating distance between minimal pairs, rely on few tokens per speaker. Hay *et al.* (2006) introduced an alternative approach that accounts for the variability between two vowel clusters, taking formant values as input, rather than averages. The measure is the Pillai-Bartlett statistic [Baayen (2008)], an output of a multivariate analysis of variance (MANOVA), which represents the proportion of one variance that can be predicted by another variance. A higher Pillai value indicates a lower degree of overlap between two vowel clusters in F1/F2 space. Since the value is derived from a MANOVA, Pillais can account for known internal factors influencing the production of merger, such as phonological environment, thereby reducing the need to obtain minimal pair lists. This talk argues for using Pillais as measures of merger by comparing results from low back merger in California English [Hall-Lew (2009)] with the analysis of front vowel merger by Hay *et al.* (2006).

5aSC17. An acoustic study of front rounded vowels in Shetland dialect. Man Gao and Peter Sundkvist (Acad. of Humanities and Media Studies, Dalarna Univ., SE-79160 Falun, Sweden)

This paper presents an acoustic analysis of front rounded vowels (FRVs) in the dialect spoken in the Shetland Islands, the northernmost locality of the British Isles. FRVs are typologically marked and estimated to occur in only 6.6% of the world's languages [I. Maddieson, in Haspelmath *et al. The World Atlas of Language Structures* (2005)]. Their occurrence in the Shetland dialect is, at least partly, attributable to a Scandinavian substratum language. There is significant variation across the archipelago regarding several aspects such as (1) the number of lexically contrastive FRVs, (2) phonetic quality (close to half-close), (3) contrastive length, and (4) lexical distribution and support. This paper presents an investigation of three speakers from one locality in which FRVs have retained firm lexical support. The issues addressed concern the dialect's overall acoustic vowel space (based on F1, F2, and F3), the position of FRVs within the acoustic space, and what the contrasts among FRVs and other adjacent vowels appear to rest on acoustically. Special focus is directed to phonetic contexts that support the greatest number of vowel contrasts and display the most crowded acoustic vowels spaces.

5aSC18. A new non-linear regression model for formant trajectories in English monosyllables incorporating dual targets for vowels. Terrance M. Nearey (Dept. of Linguist., Univ. of Alberta, 4-32 Assiniboia Hall, Edmonton, AB, T6G 2E7, Canada, t.nearey@ualberta.ca)

A new non-linear regression model is proposed to characterize the formant trajectories of the vocalic portion of English CVC syllables in the data described by Hillenbrand *et al.* [J. Acoust. Soc. Am. **109**, 748–763 (2001)]. The modeling framework builds on work of Broad and Clermont [J. Acoust. Soc. Ame. **81**, 155–165 (1987)], wherein formant trajectories were modeled via three additive components: (1) a single vowel target, (2) an exponential approach (in time from onset) toward the vowel target from an initial consonant onset value, and (3) an exponential approach (in time from offset) toward the vowel target from a final consonant offset value. The new model extends this to allow for a dual specification (nucleus + offglide) of the vowel targets [T. Nearey and P. Assmann, J. Acoust. Soc. Am. **80**, 1297–1308 (1986)]. Initial results suggests that inclusion of a second vowel target provides substantial reduction (about 40%, 23% and 7% respectively for F1, F2, and F3) of error variance on trajectories averaged across 12 speakers. More detailed statistical analyses of variants of the new model are underway and will be reported for both the data described above and that reported on by Assmann *et al.* [this meeting].

5aSC19. The effect of increased loudness on anticipatory coarticulation of steady-state formants in a vowel-consonant-vowel context for patients with Parkinson's disease. Jennifer A. Kamphaus, Joan E. Sussman, Elaine T. Stathopoulos, Jessica E. Huber, Kelly C. Richardson, and Brit A. Boyarsky (Dept. of Communicative Disord. and Sci., Univ. at Buffalo, SUNY, 3435 Main St., Buffalo, NY 14214)

The current investigation examines the effect of increased loudness on anticipatory coarticulation of the vowels [i, ɑ, u] on the preceding schwa vowel for patients with Parkinson's disease. Four speakers, three males and one female with speech severity levels between 8% and 49%, are involved in pre-treatment, treatment, and post-treatment conditions. During treatment, participants use an auditory device which plays speech-babble into one ear while they are speaking. The speech-babble competition results in an automatic loudness increase (Lombard effect) in the talker wearing the device. Participants produced target nonsense CVC words embedded in carrier sentences at comfortable loudness levels and at an average of 3 dB above that level. The steady-state F1, F2, and F3 formant frequencies of the preceding [ə] were analyzed to determine whether increased loudness results in increased anticipatory coarticulation from the [i, ɑ, u] vowels in the CVC words, as treatment progresses. Results using steady-state formant frequency measures from this study will be compared with previous studies that used F2 trajectory measures [Tjaden and Sussman (2006); Weismer *et al.* (1995); Tjaden (2003)]. (Work supported by NIH 1R01DC009409-01)

5aSC20. Investigating within and between talker variability in the optical characteristics of American English vowels. Edward T. Auer, Jr. and Laura Welch (Dept. of Speech-Lang.-Hearing, Univ. of Kansas, 1000 Sunnyside Ave., Rm. 3001, Lawrence, KS 66045, auer@ku.edu)

Previous research investigating vowel production provides evidence of substantial within and cross-talker variation in acoustic characteristics. The current study is designed to investigate whether similar within and cross-talker variation exists in the optical characteristics of American English vowels. Additionally, potential shared acoustic-optical variation across tokens will also be examined. Measures taken from three-dimensional motion data for a set of 13 markers positioned around the lips, cheeks, and chin sampled at 100 frames/s with millimeter spatial resolution along with simultaneous video (50 frames/s) and audio for each of ten repetitions of 11 vowels spoken by multiple talkers will be reported. Preliminary analysis of motion and acoustic data from12 repetitions of 11 vowels spoken by one male talker provides evidence of substantial within vowel variation in both vertical and horizontal lip separations measured at the midpoint of the vowel as determined by analysis of the acoustic signal. Correlations were observed between horizontal lip separation and second formant frequency ($r = 0.48$) and third formant frequency ($r = 0.66$) at the vowel midpoint. No correlations were obtained with vertical lip separation measure. Results will be discussed in terms of potential implications for talker intelligibility in visual only presentation conditions.

5aSC21. Effects of ambient pressure and gas mixture on a numerical model of subglottal acoustics and vowel spectra. Steven M. Lulich (Dept. of Psych., Washington Univ., 1 Brookings Dr., Saint Louis, MO 63130, slulich@artsci.wustl.edu)

Divers' speech in hyperbaric heliox environments becomes significantly distorted, making communication between divers and with surface-based personnel difficult. Previous research identified two basic mechanisms underlying this distortion. First, the speed of sound increases significantly in heliox, causing a linear increase in the second and higher formant frequencies. Second, in hyperbaric conditions the specific impedance of air in the vocal tract approaches that of the vocal tract walls, leading to a nonlinear increase in the first formant frequency. Effects of ambient pressure and gas mixture on subglottal acoustics and subglottal-vocal tract coupling in vowel spectra have not been sufficiently investigated. In this paper, such an investigation is carried out using a numerical model of subglottal and vowel acoustics. It is shown that subglottal resonance frequencies increase linearly as the speed of sound increases, and the corresponding subglottal pole-zero pairs in vowel spectra become disproportionately prominent as

ambient pressure increases. Increased acoustic coupling between the subglottal system and the vocal tract in hyperbaric heliox therefore constitutes a third significant source of speech distortion. The results have implications for understanding subglottal coupling in vowels and for heliox speech unscrambling techniques. [This work was supported in part by NSF Grant No. 0905250.]

5aSC22. Developing vowel mappings for an interactive voice synthesis system controlled by hand motions. Karl I. Nordstrom (Media and Graphics Interdisciplinary Ctr., Univ. of British Columbia, Forest Sci. Ctr. Bldg., FSC 3640-2424 Main Mall, Vancouver, BC, V6T 1Z4, Canada, karl@karlnordstrom.ca), Sidney Fels, Cameron D. Hassall, and Bob Pritchard (Univ. of British Columbia, Vancouver, BC, V6T 1Z2, Canada)

This study investigates vowel mappings for a voice synthesizer controlled by hand gestures for artistic performance. The vowel targets are on a horizontal plane navigated by the movement of the right hand in front of the performer. Two vowel mappings were explored. In one mapping, the vowels were evenly distributed in a circle to make the vowel targets easier for the performer to find. In the other mapping, the vowels were arranged according to the F2 versus F1 space. Linear hand motions were then made through the vowel space while plotting the formant trajectories. The evenly distributed mapping resulted in formant trajectories that were not monotonic; the F1 and F2 pitch contours varied up and down as the hand carried out the linear motions. This had the unintended result of producing multiple diphthongs. In contrast, the F2 versus F1 mapping enabled the performer to create monotonic formant trajectories and the perception of a single diphthong. The performer found it easier to speak and sing through the system when a single linear hand motion resulted in a single diphthong. [This project was supported by Canada Council for the Arts, Natural Sciences and Engineering Council of Canada, and Media and Graphics Interdisciplinary Centre.]

5aSC23. Psychometric functions for rough voice quality. David A. Eddins (Univ. of Rochester, 2365 S. Clinton Ave., Ste. 200, Rochester, NY 14618, david_eddins@urmc.rochester.edu) and Rahul Shrivastav (Univ. of Florida, Gainesville, FL 32611)

Dysphonic voices arising from laryngeal lesions are generally believed to vary across three perceptual dimensions—breathiness, roughness, and strain. This experiment sought to evaluate the psychometric functions for roughness and to determine the acoustic cues for its perception. Ten normal-hearing listeners, all native speakers of American English, were recruited for this experiment. The perception of roughness in dysphonic voices was evaluated for 34 voices from the Kay Elemetrics Disordered Voice Database (Kay-Pentax, Inc., Lincoln, NJ). Listeners compared the roughness of these test stimuli against that for a sawtooth wave with a 40-Hz squared-cosine amplitude modulation (AM). The modulation depth of the sawtooth wave was varied from low to high in a paired comparison task. Psychometric functions for roughness were derived by plotting the listener response for each stimulus pair against the modulation depth of AM sawtooth wave. The data for each stimulus were fitted with a logistic function, and various parameters (threshold, slope, and saturation point) were computed. These parameters were then compared to various acoustic measures obtained from each voice to determine candidate acoustic cues for roughness.

5aSC24. Glottal aperture monitoring with external lighting and sensing photoglottography. Kiyoshi Honda (LPP, UMR7018 CNRS-Univ. Paris3, 19 rue des Bernardins, 75005 Paris, France), Shinji Maeda (TELECOM ParisTech, F-75634 Paris Cedex 13, France), and Tatsuya Kitamura (Konan Univ., Kobe 658-8501, Japan)

A non-invasive photoglottographic method has been developed for monitoring glottal aperture changes during speech for the purpose of phonetic and clinical studies. The system includes light-source and sensor units both placed externally on the neck. An LED light source on the side of the neck illuminates the hypopharynx diffusely, and a photo-sensor unit on the front neck below the cricoid cartilage detects light passed through the glottis. An ambient light rejection circuit was newly added to avoid the effect of room light. The photoglottography (ePGG) system is free from interference due to tongue retraction and thus operational both in high- and low-vowel environments, while it is susceptible to articulatory movements of the jaw and larynx. We will present new ePGG/airflow data to explain why the apparent word-initial strengthening of glottal opening occurs in our ePGG, as often observed in other previous PGG data. [Work supported by ESAPVI/ANR and Kakenhi 21300071.]

5aSC25. Breathy phonation in Gujarati: An acoustic and electroglottographic study. Sameer ud Dowla Khan (Dept. of Linguist., Cornell Univ., 203 Morrill Hall, Ithaca, NY 14853, sameeruddowlakhan@gmail.com)

Recent electroglottographic research on Gujarati [Khan (2009)] reveals that speakers consistently distinguish breathy and modal vowels (e.g., /bar/ "twelve" vs /bAr/ "outside;" capitalization represents breathiness) by both closed quotient and closing velocity. Despite this interspeaker uniformity measured at the voice source, the acoustic correlates of the contrast measured in the speech output vary considerably across speakers. While some speakers mark breathiness with a larger H1-H2 difference, others use lower periodicity (CPP) or greater changes in intensity (rms energy). It is unclear how breathy vowels are contrasted with modal vowels following breathy consonants (e.g., /bAr/ "outside" vs /Bar/ "burden") or to what extent the preceding consonant manner can affect the spectral acoustics of the vowel (e.g., /pAr/ "mountain" vs /vAn/ "vehicle"). To better capture the variation in both vowel and consonant phonations, the current study examines acoustic and electroglottographic data collected from naturalistic productions of near-minimal sets from a larger pool of Gujarati speakers, using a wider range of vowel and consonant types. Preliminary results suggest that while all speakers distinguish phonation types in both consonants and vowels based on electroglottographic measures, the acoustic cues in the output are far more complex. [Work supported by NSF.]

5aSC26. Effects of asymmetric vocal fold activation on phonation. Dinesh K. Chhetri and Juergen Neubauer (Div. of Head and Neck Surgery, 62-132 CHS, 10833 Le Conte Ave., Los Angeles, CA 90095, dchhetri@mednet.ucla.edu)

The effects of asymmetric vocal fold activation on phonation were studied using an *in vivo* canine model and graded neuromuscular stimulation of the recurrent laryngeal nerve (RLN). One RLN was stimulated at 21 levels of graded stimulation, from threshold activity to maximal contraction, at three levels of contralateral vocal fold contraction (low, medium, and high). Phonation onset pressure (Pth) was recorded at each condition. The effects of airflow and cricothyroid (CT) muscle activation were studied by varying airflow and CT activation levels. Pth remained relatively constant over nearly all conditions while the level of graded stimulation needed to reach Pth varied. Increasing airflow and higher level of contralateral vocal fold activation allowed Pth to be reached at lower levels of graded stimulation, while activation of CT muscles had the opposite effect. At maximal CT activation, Pth was reached only at high levels of contralateral vocal fold activation but Pth was doubled. Results show that in vocal fold paresis /paralysis, phonation onset can be achieved by increasing either airflow or activation level of the normal vocal fold, and that CT activation increases the phonatory effort. These results provide further insights into the compensatory mechanisms required for phonation in these common laryngeal pathologies.

5aSC27. An acoustic analysis of pulmonic ingressive speech in the Shetland Islands. Peter Sundkvist, Man Gao (Acad. of Humanities and Media Studies, Dalarna Univ., SE-79160 Falun, Sweden, psn@du.se), and Gunnel Melchers (Stockholm Univ., SE-10691 Stockholm, Sweden)

The use of a pulmonic ingressive airstream mechanism in the pronunciation of certain discourse particles, typically variants of "yes" and "no," is a well-known and salient feature of Scandinavian languages. It has been suggested, however, that this may be a more general North Atlantic phenomenon—occurring as far west as Newfoundland and New England—which spread via migration and trade routes. Unfortunately, there seem to be very few audio recordings available from areas other than Scandinavia and Newfoundland (perhaps partly attributable to various elicitation difficulties) and very little acoustic analysis has been presented [E. Thom, MA thesis, UCL (2005); R. Eklund, J. Int. Phonetic Assoc. **38**, 235–325 (2008)]. This paper contains a study of ingressive discourse particles in the Shetland Islands, which have strong historical links to Scandinavia. A significant number of ingressives were found in field recordings from 1980–1982. This paper presents an acoustic pilot study of ingressive dis-

course particles, focusing on issues such as formant structure and voicing /phonation characteristics. A comparison is also made with previous analyses [E. Thom, MA thesis, UCL (2005); R. Eklund, J. Int. Phonetic Assoc. **38**, 235–325 (2008)] as well as audio samples from other localities within the North Atlantic region.

5aSC28. The surface wave model of phonation threshold pressure and physical models of the vocal fold mucosa: Theory and experiment. Lewis P. Fulcher and Ronald C. Scherer (Bowling Green State Univ., Bowling Green, OH 43403)

One of the simpler manifestations of the role of the vertical phase difference in transferring energy from the glottal airflow to the motion of the vocal folds is the surface wave model (SWM) developed by Titze in 1988. He predicted that the phonation threshold pressure (PTP) should decrease as the glottal half width decreases and as the vocal fold thickness increases, and increase as the tissue damping increases, if no vocal tract is present. Further, his treatment of the SWM predicts that for a given glottal half width, converging glottal shapes should have a higher PTP than diverging glottal shapes. Although some of the experiments done with physical models of the vocal fold mucosa support these predictions, the measurements of the angle dependence of the PTP [Chan *et al.*, "Further studies of phonation threshold pressure in a physical model of the vocal fold mucosa," J. Acoust. Soc. Am. **101**, 3722–3727 (1997)] do not follow the expected trend. A recent re-examination of the SWM found that the diverging-converging question is sensitive to the value of the entrance loss coefficient. Values of the coefficient near 1.37 seem to remove the discrepancy with the data. [Work supported by NIH R01DC03577.]

5aSC29. An acoustic and electroglottographic study of phonation contrast in Yi. Jianjing Kuang (UCLA, Phonet. Lab., Dept. Linguist., Los Angeles, CA 90095-1543)

This study examines the phonation contrast of Yi, a Tibeto-Burman language of Southwestern China with phonation as a phonemic dimension (traditionally described as tense versus lax contrast). The language has seven monophthongs as well as three tones (high, mid, and low). Tense versus lax phonation contrast can apply to all the vowels and two tones (mid and low) in the language. In this study, both acoustic and electroglottographic data were collected with minimal pairs for all combinations of tones and vowels. Extensive acoustic measures were done by VOICESAUCE, including F0, H1, H2, H1-H2, H2-H4, H1-A1, H1-A2, F1, F2, and cepstral peak prominence (CPP); EGG measures were closed quotient (CQ) and peak-velocity (PV). Preliminary data suggest that H1-H2, CPP, CQ, and PV measures can exclusively distinguish the two phonation types. Moreover, EGG data also suggest voice quality interacts with tones, but the patterns vary among speakers. This might due to the different strategies used by speakers to produce the tense versus lax contrast. In addition, formant frequency measures also show salient differences between tense and lax vowels; tense vowels generally have higher F1 than the lax counterparts. All of the facts suggest that phonation contrasts in Yi are realized across different phonetic dimensions.

5aSC30. Acoustic analysis of phonation and tone interactions in Mazatec. Marc Garellek (Dept. of Linguist., UCLA, 3125 Campbell Hall, Los Angeles, CA 90095-1543, marcgarellek@ucla.edu)

Jalapa de Diaz Mazatec is unusual in contrasting three phonation types (breathy, modal, and laryngealized) and three tone heights: low, mid, and high, including tone contours. Using the acoustic measures H1-H2, H1-A2, and cepstral peak prominence (CPP), previous research has shown that the three phonation types on mid tones are best distinguished at the beginning of the vowel, with each phonation gradually tending toward breathiness [Blankenship (2002)]. The present study extends previous findings by investigating tone and phonation interactions in over 650 Mazatec words and for a large range of acoustic measures. The speech samples, from the UCLA Phonetics Archive, were produced by six female and eight male speakers and vary across the three phonation types and two tonal groups (non-low and low). Using the voice analysis program VOICESAUCE [Shue *et al.* (2009)], acoustic measures such as harmonic amplitudes, F0, energy, CPP, formants, and bandwidths were extracted. The results generally support previous findings. Several measures also show effects of tone on phonation. In addition, how the phonation types and tone groups differ in timing and the effect of preceding consonants on phonation were investigated. Results show that preceding aspiration changes the timing and degree of phonation. [Work supported by NSF.]

5aSC31. A spectral-slope compensated scale for measuring perception of vocal aperiodicity. Bruce R. Gerratt and Jody Kreiman (Div. of Head/Neck Surgery, UCLA School of Medicine, 31-24 Rehab Ctr., Los Angeles, CA 90095-1794)

The influence of sound intensity on listeners' perception of pitch and of sound frequency on the perception of loudness are well known. Similar interaction effects occur in voice quality perception, but are not well understood. Previous studies suggest that listeners' sensitivity to noise levels in voice depends on the shape of the harmonic spectrum: As the amount of high-frequency harmonic energy present in the voice spectrum increases, listeners require a corresponding increase in noise energy to perceive a constant noise level. These results indicate that perceptually meaningful measurement of spectral noise in voice requires derivation of a spectral-slope-compensated noise scale (similar to equal loudness curves). Based on 12 natural voices, series of stimuli will be created by modifying (1) the noise-to-harmonics ratio (NHR) for different source spectral slopes and (2) the source spectral slope for different NHR values. Just-noticeable differences for each parameter will be plotted as a function of the other, to create a set of equal noise contours reflecting the perceptual interactions of these two acoustic attributes. [Work supported by NIH.]

5aSC32. Voice quality as a cue to location in a speaker's fundamental frequency f0 range: A perceptual study of English and Mandarin. Jason B. Bishop (Dept. of Linguist., UCLA, 3125 Campbell Hall, Los Angeles, CA 90095, j.bishop@ucla.edu)

Recent research shows that listeners can locate a specific f0 within a speaker's individual range without prior experience with the speaker's voice [Honorof and Whalen, J. Acoust. Soc. Am. **117**, 2193–2200 (2005)], suggesting that perhaps some acoustic parameters co-vary with f0 range and are available to listeners. Here we tested Honorof and Whalen's hypothesis that this information lies in voice quality. English- and Mandarin-speaking listeners heard brief, steady-state /ɑ/ tokens from various locations throughout the f0 ranges of ten English and ten Mandarin voices and were asked to identify where in the speaker's pitch range a given token came from. To test for listeners' use of voice quality in the task, we compared mixed effect linear models of responses that included three acoustic measures of the stimuli associated with voice quality: H1-H2, H2-H4, and cepstral peak prominence. Preliminary findings show (1) each of the voice quality measures contributed significantly to the models, although they accounted for only a small portion of the variance in responses compared to f0 and (2) models improved significantly when the language of the voice, but not of the listener, was included; this variable represents further language-specific properties of the voices still to be explored.

5aSC33. Online monitoring of auditory feedback is sensitive to language experience. Zhaocong Chen, Peng Liu (Dept. Rehabilitation Medicine, Sun Yat-Sen Univ., Guangzhou 510080, China), Emily Q. Wang (Rush Univ. Medical Ctr., Chicago, IL 60612), Charles R. Larson (Northwestern Univ., Evanston, IL 60208), and Hanjun Liu (Sun Yat-Sen Univ., Guangzhou 510080, China)

It has been demonstrated that vocal responses to pitch perturbations vary as a function of stimulus parameter and can be modulated according to the specific demands of vocal task. The purpose of this cross-language study was to examine whether the online monitoring of auditory feedback is sensitive to language experience during vowel phonation. Native speakers of Cantonese and Mandarin participated in the experiments. They were asked to vocalize a vowel sound /u/ at their conversational pitch, during which their voice pitch feedback was unexpectedly shifted ($\pm$50, $\pm$100, $\pm$200, or $\pm$500 cents, 200 ms duration) and fed back to them over headphones. The results showed that, as compared to previous findings in English speakers [Chen *et al.* (2007)], both Mandarin and Cantonese speakers produced smaller but faster responses to pitch perturbations. In addition, Mandarin speakers produced larger response magnitudes than Cantonese speakers, and the modulation of response magnitudes as a function of stimulus magnitude was observed in Cantonese but not in Mandarin speakers. These findings demonstrate that voice F0 control is language dependent. Further, the dif-

ferent patterns of vocal responses between Mandarin and Cantonese speakers indicate that this highly automatic feedback mechanism works within the specific tonal system of each language.

5aSC34. The role of creaky voice quality in Cantonese tonal perception. Hiu-Wai Lam and Kristine M. Yu (Dept. of Linguist., Univ. of California, Los Angeles, 3125 Campbell Hall, Los Angeles, CA 90095, hiuwai208@ucla.edu)

Vance (1976) found a response bias against Tone 4 (mid-low falling) in a tonal perception experiment in Cantonese where synthesized stimuli varied only in F0, and Vance (1977) explained this by suggesting that creaky voice quality is a redundant cue for Tone 4. Indeed, there is evidence that creaky voice quality plays a role in tonal perception: in Mandarin, a language where creak is well-known to be a redundant cue for one of the tones, Tone 3 (low fall-rise), Belotel-Grenié and Grenié (1994) found that creaky instances of Tone 3 were recognized faster than non-creaky instances. The effect of creaky voice quality on the perception of Tones 4 and 6 (mid-low level) in Cantonese will be investigated using a 2AFC identification task of natural stimuli that were elicited in isolation and in connected speech. Variability in creak in the realization of Tone 4 occurred naturally in the elicited stimuli. If creaky voice quality plays a role in tonal perception, we hypothesize that overtly audible creak, as well as low H1-H2, a spectral index of creak, will bias listeners toward identification as Tone 4, as measured by d' scores, and may also speed Tone 4 recognition.

5aSC35. Perceptual similarities between native and non-native tones. Xianghua Wu (Dept. of Linguist., Simon Fraser Univ., 8888 Univ. Dr. Burnaby, BC V5A 1S6, Canada, xianghua_wu@sfu.ca)

This study investigated the effects of L1 and L2 experience on the perceptual assimilation of non-native tones by native Mandarin or Thai listeners. Of these, 32 had 0.5–1.5 years of L2 learning experience while 40 had none. All listeners participated in a tonal assimilation task in which they first identified which tone in Mandarin or Thai sounded most similar to the Thai or Mandarin tone they heard, and then rated its goodness on a five point Likert scale. Stimuli included four Mandarin tones (high level, rising, falling-rising, and falling tones) and five Thai tones (mid, low-, falling, high-, and rising tones) on four monosyllables: /tuo/, /fej/, /kha/, /siau/, and a hum. The Thai listeners, regardless of L2 experience, assimilated more L1 tone categories to L2 than did the Mandarin listeners. Nonetheless, the experienced listeners from the two languages showed a high degree of consistency in terms of which tones were assimilated. The perceived similarities between native and non-native tones were not always predictable from their acoustic similarities, and varied with L1 and L2 experience. Results will be discussed in terms of some well-known perceptual assimilation models, such as PAM. [Work supported by GIS.]

5aSC36. Production and perception of lexical tones in Beijing and Taiwan Mandarin. Chiung-Yun Chang and Robert Allen Fox (SPA Labs, Speech and Hearing Sci. Ohio State, 1070 Carmack Rd., Columbus OH 43210-1002, chang.553@osu.edu)

The acoustic properties of four lexical tones between two regional varieties of Mandarin Chinese, Beijing Mandarin (Putonghua), and Taiwan Mandarin (Guoyu) were examined in terms of duration, pitch contours, and rms amplitude. Tokens included CV and V monosyllables, representing each of the four tones of Mandarin Chinese, and were produced in isolation and in sentence context by 15 adult native speakers. A different durational pattern of citation tones emerged for two dialect variety groups. In Taiwan Mandarin, it was T2>T1>T3>T4; whereas, it was T3>T2>T1>T4 in Beijing Mandarin [Deng *et al.* (2006)]. The durational discrepancy in isolated T3 may be related to different realization of T3 between two dialect groups. While T3 exhibited a falling-rising pitch contour in Beijing Mandarin, it was falling in Taiwan Mandarin. Such dialectal divergence in T3 contours shapes can be verified from the amplitude contours. Furthermore, pitch contours of other tones in two dialects will be compared to see if there is tonetic sound change in other Taiwan Mandarin tones. These surface acoustic variations in linguistically identical categories can result in perceptually ambiguous tones. A gating experiment was utilized to examine how native and non-native listeners adapt to speaker and dialect variability in the stimuli.

5aSC37. Effects of tone on the three-way laryngeal distinction in Korean: An acoustic and aerodynamic comparison of the Seoul and South Kyungsang dialects. Hyunjung Lee and Allard Jongman (Dept. of Linguist., Univ. of Kansas, 1541 Lilac Ln., Lawrence, KS 66044, elvisdj@ku.edu)

The three-way laryngeal distinction among voiceless Korean stops has been well documented for the Seoul dialect. The present study compares the acoustic and aerodynamic properties of this stop series between two dialects, non-tonal Seoul and tonal South Kyungsang Korean. Sixteen male Korean speakers (eight from Seoul and eight from Kyungsang) participated. Measures collected included VOT, f0 at vowel onset and midpoint, H1-H2, and air pressure and airflow. The presence versus absence of tone affects both the acoustic and aerodynamic properties. First, Seoul speakers primarily use f0 to distinguish the three laryngeal gestures of Korean stops, while Kyungsang speakers mainly use VOT. Second, the high versus low tonal contrast for Kyungsang speakers makes f0 an unreliable acoustic cue for the three Korean stops. Third, dialectal differences in VOT to mark the three-way distinction support the notion of a diachronic transition whereby VOT differences between the lenis and aspirated stops in Seoul Korean have been decreasing over the past 50 years. Finally, the aerodynamic results make it possible to postulate the articulatory state of the glottis. Based on the acoustic and aerodynamic results, different phonological representations for the tonal and non-tonal dialects are suggested.

5aSC38. Temporal changes in Mandarin tone due to speaking rate variation. Joan A. Sereno and Hyunjung Lee (Dept. Linguist., Univ. of Kansas, 1541 Lilac Ln., Lawrence, KS 66045, sereno@ku.edu)

The present research investigates the effects of variation in speaking rate on the production of Mandarin tone. Fourteen speakers (6M, 8F) produced 15 syllables, each with the four different Mandarin tones. Speakers produced these syllables at fast, normal, and slow speaking rates in isolation. To induce rate change, the 60 target words were presented on a computer screen at different tempos. Consonant, vowel, and syllable duration were measured as well as turning point (TP) for the contour tones, Tones 2 and 3. TP is the time interval from tone onset to the lowest f0 value. Duration data of each tone revealed significant ambiguity across tones due to speaking rate. Specifically, for the contour tones, results indicated significant overlap in terms of duration and, as speaking rate increased, the TP for Tone 2 decreased to a lesser extent as compared to Tone 3. Moreover, the TP values for Tones 2 and 3 showed a sizable range, with the ambiguous region of overlap observed not at the faster but at the slower speaking rates. These findings will be discussed in terms of the temporal adjustments that occur in production when speaking rate changes. [Research supported by NSF.]

5aSC39. An acoustic and electroglottographic study of Cantonese tone. Kristine M. Yu, Hiu-Wai Lam, and Shing-Yin Li (Dept. of Linguist., Univ. of California, Los Angeles, 3125 Campbell Hall, Los Angeles, CA 90095, krisyu@humnet.ucla.edu)

Cantonese is a tone language with six tones (traditionally described as high level, high rising, mid level, mid-low falling, mid-low rising, and mid-low level), and also three "stopped" tones in CVC words, not studied here. The interest of this study was (1) how different acoustic cues can be used to classify the different tones, particularly in connected speech and (2) the interaction of voice quality and tone in Cantonese. Twelve speakers were recorded producing minimal pairs as in Wong [(2006)] in isolation, in isolated disyllables, and in sentence-medial disyllables, where the disyllables ranged over all possible 36 bitones in the language; all speakers also made electroglottographic (EGG) recordings. Acoustic measures were F0, F0′, cepstral peak prominence, and harmonic amplitudes $H1^*$ and $H2^*$, $H1^*$-$H2^*$, $H1^*$-$A1^*$, $H1^*$-$A2^*$, $H1^*$-$A3^*$, and $H2^*$-$H4^*$. EGG measures were closed quotient and peak of increasing contact. Measures were made automatically using VOICESAUCE and EGGWORKS. Preliminary results indicate variability in

the presence of creak in the realization of the lowest tone (mid-low falling) as well as variability in the presence of creak at the low f0 regions of the rises.

5aSC40. Identification of prominence and discrimination of pitch patterns by Japanese and American listeners. Irina A. Shport and Susan Guion-Anderson (Dept. of Linguist., Univ. of Oregon, 1290 Eugene, OR 97403, ishport@uoregon.edu)

This study examines how native language shapes the perception of prominence in three-syllable nonce words *nenema* with F0 patterns varying in F0 peak alignment and F0 fall. F0 is the fundamental cue to perception of pitch accent in Japanese, in which the accent location and accent type (accented versus unaccented phrases) are mainly defined by the relationship between the F0 peak, which is associated with the accented syllable, and the F0 fall, which follows the peak. In English, F0 fall is not considered to be a cue to stress. In two experiments, the alignment of the F0 peak (eight locations) and the F0 fall (no fall, moderate fall, steep fall) were manipulated. In the identification task, participants were asked to decide whether the first or the second syllable sounded more prominent to them. In the discrimination task, participants decided whether the pitch patterns of two words were the same or different. Japanese listeners were expected to be more sensitive to the F0 fall than American listeners for all F0 peak locations. Difference in the perception of peak location between the groups was also predicted, as a reflection of peak delay typical to the native language.

5aSP1. Statistical pattern classification: A review and some current problems/paradigms. David J. Miller (Dept. of Elec. Eng., The Penn State Univ., Rm. 227-C EE West Bldg., Univ. Park, PA 16802)

Unsupervised clustering is the ability to automatically partition a set of data patterns into meaningful groups without prior knowledge of the groups or their number. Supervised classification is the ability to automatically recognize a data pattern as an instance from one of a known set of classes. These problems are fundamental to a variety of application domains, including scientific (e.g., bioinformatics), engineering (e.g., speech recognition), business (e.g., marketing and document clustering), and military (target detection). In this talk, we first review the basic supervised and unsupervised classification problems, standard solution methodologies, and how to characterize their performance. We then discuss some recent problem variants and associated paradigms, including semisupervised learning, unsupervised clustering in high-dimensional feature spaces, and decision fusion techniques.

8:00

5aSP2. Target/clutter discrimination using Bayesian active/passive data fusion. Brian R. La Cour, Jason M. Aughenbaugh, Bryan A. Yocom, and Thomas W. Yudichak (Appl. Res. Labs., The Univ. of Texas at Austin, P.O. Box 8029, Austin, TX 78713-8029)

Discriminating targets of interest from background clutter is a key challenge in undersea active sonar. This is particularly true in littoral areas, where scattering from the bottom, motion in the water column, and activity on the surface all contribute to produce echoes which are difficult to distinguish from targets of interest. Statistically, these effects manifest themselves in non-Rayleigh, heavy-tailed amplitude distributions. An approach to target/clutter discrimination is described which uses the complementary information from both active and passive acoustic sensors to facilitate this task. The method uses an efficient, grid-based Bayesian track-before-detect scheme to combine data from the two types of sensors by carefully modeling the effects of array processing, replica correlation, normalization, and clutter statistics. Representing measurements and uncertainty in terms of likelihood functions then provides a common framework for fusion. In this manner, active returns with coincident and appropriate passive signals are given more credence, while the presence of only one or the other, while perhaps suggestive, is not as compelling. The presentation will give a general overview of the approach, and an example will be used to illustrate the potential power of using passive data to mitigate active clutter. [Work supported by the Office of Naval Research.]

8:20

5aSP3. Moments in history. Leon Cohen (Dept. of Phys., Hunter College of CUNY, 695 Park Ave., New York, NY 10065)

We discuss how moments and functions of moments have been historically used to characterize and classify distributions, as well as to construct distributions. Among the methods that have been devised are the Gram-Charlier and Edgeworth series, which are methods used to improve on the Gaussian distribution when the moments deviate from Gaussian. We show how these series can be generalized and how any two distributions can be transformed into each other by systematically changing the moments. In this manner, one can develop families of distributions. We illustrate the methods by applying them to pulse propagation in a dispersive medium where the moments can be deterministic or stochastic. [Work supported by the Office of Naval Research.]

8:40

5aSP4. Computationally enabled alternatives to Gaussian classification and tracking—A survey. John R. Sacha (Appl. Res. Lab., Penn State, P.O. Box 30, State College, PA 16804, jrs9@psu.edu)

The normal distribution is a good model of physical phenomena in numerous situations where central limit theorem effects come into play. It has a prominent place historically because the many special properties of the Gaussian PDF often yield mathematically elegant closed-form solutions to problems. This role was especially important when numeric calculation was expensive. Normality is not a valid assumption in many applications of modern acoustical signal processing, perhaps especially involving classification and tracking. For pattern recognition, Gaussian classifiers are a straightforward methodology requiring mean and covariance estimates of the class distributions. However, in many cases, feature PDFs themselves are not multivariate-Gaussian; even if they are, estimating parameters in large feature spaces with limited data is difficult. In tracking, the Kalman filter is the canonical formulation, but it requires normally distributed process noise and measurement errors. The advent of cheap computation power has made practical a host of alternative models. In classification, this includes empirical PDF estimation via binning, fuzzy logic, neural nets, support vector machines, featureless classification, Bayesian belief nets, and decision trees. For tracking, particle filters are used to model densities as clouds of point estimates; although computationally expensive, they admit arbitrary densities and are amenable to parallel implementation. [Portions of this work were sponsored by ONR.]

9:00

5aSP5. Estimation of densities and information measures: An overview and some recent results. Sanjeev R. Kulkarni (Dept. of Elec. Eng., Princeton Univ., Princeton, NJ 08544)

A fundamental problem that arises in many applications is to estimate an unknown probability distribution from a set of observations drawn according to this distribution. Of particular interest is the case of non-parametric estimation in which little or nothing is known about the underlying distribution. Surprisingly, consistent estimators can be obtained even in this case and the resulting methods are called universal. A related problem is to estimate various information measures based on observations drawn one or two unknown distributions. This talk provides an overview of universal density estimation and the problem of estimating information measures. Some recent results and applications are also described.

9:20

5aSP6. Classification of non-Gaussian reverberation as a mixture. Nicholas P. Chotiros (Appl. Res. Labs., The Univ. of Texas at Austin, 10000 Burnet Rd., Austin, TX 78758, chotiros@arlut.utexas.edu)

There are a few different ways to obtain non-Gaussian statistics, one of which is through the heterogeneity of the seafloor. It is often the case that the seafloor is a patchwork of different bottom types. Measurements of seafloor reverberation, using omni-directional sources and receivers, often show Gaussian statistics, because it is the result of the superposition of a large number of random contributions, satisfying the central limit theorem. For sonar systems that have the spatial resolution to resolve the patches, the statistics of the reverberation will change from one resolution cell to the next. Due to positional inaccuracies associated with most sonar systems, it is often not possible or feasible to separate the reverberation from each bottom type. When taken as a whole, the reverberation will have non-Gaussian statistics. The statistical properties will be explored. [Work supported by the Office of Naval Research, Ocean Acoustics Program.]

9:40

5aSP7. Characterization of non-Gaussian, bistatic, acoustic clutter on the Malta Plateau. John R. Preston (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804)

Sonar clutter is one of the primary limitations to active ASW. This work focuses on statistical analysis of clutter from some bistatic measurements. Non-Gaussian characterizations of bistatic clutter from a mud volcano field, a shipwreck and a high clutter patch of the Malta Plateau are presented. The received data are taken from the five octave research array (FORA) that has been used to collect extensive monostatic and bistatic data in two recent sea trials on the Malta Plateau off Sicily called Clutter 07 and BASE 07. This work uses data from the above mentioned sea trials to characterize non-Gaussian behavior of bistatic clutter from pulsed sources in the 8009576;3500-Hz band and to compare bistatic clutter with monostatic clutter. K-distributions with their shape and scale parameters are used to describe non-Gaussian behavior together with the models of Abraham and Lyons to infer scatterer densities. The ability to geo-reference key statistical measures of clutter can allow CFAR processors to adaptively set thresholds and reduce false alarms. Examples are shown to demonstrate this. Also included are presentations of the shape parameter vs bistatic aspect angle where appropriate. [Work supported by ONR Code 321US].

10:00—10:20 Break

10:20

5aSP8. Active sonar clutter classification using higher order moments. James M. Gelb and Andrew W. Oldag (Appl. Res. Labs., Univ. of Texas at Austin, 10000 Burnet Rd., Austin, TX 78758, gelb@arlut.utexs.edu)

The statistics of normalized matched-filter echoes from an active sonar system operating in a myriad of oceanic environments has been studied extensively for three broad clutter classes including using low-order cumulants to classify subregions of the data [Gelb *et al.*, Proceedings of the ISURC (2008) and references therein]. That work compared empirical distributions to parametric models (e.g., the *K* distribution and the generalized Pareto distribution). A report on extensions of this work is presented including studies of the accuracy of analytic parameter estimation methods and the efficacy of using higher order moments in the classification process. For each class, with increasingly heavy non-Rayleigh distributed tails, comparisons are made of brute force parameter estimation with the use of analytic estimators. Additionally, comparisons of higher order moments (including skew and kurtosis) computed from the data are made with analytic fits to the data. Using a feature-based classifier, the gains of using increasingly higher order moments are assessed. [Work sponsored by the Office of Naval Research (ONR).]

10:40

5aSP9. Improving anti-submarine warfare tracking performance by incorporating classification information. William H. Mortensen, David W. Krout, and Jack McLaughlin (Appl. Phys. Lab, Univ. of Washington, 1013 NE 40th St., Box 355640, Seattle, WA 98105-6698, william5@u.washington.edu)

Prior research has shown that more accurate classification of contact amplitudes can improve tracking performance. In this work, we augment standard, contact-based trackers with a classifier run on features of the received time series from which the contacts were extracted. Ground truth information from benchmark datasets is used in a flexible simulation framework built around the sonar simulation toolset (SST) to generate simulated target and clutter returns. The simulated returns are used as input to the classifier and the contacts from the benchmark datasets as input to the tracker. The classification information provides an additional input to the association step in the probabilistic data association (PDA) and joint PDA trackers, and to the probability of target for each contact in the Bayesian tracker. The results show that even relatively poor classification can make a noticeable improvement in tracking performance. [This work was funded by the U.S. Office of Naval Research, Contract No. N00014-01-G-0460, Delivery Order #36.]

11:00

5aSP10. Model-based detection of buried objects. Edmund J. Sullivan (EJS Consultants, 46 Lawton Brook Ln., Portsmouth, RI 02871, paddypriest@aol.com) and Ning Xiang (Rensselaer Polytechnic Inst., Troy, NY 12180)

An approach to the detection of buried objects is to excite the ground with low-frequency, high-energy sound waves, which then excites a resonance in the buried object. The ensuing vibration causes a detectable signal on the surface of the ground, which can be detected using a laser doppler vibrometer (LDV). The original detection technique used a sliding bandpass filter to process the scattered LDV energy, providing an energy map of the area scanned by the LDV, which indicates the location of the object. The performance of detection is often limited by speckle noise, a type of noise arising from the coherent nature of the laser beam. A more recent technique utilizes an autoregressive model of this noise. This leads to an inverse filter that whitens the noise. Upon the appearance of any target data in the signal, a whiteness test indicates a detection. This approach has demonstrated improvement over the bandpass filter approach. This paper demonstrates a further improvement by augmenting the prewhitener with a model of the mine itself. This provides significant improvement by both enhancing the mine signal and improving the detection performance. Experimental results are shown.

11:20

5aSP11. Sonar waveform design for detection of elastic objects. Brandon Hamschin (Dept. of ECE, Univ. of Pittsburgh, 348 Benedum Hall, Pittsburgh, PA 15261, bmh52@pitt.edu) and Patrick Loughlin (Univ. of Pittsburgh, Pittsburgh, PA 15261)

Animals that navigate and hunt by echolocation, such as some bats and marine mammals, have been observed to change their sonar pulse depending on the environment, as well as during hunting. It has become of interest to incorporate these strategies into man-made sonar waveform and receiver design. We examine the benefits of optimal waveform design versus transmitting a linear FM waveform for detecting elastic objects. Performance loss suffered by assuming a point target is also examined. Our approach utilizes a method recently proposed by Kay to design the optimal power spectrum of the transmit waveform. Because there is an unlimited number of waveforms with the same power spectrum, we further impose a time domain constraint, in terms of the signal duration, to obtain a unique optimal waveform. [Work supported by ONR 321US.]

11:40

5aSP12. Error bounds for classifying targets in non-Rayleigh clutter. Douglas A. Abraham (CausaSci LLC, P.O. Box 5892, Arlington, VA 22205, abrahad@ieee.org)

False alarms in active sonar systems are often represented statistically as having a probability density function (PDF) with tails heavier than the traditionally assumed Rayleigh PDF. Distributions such as the Weibull, *K*, and Poisson–Rayleigh have been used to represent such non-Rayleigh clutter and to derive the associated probabilities of false alarm and detection, the latter for standard target models (e.g., nonfluctuating and fluctuating). In this presentation, the probability of at least one misclassification per ping (P_c) is evaluated when classifying the standard target types against non-Rayleigh clutter having equal average power. The Bhattacharyya bound is used as an upper bound for the Bayesian error probability (P_e) of a classifier operating on a single cluster and combined with the average number of clusters per ping (N_c) to form P_c. As expected, P_c increases as the clutter becomes more non-Rayleigh. Clutter statistics are seen to affect P_c through both P_e and N_c. However, the effect of clutter statistics on N_c is significantly greater than on P_e. Increasing bandwidth reduces P_c (and therefore P_e) when its impact is modeled as an increase in the number of independent samples available for classification. [Work sponsored by the Office of Naval Research under Contract No. N00014-09-C-0318.]

1:00

5pAA1. Comparison of two just-noticeable-difference test methods for clarity index (C80). Clothilde B. Giacomoni, Christopher M. Jasinski, Robert D. Celmer, and Michelle C. Vigeant (Dept. Mech. Eng., Acoust. Prog. and Lab., Univ. of Hartford, 200 Bloomfield Ave., West Hartford, CT 06117, vigeant@hartford.edu)

The just noticeable difference (JND) or smallest detectable increment of clarity index (C80) has been investigated due to the lack of consensus in the existing literature. The purpose of this study was to determine how the JND of C80 varies as a function of the test procedure. Test signals, with varying amounts of clarity, were generated and combined with short anechoic recordings of orchestral music. The testing took place in the University of Hartford's anechoic chamber, and the signals were played back over eight spatially arranged loudspeakers. Two testing methods were compared, which both consisted of the subject hearing two signals, A and B, and deciding if the signals were the same or different in terms of clarity. For Test Method 1, the subjects were required to listen to all of signal A and then all of signal B before selecting their response. For Test Method 2, the subjects were allowed to switch between signals A and B in real-time. The difference in the JND of C80 for the two test methods, along with a comparison to previously published results, will be discussed. [Work is supported by the Paul S. Veneklasen Research Foundation.]

1:15

5pAA2. The effect of motif length in reverberation-time listening tests using the double-blind testing method ABX. Scott S. Edwards, Daniel A. Ignatiuk, Robert D. Celmer, and Michelle C. Vigeant (Dept. Mech. Eng., Acoust. Prog. and Lab., Univ. of Hartford, 200 Bloomfield Ave., West Hartford, CT 06117, vigeant@hartford.edu)

Subjective listening tests are often conducted to determine the relationship between an objective parameter and human perception. These tests can consist of auralizing measured or predicted room impulse responses (RIRs) that have been convolved with anechoic recordings. However, no previous research exists that provide guidelines in terms of how auditory memory affects the chosen length of the musical motif convolved with the RIR. Research in the field of auditory memory suggests that there is both short auditory memory of approximately 200 ms and long auditory memory lasting several seconds [Cowan, Psychol. Bull. **96**, 341–370 (1984)]. A study was carried out using two motifs with three different lengths: 5, 7, and 10 s, where the successively longer motifs contained the same passages as the shorter ones. A relatively straightforward parameter of reverberation time was the independent variable, and signals were created with reverberation times between 1.0–1.5 s. The subjects were presented three signals, A, B, and X, where the difference in reverberation time ranged between 0.3–0.5 s. The subjects were required to identify which signal A or B matched the test signal X. The effect of motif length on the percent correct will be discussed. [Work is supported by the Paul S. Veneklasen Research Foundation.]

5pAA3. Modeling specular reflection in enclosures with energy-intensity boundary elements and an iterative relaxation method. Krista A. Michalis, Donald B. Bliss, and Linda P. Franzoni (Pratt School of Eng., Duke Univ., 1111 Hudson Hall, Durham, NC 27708, kam49@duke.edu)

Steady-state sound fields in enclosures with specular reflection boundaries are modeled by an energy-intensity boundary element method using uncorrelated broadband directional sources. The specular reflection case is solved using an iterative relaxation method extended from a three dimensional (3-D) diffuse reflection solution. When chosen properly, few directivity harmonics are required. Starting with a diffuse calculation, higher harmonics are estimated by post-processing, and the original diffuse influence matrix is refined accordingly and converges in few relaxation steps. The method is higher-order accurate and similar to the diffuse case in that it includes strict enforcement of energy conservation. The method is computationally efficient, making it useful for the design of acoustic spaces. This new 3-D energy-intensity boundary element method utilizes an absorption scaling theory, allowing for direct solution of the element power distribution that describes the primary spatial variation caused by the effects of specular reflection, the absorption dependence on incidence angle, and the nonuniform spatial distribution of absorption and input power in the enclosure. Sample results show that differences between diffuse and specular solutions are often fairly small. The iterative relaxation method, with a limited number of specular harmonics, appears to provide a reasonable approach in practice. [Sponsored by NSF.]

5pAA4. Control algorithms for adaptive time-frequency test signal synthesis for architectural acoustics measurements during music concerts. Gang Ren (Dept. of Elec. and Comput. Eng., Edmund A. Hajim School of Eng. and Appl. Sci., Univ. of Rochester, Rochester, NY 14627), Justin Lundberg (Univ. of Rochester, Rochester, NY), Dave Headlam, and Mark F. Bocko (Edmund A. Hajim School of Eng. and Appl. Sci., and Appl. Sci., and Univ. of Rochester, Rochester, NY)

A system was proposed by G. Ren *et al.* [158th Meeting of the ASA (2009)] to perform field acoustics measurements during ongoing music concerts. It addresses the long-standing problem of performing architectural acoustic measurements with an audience present. In this system, an adaptive time-frequency synthesis algorithm was employed to generate test signals with time-frequency energy distributions that conform to predicted "masked measurement vacancies" to ensure that the acoustic response of the test signals can be separated from the music and that the test signals are inaudible to the audience by taking advantage of auditory masking phenomena. In the present paper, approaches utilizing higher-level structure of music are exploited to reduce the number of conflicts between the test signals and the music. Three approaches are described: a music theory based probabilistic prediction algorithm, using prior knowledge of the score, and the third exploits the availability of previous recordings of the music being performed. These control algorithms are adapted to architectural acoustic measurement procedures conforming to ISO3382-1/2(2009). The proposed system achieves similar performance compare to conventional acoustic test procedures, which emit loud test signals in empty music halls.

2:00

5pAA5. Improving FSTC (field sound transmission class) and FIIC (field-impact isolation class) of standard wall and floor/ceiling configurations. Bonnie Schnitta, Melissa Russo, Trish Kern, and Greg Greenwald (SoundSense, LLC, 46 Newtown Ln., Ste. One, East Hampton, NY 11937)

Every acoustic floor or wall design requires an analysis in order to provide a sustainable design. This is true whether the design is a single family residence with the goal of achieving a desired level of quietude, or a multi-family, or commercial dwelling required to meet various codes and/or standards. Since IIC and STC measurements taken in the field produce a lower STC or IIC than laboratory controlled values, this presentation will begin by reviewing the variables that are not present in the controlled laboratory setting for their acoustic impact. This presentation will further provide field readings of well known documented basic floor and wall configurations. With this foundation standard floor and wall configurations will be reviewed for their FSTC and FIIC improvement with standard readily available acoustic materials to address variables consistent with the degradation of the configuration's acoustic efficacy. The FIIC and FSTC values of the same floors and walls will be further compared to walls and floors with unique and innovative installation methodologies and configuration upgrades. The summary will be a detailed approach to the best field practices and innovative configuration upgrades, inclusive of a few new patented and patent pending products, for optimum field acoustic efficacy.

2:15

5pAA6. Modeling diffuse and specular reflection surfaces and their effect on broadband interior sound field level and intensity flow. Donald B. Bliss, Linda P. Franzoni, and Krista A. Michalis (Mech. Eng., Duke Univ., Durham, NC 27708, dbb@duke.edu)

For steady-state broadband sound fields in enclosures, surfaces may be modeled as diffuse reflectors, specular reflectors, or some combination. Modeling of reflection surfaces when using energy-intensity based boundary elements is reviewed, and the proper energy-intensity source characteristics are derived. These characteristics depend on local correlation effects, the angular distribution of the incident field, and the angular dependence of reflection coefficient. Specular reflection surfaces subjected to fairly random reverberant sound fields exhibit behavior similar to diffuse reflection surfaces to lowest order. Simple solutions are obtained to illuminate the basic difference in interior sound fields caused by different reflection types. For example, random incidence sound propagating down a long corridor with non-absorbing walls exhibits different behavior depending on whether the surfaces are diffuse or specular reflectors. The diffuse case exhibits a spatial gradient in mean-square pressure along the corridor, whereas the specular case gives a uniform field. These solutions are also used to clarify the relationship between the flow of intensity and the gradient of mean-square pressure. This relationship has been represented simplistically and incorrectly in some energy based methods. The importance of benchmarking energy based methods against analytical solutions, rather than experimental data, is stressed.

2:30

5pAA7. Architectural impacts on speech intelligibility in atrium spaces: Two case studies. Julie E. Fischer (Shen Milsom & Wilke, LLC, 3300 N Fairfax Dr., Ste. 302, Arlington, VA 22201, jfischer@smwllc.com)

Case study reviewing the speech transmission index and voice intelligibility design and implementation of two atrium spaces where dedicated public address systems were implemented. The architectural design and selection of finishes has a great impact on the capability of any public address loudspeaker system distinct from any system performance characteristics. The presentation will review the design process, acoustical modeling, and testing results outlining the issues associated with meeting the NFPA 72 Common Intelligibility Score suggested goals. Architectural design requirements such as day-lighting and views are increasing large areas of glass in atrium spaces. These designs are making intelligibility increasingly difficult and the electronic systems and loudspeaker designs can only accomplish so much without architectural acoustical finishes as part of the design.

2:45

5pAA8. Characterization of classroom noise and noise control techniques and their effect on speech comprehension while learning. Sooch SanSouci, Line Guerra (Dept. of Res., AiA-Audition, Intelligibility, Acoust., 47 rue Le Corbusier, 92100 Boulogne, France, s.sansouci@aiacoustique.com), and Dick Campbell (Bang-Campbell Assoc., Falmouth, MA)

Classrooms have been shown to be prone to elevated occupied noise levels that reduce speech comprehension and inhibit learning. This presentation discusses a current study that includes three parts: (1) the characterization of masking invoked by noise commonly found in today's classrooms, (2) the formulation of a metric that intends to associate masking risk to noise features, and (3) the attempt to quantify any increase in speech comprehension resulting from interior acoustic designs that aspire to reduce noise in occupied classrooms. Calibrated recordings made during classroom activities in 9 schools are post processed to allow noise characteristics to be rated based on attributes related to the noise source or type, duration, rate of recurrence, spectra, level, envelope, and peak energy. Binaural and monaural recordings are compared. Speech to noise ratios are statistically weighted over various time frames and activities in an attempt to refine reproducibility among different activities. All recordings were made in occupied rooms both before and after the various treatments were integrated. The results suggest that there are misconceptions in the literature in terms of today's classroom design trends and a few novel principles emerged as being highly effective.

Animal Bioacoustics and Psychological and Physiological Acoustics: Auditory Attention, Learning and Memory: From Neurons to Behavior

Cynthia F. Moss, Chair
Univ. of Maryland, Dept. of Psychology, College Park, MD 20742

Invited Papers

1:00

5pAB1. Focusing, maintaining, and switching attention. Barbara G. Shinn-Cunningham (Hearing Res. Ctr., Boston Univ., 677 Beacon St., Boston, MA 02215)

Humans and other animals have an amazing ability to selectively attend to whatever sound source is most relevant, a task that requires the brain to separate a sound mixture into distinct perceptual objects. Results from a number of recent behavioral and neuroimaging studies from our laboratory and others have begun to tease apart the processes and mechanisms that enable us to select an important source from a sound mixture and attend to it as its meaning unfolds, as well as to switch attention if the need arises. As reviewed in this talk, the processes of focusing, maintaining, and switching auditory attention involve dynamics that directly impact our ability to understand sounds in complex settings. For instance, there is a cost associated with the process of disengaging attention from one source and focusing on another. On top of this switching cost, there is a benefit of maintaining attention to an ongoing source that yields improvements in performance over time. These processes interact with the way we store and remember signals and directly influence how we function in complex auditory scenes, especially social settings like the Speech Communication Poster Session or the Thursday Evening Buffet Social.

1:25

5pAB2. The role of innate and attentional mechanisms in parsing complex acoustic scenes: A neural and behavioral study. Mounya Elhilali (Dept. of Elec. & Comput. Eng., Johns Hopkins Univ., 3400 N. Charles St., Baltimore, MD 21218, mounya@jhu.edu)

The mechanisms by which a complex auditory scene is parsed into coherent objects depend on poorly understood interactions between task-driven and stimulus-driven attentional processes. We use a simultaneous psychophysical-neurophysiological experimental paradigm to manipulate human listeners attention to different features of auditory scenes. In a series of experiments, our findings reveal a role of attention in enhancing the sustained neural representation of the foreground. This enhancement, in both power and phase coherence, originates in auditory cortex, occurs exclusively at the frequency of the target rhythm, and is only revealed when contrasting two attentional states that direct subjects focus to different features of the acoustic scene. It also interacts with innate processes of the auditory system, particularly its differential sensitivity to temporal dynamics of sounds. These results have substantial implications for models of foreground/background organization and mechanisms mediating auditory object formation.

1:50

5pAB3. Intention and attention: Top-down influences on the representation of task-relevant sounds. Jonathan B. Fritz (Inst. for Systems Res., ECE, Univ. of Maryland, College Park, MD 20747, ripple@isr.umd.edu), Stephen V. David, Daniel Winkowski, Pingbo Yin (Univ. of Maryland, College Park, MD 20747), Mounya Elhilali (Johns Hopkins Univ., Baltimore, MD 21218), and Shihab A. Shamma (Univ. of Maryland, College Park, MD 20747)

To explore the role of top-down projections from frontal cortex (FC) to auditory cortex (AC), which may play a role in adaptive reshaping of A1 receptive fields to attended acoustic stimuli during behavior, simultaneous recordings were made from single neurons in FC and AC in behaving ferrets, trained on multiple auditory detection and discrimination tasks in positive and negative reinforcement paradigms. Performance required selective attention to different salient spectral frequency and/or temporal cues. Previous observations revealed task-specific transformations in receptive fields in AC [Fritz *et al.* (2003); (2005); (2007); (2009); Atiani *et al.* (2009)]. In contrast, FC neurons showed recognition responses, which categorically distinguished between acoustic foreground and background stimuli. FC responses to targets were often independent of the acoustic properties of the target and thus encoded an abstract representation of the class of target stimuli [Fritz *et al.* (2009)]. Stimulation of FC, paired with tones, lead to receptive field transformations similar to those observed in behavior. These results emphasize the importance of interactions between multiple areas during selective attention, and the tight coupling of target recognition and auditory attention that enhances auditory cortical filters for attended acoustic stimuli, thus creating a functional representation of task-salient sounds during behavior. [This work was supported by grants from NIDCD, NIH.]

2:15

5pAB4. Learning alters the coding capacity of single neurons and populations in the auditory forebrain. James Jeanne (Neurosci. Graduate Program, Univ. of California San Diego, La Jolla, CA 92093), Tatyana Sharpee (Salk Inst. for Biological Studies, La Jolla, CA 92037), and Timothy Gentner (Univ. of California, San Diego, La Jolla, CA 92093)

To control adaptive behaviors, vertebrate neural systems must extract information from large numbers of diverse, physically complex signals in the natural world. Sensory experience helps neural systems to meet this challenge by evoking long-lasting changes that bias cortical circuits toward representations of behaviorally relevant signals. Such circuits may encode stimuli using highly selective individual neurons or by larger populations of neurons, thereby greatly expanding coding capacity. I will describe studies investigating the representation of a complex acoustic communication signal, birdsong, across multiple forebrain regions that are analogous to secondary auditory cortices in mammals. I will show that single neurons and populations of neurons in these regions are tuned to the complex spectro-temporal features in songs that birds have learned to recognize. These results demonstrate that learning mechanisms can act and different organizational levels in the brain, and provide biological support for specific population coding schemes.

2:40

5pAB5. Top-down vocal feedback control in active hearing. Xiaoqin Wang (Dept. of Biomedical Eng., Johns Hopkins Univ., 720 Rutland Ave., Baltimore, MD 21205, xiaoqin.wang@jhu.edu)

Speaking is a sensory-motor process that involves constant self-monitoring to ensure accurate vocal production. This monitoring of vocal feedback allows a speaker to quickly adjust speech production to correct perceived errors between intended and actually produced vocal sounds. The self-monitoring in speaking is crucial for learning to speak native as well as foreign languages. An important behavior in vocal feedback control for both human speech and animal vocalizations is the compensatory change in speech or vocalizations (e.g., pitch, frequency, and intensity) when there is a mismatch between intended and perceived vocal sounds. Such a behavior requires mechanisms for continuously monitoring auditory feedback during vocal production. We have found that disruption of auditory feedback during vocalization alters coding properties of auditory cortex neurons in marmosets (a highly vocal primate species). Furthermore, when marmosets compensate for changes in vocal feedback, there are corresponding changes in their cortical neural activity. These findings suggest that the neural network underlying self-monitoring of vocal production likely consists of both sensory processing and top-down modulations via higher-cortical areas involving planning and memory.

5pAB6. Production and perception of sequential patterns in budgerigar (*Melopsittacus undulatus*) warble: Evidence for a magic number. Hsiao-Wei Tu and Robert J. Dooling (Dept. of Psych., Univ. of Maryland, College Park, MD 20742, hsiaowei@umd.edu)

The warble song of budgerigars (*Melopsittacus undulatus*) is composed of a large number of elements uttered in streams lasting from a few seconds to a few minutes without obvious repetition of particular patterns. Previous work showed that warble elements can be classified into eight acoustic categories for which budgerigars have corresponding perceptual categories. Here, we analyzed long sequences of natural warble to determine the proportion of these categories in warble as well as any sequential patterns of these categories in warble. Results showed that elements were not randomly arranged and that warble has at least a fifth-order Markovian structure. This suggests that budgerigars may have a motor control of approximately five elements during the production of warble. Investigations of the budgerigars' ability to perceive warble sequences of various lengths showed convergent evidence that budgerigars are able to master a novel sequence between four and seven elements in length. In other words, budgerigars may have an attention span of about five elements which may be a limit of their capacity of neural processing. Through gradual training with chunking (about five elements), birds are able to learn sequences up to 50 elements. [Work supported by NIH/NIDCD R01DC000198 to R.J.D.]

3:35

5pAB7. Perception of alterations in natural budgerigar (*Melopsittacus undulatus*) warble: Implications of animal "syntactical capability." Hsiao-Wei Tu and Robert J. Dooling (Dept. of Psych., Univ. of Maryland, College Park, MD 20742, hsiaowei@umd.edu)

The warble song of male budgerigars (*Melopsittacus undulatus*) is an extraordinarily complex, multisyllabic, learned vocalization that is produced continuously often for minutes at a time. Previous work has shown that warble elements form acoustic and perceptual categories for budgerigars and these birds can detect ordering changes in artificial sequences of warble elements. Using operant conditioning and a psychophysical paradigm, we examined the sensitivity of budgerigars for detecting different types of insertions (e.g., targets) in a running background of warble up 1000 elements in length. When the inserted targets are warble calls taken directly from the background, budgerigars show a species-specific ability to detect them solely based on sequence violations in the natural ordering of warble elements. Moreover, budgerigars, but not other species, are especially sensitive to temporally reversed warble elements inserted in natural warble sequences, indicating that the acoustic details of warble elements are also perceptually significant to budgerigars besides sequential cues. Although it is still unclear whether budgerigars perceive their warble as a rule-govern sequence or a pattern-based vocalization, the findings here open the door to studies of serial order learning in a natural, non-human communication system. [Work supported by NIH/NIDCD R01DC000198 to R.J.D.]

5pAB8. Bioacoustic and behavioral correlates of spatial memory in echolocating bats. Jonathan R. Barchi (Dept. of Neurosci., Brown Univ., 185 Meeting St., Providence, RI 02912, barchi@brown.edu), Jason E. Gaudette, Jeffrey M. Knowles, and James A. Simmons (Brown Univ., Providence, RI 02912)

Echolocating bats face a unique orientation problem due to their reliance on echolocation over visual orientation. Each observation (sonar vocalization) only contains information about objects in front of and within at most 5–10 m of the animal. Because their behavior extends over much larger distances, spatial memory might be particularly important during foraging activity and free flight to integrate the shorter views provided by sonar. To investigate memory for object locations, *Eptesicus fuscus* were allowed to fly freely in an instrumented flight room populated with sparse obstacles (hanging chains). Bat position and vocalization were monitored with a stereo-registered pair of thermal cameras and an array of ultrasonic microphones synchronized to the video. Data were analyzed for correlates of spatial memory-flight path dynamics, head aim, and temporal structure of echolocation signals. Data recorded from bats free-flying in the chain array are consistent with memory of obstacle locations and high-level planning of a flight path through the entire space. These data reflect the behavior of bats flying in natural conditions. [Work supported by ONR and NSF.]

4:05

5pAB9. Effect of ototoxic drugs on Rana catesbeiana tadpole orientation behavior and caspase-3 expression. Erika Alexander, Brian Schmidt, and Andrea Simmons (Dept. of Psych., Brown Univ., 89 Waterman St., Providence, RI 02912, erikaealexander@gmail.com)

Treatment with the ototoxic antibiotic gentamicin results in specific damage to hair cells of the inner ear and possibly of the lateral line system. In amphibians, damaged hair cells may spontaneously recover. Rana catesbeiana tadpoles were treated with different dosages of gentamicin solution, including a nontreated control, for 24 h. Animals were tested behaviorally and then sacrificed either immediately or after a 7 day recovery period. Their brains were processed for immunohistofluorescent labeling of caspase-3, a marker for apoptosis. Behavioral changes associated with gentamicin treatment included a disruption of balance, altered swimming, and an inability to detect water currents. Animals treated with gentamicin showed increased caspase-3 expression in multiple brain areas compared to non-treated controls. Animals allowed a 7 day recovery period that showed lower caspase-3 label across brain areas than animals sacrificed immediately after treatment. These results suggest that ototoxic damage is associated with increased caspase-3 expression in the central nervous system. In tadpoles, affected behaviors undergo spontaneous recovery, which is itself correlated with decreases in caspase-3 expression. [Work supported by NSF GRFP, NIH, and RI Space Grants.]

5pBB1. Ultrasonic characterization of cancellous bone. Biot approach: Pros and cons. Pascal Laugier (Laboratoire d'Imagerie Parametrique, Univ. Pierre et Marie Curie-CNRS,)

Reliable quantification of microstructural and mechanical bone properties remains an open issue with relevance for the diagnosis of bone quality disorders, such as osteoporosis. The reconstruction of such parameters from nondestructive testing based on ultrasound testing and model-based solution of the identification inverse problem have been suggested by several investigators as novel techniques with high potential not only due to the reduced cost and its non-ionizing nature, but for the direct relationship and sensitivity of the propagation characteristics estimates to relevant bone properties that determine mechanical strength, Recently, approaches taking advantage of the poroelastic nature of cancellous bone have been developed. These approaches assume that the Biot theory is a valid model of wave propagation and are aiming at either (i) recovering the properties of the fast and slow waves or (ii) directly reconstructing the bone properties that govern Biot's theory. However, the most recent literature reveals inconsistencies between Biot model and experimental results, thereby suggesting that Biot model may not be the most appropriate theoretical framework for solving the inverse problem. The most recent results will be reviewed and future research directions will be highlighted to overcome the observed inconsistencies.

1:15

5pBB2. Structural and mechanical assessment of trabecular bone by *in vivo* magnetic resonance imaging. Felix Wehrli (Dept. of Radiology, 3400 Spruce St., Philadelphia, PA 19104, wehrli@mail.med.upenn.edu)

Bone is a complex composite material whose strength is determined by a combination of the material's intrinsic mechanical properties, its overall volume fraction, and architecture at the macro-, micro- and ultrastructural levels. Trabecular bone, the type of bone prevalent in the vertebrae and ends of long bones, is particularly prone to fracture in osteoporosis. It consists of a network of interconnected plates and struts of about 100-μm thickness immersed in a matrix of marrow. Advances in magnetic resonance imaging technology, including development of high-field magnets and radiofrequency coil technology, along with improved image processing and analysis techniques, now allow acquisition of images from which the three-dimensional (3D) microarchitecture can be retrieved, at least at peripheral skeletal locations such as the distal radius and tibia. From these data measures of topology, scale and orientation of the trabecular network, all contributing to the bone's mechanical competence, can be derived with high-serial reproducibility. The processed images can also be used to create 3-D meshes and mechanical parameters such as elastic and shear moduli computed by micro-finite-element analysis. The translation of this technology to clinical medicine is highlighted with examples from recent drug intervention studies, allowing direct assessment of structural and mechanical consequences of treatment.

1:30

5pBB3. The effect of structural anisotropy on the fast wave propagation in cancellous bone. Mami Matsukawa, Katsunori Mizuno (Lab. of Ultrasonic Electron, Doshisha Univ., Kyotanabe 610-0321, Japan, mmatsuka@mail.doshisha.ac.jp), and Yoshiki Nagatani (Kobe City College of Technol., Kobe, 651-2194, Japan)

QUS parameters are closely related to the structural properties and elastic properties of bone, which can provide important information related to bone quality and bone strength. One should be very careful, however, that bone contains complicated structure from microscopic to macroscopic levels. For example, the cancellous bone inside the epiphysis is composed of a complicated trabecular network in the bone marrow, showing strongly anisotropic and heterogeneous structure. We have then observed the longitudinal wave propagation in this complicated medium, paying special attention to the two wave phenomenon. The fast wave, which mainly propagates in the trabecular part of the cancellous bone, is more sensitive to the network structure. With the help of x-ray micro-computed tomography, three dimensional anisotropic trabecular structure and fast wave propagation were investigated using bovine cancellous bones. We can find the strong effect of anisotropic trabecular structure on the fast wave velocity. The mean intercept length (the information of average trabecular length) was a good parameter to describe the three dimensional trabecular structure and showed good correlation with the fast wave velocity.

5pBB4. Multi-emitters and multi-receivers probe for long cortical bone assessment. Jean-Gabriel Minonzio, Maryline Talmant, and Pascal Laugier (UPMC Univ Paris 06, UMR 7623, LIP, 15 rue de l école de médecine, F-75006 Paris, France)

Different quantitative ultrasound techniques are currently developed for clinical assessment of human bone status. This paper is dedicated to axial transmission: emitter(s) and receiver(s) are linearly arranged on the same side of the skeletal site. A multiparameter approach might be relevant to improve bone diagnosis and this be could achieved by accurate measurement of guided wave phase velocities. Clinical requirements and bone/soft tissue heterogeneities constrain the length probe to about 10 mm. Thus efficiency of conventional spatio-temporal Fourier transform is reduced. Signal processing to obtain reliable guided wave velocities is a key point. Here the guided mode phase velocities are obtained using a projection in the singular vectors basis determined by the singular values decomposition of the transmission matrix between the two arrays. This method has been first validated on metallic plates. A set of excised human radius were then probed. Attention was paid to observation of cut-off frequencies because of their high power of discrimination of relevant bone properties (thickness and elasticity). The analysis of the whole spectrum including several branches of intermediate phase velocities is under progress. The so-called bi-directional correction of the soft tissue thickness variations under the probe is used for the *in vivo* measurements.

2:00

5pBB5. Discrimination of bone fractures by low-frequency axial transmission velocity in the radius and tibia. Petro Moilanen (Dept. of Phys., Univ. of Jyväskylä, P.O. Box 35, 40014 Jyväskylä, Finland, petro.moilanen@jyu.fi), Mikko Määttä (Univ. of Oulu, 90014 Oulu, Finland), Vantte Kilappa, Leiting Xu (Univ. of Jyväskylä, 40014 Jyväskylä, Finland), Timo Jämsä (Univ. of Oulu, 90014 Oulu, Finland), Jussi Timonen, and Sulin Cheng (Univ. of Jyväskylä, 40014 Jyväskylä, Finland)

Low-frequency axial transmission velocity of the first arriving signal (V_{LF}, 0.4 MHz) has a wavelength (8–10 mm) sufficient to probe osteoporotic changes in subcortical bone. Purpose of the present study was to evaluate V_{LF} on retrospective fracture discrimination, using a custom-made ultrasonometer in the midshaft radius and tibia. Preliminary data for 49 nonfractured (NF; 45–87 years) and 16 fractured (F; 56–81 years) postmenopausal females were analyzed. The fractures included were caused by low or moderate trauma and mostly occurred in the forearms or lower legs. Subjects with disease or medication affecting bone metabolism were excluded. Areas under receiver operating characteristic curve were 0.76 for the radius and 0.60 for the tibia V_{LF}. When adjusted for age and BMI, odds ratio for the radius V_{LF} was 1.97 (95% CI: 1.11–3.48), while that for the tibia V_{LF} was not statistically significant. In the contrary, dual-energy x-ray absorptiometry (DXA; whole-body, femoral neck, and L2–L4) was unable to differentiate between the F and NF groups. Despite the small study population, these results suggest that V$\mathfrak{LF}$ in the radius discriminates osteoporotic fractures in cases of peripheral fractures, in particular, for which DXA has a limited sensitivity.

2:15

5pBB6. Decomposition of two-component pulses: Simulation and phantom experiment. Keith A Wear (FDA Ctr. for Devices and Radiological Health, Bldg. 62, Rm. 3108, 10993 New Hampshire Ave., Silver Spring, MD 20993)

Porous media often support propagation of two compressional waves. When cancellous bone samples are interrogated in through-transmission with broadband sources, these two waves often overlap in time. A method for measuring attenuation and velocity of the two component waves was developed. The method (1) assumes that the transfer function is the sum of two exponentially modulated sinusoids and (2) minimizes the sum of the squared error between a model fit and the data. The method was tested for decomposing a 500-kHz-center-frequency signal containing two overlapping components: one passing through a polycarbonate plate (fast wave) and another passing through a cancellous-bone-mimicking phantom (slow wave). The method yielded estimates of attenuation slopes accurate to within 7% (polycarbonate plate) and 2% (cancellous bone phantom). The method yielded estimates of phase velocities accurate to within 1.5% (both media). The method was tested on simulated data generated using attenuation slopes and phase velocities corresponding to bovine cancellous bone. Throughout broad ranges of signal-to-noise ratio and fast-slow-wave-velocity differential, the method yielded estimates of attenuation slope that were accurate to within 10% and estimates of phase velocity that were accurate to within 5% (fast wave) and 2% (slow wave).

2:30

5pBB7. Recovery of structural degradation indicators of human bones using elastic waves. Erick Ogam, Zine El Abeddine Fellah (Laboratoire de Mcanique et d'Acoustique, UPR 7051 CNRS, 31 chemin Joseph Aiguier, Marseille 13402, France), Jean-Philippe Groby (Universit du Maine, 72085 Le Mans Cedex 09, France), Robert Gilbert (Univ. of Delaware, Newark, DE 19716), and Armand Wirgin (Laboratoire de Mcanique et d'Acoustique, Marseille 13402, France)

Non-ionizing techniques of bone characterization have mostly been based on ultrasonic wave propagation. In this study, bone is characterized via its linear response to vibratory solicitations. The analysis of the response of bones to transient mechanical excitation is made both theoretically and experimentally. An orthotropic three-dimensional finite element interaction model (FEIM) using computerized tomography scan image geometries of excised dry human tibiae bones is developed. The model parameters (nine elastic constants) are recovered by solving an inverse eigenvalue problem using resonance frequencies from vibration spectroscopy. Transient waves are excited and signals acquired along the diaphysis of the tibiae, experimentally by employing piezoelectric transducers and numerically using FEIM and a time integration scheme. The elastic waves propagating as

guided modes in the bone are investigated using reassigned bilinear time-frequency distribution. To avoid ambiguity in determining the elastic wave phase velocities due to the dispersive nature of propagation in bone, the longitudinal $L(0,1)$ and flexural $F(1,1)$ phase velocities, measured at their asymptotes, i.e., the bar and Rayleigh velocities respectively, are proposed as indicators for assessing the strength of long bones. Their sensitivity to changes in bone state like the effect of cortical thickness variation due to aging and osteoporosis is examined.

2:45

5pBB8. On the relation between effective properties of cancellous bones and quantification of the microstructure. Miao-jung Yvonne Ou (Joint Inst. for Computational Sci., Oak Ridge Natl. Lab., 1 Bethel Valley Rd., Oak Ridge, TN 37831) and Robert Lipton (Louisiana State Univ., Baton Rouge, LA 70803)

The effective properties of a two-phase composite depends both on the constituent materials and the microstructure. Starting from David J. Bergman's work on the integral representation formula (IRF) approach for deriving bounds on dielectric properties of composites with isotropic constituents, followed by Golden & Papanicolaou's work on establishing the link between IRF and spectral theory, the IRF is on now a firm mathematical background for further generalization from isotropic constituents to general constituents. The key feature we are looking for is the separation of information on material contrast from that of microstructure in the IRF. This is especially important for (visco)elastic composites because their current available IRFs do not have this feature, even when constituents are isotropic. In this talk, we will present a recently derived IRF for general (visco)elastic composites with the above feature. The relation between IRF and the quantification of microstructure (as spectrum of a generalized Helmholtz projection operator) will be explained. If time permits, numerical results will be presented and the connection between the IRF and the fabric tensor introduced by Stephen C. Cowin will also be discussed.

5pBB9. Multiscale structure-functional modeling of lamellar bone. Kay Raum (Julius Wolff Institut, & Berlin-Brandenburg School for Regenerative Therapies, Charité Universittsmedizin Berlin, Augustenburger Platz 1, 13353 Berlin, Germany, kay.raum@charite.de), Quentin Grimal (Universit Pierre et Marie Curie-Paris 6, F75006 Paris, France and CNRS, F75006 Paris, France), and Alf Gerisch (Universitt Darmstadt, Darmstadt, Germany)

Bone is a natural example of achieving a unique combination and variability of stiffness and strength. One of the striking features of bone tissue is the ability to adapt to variable loading conditions by multiple but well organized structural arrangements of mineralized collagen fibrils at several levels of hierarchical organization. A profound understanding of the structure-function relations in bone requires both experimental assessment of heterogeneous elastic and structural parameters and theoretical modeling of the elastic deformation behavior. A bottom-up approach for experimental assessment and numerical modeling of the hierarchical structure from the nanoscale to the macroscale will be presented. Experimental data are obtained by scanning acoustic microscopy between 50 MHz and 1.2 GHz and provide anisotropic elastic and structural information at the lamellar (nanoscale) and at the tissue matrix (microscale) level. These data are directly translated into a finite element mesh. By numerical deformation analyses, the homogenized elastic stiffness tensor of the next hierarchical levels (microscale to macroscale) is derived. At each level the numerical results are cross-validated by experimental data. It will be shown that local variations in elastic anisotropy within the femoral shaft are related to an inhomogeneous strain distribution resulting from external stresses by weight and muscle forces.

3:45

5pBB10. Role of absorption mechanisms for ultrasound attenuation in cancellous bone: Macroscopic modeling and experiment. Michal Pakula and Mariusz Kaczmarek (Inst. of Mech. and Comp. Sci., Kazimierz Wielki Univ., Kopernika 1, Bydgoszcz, Poland, michalp@ukw.edu.pl)

Evaluation of the relative contribution of physical mechanisms responsible for attenuation of ultrasonic wave in cancellous bone is one of the crucial issues from the point of view of modeling elastic wave propagation and related model-based identification of the structural and mechanical properties of bone material. Considering trabecular bone as a porous material filled with fluid, the wave attenuation may stem from (i) intrinsic absorption in the fluid and solid phase, (ii) friction at the fluid-solid interface, as well as (iii) wave scattering by inhomogeneities (pores/trabeculaes). The commonly used for modeling ultrasound propagation in cancellous bone of the macroscopic Biot's theory will be discussed in context of its potential applicability for prediction of wave parameters: phase velocity and attenuation coefficient as functions of frequency. Since the model was introduced for long wavelength range, the scattering effects are neglected, and the analysis will be focused on the absorption mechanisms responsible for attenuation of ultrasonic waves in bone material. The suitability of the model will be verified by comparison of results of sensitivity analysis of the model with *in vitro* experimental ultrasonic data obtained for cancellous bones filled with different fluids.

5pBB11. Characterization of cortical bone fracture with scanning confocal ultrasound and longitudinal acoustic velocity. Yi-Xian Qin, Jiqi Cheng, Suzanne Ferreri, and Wei Lin (Dept. of Biomedical Eng., Stony Brook Univ., 350 Psych.-A Bldg., Stony Brook, NY 11794, yi-xian.qin@sunysb.edu)

Non-invasive assessment of fracture, particularly in non-typical fracture, is a critical health problem. As a promising alternative to the x-ray, ultrasound has demonstrated potentials in early fracture diagnosis. A real-time scanning confocal ultrasound image was developed to evaluate bone defect and bone loss. The objectives of this study were to evaluate the cortical fracture gap size using quantitative ultrasound imaging and the longitudinal ultrasound velocity in bone to predict the fracture gap size. The total fractures were created by MTE compression at the middle diaphysis, with gap size varied from 1–5 mm ($N=4$). Fractures were tested with the ultrasound scanning with 0.5-mm resolution. The measured ultrasound signals were analyzed to calculate BUA (dB/MHz), ATT (dB), and transverse velocity (m/s). The longitudinal wave velocity was tested using three surface transducers. Strong correlations were observed between ultrasound and x-ray images in fracture size ($R2=0.91$). High correlation was found between gap size and the longitudinal velocity from 4000 to 3000-m/s for 0–5-mm gaps ($R2=0.93$). These results suggest that ultrasound is capable to predict bone fracture

and provide useful information for longitudinal assessment of complications, such as non-union fracture, and for evaluating healing. [Work supported by NSBRI/NASA and NIH.]

4:15

5pBB12. Dynamic acoustoelastic testing for noninvasive detection of microdamage in cortical tissue of long bones. Guillaume Renaud, Maryline Talmant, and Pascal Laugier (Laboratoire d'Imagerie Paramétrique, CNRS UMR7623, Université Pierre et Marie Curie, 15 rue de l'école de médecine, 75006 Paris, France, renaud_gu@yahoo.fr)

First developed for trabecular bone, dynamic acoustoelastic testing (DAT) is based on the measurement of ultrasound (US) pulses time of flight and energy modulations (TOFM and EMs) induced by a low-frequency (LF) acoustic wave, synchronously injected in the probed medium. The technique needs the LF wave to be quasi-uniform in the investigated region and quasi-static in time (compared with the US TOF). US TOFM and EM are related to elastic and dissipative nonlinearities, respectively. Here is presented the application of the technique to cortical tissue of long bones. A LF vibration is generated along the axis of the sample whose frequency corresponds to the first compressional resonance mode. Simultaneously, US pulses are emitted and received by a dedicated probe, after propagation along the axis of the sample. The emitter-receiver distance is chosen and the position of the US probe is adjusted so that the head wave arrives first in time. US TOFM and EM are thus computed using the head wave. After validation in an aluminum cylinder where no dissipative nonlinearity but weak quadratic elastic nonlinearity is observed, *in vitro* results are presented for bone. DAT is performed on diaphyseal bone sections before and after mechanical damage was induced.

4:30

5pBB13. Bone quality assessment at multiple skeletal sites using quantitative ultrasound imaging. Frederick Serra-Hsu, Jiqi Cheng, Wei Lin, and Yi-Xian Qin (Dept. of Biomed Eng., SUNY Stony Brook, HSC T18, Rm. 030, Stony Brook, NY 11794, fserrahs@ic.sunysb.edu)

Osteoporosis is responsible for nearly 1.5×10^6 fractures annually in U.S. with the most typical sites at the hip, spine, and wrist. Early diagnosis is essential for the prediction of fracture risk. While BMD only represents quantitative information of bone, current quantitative ultrasound (QUS) typically employs index using attenuation (BUA) and velocity (UV) measurements at the calcaneus. The objective of this study aims to develop an image based QUS technology for enhanced diagnostic readings at multiple anatomical sites. With a newly developed scanning confocal acoustic diagnosis system, five embalmed cadaver forearms were disarticulated from the wrist joint, cut at the mid shaft, leaving the interosseous membrane intact, and scanned by the ultrasound. Acoustic phantoms scanned with the new system and basic water coupling show low variation ($<7\%$ of mean BUA) with highly linear BUA curves (mean $R2=0.96$). BUA and UV were analyzed at the distal radius using existing algorithms; however, the distal radius geometry provides much different BUA and UV schemes than the calcaneous so site-specific calculation algorithms are needed. DXA, mCT, and mechanical testing are currently under evaluation. These preliminary data demonstrated feasibility of ultrasound imaging in critical skeletal site, i.e., wrist. [Work supported by NSBRI/NASA and NIH.]

4:45

5pBB14. Separating individual modes from multimodal guided wave signals in long cortical bones. K. L. Xu, D. A. Ta (Dept. of Electron. Eng, Fudan Univ., Shanghai 200433, China), P. Moilanen (Univ. of Jyväskylä, Finland), and W. Q. Wang (Fudan Univ., Shanghai 200433, China)

Time-frequency representation (TFR) is one of the classical methods used for guided wave signal processing in assessment of long cortical bones. In this paper, we first used a crazy-climber ridge detection method to separate individual modes from multimodal guided wave signals in the time-frequency domain. Second, a penalization algorithm, based on spline smoothing, was employed to reconstruct the individual modes separately in the time domain. Robustness of these methods was evaluated by analyzing highly noisy simulated signals and experimental signals on bovine tibiae. It was found that the separated TFR ridges, provided by the crazy-climber algorithm, were clearer than using the TFR alone and these corresponding trajectories were in good agreement with theoretical dispersion curves. The penalization algorithm, on the other hand, showed promising performance by yielding good accordance between the reconstructed individual modes and the theoretical predictions. Both the crazy-climber and the penalization algorithms were thus useful for TFR analysis of multimodal signals, even under strongly noisy conditions, by separating and reconstructing the individual contributions in the time domain. These methods can thus significantly improve ultrasonic guided wave signal processing by providing a feasible quantitative assessment of individual modes in temporal multimode signals, recorded in long bones.

5pEA1. Stratified layer imaging using synthetic aperture processing. Steven Schock and Victoria Ringle (Dept. of Ocean and Mech. Eng., Florida Atlantic Univ., 777 Glades Rd., Boca Raton, FL 33431)

Synthetic aperture processing is applied to seabed reflection data to improve images of stratified sediment layering. Vertical profiles of sediments are limited in dynamic range by sediment scattering. Synthetic aperture processing, which increases the effectiveness along track length of the sonar transmitter and receiver, suppresses scattering noise, thereby allowing detection of stratified layering with weaker reflection coefficients. The image improvement resulting from the application of synthetic aperture processing is determined by comparing reflection profiles generated with and without synthetic aperture processing. The processing algorithm used in the analyses is not the conventional synthetic aperture processing algorithm which is coherent for point scatterers, but is an algorithm that provides coherent processing for planar reflectors.

1:25

5pEA2. Fast array processor for the noiselet reverberation model. Edmund J. Sullivan, Robert P. Goddard (Prometheus Inc., 21 Arnold Ave., Newport, RI 02840, ed@prometheus-us.com), Hyman A. Greenbaum (Information Technol., Middletown, RI 02842), and Carlos Godoy (Naval Undersea Warfare Ctr., Newport, RI 02841)

The noiselet reverberation model, instead of transmitting the pulse itself, transmits a superposition of many copies of the pulse, each copy with a random amplitude and phase. This allows the simulation to mimic the point scatterer method without requiring a prohibitively large number of scatterers. It uses the GRAB ray model to introduce the propagation information. It provides a real-time high-fidelity simulation, providing element-level time series as an output for a planar array of receivers. However, it is presently limited by the phase shift calculations required by the frequency-domain beamformer to about 20 receivers without an unacceptable trimming of the number of rays used. Here, an approach is demonstrated that significantly improves the speed of this computation by identifying those receivers requiring the same phase shift to within a given specified error, such that only a single phase shift computation is required. These receivers fall onto a finite width strip, or quasi stave, that is not required to be parallel to element rows or columns. Along with providing a significant speed-up to the calculation, the approach becomes more efficient as the number of receivers increases, thereby allowing real time simulations using receiver arrays of over 100 elements.

1:45

5pEA3. Multidomain modeling of transducers and acoustical systems. Stephen C. Thompson (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804)

Multidomain modeling, recently also called multiphysics modeling, is appropriate for systems in which different parts of the system are modeled using different equations and different modeling variables. Each such domain is modeled using the variables and equations that are appropriate for it, and the domains are coupled by additional equations at their boundaries and in regions of overlap. Acoustic transducers are an obvious example of multidomain systems. Historically, electrical circuit analog modeling was an approach for multidomain analysis. In addition, specific domain couplings have been hard-coded into particular FEA codes for the analysis of some kinds of coupled systems. Today there are FEA codes, as well as codes based on simpler ordinary differential and algebraic equation analysis, that provide a robust framework for this kind of modeling. This paper will discuss these anaylsis methods and provide computational examples from some simple multidomain systems that include acoustic transducers. [Work supported in part by the Office of Naval Research.]

5pEA4. Ducted propagation in the atmosphere, from audible sound to infrasound. Roger Waxler, Carrick Talmadge, Kenneth Gilbert, Xiao Di, Phillip Blom, Jelle Assink, and Claus Hetzer (NCPA, Univ. of Mississippi, University, MS 38677)

Earth's atmosphere supports complicated and highly variable winds and temperature gradients. Temperature inversions and wind jets provide ducts in which sound can propagate efficiently to great distances from the source. Due to the intrinsic variability of the atmospheric winds, these sound ducts are also quite variable, both temporally and spatially. Further, the direction of the atmospheric winds

can change dramatically with increasing altitude so that the behavior of the propagated field can become quite complex as the range from the source increases. Despite this, some systematic behavior has been observed in long range sound propagation. An overview will be presented, with an emphasis on the systematic behavior. The current state of our understanding of the sources and consequences of the atmosphere's variability will be discussed.

5pEA5. Atmospheric sound scattering model to test signal coding methods for acoustic wind profiling. Paul Kendrick and Sabine von Hünerbein (School of Computing, Sci. and Eng., Univ. of Salford, Salford M5 4WT, United Kingdom, p.kendrick@salford.ac.uk)

This presentation concerns simulation of atmospheric sound propagation, including the backscatter of acoustic waves from moving temperature fluctuations. The model has been developed to evaluate the performance of acoustic wind speed profiling techniques, in particular, the use of pulse coding methods which aim to increase range resolution, accuracy, and data availability. Stepped frequency chirps are propagated through the model and the results used to optimize matched filtering algorithms. Results from simulations are presented and the performance of several different signal detection algorithms evaluated. This methodology provides insight into particular problems encountered by the signal detection algorithm and will be utilized to aid the design of an experimental acoustic wind speed profiler. [Work funded by the Engineering and Physical Sciences Research Council (EPSRC).]

5pEA6. A finite difference model for low frequency sound measurement in kraft recovery boilers. Robert Hildebrand (Lake Superior State Univ., 650 W. Easterday Ave., Sault Ste. Marie, MI 49783, rhildebrand@lssu.edu), Matthew Carroll (Texas A & M Univ. at Galveston, Galveston, TX 77553-1675), Ville Jarvinen, and Juha Miettinen (Tampere Univ. of Technol., Tampere, Finland)

Kraft recovery boilers greatly enhance the efficiency of paper pulp mills by burning the organic wastes recovered from the pulp making process and generating electricity, but significant smelt-water explosion hazards exist when steam is used as the working fluid due to sodium compounds in the sludge from the waste incineration process. Current practice is to use acoustic emission sensors to monitor for leaks in the bottom wall and to initiate an automatic shutdown sequence for the boiler once a leak is detected. A high-frequency model previously developed by the authors and verified by measurements performed in Skoghall, Sweden indicated strong attenuation in the sludge between the point of leakage and the detectors, but experimental results demonstrated a pass band at low frequencies (under 20 kHz). In this paper the authors develop a two-degree-of-freedom finite difference model for the prediction of acoustic attenuation at low frequencies. The bottom wall is modeled as a periodic tube and fin arrangement, and a time-domain finite difference method is used whereby the fin and tube are simple lumped elements. The model is then compared to previous experimental results, with which excellent agreement is obtained.

2:55

5pEA7. Analytical and finite element modeling of vibro-acoustic modes of a fluid-filled thick-walled hollow microcylinder and applications in low-power particle manipulation. Muhammet K. Araz and Amit Lal (SonicMEMS Lab., School of Elec. and Comput. Eng., Cornell Univ., Ithaca, NY 14853, mka22@cornell.edu)

Nonlinear acoustic interactions such as acoustic radiation forces or acoustic streaming require high-amplitude acoustic pressure or velocity terms to generate observable effects. While at the macro-scale these effects are not widely used; due to the highly compliant microstructures, high-amplitude acoustic pressure and velocity terms have been reached in a microscopic cavity even at very low-voltage drives (1–10 Vpp). Here, vibrational and acoustic modes of a thick-walled fluid-filled hollow cylindrical glass capillary are introduced. Vibrations are coupled to the capillary through a laser cut, C-shaped lead zirconate titanate plate. Mode shapes and dispersion relationships are obtained both analytically and from finite element modeling in ANSYS. Analytical modeling of the microcavity resonator shows excellent agreement with the computational models developed in ANSYS and the experimental results. Coupling of the vibrational modes of the capillary to the fluid enclosed plays an essential role in manipulation and separation of micro- and nanoparticles and biological entities in acoustically excited portable microfluidic platforms. In this regard, proper modeling of the vibroacoustic modes enables calculation of acoustic radiation force field generated inside the microfluidic capillary. Experimental results on particle collection and separation will be presented at the meeting.

3:10

5pEA8. Shock wave formation on turbulent coanda surfaces. Thomas Dowd (Dept. of Mathematics, James Madison Univ., 800 S Main St., Harrisonburg, VA 22807, dowd.thomas@gmail.com)

In the petroleum industry a procedure called flaring is used, which is the burning off of unwanted gas. Modern day flares use the Coanda effect,which states "when a jet of fluid is passed over a curved surface it bends to follow the surface entraining large amounts of air" to achieve smokeless combustion, increased combustion efficiency, and decreased thermal radiation due to the entrainment of large amounts of air. These advantages are at the cost of increased noise pollution, due to shock wave formation caused by the difference in the nozzle exit pressure and the ambient pressure. Sound called shock-associated noise is generated by the interaction of downstream propagating turbulent eddies and the stationary quasi-periodic shock-cell structure contained in the supersonic jet. A model of shock-associated noise near turbulent Coanda surfaces will be presented and compared with experimental data along with suggestions for reducing noise. Also a visualization of these shock wave formations and their intricacies will be presented if time allows.

3:25

5pEA9. Acoustic scattering from layered pentamode materials. Clyde L. Scandrett (Dept. of Appl. Mathematics, Naval Postgrad. School, Monterey, CA 93943), Jeffrey E. Boisvert, and Thomas R. Howarth (NAVSEA Newport, Newport, RI 02841-5047)

While receiving less attention in the literature than in the field of electromagnetic scattering, theoretical efforts to define and create acoustic skins capable of reducing scattered energy from obstacles by way of mimicking coordinate transformations through use of meta-materials have begun. The present work extends recent analysis of Norris by considering a variety of acoustic skins, from those comprised of fluid layers which are isotropic in bulk moduli with anisotropic density to those having anisotropic bulk moduli and isotropic density. In all but pure inertial types, fluid layers comprising the skins are pentamode materials governed by a special scalar acoustic equation for pseudo-pressure derived by Norris. In most cases presented, material properties of the fluid/pentamode layers are based upon target values specified by continuously varying properties resulting from theoretical coordinate transformations geared to minimize scattered pressure limited by realistic goals. The present work analyzes acoustic skins for the specific case of plane wave scattering from an acoustically hard sphere. An initial exploration of the parameter space defining such skins (for example, material properties of its constituent layers and operating frequency) is undertaken with a view toward "optimal" design. [Work supported by the NAVSEA Newport In-House Laboratory Individual Research (ILIR) Program.]

3:40

5pEA10. Power analysis for decoding of the digital audio encoding format MP3: Decoding the central processing unit and the graphics processing unit. Seung Gu Kang, Pil Joung Sun, Cheol Hong Kim (Chonnam Natl. Univ., Chonnam, Korea, chkim22@chonnam.ac.kr), and Jong-Myon Kim (Univ. of Ulsan, Ulsan, Korea)

Power consumption is one of the major design considerations for recent computing systems. MP3 players require MP3 decoding performed on the processor. We analyze the power consumption for MP3 decoding varying the processor type [central processing unit (CPU) and graphics processing unit (GPU)]. In general, the MP3 decoding is performed on CPU . GPU, which is a specialized processor that offloads three dimensional graphics rendering from the CPU, can be used for MP3 decoding since it is used for various computations as well as graphics rendering. At first, we analyze the power consumption for the MP3 decoding performed on CPU by using Inspector tool. And then, we analyze the power consumption for the MP3 decoding performed on GPU. To analyze the power efficiency of the GPU for MP3 decoding, we use CUDA for translating the MP3 decoding process from CPU to GPU. Computer unified device architecture (CUDA) is the computing engine in NVIDIA GPUs that is accessible to software developers through industry standard programming languages. According to our experimental results, the MP3 decoding performed on GPU saves power consumption by 23% compared to that on CPU. [Work supported by the MKE, Korea, under the ITRC supervised by the IITA (IITA-2009-(C1090-0903-0008).]

5pPAa1. Ground effects in time-domain simulations of outdoor sound propagation. Didier Dragna, Philippe Blanc-Benon (LMFA, UMR CNRS 5509, Ecole Centrale de Lyon, 69134 Ecully Cedex, France, didier.dragna@ec-lyon.fr), and Franck Poisson (SNCF, Direction de l'Innovation et de la Recherche, 75379 Paris Cedex 08, France)

Finite-difference, time-domain (FDTD) methods are precise and powerful tools to solve linearized Euler equations. Interaction between the acoustic waves with local wind or temperature gradients as well as a complex topography can be taken into account. Recently, a time-domain boundary condition has been proposed [Cotté *et al.*, AIAA J. **47**, 2391–2403 (2009)] and has been implemented in a FDTD solver using methods developed in the computational aeroacoustics community [Bogey and Bailly, J. Comput. Phys. **194**, 194–214 (2004)]. Propagation of an initial pulse over a distance of 500 m in a two-dimensional geometry is considered in a frequency band up to 1200 Hz. Surface waves which propagate close to and parallel to impedance grounds are exhibited. To validate the obtained results, a comparison is made in the time-domain with an analytical solution. Ground effects are discussed depending on the impedance of the ground. [This work was performed using HPC resources from GENCI-IDRIS (Grant 2009-022203).]

5pPAa2. Metamodel predictions for long range speech intelligibility using parabolic equation calculations. Amanda D. Hanford, Andrew R. Barnard, Michael L. Jonson, and Jay D. Martin (Appl. Res. Lab, The Penn State Univ., P.O. Box 30, State College, PA 16804)

The Crank–Nicholson parabolic equation (CNPE) method was used to calculate speech intelligibility for long range propagation of voice messages. How intelligible a voice message will be at long range is very sensitive to atmospheric conditions and parameters such as source height and background noise levels. In order to identify this sensitivity, four independent variables were identified and varied throughout the study. These independent variables are the atmospheric refraction index, which takes into account both temperature and wind gradients within the atmosphere, ambient temperature, source height, and background noise level. CNPE computations were performed for 31 optimally chosen cases where all four of the independent variables were random variables and were inputted into a metamodel. This allows for curve fitting and extrapolation of the existing data to determine intermediate results for any operation scenario defined within the bounds of the current study. Upon doing this, it was determined that the atmospheric refraction index is the most sensitive variable. In addition, there is virtually no dependence on ambient surface temperature.

1:30

5pPAa3. Wind velocity measurements with acoustic daylight. Oleg A. Godin (CIRES, Univ. of Colorado and NOAA/Earth System Res. Lab., Boulder, CO 80305, oleg.godin@noaa.gov), Vladimir G. Irisov, and Mikhail I. Charnotskii (ZelTechnologies LLC and NOAA/Earth System Res. Lab., Boulder, CO 80305-3328)

Ambient acoustic noise in ocean and atmosphere provides acoustic illumination, which can be used, akin to daylight, to visualize objects and characterize the environment [Buckingham *et al.*, Nature(London) **356**, 327–329 (1992)]. It has been shown theoretically [O. A. Godin, Phys. Rev. Lett. **97**, 054301 (2006)] that deterministic travel times of acoustic waves propagating in opposite directions between two points in an inhomogeneous, moving, time-independent medium can be retrieved from the cross-correlation function of non-diffuse acoustic noise recorded at the two points. Thus, the noise cross-correlation function contains information on non-reciprocity of sound propagation, which can be utilized to measure flow velocities small compared to the sound speed. This paper presents an experimental verification of the theoretical predictions. Deterministic travel times have been retrieved from cross-correlations of noise recorded at three microphones about 20 m apart and inverted for the sound speed and two horizontal components of the wind velocity. Traffic noise served as the acoustic daylight in the experiment. Accuracy of the passive acoustic measurements of sound speed and wind velocity has been confirmed by comparison with contact measurements of wind, air temperature, and humidity. Possible uses of acoustic daylight for a low-cost environmental monitoring will be discussed.

1:45

5pPAa4. Acoustic location under metal foam windscreens. Jeremy Webster, Richard Raspet (Nat. Ctr. for Phys. Acoust., Univ. of Mississippi, University, MS 38677), Jason Beam (Birmingham-Southern College, Birmingham, AL 35254), and Kelsey Dudziak (Rhodes College, Memphis, TN 38112)

Large wind noise reduction outdoors can be achieved by the use of metal foam layers mounted flush with the surface. In this research, a triangular array for source direction determination is mounted under different thickness metal foams. The performance of the array in locating a spark source is determined by measurements with and without metal foam covers. The performance is quantified by agreement with the actual direction and by the chi squared values of the fit to the direction and the speed of sound. Some geometries produced large errors in speed of sound but the corresponding directions were reasonably accurate. Relatively thin layers of metal foam produced accurate estimates for the direction and sound speed. With the microphones mounted just under a 0.5-in.-thick foam, the direction could be measured to within a few degrees. [This work is funded by the Armaments Research, Development, and Engineering Command (ARDEC)].

2:00

5pPAa5. Gunshot localization using distributed acoustic sensors. Xiao Di, W. Garth Frazier, and Kenneth E. Gilbert (Natl. Ctr. for Physical Acoust., Univ. of Mississippi, University, MS 38677)

For detecting and localizing gunshot sound, distributed acoustic sensors with various baseline separations (several meters to dozens of meters) are used in our field experiments. The large baselines of the distributed sensor networks, based on the time difference of arrival method, provide improved localization accuracy and have distinct advantages over small arrays. Results are reported and compared for various baseline separations, detection distances, numbers of sensors, and weather conditions. The sound source used is a propane cannon. Several least squares methods are used in the data analysis and source localization. Results from the experiment are presented and discussed. The localization errors are analyzed as a function of combined error sources (GPS, timing, weather, etc.). Possible ways to improve the localization accuracy are suggested. [Research supported by the U. S. Army TACOM-ARDEC at Picatinny Arsenal, NJ.]

5pPAa6. Investigation of dominant sources of infrasonic wind noise in ground level microphones. John Paul R. Abbott, Richard Raspet, Jeremy Webster, and Jiao Yu (Dept. of Phys. and Astronomy, Natl. Ctr. for Physical Acoust, Univ. of Mississippi, University, MS 38677)

A two part project has investigated whether the pressure fluctuations (infrasonic wind noise) at the ground, as measured in an open field, can be predicted from the vertical wind velocity measured above the ground. The dominant region contributing to the pressure on the ground is calculated theoretically and displayed with contour plots. Experimentally, time dependent correlations between the measured pressure and wind velocities were done. The correlation coefficients were very low, typically between 0.08–0.15, for broadband frequencies up to 5 Hz. Cross spectrum analysis and application of octave band pass filters showed the dominant frequencies for correlations to be around 0.07–0.1 Hz, with correlation coefficients typically between 0.3–0.5. [Project funded by the US Army Space and Missile Defense Command.]

2:30

5pPAa7. Acoustic response of rigid pipe wind-noise reducers for infrasound measurement. Matthew E. Poese and Thomas B. Gabrielson (Appl. Res. Lab., The Penn State Univ., P.O. Box 30, State College, PA 16804)

A network of rigid pipes with multiple inlets is one commonly employed strategy to filter out pressure fluctuations generated by wind when making infrasound measurements. This talk presents a model of the transfer function of such a rosette filter using a computer model (DeltaEC) that includes thermo-viscous effects at the walls of the pipes. Measurements of this transfer function have been made utilizing the coherence between a calibrated reference microphone and a calibrated microphone shielded by the wind-reduction rosette and these data will be compared to the model. Rosettes with pipes of varied lengths were tested and modeled. The response of the rosette as a function of the vertical arrival angle of the incident plane wave will also be presented. [Work supported by US Army Space and Missile Defense Command.]

2:45

5pPAa8. Acoustical characterization of rigid porous materials. Kai Ming Li and Sheng Liu (Ray W. Herrick Labs., School of Mech. Eng., Purdue Univ., 140 S. Martin Jischke Dr., West Lafayette, IN 47907-2031, mmkmli@purdue.edu)

In an earlier study [K. M. Li, J. Acoust. Soc. Am. Soc. **123**, 1352–1363 (2008)], an analytical expression has been derived to predict the penetration of sound into a rigid porous ground due to a monopole source. In the present study, this analytical formula has been exploited for a numerical method to characterize the acoustical properties of rigid porous materials. They can be obtained from a pair of excess attenuation spectra measured above and below a thick layer of the material. Specifically, its propagation constant and complex density ratio can be determined from the measured data by a downhill simplex method. A series of preliminary indoor measurements was conducted in an anechoic chamber for measuring the propagation of sound above and below a layer of glass beads of different sizes. Based on the measured excess attenuation spectra, the acoustical characteristics of two different sizes of glass beads were determined numerically. These acoustical parameters were compared with the predictions based on the classical impedance model.

3:00

5pPAa9. A theoretical and experimental study of sound propagation above a rigid porous ground. Sheng Liu and Kai Ming Li (Ray W. Herrick Labs., School of Mech. Eng., Purdue Univ., 140 S. Martin Jischke Dr., West Lafayette, IN 47907-2031, mmkmli@purdue.edu)

The sound propagation due to a monopole source near a rigid porous ground is reviewed. Closed form approximation solutions for predicting the sound field above the ground surface were derived analytically by (1) the method of pole subtraction and (2) the use of an effective impedance approach. The locations of the surface wave pole according to both methods were examined. These two approximate solutions were compared with an exact evaluation of the Fourier integral representing the sound field above the rigid porous ground. It is found that the approximate solution using the effective impedance approach offers relatively better agreements with the exact numerical solution. In addition, the effective impedance approach generally leads to a more accurate uniform asymptotic solution for the sound field above the rigid porous ground. In this presentation, the reason for this good agreement is explained. The finding is further supported by experimental data obtained by conducting indoor measurements over a layer of glass beads.

5pPAb1. Interaction of shear horizontal ultrasonic waves with a surface grating: Analytical and experimental results. Tony Valier-Brasier (Lab. d'Acoustique de l'Univ. du Maine (LAUM), UMR CNRS 6613, Ave. Olivier Messiaen, 72000 Le Mans Cedex 09, France, tony.valier-brasier.etu@univ-lemans.fr), Damien Leduc (Universit du Havre, 76610 Le Havre, France), Catherine Potel (Univ. du Maine, 72000 Le Mans Cedex 09, France), Bruno Morvan (Univ. du Havre, 76610 Le Havre, France), Michel Bruneau (Univ. du Maine, 72000 Le Mans Cedex 09, France), and Jean-Louis Izbicki (Univ. du Havre, 76610 Le Havre, France)

This paper deals with the propagation of shear horizontal (SH) ultrasonic waves on a plate with one surface grating. The theoretical acoustic field in the corrugated plate is obtained from a linear combination of the Neumann eigenmodes of a plane plate waveguide which bounds outwardly the perturbed surface of the plate considered. Coupling of the eigenmodes with the rough walls is studied using the integral formulation. The effect of the roughness is expressed in such a way that two intermodal coupling mechanisms are highlighted: a bulk coupling and a surface coupling. The first one depends only on the depth of the roughness and the second one on both its depth and its slope. Moreover, the coupling between SH modes is studied experimentally. An electromagnetic acoustic transducer enables a noncontact emission of the SH waves. Notably, the energy transfer from a mode to others so appears to be strongest at frequencies where a relation between the period of the grating and the wavenumbers of the coupled SH modes is verified.

5pPAb2. High-quality acoustic cavities based on radial sonic crystals. Daniel Torrent (Dept. Electron Eng., Polytechnic Univ. of Valencia, datorma1@upvnet.upv.es) and José Snchez-Dehesa (Polytechnic Univ. of Valencia.)

Radial sonic crystals are radially inhomogeneous systems that present a dispersion relation similar to one dimensional sonic crystals, with the peculiarity of having low-frequency band gaps. These structures are here employed to design high-quality circularly symmetric acoustic cavities. The presence of band gaps in their dispersion relation allows to localize sound in the cavity centers, leading to strong resonances whose frequency depends on the symmetry of the field. Therefore, it is possible to design cavities with monopolar, dipolar, quadrupolar, etc., symmetry. A proposal for its physical realization is also described, showing that radial sonic crystals are possible to build by using the concept of acoustic metamaterials. [Work supported by MCIIN of Spain and ONR.]

1:30

5pPAb3. Ultrasonic characterization of fluid saturated absorbing polymethylacrylate porous plates. Serge Derible (LOMC GOA, FRE CNRS 3102, FANO FR CNRS 3110, Univ. Le Havre, 76600 Le Havre, France), Pierre Campistron, Georges Freiha (Univ. de Valenciennes et du Hainaut Cambrésis, 59313 Valenciennes, France.), Hervé Franklin (Univ. Le Havre, 76600 Le Havre, France), and Bertrand Nongaillard (Univ. Valenciennes et du Hainaut Cambrésis, 59313 Valenciennes, France)

Experiments are led on five manufactured porous polymethylmethacrylate (PMMA) samples, numbered 1–5. Their constituting materials are packed beads whose diameters run from 200–300 μm for plate 1 up to 600–700 μm for plate 5. The plates are normally insonified by wide band transducers acting within the frequency range 100–800 kHz. The samples obey Biot's theory taking into account the viscoelasticity of the solid frame. The reflection and transmission coefficients are measured and then added or subtracted to give the two transition terms, issued from S-matrix theory. They are connected to the symmetrical or asymmetrical motions of the faces of the plates. Those terms allow us a characterization of the porous media by means of a computer program that seeks the values of the Biot parameters giving the best agreement between theory and experiments.

1:45

5pPAb4. Evaluation of surface waves in bone-conducted sound. Margaret Wismer, William O'Brien (BRL, Univ. of Illinois, Urbana, IL), Odile Clavier, and Anthony Dietz (Creare, Hanover, NH)

In order to better understand the basic physical principles of bone-conducted sound, the skull is approximated as a thin spherical fluid-filled shell. Results for sound waves propagating through and around this structure have been determined for a range of frequencies, media, and shell sizes. Since the early 1950s researchers have studied the problem of what happens when waves hit solid targets. Most of the research is concerned with the back-scatter signal but recognize that the interaction of the wave with the object influences these results. For the bone-conducted sound study, the interaction between the incident signal and the object is the critical information. For acoustic noise interacting with the human skull, the ka is below 5. The structure supports the existence of surface waves as the predominant mechanism of energy transfer within the skull. Multiple types of surface wave for this structure of a thin, curved fluid-solid interface exist. Signals which propagate on the air side of the surface due to the curvature are known as Franz or Stoneley waves. Since the shell is thin compared to the typical wavelength of sound, waves within the shell are lower order Lamb or plate waves. All of these waves are dispersive in nature with group speeds considerably smaller than the speed of sound in bone.

2:00

5pPAb5. Acousto-optic monitoring of high-intensity focused ultrasound lesion formation in optically diffuse tissue. Puxiang Lai, James R. McLaughlan, Andrew B. Draudt (Dept. of Mech. Eng., Boston Univ., 110 Cummington St., Boston, MA 02215), Todd W. Murray (Univ. of Colorado at Boulder, Boulder, CO 80309), Robin O. Cleveland, and Ronald A. Roy (Boston Univ., Boston, MA 02215)

Tissue heating by high-intensity focused ultrasound (HIFU) is a promising modality for minimally invasive therapy. However, real-time treatment monitoring still poses significant challenges, particularly at the lower exposure levels where stable cavitation and/or boiling does not result. Bubble-

-free HIFU lesions offer little acoustic contrast; however, one does observe significant contrast in both optical scattering and absorption. We employ acousto-optic (AO) imaging to sense, in real time, optical changes induced by lesion formation. By using a transducer to simultaneously heat a tissue volume and pump the AO interaction, lesions generated in excised chicken breast are monitored in real time. The change in AO response with time is linearly related to the time-dependent lesion volume, provided the diameter of the lesion does not exceed the width of the optical beam. Therefore, AO sensing can be used to both determine the onset of lesion formation and the resulting volume of the necrosed region. The feasibility of using the observed change AO signal amplitude as the criteria to guide HIFU exposure in real time is demonstrated. [Work supported by the Center for Subsurface Sensing and Imaging Systems, NSF ERC Award No. EEC-9986821.]

5pPAb6. Fiber based transduction. Ethan N. Phung, Barbara Deschamp, and Charles Thompson (Dept. of Elec. and Computing Eng., Univ. of Massachusetts Lowell, One Univ. Ave., Lowell, MA 01854, narinphung86@hotmail.com)

In this work we will examine the conversion of mechanical vibration into electrical energy. This is done by using a conductive fiber in close proximity to a conductive plate. In this configuration it is shown that the fiber behaves as a square law detector. This observation may make it useful for mechanical power conversion for radio frequency demodulation. Based on the previous findings, the mechanical vibration of the fiber can be modeled by a simple damped oscillator with external applied source. The result indicated that the original signal can be recovered.

1:05

5pSC1. A novel algorithm for sparse classification. Sujeeth Bharadwaj and Mark Hasegawa-Johnson (Beckman Inst., Univ. of Illinois at Urbana-Champaign, sbhara3@illinois.edu)

A recent result in compressed sensing (CS) makes it possible to perform non-parametric speech recognition that is robust to noise and that requires few training examples. By taking fixed length representations of training examples and stacking them in a matrix, a frame or an over-complete basis can be constructed. Gemmeke and Cranen showed that sparse projections onto this frame recover the correct transcription with 91% accuracy at -5-dB SNR. The goal of speech recognition is not sparse projection onto training tokens, but onto training types. Sparse projection onto types can be achieved by building a frame for each word in the dictionary and stacking the frames to form a rank 3 tensor. Speech recognition is performed by convex linear projection onto the tensor, with sparsity enforced only in the index that specifies type. A mixed L1/L2 relaxation was derived, leading to a Newton descent algorithm that converges to the global optimum.

1:25

5pSC2. Speech classification using penalized logistic regression with hidden Markov model log-likelihood regressors. Øystein Birkenes (TANDBERG, Philip Pedersens vei 20, 1366 Lysaker, Norway, oystein.birkenes@tandberg.com), Tomoko Matsui (The Inst. of Statistical Mathematics, Tokyo, Japan), Kunio Tanabe (Waseda Univ., Tokyo, Japan), and Magne Hallstein Johnsen (Norwegian Univ. of Sci. and Technol., Trondheim, Norway)

Penalized logistic regression (PLR) is a well-founded discriminative classifier with long roots in the history of statistics. Speech classification with PLR is possible with an appropriate choice of map from the space of feature vector sequences into the Euclidean space. In this talk, one such map is presented, namely, the one that maps into vectors consisting of log-likelihoods computed from a set of hidden Markov models (HMMs). The use of this map in PLR leads to a powerful discriminative classifier that naturally handles the sequential data arising in speech classification. In the training phase, the HMM parameters and the regression parameters are jointly estimated by maximizing a penalized likelihood. The proposed approach is shown to be a generalization of conditional maximum likelihood (CML) and maximum mutual information (MMI) estimation for speech classification, leading to more flexible decision boundaries and higher classification accuracy. The posterior probabilities resulting from classification with PLR allow for continuous speech recognition via N-best or lattice rescoring.

1:45

5pSC3. Integrating evidence over time: A look at conditional models for speech processing. Eric Fosler-Lussier, Jeremy Morris, Ilana Heintz, and Rohit Prabhavalkar (Dept. of Comput. Sci. and Eng., The Ohio State Univ., 2015 Neil Ave., Columbus, OH 43210, fosler@cse-ohio-state.edu)

Many acoustic events, particularly those associated with speech events, can be thought of as events in a rich descriptive subspace where the dimensions of the subspace can be thought of as a sort of decomposition of the original event space. In phonetic terms, we can think of how phonological features can be integrated to determine phonetic identity; for auditory scene analysis we can look how features like harmonic energy and cross-channel correlation come together to determine whether a particular frequency corresponds to target speech versus background noise. Some success has been achieved by thinking of these problems as probabilistic detection of acoustic (sub-)events. However, event detectors are typically local in nature and need to be smoothed out by looking at neighboring events in time. This talk describes using conditional random fields models within the automatic speech recognition setting to combine bottom-up speech event detectors. The talk will explore some of the successes and limitations of this log-linear method which integrates local evidence over time sequences.

2:05

5pSC4. Posterior-based attributes in machine recognition of speech. Hynek Hermansky (Ctr. for Lang. and Speech Processing, The Johns Hopkins Univ., Baltimore, MD)

Current ASR uses two main sources of information, the top-down prior knowledge in the form of a statistical language and the bottom-up information from acoustic speech signal. The information from acoustic signal is presented in so called speech attributes that are derived from the signal. Any information that gets lost during attribute extraction cannot be recovered. Any preserved information that is irrelevant to the ASR task could complicate further processing. Attributes in conventional ASR are derived by some transformation of the short-term spectrum of speech that represents magnitude frequency components of a short segment of the signal. Origins of this representation can be traced to speech vocoding. For a past decade, we are working on attributes that are derived from posterior probabilities of speech sounds that are estimated by multilayer perceptron trained on large amounts of labeled data. This speech representation is now used in most leading state-of-the-art experimental systems. The talk will describe several research issues that influence the effectiveness of these posterior-based attributes. These issues include the choice of classes of speech sounds, input evidence for the posterior estimation, architecture and training of the posterior probability estimator, and post-processing of posterior estimates for use with conventional GMM-HMM ASR.

2:25

5pSC5. Machine learning strategies for recovering speech articulatory trajectories and gestures from speech. Vikramjit Mitra, Hosung Nam, Carol Y. Espy-Wilson, Elliot Saltzman, and Louis Goldstein (Dept. of Elec. and Comput. Eng., Speech Commun. Lab., Inst. of Systems Res., Univ. of Maryland, College Park, MD 20742, vmitra@umd.edu)

Articulatory information can improve the performance of automatic speech recognition systems. Unfortunately, since such information is not directly observable, it must be estimated from the acoustic signal using speech-inversion techniques. Here, we first compare five different machine learning techniques for inverting the speech acoustics generated using the Haskins Laboratories speech production model in combination with HLsyn. In particular, we compare the accuracies of estimating two forms of articulatory information (a) vocal tract constriction trajectories and (b) articulatory flesh-point pellet trajectories. We show that tract variable estimation can be performed more accurately than pellet estimation. Second, we also show that estimated tract variables can improve the performance of an autoregressive neural network model for recognizing speech gestures. We compare gesture recognition accuracy for three different input conditions: (1) generated acoustic signal and estimated tract variables, (2) acoustic signal and the original (or groundtruth) tract variables, and (3) acoustic signal only. Results show that gesture recognition accuracy was, not surprisingly, best for condition (2) and worst for condition (3). Importantly, however, condition (1) yielded better performance than (3), demonstrating that estimated tract-variable articulatory information is indeed helpful for automatic speech recognition.

2:45

5pSC6. Margin based discriminative training techniques for automatic speech recognition. Fei Sha (Dept. of Comput. Sci., Univ. of Southern California, Los Angeles, CA 90089), Chih-Chieh Cheng, and Lawrence Saul (Univ. of California, La Jolla, CA 92093)

Recently, large margin techniques have gained popularity for discriminative training of continuous-density hidden Markov models. These techniques are motivated by statistical learning theory, aiming to strike a balance between model complexity and generalization error. When used in speech recognition, these techniques separate discriminant scores from the correct transcriptions from all incorrect recognizer outputs. The parameters of acoustic models are adjusted to maximize the separation—margin—that is proportional to recognition errors. Many of such techniques have been successfully applied to large vocabulary speech recognition tasks and have improved the performance of existing systems with traditional approaches for parameter estimation. In this talk, I will review some of the work that my collaborators and I have undertaken in this direction. I will also describe a few new advances, including online learning of large margin separation as well as applying margin based techniques to adaptively transform acoustic features jointly with acoustic models.

5pSC7. Spoken Hindi paired word recognition using probabilistic neural network. Dinesh Kumar Rajoriya , R. S. Anand, and R. P. Maheshwari (Dept. of Elec. Eng., Indian Inst. of Technol. Roorkee, Roorkee, Uttarakhand 247 667, India, dineshrajoriya@gmail.com)

Automatic speech recognition system plays significant role in the development of real world applications. This paper demonstrated spoken Hindi (Indian national language) paired word recognition (SHPWR) system, which has been examined with the help of probabilistic neural network as a classifier. This type of network is a combination of radial basis layer and a competitive transfer function layer which picks the maximum probabilities as a final result. SHPWR is pattern recognition (PR) problem. A PR technique encompasses two fundamental tasks; description and classification. In the description process, features are extracted from the Hindi paired word templates, and probabilistic neural network is used as a classifier. For the experimental point of view 1000 Hindi paired word templates have been recorded from individuals with different environment condition, gender, and age groups. Speaker dependent SHPWR systems achieved close to 100% while the accuracy of speaker independent SHPWR systems is quite adequate.

5pSP1. Formulation for statistics of echoes due to a finite number of scatterers and patches of scatterers in a directional sonar beam. Timothy K. Stanton (Dept. Appl. Ocean Phys. and Eng., Woods Hole Oceanograph. Inst., MS 11, Woods Hole, MA 02543, tstanton@whoi.edu)

A general theoretical formulation is developed for echo statistics associated with a finite number of scatterers and patches of scatterers, each being randomly located in a directional sonar beam. This is the case of a direct-path sonar where there are no echoes from the seafloor and sea surface. The formulation is derived by combining the equations of Ehrenberg and colleagues (single scatterer randomly located in sonar beam) and Barakat (sum of finite number of random variables). Each scatterer or patch of scatterers is independent and can have its own echo probability density function (PDF) (before beampattern effects). Examples show that the PDF of the echo (as received by the sonar) is strongly non-Rayleigh due to beampattern effects and finite number of scatterers or patches. Numerical simulations are made for validation. [Work supported by ONR.]

1:20

5pSP2. Featureless classification for active sonar systems. Mary E. Soules and Joshua B. Broadwater (The Johns Hopkins Appl. Phys. Lab., 11100 Johns Hopkins Rd., Laurel, MD 20723)

Active sonar systems depend on classification algorithms to identify target echoes and suppress false alarms. Historically, classifiers use a set of empirically derived features that exhibit some statistical separation between background clutter and target echoes. In an ideal scenario, these features would form a sufficient set of statistics capturing all of the information required to classify an echo return. Unfortunately, due to their empirically derived nature, features are rarely provably sufficient. To overcome this drawback, a featureless classifier will be presented. Instead of features, the raw data samples, which form a trivial but provable set of sufficient statistics, are used. The adaptive cosine estimate algorithm has a history of success with featureless classification in other applications and is well suited for underwater acoustics. An in-depth look at the featureless algorithm that will include comparisons to several traditional active sonar classifiers will be provided.

1:40

5pSP3. Clustering classification methods for acoustic applications including the analysis of clicking whale data. Juliette W. Ioup, George E. Ioup, Lisa A. Pflug (Dept. of Phys., Univ. of New Orleans, New Orleans, LA 70148, jioup@uno.edu), Natalia A. Sidorovskaia (Univ. of Louisiana at Lafayette, Lafayette, LA), Christopher O. Tiemann (Univ. of Texas at Austin, Austin, TX), and Charles H. Thompson (NOAA/NMFS/SEFSC, Stennis Space Ctr., MS)

Several clustering methods are available to group like objects into classes. The K means approach is well established. Both standard and homegrown algorithms have been tested in the following applications. One neural network technique is self-organizing map clus-

tering [T. Kohonen, *Self-Organizing Maps*, 2nd ed. Springer, New York (1997)]. Although it has some similarities to K means, it has notable differences which can be quite helpful in classification. An advantage is that it has the ability to limit the number of clusters automatically. This can be an important aspect when the number of classes is unknown. After a review of the basics of these techniques, the power of the methods is illustrated by applications to the study of clicking whales. The Littoral Acoustic Demonstration Center has acquired underwater acoustic data from clicking whales in the Gulf of Mexico, and it has access to data from the third and fourth International Workshops on Detection, Classification and Localization of Marine Mammals Using Passive Acoustics. Application of K means and SOM clustering to these data is an important component of identifying individual whales acoustically. Additional details on these results are being presented in Animal Bioacoustics sessions at this meeting. [Research supported by ONR and SPAWAR.]

2:00

5pSP4. Waveguide invariant minimum variance scatterer depth classification for active sonar. Ryan Goldhahn, Granger Hickman, and Jeffrey Krolik (Dept. of ECE, Duke Univ., 130 Hudson Hall, Durham, NC 27708-0291)

Active sonar systems are plagued by false alarms due to confusion between returns from water-column targets and backscatter from the bottom. Both feature-based and physics-based classifiers are notoriously susceptible to mismatch of the environment used for training and/or modeling active sonar returns. In this paper, in order to achieve more robust classification, uniformly sub-sampled DFT-coefficients from a single snapshot of the wideband active sonar return are used to define a waveguide-invariant spectral density matrix (WI-SDM). The WI-SDM facilitates adaptive matched-filtering based approaches for target depth estimation, where the waveguide invariant property is exploited to obtain uncorrelated snapshots without inflating covariance matrix rank. Depth classification is then performed by designing a waveguide-invariant minimum variance filter (WI-MVF) with adaptive weights which minimize ambiguous depth sidelobes. Simulation and real data results in a shallow-water Mediterranean environment are presented to illustrate the approach. [Work sponsored by ONR.]

5pSP5. Testing the temporal robustness of an automatic aural classifier. Stefan Murphy and Paul C. Hines (Defence R&D Canada, P.O. Box, 1012 Dartmouth, Nova Scofia, B2Y 3Z7, Canada stefan.murphy@drdc-rddc.gc.ca)

Military sonar systems must detect and classify submarine threats at ranges safely outside their circle of attack. However, in littoral environments, echoes from geological features (clutter) are frequently mistaken for targets of interest, resulting in degraded performance. Perceptual signal features similar to those employed in the human auditory system can be used to automatically discriminate between target and clutter echoes, thereby improving sonar performance. [J. Acoust. Soc. Am. 122, 1502–1517 (2007)] The present work examines the temporal robustness of the aural classifier using data from two field trials: the first in 2007 and the second in 2009. The experiments were conducted on the Malta Plateau using a cardioid towed-array receiver, and a broadband source transmitting linear FM sweeps from 600–3500 Hz. The data set consists of hundreds of pulse-compressed echoes from several surrogate targets and geological clutter objects. The echoes are examined using an automatic classifier that processes each echo to extract perceptual features. Each echo is classified as target or clutter based on the position vector formed by these features. The classifier establishes a boundary between clutter and target echoes in the feature space using the 2007 experiment. Temporal robustness is investigated by testing the classifier on echoes from the 2009 experiment. In this work, the experiments are reviewed and initial results are presented.

2:35

5pSP6. On the use of instantaneous acoustic intensity for the classification of defects in air-filled pipes. Kirill Horoshenkov, Tareq Bin Ali, Simon Tait (School of Eng., Univ. of Bradford, Bradford BD7 1DP, United Kingdom), and Alexandra Tolstoy (ATolstoy Sci., McLean, VA 22101)

The sound pressure in an air-filled pipe has been measured using six pairs of matched microphones. These data have then been analyzed to determine the six vectors of instantaneous particle velocity and acoustic intensity. The acoustic intensity vectors have been processed coherently using the matched field processing (MFP) technique to study the effect of changes such as blockages and cracks on the ambiguity surface. The results show that the technique is sensitive to very small changes in the pipe cross-section and the boundary conditions on the pipe wall. It enables us to locate a defect to within 1% of the measurement range. It also enables us to discriminate between blockages and wall cracks using the spectral characteristics of the ambiguity surface predicted via the MFP. This technique does not require acoustic modeling of the sound field in the pipe, but it relies on the sound pressure data recorded on three or more microphones in the absence and presence of a defect.

2:50

5pSP7. Source depth classification of passive sonar signals using amplitude statistics. R. Lee Culver, Colin W. Jemmott (Appl. Res. Lab. and Grad. Program in Acoust., Penn State Univ., P.O. Box 30, State College, PA 16804), Brett E. Bissinger, and N. K. Bose (Penn State Univ., State College, PA 16804)

A number of at-sea measurements have shown that fluctuations in the amplitude of passive sonar signals are affected by source depth, range, and the propagation path from the source to the receiver. However, to date, received signal statistics have not been incorporated into passive sonar classification algorithms because the field results have not been accompanied by development of a statistics-based classifier architecture whose performance can be assessed using accepted signal processing metrics, e.g., a receiver operating characteristic curve. The performance of a statistics-based classifier depends critically upon statistical knowledge of the received signal, which in turn depends upon statistical knowledge of relevant environment parameters (sound speed in the water column and sediment, for example). Thus the classifier architecture must make use of the environmental information which in reality is only approximately known and must be described in statistical terms. Given a statistical description of the environment, an ocean acoustic propagation model and Monte Carlo simulation can be used to predict received signal statistics. Once received signal statistics are available for the different classes, a classifier can be designed. Here we examine a likelihood ratio binary source depth classifier for passive sonar. [Work sponsored by ONR Undersea Signal Processing.]

3:05

5pSP8. Minimum Hellinger distance classification for passive sonar in the presence of noise. Brett E. Bissinger (Dept. of Elec. Eng., and Appl. Res. Lab, Penn State Univ., P.O. Box 30, State College, PA 16804), R. Lee Culver, and N. K. Bose (Penn State Univ., State College, PA, 16804)

Passive source classification in the underwater environment is a challenging problem in part because propagation through the space- and time-varying media introduces variability and uncertainty in the signal. Acoustic

propagation models can predict received fields accurately, but they are sensitive to input environmental parameters which cannot be known exactly. This uncertainty in environmental knowledge used in signal predictions results in imperfect statistical class models. Classifiers that rely on simulations of the environment must therefore be robust to these imperfections. The minimum Hellinger distance classifier (MHDC) has been shown to be robust to such mismatches in situations with no noise. Low-noise situations allow demonstration of the properties of the classifier; however, real passive sonar tends to have significant noise levels. Therefore the MHDC's performance is examined and compared to that of a log-likelihood ratio classifier when applied to narrowband passive underwater acoustic signals in the presence of noise. Both classifiers are applied to synthetic Gaussian data, synthetic acoustic data, and actual acoustic data, all with noise. Classifiers are evaluated using receiver operating characteristic curves, a traditional performance metric in signal processing. [Work supported by ONR Undersea Signal Processing.]

3:20

5pSP9. Speech forensics: Automatic acquisition device identification. Daniel Garcia-Romero and Carol Espy-Wilson (Dept. of Elec. Eng., Univ. of Maryland, College Park, MD 20742, dgromero@umd.edu)

Automatic identification-of-the-source is an important problem in the field of speech forensics. That is, given a speech recording, the problem is to determine how to automatically determine the exact make and model of the acquisition device regardless of the speaker and speech content. Recent work developed by the authors have shown that statistical modeling of the device characteristics in terms of MFCCs provides excellent discriminative power when the recordings are obtained under controlled conditions (i.e., all recordings come from the same room and a unique device per class is used). In this study we propose to expand these results by analyzing the effects that room acoustics and intra-device variability have in the source identification accuracy. To perform this analysis, the NIST 2008 SRE dataset will be used. This corpus provides recordings acquired with multiple devices of the same make and model in different rooms.
